David Schlossberg edited the first two editions of this textbook. When he died on February 28, 2019, the infectious diseases community lost one of its most accomplished and admired members.

As a Yale undergraduate, David majored in English literature and excelled as both a scholar and a wrestler. He was an AOA graduate of Tufts University School of Medicine. While a student at Tufts, David encountered the legendary Louis Weinstein, one of the giants of infectious diseases. David asked Dr. Weinstein if he could follow him around for a month. Dr. Weinstein agreed, and David enjoyed what was probably the very first student elective in infectious diseases in the United States. David was a medicine resident at Mount Sinai in New York and an infectious diseases fellow at Emory University in Atlanta.

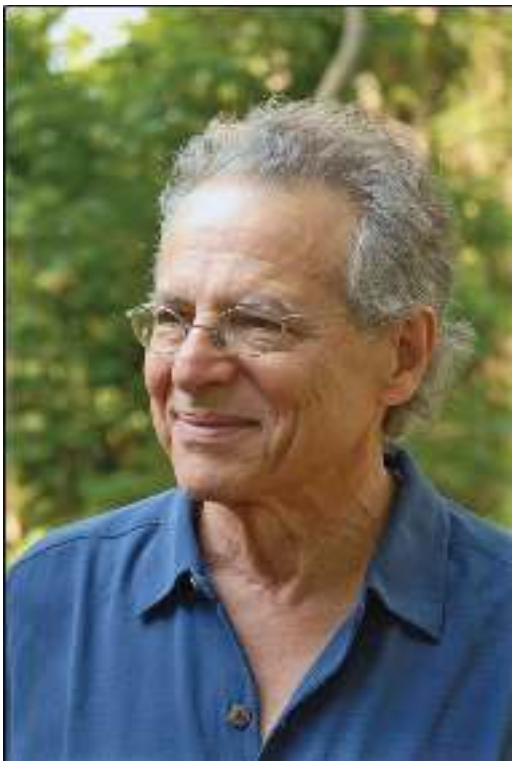
David served for 2 years in the US Navy as Chief of Infectious Diseases at the Naval Regional Medical Center in Portsmouth, Virginia. After his Navy service he became Chair of the Department of Medicine at the Polyclinic Medical Center in Harrisburg, Pennsylvania, following which he served for 16 years as Chair of the Department of Medicine and Head of Infectious Diseases at Episcopal Hospital in Philadelphia. Later he became Director of Medical Services at Merck and most recently served as the Head of the TB control program for the City of Philadelphia. He held adjunct faculty positions at Temple University, Jefferson University, and the University of Pennsylvania, and for almost 20 years made rounds each Monday with the Temple infectious diseases consult team.

David was a consummate clinician and educator and a true polymath. He edited or authored 28 textbooks—not 28 editions of books: 28 individual titles. He was a martial arts expert and a Talmudic scholar. He spoke about 10 languages including Yiddish, Chinese, and Polish. He could sing the words to every major Broadway show tune. He read widely and deeply, and he knew a good single malt whisky.

After the death of his father, David became the patriarch of the Schlossberg clan. Family was of paramount importance to David, and, along with Yuan Mirow, his dear partner of 25 years, he gathered together his siblings, children, and grandchildren each Thanksgiving and Passover and each summer for a week at the New Jersey shore. Attendance at these family events was mandatory, no excuses. While at the shore, David arose early each morning to buy newspapers and a special crumb cake that all the Schlossbergs loved.

David Schlossberg was smart, warm, kind, and generous with his time. He was everyone's friend. He had a genuine interest in people and had a way of making you feel that you had his full attention. He loved a good story and could tell one. He had a strong handshake, a ready smile, and looked you directly in the eye when you spoke with him. He was a loyal friend. He was honest and forthright, a man of the finest character, a mensch. The world has lost a very good man. This third edition of Clinical Infectious Diseases is dedicated to his memory.

—Bennett Lorber, MD, MACP



Contents

Section 5—Clinical syndromes: Respiratory tract

Section 6—Clinical syndromes: Heart and blood vessels

Section 7—Clinical syndromes: Gastrointestinal tract, liver, and abdomen

Section 10—Clinical syndromes: Neurologic system

Section 11—The susceptible host

Section 23—Specific organisms: Viruses

Section 24—Specific organisms: Parasites

Preface

I was not expecting Dr. Schlossberg's call asking me to be co-editor for the next edition of *Clinical Infectious Disease.* Previously, in the second edition, I felt most fortunate to have been a contributor. Needless to say, I was surprised, delighted, and honored to be asked by David to be co-editor of *Clinical Infectious Disease*, his clinically oriented infectious disease textbook for practitioners. *Clinical Infectious Disease* remains the only single-volume, easy-to-use, handy, clinically based infectious disease desktop reference. Subsequently, we had many conversations regarding plans for the third edition of *Clinical Infectious Disease* to be published by Oxford University Press. David was, as usual, confident, enthusiastic, and happy. His great sense of humor was always part of our discussions about *Clinical Infectious Disease*, the practice of infectious diseases, and about life. David was at the peak of his distinguished career.

All was progressing as planned when the unthinkable happened. I learned that David had passed away at the end of February. This sweet man of substance, religion, experience, empathy, and kindness had, without warning, left us. David was an incomparable clinician, teacher, and educator. Prolific and accomplished, he wrote or edited more books on infectious diseases than anyone, some 28 in total. Early on, he was greatly influenced by the clinical approach of Dr. Louis Weinstein. Throughout his career, David's main focus was always on the clinical aspects of infectious disease, which is evident in his *Clinical Infectious Disease.* Dr. Bennett Lorber was a lifelong colleague and friend of David's and has kindly written the Dedication to David and provides a personal perspective on David's life.

Under these circumstances, I assumed the duties as editor of *Clinical Infectious Disease* (3rd edn.). I was determined to continue in the tradition of David's *Clinical Infectious Disease* emphasis on clinical diagnosis and management. To honor him, I had the book, in its third edition, renamed *Schlossberg's Clinical Infectious Disease*. *Schlossberg's Clinical Infectious Disease* (3rd edn.) perspective and organization remains the same.

It has been difficult, given the severity and duration of the global covid-19 pandemic, for contributors with their primary responsibilities to patients during the pandemic to update or complete their chapters. I am pleased that *Schlossberg's Clinical Infectious Disease* is completed, and there have been two new, timely chapters added, one on COVID-19 and the other on antimicrobial stewardship.

David's memory and professional perspective as an infectious disease clinician and educator par excellence are reflected in the pages of *Schlossberg's Clinical Infectious Disease* (3rd edn.). I am humbled and honored that David entrusted me with his *magnum opus,* and I hope that he is pleased that his work continues to provide infectious disease clinicians with a single-volume, easy-to-use desktop reference.

—Cheston B. Cunha

The Dr Eugene N. Meyers Professor and Chairman of Otolaryngology
Professor
Department of Oral and Maxillofacial Surgery
School of Dental Medicine
University of Pittsburgh
Pittsburgh, PA

Royce H. Johnson, MD, FACP
Professor of Medicine at UCLA
Chief Infectious Disease, Kern Medical
Director, Valley Fever Institute
Bakersfield, CA, USA

Ronald N. Jones, MD, FAAM, FASCP, FCAP, FIDSA
Chairman and Founder
Jones Microbiology Institute (JMI)
JMI Laboratories
North Liberty, IA, USA

Elaine C. Jong, MD, FIDSA, FASTMH
Clinical Professor Emeritus
Department of Medicine
Division of Allergy and Infectious Diseases
University of Washington School of Medicine
Seattle, WA, USA

Leeja Joseph, MD
Fellow, Division of Infectious Diseases
Department of Internal Medicine
Medical College of Georgia
Augusta University
Augusta, GA, USA

Jonathan J. Juliano, MD
Clinical Assistant Professor of Medicine
School of Medicine
University of North Carolina
Chapel Hill, NC, USA

Lili G. Kaplan, MD
Ophthalmologist and Retina Specialist
Retina Associates of Cleveland
Beachwood, OH

Shanthi Kappagoda, MD
Associate Professor of Medicine
Division of Infectious Disease
Stanford University
Emeryville, CA, USA

Ravi Karra, MD, MHS
Medical Instructor, Division of Cardiology
Duke University Medical Center
Durham, North Carolina

Keith S. Kaye, MD
Professor of Medicine
Wayne State University and Detroit Medical Center
Detroit, MI, USA

M. Paul Kelly, MD, FRCP
Professor of Tropical Gastroenterology
Blizard Institute
Barts & The London School of Medicine
Queen Mary University of London
London, UK
and
Tropical Gastroenterology & Nutrition Group
University of Zambia School of Medicine
Nationalist Road
Lusaka, Zambia

Louis E. Kennedy, REHS, BS
Clinical Research Assistant
Ealing Hospital NHS Trust
Southall, UK

Jay S. Keystone, MD, MSc (CTM), FRCPC
Tropical Disease Unit
Division of Infectious Disease
Toronto General Hospital
UHN, Toronto, Canada
Professor of Medicine
University of Toronto
Toronto, Canada

Stephen A. Klotz, MD
Professor of Medicine and Family and Community Medicine
Division of Infectious Diseases
University of Arizona
Tucson, AZ, USA

Evelyn K. Koestenblatt, MS, BS, CCRC, ASCP
Retired
Bellerose Village, NY, USA

Rachel Kominsky, MD
Otolaryngology, Head and Neck Surgery
Case Western Reserve University
Cleveland, OH, USA

Peter J. Krause, MD
Senior Research Scientist
Yale School of Public Health
Yale School of Medicine
New Haven, CT, USA

Amy Kritzer, MD
Attending Physician
Division of Genetics and Genomics
Instructor
Harvard Medical School
Boston, MA, USA

Ilona Kronig
Division of Infectious Diseases
Department of Specialties of Internal Medicine
Geneva University Hospitals and Faculty of Medicine
Geneva, Switzerland

David Kuhar, MD
Team Lead, Hospital Infection Prevention Team
Division of Healthcare Quality Promotion
Centers for Disease Control and Prevention
Atlanta, GA, USA

Sampath Kumar, MD
Infectious Diseases Attending
Metro Infectious Diseases
Chicago, IL
University of Illinois
Chicago, IL

Chuen-Yen Lau, MD, MS, MPH
Staff Clinician
HIV Dynamics and Replication Program, National Cancer Institute
National Institutes of Health
Bethesda, MD, USA

Sixto M. Leal, MD, PhD
Assistant Professor
Department of Pathology
Director, Clinical Microbiology, Director Fungal Reference Laboratory
University of Alabama at Birmingham
Birmingham, AL, USA

William J. Ledger, MD
The Given Foundation Professor Emeritus of Obstetrics and Gynecology
Weill Cornell Medical College
New York, NY, USA

Matthew E. Levison, MD
Adjunct Professor of Medicine, Professor of Public Health
Drexel University
Bryn Mawr, PA, USA

Stuart M. Levitz, MD
Professor
Department of Medicine
University of Massachusetts Medical School
Worcester, MA

Daniel Lew, MD
Division of Infectious Diseases
Department of Specialties of Internal Medicine
Geneva University Hospitals and Faculty of Medicine
Geneva, Switzerland

Neil S. Lipman, VMD
Center of Comparative Medicine and Pathology
Memorial Sloan Kettering Cancer Center, Hospital for Special Surgery, and Weill Cornell Medicine
New York, NY, USA

Pamela A. Lipsett, MD, MHPE
Professor
Department of Surgery
Johns Hopkins University School of Medicine
Baltimore, MD, USA

Peter Liu, MD
Assistant Professor of Clinical Medicine
Division of Infectious Diseases
University of Pennsylvania Perelman School of Medicine
Philadelphia, PA, USA

Ann-Marie Lobo, MD
Assistant Professor of Ophthalmology, Ocular Immunology and Uveitis Specialist
Massachusetts Eye and Ear Infirmary, Harvard Medical School
Boston, MA, USA

Sarah S. Long, MD
Section of Infectious Diseases
Department of Pediatrics
St. Christopher's Hospital for Children, Drexel University College of Medicine
Philadelphia, PA, USA

Bennett Lorber, MD, MACP
Thomas M. Durant Professor of Medicine, Professor of Microbiology and Immunology
Temple University School of Medicine
Philadelphia, PA, USA

Alice Lorch, MD
Resident in Ophthalmology, Massachusetts Eye and Ear Infirmary
Harvard Medical School
Boston, MA, USA

Benjamin J. Luft, MD
Professor
Department of Internal Medicine
Stony Brook University Hospital
Stony Brook, NY, USA

Larry I. Lutwick, MD
Professor of Medicine
Mayo Clinic School of Medicine and Science
Infectious Diseases, Mayo Clinic Health System
Eau Claire, WI, USA

John Maa, MD
Department of Surgery
University of California
San Francisco, CA, USA

Rodger D. MacArthur, MD
Professor of Medicine
Division of Infectious Diseases, Department of Internal Medicine
Medical College of Georgia
Augusta University
Augusta, GA, USA

Karl Madaras-Kelly, PharmD, MPH
Professor
Department of Pharmacy Practice and Administrative Sciences
Idaho State University College of Pharmacy
Meridian, Idaho

Joanne T. Maffei, MD
Professor
Department of Medicine, Section of Infectious Diseases
LSU Health Sciences Center New Orleans
New Orleans, LA, USA

Rafael Gerardo Magaña, MD
NYC Plastic Surgery
New York, NY, USA

Eleni E. Magira, MD, PhD
Associate Professor
First Department of Critical Care Medicine
Evangelismos Hospital
National and Kapodistrian University of Athens Medical School
Athens, Greece

James H. Maguire, MD, MPH
Professor of Medicine
Harvard Medical School
Boston, MA, USA
Division of Infectious Disease
Brigham and Women's Hospital
Boston, MA, USA

Francis S. Mah, MD
Ophthalmologist
Scripps Health
San Diego, CA

Anita Mahadevan, MD
Associate Professor
Neuropathology National Institute of Mental Health & Neurosciences
Bangalore, India

Gina Maki, DO
Division of Infectious Disease
Henry Ford Hospital
Detroit, MI, USA

Mark A. Malangoni, MD
Emeritus Professor of Surgery
Department of Surgery
Case Western Reserve University School of Medicine
Cleveland, OH, USA

Alexandre E. Malek
Onco-Transplant Infectious Diseases Fellow
Department of Infectious Diseases, Infection Control and Employee Health
The University of Texas MD Anderson Cancer Center
Houston, TX, USA

Choukri Ben Mamoun, PhD
Professor of Medicine and Microbial Pathogenesis
Section of Infectious Disease
Yale University School of Medicine
New Haven, CT, USA

Brandi Manning, DO
Assistant Professor of Medicine
Division of Infectious Diseases
Ohio State University
Columbus, OH, USA

Suzaan Marais, MBChB, FC NeuroI(SA), PhD
Senior Research Officer
Clinical Infectious Diseases Research Initiative
Institute of Infectious Disease and Molecular Medicine (IIDMM)
University of Cape Town
Cape Town, South Africa
Department of Medicine
University of Cape Town
Cape Town, South Africa

Peter Mariuz, MD
Professor of Medicine, Infectious Diseases
University of Rochester
Rochester, NY, USA

Thomas J. Marrie, MD, FRCPC
Consultant
Retired from Department of Medicine
Dalhousie University
Halifax, NS, Canada

Paul Martin, MD, FRCP, FRCPI
Chief, Division of Digestive Health and Liver Diseases, Professor of Medicine
Mandel Chair in Gastroenterology
Miller School of Medicine, University of Miami
Miami, FL, USA

Richard A. Martinello, MD
Associate Professor
Departments of Internal Medicine and Pediatrics, Infectious Diseases
Yale School of Medicine
Medical Director, Infection Prevention
Yale New Haven Health
New Haven, CT, USA

Amy J. Mathers, MD, D(ABMM)
Associate Professor
Medicine and Pathology
University of Virginia
Charlottesville, VA, USA

Anne E. McCarthy, MD
Professor of Medicine
Division of Infectious Diseases
University of Ottawa
Ottawa, Canada

Todd P. McCarty, MD
Assistant Professor, Division of Infectious Diseases
University of Alabama at Birmingham School of Medicine
Birmingham VA Medical Center
Birmingham, AL, USA

Shelly McNeil
Professor
Division of Infectious Diseases
Dalhousie University
Nova Scotia, Canada

J. Anthony Mebane, MD
Division of Infectious Diseases
VA Medical Center
Boise, Idaho

Jay B. Mehta, MD, FCCP
Professor of Medicine, Chief of Division of Preventive Medicine and Epidemiology
East Tennessee State University, James H. Quillen College of Medicine
Johnson City, TN, USA

Jeffrey L. Meier, MD
Associate Professor
Department of Internal Medicine, Division of Infectious Diseases
University of Iowa Carver College of Medicine
Iowa City Veterans Affairs Healthcare System
Iowa City, IA, USA

Graeme Meintjes, PhD in Medicine
Professor and the Second Chair & Deputy Head
Department of Medicine
University of Cape Town
Cape Town, Western Cape, South Africa

Rodrigo E. Mendes, PhD
Director
Department of Molecular & Microbiology
JMI Laboratories
North Liberty, IA, USA

Gregory Mertz, MD, FIDSA, FACP
Emeritus Professor of Internal Medicine
Center for Global Health
University of New Mexico Health Sciences Center
Albuquerque, NM, USA

Burt R. Meyers, MD, FACP
Adjunct Professor of Medicine
New York Medical College
Valhalla, NY

Ian C. Michelow, MD, MMed, DTM&H
Associate Professor
Department of Pediatrics, Division of Infectious Diseases
Center for International Health Research
The Warren Alpert Medical School of Brown University
Providence, RI, USA

Aaron Mishkin, MD
Assistant Professor of Medicine, Section of Infectious Diseases
Lewis Katz School of Medicine at Temple University
Philadelphia, PA, USA

Amirkaveh Mojtahed, MD
Resident Physician
Internal Medicine Board Certified Anatomic Pathologist
Scripps Green Hospital
La Jolla, CA

Gentiane Monsel, MD
Consultant
Department of Internal Medicine
Centre Hospitalier intercommunal de Crèteil
Crèteil, France
Department of Dermatology, AP-HP
Hôpital Henri-Mondor
Crèteil, France

Douglas R. Morgan, MD, MPH
Associate Professor of Medicine
Division of Gastroenterology, Hepatology, and Nutrition,
Vanderbilt Ingram Cancer Center (VICC)
Vanderbilt Institute for Global Health (VIGH)
Vanderbilt University
Nashville, TN, USA

Anisa Mosam
Department of Dermatology
Nelson R Mandela School of Medicine
University of Kwazulu Natal
Durban, South Africa

Jessica Moskovitz, MD
Division of Otolayngology
University of Pittsburgh Medical Center
Pittsburgh, PA, USA

Daniel Mueller, MD
Physician
Department of Internal Medicine
Lewis Katz School of Medicine at Temple University
Philadelphia, PA, USA

Maurice A. Mufson, MD, MACP
Professor of Medicine Emeritus and Chairman Emeritus
Department of Medicine
Marshall University Joan C. Edwards School of Medicine
Huntington, WV, USA

Jorge Murillo, MD, FACP, FIDSA
Associate Professor of Medicine
Herbert Wertheim College of Medicine
Florida International University
Miami, FL, USA
Consultant in Infectious Disease and Tropical Medicine
Baptist Health
Miami, FL, USA

Daniel Musher, MD
Distinguished Service Professor of Medicine
Baylor College of Medicine
Houston, TX, USA
Professor of Molecular Virology and Microbiology
Baylor College of Medicine
Houston, TX, USA
Infectious Disease Physician
Michael E. DeBakey VA Medical Center
Houston, TX, USA

Hannah Nam, MD
Assistant Professor of Medicine
Division of Infectious Diseases
University of California
Irvine, CA, USA

Avindra Nath
Chief, Section of Infections of the Nervous System
National Institute of Neurological Disorders and Stroke
National Institutes of Health
Bethesda, MD, USA

Kari Neeman, MD
Assistant Professor
Pediatric Infectious Disease
University of Nebraska Medical Center
Omaha, Nebraska

Ronald L. Nichols, MD, MS, FACS
William Henderson Professor of Surgery—Emeritus; Professor of Microbiology and Immunology
Department of Surgery
Tulane University School of Medicine
New Orleans, LA, USA

Lindsay E. Nicolle, MD, FRCPC
Professor Emeritus
University of Manitoba
Winnipeg, MB, Canada

Obinna N. Nnedu, MD
Program Director, Infectious Diseases Fellowship Program
Department of Infectious Disease
Ochsner Clinic Foundation
New Orleans, LA, USA

Nancy B. Norton, MD
Associate Professor
Department of Anatomy and Pathology
Marshall University Joan C. Edwards School of Medicine
Huntington, WV, USA

Judith A. O'Donnell, MD
Hospital Epidemiologist and Director
Department of Infection Prevention & Control
Chief
Division of Infectious Diseases, Penn Presbyterian
Medical Center
Professor of Clinical Medicine
Division of Infectious Diseases
University of Pennsylvania Perelman School of Medicine
Philadelphia, PA, USA

Anthony Ogedegbe, MD
Assistant Professor of Clinical Medicine
Weill Cornell Medical College
New York, NY, USA

Todd D. Otteson, MD, MPH
Division Chief
Pediatric Otolaryngology
University Hospitals Case Medical Center
Cleveland, OH
Associate Professor
Otolaryngology and Pediatrics
Case Western Reserve University
School of Medicine
Cleveland, OH

Robert L. Owen, MD
Department of Veteran Affairs Medical Center
San Francisco, CA, USA

George A. Pankey, MD
Director, Infectious Diseases Research
Department of Infectious Disease
Ochsner Clinic Foundation
New Orleans, LA, USA

George Pappas, MD
Institute for Continuing Medical Education of Ioannina
Greece

Peter G. Pappas, MD, FACP
Professor of Medicine
Chief Scientific Advisory Committee, MSGERC
Division of Infectious Diseases
University of Alabama at Birmingham School of Medicine
Birmingham, AL, USA

Diane Parente, PharmD, BCIDP
Clinical Pharmacist Specialist, Infectious Diseases and
Antimicrobial Stewardship
Assistant Professor of Medicine, Alpert Medical School of Brown
University
Providence, RI, USA

Richard H. Parker, MD, FIDSA
Infectious Diseases and Internal Medicine,
Supervisor of Primary Care and HIV Medicine
Andromeda Transcultural Health Center
Washington, DC, USA

Amee Patrawalla, MD, MPH
Associate Professor
Medicine—Pulmonary and Critical Care
Rutgers New Jersey Medical School
Newark, NJ, USA

Andrew T. Pavia, MD
George and Esther Gross Presidential Professor
Chief, Division of Pediatric Infectious Diseases
University of Utah
Salt Lake City, UT, USA

Zbigniew S. Pawlowski, MD, DTMH Dr honoris causa Warsaw
Professor Emeritus, Clinic of Tropical and Parasitic Diseases
University of Medicine
Poznan, Poland

Richard Pearson, MD
Harrison Distinguished Professor of Medicine
Division of Infectious Diseases and International Health
University of Virginia School of Medicine
Charlottesville, VA, USA

Stephen I. Pelton, MD
Professor of Pediatrics and Epidemiology
Boston University Schools of Medicine
and Public, Health
Boston, MA, USA

Christopher M. Perrone, MD
Assistant Professor of Clinical Neurology
Perelman School of Medicine
University of Pennsylvania
Philadelphia, PA, USA

Simone Pessato, MD
Dermatologist
Brazilian Society of Dermatology
Private Office
Porto Alegre, Rio Grande do Sul, Brazil

K. Shad Pharaon, MD
Department of Surgery
PeaceHealth Southwest Medical Center
Vancouver, WA, USA

Phillippa Poole, MD
Professor and Head
School of Medicine
University of Auckland
Auckland, New Zealand

William G. Powderly, MD, FRCPI
Dr. J. William Campbell Professor of Medicine
Larry J. Shapiro Director, Institute of Public Health
Chief, Division of Infectious Diseases
Washington University School of Medicine
St. Louis, MO, USA

Krista Powell, MD, MPH
Deputy Chief, Prevention and Response Branch
CDC, Division of Healthcare Quality Promotion

Laurel C. Preheim, MD
Professor, Department of Internal Medicine
Division of Infectious Diseases
Creighton University Medical Center
Omaha, NE, USA

Thomas C. Quinn, MD, MSc
Professor of Medicine and Pathology
Division of Infectious Diseases
Johns Hopkins University School of Medicine
Baltimore, MD, USA

Issam I. Raad, MD
Department Chair and Professor
Department of Infectious Diseases, Infection Control and Employee Health
The University of Texas MD Anderson Cancer Center
Houston, TX, USA

Sanjay Ram, MD
Associate Professor
Department of Medicine
University of Massachusetts Medical School
Worcester, Massachusetts

Mayur Ramesh, MD
Division of Infectious Disease
Henry Ford Hospital
Detroit, MI, USA

Carlos R. Ramírez-Ramírez, MD
Department of Medicine
University of Puerto Rico School of Medicine
San Juan, Puerto Rico

Carlos H. Ramírez-Ronda, MD, MACP
Professor of Medicine
University of Puerto Rico School of Medicine
San Juan, Puerto Rico

Jean-Pierre Raufman, MD
Moses and Helen Golden Paulson Professor of Medicine
Head, Division of Gastroenterology & Hepatology
University of Maryland School of Medicine
Baltimore, MD, USA

Raymund R. Razonable, MD
Professor of Medicine
Chair, Transplantation
Virology and Infectious Diseases
Division of Infectious Diseases
Mayo Clinic
Rochester, Minnesota

Paulina A. Rebolledo, MD, MSc
Assistant Professor of Medicine and Global Health
Emory University
Atlanta, GA, USA

Robert V. Rege, MD
Professor of Surgery and Associate Dean for Undergraduate Medical Education
UT Southwestern Medical Center
Dallas, TX, USA

Michael F. Rein, MD, MACP
Professor Emeritus of Medicine
Division of Infectious Diseases and International Health,
Department of Medicine
University of Virginia
Charlottesville, VA, USA

Dalilah Restrepo, MD
St. Luke's—Roosevelt Hospital
New York, NY, USA

Bruce S. Ribner, MD, MPH
Professor of Medicine, Emory University School of Medicine
Principal Investigator, National Emerging Special Pathogens Training and Education Center
Medical Director, HHS Region 4 Special Pathogens Training and Education Center
Atlanta, GA, USA

Emiko Rimbara, PhD
Department of Bacteriology II
National Institute of Infectious Diseases
Tokyo, Japan

Mark Robbins, MD, MSc
Assistant Professor
Division of Infectious Diseases
Dalhousie University
Nova Scotia, Canada

Eduardo Rodríguez-Noriega, MD
Chief, Infectious Diseases
Hospital Civil de Guadalajara, Fray Antonio Alcalde
Centro Universitario Ciencias de la Salud, Universidad de Guadalajara
Guadalajara, Jalisco, Mexico

Ralph Rogers, MD
Assistant Professor of Medicine, Clinician Educator
Division of Infectious Disease
Warren Alpert Medical School of Brown University
Providence, RI, USA

Allan Ronald, MD, OC, OM, FRCPC
Distinguished Professor Emeritus
Departments of Internal Medicine and Medical Microbiology
University of Manitoba
Canada

Andrew Rosenbaum, MD
Assistant Professor of Medicine
Department of Cardiovascular Medicine
Mayo Clinic College of Medicine
Rochester, MN, USA

Sergio D. Rosenzweig, MD, PhD
Chief, Immunology Service
Department of Laboratory Medicine, Clinical Center
National Institutes of Health
Bethesda, MD, USA

Virginia R. Roth, MD, FRCPC
Associate Professor of Medicine
University of Ottawa
Director
Infectious Prevention and Control
Program, The Ottawa Hospital
Ottawa, Canada

Nadine G. Rouphael
Assistant Professor of Medicine
Division of Infectious Diseases
Emory University School of Medicine
Atlanta, Georgia

Thomas A. Russo, MD, CM
Professor and Chief, Division of Infectious Diseases
Department of Medicine
Jacobs School of Medicine and Biomedical Sciences
University at Buffalo
Buffalo, NY, USA

William A. Rutala, MS, MPH, PhD
Professor of Medicine, Director of Statewide
Program for Infection Control and Epidemiology, Director of Hospital Epidemiology
Occupational Health and Safety Program
University of North Carolina School of Medicine
Chapel Hill, NC, USA

Amar Safdar, MD
Associate Professor of Medicine, Director Transplant Infectious Diseases
NYU Langone Medical Center, NYU School of Medicine
New York, NY, USA

Wilmara Salgado-Pabón, MS, PhD
Post-Doctoral Fellow
University of Iowa
Carver College of Medicine
Iowa City, Iowa

Rohini Samudralwar, MD
Department of Neurology
Multiple Sclerosis/Neuroimmunology Division
The University of Texas Health Science Center at Houston
Houston, TX, USA

Rafik Samuel, MD
Professor of Medicine, Chief, Section of Infectious Diseases
Lewis Katz School of Medicine at Temple University
Philadelphia, PA, USA

Patrick M. Schlievert, PhD
Professor, Microbiology and Immunology and Internal Medicine
University of Iowa Carver College of Medicine
Iowa City, IA, USA

Steven K. Schmitt, MD, FIDSA, FACP
Head, Section of Bone and Joint Infections
Associate Professor of Medicine, Department of Infectious Disease
Vice Chair for Professional Staff Affairs, Medicine Institute
Cleveland Clinic
Cleveland, OH, USA

William A. Schwartzman, MD
Associate Clinical Professor of Medicine
UCLA School of Medicine
Los Angeles, CA, USA
Chief, Infectious Diseases, Sepulveda VA OPC
Sepulveda, CA, USA
Chair, Infection Control Committee
Attending in Infectious Diseases, VA Greater
Los Angeles Healthcare System
Los Angeles, CA, USA

Andréa Sciberras, DO, AAHIVS, FACOI, FACP
Assistant Professor
Department of Medicine
Mount Sinai South Nassau
Assistant Professor
Icahn School of Medicine at Mount Sinai
Oceanside, NY, USA

Ramin Sedaghat Herati, MD
Assistant Professor
Department of Medicine, Division of Infectious Diseases and Immunology
NYU School of Medicine
New York City, NY, USA

Pritha Sen, MD
Instructor in Medicine
Department of Medicine, Division of Infectious Diseases
Massachusetts General Hospital
Boston, MA, USA

Arlene C. Seña, MD, MPH
Associate Professor of Medicine
Division of Infectious Diseases
University of North Carolina at Chapel Hill
Chapel Hill, North Carolina
Medical and Laboratory Director
Durham
County Department of Public Health
Durham, North Carolina

John W. Sensakovic, MD, PhD
Infectious Disease, St. Michael's Medical Center
Newark, NJ, USA

Susan K. Seo, MD, FACP, FIDSA
Director, Antibiotic Management Program
Clinical Member
Infectious Disease Service
Memorial Sloan Kettering Cancer Center
Professor of Clinical Medicine
Weill Cornell Medical College
New York, NY, USA

Rajeev Shah, PharmD
Clinical Pharmacist Specialist, Infectious Diseases
Assistant Professor of Medicine
Alpert Medical School of Brown University
Providence, RI, USA

Dennis J. Shale, MD
Clinical Professor
Institute of Molecular and Experimental Medicine
Cardiff University
Cardiff, UK

Susarla K. Shankar, MD
Emeritus Professor
Department of Neuropathology
National Institute of Mental Health and Neurosciences
Bangalore, India

Sylvia J. Shaw, MD
Assistant Professor of Clinical Medicine
Keck School of Medicine
University of Southern California
Los Angeles, CA

Sheela Shenoi, MD, MPH
Assistant Professor of Medicine
Section of Infectious Diseases, Department of Medicine
Yale University School of Medicine
New Haven, CT, USA

Upinder Singh, MD
Associate Professor of Medicine (Infectious Diseases and Geographic Medicine) and Microbiology and Immunology
Stanford School of Medicine
Stanford, CA

Kamaljit Singh, MD, D(ABMM)
Associate Professor
Infectious Diseases
Rush University Medical Center
Chicago, IL

Linda A. Slavoski, MD
Doctor of Infectious Disease Medicine and Internal Medicine
Wilkes Barre, PA, USA

Leon G. Smith, MD
Chairman
Department of Medicine
St. Michael's Medical Center
Newark, NJ, USA
Chairman
Department of Medicine
Seton Hall University School of Graduate Medical Education
Professor of Preventative Medicine
Newark, NJ, USA
Medical School
New Brunswick, NJ, USA

James W. Smith, MD
Professor of Internal Medicine and Infectious Diseases
University of Texas Southwestern Medical School
Dallas, TX, USA

Jessica N. Snowden, MD
Assistant Professor
University of Nebraska Medical Center
Omaha, Nebraska

Jack D. Sobel, MD
Division of Infectious Diseases
Wayne State University School of Medicine
Detroit, MI, USA

M. Rizwan Sohail, MD
Assistant Professor of Medicine
Divisions of Infectious Diseases and Cardiovascular Diseases
Department of Medicine
Mayo Clinic College of Medicine
Rochester, MN

Emily Souder, MD
Attending Physician
Section of Pediatric Infectious Diseases
St Christopher's Hospital for Children
Philadelphia, PA, USA

Amy Spallone, MD
Division of Infectious Diseases
Department of Medicine
Baylor College of Medicine
Houston, TX, USA

Barbara W. Stechenberg, MD
Professor of Pediatrics, Tufts University School of Medicine
Springfield, MA
Associate Program Director, Pediatrics Residency Program, Baystate Medical Center
Springfield, MA, USA

James M. Steckelberg, MD
Professor of Medicine
Division of Infectious Diseases
Department of Medicine
Mayo Clinic College of Medicine
Rochester, MN

David S. Stephens, MD
Stephen W. Schwarzmann Distinguished Professor of Medicine
Vice President for Research
Woodruff Health Sciences Center
Chair, Department of Medicine
Emory University School of Medicine
Atlanta, GA, USA

Dennis L. Stevens, MD, PhD
Professor of Medicine
University of Washington School of Medicine
Seattle, Washington
Chief
Infectious Disease, VAMC
Boise, Idaho

Hillary C. Stiefel, MD
Assistant Professor of Ophthalmology and Ocular Pathology
Casey Eye Institute
Oregon Health and Science University
Portland, OR, USA

Charles Stratton
Associate Professor of Medicine and Pathology
Vanderbilt University School of Medicine
Director, Clinical Virology and Immunopathology Laboratory
Vanderbilt University Medical Center
Nashville, TN, USA

Kathryn N. Suh, MD, FRCPC
Associate Professor of Medicine
Division of Infectious Diseases
University of Ottawa
Ottawa, Canada

Domizio Suvà
Division of Orthopaedic and Trauma Surgery
Department of Surgery
Geneva University Hospitals and Faculty of Medicine
Geneva, Switzerland

Babafemi O. Taiwo, MBBS
Associate Professor of Medicine
Division of Infectious Diseases
Feinberg School of Medicine
Northwestern University
Chicago, IL

Naasha J. Talati, MD, MSCR
Assistant Professor
University of Pennsylvania
School of Medicine
Assistant Hospital Epidemiologist and Director of Antimicrobial Stewardship
Penn Presbyterian Medical Center
Philadelphia, PA, USA

Michael Thompson, DO
Clinical Assistant Professor, George Washington University School of Medicine
Adult Hospital Medicine and Infectious Diseases
Anne Arundel Medical Center
Annapolis, Maryland

Kenneth J. Tomecki, MD
Department of Dermatology
Cleveland Clinic
Cleveland, OH

Marc Traeger, MD
Department of Preventative Medicine
Whiteriver Service Unit/Indian Health Service
Whiteriver, AZ, USA

Edmund C. Tramont, MD
Associate Director of Special Projects
National Institute of Allergy and Infectious Diseases
National Institutes of Health
Bethesda, MD, USA

Sonya Trinh, MD, MPH
Senior Lecturer
Faculty of Medicine
University of Queensland Ochsner Clinical School
New Orleans, LA, USA

Grishma R. Trivedi, MD
Department of Medicine
Jacobs School of Medicine and Biomedical Sciences
University at Buffalo
Buffalo, NY, USA

Donald D. Trunkey, MD
Department of Surgery
Oregon Health & Science University
Portland, Oregon

Elmer Y. Tu, MD
Associate Professor of Clinical Ophthalmology
Department of Ophthalmology and Visual Science
University of Illinois Eye and Ear Infirmary
Chicago, IL, USA

Allan R. Tunkel, MD, PhD
Professor of Medicine and Medical Science
Senior Associate Dean for Medical Education
The Warren Alpert Medical School of Brown University
Providence, RI, USA

Ilker Uçkay, MD
Division of Infectious Diseases
Department of Specialties of Internal Medicine
Division of Orthopaedic and Trauma Surgery
Department of Surgery
Geneva University Hospitals and Faculty of Medicine
Geneva, Switzerland

Travis Vandergriff, MD
Assistant Professor
Department of Dermatology
University of Texas Southwestern Medical Center
Dallas, TX

Pierre Vaudaux, PhD
Division of Infectious Diseases
Department of Specialties of Internal Medicine
Geneva University Hospitals and Faculty of Medicine
Geneva, Switzerland

Manasa Velagapudi, MBBS
Assistant Professor
Department of Internal Medicine
Division of Infectious Diseases
CHI Health Creighton University Medical Center
Omaha, NE, USA

Karen J. Vigil, MD
Assistant Professor
Division of Infectious Diseases
The University of Texas Health Science Center at Houston—Medical School
Houston, TX, USA

Trung T. Vu, MD
Infectious Diseases
Springfield, MA, USA

Duc J. Vugia, MD, MPH
Chief, Infectious Diseases Branch
California Department of Public Health
Richmond, CA, USA
Clinical Professor
Department of Epidemiology & Biostatistics
University of California, San Francisco
San Francisco, CA, USA

Jatin M. Vyas, MD, PhD
Associate Professor
Department of Medicine
Massachusetts General Hospital/Harvard Medical School
Boston, MA, USA

Keyur S. Vyas, MD
Associate Professor of Medicine
Department of Internal Medicine, Division of Infectious Diseases
University of Arkansas for Medical Sciences
Little Rock, AR, USA

Ken B. Waites, MD
Professor
Department of Pathology
Director, Diagnostic Mycoplasma Laboratory
University of Alabama at Birmingham
Birmingham, AL, USA

Noah Wald-Dickler, MD
Assistant Professor of Population and Public Health Sciences and Medicine
University of Southern California
Los Angeles, CA, USA

Rebecca A. Ward, PhD
Medical Writer
Department of Medicine
Massachusetts General Hospital
Boston, MA, USA

Richard R. Watkins, MD, MS, FACP, FIDSA, FISAC
Professor of Internal Medicine
Northeast Ohio Medical University
Rootstown, OH, USA

David J. Weber, MD, MPH
Professor of Medicine and Pediatrics
University of North Carolina School of Medicine
Chapel Hill, NC, USA
Professor of Epidemiology, Gillings School of Global Public Health
Chapel Hill, NC, USA

Andrew S. Webster, MD
Instructor
Department of Medicine, Division of Infectious Diseases
Emory University School of Medicine
Atlanta, GA, USA

Jeffrey M. Weinberg, MD
Dermatology
Icahn School of Medicine at Mt Sinai
New York, NY, USA

Debra L. Weiner, MD, PhD
Attending Physician Emergency Medicine
Boston Children's Hospital
Assistant Professor of Pediatrics
Harvard Medical School
Boston, MA, USA

Steven M. Weiss, MD, FACP
Director, Internal Medicine Residency Training Program
Department of Medical Education
Mount Sinai South Nassau
Clinical Associate Professor, Icahn School of Medicine at Mount Sinai
Oceanside, NY, USA

Richard J. Whitley, MD
Distinguished Professor
Loeb Eminent Scholar Chair in Pediatrics
Professor of Pediatrics, Microbiology, Medicine and Neurosurgery
University of Alabama at Birmingham
Birmingham, AL, USA

Mary E. Wilson, MD
Clinical Professor of Epidemiology and Biostatistics
School of Medicine
University of California
San Francisco, CA, USA

Brian Wispelwey, MS, MD
Professor of Medicine
Clinical Chief, Infectious Diseases
University of Virginia School of Medicine
Charlottesville, VA, USA

Uni Wong, MD
Assistant Professor of Medicine
Division of Gastroenterology & Hepatology
University of Maryland School of Medicine
Baltimore, MD, USA

Patricia Wong, MD, MSCE
Lankenau Hospital/Main Line Gastroenterology Associates
Philadelphia, PA, USA
Adjunct Assistant Professor of Medicine
Johns Hopkins University
Baltimore, MD, USA

Henry M. Wu, MD, DTM&H
Associate Professor
Department of Medicine
Emory University School of Medicine
Atlanta, GA, USA

Bian Wu, MD
Resident
UCSF School of Medicine
San Francisco, CA, USA

Neal S. Young, MD
Chief of Hematology Branch, Director of Trans-NIH Center for Human Immunology, Autoimmunity and Inflammation
National Heart, Lung and Blood Institute, National Institutes of Health
Bethesda, MD, USA

Roger W. Yurt, MD
Chief of Burns, Critical Care and Trauma
New York Presbyterian Hospital
New York, NY, USA

Tirdad T. Zangeneh, DO
Associate Professor of Medicine
Division of Infectious Diseases
University of Arizona
Tucson, AZ, USA

Matthew D. Zelhart, MD, FACS, FASCRS
Associate Program Director, Residency
Director, Masters in Surgical Clinical Research Program
Assistant Professor
Department of Surgery
Tulane University School of Medicine
New Orleans, LA, USA

Marcus Zervos, MD
Professor of Medicine
Wayne State University School of Medicine
Chief, Infectious Disease Division
Henry Ford Health System
Detroit, MI, USA

Alimuddin Zumla, MD, PhD, FRCP, FRCPath, FAAS, FRSB
Professor of Infectious Diseases and International Health
Department of Infection and Immunity
University College London
London, UK

Section 1

Clinical syndromes: General

1

Fever of unknown origin

Cheston B. Cunha and Burke A. Cunha

Overview

Fever of unknown origin (FUO) describes prolonged fevers >38°C/101°F lasting for 3 or more weeks that remain undiagnosed after a focused FUO outpatient/inpatient workup. The causes of FUO include infectious and noninfectious disorders. A variety of infectious, malignant, and rheumatic/inflammatory disorders may be associated with prolonged fevers, but relatively few persist undiagnosed for sufficient duration to be classified as FUOs.

Causes of FUO

The distribution of disorders causing FUOs is dependent on age, demographics, family history, zoonotic exposures, and previous/current conditions (e.g., malignancies, rheumatic/inflammatory disorders, cirrhosis). Each category of FUO may also be approached by subgroups (e.g., elderly, immunosuppressed, transplants, febrile neutropenia, zoonoses, HIV, nosocomial, returning travelers). The differential diagnosis in each subgroup reflects the relative distribution of disorders within the subgroup and the geographic distribution of endemic diseases. The relative distribution of causes of FUO has changed over time, but, with few exceptions, the disorders responsible for FUOs have remained relatively constant over time (Table 1.1).

Diagnostic approach to FUOs

In patients presenting with prolonged fevers, the clinician should first determine if the patient indeed has an FUO. Because there are many causes of FUO, there is no "cookbook" or algorithmic approach for diagnosing FUOs. In medicine, the history provides important initial diagnostic clues and a general sense of the likely FUO category (e.g., weight loss with early anorexia suggests malignancy, arthralgias/myalgias suggest a rheumatic/inflammatory disorder, and fever with chills suggests an infectious etiology).

After an FUO category is suggested by historical clues, the physical examination should focus on history-relevant findings in the differential diagnosis. The physical examination should not be comprehensive but, more importantly, should be carefully focused on demonstrating the presence or absence of key findings in the differential diagnosis (e.g., a complete neurologic exam is unhelpful in an FUO patient with probable adult Still's disease). On physical examination particular attention should be given to eye findings, liver, spleen, lymph nodes, joint findings, and skin lesions (Table 1.2). At this point, based on the presence or absence of history and physical examination clues, the initial FUO diagnostic workup (e.g., nonspecific laboratory tests) should also be focused on ruling in or ruling out the most likely diagnostic possibilities. Since the patient has already been seen by one or more physicians prior to presentation, routine laboratory tests have already been done (e.g., CBC, liver function test [LFTs],

TABLE 1.1 **CLASSIC CAUSES OF FEVER OF UNKNOWN ORIGIN (FUO)**

Type of disorder	Common	Uncommon	Rare
Malignancy/neoplastic disorders	Lymphoma[a] Hypernephromas/ renal cell carcinoma (RCC)	Pre-leukemias (AML)[a] Myeloproliferative disorders (MPDs)	Atrial myxomas Multiple myeloma Colon carcinoma Pancreatic carcinoma CNS metastases Hepatomas Liver metastases
Infectious diseases	Miliary TB SBE Brucellosis[a] Q fever[a]	Intra-abdominal/pelvic abscess Intra/perinephric abscess Typhoid fever/enteric fevers[a] Toxoplasmosis Cat-scratch disease (CSD)[a] EBV CMV HIV Extrapulmonary TB (renal TB, CNS TB)	Periapical dental abscess Chronic sinusitis/mastoiditis Subacute vertebral osteomyelitis Aortoenteric fistula Relapsing fever[a] Rat-bite fever[a] Leptospirosis[a] Histoplasmosis Coccidiomycosis Visceral leishmaniasis (kala-azar) LGV Whipple's disease[a] Castleman's disease[a] (MCD) Malaria Babesiosis Ehrlichiosis
Rheumatologic/ inflammatory disorders	Adult Still's disease[a] Giant cell arteritis (GCA)/temporal arteritis (TA)[a]	PAN/MPA[a] Late-onset rheumatoid arthritis (LORA)[a] SLE[a]	Takayasu's arteritis[a] Kikuchi's disease[a] Sarcoidosis (CNS) Felty's syndrome Gaucher's disease Polyarticular gout[a] Pseudogout[a] Schnitzler's syndrome[a] Behçet's disease[a] FAPA syndrome[a] (Marshall's syndrome)
Miscellaneous disorders	Drug fever[a] Alcoholic cirrhosis[a]	Subacute thyroiditis[a] Regional enteritis (Crohn's disease)[a]	Pulmonary emboli (small/multiple) Pseudolymphomas Kikuchi's disease[a] Rosai–Dorman disease[a] Erdheim–Chester disease (ECD)[a] Cyclic neutropenia[a] Familial periodic fever syndromes[a] • FMF • Hyper IgD syndrome[a] • TNF receptor-1-associated periodic syndrome (TRAPS) • Muckle–Wells syndrome Systemic mastocytosis Hypothalamic dysfunction Hypertriglyceridemia Factitious fever[a]

[a]Also cause of recurrent FUOs.

Disorders with FUO potential include any not easily diagnosed disorder with prolonged fevers, travel-related infections with prolonged fevers presenting in nonendemic areas, any relapsing/recurrent disorder with prolonged fevers, or any disorder with prolonged fevers with unusual clinical findings.

AML, acute myelogenous leukemia; CMV, cytomegalovirus; CNS, central nervous system; EBV, Epstein–Barr virus; FAPA, fever, aphthous ulcers, pharyngitis, adenitis; FMF, familial Mediterranean fever; HIV, human immunodeficiency virus; LGV, lymphogranuloma venereum; MCD, multicentric Castleman's disease; MPA, microscopic polyangiitis; PAN, periarteritis nodosa; SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus; TB, tuberculosis; TNF, tumor necrosis factor.

TABLE 1.2 **HISTORY AND PHYSICAL EXAMINATION CLUES TO FEVER OF UNKNOWN ORIGIN (FUO) CATEGORIES**

	Historical features	Clues from the history	Physical examination findings	Clues from the physical examination
Malignant/ neoplastic disorders	• PMH/FMH malignancy	• Possibility of same disease likely	• Fever pattern: Relative bradycardia Hectic/septic fevers (Pel-Ebstein)	
	• HA/mental confusion	• CNS metastases, lymphomas, multiple myeloma, atrial myxoma (CNS emboli)		• CNS, malignancies, lymphomas • Lymphomas
	• Weight loss (with early decreased appetite)	• Any malignant/neoplastic disorder	• Cranial nerve palsies	• CNS lymphomas, CNS neoplasms
	• Early satiety	• Lymphomas, any malignant/ neoplastic disorder causing splenomegaly	• Fundi: Roth spots • Fundi: cytoid bodies (cotton wool spots)	• Lymphomas, atrial myxoma • Atrial myxoma
	• Pruritus (post hot shower/ bath)	• Lymphoma, MPDs	• Fundi: retinal hemorrhages	• Pre-leukemia (AML)
	• Night sweats	• Any malignant/neoplastic disorder	• Adenopathy	• Lymphoma, Kikuchi's disease, Rosai–Dorfman disease
	• Abdominal discomfort/ pain	• Hypernephroma, hepatoma, liver metastases, colon carcinoma, pancreatic carcinoma	• Sternal tenderness • Heart murmur	• Pre-leukemia (AML), MPDs • Marantic endocarditis, atrial myxoma
	• Testicular pain	• Lymphoma	• Hepatomegaly	• Hepatoma, hypernephroma, liver metastases
	• Bone pain	• Multiple myeloma, any malignant/neoplastic disorder with bone involvement	• Splenomegaly • Splinter hemorrhages • Epididymitis	• Lymphomas, MPDs • Atrial myxoma • Lymphomas
Infectious diseases	• PMH/FMH of infections	• Possibility of same disease high	• Fever pattern: Relative bradycardia	
	• HA/mental confusion	• Brucellosis, CSD, ehrlichiosis, Q fever, malaria, leptospirosis, Whipple's disease, typhoid fever/enteric fevers, rat-bite fever, relapsing fever, CNS TB, HIV, LGV		• Typhoid fever/enteric fevers, leptospirosis, Q fever, malaria, babesiosis, ehrlichiosis
			Double quotidian fever	• Visceral leishmaniasis (kala-azar)
			Camelback fever curve	• Ehrlichiosis, leptospirosis, brucellosis, rat-bite fever (*S. minus*)
	• Recent/similar illness exposure	• Possibility of same disease high	Morning temperature spikes	• Miliary TB, typhoid fever/ enteric fevers
	• Surgical/invasive procedures	• Abscess, SBE		
	• Aortic aneurysm/repair	• Q fever, enteric fever	Relapsing fevers	• Brucellosis, malaria, rat-bite fever (*S. moniliformis*)
	• STD history	• LGV	• Abducens (CN VI) palsy	• CNS TB
	• Recent travel	• Typhoid/enteric fevers, leptospirosis, malaria, visceral leishmaniasis (kala-azar), brucellosis, Q fever	• Conjunctival suffusion • Conjunctival hemorrhages	• Trichinosis, relapsing fever, leptospirosis • SBE
	• Insect exposure	• Malaria, ehrlichiosis, babesiosis, visceral leishmaniasis (kala-azar), relapsing fever	• Chorioretinitis • Choroid tubercles	• Toxoplasmosis, TB, histoplasmosis • Miliary TB
	• Pet/animal contact	• Q fever, CSD, toxoplasmosis, rat-bite fever, relapsing fever, leptospirosis, brucellosis	• Roth spots • Palatal petechiae	• SBE • EBV, CMV, toxoplasmosis
	• Unpasteurized milk/cheese consumption	• Q fever, brucellosis	• Tongue ulcer • Adenopathy	• Histoplasmosis • CSD, EBV, CMV

(continued)

TABLE 1.2 CONTINUED

	Historical features	Clues from the history	Physical examination findings	Clues from the physical examination
	• Undercooked meat consumption	• Toxoplasmosis, trichinosis	• Heart murmur • Spinal tenderness	• SBE • Subacute vertebral osteomyelitis, typhoid fever/enteric fever, skeletal TB, brucellosis
	• Blood transfusions	• Malaria, babesiosis, ehrlichiosis, CMV, HIV	• Hepatomegaly	• Q fever, typhoid fever/ enteric fevers, brucellosis, visceral leishmaniasis (kala-azar), rat-bite fever, relapsing fever
	• Poor dentition	• SBE, apical root abscess		
	• Sleep disturbances	• Brucellosis, relapsing fever, leptospirosis	• Splenomegaly	• Miliary TB, EBV, CMV, typhoid fever/enteric fevers, brucellosis, histoplasmosis, ehrlichiosis, malaria, Q fever, SBE, CSD Rat-bite fever, relapsing fever
	• Early satiety	• EBV, CMV, Q fever, brucellosis, SBE, miliary TB		
	• Arthralgias	• Rat-bite fever, LGV, Whipple's disease, brucellosis	• Splinter hemorrhages • Ostler's nodes/Janeway lesions	• SBE • SBE
	• Myalgias	• Q fever, leptospirosis, relapsing fever, trichinosis	• Skin hyperpigmentation	• Visceral leishmaniasis (kala-azar), Whipple's disease
	• Sinusitis	• Chronic sinusitis		
	• Night sweats	• Miliary TB, histoplasmosis	• Epididymitis	• EBV, renal TB, brucellosis
	• Weight loss	• Miliary TB, histoplasmosis		
	• Tongue pain	• Histoplasmosis, relapsing fever		
	• Neck pain	• Subacute vertebral osteomyelitis, chronic mastoiditis		
	• Tender finger tips	• SBE		
	• Abdominal pain	• Relapsing fever, leptospirosis, typhoid fever/enteric fevers, trichinosis		
	• Back pain	• Subacute vertebral osteomyelitis, brucellosis, SBE		
	• Testicular pain	• EBV		
Rheumatic/ inflammatory disorders	• PMH/FMH of rheumatic disorders	• Possibility of the same disease likely	• Fever pattern:	
	• HA/mental confusion	• GCA/TA, CNS sarcoidosis, adult Still's disease	Double quotidian fever Morning temperature spikes	• Adult Still's disease • PAN
	• Transient facial edema	• Takayasu's arteritis		
	• Hearing loss	• PAN	• Lacrimal gland enlargement	• LORA, sarcoidosis, SLE
	• Nasal stuffiness	• Sarcoidosis	• Parotid gland enlargement	• Sarcoidosis
	• Joint pain/swelling	• SLE, LORA, sarcoidosis, adult Still's disease	• Rash	• Sarcoidosis, SLE, adult Still's disease
			• Unequal pulses	• Takayasu's arteritis
	• Eye symptoms	• PAN, sarcoidosis	• Conjunctival nodules	• Sarcoidosis
	• Transient blindness	• PAN, SLE, GCA/TA, Takayasu's arteritis	• Dry eyes	• Sarcoidosis
	• Neck/jaw pain	• GCA/TA, Takayasu's arteritis	• Watery eyes	• PAN
	• Sore throat	• SLE, adult Still's disease	• Argyll-Robertson or Adies' pupils	• Sarcoidosis
	• Tongue tenderness	• GCA/TA	• Band keratopathy	• Adult Still's disease, sarcoidosis
	• Mouth ulcers	• SLE	• Episcleritis	• GCA/TA, LORA, PAN
	• Night sweats	• Takayasu's arteritis	• Scleritis	• SLE
	• Rash	• Adult Still's disease, SLE, sarcoidosis	• Iritis	• Adult Still's disease, SLE, sarcoidosis

TABLE 1.2 **CONTINUED**

	Historical features	Clues from the history	Physical examination findings	Clues from the physical examination
	• Dry cough	• Sarcoidosis, GCA/TA	• Uveitis	• Adult Still's disease, SLE, LORA, sarcoidosis
	• Acalculous cholecystitis	• SLE	• Fundi: optic neuritis with "macular star"	• PAN
	• Intermittent abdominal pain	• SLE, PAN, adult Still's disease		
	• Tender finger tips	• SLE, PAN		
	• Testicular pain	• PAN, SLE	• Fundi: cytoid bodies (cotton wool spots)	• SLE, GCA/TA, PAN, adult Still's disease
			• Fundi: "candlewax drippings"	• Sarcoidosis
			• Fundi: Roth spots	• SLE, PAN
			• Fundi: central/branch retinal artery occlusion	• SLE, GCA/TA, Takayasu's arteritis
			• Fundi: central retinal vein occlusion	• SLE, sarcoidosis
			• Oral ulcers	• SLE, Behçet's disease, FAPA syndrome
			• Tongue ulcers	• GCA/TA
			• Adenopathy	• SLE, LORA, sarcoidosis
			• Splenomegaly	• Felty's syndrome, SLE, adult Still's disease, sarcoidosis
			• Heart murmur	• SLE (Libman–Sacks)
			• Arthritis/joint effusion	• Any rheumatic/ inflammatory disorder
			• Epididymitis	• PAN, SLE, sarcoidosis
Miscellaneous disorders	• Negative HPI/PMH for infectious, inflammatory, rheumatic/malignant/ neoplastic disorders	• Non-miscellaneous disorders unlikely	• Fever pattern: Relative bradycardia	• Drug fever, factitious fever
	• PMH of periodic fevers (FMF, hyper IgD syndrome, TRAPS, Muckle– Wells syndrome)	• Possibility of same disease likely	• Periorbital edema • Parotid enlargement • Episcleritis	• TRAPS • Alcoholic cirrhosis • Regional enteritis (Crohn's disease)
	• Drugs/medications • Fume exposure • Alcoholism	• Drug fever, pseudolymphoma • Fume fever • Alcoholic cirrhosis	• Fundi: lipemia retinalis • Oral ulcers • Adenopathy	• Hypertriglyceridemia • Hyper IgD syndrome • Pseudolymphoma, hyper IgD syndrome (cervical), Schnitzler's syndrome (axillary/inguinal)
	• Regional enteritis (Crohn's disease)	• Abscess	• Signs of alcoholic cirrhosis	• Alcoholic cirrhosis
	• Thyroid disease • Hyperlipidemia • Medical personnel • Sore throat	• Subacute thyroiditis • Hypertriglyceridemia • Factitious fever • Subacute thyroiditis, hyper IgD syndrome	• Hepatomegaly • Splenomegaly	• Schnitzler's syndrome, hyper IgD syndrome • Regional enteritis (Crohn's disease), alcoholic cirrhosis, FMF, hyper IgD syndrome, Muckle–Wells syndrome, Schnitzler's syndrome
	• Neck/jaw pain • Intermittent abdominal pain	• Subacute thyroiditis • Regional enteritis (Crohn's disease), FMF, Muckle–Wells syndrome	• Epididymitis • Perirectal fistula	• FMF, TRAPS • Regional enteritis (Crohn's disease)

Historical features	Clues from the history	Physical examination findings	Clues from the physical examination
• Arthralgias/joint pains	• FMF, hyper IgD syndrome, TRAPS, Muckle–Wells syndrome, cyclic neutropenia, Schnitzler's syndrome		
• Testicular pain	• FMF, TRAPS		
• Bone pain	• Schnitzler's syndrome		
• Intermittent urticaria	• Schnitzler's syndrome Hyper IgD syndrome		

AML, acute monocytic leukemia; CMV, cytomegalovirus; CN VI, cranial nerve VI; CNS, central nervous system; CSD, cat scratch disease; EBV, Epstein–Barr virus; ESR, erythrocyte sedimentation rate; FAPA, fever, aphthous ulcers, pharyngitis, adenitis; FMF, familial Mediterranean fever; FMH, family medical history; GCA, giant cell arteritis; HA, headache; HIV, human immunodeficiency virus; LGV, lymphogranuloma venereum; LORA, late-onset rheumatoid arthritis; MPA, microscopic polyangiitis; MPDs, myeloproliferative disorders; PAN, periarteritis nodosa; PMH, past medical history; RCC, renal cell carcinoma; SBE, subacute bacterial endocarditis; SLE, systemic lupus erythematosus; STD, sexually transmitted disease; TA, temporal arteritis; TB, tuberculosis; TRAPS, tartrate-resistant acid phosphatase.

urinalysis [UA]), but these tests should be carefully re-reviewed for diagnostic clues (e.g., relative lymphopenia).

The "shotgun" approach to laboratory testing for FUOs should be avoided. Since the number of FUO causes are legion, it is not clinically or cost effective to test for every cause of FUO. When asked why he robbed banks, Willy Sutton replied, "Because that's where the money is!" Similarly, a focused FUO workup should be directed at the most likely—not all—diagnostic possibilities as suggested by the history, physical, and nonspecific laboratory tests. Nondirected testing often provides misleading information. It makes no sense to obtain thyroid function tests (TFTs) in FUOs with joint symptoms; neither should TFTs be obtained in FUOs likely due to adult Still's disease, giant cell arteritis/temporal arteritis (GCA/TA), or periarteritis nodosa (PAN).

Blood cultures should not be obtained in all cases of FUO. If the FUO differential diagnosis includes adult Still's disease, subacute thyroiditis, or GCA/TA, blood cultures make little sense. Even if an infectious etiology is likely, blood cultures should not always be obtained (e.g., Epstein–Barr virus [EBV], cytomegalovirus [CMV], HIV). Blood cultures are ordered to rule out subacute bacterial endocarditis (SBE). The diagnosis of SBE is based on an otherwise unexplained high-grade/continuous bacteremia (with a known endocarditis pathogen) *plus* a cardiac vegetation. The diagnosis of culture-negative endocarditis (CNE) is not based on the presence of negative blood cultures and a vegetation. Rather, the diagnosis of CNE is based on three essential key findings: a cardiac vegetation, negative blood cultures, *plus* peripheral signs of SBE. The differential diagnosis of CNE includes marantic endocarditis (usually due to a malignancy). The diagnosis of marantic endocarditis is based on the size/shape of vegetation (different from SBE vegetations). Alternately, if an infectious etiology of CNE is suspected, then serologic tests for brucella and Q fever should be obtained. While brucella SBE vegetations are easily seen, Q fever SBE vegetations may be small or undetectable.

Because the appropriateness of therapy is based on a correct diagnosis, the main focus of the clinical approach to FUOs is diagnostic rather than therapeutic. The diagnostic workup should be focused based on signs, symptoms, and nonspecific laboratory abnormalities that may either enhance or diminish particular diagnostic possibilities. Nonspecific laboratory tests often provide important, albeit often subtle, clues in the FUO workup. By definition nonspecific laboratory tests are nonspecific, but when considered in concert often are helpful in narrowing diagnostic possibilities and in prompting specific diagnostic testing to rule in or rule out the most likely diagnoses being considered. Importantly, the diagnostic workup should not be excessive and should not include every conceivable cause of FUO. Focused diagnostic testing should be based on the pertinent aspects of the history, the presence or absence of characteristic physical findings, and a presumptive syndromic diagnosis based on combining key nonspecific laboratory findings.

Nonspecific laboratory test clues

Nonspecific laboratory clues are important in focusing the FUO diagnostic workup. In addition to the initial history and physical examination, selected nonspecific laboratory tests are helpful. If malignancy is a likely cause of an FUO, highly elevated ferritin, LDH, or B_{12} levels often point to an occult malignancy. Serum protein electrophoresis (SPEP) is helpful in demonstrating monoclonal or polyclonal gammopathy, which may be a clue to specific disorders. As with all laboratory tests, nonspecific findings should be interpreted in the appropriate clinical context (e.g., an FUO with polyclonal gammopathy, heart murmur, negative blood cultures, and peripheral signs of endocarditis) and should suggest an atrial myxoma. In an adult with FUO, otherwise unexplained highly elevated serum ferritin levels should suggest either a neoplasm/malignancy, myeloproliferative disorder (MPD), or a rheumatic/inflammatory disorder. Elevated serum ferritin levels are also present in systemic lupus erythematosus (SLE) flares, adult Still's disease, and GCA/TA. Elevated ferritin levels also have exclusionary diagnostic importance in FUOs; for example, malignancy is less likely with unelevated/minimally elevated serum ferritin levels (Box 1.1, Tables 1.3 and 1.4).

Therapeutic considerations

The clinical approach to FUO is based on making a correct diagnosis. Empiric therapy is rarely justifiable unless a potentially treatable life-threatening disease is a definite/highly probable diagnosis. Antipyretics should be used only under unusual circumstances. Fever, per se, should not be treated because treatment eliminates a potentially important diagnostic sign (i.e., the fever curve). Temperature–pulse relationships may also have important diagnostic implications (i.e., relative bradycardia). With an FUO, if the differential diagnosis is between malignancy and infection, the Naprosyn test (naproxen 375 mg orally q12h × 3 days) is useful for *diagnostic* purposes. During the 3 days of Naprosyn little/no decrease in temperature points to an infectious disorder (a *negative*

A focused diagnostic approach and non-specific tests in the diagnosis of FUO. In: Cunha BA (ed.) *Fever of Unknown Origin*. New York: Informa Healthcare; 2007: pp. 9–16, 151–158.

Naprosyn test), whereas a sustained decrease in the febrile response points to a malignancy (*positive* Naprosyn test). The Naprosyn test should not be used and is not interpretable if a rheumatic/inflammatory or miscellaneous cause of FUO is suspected.

If an FUO is likely due to miliary tuberculosis (TB), empiric anti-TB therapy may be life-saving. Among rheumatic/inflammatory disorders, empiric therapy of polymyalgia rheumatica (PMR) with low-dose prednisone (5–10 mg/d orally) is both diagnostic and therapeutic. Patients with FUO due to GCA/TA may develop acute unilateral visual impairment, and blindness may be prevented with high-dose steroid therapy (prednisone 60–80 mg/d).

Once the cause of the FUO has been determined, specific therapy, if available, may be given. Therapy may also involve removal of the underlying cause of the FUO (e.g., discontinuing the drug causing drug fever, abscess drainage, specific therapy of treatable infections and rheumatic/inflammatory disorders).

Sepsis

Leeja Joseph and Rodger D. MacArthur

Introduction

Sepsis is a complex syndrome that results from the host's dysregulated immune response to infection. It is regarded as one of the most complex and challenging syndromes described in medicine. Historically, Hippocrates described sepsis as the process by which "flesh rots, swamps generate foul air and wounds fester," Later, with the introduction of germ theory, sepsis was described as "blood poisoning" and considered the invasion of pathogens into the bloodstream. To this day, old terms such as "septicemia" persist. Since the 1930s, in the era of antibiotic treatment for serious infections, it has become clear that patients with sepsis die of complications of the sepsis syndrome and not from the microbes responsible for that syndrome.

The International Consensus Panel in 1992 redefined sepsis as the *systemic inflammatory response syndrome* (SIRS) rising from infection. Clinically, SIRS is identified by the presence of at least two of the following: fever or hypothermia, tachycardia, tachypnea, and leukocytosis or leukopenia. *Severe sepsis* is sepsis with acute organ dysfunction or tissue hypoperfusion. *Septic shock* is sepsis with hypotension refractory to fluid resuscitation, often in the setting of hyperlactatemia due to decreased tissue perfusion.

Definitions and key concepts

Sepsis can be thought of as life-threatening organ dysfunction resulting from dysregulated host responses due to infection. Septic shock is a subset of sepsis in which underlying circulatory, cellular, and metabolic abnormalities are profound enough to substantially increase the rate of mortality.

Severity of organ dysfunction has been assessed with various scoring systems that quantify abnormalities according to clinical findings, laboratory data, or therapeutic interventions (Table 2.1). There are two scoring systems available: the sequential organ failure assessment (SOFA) (Table 2.2) and SIRS. Differences in the definitions of the scoring systems have led to inconsistencies in estimates of the incidence of sepsis as well as debates as to which system is "better."

Using the SOFA score, the historical categories of sepsis, severe sepsis, and septic shock have been changed to infection (in the absence of sepsis), sepsis, and septic shock. Thus, sepsis has been redefined as the presence of an infection combined with an acute change in SOFA score of 2 points or more (baseline assumed to be zero in patients not known to have preexisting organ dysfunction).

A simplified scoring system based on using just three criteria and identified from a large retrospective analysis of large databases was termed *quick SOFA* (qSOFA). Patients were considered "high risk" if they met at least two of the following criteria: alteration in mental status, systolic blood pressure of <100 mm Hg, or a respiratory rate of >22 breaths per minute (Table 2.3). High risk is defined as having a mortality risk of >10%.

TABLE 2.1 **SEPSIS-RELATED TERMINOLOGY AND DEFINITIONS**

Infection	A pathologic process caused by invasion of normally sterile host tissue by pathogenic microorganisms
Bacteremia	The presence of viable bacteria in blood
SIRS	The systemic inflammatory response to a wide range of infectious and noninfectious conditions. Currently used criteria include two or more of the following: temperature >38°C/100°F or <36°C/97°F heart rate >90 beats/minute: respiratory rate >20 breaths/ minute, or $PaCO_2$ <32 mm Hg: WBC >12,000 cells/mm^3 or <4,000 cells/mm^3, or >10% immature (band) forms
SOFA	The sequential organ failure assessment score: A system that assesses the status of several organ systems in the body (neurologic, blood, liver, kidney, and blood pressure/hemodynamics). A score is assigned based on the data from each category. The higher the SOFA score, the higher the mortality rate.
Septic shock	Pre 2016: Systolic blood pressure (SBP) <90 mm Hg or mean arterial pressure (MAP) <70 mm Hg or a SBP decrease >40 mm Hg or a SBP less than two standard deviations below normal for age in the absence of other causes of hypotension Current: Persistent hypotension after fluid resuscitation requiring vasopressors to maintain MAP >65 mm Hg or a serum lactate level of >2 mmol/L
MODS	Multiple organ dysfunction syndrome: The presence of altered organ function in an acutely ill patient such that homeostasis cannot be maintained without intervention. Primary MODS occurs early and can be directly attributable to an insult itself (such as trauma or neoplasia); secondary MODS develops as consequence of a host response and is identified in the context of SIRS

In patients with suspected sepsis who eventually required admission to the ICU, the qSOFA score was found to be marginally superior to SIRS criteria in predicting mortality risk and ICU-free days in the high-risk group. qSOFA does not require laboratory tests and can be assessed quickly and repeatedly. From a practical standpoint, based on the qSOFA score, clinicians can decide to order additional studies to assess organ dysfunction, initiate or escalate therapy as appropriate, and consider referral to a critical care unit or increase the frequency of monitoring. Positive qSOFA criteria should prompt consideration of possible infection in patients not previously recognized as infected.

The main limitation of using SIRS criteria for identifying individuals with suspected sepsis is that it has a lower specificity compared to SOFA. However, SIRS is more sensitive than SOFA in identifying patients with suspected sepsis. Thus, it remains in place at many medical centers, often incorporated in the electronic medical record (EMR) as a "sepsis alert" or warning.

Epidemiology

The true incidence of sepsis probably is underestimated or unknown. The methods to record the incidence depend on clinician reporting and coding in the EMR, which is not standardized across the country.

TABLE 2.2 **SEQUENTIAL ORGAN FAILURE ASSESSMENT (SOFA) SCORING SYSTEM**

Organ system	SOFA score 1	SOFA score 2	SOFA score 3	SOFA score 4
Respiration PaO_2/FiO_2	<400	<300	<200	<100
Coagulation Platelet count (number per mL)	<150,000	<100,000	<50,000	<20,000
Liver Bilirubin mg/dL	1.2–1.9	2.0–5.9	6.0–11.9	>12
Cardiovascular Hypotension; vasoactive dosing as micrograms per kg per minute	MAP <70 mm Hg	Dopamine ≤5; or dobutamine (any amount)	Dopamine >5 or epinephrine ≤0.1 or norepinephrine ≤0.1	Dopamine >15 or epinephrine >0.1 or norepinephrine >0.1
CNS Glasgow Coma Scale	13–14	10–12	6–9	<6
Renal Creatinine mg/dL	1.2–1.9	2.0–3.4	3.5–4.9	>5.0

TABLE 2.3 **QUICK SEQUENTIAL ORGAN FAILURE ASSESSMENT (QSOFA) SCORING**

Quick SOFA (qSOFA) criteria	Points
Respiratory rate >22/min	1
Change in mental status	1
Systolic blood pressure <100 mm Hg	1

A retrospective analysis of more than 2.9 million adults admitted to 409 US hospitals in 2014 found that sepsis was present in 6% of hospitalized patients, of whom 21% died in the hospital or were discharged to hospice. Sepsis was present in 35% of all hospitalizations that culminated in death. Sepsis incidence rates using clinical data were stable from 2009 to 2014; in-hospital mortality rates declined, but there was no significant change in the combined outcome of death or discharge to hospice. There likely is significant underreporting of the incidence of sepsis, especially in older populations where other comorbidities exist. Often, it is the final event in patients with comorbidities such as malignancy or kidney injury listed as the discharge diagnosis in the EMR.

Pathogenesis

The clinical manifestations of the sepsis syndrome are caused by the host's response to infection when a microbial pathogen-associated molecular pattern is recognized by pattern recognition receptors (PRRs) on the surface of the host immune cells. These receptors are key components of the innate immune system that recognize "danger signals" on invading bacteria and other pathogens. Conserved motifs expressed by pathogens (pathogen-associated molecular patterns or PAMPs) include lipopolysaccharide (LPS), peptidoglycan, lipopeptides, lipoteichoic acid (gram-positive bacteria), and flagellin (a motility factor for bacteria). PRRs also can recognize endogenous "danger signals," called alarmins or danger-associated molecular patterns (DAMPs), which are released during the inflammatory insult. Toll-like receptors express leucine-rich repeats that mediate the recognition of PAMPs. Ten TLRs have been identified in humans; they can be expressed on the cell surface or intracellularly.

Peptidoglycan of gram-positive bacteria is recognized by TLR2; LPS of gram-negative bacteria is recognized by TLR4. The involvement of TLRs elicits a signaling cascade via the cytosolic nuclear factor-kappa b (NF-κB). Activated NF-κB moves from the cytoplasm to the nucleus, binds to the transcription sites and induces activation of a large set of pro-inflammatory cytokines (e.g., tumor necrosis factor [TNF]-α; interleukin (IL)-1β, IL-2, IL-6, IL-8, IL-10). This activation occurs within minutes to hours after macrophages have been activated. TNF-α is the most important cytokine in sepsis. IL-1β has similar effects. The two stimulate the release of stress hormones, other cytokines (e.g., IL-2, IL-6, IL-8, IL-10), and other inflammatory mediators of sepsis (e.g., nitric oxide, lipoxygenase and cyclooxygenase metabolites, platelet activating factor, interferon-γ, and adhesion molecules). All of these interact in a complex fashion to effect various changes to multiple organ systems.

The resulting sepsis, multiorgan system failure, and death were previously believed to be solely from an exaggerated, uncontrolled inflammatory response known as a "cytokine storm." But it is now thought that they also arise from subsequent immunosuppression—the result of an "injured" adaptive immune response. This state includes the alteration of neutrophil migration at multiple stages, as these cells become more rigid and sequestered in organs (limiting blood flow, causing tissue ischemia and multiorgan failure), as well as suppressed activity because of reduced TLR expression and signaling. Nitric oxide blocks neutrophil migration and the interaction between leukocytes and endothelial cells. Likewise, peroxisome proliferator-activated receptor (PPAR)-γ contributes to neutrophil chemotaxis suppression. There also is evidence that gene expression of TNF-α and interferon-β stops with continued insult, necrosis, and infection. The initial release of and exposure to high levels of chemoattractants "desensitizes" G-protein-coupled receptor (GPCR) responsiveness, resulting in downregulation of GPCR cell surface expression. All of these effects show that the innate immune system seems unable to respond to continuous inflammatory

TABLE 2.4 **SOME PRO-INFLAMMATORY AND ANTI-INFLAMMATORY CYTOKINES IN SEPSIS**

Cytokine	Cell origin	Function	Role in sepsis
Pro-inflammatory			
IL-6	T-cells, macrophages, endothelial cells	Cell growth, differentiation, cytokine production	Disease severity, mortality, biomarker
IL-8	Macrophages, epithelial cells endothelial cells	Chemotaxis, angiogenesis	Mortality, biomarker
IL-18	Macrophages, monocytes, dendritic cells	IFN-γ production, antimicrobial immunity	Disease severity, biomarker
TNFα	Macrophages, T cells, NK cells	Cytokine production, cell proliferation, apoptosis, anti-infection, tumor necrosis	Disease severity, survival, biomarker
Anti-inflammatory			
IL-10	Th2 cells, B cells, monocytes	Potent inhibitor of pro inflammatory cytokine production	Disease severity, mortality

stimuli, progressing to a dysfunctional stage and ending in an irreversible phase of sepsis and end-organ injury. Table 2.4 summarizes the role of some of these cytokines in sepsis.

Excessive "cross-talk" exists between coagulation and inflammation during sepsis, characterized by inflammation-induced activation of coagulation with concurrent impairment of anticoagulant systems, fibrinolysis, and endothelial function. Furthermore, during sepsis, inflammation-induced coagulation contributes to further inflammation. The intensity of both the pro-inflammatory and immunosuppressive phases of sepsis likely depends on multiple factors, including genetics and comorbidities (host factors), and the type, virulence, and burden of invading pathogen (organism factors). Various single nucleotide polymorphisms (SNPs) are associated with increased susceptibility to infection and to poor outcome. SNPs are used as genetic markers. They include SNPs of genes that encode cytokines, cell surface receptors, lipopolysaccharide ligands, mannose binding lectin, heat shock protein 70, angiotensin 1 converting enzyme, plasminogen activator inhibitor, and caspase-12.

The role of the complement system in sepsis is complex. Mice lacking C3, the central component of the complement system, have increased sepsis-related mortality. Complement is activated in many ways. For instance, C1 can bind to antigen-antibody complexes as well as to DAMPs. C1 also can bind to C-reactive protein (CRP) and serum amyloid protein, both of which recognize PAMPs. On the other hand, inhibition of C5a signaling improves survival of animals in experimentally induced sepsis. Thus, it now is believed that, early in sepsis, activation of the complement system improves survival by its role in decreasing inflammation and vascular permeability. Later in sepsis, increased C5a activity contributes to the development of multiorgan dysfunction.

Other systemic effects of sepsis

Tissue ischemia occurs secondary to microcirculatory dysfunction. Microcirculatory dysfunction is associated with worse outcomes. Tissue ischemia can occur due to a systemic or local mismatch between oxygen delivery and tissue demand. Mitochondrial dysfunction occurs during sepsis and contributes to failure of tissue oxygen extraction despite sufficient oxygen delivery (cytopathic hypoxia). Mitochondrial dysfunction, tissue hypoxia, and apoptosis (programmed cell death) are important mediators of organ dysfunction during sepsis. Coagulopathies seen in sepsis range from microthrombosis to massive thromboembolism and hemorrhage (disseminated intravascular coagulation or DIC).

During microbial attack and invasion of the host cells, microbial pathogen associated molecular pattern (PAMPs) is recognized by Pattern Recognition Receptors (PRRs) situated on the surface of the host immune cells. Some of the bacteria undergo phagocytosis in optimal conditions (Figure 2.1). The pro-inflammatory responses lead to cellular or tissue damage and anti-inflammatory response leads to immune system impairment. The inflammatory changes occur secondary to release of cytokines and protease, complement activation, B and T cell impairment, leukocyte activation, and activation of coagulation cascade. The release of stress hormones, cytokines, and inflammatory mediators of sepsis interact in a complex fashion to cause multi-organ dysfunction and subsequent failure. This is facilitated by genetic factors, advanced age, nutritional deficiencies, diabetes, immunosuppression, and recent surgeries. Multiple organ dysfunction manifests as altered mental status, circulatory collapse, tachycardia, renal failure, respiratory failure, liver failure, and GI dysfunction.

Etiology

Historically, antibiotic recommendations for therapy of sepsis and septic shock were based on coverage of gram-negative organisms. However, sepsis caused by gram-positive organisms is clinically identical to sepsis caused by gram-negatives. After 1987, gram-positive bacteria became the predominant pathogens in most areas. In recent studies, 47% to 55% of sepsis cases were due to gram-positives (e.g., *Staphylococcus aureus*, coagulase-negative staphylococci, *Streptococcus pneumoniae,* and enterococci), while gram-negatives made up 38% to 51%. *Escherichia coli* has remained the most common gram-negative pathogen in community and nosocomial infections. *Staphylococcus epidermidis* has become the most common cause of nosocomial bacteremias, followed by *S. aureus*, enterococci, and *Candida* species. Infections caused by vancomycin resistant enterococci (VRE), particularly *Enterococcus faecium* (resistant to ampicillin and aminoglycosides) and non-albicans *Candida* species have become more common. Gram-negative bacteria, including multidrug-resistant (MDR) *Pseudomonas aeruginosa,* extended-spectrum β-lactamase (ESBL)-producing Enterobacteriaceae, *Enterobacter* species and other plasmid-mediated AmpC β-lactamase producing bacteria, and *Acinetobacter* species, are increasing and becoming resistant to multiple antibiotics. Sepsis caused by anaerobic organisms is uncommon, perhaps because anaerobic gram-negative anaerobes lack lipid A (endotoxin), a potent trigger of the sepsis cascade.

Diagnosis

Diagnosis starts with a thorough history and physical examination. The history should focus on symptoms, recent surgery, underlying disease(s), recent antibiotic use, travel. and known risk factors such as the presence of indwelling catheters and other devices.

Physical examination includes vital signs. While fever is the most common manifestation of sepsis, hypoxia and/or hypotension are present in approximately 30% to 40%. Absence of fever is more likely in individuals with extremes of age or those in debilitated condition.

Table 2.5 lists the diagnostic criteria for sepsis (SIRS-based).

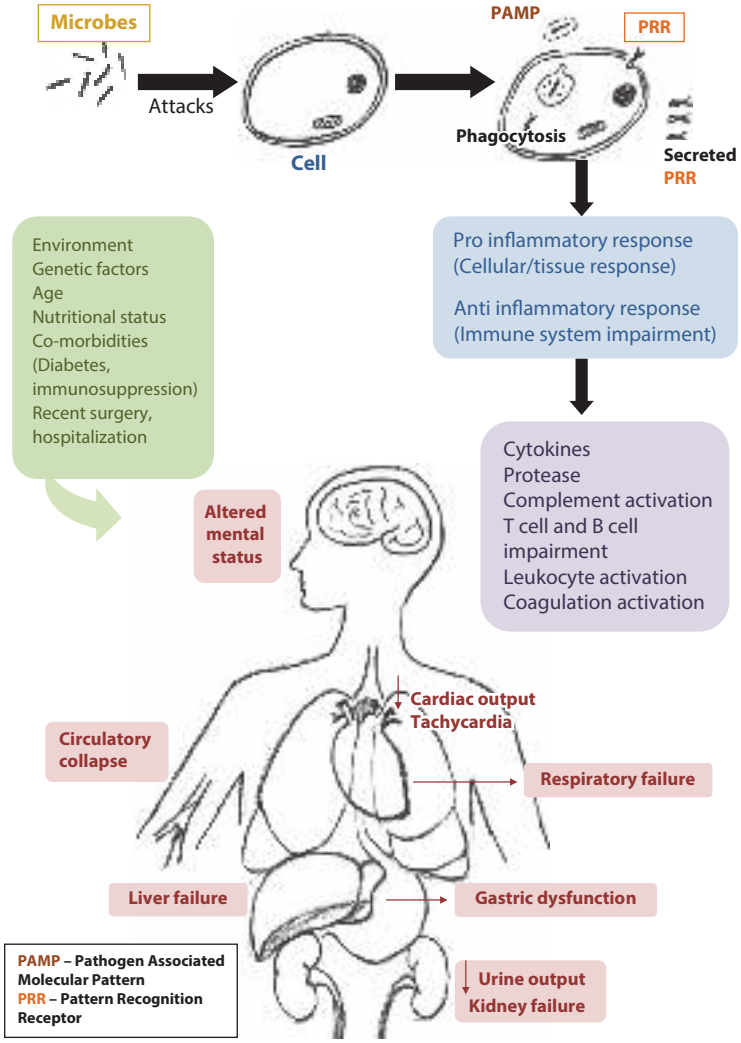

FIGURE 2.1 The pathogenesis of sepsis.

TABLE 2.5 DIAGNOSTIC CRITERIA FOR SEPSIS

Infection (documented or suspected) and some of the following parameters must be present:

General parameters	(1) Fever (>38°C/100°F), (2) hypothermia (core temperature <36°C/97°F), (3) heart rate >90 beats/min or greater than two SDs above the normal value, (4) tachypnea, (5) altered mental status, (6) significant edema or positive fluid balance (>20 mL/kg over 24 hours), (7) hyperglycemia (plasma glucose>140 mg/dL or 7.7 mmol/L) in the absence of diabetes
Inflammatory parameters	(1) Leukocytosis (white blood cell count >12 000/μL), (2) leukopenia (white blood cell count <4,000/μL), (3) normal white blood cell count with >10% immature forms, (4) plasma C-reactive protein (CRP) greater than two SDs above the normal limit, (5) plasma procalcitonin greater than two SDs above the normal limit
Hemodynamic parameter	(1) Arterial hypotension (SBP <90 mm Hg, MAP <70 mm Hg, or an SBP decrease of >40 mm Hg in adults or greater than two SDs below normal for age
Organ dysfunction parameters	(1) Arterial hypoxemia (PaO_2/FiO_2 <300), (2) acute oliguria (urine output <0.5 mL/kg/h for at least 2 hours despite adequate fluid resuscitation), (3) creatinine increase >0.5 mg/dL or 44.2 μmol/L, (4) coagulation abnormalities (INR >1.5 or aPTT >60 s), (5) ileus (absent bowel sounds), (6) thrombocytopenia (platelet count <100 000/μL), (7) hyperbilirubinemia (plasma total bilirubin >4 mg/dL or 70 μmol/L)
Tissue perfusion parameters	(1) Hyperlactatemia (>1 mmol/L), (2) decreased capillary refill or mottling

Abbreviations: SBP = systolic blood pressure; MAP = mean arterial pressure; SD = standard deviation; INR = international normalized ratio; aPTT = activated partial thromboplastin time.
In the pediatric population, the diagnostic criteria for sepsis are (1) signs and symptoms of inflammation plus (2) infection with (3) hyper- or hypothermia (rectal temperature >38.5°C/101°F or <35°C/95°F), (4) tachycardia (may be absent in hypothermic patients), and at least one of the following indications of altered organ dysfunction: (a) altered mental status, (b) hypoxemia, (c) increased serum lactate level, or (d) bounding pulses.

Recommended investigations include a CBC with differential, basic metabolic panel, hepatic function panel, coagulation studies, lactate level, and urinalysis. Clinically suspected respiratory infections should be assessed with a chest x-ray and arterial blood gas analysis (evaluation of hypoxemia and acid–base abnormalities).

Multiple cultures from suspected infected sites need to be obtained. All cultures should be delivered promptly to the microbiology laboratory. Gram staining should be done and read as soon as possible on specimens submitted for cultures. Ideally, cultures should be obtained before starting antibiotics. For clinically and hemodynamically unstable patients, antibiotics should be given as early as possible and certainly within 3 hours of presentation.

At least two sets of cultures from different sites should be obtained from all sepsis suspects. Each blood culture set consists of one aerobic and one anaerobic bottle. Typically, 6 to 10 mL of blood needs to be injected into each bottle to increase the likelihood of culturing pathogens. If an indwelling venous or arterial catheter is present, it is important to obtain additional cultures through each one of the ports, unless the device is recently placed (within 48 hours). DNA probes (polymerase chain reaction [PCR]-based) have become increasingly common for more rapid detection of certain pathogens (e.g., methicillin-resistant *S. aureus* [MRSA]).

Sputum for culture can be spontaneously expectorated or induced by 3% saline nebulization or obtained by nasotracheal, endotracheal, or transtracheal techniques. Specimens should have >25 polymorphonuclear cells and <10 squamous epithelial cells per low-power microscopic field to decrease the chance that the specimen is contaminated with upper airway flora. Semi-quantitative or quantitative cultures may be used for ventilator-associated pneumonia (VAP) diagnosis. Nasotracheal swabs (DNA probes) are particularly useful for detecting viral pathogens as well as bacteria such as *Legionella* species.

Urine for culture should be obtained in most cases. Urine also should be sent for legionella and pneumococcal antigens as part of the determination of bacterial causes of pneumonia. Stool for detection of *Clostridium difficile* toxins A and B should be obtained from individuals presenting with diarrhea and recent antibiotic use. Enzyme immunoassay (EIA) testing for toxins A and B is faster but less sensitive than cell-based cytotoxin assays. The two-step method, starting with EIA to detect glutamate dehydrogenase followed by the cell-based assay, increases sensitivity. In our institution, we use *C. difficile* PCR to detect the toxins, which is much more sensitive and specific than EIA testing. Testing should be done only on symptomatic patients since many are colonized with *C. difficile*.

When suspecting fungal causes of sepsis, fungal blood cultures and/or histopathologic evidence are considered gold standards. Other diagnostic tests also are available. These include the 1,3 β-D glucan assay (Fungitell), which is helpful for diagnosing certain invasive fungal infections such as those caused by candida and aspergillus species. The galactomannan enzyme immunoassay provides a presumptive diagnosis for invasive aspergillosis. The serum capsular antigen for cryptococcus species and urine polysaccharide cell wall antigen for histoplasmosis and blastomycosis species are useful in certain circumstances. Invasive pulmonary aspergillosis may be diagnosed using galactomannan antigen detection in bronchoalveolar lavage fluid. It is important to recognize that not all fungal infections will produce a positive Fungitell. Furthermore, clinicians must consider the possibility of a false-positive result which may occur in patients who recently received β-lactam antibiotics or due to the use of cellulose filters in hemodialysis. The galactomannan assay also may be falsely positive in patients who received fluids containing gluconate or citric acid, as occurs in platelet transfusions or total parental nutrition.

Depending on clinical suspicion, other lab tests may be useful. Rapid influenza antigen testing should be done during influenza season. In our institution, we prefer Influenza A and B plus respiratory syncytial (RSV) PCR because processing time is only 6 hours, and the sensitivity and specificity of the test are excellent. PCR-based respiratory pathogen panels, as well as PCR testing for SARS-CoV-2, can be very useful when patients present with a respiratory source for sepsis.

A CT scan of the abdomen may reveal previously overlooked fluid collections that may be accessible by needle aspiration. Certain infections prevalent in intravenous (IV) drug users, such as epidural abscesses and psoas muscle abscesses, may be diagnosed by MRI. Ultrasonography is useful for detecting ascites and biliary and pancreatic pathologic conditions. A portable (bedside) ultrasound can be obtained for critically ill patients who are too unstable to be transported to the radiology department. Echocardiography is recommended for the diagnosis of infective endocarditis and should be performed in patients with murmurs or suspected IV drug use.

A lumbar puncture for cell count, protein, glucose, bacterial and viral antigens, fungal studies (e.g., cryptococcal antigen), Gram stain, and culture should be performed on septic patients with unexplained altered mentation and on patients with suspected meningitis.

Despite the widespread availability of sensitive and specific diagnostic tests, recognizing sepsis still is not optimal. Studies have estimated that physicians correctly diagnosed sepsis between 73% and 77% of the time. This unsatisfactory rate of diagnosis is why numerous biomarkers (e.g., IL-6) have been under investigation. The hope is to discover a marker that will assist clinicians in reliably distinguishing sepsis from other inflammatory conditions and early enough to improve clinical outcomes.

Management of sepsis

Early goal-directed therapy (EGDT) emphasizes a timely (within the first 3–6 hours of presentation) and coordinated approach to sepsis management, with a significant mortality benefit when efforts are made for early diagnosis, risk stratification, fluid resuscitation, early administration of antimicrobials, control of the source of infection, and hemodynamic optimization utilizing vasoactive drugs.

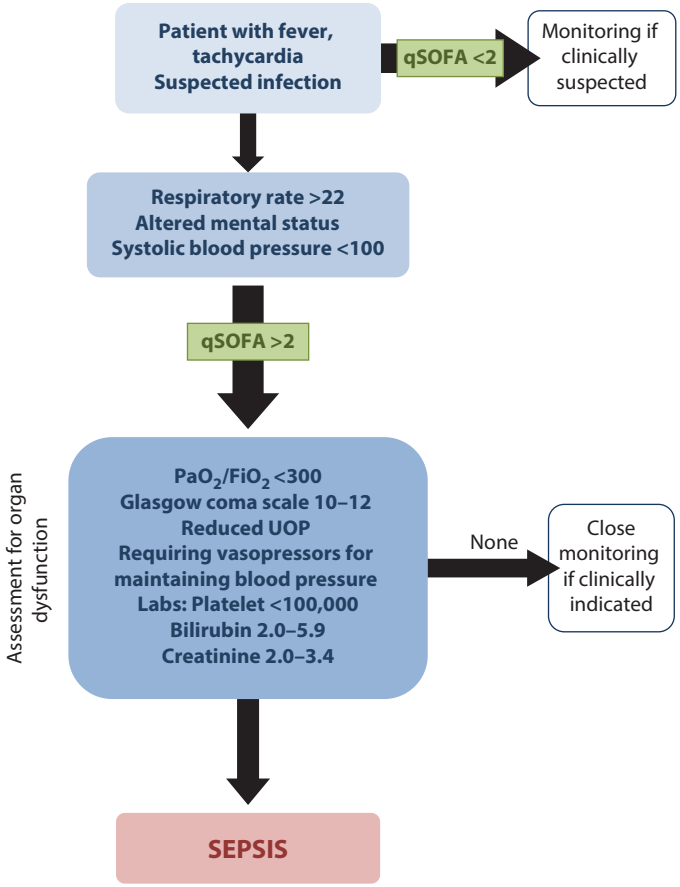

FIGURE 2.2 Assessment of patient in the emergency department.

Effective treatment should focus on timely intervention, including the removal of sources of infection. Aggressive assessment for an unrecognized source or undrained abscess through appropriate initial evaluation, laboratory testing, and diagnostic imaging is critical. Early initiation of appropriate antimicrobial therapy, restoration of tissue perfusion via fluid resuscitation, and advanced interventions guided by assessment of the adequacy of the efforts at resolution of organ dysfunction should be part of initial and ongoing sepsis management.

Broad-spectrum antibiotics need to be administered within the first 3 hours of presentation. Begin rapid administration of 30 mL/kg of crystalloid fluids or balanced crystalloid fluids (e.g., Ringer's lactate or Hartmann's solution) for hypotension or in those with serum lactate levels of >4 mmol/L. Initiate vasopressors if the patient is hypotensive during or after fluid resuscitation to maintain a mean arterial pressure (MAP) of ≥65 mm Hg.

Source control should be done early, keeping in mind the risks and benefits of both surgical and medical intervention. Observational data have shown that inadequate source control is associated with an increase in 28-day all-cause mortality from 26.7% to 42.9%.

Figures 2.2 and 2.3 illustrate a management approach for patients starting with presentation to the emergency department (ED).

Table 2.6 lists some specific organisms to consider in certain clinical situations.

Antimicrobial therapy: Selection and duration

The initial empiric antibiotic regimen (AR) should include coverage for common gram-positive and gram-negative aerobes. As soon as the pathogen is isolated or drug sensitivities are known, the antibiotic spectrum may be narrowed. De-escalation (narrowing the spectrum) of the AR should be considered daily based on the clinical course of the patient.

Giving effective antimicrobials within the first 3 hours of admission to the hospital increases survival to hospital discharge in adults with septic shock. Delayed antimicrobial therapy is associated with increased mortality in severe infections that have the potential to progress to septic shock. The choice of antimicrobials should be based on the patient's history (e.g., recent antibiotics, previous organisms if known), comorbidities (e.g., diabetes), immunodeficiencies (e.g., HIV), clinical context (i.e., community- or hospital-acquired), suspected site of infection, presence of invasive devices, Gram stain data, and local prevalence and resistance patterns.

The antimicrobial choice should be tailored to each individual patient. A few principles are worth emphasizing. Patients with septic shock should receive combination therapy with at least two antimicrobials from different classes depending on the organisms which are considered likely pathogens and local antibiotic

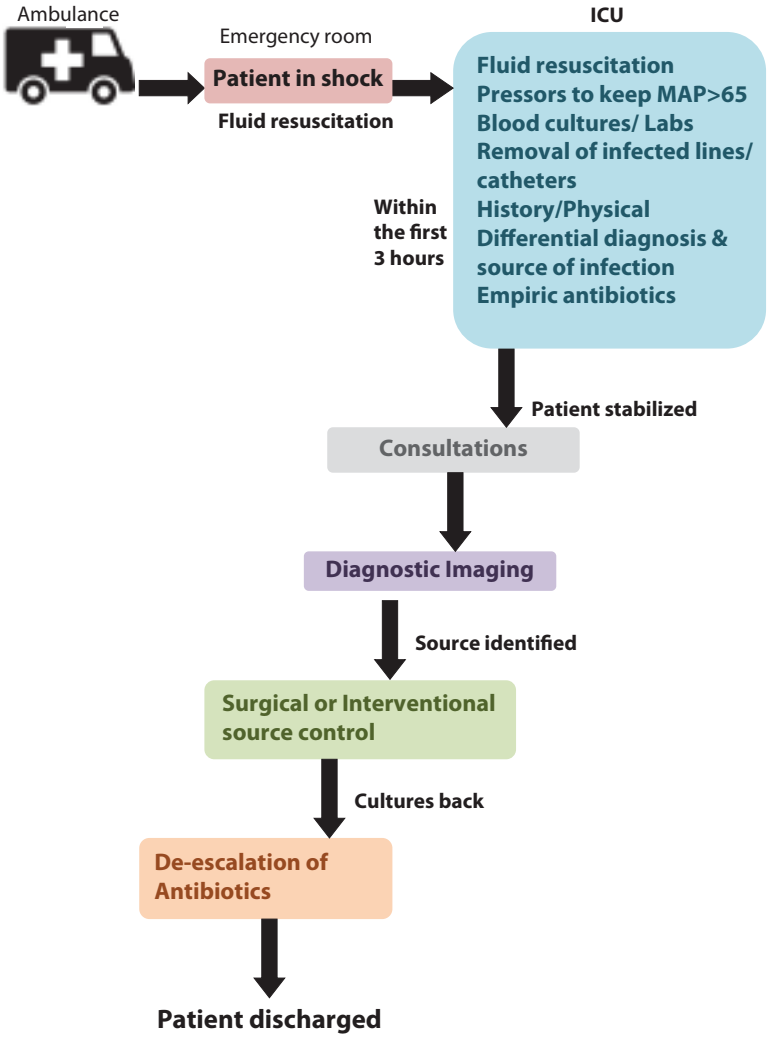

FIGURE 2.3 Management algorithm.

susceptibilities. Anti-pseudomonal agents should be used for empiric therapy for nosocomial infections. Antibiotic dosages should be optimized for the site of infection, usually the highest allowable dosage adjusted for organ dysfunction. Intravenously administered antibiotics often result in higher serum and tissue levels than oral antibiotics. Orally administered antibiotics should not be used for patients with compromised gut absorption. Community-acquired infections are likely to be caused by organisms different from those in the hospital. For example, *Pseudomonas aeruginosa* is unlikely in community-acquired infections, with few exceptions (e.g., IV drug users): consequently, anti-pseudomonal coverage is not warranted routinely for community-acquired infections. In contrast, *Streptococcus pneumoniae* is one of the most common causes of community-acquired sepsis and should be covered adequately.

TABLE 2.6 SPECIAL CIRCUMSTANCES AND PATHOGENS

Circumstances	Possible pathogens
Splenectomy	Encapsulated organisms; *Streptococcus pneumoniae, Hemophilus influenzae,* and *Neisseria meningitidis*
Neutropenia	Gram negatives such as *Pseudomonas*. Gram positives (*Staphylococcus aureus*) and fungi
Hypogammaglobulinemia	*Streptococcus pneumoniae, Eschericia coli*
Burns	MRSA, *Pseudomonas aeruginosa*, resistant gram-negatives and *Candida* species
AIDS	*Salmonella* species, *Staphylococcus aureus*, and *Pneumocystis jirovecci*
Intravascular devices	*Staphylococcus aureus* and *Staphylococcus epidermidis*
Nosocomial infections	*Staphylococcus aureus* (especially MRSA), *Enterococcus* species, resistant gram-negatives, and *Candida* species

Antibiotics need to achieve therapeutic drug levels in infected tissues and fluid throughout the dosing interval. Achieving adequate levels in lung parenchyma can be challenging with the aminoglycosides and daptomycin; achieving adequate cerebrospinal fluid levels typically requires the inclusion of a third-generation cephalosporin or a carbapenem.

Aminoglycosides offer rapid killing of gram-negative aerobic bacteria in a concentration-dependent manner. The risk of nephrotoxicity and ototoxicity, the poor penetration of aminoglycosides into abscesses and lung parenchyma, and the lack of data to indicate that the addition of aminoglycosides affects outcomes in sepsis call for their judicious use. We suggest aminoglycosides be used as follows: (1) large single daily doses (e.g., 5 mg/kg) when used for synergy against streptococcal and enterococcal infections and (2) use only for the first few days for empiric coverage of aerobic gram-negative bacteria, especially *P. aeruginosa*. Note that the potential advantages of using two antibiotics, each with activity against the same likely pathogen include (1) a higher probability that the infecting pathogen will be covered by at least one of the antimicrobials, (2) a potential synergistic killing effect, and (3) possibly preventing the emergence of bacterial resistance.

Clinicians need to be cognizant of underlying medical conditions (e.g., avoidance of trimethoprim-sulfamethoxazole in patients with renal failure, and imipenem in patients with seizure disorders). It also is prudent to consider suspected organisms and target them appropriately. For example, carbapenems are preferred for infections caused by ESBL-producing bacteria, as well as Amp C β-lactamase-producing bacteria (the "SPICE" organisms: *Serratia*, *Providencia*, indole-positive bacteria such as Proteus, Citrobacter, and Enterobacter species). Cephalosporins should be avoided in organisms that tend to become constitutive producers of β-lactamases, such as *Enterobacter* species)

The incidence of nosocomial β-lactam-resistant gram-positive organisms has been increasing, as has the incidence community-acquired MRSA infections. The inclusion of an anti-MRSA antibiotic (e.g., vancomycin, linezolid, or daptomycin) in the AR is recommended when the prevalence of MRSA in the community exceeds 10% to 20% of all *S. aureus* isolates. Physicians need to be aware of the pattern of antimicrobial resistance in their places of practice and surrounding communities.

Fungi account for only 5% of all cases of severe sepsis or septic shock. Therefore, routine antifungal therapy is not recommended in sepsis unless the patient is at higher risk of fungal infections (e.g., neutropenic or post bone marrow transplant, undergoing chemotherapy, or receiving total parental nutrition).

Macronodular skin lesions with biopsies consistent with *Candida* infection and candida endophthalmitis are each synonymous with dissemination. Since only a fraction of patients with systemic candidiasis have positive blood cultures, a number of approaches have been developed to estimate the risk of systemic fungal infection in hospitalized patients. In general, when *Candida* species are isolated from three or more non-blood sites, the risk of subsequent infection of the blood by these colonizing fungi increases. Initiating AR therapy in such situations depends on the total clinical picture, but most physicians would add an antifungal agent to the AR if fever or other signs of infection were present. In any case, the efficacy of the azole antifungals (e.g., fluconazole) and their favorable toxicity profiles have made their empiric use more acceptable, especially in non-neutropenic patients. Nevertheless, a non-azole antifungal (e.g., micafungin) is preferred initially at institutions with high rates of azole resistance, especially for the moderately severe to severely ill individual. Micafungin or another antifungal from the echinocandin class also is used in places with high rates of glabrata and krusei species of candida. These organisms have high rates of resistance to the azoles.

Duration of antibiotic therapy depends on the clinical response and, occasionally, the infecting pathogen. Bacteremia typically is treated with 10 to 14 days of therapy, although shorter courses may be possible if improvement is rapid. If bacteremia with *S. aureus* is prolonged (>48 hours), therapy is given for at least 4 weeks, although during some percentage of that time the antibiotic may be given orally. Endocarditis and osteomyelitis, regardless of pathogen, typically are treated for 6 weeks.

Antibiotic decisions should be re-evaluated at least daily. Changes need to be considered as culture and susceptibility results become available or as the clinical course dictates. A patient who has not responded or who has relapsed after an initial improvement needs to be re-evaluated thoroughly. Additional diagnostic studies may be indicated, and repeat cultures should be obtained to search for new or resistant pathogens. If the clinical syndrome is determined to be noninfectious, antibiotics should be stopped.

The persistently febrile neutropenic patient presents an especially challenging problem. Empiric antifungal therapy should be started (and testing for invasive fungal infections should be done) if fever persists or is recurrent despite broad-spectrum antibiotic coverage for more than 4 to 7 days, as well as for febrile neutropenia expected to last for more than 7 to 10 days.

Poor decisions about antibiotic use have potential immediate and future negative consequences. Long-term antibiotics will not protect patients from infection; rather this approach will cause emergence of multidrug-resistant organisms. The best way to avoid widespread resistance is to continuously re-evaluate the need for antibiotic therapy and to de-escalate when microbial susceptibility panels become available. In addition, side effects, such as cumulative antibiotic toxicity and superinfection with multidrug-resistant pathogens and *C. difficile*, are much more common after long courses of multiple antibiotics. Antibiotic stewardship has been shown to reduce the incidence of infection with multidrug-resistant organisms.

Table 2.7 lists some antibiotic combinations to consider based on selected clinical circumstances.

Source control

Source control remains an important aspect of treatment in patients with sepsis and septic shock. Source control entails rapidly identifying the anatomical site involved, followed by the removal of the infected material (e.g., drainage of abscesses). For the skin and

TABLE 2.7 **SELECTED EMPIRICAL ANTIMICROBIAL THERAPY**

Diagnosis	Suspected pathogen	Empiric therapy
Bacteremia, catheter associated	**Staphylococci, Enterococci, Enterobactereciae**	Vancomycin + Piperacillin/tazobactam Hemodialysis patients Cefepime + vancomycin Critically ill or neutropenic patients Cefepime + vancomycin + tobramycin Severe β-lactam allergy Aztreonam + tobramycin + vancomycin
Meningitis	***S. pneumoniae*, *N. meningitidis*, *Listeria monocytogenes* (EtOH use, age >50)**	Ceftriaxone + vancomycin (add ampicillin if risk factors for *Listeria* present)
Intra-abdominal infection	**Enterobacteriaceae, *Bacteroides* sp. Enterococci, Streptococci, *P. aeruginosa*, Staphylococci**	Cefepime + Metronidazole Piperacillin/tazobactam Meropenem especially with a prior history of ESBL-producing organisms in the past 12 months) Severe β-lactam allergy: Aztreonam + metronidazole + vancomycin
Pneumonia: Hospital-acquired/ ventilator-associated	**Enterobactereiacea, *P. aeruginosa*, *Staphylococcus aureus***	Cefepime (or piperacillin/tazobactam) + vancomycin (or linezolid in ICU patients only) ± tobramycin Piperacillin/tazobactam + Severe beta lactic allergy: Aztreonam + vancomycin (or (linezolid in ICU patients only) ± tobramycin Add azithromycin for patients presenting from the community who are at risk for Legionella species
Pneumonia: Community-acquired	***S. pneumoniae*, *H. influenzae*, *Legionella* species**	Azithromycin + Ceftriaxone Severe β-lactam allergy: Moxifloxacin For ICU patients with suspected MRS, add vancomycin or linezolid
Urinary tract infection, healthcare-associated	**Enterobacteriaceae, Enterococci, *P. aeruginosa***	Cefepime + vancomycin ± tobramycin

soft tissue infections, it includes actions such as wound care, incision and drainage, debridement, and, in some cases, amputation. All infected devices should be removed promptly.

In intra-abdominal infections, the appropriate interventions to determine the adequacy of the source control are dictated by the clinical scenarios. High-risk patients with compromised hemodynamic status benefit from minimally invasive procedures, including percutaneous or endoscopic procedures. Recent recommendations on source control and peritonitis use "damage control" surgery (i.e., more limited surgery) for critically ill patients. If patients with intra-abdominal infections are stable, source control measures include surgical incision and drainage of abscesses, debridement of infected necrotic tissues, removal of potentially infected devices, and extensive intra-abdominal irrigation to decrease the peritoneal inoculum.

Similarly, empyemas need to be drained, and obstructive pyelonephritis needs to include surgical involvement. Failure to adequately control the source, regardless of the severity of the illness, typically results in poor survival rates and additional complications in those who do survive.

Supportive therapy

After initial fluid resuscitation, the fluid responsiveness should be assessed in patients with continued hemodynamic instability. All currently available methods for assessing fluid responsiveness have limitations. Dynamic methods such as responsiveness to stroke volume and cardiac output to passive leg raise are helpful, although they may be practically challenging at the bedside.

Crystalloids are the recommended fluid for initial resuscitation. Among crystalloids, there is increasing interest in the comparison between using balanced crystalloid solutions (Ringer's lactate and Hartmann's solution) with normal saline. No consensus exists at present. There is emerging evidence that a chloride-restrictive

resuscitation strategy is associated with reduced incidence of both acute kidney injury and the need for renal replacement therapy.

Monitoring central venous oxygen saturation ($SVCO_2$) and blood lactate levels, though controversial, seem to have improved the outcomes of sepsis.

Patients who fail to maintain a MAP of >65 require vasopressor support. Norepinephrine is the preferred first-line vasopressor due to its increased potency and reduced risk for arrhythmias. Vasopressin administration allows for reduction of the dose of catecholamine vasopressors, but does not appear to independently improve patient mortality. The US Food and Drug Administration recently approved angiotensin II as a new vasopressor for the treatment of septic shock. However, this approval was not based on any mortality benefit as the study (ATHOS-3) was not designed to detect such differences. In addition, limited safety data exist. Note that angiotensin II has pro-inflammatory properties, can increase IL-6 levels, and also is pro-thrombotic.

Contrary to previous recommendations to tightly control glucose levels, the current consensus is to simply maintain serum glucose at <180 mg/dL. Many controversies continue to exist in nutritional support regarding the timing and route of administration. Several trials have failed to show benefits of enteral feeding compared with the parenteral route.

The role of corticosteroids in patients with sepsis remains controversial. There are some data to suggest that there is some benefit in using corticosteroids in the subset of patients with shock. There also is some evidence to suggest that corticosteroids are associated with ICU-acquired weakness. Multiple clinical trials with different doses of corticosteroids have failed to show a 30-day survival benefit. Two recent clinical trials using an endpoint of 90-day survival came to opposite conclusions, with one trial (APROCHSS) showing a benefit and the other (ADRENAL) showing no benefit.

Mesenchymal stem cells for treatment of the acute respiratory distress syndrome (ARDS) have shown some promise. Interferon-β also is being studied in patients with moderate to severe ARDS. Endotoxin removal via polymyxin B hemoperfusion is a novel therapeutic approach for patients with septic shock and is under investigation. Activated protein C (drotrecogin) was withdrawn from the market after multiple subsequent trials could not replicate the findings of benefit in 30-day survival found in the initial trial.

Sepsis is a clinical syndrome rather than a disease. It is associated with high mortality and long-term morbidity. Many survivors of sepsis are admitted to long-term care facilities, and readmissions to hospitals are frequent. Many sepsis survivors report a decreased quality of life and substantial cognitive impairment in addition to functional disability. Continued effort is required to improve the long-term outcomes of patients with sepsis and septic shock.

Chronic fatigue syndrome

Stephen J. Gluckman

Introduction: Nature of the syndrome

Chronic fatigue syndrome (CFS) is a syndrome of subjective complaints most prominently featuring profound and prolonged physical exhaustion. Many experts suggest that this syndrome is the late-twentieth-century formulation of an illness that has been described under various designations in medical literature for centuries, such as *febricula* ("little fevers") in the eighteenth century, *neurasthenia* in the nineteenth century, and *myalgic encephalomyelitis* (ME) in Great Britain and Canada or *chronic fatigue and immune dysfunction syndrome* (CFIDS) in the United States during the late twentieth century. The designation *chronic fatigue syndrome* was adopted by the US Centers for Disease Control and Prevention (CDC) and the National Institutes of Health (NIH) because this name does not assume a direct role for infection, inflammation, or immune system dysfunction in the genesis of the symptoms. Indeed, an abundance of research has failed to attribute the syndrome to any specific infection or immunologic disturbance. Patients may complain of neurologic, cardiac, gastrointestinal, rheumatologic, psychiatric, and endocrine symptoms. CFS concerns infectious disease physicians because it is frequently ascribed to an active infection or a sequel of infection (i.e., as postviral or postinfectious fatigue).

The association of chronic fatigue and infection was first examined systematically in a study of chronic brucellosis. In a 1951 study, Wesley Spink found that 20% of patients with serologic evidence of brucellosis went on to develop persistent fatigue, muscle weakness, myalgia, mental confusion, and depression without evidence of ongoing infection with *Brucella*. He suggested that the symptoms of chronic brucellosis depended on both a previous *Brucella* infection and a psychological predisposition. Evidence for this theory was provided by investigators from Johns Hopkins during the Asian influenza pandemic of 1957–1958. During that epidemic season, these investigators conducted a retrospective cohort analysis of military personnel and their dependents who had completed the Minnesota Multiphasic Personality Inventory (MMPI) prior to the epidemic. Prolonged convalescence after influenza was associated with unfavorable scores on the test. Moreover, the MMPI profiles of subjects with prolonged postinfluenza symptoms were nearly identical to MMPI profiles of the previously studied patients with chronic brucellosis. This observation implies that the persistent fatigue and associated symptoms may reflect a programmed response to a variety of different infections in predisposed subjects.

Acute mononucleosis has also long been postulated to be a precipitant of prolonged postinfectious fatigue. Consequently, when two large studies in 1985 reported an association between chronic fatigue and elevated titers of Epstein–Barr virus (EBV) antibodies, EBV became a leading candidate as the etiologic agent, and "chronic mononucleosis" became a popular designation for fatigue syndrome. As with other attempts to link CFS to a specific infectious agent, the association between active EBV and CFS was not confirmed by subsequent virologic studies. EBV infection is now best understood as one of the infectious precipitants of the syndrome rather than as a chronic active infection that is a direct cause of the persistent symptoms. A recent prospective study of 301 adolescents diagnosed with infectious mononucleosis found that 13%, 7%, and 4% met criteria for pediatric CFS 6, 12, and 24 months after the onset

BOX 3.1

Case definition of chronic fatigue syndrome

All three of the following:

1. A substantial reduction or impairment in the ability to engage in pre-illness levels of occupational, educational, social, or personal activities that persists for >6 months and is accompanied by fatigue, which is often profound, is of new or definite onset (not lifelong), is not the result of ongoing excessive exertion, and is not substantially alleviated by rest.
2. Post-exertional malaise: Physical, psychological, or emotional exertion
3. Unrefreshing sleep

Plus, one or two of the following:
One of the following:

1. Cognitive impairment
2. Orthostatic intolerance

Institute of Medicine. http://iom.nationalacademies.org/Reports/2015/ME-CFS.aspx

of symptoms, respectively, regardless of whether steroids were used during the acute illness. Similarly, infections with enteroviruses, cytomegalovirus, Ross River virus, parvovirus, human herpesvirus 6, *Borrelia burgdorferi*, *Coxiella burnetii*, *Candida albicans*, and *Giardia lamblia* have also been cited as potential triggering events. The notion that CFS is a direct consequence of chronic active infection with any of these agents is not supported by existing evidence. Studies are either inconclusive or definitively negative. Making a distinction between infection as an acute precipitant and as a chronic persistent cause of the syndrome is critical. It explains why attempts to treat the syndrome with antibiotics, antivirals, and antifungals have been uniformly disappointing. Further, it has been suggested that non-infectious life stresses can also initiate CFS.

In the absence of a simple etiology or a uniformly applicable diagnostic test for CFS, the NIH and the CDC proposed a consensus definition of the syndrome intended to serve as a standard for future studies. In 2015, the Institute of Medicine proposed a simplified case definition as noted in Box 3.1. Because fatigue is one of the most common complaints encountered in general medicine, the definition excluded patients with trivial or medically explainable fatigue states and captured those with illnesses that were characteristic of the syndrome. However, there are problems with both specificity and sensitivity of a case definition of this kind. Clinical case definitions of a disease where there is no definitive diagnostic test should be used with caution when applied to a specific patient. They are more appropriately considered epidemiologic or research tools. Thus, rigid application of the CFS criteria (e.g., requiring 6 symptomatic months) may exclude patients who might profit from an early intervention.

Epidemiology

Idiopathic chronic fatigue is very common (5–10% of patients in general medical practice), but very few (≤1%) can be diagnosed with CFS using the proposed criteria. The US national prevalence of CFS was estimated by the CDC through a network of physicians in four American cities. The prevalence ranged from 3 to 11 per 100 000 population, and the gender and age distribution were similar in all four sites. Most patients were female (7:1) in the fourth and fifth decades of life. Estimates from clinic-based studies in Australia and the United Kingdom yield similar results. However, a population-based survey in San Francisco and other community-based studies elsewhere suggest a prevalence of about 0.2%, with a larger proportion of males, ethnic minorities, and those of lower socioeconomic classes. The discrepancy between community- and clinic-based studies is attributable to the greater utilization of clinical services by middle- and upper-class women. It belies the notion of a "yuppie flu," a pejorative term applied to this disorder in the past.

Illnesses consistent with CFS also occasionally occur in epidemic fashion. In some instances, the outbreaks may be associated with an infectious event; however, in others, the distribution of illness among the populations at risk clearly does not resemble the spread of an infection. Examples of the latter type include the large hospital-based outbreaks in Los Angeles, California, and London, that affected the hospital professional staff but not the hospitalized patients or nonprofessional staff.

Pathophysiology

The majority of patients have an acute onset of the syndrome. A small proportion can be traced to a diagnosed infectious disease. CFS may also follow other physically and psychologically stressful events, such as surgeries, accidents, deaths, and divorces. A smaller number of patients have an insidious onset with no definite precipitating event. Regardless of the onset, the majority of patients have past or current psychiatric disorders, but a large minority has no active or past psychiatric symptoms.

Numerous infections have been associated with CFS, but evidence that the syndrome is not associated with any specific infectious agent is of three main types. First, there is no single infectious agent that is detectable in all cases of CFS; the disorder may occur even in the absence of the most common agents, such as EBV. Second, the development of the same syndrome occurs during convalescence after infections with non-overlapping geographic distribution (e.g., Ross River virus, Q fever, or Lyme disease). Third, attempts to treat CFS with anti-infectives have been uniformly disappointing. It may be true that only a specific type of infection with prolonged duration or severity is necessary to precipitate CFS. Indeed, patients seen in general practice for common, simple infections do not have an increased frequency of prolonged fatigue relative to patients seen for other medical problems. However, postinfectious cases and those with no apparent precipitant are clinically indistinguishable with respect to symptoms and psychosocial features once the defining

criteria are met. These observations lead to the conclusion that the syndrome is a nonspecific sequel to a variety of infections or other precipitants. The inability to determine a single cause may be frustrated by the fact that there is, in reality, no single cause but rather a number of triggers. Whether patients who have CFS will reactivate latent viruses more frequently than well individuals is an unsettled issue, but no correlation between viral reactivation (e.g., EBV) and the expression of symptoms has been demonstrated.

From time to time, sensational reports appear linking a persistent infectious agent with the syndrome, as in 1985 with EBV. The latest of these events occurred in late 2010, when an article appeared in *Science* reporting the presence of a xenotropic murine retrovirus (XMRV) in two-thirds of a panel of CFS patients and only approximately 4% of controls. The putative presence of this virus was later shown to be due to contamination of samples with mouse DNA, and the original article supporting the claim was subsequently retracted. Clinicians should maintain skepticism about claims of this kind since the attribution of CFS to a single transmissible agent is not easy to reconcile with the clinical and epidemiologic features described earlier.

In addition to a quest to find an infectious etiology, attention has been focused on immunologic, endocrine, and neuropsychiatric causes. Subtle alterations have been noted but the findings are inconsistent, minor, and do not correlate with disease severity. The hypothesis that the central nervous system is the principal site of the pathophysiology in CFS has gained support in recent years. This hypothesis is bolstered by the presence of neuropsychological symptoms in the active syndrome, the observation of prior or pre-existing psychiatric disorders in a large proportion of patients, and subtle alterations of hormones regulated at the hypothalamic level. Previous or concurrent depression is frequently present in CFS. When patients in general practice are evaluated for "viral" illnesses, the psychiatric morbidity and the patient's belief structure concerning the illness are better predictors of subsequent chronic fatigue than are the severity of symptoms at the time of presentation. More objective evidence of central nervous system involvement includes the observed disruption of the hypothalamic-pituitary-adrenal (HPA) axis. As a group, patients with CFS appear to have lower HPA axis activity than age- and gender-matched controls. Most evidence points to the hypothalamus as the affected element of the axis; however, it is not known whether any of these findings are primary or secondary to inactivity, sleep disruption, or continuing stress accompanying CFS. Nevertheless, the decreased HPA activity in CFS contrasts with the increased activity of the HPA axis observed in patients with major depressive disorder. It is more consistent with findings in posttraumatic stress disorder (PTSD), suggesting that CFS may represent a dysfunctional capacity to respond to both physical and psychological stress, either acquired or genetic or both.

Some evidence for a genetic predisposition to CFS has been generated by twin studies. Studies in the United States, Australia, and Great Britain have shown an increased concordance in monozygotic, rather than dizygotic, twins. However, a microarray analysis of the transcriptome of monozygotic twins who are discordant for CFS failed to show any significant differences. These observations and the other findings mentioned earlier support a pathophysiologic theory of CFS that depends on a predisposition involving genetic or environmental factors or both. In the presence of an acute provocation, such as an infection, the stress response system fails and results in both the production and perpetuation of subjective symptoms (i.e., fatigue, pain, disrupted sleep, poor cognition) and detectable immune alterations.

Diagnosis

CFS is a clinical diagnosis that depends almost entirely on the history and the patient's report of symptoms. There are no characteristic clinical signs. There are no laboratory tests that can be used with any reliability to rule in or rule out the diagnosis. The purpose of the physical examination and basic laboratory testing is to confirm that there is not another medically definable condition that may be causing the symptoms. In the absence of any confounding medical conditions, the diagnosis of CFS may be guided by the published consensus criteria. For reasons explained earlier, the clinician should not apply these criteria stringently for individual patients.

In postinfectious fatigue, the chronic symptoms may appear to be an extension of the inciting infection. Most often, there is no identifiable precipitating event, and the same flu-like symptoms develop gradually. They include sore throat, low-grade fever, tender cervical lymphadenopathy, generalized myalgia or arthralgia, headache, sleep disturbances, and a perception of impaired cognition. Objective physical findings accompanying these symptoms (e.g., pharyngeal erythema or exudate, fever >38°C/100°F, muscle weakness, signs of arthritis, or enlarged lymph nodes) are rare. The presence of any of these signs should raise suspicion of an alternative diagnosis and be evaluated accordingly.

The cardinal symptom of the syndrome is persistent and disabling fatigue, and the fatigue has several characteristic qualities. Most importantly, it is unrelenting and of long duration. It is not improved by rest but worsens after physical or emotional exertion. Postexertional malaise may persist for hours to days after even a modest expenditure of effort. Many patients perceive a limited allotment of energy to expend each day, and, once it is used, they cannot function.

Most patients describe impaired concentration and poor short-term memory. Standard neuropsychological testing typically shows no evidence of an organic syndrome and need not be ordered unless there is objective evidence for cognitive or memory deficit on physical examination. This problem may be the most alarming for the patient who fears a loss of intellectual function; however, such patients can be reassured that the "mental fog" that they experience will lift as the physical symptoms improve.

Most patients will also report either insomnia or excessive sleep. A thorough sleep history is important because many primary sleep disorders present with chronic fatigue as the chief complaint. If there is a suspicion of sleep apnea or a nocturnal movement disorder, a formal polysomnography is indicated. Understandably, many patients will have symptoms of depression or anxiety. Their pre-CFS life has been restricted. The clinician must determine whether these symptoms are reactive to CFS, or primary,

accounting for all of the patient's symptoms. If all of the symptoms can be attributed to major depression or anxiety, then a diagnosis of CFS is excluded.

A limited laboratory evaluation should be done to exclude unrecognized medical conditions. All patients should have a CBC, a chemistry profile, urinalysis, and thyroid function testing. Additional testing may be ordered to rule out other specific medical conditions if the history or physical examination is suggestive. However additional testing should be done judiciously and only if there is a suggestion in the history or physical. Testing when there is a low pre-test probability for a specific disease runs a high risk for false-positive results and potentially additional unnecessary testing and treatments. For example, 15–54% of patients may have a low-titer antinuclear antibody test. This is usually nonspecific, and anti-DNA antibodies and antibodies to extractable nuclear antigens are typically absent. Lupus and other such inflammatory disorders have objective physical findings. Patients with CFS are more likely than healthy controls to have small areas of increased single intensity by brain MRI. These are usually nonspecific and easily distinguished from plaques of demyelinating disease. Urinary free cortisol levels may be relatively low in CFS, but this finding is not reliable enough to be of any diagnostic value. Hormonal testing, other than thyroid-stimulating hormone, should be ordered only when a particular disorder is suspected. Similarly, measurement of the 2′,5′-oligoadenylate synthetase pathway can be ordered from some commercial laboratories. Although opinions differ about the value of these tests, this author finds them insufficiently sensitive and specific to be useful. EBV, Babesia, Lyme disease, and CMV serologies are uninformative both for diagnosis and follow-up of CFS. The clinical syndrome of CFS does not overlap with these disorders. Finding antibodies to these agents may result in unnecessary and occasionally harmful treatments.

CFS often overlaps or coexists with other common idiopathic disorders. Patients with CFS may also meet diagnostic criteria for fibromyalgia, irritable bowel syndrome, interstitial cystitis, premenstrual syndrome, migraine, restless leg syndrome, neurally mediated hypotension or postural orthostatic tachycardia, atypical depression, or spastic dysphonia. The pathophysiologic relationship between these entities and CFS is unclear, but it is important to identify these coexisting disorders because they often respond to treatments that are not necessarily appropriate for use in CFS alone.

Treatment

Guiding principles

At present, the pathophysiology of CFS is not sufficiently understood to inform specific therapy. Consequently, specific medical or psychiatric therapy is indicated only when there is an alternate or coexisting diagnosis. There is no rationale for treating infectious agents. Antivirals and other anti-infective agents are not of value in treating the symptoms of CFS.

In the absence of specific therapy for CFS, treatment should be focused on the remediation of symptoms, nonpharmacologic interventions, and physical rehabilitation. There are only a few treatment modalities that can be recommended based on consistent efficacy demonstrated in well-designed, controlled studies (Table 3.1). Because evidence-based information is inconclusive, clinicians must use their own judgment when using empirical, symptomatic therapies based on the patient's complaints and their own comfort when prescribing the medications. Several other treatments have been proposed, but a preponderance of studies suggests that they are unhelpful or potentially harmful (Table 3.1). Clinicians should also be aware that there is typically a robust placebo effect in trials with CFS patients; therefore, treatment trials that lack appropriate control groups are uninterpretable.

When initiating treatment, it is useful to objectify the symptoms as much as possible. Patients should be asked to rate their symptoms and to keep personal logs so that their response to any treatment can be assessed. This approach is consistent with the principles of one of the possibly effective treatments, cognitive-behavioral therapy (CBT). Therapeutic interventions should be initiated sequentially so that their positive and negative effects can be assessed. In addition, it is especially important to document unconventional or alternative therapies because many patients may resort to using these products. Polypharmacy, including alternative treatments, may confuse the patient's ability to assess their response to any particular treatment that may be prescribed. In general, both the empirical use of allopathic medications and the patient's experimentation with alternative therapies should be guided by concerns for safety and cost, and empirical trials of treatment should be undertaken systematically in a manner that allows the patient and the doctor to assess the value of the intervention.

Critically important aspects of treatment

The most important components of treatment include giving the patient enough time; making it clear to the patient that this is not a new disease; making it clear to the patient that their symptoms are valid; and reviewing with the patient that it is not unusual for them to have had the response from their family, employers, friends, and other healthcare providers that their symptoms were not legitimate. They have a disabling illness that is not their fault, they cannot wish away, and is chronic. Their disability does not allow them to function at a level that they were functioning prior to the development of CFS. Like any other person with a disability they will need to learn a new reality to be able to get the most they can out of their situation.

Empirical treatment of symptoms

Certain medications may be useful for symptomatic therapy in selected patients. Non-narcotic pain relievers for myalgia, arthralgia, or headache may be helpful. Some combination of nonsteroidal anti-inflammatory medications, acetaminophen, and tramadol may improve symptoms in some patients with prominent pain symptoms. Pregabalin, gabapentin, Cymbalta have all been used with some benefit in some patients.

TABLE 3.1 **TREATMENTS FOR CHRONIC FATIGUE SYNDROME**

Critical therapeutic strategies: Educating the patient: 1. This is not a new disease, just a new diagnosis. Therefore, we know a lot about it 2. Symptoms are completely valid and often disabling, though because they are not "visible" and testing is normal patients often have to defend the legitimacy (see IOM paper). These people are suffering. They want their pre-CFS lives back. They are not malingering.	
Therapies supported by several randomized controlled trials:	None
Empiric, symptomatic treatments	Nonnarcotic pain relievers: Cymbalta, pregabalin, gabapentin, amitriptyline Antidepressants Sleep hygiene Sleep aids
Controversial treatments supported by some studies but not by others:	Graded exercise program Cognitive-behavioral therapy
Inappropriate treatments without out clinical support or proved ineffective in controlled trials: Antibiotics, antivirals, antifungals Hydrocortisone Galantamine Fludrocortisone Dehydroepiandrosterone (DHEA) IV immunoglobulin Interferons Vitamins Nutritional supplements Restrictive diets	

Although studies conflict on the value of antidepressant therapy, there are two rationales for their use in selected patients: (1) certain antidepressants are generally considered effective treatment (e.g., for mood disturbances, anxiety, insomnia, pain, poor concentration), and (2) it is expected that chronic illness and disability will result in some degree of depression. Treating depression will help them cope better with their disability, and (3) CFS and fibromyalgia frequently coexist or have substantial symptom overlap, and a benefit of tricyclic antidepressants and similar medications has been demonstrated in fibromyalgia. It should be noted that studies that show benefit of these agents in CFS generally report relief of the associated symptoms noted earlier rather than the cardinal symptom of fatigue. Therefore, a particular antidepressant may be favored for a given patient depending on the intensity of these symptoms. The remarkable safety profile of antidepressants makes them a reasonable choice for an empirical trial.

Many CFS patients also suffer from sleep disturbances. Pharmacologic sleep aids (e.g., eszopiclone, zolpidem, clonazepam) may be helpful short term but risk creating dependency. Various antidepressants (e.g., low-dose trazodone or amitriptyline) may be better suited for long-term use. Melatonin is a popular over-the-counter sleep remedy, but CFS patients have normal levels and timing of endogenous melatonin secretion. A trial of high-dose melatonin improved CFS symptoms in patients with delayed melatonin secretion; however, the trial used historical controls and must be interpreted with caution.

Perhaps as important as pharmacologic agents is some attention to sleep hygiene. All patients should be instructed to keep regular sleep hours. Patients who are sleeping excessively should be encouraged to reduce their hours of sleep gradually. Those with insomnia should be encouraged to reduce daytime napping to <1 hour a day.

Controversial therapies

While some studies have demonstrated that graded aerobic exercise is helpful in reducing the symptoms of CFS, others have not. If undertaken they must be done cautiously because of the characteristic exacerbation of symptoms by exercise. A program of exercise tailored to the individual patient's tolerance should be a part of any treatment effort. The form of exercise should be aerobic and quantifiable. An approach that targets a specified exercise duration is likely to give the best results. This is best done under the supervision of an experienced physical therapist. Adherence to such a program usually requires substantial oversight by the physician and physiotherapist, especially among patients who experience serious post-exertional fatigue. In contrast, there is no evidence to support the prescription of bed rest and some suggestion that continuous inactivity may both reinforce illness behavior and lead to complicating myofascial pain syndromes.

CBT is can be helpful for symptom control in a variety of organic diseases, so it is not surprising that it also benefits some CFS patients. CBT involves a restructuring of the patient's beliefs about the illness and encourages objective assessment of the symptoms and disabilities. One innovative approach developed by a Dutch research group used an internet-based CBT program for treating adolescents and found it more effective for increasing school attendance than a treatment program based in a tertiary care center. Unfortunately, CBT is not universally available; however, the physician can integrate some of the principles into routine medical care. Educating the patient about the causes and manifestations of CFS is critical, particularly when there are misconceptions that may lead to counterproductive behaviors. Having the patient objectify their symptoms and identify factors that exacerbate or relieve them may also be helpful in management. A rational and sympathetic approach to the patient is essential. Challenging the reality of symptoms or attributing them to some other cause (e.g., depression in the absence of standard criteria) is distinctly unhelpful because these ideas will not be consistent with the patient's own experience and beliefs. Similarly, classical insight-oriented psychotherapy should be reserved for those patients who have significant emotional stress.

Contraindicated therapies

Several specific therapies for CFS have been tried based on a particular pathophysiologic hypothesis. Until now, none of these therapies has been shown to have meaningful benefit. For instance, a carefully conducted trial of anti-herpesvirus therapy with acyclovir to test the hypothesis that EBV replication is associated with ongoing symptoms failed to show any benefit over placebo (both showed some benefit). Similarly, a randomized therapeutic trial of oral nystatin was conducted to assess the effect on CFS-like symptoms in patients who claimed to have yeast hypersensitivity. The only benefit was a slight reduction in *Candida* vaginitis in the treatment group.

The finding of depressed HPA axis activity prompted a trial of low-dose hydrocortisone and subsequently a trial of galantamine (to stimulate HPA axis activity centrally). Investigators judged that the bone mineral loss and prolonged suppression of the HPA axis that resulted from hydrocortisone therapy was not justified by the minimal benefit gained by treatment. The study of galantamine showed no substantial benefit. Another neuroendocrine hypothesis involves the hormone dehydroepiandrosterone (DHEA). DHEA supplementation in CFS has reportedly improved fatigue and other symptoms in patients with depressed levels of this enzyme at baseline; however, there has been no controlled trial of this treatment, and it should be regarded skeptically. A study connecting neurally mediated hypotension (diagnosed by a 45-minute tilt table protocol) with CFS prompted therapeutic trials of volume expansion with fludrocortisone. Two independent studies showed no significant benefit of this approach.

Using a model of immune dysfunction as a key factor in the production of CFS symptoms, immune modulation with immunoglobulins and interferons has been studied. In particular, patients should be cautioned about unproved, costly, inconvenient, and potentially dangerous treatments. Other therapies that have been ineffective or conflicted in randomized controlled trials include the thiamine precursor sibutramine, growth hormone, homeopathic preparations, and essential fatty acids.

Occasionally, patients report relief of symptoms with specialized dietary alterations. A common example is the restrictive diet recommended to reduce intestinal "yeast." There is no experimental evidence to support these diet therapies in CFS, and highly restrictive diets may impair nutrition and general health. Trials of nutritional supplements (e.g., vitamins, liver extract) have also been discouraging.

Physicians and patients should be aware that there is a lucrative internet market catering to desperate patients with CFS whose primary care physicians are dismissive. Most of the online sales involve unproved supplements and remedies. Many are very expensive (such as replacement of all amalgam dental fillings) and some may be hazardous (such as various hormones and ephedra). Some patients with CFS are motivated to take risks and spend abundantly from their personal resources to achieve relief from their suffering. Sympathetic physicians should not be judgmental but rather attempt to guide patients through this morass of "treatments" to protect them from financial exploitation or harm.

One final caveat: it is important to evaluate each new symptom in a patient with CFS before ascribing it to CFS. Patients with CFS are, of course, are at risk for any additional disease. Before assuming this is just another manifestation of CFS, consideration must be given to an alternative and potentially specifically treatable cause.

Conclusion

CFS may occur spontaneously or as a result of an acute stressor, such as an infection. However, there is no evidence that a chronic infection is the cause of the chronic symptoms. Diagnostic criteria have been established by expert consensus in an attempt to standardize research on this disorder. Diagnosis based on the patient's subjective report, physical examination, and laboratory tests is useful only to rule out confounding medical conditions. Medical treatments directed at specific symptoms may be helpful in individual patients. Treatments based on a pathophysiologic hypothesis of the disorder have been uniformly disappointing. Consequently, the most important elements of care include (1) educating the patient with restructuring of beliefs and perceptions of the illness, (2) evaluating symptomatic treatments, and (3) protecting the patient from physical or financial harm associated with unproved therapies.

Clinical syndromes: Head and neck

4

Pharyngotonsillitis

Itzhak Brook

Pharyngotonsillitis (PT) is an inflammation of the pharynx and tonsils characterized by the presence of increased pharyngeal and tonsillar redness and finding of an exudate, ulceration, or a membrane covering the tonsils. Because the pharynx is served by lymphoid tissues of the Waldeyer ring, an infection can spread to include various parts of the ring such as the nasopharynx, uvula, soft palate, tonsils, adenoids, and the cervical lymph glands. Based on the extent of the infection, it can be described as pharyngitis, tonsillitis, tonsillopharyngitis, or nasopharyngitis. The duration of any of these illnesses can be acute, subacute, chronic, or recurrent.

Etiology

The diagnosis of PT generally requires the consideration of group A β-hemolytic streptococci (GABHS) infection. However, other bacteria, viruses, and other infections and noninfectious causes should be considered. Recognition of the cause and choice of appropriate therapy are of utmost importance in assuring rapid recovery and preventing complications.

Table 4.1 lists the different causative agents and their characteristic clinical features. The occurrence of a certain etiologic agent depends on multiple variables that include environmental conditions (season, geographic location, exposure) and individual variables (age, host resistance, and immunity). The most prevalent agents accounting for PT are GABHS, adenovirus, influenza virus, parainfluenza virus, Epstein–Barr virus (EBV), and enterovirus. However, the exact etiology is generally not determined, and the role of some potential pathogens is not certain.

Interactions between various organisms, including GABHS, other aerobic and anaerobic bacteria, and viruses, may occur during PT. Some of these interactions may be synergistic (i.e., between EBV and anaerobic bacteria), thus enhancing the virulence of some pathogens, whereas others may be antagonistic (i.e., between GABHS and certain "interfering" α-hemolytic streptococci). Furthermore, β-lactamase-producing bacteria (BLPB) can protect themselves and other bacteria from β-lactam antibiotics. Bacterial biofilms may be a causative factor in the pathogenesis of chronic tonsillitis. Bacterial biofilms are recalcitrant to antibiotic therapies and immune clearance due to biochemical factors, molecular mechanisms, and altered host environment.

Aerobic bacteria

Because of the potential of serious suppurative and nonsuppurative sequelae, GABHS are the best known cause of sore throat. Occasionally non-B groups, large colony C, and G β-hemolytic streptococci are responsible. However, the other groups are generally not associated with acute rheumatic fever due to biochemical factors, molecular mechanisms, and altered host environment fever.

The clinical presentation of PT is generally identical for all groups and is characterized by exudation, palatal petechiae, follicles, tender cervical adenitis, and scarlet fever rash. What are generally absent are the

classical signs of viral infections such as cough, rhinitis, conjunctivitis, and diarrhea.

There is no symptom or single sign that reliably identifies GABHS pharyngitis. Symptoms in children younger than 3 years of age are atypical and include nasal congestion and discharge, low-grade fever, and tender anterior cervical lymph nodes. GABHS should be suspected in the presence of abrupt onset of fever in a child older than 3 years (with or without "sore throat"), higher temperature, ill appearance, headache, neck muscle pain, tenderness, abdominal pain, nausea, or vomiting, flushed cheeks, circumoral pallor, palatal "petechiae" and semicircular red marks, early strawberry tongue and/or scarlatiniform rash, a history of exposure to the organism, winter season, and the presence of a peculiar, sour-sweet, yeasty breath odor.

The isolation rate of GABHS varies with patient age, with the highest prevalence in school years (15–30% of all PT). The isolation rate of non-GABHS is higher in adults than in children.

There was a marked decrease in the incidence of acute rheumatic fever in the United States over the past 50 years that is correlated with the replacement of rheumatogenic types by non-rheumatogenic types. However, streptococcal tonsillitis is still a potential serious illness because rheumatic fever still occurs, and GABHS is manifesting increased virulence. More cases of invasive disease such as sepsis, necrotizing fasciitis, pneumonia, and toxic shock syndrome due to streptococci have been observed in recent years. Streptococci can be involved in suppurative complications of tonsillitis such as peritonsillar and retropharyngeal abscesses.

Streptococcus pneumoniae can also be involved in PT that can either subside or spread to other sites.

Corynebacterium diphtheriae can cause a "bull neck," as can *Arcanobacterium hemolyticum*, and both can cause an early exudative PT with a grayish-green thick membrane that may be difficult to dislodge and often leaves a bleeding surface when torn off. The infection can spread to the throat, palate, and larynx. It is rare in developed countries where children are vaccinated against it.

Arcanobacterium hemolyticum produces a lethal systemic exotoxin. *A. hemolyticum* incidence of causing PT is 2.5% to 10%, occurs mostly in 15- to 18-year-old individuals, and about half of the patients have a scarlatiniform rash.

Neisseria gonorrhoeae is common in homosexual males and can be detected in sexually active adolescents with pharyngitis. The infection is often asymptomatic but can exhibit ulcerative or exudative pharyngitis, may result in bacteremia, and can persist after treatment. *Neisseria meningitidis* can cause symptomatic or asymptomatic PT that can be a prodrome for septicemia or meningitis.

Nontypeable *Haemophilus influenzae* and *H. parainfluenzae* can be recovered from inflamed tonsils. These organisms can cause invasive disease in infants and elderly persons, as well as acute epiglottitis, otitis media, and sinusitis.

Staphylococcus aureus is often recovered from chronically inflamed tonsils and peritonsillar abscesses. Methicillin-resistant *S. aureus* (MRSA) was isolated from 16% of recurrently infected tonsils. It can produce the enzyme β-lactamase that may interfere with the eradication of GABHS. High tissue concentration of *H. influenzae*, *S. aureus*, and GABHS correlates with recurrent infection and hyperplasia of the tonsils.

Francisella tularensis infection (tularemia) is rare and should be considered in patients unresponsive to penicillin. It can be contracted by ingestion of contaminated water as well as in poorly cooked wild

animal meat. Clinical presentation of PT includes fever, painful ulcerative-exudative pharyngitis, and cervical lymphadenitis.

Other rare causes of PT are *Treponema pallidum*, *Mycobacterium* spp., and *Toxoplasma gondii*.

Anaerobic bacteria

The anaerobic species that have been implicated in PT are *Actinomyces* spp., *Peptostreptococcus* spp., *Fusobacterium* spp., and pigmented *Prevotella* and *Porphyromonas* spp.

The role of anaerobes is supported by their predominance in tonsillar or retropharyngeal abscesses and Vincent's angina (*Fusobacterium* spp. and spirochetes). Furthermore, patients with non-GABHS tonsillitis as well as infectious mononucleosis respond to antibiotics directed only against anaerobes (metronidazole), and elevated serum levels of antibodies to *Prevotella intermedia* and *Fusobacterium nucleatum* were found in patients with acute and recurrent non-GABHS tonsillitis and peritonsillar cellulitis and abscess.

Fusobacterium necrophorum has been recovered in recent studies from the United Kingdom and Denmark of adolescents and young adults with streptococcal as well as non-streptococcal PT. Other studies also suggest a role for *F. necrophorum* in recurrent or persistent sore throat. It is also the etiology of most cases of Lemierre's syndrome, which generally occurs in previously healthy adolescents and young adults. The syndrome includes necrotizing tonsillopharyngitis associated with *Fusobacterium* bacteremia, septic internal jugular vein thrombophlebitis, and metastatic pulmonary infection. Clinical findings include fever (>39°C/102°F), rigors, respiratory symptoms, and unilateral neck pain and/or swelling.

Mycoplasma

Mycoplasma pneumoniae and *Mycoplasma hominis* can cause PT usually as a manifestation of a generalized infection. Mycoplasma accounts for 5% to 15% of cases of PT, and most cases occur in those older than 6 years.

Chlamydia

Chlamydia pneumoniae may cause PT in young adults, often accompanying pneumonia or bronchitis.

Viruses

Viral PT is generally characterized by the absence of an exudate, the presence of ulcerative lesions, minor nontender adenopathy, enanthems, cough, rhinitis, hoarseness, conjunctivitis, or diarrhea.

The viruses known to cause PT are adenovirus (concomitant conjunctivitis), Coxsackie A virus, influenza and parainfluenza viruses (seasonal with high fever, cough, headache, and myalgias), coronavirus, enteroviruses (posterior pharyngeal vesicles or ulcers, vesicles on palms and soles in summer), Epstein–Barr virus (exudative pharyngitis, liver and spleen enlargement, cervical adenopathy), herpes simplex (HSV; most caused by HSV-1, anterior oral and lip ulcers, fever), rhinovirus, respiratory syncytial virus (RSV), rubeola (oral erythema and Koplik spots prior to exanthema), and cytomegalovirus (CMV).

Primary HIV infection may cause an acute retroviral syndrome which is similar to infectious mononucleosis. The symptoms usually occur within days to weeks after exposure, and infection includes fever, weight loss, rash, lymphadenopathy, and splenomegaly.

Mixed infections

PT can be caused by multiple pathogens. Mixed viral/bacterial pathogens were found in 26 of 127 patients (20.5%) and none of the controls ($p < 0.0001$). Combined pathogens included double bacterial infection with GABHS plus *C. pneumoniae* or *M. pneumoniae* plus *C. pneumoniae* with *M. pneumoniae*; and viral and bacterial infection with GABHS plus RSV, adeno and influenza B and parainfluenza type 1 viruses, *C. pneumoniae* plus RSV or adeno virus, and *M. pneumoniae* plus adeno virus.

A concomitant GABHS and influenza A virus PT, as evident by increased antistreptolysin O (ASO) and anti-DNase B titers, was found in 4 of 12 (33%) patients who had both of these organisms isolated in their upper airways.

Clinical findings

PT has generally a sudden onset, with fever and sore throat, nausea, vomiting, headache, and rarely abdominal pain. At an early stage, redness of throat and tonsils is observed, and the cervical lymph glands become enlarged. The clinical manifestations may vary by causative agent (see earlier discussion and also Table 4.1) but are rarely specific. Erythema is common to most agents; however, the occurrence of ulceration, petechiae, exudation, or follicles varies. The common features are exudative pharyngitis in GABHS infection, ulcerative lesions in enteroviruses, and membranous pharyngitis in *C. diphtheriae*. Petechiae can often be seen in GABHS, Epstein–Barr, measles, and rubella viruses infections.

Viral disease is generally self-limited, lasts 4 to 10 days, and is generally associated with the presence of nasal secretions. Bacterial illness lasts longer if untreated. The most unique features of anaerobic tonsillitis or PT are enlargement and ulceration of the tonsils associated with fetid or foul odor and the presence of fusiform bacilli, spirochetes, and other organisms on Gram stain.

Diagnosis

Determining if GABHS is the cause of the PT is very important because early antimicrobial therapy shortens the illness, prevents suppurative and nonsuppurative complications, reduces transmission of the pathogen, and prevents misuse of antimicrobials.

GABHS PT can be diagnosed by either a positive throat culture or rapid test. Culture is obtained when microbiologic isolation is needed. Throat culture should be obtained before initiation of antimicrobial therapy. Vigorous swabbing of both tonsillar surfaces and the posterior pharyngeal wall, and plating the specimen on sheep blood agar media is the standard. Incubation in anaerobic condition and use of selective media can increase the recovery rate of GABHS. More than 10 colonies of GABHS per plate are considered to represent a true infection rather than colonization. However, using the number of colonies of GABHS in the plate as an indicator for the presence of true infection is difficult to implement because there is overlap between carriers and infected individuals. A single throat culture has the sensitivity of 90% to 95% in detection of GABHS in the pharynx. False-negative results can occur in patients who received antibiotics. Throat cultures that generally identify GABHS by direct growth may take 24 to 48 hours. Re-examination of plates at 48 hours is advisable. The use of a bacitracin disk provides presumptive identification. Attempts to identify β-hemolytic streptococci, other than group A, may be worthwhile in older individuals. Commercial kits containing group-specific antisera are available for identifying the specific streptococcal group.

Rapid methods for detection of GABHS that take 10 to 60 minutes are available. They are more expensive than the routine culture but allow for rapid administration of therapy and reduction of morbidity. Antigen tests depend on the detection of the surface Lancefield group A carbohydrate. Newer tests use nucleic acid (DNA) probes and polymerase chain reaction (PCR) with greater sensitivity and identify more pathogenic serotypes of GABHS. Early kits showed low sensitivity, but the currently available ones have 85% to 90% sensitivity but are still associated with 5% to 15% false-negative results. It is therefore recommended that a bacterial culture be performed in instances where the rapid streptococcal test is negative. Unfortunately, neither rapid test nor throat culture can differentiate patients with PT due to GABHS from viral infection in a GABHS carrier.

A rise in antistreptococcal antibody titers (e.g., antistreptolysin O, antideoxyribonuclease B, streptokinase, hyaluronidase, or nicotinic acid dehydrogenase) after 3 to 6 weeks can provide retrospective evidence for GABHS infection and assist in differentiating between the carrier state and infection.

Other less common pathogens should be identified in specific situations when no GABHS is found or when a search of other organisms is warranted. Because many of the other potential pathogens are part of the normal pharyngeal flora, interpretation of these data can be difficult. When tularemia is suspected serologic testing is advisable. Pharyngeal cultures for *N. gonorrhoeae* require special media (Thayer–Martin agar). Attempts to identify corynebacteria should be made whenever a membrane is present in the throat. Cultures should be obtained from beneath the membrane using special moisture-reducing transport media. A Loeffler slant, a tellurite plate, and a blood agar plate should be inoculated. Identification by fluorescent antibody technique is possible. *Arcanobacterium haemolyticum* grows slowly on sheep blood agar plates and produces a tiny zone of β-hemolysis after at least 3 days of incubation.

Viral cultures or rapid tests for some viruses (i.e., influenza, respiratory syncytial and herpes simplex viruses) are available. A heterophile slide test or other rapid tests for infectious mononucleosis can also provide a specific diagnosis. Laboratory features of primary HIV infection may include lymphopenia and increased transaminase levels. HIV viral load and HIV antibodies tests may be helpful.

Therapy

Many antibiotics are available for the treatment of PT caused by GABHS. However, the recommended optimal treatment for GABHS infection is penicillin administered three times a day for 10 days (Table 4.2). Oral penicillin VK is used more often than intramuscular (IM) benzathine penicillin G. However, IM penicillin can be given as initial therapy in those who cannot tolerate oral medication or to ensure compliance. An alternative medication is amoxicillin, which is as active against GABHS, but its absorption is more reliable, blood levels are higher, plasma half-life is longer, and protein binding is lower, giving it theoretical advantages. Furthermore, oral amoxicillin has better compliance (better taste). Amoxicillin should not be used, however, in patients suspected of infectious mononucleosis, where it can produce a skin rash.

The frequently reported inability of penicillin to eradicate GABHS from patients with PT despite its excellent in vitro efficacy

For dosages and length of therapy, see Table 4.2.

is of concern. Although about half of the patients who harbor GABHS following therapy may be carriers, the rest may still show signs of infection and represent true clinical failure. Studies have shown that the recommended doses of either oral penicillin V or IM penicillin failed to eradicate GABHS in acute-onset pharyngitis in 35% of patients treated with oral penicillin V and 37% of those treated with IM penicillin.

Penicillin failure in eradicating GABHS tonsillitis has several explanations (Table 4.3). These include noncompliance with the 10-day course of therapy, carrier state, reinfection from another person or object, and penicillin tolerance. Some postulate that bacterial interactions between GABHS and members of the pharyngotonsillar bacterial flora can explain these failures. These explanations include the "shielding" of GABHS from penicillins by BLPB that colonize the pharynx and tonsils, the absence of normal flora organisms that interfere with the growth of GABHS, and the coaggregation between *Moraxella catarrhalis* and GABHS. Repeated penicillin administration can induce many of these changes. It can result in a shift in the oral microflora with selection of β-lactamase-producing strains of *S. aureus*, *Haemophilus* spp., *M. catarrhalis*, *Fusobacterium* spp., pigmented *Prevotella* and *Porphyromonas* spp., and *Bacteroides* spp.

It is possible that BLPB can protect the GABHS from penicillin by inactivating the antibiotic. Such organisms in a localized soft-tissue infection may degrade penicillin in the area of the infection, protecting not only themselves but also penicillin-susceptible pathogens such as GABHS. Thus, penicillin therapy directed against a susceptible pathogen can be rendered ineffective. An increase in in vitro resistance of GABHS to penicillin was observed when GABHS was inoculated with *S. aureus*, *Haemophilus* spp., and pigmented *Prevotella* and *Porphyromonas* spp. *Bacteroides* spp. protected a penicillin-sensitive GABHS from penicillin therapy in mice. Both clindamycin and the combination of penicillin and clavulanic acid (a β-lactamase inhibitor), which are active against both GABHS and *Bacteroides* spp., eradicated the infection.

Penicillin therapy can also reduce the number of aerobic and anaerobic bacteria that can interfere with the growth of GABHS. The oropharyngeal flora of >85% of individuals who are not tonsillitis-prone contains numerous types of organisms that are capable of interfering with the in vitro growth of potential pathogens. In contrast, only 25% to 30% of children who suffer from recurrent tonsillitis harbor interfering organisms.

Acute pharyngotonsillitis

Oral penicillin given for 10 days is still recommended as the antibiotic of choice given its proved efficacy, safety, narrow spectrum, and low cost. Other effective antibiotics included cephalosporins, lincomycin, clindamycin, macrolides, and amoxicillin-clavulanate. Some of these agents were more effective than penicillin in acute (cephalosporins, macrolides) and others in recurrent (lincomycin, clindamycin, and amoxicillin-clavulanate) GABHS PT.

There are patients in whom more effective antimicrobials that are less likely to fail to eradicate GABHS should be considered. Individual medical, economical, and social issues should be considered in each patient prior to selecting an antimicrobial for the treatment of GABHS PT (Box 4.1). These include the existence of a high probability for the presence in the pharyngotonsillar area of BLPB and the absence of interfering organisms, the recent failure of penicillin therapy, or a history of recurrent GABHS PT.

The macrolides are also an alternative choice in therapy of PT. Compliance with the newer macrolides (clarithromycin and azithromycin) is better compared with erythromycin because of their longer half-life and reduced adverse gastrointestinal side effects. However, the increased use of macrolides for the treatment of various respiratory and other infections has been associated with increased GABHS resistance to these agents. Resistance of GABHS to macrolides has reached 70% in Finland, Italy, Japan, and Turkey.

BOX 4.1

Possible reasons for antibiotic failure or relapse in GABHS tonsillitis

Bacterial interactions

- The presence of β-lactamase-producing organisms that "protect" GABHS from penicillins
- Co-aggregation between GABHS and *Moraxella catarrhalis*
- Absence of members of the oral bacterial flora capable of interfering with the growth of GABHS (through production of bacteriocins and/or competition on nutrients)
- Presence of bacterial biofilm that causes resistance to antimicrobial due to biochemical factors, molecular mechanisms, and altered host environment

Internalization of GABHS (survives within epithelial cells, thus escaping eradication by penicillins)
Resistance (i.e., erythromycin) or tolerance (i.e., penicillin) to the antibiotic used
Inappropriate dose, duration of therapy, or choice of antibiotic
Poor compliance with taking medication
Reacquisition of GABHS from a contact or an object (i.e., toothbrush, dental retainer, or dental braces)
Carrier state, not disease

Of concern is the significant increase of such resistance in the United States that reached 48% in specific populations. The current resistance of GABHS to macrolides in the United States is 5% to 16%. It is therefore advisable to avoid the routine use of macrolides for GABHS PT and save these agents for those patients who are type I penicillin allergic.

The success rate of treatment of acute GABHS tonsillitis was consistently found to be higher with cephalosporins than with penicillin. The cephalosporins' increased efficacy may be due to their activity against aerobic BLPB such as *S. aureus*, *Haemophilus* spp., and *M. catarrhalis*. Another possible reason is that the nonpathogenic interfering aerobic and anaerobic bacteria that compete with GABHS and help to eliminate them are less susceptible to cephalosporins than to penicillin. These organisms are therefore more likely to survive cephalosporin therapy.

The length of therapy of acute tonsillitis with medication other than penicillin has not been determined by large comparative controlled studies. However, certain new agents have been administered in shorter courses of ≥5 days (Table 4.2). Early initiation of antimicrobial therapy results in faster resolution of signs and symptoms. However, spontaneous disappearance of fever and other symptoms generally occurs within 3 to 4 days, even without antimicrobials. Furthermore, acute rheumatic fever can be prevented even when therapy is postponed up to 9 days.

Prevention of recurrent tonsillitis due to GABHS by prophylactic administration of daily oral or monthly benzathine penicillin should be attempted in patients who suffered from rheumatic fever. American Heart Committee guidelines on the prevention of rheumatic fever should be followed, and if any family members are carrying GABHS, the disease should be eradicated and the carrier state monitored.

Macrolides are the drugs of choice for *A. haemolyticum* that is unresponsive to penicillin. When *C. diphtheriae* infection is suspected, erythromycin is the drug of choice, and penicillin or rifampin are alternatives. Supportive therapy of PT includes antipyretics and analgesics, such as aspirin or acetaminophen, and attention to proper hydration.

Pharyngeal *N. gonorrhoeae* infection appears to be more difficult to treat and can serve as an important reservoir of infection. The recommended treatment is a single injection of ceftriaxone (250 mg IM) plus azithromycin (1 g PO). Doxycycline (100 mg PO BID for 7 days) is an alternate therapeutic option as a second agent to administer with ceftriaxone. HSV infection is treated with acyclovir.

Antiviral therapy may be provided to those with influenza virus if the diagnosis is made early in the course of illness and the symptoms are severe.

Recurrent and chronic pharyngotonsillitis

Penicillin failure in treatment of recurrent and chronic tonsillitis is even higher than the failure of therapy of acute infection. Several clinical studies demonstrated the superiority of lincomycin, clindamycin, and amoxicillin-clavulanate over penicillin. These antimicrobial agents are effective against aerobic as well as anaerobic BLPB and GABHS in eradicating recurrent tonsillar infection.

BOX 4.2

Indications for the use of antimicrobials other than a penicillin for GABHS tonsillitis

- Presence of β-lactamase-producing bacteria (recent antibiotic exposure, winter, region)
- Absence of "interfering flora" (recent antibiotic therapy)
- Recurrent GABHS tonsillitis
- Past failures to eradicate GABHS
- High failures of penicillins in the community
- Comorbidities
- When failure is a medical, economical, or social hardship
- Penicillin allergy (non-type I)

Clindamycin also provides coverage against many MRSA that can resist other antimicrobials such as amoxicillin-clavulanate. However, no studies showed them to be superior to penicillin in treatment of acute tonsillitis. Other drugs that may also be effective in the therapy of recurrent or chronic tonsillitis are penicillin plus rifampin and a macrolide (e.g., erythromycin) plus metronidazole (see Box 4.2). Referral of a patient for tonsillectomy should be considered only after these medical therapeutic modalities have failed.

Infectious thyroiditis

Jeanne Carey and Stephen G. Baum

Introduction

Acute suppurative thyroiditis (AST) is a rare but potentially life-threatening infection. AST is usually bacterial in etiology, although fungal, parasitic, and mycobacterial organisms have also been documented causes. The routes of infection are predominantly hematogenous or lymphatic; however, thyroid infections may also be the result of direct spread from an adjacent deep fascial space infection, an infected thyroglossal fistula, or anterior perforation of the esophagus. Thus, infectious thyroiditis may occur either as a local infection or as part of a disseminated systemic infection. Because prognosis depends on prompt diagnosis and treatment, it is important to differentiate AST from the noninfectious inflammatory conditions of the thyroid and other inflammations in the neck that it may closely resemble.

Pathogenesis

The thyroid gland is rarely infected, and several protective factors have been postulated to explain why the gland is relatively resistant to infection. First, there is a rich blood supply to and extensive lymphatic drainage from the thyroid. Second, the high iodine content of the gland may be bactericidal; however, there are no data to show that the concentration of iodine present in the thyroid would be enough to inhibit the growth of microorganisms. Third, in addition to being surrounded by a complete fibrous capsule, the thyroid is separated from the other structures of the neck by fascial planes.

Primary infections of the thyroid are most likely to occur in individuals with preexisting thyroid disease or with certain congenital anomalies. Goiters, Hashimoto's thyroiditis (chronic lymphocytic thyroiditis), or thyroid cancer have been present in up to two-thirds of women and one-half of men with infectious thyroiditis. With respect to congenital anomalies, which are associated with AST more frequently in children than in adults, transmission of infective organisms via a pyriform sinus fistula is the most common direct route of thyroid infection (Figure 5.1). The fistula arises from the apex of the pyriform recess and often ends in or near the thyroid gland, allowing bacterial infection to develop in or around the thyroid.

Episodes of AST are often preceded by an upper respiratory infection or another factor (e.g., injury or obstruction of the fistula by food or foreign bodies) that may induce inflammation of a pyriform fistula and thus facilitate transmission of pathogens to the thyroid. Particularly in children, the left lobe is more commonly involved, reflecting the observation that pyriform sinus fistulas predominantly occur on the left.

Infected embryonic cysts of the third and fourth branchial pouches have also been identified as causes of AST. Infectious organisms may also spread directly to the thyroid via a patent thyroglossal duct fistula (Figure 5.2). AST may be caused by spread of microbes from adjacent sites of infection, such as the oropharynx and middle ear, although this occurs infrequently, presumably because the thyroid is encapsulated within its fibrous sheath. Perforation of the esophagus may also result in direct spread of infection to the thyroid gland.

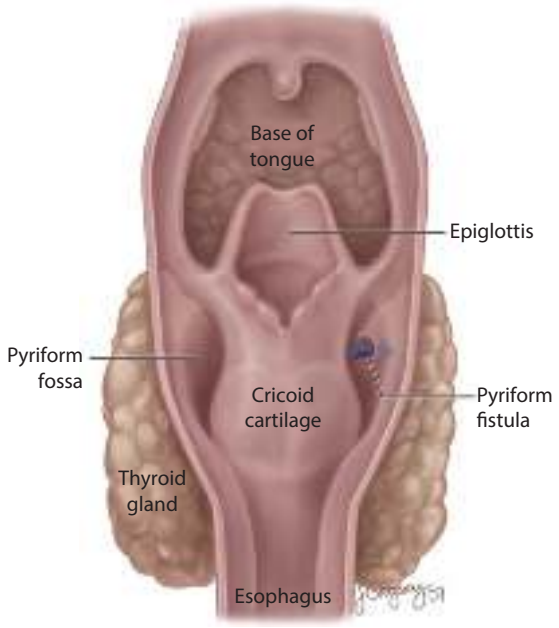

FIGURE 5.1 Anatomy of the thyroid gland and oropharynx, demonstrating the relationship to a pyriform fistula, anterior view.

Bacterial AST may also result from trauma to the anterior neck. One of us (SGB) has seen a single case of direct spread of infection to the thyroid from a neck wound. The patient was a mechanic who scraped his anterior neck while working on his back underneath an automobile. The wound appeared superficial, but infection spread to the thyroid with abscess formation. The offending organism was a staphylococcus. Even fine-needle aspiration (FNA) of thyroid nodules has resulted in thyroid infection.

Immunosuppressed patients, such as those with HIV infection or hematologic malignancies, as well as patients with autoimmune diseases or organ transplants treated with immunosuppressive agents, are at risk for suppurative thyroiditis, which can occur as part of a disseminated infectious process. These infections arise when pathogens reach the thyroid hematogenously or through the lymphatic system.

Microbiology

Gram-positive organisms are the most common etiologic pathogens in AST, although a wide variety of bacteria have been isolated as causative agents in case reports (Box 5.1). In a review of 224 cases of thyroid infections reported between 1900 and 1980, staphylococci, found in 23 of 66 (35%) of culture-positive specimens, were the most frequently identified organisms; *Staphylococcus aureus* was the predominant species. *Streptococcus pyogenes*, presumably acquired after a recent pharyngeal infection or colonization; *Streptococcus pneumoniae*; and other streptococci were also commonly recovered. In a subsequent review of an additional 191 cases of AST reported between 1980 and 1997, in which 130 microorganisms were isolated, Yu et al. found that the most common bacterial isolates were gram-positive aerobes (39%), gram-negative aerobes (25%), and anaerobes (12%, mostly in mixed culture). More recently, the prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) has been increasing.

When anaerobic bacteria are isolated from the infected thyroid, they are usually members of the oropharyngeal flora. The true involvement of anaerobic bacteria in AST is unknown because past studies have not used uniform methods for the recovery

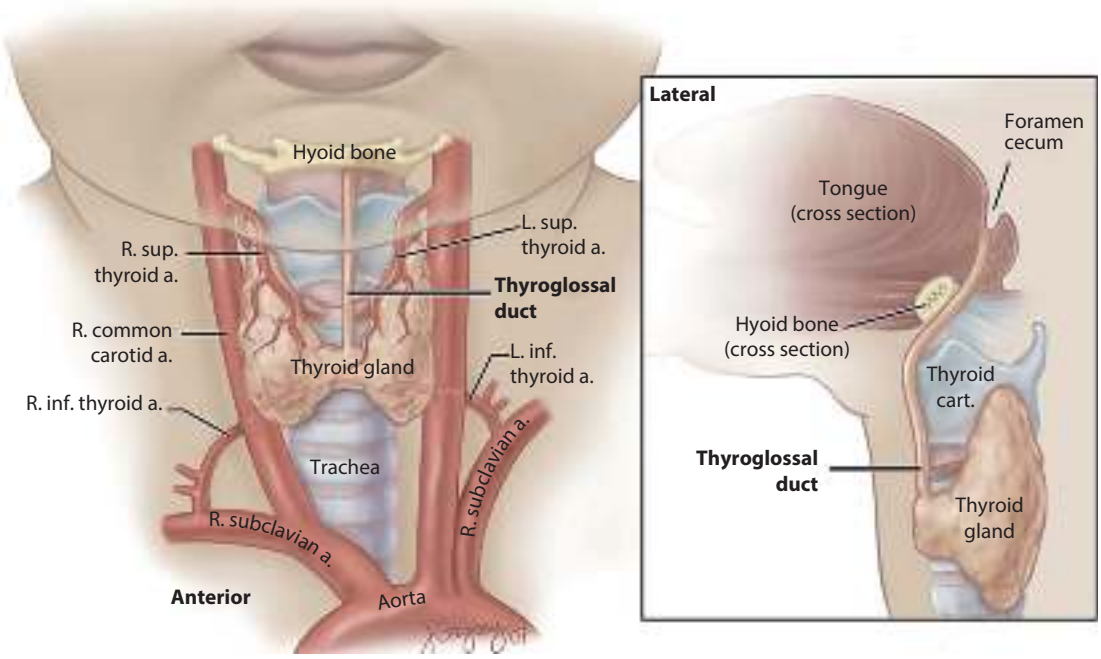

FIGURE 5.2 Anatomy of the thyroid gland and neck. A thyroglossal duct fistula is shown in frontal and lateral views.

BOX 5.1

Microbiology of infectious thyroiditis

Nonimmunocompromised host

Staphylococcus aureus
Staphylococcus epidermidis
Streptococcus pyogenes
Other streptococcal species
Klebsiella species, especially in diabetic patients
Other Enterobacteriaceae
Anaerobic oral flora (foul smell on needle aspiration may give hint of this)
Other gram-negative bacteria free-living in water secondary to upper respiratory tract infection
Mycobacterium tuberculosis
Mycobacterium bovis
Actinomyces spp.

Immunocompromised host

Mycobacterium avium-intracellulare
Nocardia spp.
Pneumocystis jirovecii

Modified from Shah and Baum, 2000.

of anaerobes. Because anaerobes are more difficult to isolate, it is possible that culture-negative cases of AST may represent purely anaerobic or mixed infections, an important consideration when choosing empiric therapy for AST.

The bacterial pathogens implicated in AST in children are similar to those found in adults. *S. aureus, S. pyogenes, Staphylococcus epidermidis*, and *Streptococcus pneumoniae* are the most commonly isolated organisms in pediatric cases of AST.

Following bacteria, fungi are the second most common microorganisms to infect the thyroid, representing 15% of cases of AST in the review by Yu and colleagues. Fungal thyroiditis most commonly occurs in immunocompromised patients, such as those with leukemia, lymphoma, and autoimmune diseases and in organ transplant patients on immunosuppressive therapy. In a review of 41 fungal thyroiditis cases published between 1970 and 2005, Goldani et al. found that *Aspergillus* species (spp.) were the most commonly reported cause of fungal thyroid infection. Thyroid involvement by *Aspergillus* spp. was found at autopsy as part of disseminated aspergillosis in 13 (62%) of 21 patients, most of whom lacked clinical manifestations and laboratory evidence of thyroid dysfunction. After *Aspergillus* spp., *Candida* spp. were the second most common cause; other fungal etiologies reported include *Cryptococcus neoformans, Coccidioides immitis, Histoplasma capsulatum*, and *Pseudallescheria boydii*.

Pneumocystis jirovecii (then called *Pneumocystis carinii*), now classified as a fungus, was not included in the review by Goldani et al.; however, *P. jirovecii* has been found to be a cause of thyroid infections, almost exclusively in patients with AIDS. Yu et al. identified *P. jirovecii* as the causative agent in 16 of 19 cases of fungal thyroiditis in their literature review.

Mycobacterium tuberculosis as well as atypical mycobacteria have been described as causes of thyroid infection. Thyroidal tuberculosis occurs in the setting of miliary or disseminated disease. Disseminated *Mycobacterium avium-intracellulare* infection in patients with AIDS has resulted in thyroidal infection. In their literature review, Yu et al. found that mycobacterial organisms were isolated in 12 of 130 (9%) cases of culture-positive AST. Unlike patients with pyogenic bacterial AST, those with mycobacterial thyroiditis are typically symptomatic for months and are much less likely to experience pain, tenderness, and fever.

Involvement of the thyroid gland by parasites is extremely rare and typically occurs in the setting of disseminated disease. In the United States, only nine cases of echinococcal (tapeworm) thyroiditis have been reported. These patients had chronic symptoms (1.5–35 years in duration), were generally diagnosed as having goiters, and were discovered to have thyroidal echinococcosis at the time of surgery. *Strongyloides stercoralis*, which is endemic in the southeastern United States and tropical climates, has been reported as a cause of thyroid infection only in the setting of disseminated disease in immunocompromised patients.

Although several viruses (including influenza, Epstein–Barr, adenovirus) have been associated with subacute thyroiditis, viral infection causing AST has never been definitively proved. In postmortem studies of patients with AIDS, cytomegalovirus (CMV) inclusions have been found in thyroid tissue in association with disseminated CMV infection. However, symptomatic thyroiditis due to CMV has not been reported in these patients.

Clinical manifestations

The symptoms and signs of AST may be indistinguishable from those of a variety of both infectious and noninfectious inflammatory conditions of the anterior neck. Most patients with AST present with fever, pain, and a tender, firm swelling in the anterior aspect of the neck that moves on swallowing and develops over days to a few weeks. In this clinical scenario, the differential diagnosis includes such entities as subacute thyroiditis, Graves' disease (toxic diffuse goiter), thyroid cancer, hemorrhage into the thyroid, cervical lymphadenitis, and cellulitis (Box 5.2).

Other typical signs and symptoms of AST include dysphagia, dysphonia (both of which have been attributed to compression of local structures, including the recurrent laryngeal nerve), and concurrent pharyngitis. On examination the thyroid is tender, with warmth and erythema of the overlying skin and, in the case of abscess formation, fluctuance. Suppurative areas may include one lobe, both lobes, or only the isthmus of the gland. Because a firm nodule may progress to become fluctuant over the course of 1 to 3 days, repeated physical examinations are advisable.

Children with AST present similarly; however, there are a few noteworthy differences. The left lobe of the thyroid gland

is more frequently involved in pediatric cases because pyriform fossa fistulas are predominantly observed on the left. Neonates and infants are more likely than adults to present with stridor and respiratory distress from tracheal compression by an enlarged thyroid gland.

Suppurative thyroiditis that occurs as part of a disseminated infectious process differs from locally spread bacterial thyroiditis in several important ways. First, suppurative thyroiditis due to a systemic infection often occurs in the absence of any clinical manifestations of thyroiditis. Second, the etiologic organisms are typically opportunistic pathogens such as fungi, *P. jirovecii*, and mycobacteria, which tend to present with a chronic, insidious course. Finally, in contrast to bacterial thyroiditis, preexisting thyroid disease is not a significant risk factor for suppurative thyroiditis that occurs as part of a disseminated infection; rather, patients who are immunocompromised are at particular risk for the latter type of infectious thyroiditis.

FIGURE 5.3 CT scan of neck with contrast showing an abscess of the left lobe of the thyroid gland (*arrow*).

From Jacobs A, David-Alexandre CG, Gradon JD. Thyroid abscess due to *Acinetobacter calcoaceticus*: Case report and review of the causes of and current management strategies for thyroid abscesses. *South Med J*. 2003;96:300–307.

Diagnosis

Leukocytosis and an elevated erythrocyte sedimentation rate and C-reactive protein level are nonspecific but are commonly seen in AST. Although thyroid function test results are within normal limits in the majority of patients with AST, destruction of glandular tissue with release of preformed thyroid hormone into the circulation can lead to transient thyrotoxicosis. Hypothyroidism has also been reported. Although most patients with bacterial AST are euthyroid, Yu et al. found that those with fungal infections were often hypothyroid (63%) and that half of patients with mycobacterial infections were hyperthyroid.

Imaging studies help to differentiate AST from other causes of anterior neck pain and fever (Box 5.2). Plain neck radiography may reveal tracheal deviation or soft-tissue gas formation indicative of infection with anaerobic gas-forming organisms, such as *Clostridium* spp. CT, ultrasonography (US), and MRI often reveal unilobular thyroidal swelling and are extremely useful in the identification of parathyroidal abscesses and spread of infection to contiguous structures (Figure 5.3). For acutely ill patients with suspected AST, the preferred initial imaging modality is CT, which provides a comprehensive view of the neck and upper mediastinum and can thus be used to identify potential extrathyroidal involvement.

In a review of imaging studies performed on 60 patients with AST, Masuoka and colleagues found that, during the acute stage of AST, both CT and US may show nonspecific inflammation in and around the affected thyroid lobe, which may lead to an erroneous diagnosis of subacute thyroiditis. US may be very helpful in leading to the correct diagnosis, as specific US findings differ between AST and subacute thyroiditis; for example, in cases of AST, hypoechoic lesions are typically unifocal, and the hypoechoic lesions seen in subacute thyroiditis are usually multiple and often bilateral.

The most useful test in AST is FNA, which will frequently be diagnostic. FNA is especially helpful when there is no associated bacteremia or fungemia and when the patient's tenderness is limited to a localized area. Specimens for cytology, Gram stain, and aerobic and anaerobic cultures should be obtained. In the appropriate clinical setting, mycobacterial and fungal cultures as well as special stains for *P. jirovecii* and acid-fast bacilli should also be performed.

BOX 5.2

Causes of painful anterior neck mass

Thyroid-related

- Hashimoto's thyroiditis (chronic lymphocytic thyroiditis)
- Graves' disease (toxic diffuse goiter)
- Thyroid cancer, with or without hemorrhage
- Hemorrhage into the thyroid secondary to trauma
- Radiation damage to thyroid
- Acute suppurative thyroiditis

Nonthyroid-related

- Cervical lymphadenitis due to infection or malignancy
- Cellulitis
- Infections of thyroglossal duct remnant, branchial cleft cyst, or cystic hygroma

Modified from Shah and Baum, 2000.

Management

Antimicrobial treatment must be targeted at the underlying etiology of AST. In cases of bacterial AST high-dose parenteral antibiotics should be started promptly because early treatment may prevent complications such as bacteremia and abscess formation. Given the

great variety of bacterial species that can cause AST, broad-spectrum antibiotics should be administered while cultures are pending.

In adults, empiric antibiotics should be selected to include coverage for MRSA and *Streptococcus pyogenes* as well as penicillin-resistant gram aerobic gram-negative bacilli and anaerobes. Several options exist for appropriate initial antibiotic regimens: cefepime or ceftazidime along with clindamycin; a β-lactam/β-lactamase inhibitor with vancomycin; or a carbapenem with vancomycin. In the cases of patients for whom it may be preferable to avoid Vancomycin, alternative agents such as linezolid or daptomycin may be used for MRSA coverage.

In pediatric or recurrent cases of AST, it is particularly important to cover oral anaerobes, which are commonly involved in these infections. Empiric antibiotic therapy for children with AST should also provide adequate coverage for *S. aureus* and *S. pyogenes*.

If clinical examination or radiographic findings are consistent with an abscess or gas formation, surgical drainage is indicated. If an infection persists despite antibiotic treatment (e.g., continued leukocytosis and fever, progressive local inflammation) or involves extensive necrosis, lobectomy may be required.

Patients with AST should be evaluated for the presence of predisposing conditions. Any preexisting thyroid pathology that is discovered, such as a goiter or adenoma, should be treated. Because a pyriform sinus fistula is the most common route of infection in bacterial AST, most patients with their first episode and all patients with recurrent episodes should undergo a barium swallow, CT scan, or MRI of the neck to exclude the presence of a communicating fistula. Because the tract may be obscured by inflammatory material during an acute phase of infection, imaging studies may not reveal a fistula until after the completion of antibiotic therapy. Surgical excision or cauterization treatment of such fistulas is necessary to prevent recurrent infections.

With appropriate treatment the prognosis of AST is excellent, and the vast majority of patients recover completely. Rarely, however, episodes of AST are followed by hypothyroidism, which is almost always transient; vocal cord paralysis; and recurrent infection. As a result of severe, diffuse inflammation and necrosis of the gland, some patients may develop transient or prolonged hypothyroidism requiring L-thyroxine replacement therapy. Management of AST also includes diagnosing and treating any preexisting thyroid pathology, such as a goiter or adenoma, which may have served as a predisposing condition.

Suppurative thyroiditis due to pathogens other than bacteria generally occurs in the setting of a disseminated infection, most commonly in immunocompromised hosts. In such cases, systemic therapy for the underlying disease (e.g., fungal infection, mycobacterial infection) usually results in treatment of the thyroiditis.

Conclusion

AST is a rare disease, but one that carries considerable morbidity unless promptly treated. Imaging techniques are very useful in demonstrating a focus of infection in the thyroid. This infection can occur as a result of systemic infection, in which case hematogenous or lymphatic spread settles in the thyroid. It can also be a result of direct spread from a surface wound or through local invasion from infected congenital anomalies of the neck. In view of the multiplicity and variability of the potential pathogens and their antimicrobial sensitivities, every attempt should be made to identify the offending pathogen. In the case of systemic infections (e.g., bacteremias, fungemias, and disseminated tuberculosis), cultures of blood and other infected sites may be sufficient to establish the etiology. When AST is the single site of infection, prompt FNA should be performed to identify the organism and dictate appropriate therapy.

Otitis

Stephen I. Pelton

Introduction

The clinical burden from acute (AOM) and chronic suppurative otitis media (CSOM) and their associated morbidities is substantial, especially in children. In industrialized countries, AOM remains the most frequent reason for pediatric office visits and recurrent otitis media (ROM); persistent middle ear fluid and associated hearing loss reduces quality of life. In developing nations, infectious complications of AOM include suppurative intracranial infection and CSOM with severe hearing loss.

The prescription of antimicrobials increases bacterial resistance, so the role of antimicrobials in AOM has been re-evaluated, using an evidence-based approach.

ROM and CSOM usually begin in the first year of life, due to *Streptococcus pneumoniae*, nontypeable *Haemophilus influenzae* (NTHi), or *Morexalla catarrhalis*. Studies of children undergoing tympanostomy report biofilms on middle ear mucosa and positive PCR assays for otopathogens despite negative cultures. Although pneumococcal conjugate vaccine (PCV7) reduced office visits for AOM by ~15%, a multidrug-resistant nonvaccine serotype, 19A, emerged as a prevalent cause of AOM and mastoiditis. Asecond-generation conjugate vaccine (PCV13) that included pneumococcal polysaccharide 19A (as well as 1, 3, 5, 6A, and 7F) was introduced in 2010, and observational studies report a decline in AOM due to serotype 19A in young children. In children at risk for CSOM, the impact of PCV 7 has been more modest. Although disease due to the seven serotypes in PCV declined, disease due to nonvaccine serotypes increased.

Diagnosis

Current American Academy of Pediatrics (AAP) guidelines recommend diagnosing AOM in children who present with moderate to severe bulging of the tympanic membrane or new onset of otorrhea not due to otitis externa (Figure 6.1). Children with mild bulging of the tympanic membrane and recent (less than 48 hours) onset of ear pain (holding, tugging, rubbing of the ear in a nonverbal child) or intense erythema of the tympanic membrane should also be diagnosed with AOM. Older children with AOM usually describe rapid onset of ear pain. However, in young children, otalgia is suggested by tugging/rubbing/ holding of the ear, excessive crying, fever, or changes in the child's sleep or behavior pattern. The combination of a "cloudy," bulging tympanic membrane with impaired mobility was the best predictor of AOM. A tympanic membrane that was hemorrhagic, strongly red, or moderately red also correlated with the presence of AOM, but a tympanic membrane that was only "slightly red" was not helpful diagnostically.

Clinical symptoms and signs do not differentiate specific otopathogens. The one clinical finding that is consistently associated with a specific pathogen is conjunctivitis with NTHi.

Microbiology of aom in the era of universal immunization with pneumococcal conjugate vaccine

The pathogenesis of AOM reflects that nasopharyngeal otopathogens ascend the Eustachian tube into the middle ear. Therefore, although the etiology of individual episodes can only be established by sampling the middle ear (tympanocentesis), the spectrum of otopathogens colonizing the nasopharynx will define the microbiology of AOM.

The introduction of PCV7 reduced invasive pneumococcal disease due to the seven vaccine serotypes (4, 6B, 9V, 14, 18C, 19F, and 23F), decreased episodes of vaccine serotypes pneumococcal otitis media as well as overall clinical episodes and tympanostomy tube insertion, and impacted substantially on pneumococcal serotype distribution in the nasopharynx. In clinical trials of PCV7 (FinOM) a 34% overall reduction in pneumococcal otitis was reported; the reduction in vaccine serotype AOM was greater but an increase in episodes due to nonvaccine serotypes of *S. pneumoniae* was observed, providing initial evidence that "replacement" disease (that due to nonvaccine serotypes or alternative otopathogens) was significant. Initially replacement of disease due to vaccine serotype with nonvaccine serotype reduced episodes of AOM due to penicillin-nonsusceptible pneumococci. This was a result of the clustering of resistance among a limited number of pneumococcal serotypes, primarily the vaccine serotypes.

Subsequently nonvaccine serotypes, dominated by serotypes 19A and 6A, emerged. Specifically, serotype 19A became the most commonly recovered pneumococcal serotype in studies of nasopharyngeal colonization and in invasive pneumococcal disease and was a frequent cause of treatment failure in children with acute AOM. In 2010 a 13-valent pneumococcal conjugate vaccine was introduced (serotypes 1, 3, 5, 6A, 7F, and 19A), in part due to the burden of pneumococcal disease due to multidrug-resistant 19A. A decline in both nasopharyngeal colonization and invasive pneumococcal disease with serotype 19A has been observed; however, specific data on AOM is limited. Dagan has reported a decline in AOM due to the PCV13 unique serotypes in observational studies of children undergoing tympanocentesis as part of clinical management in Israel.

Knowledge of the current distribution of pathogens in children with AOM and the prevalence of penicillin-nonsusceptible *S. pneumoniae* or β-lactamase production among NTHi is limited. Studies of nasopharyngeal isolates in the postPCV13 ear demonstrate high prevalence of penicillin-nonsusceptible isolates of *S. pneumoniae* and β-lactamase production among isolates of NTHi; however, strains highly resistant to penicillin and/or ceftriaxone appear to be decreasing. Reports of isolates of NTHi with altered penicillin-binding proteins and increased minimal inhibitory concentrations for amoxicillin–clavulanate have appeared; however, such strains remain uncommon in the United States.

Treatment

Pain is a common symptom in AOM. Antibiotic therapy, even when effective, does not appear to provide symptomatic relief over the first 24 hours. Analgesics are effective for pain relief and should be prescribed regardless of whether initial management included antibiotics. Ibuprofen or acetaminophen is effective, and topical agents such as Auralgan may offer symptomatic relief. *For children with severe pain, myringotomy is an effective method to attain relief.* The treatment of otalgia is reviewed in Table 6.1.

The role of antibiotics in the treatment of AOM continues to undergo re-evalution. Multiple questions must be addressed to formulate a strategy for treatment of AOM.

Do children treated with antimicrobial therapy improve more quickly than those assigned to analgesia alone?

Antimicrobial therapy for AOM has reduced suppurative complications dramatically, specifically mastoiditis, over the past five decades. Similarly, in special populations such as Native Americans and Eskimo children, the prevalence of CSOM has declined in association with both the introduction of antimicrobial therapy and the improvement in public health and socioeconomic conditions. Today, AOM resolves in the majority of children without complications with or without antimicrobial therapy.

The observation that 20% to 30% of episodes are culture negative and that a proportion of children with acute bacterial otitis spontaneously clear the pathogen (approximately 15% of those with pneumococcal disease, 40% of those due to NTHi, and up to 75% of those with AOM due to *M. catarrhalis*) led some experts to suggest that symptomatic therapy should be the initial approach. Historically, Engelhard and associates reported greater than 70% failure in children with AOM who received myringotomy alone and Kaleida and colleagues observed a 2-fold higher failure rate among children with temperature greater than 103°F treated with myringotomy plus

TABLE 6.1 **TREATMENT OF OTALGIA**

Modality	Comments
Acetaminophen, ibuprofen	• Effective analgesia for mild to moderate pain • Readily available • Mainstay of pain management for AOM
Home remedies: (no controlled studies that directly address effectiveness) Distraction External application of heat or cold Oil	• May have limited effectiveness
Topical agents: Benzocaline (Auralgan®, Americaine Otic®) Naturopathic agents (Otikon Otic Solution®)	• Additional, but brief, benefit over acetaminophen in patients >5 years of age • Comparable to amethocaine/ phenazone drops (Anaesthetic®) in patients >6 years of age
Homeopathic agents	• No controlled studies that directly address pain
Narcotic analgesia with codeine or analogs	• Effective for moderate or severe pain • Requires prescription • Risk of respiratory depression • Altered mental status • Gastrointestinal upset and constipation
Tympanostomy/myringotomy (EBOM 227–240)	• Requires skill and entails potential risk

placebo compared with antibiotics (23.5% vs. 11.5%). They also observed an approximately 2-fold greater failure rate in children with nonsevere episodes who were treated with placebo compared with those who received amoxicillin (7.7% vs. 3.9%). However, studies by Little and coworkers challenged the impact of antimicrobial therapy on AOM symptoms. Their studies compared the outcome of AOM in children initially treated with amoxicillin with those given a prescription to be filled only if symptoms persisted for 72 hours. The authors concluded that immediate antibiotic prescription provided symptomatic benefit mainly after the first 24 hours, when symptoms were already resolving. For children who are not very unwell systemically, a wait and see approach was feasible and acceptable to parents and should substantially reduce the use of antibiotics for acute otitis media. However, both the enrollment criteria and the accuracy of diagnosis in their study were criticized. McCormick and colleagues evaluated "watchful waiting" as a strategy for children with nonsevere AOM. Increased treatment failures and persistent symptoms were observed, especially in those younger than 2 years old assigned to delayed antibiotic treatment. Although delayed resolution was observed in the cohort assigned to watchful waiting, parent satisfaction was not different among the early treatment and the initial observation groups. Increased rates of mild adverse events as well as increases in the prevalence of nonsusceptible *S. pneumoniae* in the nasopharynx were observed in the early treatment group.

Two recent randomized trials of initial antimicrobial therapy vs. placebo for infants and toddlers concluded that treatment reduced the time to resolution of symptoms and the overall symptom burden. Treatment failure with "rescue" antibiotic treatment and signs of persistent acute infection on otoscopic examination were more prevalent in the placebo group (Table 6.2). Table 6.3 summarizes the potential benefits and harms of initial antimicrobial therapy for AOM and provides the current recommendation from the American Academy of Pediatrics.

Does persistence of bacterial infection within the middle ear correlate with persistence of clinical signs or symptoms?

The outcome measure selected is critical for determining the impact of antimicrobial treatment on the course of AOM. If

TABLE 6.2 **COMPARISON OF OUTCOMES BETWEEN INITIAL TREATMENT WITH AMOXICILLIN–CLAVULANATE AND PLACEBO IN CHILDREN WITH ACUTE OTITIS MEDIA**

Outcome	Amoxicillin–clavulanate	Placebo (n = 158)	Difference (95% CI)
Treatment failure	30 (18.6%)	71 (44.9%)	−26.3 (−36.5 to −16.1)
No improvement by day 3	12 (7.5%)	22 (13.9%)	−6.5 (−13.2 to 0.3)
Worsening of condition	15 (9.3%)	32 (20.3%)	−10.9 (−18.7 to −3.2)
Tympanic membrane perforation	1 (0.6%)	5 (3.2%)	−2.5 (5.5 to 0.4)
"Rescue" treatment	11 (6.8%)	53 (33.5%)	−26.7 (−35.5 to −17.9)
Use of antipyretics/analgesic	133 (84.2%)	134 (85.9%)	−1.7 (−9.6 to 6.2)%

TABLE 6.3 **AAP RECOMMENDATIONS FOR ANTIMICROBIAL TREATMENT OF AOM ADAPTED FROM LIEBERTHAL AS. THE DIAGNOSIS AND MANAGEMENT OF ACUTE OTITIS MEDIA. *PEDIATRICS* 2013;131;E964**

Condition	Potential for benefit	Potential for harm	Denouement
Severe symptoms	Increased likelihood of more rapid resolution of symptoms. Increased likelihood of resolution of AOM	Adverse events attributable to antibiotics, such as diarrhea, diaper dermatitis, and allergic reactions. Overuse of antibiotics leads to increased bacterial resistance. Cost of antibiotics	Preponderance of benefit over harm
Nonsevere bilateral AOM in young children	Increased likelihood of more rapid resolution of symptoms. Increased likelihood of resolution of AOM	Adverse events attributable to antibiotics, such as diarrhea, diaper dermatitis, and allergic reactions. Overuse of antibiotics leads to increased bacterial resistance. Cost of antibiotics	Preponderance of benefit over harm
Nonsevere unilateral AOM in young children	Moderately increased likelihood of more rapid resolution of symptoms with initial antibiotics. Moderately increased likelihood of resolution of AOM with initial antibiotics	Adverse events attributable to antibiotics, such as diarrhea, diaper dermatitis, and allergic reactions. Overuse of antibiotics leads to increased bacterial resistance. Cost of antibiotics	Observation becomes an alternative as the benefits and harms approach balance
Nonsevere AOM in older children	Slightly increased likelihood of more rapid resolution of symptoms; slightly increased likelihood of resolution of AOM	Adverse events attributable to antibiotics, such as diarrhea, rashes, and allergic reactions. Overuse of antibiotics leads to increased bacterial resistance.	Observation is an option as the benefits and harms approach balance

outcome parameters such as resolution of signs and symptoms by day 7 to 10 or persistence of middle ear fluid at day 14 or 28 are selected, no differences between antimicrobial treatment and watchful waiting strategies can be consistently established. Effective antimicrobial therapy sterilizes the middle ear, resulting in a more rapid resolution of clinical signs (bulging and erythema) and symptoms (fever, earache, irritability). Therefore, evaluating outcomes within the first 3 to 5 days is necessary to demonstrate improved outcomes in antibiotic-treated cohorts as well as between antibiotic regimens.

Both Dagan and Carlin observed greater improvement in signs and symptoms in children with bacterial AOM when the middle ear fluid was sterilized by days 4–6 compared to children who had persistent middle ear infection. Figure 6.2 details the changes in clinical symptom score in children with effective antimicrobial therapy and sterilization of the middle ear compared to those with ineffective antimicrobial therapy and persistence of middle ear infection. The results also demonstrate that many children with persistent middle ear bacterial infection have decreased symptoms at days 4–6 compared to initial presentation.

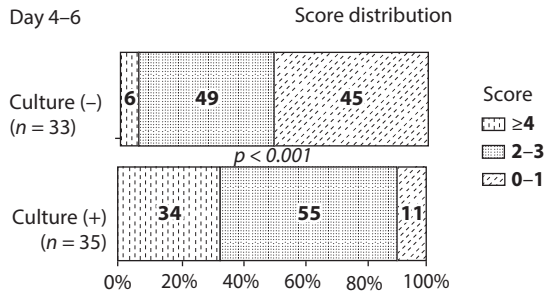

FIGURE 6.2 Symptoms score in children with acute otitis media (AOM).

Is the risk of recurrence greater in children who are not initially treated with antimicrobial therapy?

Patients with clinical improvement or cure on days 4–6 but culture-positive middle ear fluid were shown to have an increased rate of recurrent AOM compared to those with culture-negative middle ear fluid and clinical improvement or cure (Figure 6.3). Molecular analysis of the otopathogens isolated at recurrence and those identified on days 4–6 found concordance in 66% of patients. These observations emphasize the benefit of bacteriologic eradication in AOM.

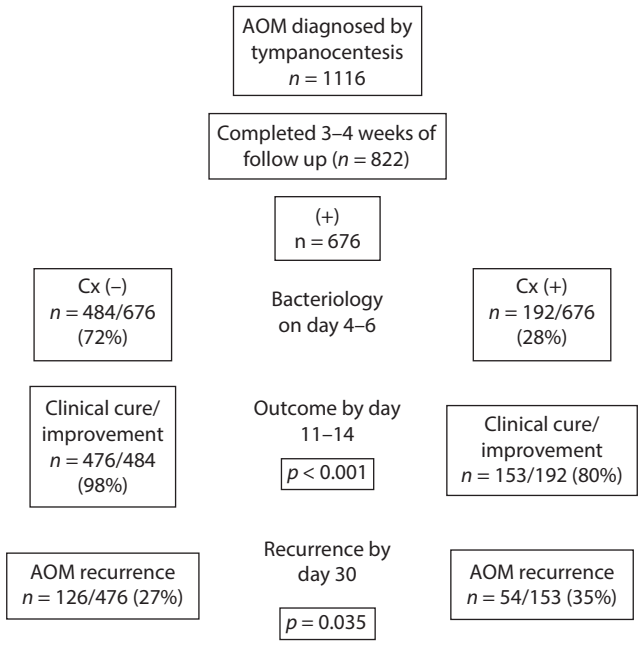

FIGURE 6.3 Association between eradication of middle ear pathogens during treatment and improvement in clinical symptoms. Cx, culture.

Does amoxicillin remain the initial drug of choice when the decision to use antimicrobial therapy has been made?

The selection of antimicrobial therapy should be based on knowledge of the microbiology of AOM, pharmacodynamic principles, and clinical trials using both clinical and microbiologic outcomes. Eighteen antibiotics are currently approved by the US Food and Drug Administration (FDA) for treatment of AOM; however, the emergence of otopathogens with reduced susceptibility to β-lactam antibiotics (SP and NTHi) has limited the efficacy of some antimicrobials. In the majority of cases of AOM, the specific pathogen is unknown, and presumptive therapy is based on the potential pathogens and their in vitro susceptibility. The proportion of isolates of NTHi-producing β-lactamase has slowly risen to nearly 50% over a 25-year period. A very limited number of β-lactamase-producing, amoxicillin-clavulanate-resistant isolates have also been reported in the United States. The recent emergence of nonvaccine serotypes of pneumococci with reduced susceptibility to β-lactam agents as well as macrolides and trimethoprim–sulfamethoxazole must also be considered in selection of antimicrobial therapy. Because there are no clinical differences between cases with resistant and susceptible pathogens, epidemiologic risk features must be assessed and tympanocentesis employed when a specific microbiologic etiology is needed.

Children with infrequent episodes of OM, without recent antimicrobial therapy, without conjunctivitis, older than 2 years, or not in day care are at low risk for drug-resistant *Streptococcus pneumoniae* (DRSP) or β-lactamase-producing NTHi. For these children the AAP guidelines recommend amoxicillin (Table 6.4).

Children with recent antimicrobial therapy or conjunctivitis are at higher risk for disease due to nonsusceptible *S. pneumoniae* or β-lactamase-producing NTHi. In these children only oral high-dose amoxicillin and intramuscular ceftriaxone achieve middle ear concentrations high enough to exceed the minimal inhibitory concentration (MIC) of all *S. pneumoniae* that are intermediately sensitive to penicillin and of many, but not all, highly resistant strains as well as strains of NTHi that do not produce β-lactamases. Cefuroxime axetil, cefprozil, and cefpodoxime represent alternatives to high-dose amoxicillin; however, each achieves sufficient middle ear concentration to be effective against only approximately 50% of *S. pneumoniae* isolates that are intermediately susceptible to penicillin. Also, cefprozil has limited activity against NTHi. Macrolides are very effective when fully susceptible isolates of *S. pneumoniae* are present. Because amoxicillin clavulanate resists destruction by β-lactamase, it effectively eradicates middle ear infection caused by NTHi. Although the AAP guidelines recommend the consideration of amoxicillin clavulanate as initial therapy only for children with severe disease, the increasing prevalence of AOM due to NTHi warrants consideration for broader use of amoxicillin clavulanate as first-line therapy in selected children.

Initial therapy for children with type I allergy to penicillin (urticaria, laryngeal spasm, wheezing, or anaphylaxis) is limited. Alternatives to β-lactams are limited because of substantial resistance among otopathogens. Macrolides, including azithromycin and clarithromycin, are active against most pneumococcal isolates; however, up to 40% of *S. pneumoniae* have MIC that are beyond the breakpoints for these agents. Resistance to trimethoprim sulfamethoxazole among *S. pneumoniae* and NTHi also is frequent. In the current era, β-lactamase-producing NTHi has emerged as the most common pathogen in children failing initial therapy with amoxicillin (Figure 6.4). The current distribution of pneumococcal serotypes found in the nasopharynx and reported from middle ear cultures includes isolates with reduced susceptibility to β-lactam antibiotics and macrolides (Table 6.5); however, the prevalence of MDR and specifically penicillin-resistant (MIC > 2.0 μg/mL) isolates has declined. For these children, a three-dose regimen of ceftriaxone (50 mg/ kg/day) has demonstrated efficacy (Table 6.6). Anecdotal data support the efficacy for clindamycin and linezolid against nonsusceptible SP; however, neither is active against *Haemophilus influenza*. High-dose amoxicillin in combination with cefixime or ceftibuten and standard-dose amoxicillin in combination with amoxicillin-clavulanate are also appropriate. Clinical studies of quinolones (specifically gatifloxacin and levofloxacin) demonstrate rapid sterilization and clinical resolution of middle ear infection due to both *S. pneumoniae* and NTHi. Currently, quinolones are not licensed for use in children for the treatment of AOM.

Prevention of recurrent acute otitis media

Middle ear disease has been identified as the most common reason for ambulatory healthcare visits, and persistent middle ear fluid with conductive hearing loss is frequent.

TABLE 6.4 **AAP/AAFP RECOMMENDED ANTIBACTERIAL AGENTS**

Temperature ≥ 39°C and/or severe earache	At diagnosis for patients being initially treated with antibacterial agents or clinically defined treatment failure at 48–72 hours after initial management with observation	
	Recommended	**Alternative for penicillin allergy**
No	Amoxicillin 80–90 mg/Kg/day	Non-type I: Cefdinir Cefuroxime Cefpodoxime Type I: Azithromycin Clarithromycin
Yes	Amoxicillin-clavulanate 90/6.4 mg/Kg/day	Ceftriaxone 1 or 3 days

AAP/AAFP Clinical Practice Guideline: Diagnosis and Management of Acute Otitis Media 2013.

Prevention of recurrent AOM can be achieved by preventing nasopharyngeal colonization with otopathogens, preventing viral respiratory infection, or providing specific antibacterial immunity. Insertion of tympanostomy tubes does not reduce the frequency of acute episodes substantially; however, the presence of such tubes shortens the duration of middle ear effusion and restores the conductive hearing loss frequently associated with such effusions. Antimicrobial prophylaxis lowers the frequency of colonization with respiratory otopathogens and decreases the number of acute episodes. Mandel and colleagues found a decrease in acute episodes from 1.04 per child per year in the placebo group to 0.28 in a group receiving prophylactic amoxicillin. The reduction in acute episodes was accompanied by a reduction in persistent MEF. The greatest benefit occurs in otitis-prone children who have multiple episodes per year and in whom recurrences continue despite increasing age; however, chemoprophylaxis offers short-term benefits only. Most otitisprone children continue to have recurrent episodes once prophylaxis is discontinued, until their immune systems and Eustachian tube function have matured.

The pathogenesis of AOM involves coinfection with respiratory viruses in more than 85% of episodes. Immunization with influenza vaccine reduces febrile AOM episodes as well as insertions of tympanostomy tubes during a winter season. Annual immunization is recommended for children with risk factors for ROM, such as attendance at out-of-home child care, family history of recurrent AOM, or early onset of disease. Seven-valent pneumococcal conjugate vaccines (PCVCRM and PCVOMP), administered at 2, 4, and 6 months with a booster at 12 to 15 months of either 7-valent PCV or 23-valent pneumococcal polysaccharide vaccine have been demonstrated to reduce AOM due to vaccine serotypes of *S. pneumoniae* by approximately 60%, and all episodes of pneumococcal otitis media by one-third. However, the overall reduction in clinical episodes of AOM was more modest (6% to 10%). A critical concern in the studies was the small increase in episodes of AOM due to nonvaccine serotypes and NTHi. Postlicensure studies have confirmed an increase in the proportion of AOM due to nonvaccine serotypes of SP. Follow-up of the original clinical trials of PCV7 in both the Northern California Kaiser Permanente cohort and the FinOM cohort identified significant reductions in tympanostomy tube insertions in the children immunized in infancy with PCV7. Studies of PCV7 in children with frequent recurrences of otitis media or those at risk for CSOM have failed to demonstrate a significant reduction in recurrent episodes. Veenhoven observed that disease due to vaccine serotypes of *S. pneumoniae* was only a small proportion of overall episodes in children with a history of ROM. Leach and colleagues found a nonsignificant reduction in episodes of chronic suppuration in the first year of life in Aboriginal children immunized with PCV7.

In 2010, PCV13 was introduced as a second-generation pneumococcal conjugate vaccine to broaden coverage against serotypes more commonly causing disease outside of North America (serotypes 1, 3, and 5) as well as replacement serotypes, specifically 19A, 7F, and 6A. Early observational data have demonstrated a further decline in overall pneumococcal AOM episodes including those due to serotype 19A.

Complications of acute otitis media

Perforation of the tympanic membrane is the most common complication of AOM and occurs most frequently in younger children. Certain ethnic groups, such as Alaskan Eskimos and Native Americans, have a higher rate of spontaneous perforation. Differentiation between AOM with perforation and acute otitis externa can be difficult. In general, the history of increasing pain with relief when otorrhea occurs is found with AOM, whereas increasing pain without relief in the face of otorrhea is seen with otitis externa. The microbiology of AOM in children with acute perforation reports a greater proportion of episodes due to group A streptococcus (GAS) and *Staphylococcus aureus*. However, *S. pneumoniae*, NTHi, and *M. catarrhalis* remain predominant. The natural history of AOM with perforation is usually complete resolution with healing of the tympanic membrane. A small proportion of patients can have persistent dry perforation or experience CSOM (otorrhea persisting for more than 6 to 12 weeks). *Streptococcus pneumoniae* and NTHi are the most common pathogens in infants and toddlers whereas *S. aureus* and *Pseudomonas aeruginosa* are frequent pathogens in older children and during the summer months. An increasing proportion of the *S. aureus* isolates, even those acquired in the community, are resistant to methicillin. Topical otic suspensions, either ofloxacin or ciprofloxacin, is the preferred therapy for uncomplicated episodes of acute otorrhea through a tympanostomy tube. Both of the quinolones are active against pseudomonas as well as the respiratory otopathogens. Amoxicillin is generally effective for acute otorrhea through a tympanostomy tube when disease is due to respiratoy pathogens, and results in rapid clearing of bacterial pathogens and a resolution of otorrhea. When methicillin-resistant *S. aureus* (MRSA) is the pathogen, fluoroquinolone and sulfacetamide ototopical medications were found to be effective. Adjunctive therapy with oral antibiotics, bactrim and clindamycin respectively, did not improve resolution rates. Topical vancomycin (25 mg/mL) drops or the use of trimethoprim–sulfamethoxazole orally in combination with gentamicin otic has also been reported as successful. Caution with both of these regimens is necessary as safety has not been established.

Facial palsy as a complication of AOM has become less prominent with the routine use of antibiotic therapy. Facial weakness and earache are the predominant symptoms. Management with antimicrobial agents and myringotomy (with or without tube insertion) is usually sufficient to achieve complete resolution.

An unusual complication, inflammatory cast of the tympanic membrane causing hearing loss, may occur after AOM with perforation. Patients present with unilateral persistent hearing loss. The diagnosis is suspected by comparison of the affected and unaffected tympanic membranes. On the affected side, a thin, hard cast is observed. Removal results in improvement in hearing.

The incidence of mastoiditis has decreased dramatically with the routine use of antimicrobial therapy. However, it remains the most common suppurative complication of AOM. Although the potential for re-emergence of mastoiditis when antimicrobial agents are withheld for AOM has been a concern, there are few convincing data to suggest an increase in incidence. The management of acute mastoiditis depends on disease classification. *Acute mastoiditis with periostitis* results from an obstruction of the connection between the middle ear and mastoid space (aditus ad antrum). Postauricular erythema, tenderness, and edema are the clinical manifestations. AOM is often but not universally present. *S. pneumoniae*, GAS, and NTHi are most common but *Pseudomonas aeruginosa* was found in 29% and *Staphylococcus epidermidis* in 31% of cases in one large series. *Pseudomonas* and *Staphylococcus* should be suspected when a history of otorrhea precedes development of acute mastoiditis.

Labyrinthitis develops when AOM spreads (through the round window) into the cochlear space. The process may be suppurative or serous (due to toxins). The onset of labyrinthitis is often sudden, with vertigo and hearing loss being characteristic. Acute surgical intervention (myringotomy with tube insertion) with antimicrobial therapy is the treatment of choice. Additional rare complications of AOM are brain abscess, lateral sinus thrombosis, and otic hydrocephaly.

Gradenigo's syndrome is a rarely seen complication of AOM where infection spreads to the apex of the petrous temporal bone. A triad of symptoms consisting of unilateral periorbital pain due to trigeminal nerve involvement, diplopia due to sixth nerve palsy, and persistent otorrhea is present. This classical triad has become very uncommon in the antibiotic era.

Otitis externa

Acute otitis externa (AOE) is primarily a pediatric disease occurring most frequently in children 6 to 12 years of age. The disease results from a disruption of integrity of the ear canal and the normal self-cleaning process of epithelial migration toward the external os. Swimming, local trauma, accumulation of debris from dermatologic conditions, or the wearing of hearing aids are predisposing factors. The early manifestations are itching, pain, and erythema of the canal but the disease can progress with severe swelling and obstruction of the external canal or extension to the bony external canal or even the base of the skull in the elderly or in patients with comorbidity (see discussion ofmalignant external otitis in Chapter 148, *Pseudomonas*, *Stenotrophomonas*, and *Burkholderia*).

Early in the course, minimal, odorless secretions and erythema of the external canal in association with mild pain and pruritus are present. As the disease progresses, erythema increases and edema of the canal becomes manifest. Seropurulent secretions may be present and acute pain is elicited by movement of the auricle or direct pressure on the tragus. Severe disease is noted by edema of the canal wall obstructing the lumen, intense pain, and extension to cervical adenitis or auricular cellulitis.

The diagnosis of AOE requires rapid onset of symptoms over several days with evidence of inflammation of the external ear canal manifest by otalgia, itching, tenderness of the tragus or pinna, and/ or diffuse erythema. Systemic manifestations such as cervical adenitis or cellulitis of the pinna may be present. Distinguishing AOE from AOM is critical as the therapy is markedly different. Identification of complications that may be manifest by facial paralysis, vertigo, or meningeal signs or cranial nerve palsy or the presence of granulation tissue at the junction of the boney and cartilaginous portions of the canal is critical. A furuncle may be observed in the external canal. Often referred to as localized otitis externa, this represents an infected hair follicle in the outer third of the external canal. History is helpful in discriminating AOE from AOM. Often the pain in AOE is progressive whereas in AOM the pain will usually abruptly improve when perforation occurs. The tympanic membrane in both AOM and AOE is frequently erythematous but in AOE pneumatic otoscopy reveals normal motility. Otomycosis may manifest as thick otorrhea, white debris with hyphae in the canal (*Candida*), or a white plug with dark debris (*Aspergillus niger*).

Topical therapy is the initial choice for diffuse, uncomplicated AOE as there is no need for systemic antimicrobials unless there are comorbid conditions that are associated with disease complications, there is progression to cellulitis of the pinna or adenitis, or topical therapy is contraindicated. AOE is primarily a bacterial disease with *Pseudomonas aeruginosa* the dominant pathogen followed by *S. aureus*. Fungal infection is uncommon except in those who have failed initial topical therapy. Mild disease can be treated with 2% acetic acid with or without a steroid. Compliance may be poor as acetic acid is irritating and frequently causes stinging when administered topically. Topical antimicrobial preparations containing an aminoglycoside, polymyxin B, or a quinolone with or without a steroid are effective but should only be used when the tympanic membrane is intact. These topicals achieve local tissue concentrations 1000-fold that of systemic administration. No significant difference in clinical outcome has been established for antiseptic vs. antimicrobial preparations, for quinolone vs. nonquinolone formulations, or for steroid-antimicrobial preparations compared with antimicrobials alone. However, when a perforation of the tympanic membrane is suspected, a tympanostomy tube is in place, or the tympanic membrane has not visualized, only quinolone formulations are approved for use. Critical for topical therapy to be successful is the delivery. Self-administration is difficult and often unsuccessful. Ototopical formulations should be administered with the patient lying on his/ her side. The canal should be filled and, if necessary, the pinna pulled forward and back to assist filling. Some clinicians use aural lavage for removal of debris either initially or, if necessary, repeatedly. Pain may limit the ability to perform aural lavage or suction. If edema is present, a wick of either compressed cellulose or ribbon gauze will enable complete delivery of the ototopical agent. Once the edema resolves, the wick may be removed and therapy continued to complete 7 to 10 days. Adverse events with topical therapy are not common; however, sensitization especially to those formulations that contain neomycin can occur. If infection has spread beyond the ear canal, or in patients at risk of rapid progression, or if signs and symptoms fail to improve, systemic antimicrobial therapy should be added based on the results of susceptibility testing of external ear canal culture.

Fungal disease, most commonly *Candida* or *Aspergillus*, is most often found in patients failing initial topical therapy. Two approaches have been used successfully: ketoconozole cream can be applied to the external canal directly once with follow-up examination in 5 to 7 days and repeat application if needed or Cresylate otic is applied three times a day. Both treatments achieve greater than 80% cure rates. Most recently, community-acquired methicillin-resistant *S. aureus* (CaMRSA) has emerged as an increasing cause of AOE. Treatments used successfully in the treatment of MRSA otitis externa were aural toilet and fusidic acid-betamethasone 0.5%. Most CaMRSA are susceptible to quinolones and it would be expected that ofloxacin or ciprofloxacin formulations should be effective.

Pain management is an integral part of treatment of AEO. Nonsteroidal anti-inflammatory agents and benzocaine otic have been used successfully to manage the discomfort of AOE.

In children with recurrent otitis externa, strategies such as the use of acidifying ear drops before or after swimming, the use of a hair dryer to dry the ear canal after swimming or bathing, or the use of ear plugs while swimming have all been used successfully. If recurrences persist, allergies or underlying inflammatory dermatologic conditions should be sought and the underlying causes addressed.

Necrotizing otitis externa is a complication of otitis externa in which infection extends from the external auditory canal to the base of the skull. It is seen commonly in elderly patients with diabetes and immunocompromised hosts, often in those with advanced HIV. The most common pathogen is *Pseudomonas aeruginosa*; however, a spectrum of pathogens including *Aspergillus* species, *S. aureus, Proteus mirabilis, Klebsiella oxytoca, Burkholderia cepacia*, and *Candida parapsilosis* has been reported. The presentation is characterized by severe pain; cranial nerve involvement is reported in a significant proportion. On physical exam granulation tissue is often visible at the bone–cartilage junction of the external auditory canal. Systemic fluoroquinolones, third-generation cephalosporins, and surgical debridement are the mainstay of treatment.

Sinusitis

Rachel Kominsky and Todd D. Otteson

Sinusitis is commonly diagnosed yet criteria for its diagnosis vary and a standard treatment protocol is nonexistent. The majority of patients with acute sinusitis improved without any therapy or with over-the-counter remedies. The temptation to treat an upper respiratory infection with antimicrobials should be avoided, especially in light of increasing bacterial resistance profiles. An understanding of the anatomy, pathophysiology with predisposing factors, and common microbiology helps drive therapeutic decision making.

Sinus anatomy

The paranasal sinuses consist of paired maxillary, ethmoid, sphenoid, and frontal sinuses. The maxillary and ethmoid sinuses are present at birth and fully pneumatize during childhood. The paired sphenoid and frontal sinuses appear in childhood and continue to pneumatize into early adulthood in some cases. The maxillary, anterior ethmoid, and frontal sinuses drain into the ostiomeatal complex (OMC). The OMC is a functional physiologic unit comprising the ethmoid infundibulum, middle meatus, and surrounding structures. The OMC and its patency are the keys to normal sinus drainage and the maintenance of physiologic mucociliary clearance.

Pathophysiology

Any anatomic anomaly, environmental exposure, or disease process, acute or chronic, that prevents the normal mucociliary clearance either by functional obstruction or by thickening of nasal secretions may result in pathogen overgrowth and sinusitis. Typically these processes or exposures affect not only the paranasal sinus mucosa but also the intranasal mucosa, prompting use of the term "rhinosinusitis." Table 7.1 outlines causes of obstruction, thickened secretions, and dysfunction of mucosal cilia. Rarely, direct inoculation of bacteria from odontogenic infection or during swimming or diving may cause acute sinusitis as well.

The bacteriology of sinusitis has been well documented. The results have been consistent for decades, with the most common organisms isolated in acute sinusitis being *Streptococcus pneumoniae*, *Haemophilus influenza*, and *Moraxella catarrhalis*. Since the vaccination of children with pneumococcal vaccine became commonplace after its introduction in 2000, there has been a decline in the recovery rate of *S. pneumoniae* and a corresponding increase in *H. influenza*. Individual resistance to antibiotics has increased. The spectrum of organisms widens in chronic sinusitis to include anaerobic bacteria, *Staphylococcus aureus*, and gram-negative organisms, particularly *Pseudomonas aeruginosa*. Much research has been dedicated to the role of biofilm formation in the pathophysiology of chronic rhinosinusitis. A biofilm is a complex polysaccharide matrix synthesized by bacteria that is protective of bacterial colonies and renders them somewhat resistant to antibiotic therapy. *Pseudomonas aeruginosa* is a known biofilm former in patients with chronic

rhinosinusitis. Anaerobic isolates are more common when the etiology of the infection is thought to be odontogenic.

Diagnosis

Diagnosis of sinusitis is based on history and physical examination with radiographic support in certain cases. The physical examination consists of anterior rhinoscopy before and after topical decongestion. Any purulent drainage or edema in the area of the middle meatus should be documented as well as the general appearance of the nasal mucosa. Nasal endoscopy allows a more detailed examination of the nasal cavity. Palpation of the paranasal sinuses may elicit focal tenderness. Transillumination of the sinuses may be helpful in adults if the exam is normal or completely absent but is not reliable in children.

Distinguishing between bacterial sinusitis and viral upper respiratory infection may be difficult but is important in planning a treatment strategy. A set of standardized definitions for rhinosinusitis based on symptom profile and duration is well accepted. Symptoms are described as major or minor and include facial pain, nasal obstruction, nasal discharge/postnasal drip, hyposmia/anosmia, purulence on examination (major), headache, halitosis, dental pain, fatigue, cough, and ear pain/pressure (minor). Rhinosinusitis is acute when symptoms last 4 weeks or less, subacute when symptoms are present for 4 to 12 weeks, and chronic for symptoms present longer than 12 weeks. Recurrent acute rhinosinusitis occurs in patients with four or more episodes per year with disease-free intervals in between. An acute exacerbation of chronic sinusitis is defined as a sudden worsening of symptoms with return to baseline after treatment. If the onset of an acute sinusitis is severe, with fever of at least 39°C (102°F) and purulent nasal discharge for at least 3 to 4 consecutive days at the beginning of the illness, the consideration to starting treatment earlier than the usual 7 to 10 days of symptoms should be entertained.

Plain films add little to the diagnosis, especially if sinuses other than the maxillary sinuses are involved. If the clinical situation warrants it, the suspicion of sinusitis is confirmed by CT, which can demonstrate characteristic changes in the paranasal sinuses and especially the OMC. The best time to obtain a CT scan is at the end of a treatment course when the patient is not acutely ill. The CT scan is crucial if any surgical intervention is required. If there is concern for invasive fungal sinusitis in an immunocompromised patient, a CT and an MRI should both be obtained. Figure 7.1A shows the paired maxillary sinuses (M) with dependent fluid in the right maxillary sinus. Note also the right nasal septal deviation. Figure 7.1B shows the ethmoid sinuses (E) with some right anterior ethmoid opacification. Note also the proximity of the ethmoid sinuses to the orbit (O); the lamina papyracea is a layer of thin bone separating the structures. The sphenoid sinuses posteriorly are also present in this image. Figure 7.1C shows the frontal sinus (F).

Treatment

The treatment of acute sinusitis involves appropriate antibiotic therapy and should improve the patency of the sinus ostia. Topical decongestants such as oxymetazoline may alleviate nasal obstruction and decreased nasal mucosal edema but they can only be used for a short time. Systemic decongestants and mucolytics may assist with clearance of secretions. While treatment with these adjunctive therapies may provide some temporary symptomatic relief in some patients, there is no evidence supporting the use of antihistamines, decongestants, nasal steroids, mucolytics, or nasal irrigations for an acute sinusitis.

Ideal antimicrobial therapy eliminates the common bacteria that cause acute sinusitis with as narrow a spectrum as possible. Current antibiotic treatment recommendations for acute bacterial rhinosinusitis take into account emerging antimicrobial resistance patterns. In children, the first-line antibiotic therapy for acute sinusitis is amoxicillin-clavulanate dosed 90 mg/kg/d twice a day and is recommended for children from locations with high rates of penicillin-nonsusceptible *S. pneumoniae*, who were recently hospitalized, or who were treated with another antibiotic course in the past month. For penicillin-allergic patients, levofloxacin is an alternative to amoxicillin–clavulanate. Treatment failure after 72 hours may require directed cultures and treatment with a broader spectrum second-line agent.

Treatment of chronic sinusitis is aimed at alleviation of symptoms and diminishing sinus inflammation. Irrigation of the nasal cavity with normal saline as well as treatment with topical steroids, systemic antihistamines, or systemic decongestants may be attempted but data supporting them are inconclusive. Longer term antimicrobial therapy lasting 4 weeks with a second-line antibiotic may improve symptoms when shorter courses have failed.

If patients with either chronic sinusitis or recurrent acute sinusitis fail to respond to these medical measures, consultation with an otolaryngologist should be considered. Investigation into the etiology of the inflammation causing rhinosinusitis, including any anatomic or physiologic source, should be undertaken and surgical management, consisting of endoscopic sinus surgery, considered. The goal of surgical intervention is to restore sinus drainage while preserving as much paranasal sinus and nasal mucosa as possible. More recent innovations such as steroid-eluting stents decrease mucosal edema and secondary scarring. Another option for patients who fail maximal medical therapy is balloon sinus dilation or sinus ostial dilation, a procedure in which sinus outflow tracts are widened endoscopically without tissue removal. This is only

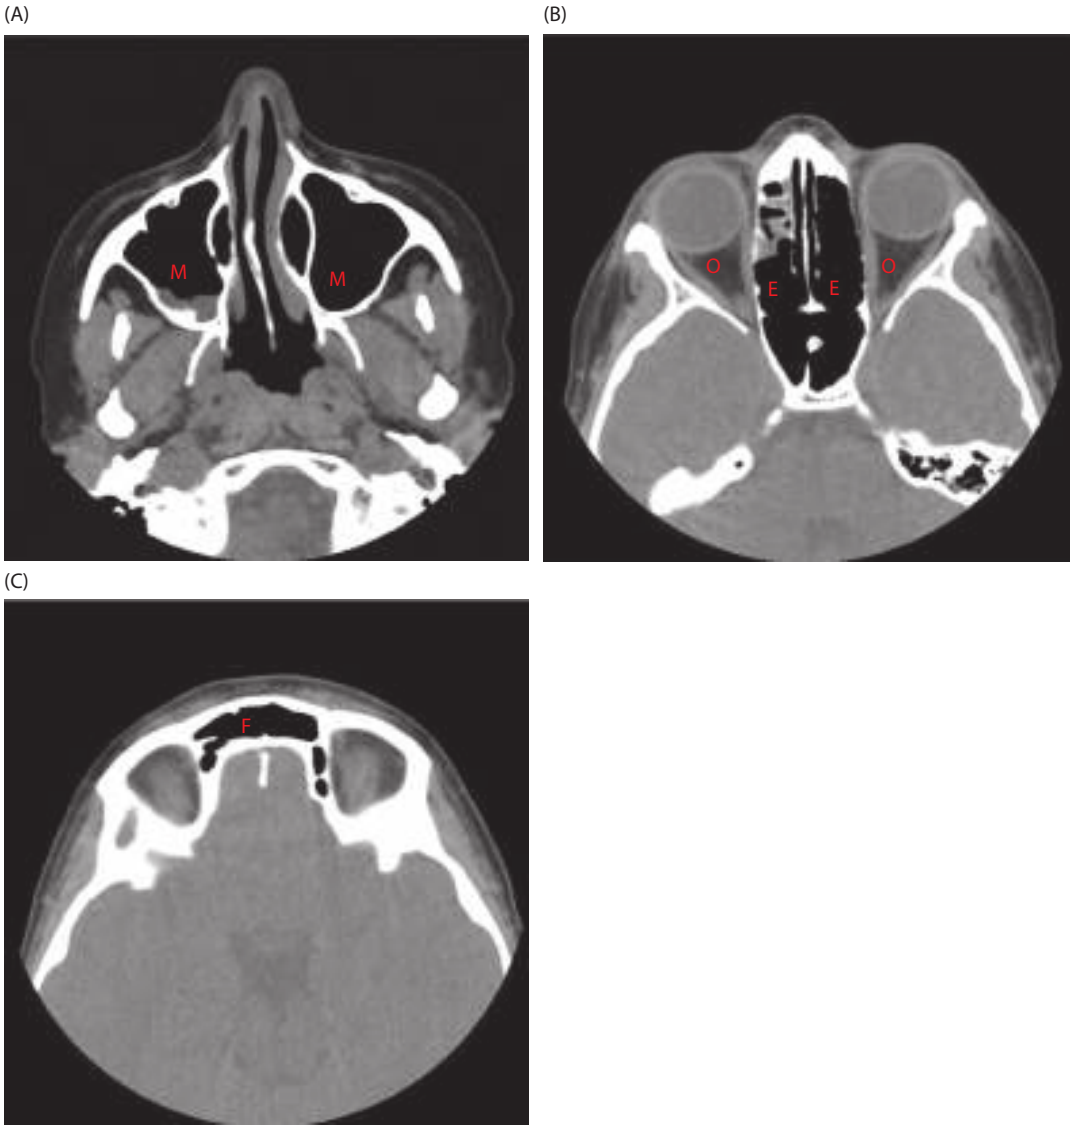

FIGURE 7.1 (A) Paired maxillary sinuses (M) with dependent fluid in the right maxillary sinus. (B) Ethmoid sinuses (E) with some right anterior ethmoid opacification and orbit (O). (C) Frontal sinus (F).

appropriate for certain patients with favorable anatomy as it generally is done as an in-office procedure with local anesthesia. Balloon dilation can be specifically useful in creating frontal sinus patency, both for patients who have not had prior surgery and patients who have had prior frontal sinusotomy with subsequent restenosis. Balloon sinus dilation has been shown to improve quality of life of patients with chronic rhinosinusitis when compared to medical therapy alone.

Complications

Complications of sinusitis are almost exclusively a phenomenon of acute sinusitis and involve spread of infection to adjacent structures. Acute ethmoid sinusitis may cause orbital infection that ranges from preseptal cellulitis to orbital cellulitis to subperiosteal orbital abscess to orbital abscess with possible secondary cavernous sinus thrombosis (Figure 7.2). Frontal sinus may precipitate meningitis or intracranial abscess. Therapy involves intravenous (IV) antibiotic therapy and possibly surgical drainage of the affected sinuses or sinuses.

Fungal sinusitis

Fungal sinusitis typically occurs in patients with immunodeficiency for any reason, including uncontrolled diabetes mellitus and patients taking immunosuppressive medications after transplant or hematologic malignancy. Treatment in these cases involves IV antifungal medications and aggressive surgical debridement. Reversal of the immunosuppression is advised if possible. Less aggressive form of

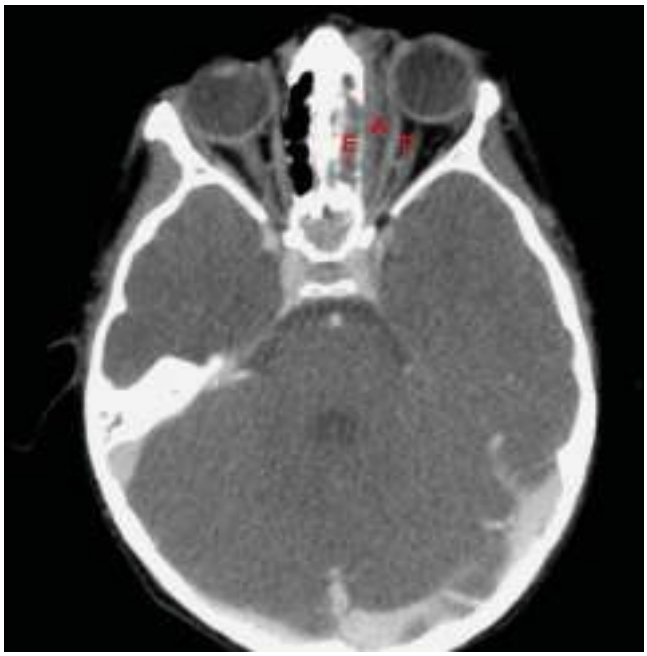

FIGURE 7.2 Axial CT demonstrating a left subperiosteal abscess (A). This image shows the opacification of the left ethmoid sinuses (E) and the abscess formation between the lamina papyracea and the periorbital contents (P).

chronic invasive fungal sinusitis has been described in immunocompetent patients.

Allergic fungal sinusitis is characterized by an allergic inflammation of the sinonasal mucosa from colonizing fungi. Tissue samples showed no mucosal invasion. The allergic response of the mucosa is immunoglobulin E (IgE)-mediated inflammation. The production of thick, tenuous, allergic mucin is pathognomonic. Histologic examination of the mucosa reveals chronic inflammation with eosinophils. The mucin demonstrates fungal hyphae characteristic of the species involved and Charcot–Leyden crystals. Treatment consists of conservative surgical debridement, either topical or systemic antifungal therapy, and topical or systemic steroids depending on the clinical situation. A fungal ball, or *mycetoma*, typically involves a single sinus, is not considered invasive, and may masquerade as chronic sinusitis. Treatment is surgical, addressing only the sinus(es) in question with no subsequent medical therapy required.

Dental infections

Jessica Moskovitz, Bridget Hathaway, Jennifer Rubin Grandis, and Jonas T. Johnson

Introduction

Odontogenic infections and their complications may be encountered by any clinician who treats diseases of the mouth and throat. Understanding the anatomy and pathophysiology related to odontogenic infection provides the basis for knowledge of how a patient will present and how the patient needs to be treated. The average hospital cost for patients treated with odontogenic infection is $9,417. Slightly more than 4 million people with dental-related complaints presented to the emergency departments in the United States between 2008 and 2010. Although treatment of early dental infections can be less expensive and performed on an outpatient basis, delayed treatment is considerably more expensive due to the serious complications that can occur. Knowledge of signs and symptoms that indicate need for inpatient treatment of is therefore important for clinicians. Additionally, prompt diagnosis and treatment at early stages may reduce the healthcare burden related to odontogenic disease. Increasing access to regular preventative dental care may reduce the morbidity and cost associated with these infections.

Anatomy

The treatment of odontogenic infections requires an understanding of maxillomandibular dentition and the fascial spaces of the face and neck (Figure 8.1).

Dentition

Although both maxillary and mandibular teeth can become infected, infections of mandibular dentition are more common. If untreated, odontogenic infections tend to erode through the thinnest, closest cortical plate. The thinner bone in the maxilla is on the labial-buccal side, the palatal cortex being thicker. In the mandible, the thinnest region is on the lingual aspect around the molars and the buccal aspect anteriorly.

Fascial spaces of the face and neck

Fascial spaces surrounding maxillary dentition

Anatomic spaces involved by maxillary infections include the canine and buccal spaces, with the orbit and cavernous sinus less commonly affected. The canine space is that region between the anterior surface of the maxilla and the levator labii superioris (Figure 8.2). Infection of this fascial space usually results from

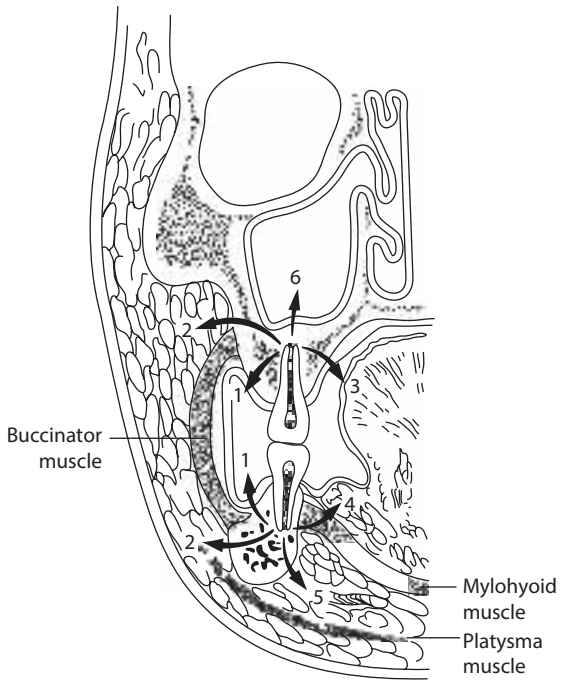

FIGURE 8.1 An odontogenic infection can express itself after erosion through jaw bone depending on the thickness of the overlying bone and the nature of the surrounding soft tissues. This illustration displays six possible locations: (1) vestibular abscess, (2) buccal space, (3) palatal abscess, (4) sublingual space, (5) submandibular space, and (6) maxillary sinus.

From Cummings CW, et al. *Otolaryngology: Head & neck surgery*, 4th ed. St. Louis: Mosby; 2005.

maxillary canine tooth infection. The buccal space is located between the buccinator muscle and the skin and superficial fascia. Infections of this space usually result from maxillary molar processes, with the premolars as the rare culprits.

Fascial spaces surrounding mandibular dentition

The primary mandibular spaces include the submental, sublingual, and submandibular fascial spaces. The submental space is that area between the anterior belly of the digastric muscle, the mylohyoid muscle, and the skin. Infection here usually results from the mandibular incisors (Figure 8.3). Medially, the sublingual and submandibular spaces are typically affected by the mandibular molars. Multiple fascial spaces can be infected simultaneously. For example, the sublingual space lies between the oral mucosa and the mylohyoid and communicates along the posterior boundary of the mylohyoid muscle with the submandibular space.

The secondary mandibular spaces include the pterygomandibular, masseteric, and temporal spaces. These fascial spaces become infected as the result of secondary spread from more anterior spaces, including the buccal, sublingual, and submandibular spaces. The pterygomandibular space lies between the medial aspect of the mandible and the medial pterygoid muscle. The masseteric space is the area between the lateral mandible and the masseter muscle, and the temporal space is superior and posterior to the pterygomandibular and masseteric spaces. Infection of these areas almost uniformly produces trismus as a result of masticatory muscle inflammation.

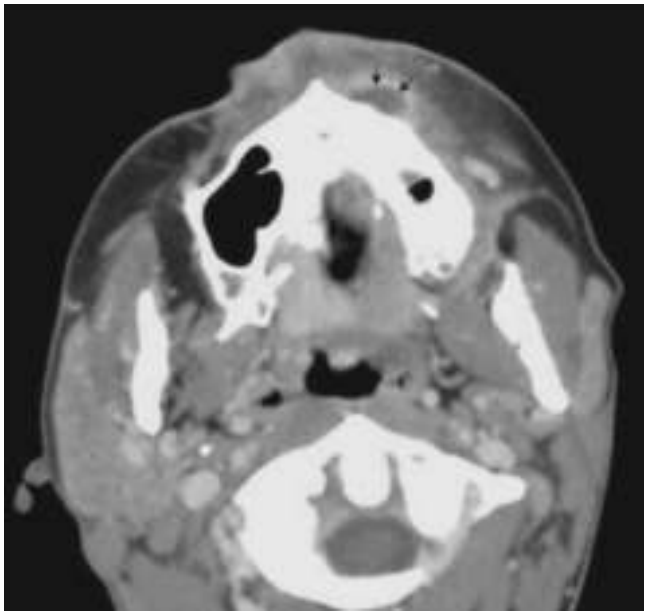

FIGURE 8.2 CT image demonstrating an abscess of the canine space (*black arrows*).

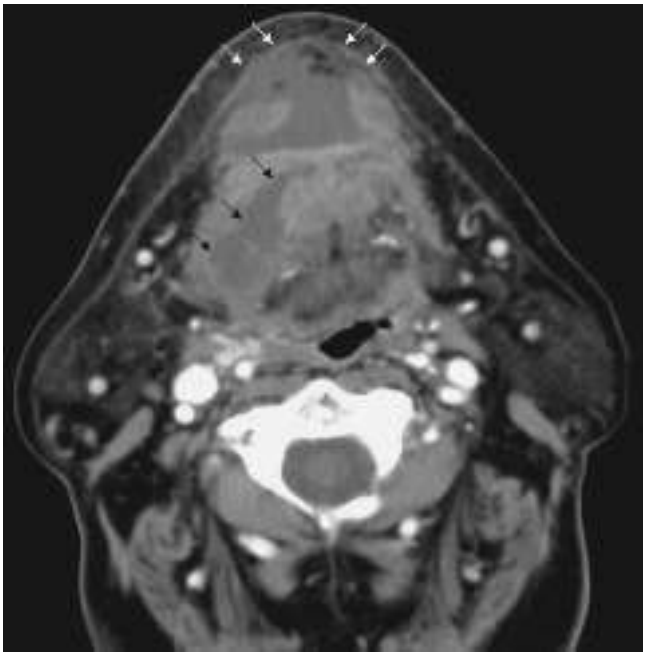

FIGURE 8.3 CT image demonstrating an abscess of the floor of mouth (*black arrows*) and submental space (*white arrows*).

Cervical fascial spaces

Odontogenic infection can extend beyond the mandibular spaces to the neck to involve the cervical fascial spaces. Infection in these spaces may progress to the deep neck spaces, which include the lateral pharyngeal (parapharyngeal) space, the retropharyngeal space, and the prevertebral space (see Chapter 10 for further detail of deep neck infections). Thirty percent of deep neck infections may result from odontogenic processes. Deep neck infections may spread distally into the mediastinum.

Pathophysiology

Most odontogenic infections are minor and self-limited, confined to the offending tooth and its apex. Under certain circumstances, however, the infectious process may break through the bony, muscular, fascial, and mucosal barriers and spread to contiguous spaces, resulting in soft-tissue infections.

Infections originate within the dental pulp, periodontal tissue, or pericoronal tissue from a carious tooth. This results in bacterial invasion and a local inflammatory response, which includes vasodilatation and edema leading to increased pressure, which exacerbates the pain and decreases the blood supply. This sequence of events exacerbates the periapical necrosis, with subsequent bacterial invasion into bone and erosion of the bony cortex into surrounding soft tissues. This nonvital pulp lacks blood supply and therefore proliferating bacteria in necrotic root canals makes it difficult for antibiotic penetration. Additionally, carious teeth result from bacterial biofilms which exhibit resistance to host defense. The spreading infection can result in a chronic sinus tract or, under the appropriate circumstances (e.g., perforation of the cortical bone above the muscular attachment), a fascial space collection.

Whether the infection is in the sublingual or submandibular space is determined by the relationship between the area of perforation and the mylohyoid attachment. Specifically, if the apex of the offending tooth is superior to that of the mylohyoid (e.g., premolars, first molar, and occasionally second molar), the sublingual space is affected; if the infection is inferior (e.g., third molar and occasionally second molar), the submandibular space is involved. Alternatively, infections involving the maxillary dentition may spread to involve the maxillary sinus and present as unilateral maxillary sinusitis. Orbital cellulitis or cavernous sinus thrombosis are unusual but serious manifestations of maxillary infection. Under such circumstances, the infection most likely spreads both by direct extension as well as hematogenously.

The microbiology of odontogenic infection reflects the normal endogenous oral flora. A large number of bacteria are contained in the mouth, particularly around the dental crevices. It has been estimated that 40% to 70% of all oral bacterial species have yet to be cultivated and phenotypically characterized. Infections that result from the spread of these organisms into surrounding soft tissue spaces are often polymicrobial and predominantly due to anaerobic bacteria.

The phyla *Firmicutes* (e.g., genera *Streptococcus*, *Dialister*, *Filifactor*, and *Pseudoramibacter*) and *Bacteroidetes* (e.g., genera *Porphyromonas*, *Prevotella*, and *Tannerella*) comprise more than 70% of the species found in dental abscesses. Other frequently identified species belong to the phyla *Fusobacteria* (e.g., genera *Fusobacterium* and *Leptotrichia*), *Actinobacteria* (e.g., genera *Actinomyces* and *Propionibacterium*), *Spirochaetes* (e.g., genus *Treponema*), *Synergistetes* (e.g., genus *Pyramidobacter*), and *Proteobacteria* (e.g., genera *Campylobacter* and *Eikenella*).

Patient evaluation and diagnostic considerations

History and physical exam

Patients with odontogenic infections commonly present with pain and swelling around the infected tooth. A sinus tract may develop with infection progression, and this is usually detected by the patient with drainage and decreased discomfort. Infectious spread into the surrounding soft tissues and fascial spaces often leads to systemic signs and symptoms such as fever, leukocytosis, and dehydration. As the infection spreads, local signs and symptoms may diminish thus obscuring the odontogenic origin of the fascial space infection. Initial evaluation should seek to determine the site and nature of the infectious process.

Signs and symptoms of fascial space involvement include swelling of the face and lateral neck, trismus, dysphagia, and airway compromise. To assess the airway for impending compromise, one should note tongue mobility, floor-of-mouth edema, uvular deviation, and lateral pharyngeal swelling.

Adjunctive testing

Imaging

Information regarding the causative dentition as well as the extent of infection may be gained through radiographic evaluation. A panoramic radiograph (Panorex) of the maxilla and mandible is useful to examine the bone morphology and presence of impacted teeth or caries. When there is clinical suspicion of infection extending to the soft tissues of the head and neck, CT or MRI is warranted.

CT with contrast is generally considered to be the first-line imaging modality given its lower cost, greater availability, and patient tolerance relative to MRI. However, in a prospective study of 47 patients, Muñoz et al. concluded that MRI was superior to CT in the initial evaluation of odontogenic infections in terms of anatomic discrimination, lesion conspicuity, and extension of the processes. MRI was also more precise in identifying the number of spaces involved. However, CT is more sensitive in detecting intralesional gas. It is yet unclear whether these advantages of MRI translate into improved patient outcomes to warrant its routine use in this setting.

Microbiology

It is often not difficult to obtain material for Gram stain and culture. One approach is needle aspiration. However, precautions should be taken to obtain the material in a sterile fashion, process it under anaerobic conditions, and make an effort to evaluate the Gram stain before starting antibiotics. Techniques for isolating and identifying anaerobic bacteria tend to be labor- and time-intensive. Molecular biology techniques including polymerase chain reaction (PCR) and pyrosequencing have enhanced our understanding of the microbiology of oral flora and odontogenic infections.

Therapeutic management

Medical

The general condition of the host (e.g., dehydration, predisposing conditions such as diabetes mellitus [DM] and immunocompromise) must be taken into consideration when devising a treatment plan. Appropriate control of blood sugar is essential. The administration of antibiotics is necessary under most circumstances and should be administered before surgical drainage or for associated cellulitis.

The choice of antimicrobial agent(s) sometimes must be made empirically and depends on the ability of the clinician to correctly predict the offending organism(s). Monotherapy is generally preferable because of reduced cost, fewer potential side effects, and greater ease of administration. Endogenous oral cavity flora most frequently leads to polymicrobial infections, and therefore antibiotics should cover both oral anaerobes and streptococci.

Penicillin G, once a first choice for odontogenic infection, is now rarely used because of the rising incidence of penicillin-resistant streptococci as well as the frequency of β-lactamase-producing *Bacteroides* species (estimated to be >30%). If one chooses a cephalosporin, it should be noted that the higher "generations" tend to sacrifice gram-positive aerobic activity for gram-negative efficacy. First-generation agents, such as cefazolin and cefoxitin, are likely more effective than other, broader spectrum drugs. Studies have shown good antibiotic susceptibility for treatment of odontogenic infections with amoxicillin, amoxicillin-clavulanate, linezolid, and clindamycin. A relatively high proportion of bacteria cultured were resistant to metronidazole, erythromycin, and azithromycin. Additionally, metronidazole is effective against oral anaerobes but not aerobic organisms and would require an additional antimicrobial. Amoxicillin or amoxicillin-clavulanate is an acceptable first-line agent for the treatment of early or mild odontogenic infections. Clindamycin is an effective alternative for penicillin-allergic patients.

Antibiotics should be administered parenterally for severe infections and in the perioperative period (e.g., 24–48 hours). Ampicillin-sulbactam is an appropriate first-line choice for parenteral therapy. Once the drainage catheters are removed and the patient is ready for discharge, the oral route of administration is adequate. Decisions regarding the duration of antimicrobial administration are made empirically, but a 2-week course usually is adequate. Macrolides should be used with caution in patients who are on other drugs that prolong the Q-T interval as this can result in a potentially lethal cardiac arrhythmia (torsades de pointes).

Surgical

Airway management

In all cases, special attention should be paid to the status of the airway. Ideally, a team of clinicians with expertise in difficult airway management is involved. In Ludwig's angina, urgent tracheotomy is usually required. Other, less rapidly progressing, maxillomandibular space infections can usually be managed with careful endotracheal intubation. Flexible fiberoptic intubation (transnasal or transoral) should be considered. If the airway compromise continues in the postoperative period, the patient should remain intubated or an elective tracheotomy should be performed.

Dental extraction

Removal of the infectious source without delay is imperative for treatment of odontogenic infections. The combination of a biofilm microenvironment in carious teeth and the lack of blood supply to necrotic pulp results in a requirement for mechanical eradication of the infectious source. This includes removal of the tooth, curettage of the socket, root canal treatment, or root scaling. Root canal treatment or root scaling may be used for restorable teeth. Dental extraction is recommended for nonrestorable teeth or restorable teeth in the setting of life-threatening infections.

The timing of dental extraction has historically been debated. The controversy has been settled for several decades as studies advocating for delayed extraction are either from the preantibiotic era or from lower level evidence studies (i.e., Level IV). Although post-antibiotic era studies were also lower level of evidence (Level III; retrospective case series), these studies noted that early extraction did not lead to central nervous system involvement or serious infection. The debate was settled with a randomized, controlled trial (Level 1b) that found severe infection was associated with delayed dental extraction. Watchful waiting with antibiotics alone is no longer considered acceptable. In patients with maxillofacial infections, extraction of the causative tooth correlates with shorter mean hospital stay compared to patients without removal of the offending tooth. Additionally, dental extraction resulted in faster resolution of biologic parameters such as axillary temperature, white blood cell count, and C reactive protein levels (Igomenakis 2015).

Incision and drainage

Evacuation of the purulent collection is the standard of care for odontogenic infections. Cellulitis may resolve with antibiotic therapy, however, the patient must be followed closely and surgery undertaken if abscess develops. Surgery may entail a minor procedure, such as drainage of a periapical abscess, or extensive debridements of adjacent fascial compartments in the case of necrotizing fasciitis.

The route of drainage should be evaluated on an individual basis. General principles to be followed include stabilization of the airway, protection of vital structures, adequate visualization at the time of drainage, copious irrigation of the abscess cavity with saline solution, and postoperative drainage of the wound. Canine and isolated sublingual space infections can usually be drained transorally. Buccal space infections can be drained transorally or extraorally with care taken to identify Stensen's duct and the buccal branch of the facial nerve. The submental space is best approached extraorally via an incision that parallels the inferior border of the mandibular symphysis. Buccal, submandibular, masseteric, pterygomandibular, and sublingual spaces can all be drained extraorally via a horizontal incision parallel to the inferior angle of the mandible.

Drainage catheters are generally used when a transcutaneous route is used and should be left in place until wound drainage has essentially ceased (≤10 mL in 24 hours). In our experience, the catheters do not serve as a route for infection (i.e., to draw bacteria inward).

Surgical emergencies

Necrotizing fasciitis

Necrotizing fasciitis is a life-threatening soft tissue infection that requires a high degree of suspicion given the lack of specific symptoms at early onset with rapid clinical deterioration. The reported hallmark for diagnosis is pain disproportionate to or in the absence of clinical exam findings. The majority of cases of necrotizing fasciitis are odontogenic in origin with a minority caused by pharyngeal etiologies or unknown/idiopathic causes. There is a propensity for development in those with immunocompromise including patients with DM, HIV, and chronic renal failure. Steroid therapy, alcoholism, intravenous (IV) drug abuse, and obesity are also risk factors. Initial physical exam signs may mimic cellulitis with tense, erythematous skin changes. Without treatment, overlying skin blisters and necrosis as well as skin anesthesia may develop. The presence of palpable subcutaneous air or air on radiographs is an indication of infection by gas-forming organisms and is pathognomic for necrotizing fasciitis. A 2018 meta analysis of 375 cases of noted that only about half (56.8%) of CT scans revealed subcutaneous air, and therefore its absence does not reliably exclude the diagnosis. Foul-smelling "dishwater pus" noted at time of surgical debridement is the most commonly cited definitive diagnostic criteria. Although the most common pathogen identified is strep, necrotizing fasciitis can also be due to polymicrobial infections.

Aggressive resuscitation and antimicrobial therapy are key to successful management; however, early surgical debridement is the single most important modality for determining patient outcome. Surgical debridement involves widely opening the neck and debriding necrotic tissue down to bleeding tissue. The wound should be packed open for observation and potential further debridement. Choice and frequency of dressing changes varies in the literature; however, several studies have shown that repeat debridement (ranging from 2.5 to 7 debridements) is usually required. Negative bacterial cultures have been reported, and surgical tissue cultures that yield the most positive results included tissue at the edge of abnormal appearing tissue. Histopathology in the early stages of disease may show dermal edema and superficial epithelial hyaline necrosis without inflammatory cells. As the disease progresses, vascular thrombosis and necrosis becomes apparent.

Early tracheostomy should be considered; however, in those with extensive involvement of the anterior and inferior part of the neck, caution should be exercised due to risk of infection tracking into the thorax. Descending cervical necrotizing mediastinitis has been reported to occur in almost one-third of patients, and the presence of mediastinal involvement should prompt consultation with a cardiothoracic surgeon. Adjunctive medical therapies that have demonstrated mortality reduction include hyperbaric oxygen therapy and IV immunoglobulin (in patients with group A strep infections).

BOX 8.1

Emergency considerations

Presence of subcutaneous air
Consider necrotizing fasciitis
Ludwig's angina—progressive severe soft-tissue edema
Consider tracheotomy

Ludwig's angina

When infection involves the primary mandibular spaces bilaterally it is known as Ludwig's angina. Patients may develop this widespread fascial space infection as a result of second or third molar infection or widespread periodontal disease. Cellulitis of the floor of mouth rapidly becomes a spreading, gangrenous process producing elevation and displacement of the tongue and brawny induration of the entire submandibular region. Airway compromise can occur precipitously (Box 8.1), hence appropriate precautions should be undertaken. Airway compromise is one of the leading causes of mortality associated with Ludwig's angina. Spontaneous sublingual hematoma, a pseudo-Ludwig's phenomenon, can occur as a complication of oral anticoagulation. Patients may have notable ecchymosis in the floor of mouth and/or anterior neck which can distinguish this scenario from infectious etiology on clinical exam. Patients should be managed with reversal of anticoagulation and securing the airway.

Conclusion

The successful treatment of odontogenic infections depends on a combination of accurate diagnosis and institution of appropriate therapy in a timely fashion. Adjunctive laboratory and radiographic tests may confirm the diagnosis and help plan the drainage procedure, but a thorough history and physical examination often

provides the clinician with sufficient information. Early recognition of potential surgical emergencies such as Ludwig's angina and necrotizing fasciitis can be life-saving.

Salivary and lacrimal gland infections

Alexandre E. Malek, Johny Fares, and Issam I. Raad

Introduction

Salivary gland infection or inflammation, also known as sialadenitis, occurs in different age groups ranging from neonates to elderly people. It constitutes the majority of non-neoplastic diseases that involve principally the major salivary glands, which comprise the paired parotid, submandibular, and, to a lesser extent, the sublingual glands. Infections can be related to a variety of organisms including mainly bacterial, viral, or mycobacterial. Acute bacterial parotitis and submandibular sialadenitis are the most frequently reported conditions. In acute bacterial suppurative parotitis, *Staphylococcus aureus* and oral aerobes and/or anaerobes are among the most encountered pathogens. Noninfectious causes can lead to salivary glands inflammation as well, including systemic inflammatory process and, recently, sialadenitis secondary to Nivolumab has been reported. Etiologic classification of sialadenitis is outlined in Box 9.1.

The salivary glands are exocrine organs responsible for saliva secretion, which provides several biologic properties and acts as a natural barrier for infection. Saliva contains many proteins like amylase, mucins, peroxidases, and lysozymes that comprehensively play a crucial role as antimicrobials. In addition, the saliva's flow inside the salivary ducts promotes debris removal and clearance of bacteria to avoid an ascending infection.

Risk factors for salivary glands infection

The cause of sialadenitis may be secondary to a variety of local or systemic factors affecting salivary output either by decreasing production or outflow. Decreased production can be related to dehydration conditions such as decreased oral intake, bowel rest, or water restriction. Medical conditions such as malnutrition, dementia, or renal failure may predispose patients to dehydration as well. Moreover, multiple medications can be associated with decreased saliva production and can contribute to oral dryness.

Additionally, local radiation or radioactive iodine therapy and autoimmune diseases such as sarcoidosis, Sjögren syndrome, primary biliary cirrhosis, and immunoglobulin (IgG4)-related disease are accompanied with decreased saliva production. Many conditions can lead to thicker saliva, such as cystic fibrosis. The disruption of outflow may be linked to either occupational or iatrogenic injuries of the salivary gland ducts or of the ductal orifice, such as trauma or dental procedures. Decreased outflow occurs secondary to ductal obstruction due to stricture, tumors, or sialolithiasis. Many other risk factors have been identified including poor oral hygiene/dental infection, systemic infection (HIV and mumps), immunosuppression, and mucositis. These risk factors are summarized in detail in Table 9.1.

BOX 9.1

Etiologic classification of sialadenitis

Acute bacterial sialadenitis

- Acute purulent parotitis
- Acute postoperative parotitis
- Acute bacterial submandibular sialadenitis

Chronic bacterial sialadenitis

- Chronic recurrent parotitis
- Chronic recurrent submandibular sialadenitis
- Chronic sclerosing sialadenitis of submandibular gland

Miscellaneous infectious causes of sialadenitis

- Actinomycosis
- Cat-scratch disease
- Tuberculosis
- Nontuberculous mycobacterium
- Parasitic

Viral sialadenitis

- Mumps
- Human immunodeficiency virus
- Cytomegalovirus infection
- Other viruses (coxsackievirus, Epstein–Barr virus, measles, echovirus, influenza A, parainfluenza, lymphocytic choriomeningitis, adenovirus, enterovirus, human herpesvirus 6, parvovirus B19, and hepatitis C)

Granulomatous sialadenitis

- Infectious causes (tuberculosis, syphilis, tularemia, toxoplasmosis, cat-scratch disease, blastomycosis, and coccidiomycosis)
- Noninfectious etiologies (sarcoidosis, Wegener's granulomatosis, Churg-Strauss granulomatosis, or Crohn's disease)

Acute bacterial sialadenitis

Suppurative or acute bacterial sialadenitis can occur when salivary stasis permits retrograde ascending transmission or seeding of the collecting ducts of the salivary glands by the oral flora bacteria. Abscess formation can in turn arise by extension of contiguous infection or hematogenous seeding to the lymph nodes either inside or around the glands, such as the parotid. While all glands can be involved, the parotid and submandibular glands are predominantly affected. A recent study by Watanabe et al. showed the incidence of acute suppurative sialadenitis is 2.9% among end-stage cancer patients, and the submandibular gland is the most common salivary gland affected.

Acute bacterial parotitis

Suppurative parotitis or pyogenic parotitis often occurs in the setting of debilitation, dehydration, or poor oral hygiene, especially among elderly postoperative patients. Historically, this entity was called "surgical mumps" because it has been attributed to postsurgical hypovolemia and fluid imbalance, particularly in abdominal surgery or intra-abdominal trauma, despite its arising in outpatients. Other risk factors are described in Table 9.1. Neonatal suppurative sialadenitis is uncommon and is usually related to prematurity, decreased saliva production secondary to prolonged orogastric or nasogastric feeds, dehydration, sialolith, and abnormalities of salivary duct. Transient bacteremia during birth is thought to contribute to the development of neonatal acute bacterial parotitis (ABP). Unlike in adults, neonatal ABP is more frequently bilateral.

The pathogenesis is largely related to ascending contamination of the Stensen's duct by the oral flora or through bacteremia seeding to intraparotid or periparotid lymph nodes.

The clinical manifestation is characterized by sudden onset of a firm, painful erythematous swelling over the parotid gland and in the preauricular area extending occasionally to the angle of the mandible. High fevers and chills are common, while further systemic

TABLE 9.1 **RISK FACTORS FOR SALIVARY GLANDS INFECTION**

Decrease saliva production

- Dehydration (neonates, elderly, recent surgery and anesthesia, bowel rest)
- Medications (anticholinergics, antidepressants, antipsychotics, antihistamines, diuretics, antihypertensives, chemotherapeutics agents, antispasmodics, antisialagogues)
- Malnutrition
- Dementia
- Renal or hepatic failure
- Local radiation
- Radioactive iodine therapy
- Autoimmune diseases (sarcoidosis, Sjögren's syndrome, primary biliary cirrhosis, and IgG4-related disease)

Decrease saliva outflow

- Cystic fibrosis
- Occupational injury (trauma)
- Iatrogenic injury (dental procedures)
- Ductal obstruction (strictures, tumors, or sialolithiasis

Other risk factors

- Poor oral hygiene
- Dental infection
- Systemic infection (human immunodeficiency, mumps, etc)
- Immunosuppression
- Mucositis

findings such as leukocytosis with left shift, elevated sedimentation rate, and increased serum amylase are frequent. Trismus and dysphagia are reported as well. Tenderness is noted in physical exams, and, in one-half of cases, purulence expressible at Stensen's duct may be observed.

The most common pathogens responsible for ABP are quite variable and usually polymicrobial. *Staphylococcus aureus* followed by anaerobes are by far the most commonly reported pathogens, with *S. aureus* being the most frequently isolated bacteria in the setting of nosocomial (hospitalized) and community-acquired infections. Group A Streptococcus, *Streptococcus viridans*, and strict anaerobes, such as *Fusobacterium* spp., *Prevotella*, *Porphyromonas* spp., and *Peptostreptococcus* spp., may also play a major role.

Brook et al. reported that 43% of patients were diagnosed with an anaerobic infection while 57% had a mixed aerobes-anaerobes etiology. Gram-negative organisms encompassing *Klebsiella* spp., *Pseudomonas, E. coli, Proteus* spp., *Eikenella*, and *Haemophilus influenza* are common in immunocompromised and critically ill patients. Rare causes of ABP include *Salmonella* spp., *Streptococcus pneumonia, Moraxella catarrhalis, Arachnia, Treponema pallidum*, cat scratch bacillus, *Actinomyces* spp., and *Mycobacterium tuberculosis.*

The diagnosis of suppurative parotitis is made mainly by a comprehensive medical history followed by a subsequent characteristic physical examination of the findings. Laboratory studies, such an elevated serum amylase in the absence of pancreatitis, support the diagnosis made. Furthermore, imaging data (when available) are very helpful in assessing for inflammation or duct obstruction by salivary stones and in ascertaining the presence of acute suppurative parotitis, abscess, or even a solid tumor. If purulent secretions are found, bacteriological studies (Gram stain and culture) are of paramount importance in narrowing the differential diagnosis and guiding the appropriate antimicrobial therapy. If abscess is present, ultrasound-guided needle aspiration is recommended, and specimens should be sent for aerobes, anaerobes, and fungi, as well as mycobacteria.

Ultrasound, CT, and magnetic resonance sialography are all options for imaging evaluation; however, ultrasound is a preferred first choice since it can localize the inflammation of the salivary gland and pinpoint the location of stones in the duct or gland parenchyma, along with its capacity to depict and differentiate between obstructive versus nonobstructive sialoadenitis. CT scan is a very sensitive tool for distinguishing parotitis from frank abscess. Magnetic resonance sialography is superior to conventional sialography as it can be used during acute infection without requiring an injection of contrast material.

The differential diagnosis of bacterial parotitis includes viral parotitis, collagen vascular and autoimmune diseases, alcoholism, and neoplasms. Causes of parotid gland enlargement are outlined in Box 9.2.

The management of suppurative parotitis is a multidisciplinary approach which entails improving hydration, reducing modifiable risk factors, and administering appropriate intravenous (IV) antibiotics. This approach should be carried out empirically based on expected microbiology including *S. aureus, H. influenza,* and anaerobes or guided by culture and susceptibility testing when available. Surgical intervention should be considered if abscess is present or no clinical response is seen after 48 hours of empirical therapy. Importantly, to ensure adequate antibacterial coverage and appropriate selection of the initial therapy, risk factor stratification should be implemented to assess whether the patient is a normal or an immunocompromised host while taking into consideration the circumstances of community-acquired or hospital-acquired infections.

BOX 9.2

Causes of salivary gland swelling

- Acute bacterial sialadenitis
- Viral sialadenitis
- Salivary gland stones
- Salivary gland tumors (benign or malignant)
- Chronic bacterial sialadenitis
- Radioactive iodine sialadenitis
- Sarcoidosis
- IgG4-related diseases
- Sjögren's syndrome
- Sialadenosis (malnutrition, anorexia nervosa, bulimia, beriberi, pellagra, diabetes, alcoholism)
- Reaction to intravenous contrast

In community-acquired sialoadenitis among immunocompetent hosts, the preferred initial antibiotic regimen suggested is ampicillin-sulbactam or cefuroxime plus metronidazole. An alternative antistaphylococcal regimen includes nafcillin or vancomycin or linezolid is recommended based on risk factors for methicillin-resistant *S. aureus* (MRSA), along with a regimen of either ceftriaxone or levofloxacin plus metronidazole or clindamycin. Knowing the risk factors for MRSA is an important step in choosing gram-positive antibiotic coverage. These factors consist of history of IV drug use, renal failure, hemodialysis, diabetes mellitus, prior stroke, decubitus ulcers, residence in a nursing home, and history of hospitalization within the last 12 months.

For immunocompromised patients or hospital-acquired infections the spectrum of initial antibiotic regimen should have additional activity against MRSA, *Enterobacteriaceae*, and *Pseudomonas*. This could take the form of a combination of vancomycin or linezolid and one of the following antibiotics: cefepime plus metronidazole or imipenem versus meropenem or piperacillin-tazobactam. The duration of therapy is tailored to the patient's risk factors and immune status, as well as the extension of the infection; generally, patients with uncomplicated infections should receive 10 to 14 days of therapy.

Adjuvant treatment incorporates optimal oral hygiene, nutritional support, warm compresses and massage, discontinuation of anticholinergic drugs that reduce salivary flow or increase the viscosity of the saliva, and usage of sialagogic agents such as lemon juice. Irradiation of the glands is no longer recommended.

Suppurative parotitis can potentially progress and spread to deep neck and head tissue leading to local or systemic complications such as osteomyelitis, respiratory obstruction, parapharyngeal space infection, and possible septic jugular thrombophlebitis, known as Lemierre's syndrome. Other described yet relatively rare complications are facial nerve palsy or fistula.

Acute bacterial submandibular sialadenitis

Acute bacterial submandibular sialadenitis (ABSS), unlike ABP, is most commonly associated with physical obstruction of Wharton's duct either by stones or strictures. Sialolithiasis occurs in 80% of cases secondary to the several reasons that predispose to stone formation. The anatomy of submandibular salivary glands, including the ductal system, is described as lying superior to the glands, having the length and thin wall of Wharton's duct and a passage of the duct within two acute bends through the muscles, as well as a narrow orifice opening (sphincteric mechanism); the glands retain alkaline and high-calcium salt contents in submandibular gland saliva. All these factors may contribute to calculus formation, obstruction, and subsequently infection.

Clinical manifestation is usually pain and swelling in the submandibular region which occur at mealtime, with frequent history of prior episodes. Cervical lymph nodes may be present. Of interest, ABSS is mainly a community-acquired infection and is less commonly associated with hospital-associated infection or dehydration in comparison to ABP. The majority of causative organisms are a mixture of oral flora comprising *S. aureus* and *Peptostreptococcus* spp. Treatment consists of antibiotic coverage similar to ABP, optimal hydration, and salivary ductal system decompression by sialolith removal via sialoendoscopy, sialolithotomy, or sialodochoplasty.

Chronic bacterial sialadenitis

Chronic bacterial sialadenitis or recurrent bacterial sialadenitis can affect the parotid or submandibular salivary glands, and it is defined as repeated episodes of ABS that are separated by periods of remission. Of interest, recent study described the presence of bacterial biofilm in the submandibular gland sections in patients with chronic sialadenitis and suggests its role in maintaining the chronicity of sialadenitis.

Chronic recurrent bacterial parotitis

This clinical entity often follows an episode of ABS, but it may be idiopathic or is sometimes associated with Sjögren syndrome, autoimmune disease, strictures, congenital ductal abnormalities, or following viral infection. It could also be manifested secondary to trauma or foreign bodies.

Two categories of chronic recurrent bacterial parotitis (CRBP) have been described; adult and juvenile forms. Chronic juvenile recurrent parotitis is a combination of a congenital ductal malformation and ascending seeding of bacteria from the oral mouth flora. It is characterized by male predilection with unilateral parotid enlargement. This form is closely related to *Streptococcus viridans* infection, while *S. aureus* is the major bacteria in adult form. Nevertheless, other species such as *Streptococcus pneumoniae*, mixed aerobic-anaerobic oral flora, and, to a lesser extent, opportunistic organisms have been described.

Clinical manifestation is characterized by unilateral or bilateral edema of the parotid gland that can vary in duration from few days to months separated by period of remission. During exacerbation episodes, constitutional symptoms might be present with increased white blood cell count and inflammatory markers such as elevated erythrocyte sedimentation rate (ESR). Sialography is the main diagnostic tool for making the diagnosis of chronic parotitis. In addition to plain radiographs, CT sialography may provide supplementary data. Histologically, parenchymal structures are replaced by fibrosis and fat. The initial treatment should be conservative; patients with chronic parotitis should be instructed to carefully massage the involved gland in a dorsoventral direction four to six times a day and to eat sour foods to stimulate parotic secretion. Systemic antibiotics and proper oral hygiene are helpful, and sialoendoscopy seems to be an ideal treatment especially by dilation of the ductal system. In spite of medical treatment, some recalcitrant cases advocate for surgical management via parotidectomy.

Chronic recurrent submandibular sialadenitis

Chronic recurrent submandibular sialadenitis (CRSS) is reported more commonly than CRBP, generally follows an acute episode of ABSS, and is usually associated with sialolithiasis. Sialography is an important test for confirming the diagnosis by demonstrating sialadenitis and showing poor gland emptying rates, which is considered a reliable sign of poor gland function.

Treatment consists of empiric antibiotics therapy, hydration, sialogogues, and sialolithotomy if indicated. Sialoadenectomy is recommended in recurrent episodes or in nonfunctional submandibular glands.

Chronic sclerosing sialadenitis

Chronic sclerosing sialadenitis of the submandibular gland (Kuttner's tumor [KT]) is a chronic inflammatory process that produces a firm (sometimes painful) swelling in the submandibular area that mimics malignancy and is difficult to distinguish from tumor. Chronic sclerosing sialadenitis is often diagnosed only after excision of the gland. Submandibular glands are most often involved, but implication of other major and minor salivary glands has been reported.

In 29% to 83% of cases, it is associated with sialolithiasis and is most commonly seen in the elderly. It is a benign disease and no additional treatment is warranted.

Acute viral sialadenitis

Viral diseases of the salivary glands are a frequent condition mainly affecting the parotid glands. Mumps, being the most common infection, is usually accompanied by a nonspecific systemic prodrome such as fever, malaise, headache, myalgias, and anorexia. However, many other non-mumps viruses have been described and may mimic mumps clinical presentation, including influenza and parainfluenza viruses (type 1 and 3), echovirus, Coxsackie viruses (A and B), Epstein–Barr virus, and lymphocytic choriomeningitis virus. HIV, cytomegalovirus (CMV), and adenoviruses have also been identified.

Mumps

Mumps virus belongs to the genus of paramyxovirus and is by far the most common viral infection of the salivary gland leading to viral parotitis. This disease is very contagious and is transmitted by aerosol droplets coming from the saliva and nasopharyngeal secretions of an infected individual. The incubation period lasts from 2 to 3 weeks, followed by 1 to 2 days of fever, chills, and headache, which in turn is succeeded by rapid and painful swelling of the parotid gland that could be unilateral or bilateral in nature. The submandibular glands may also become involved.

In 30% to 40% of the infected patients, no clinical symptoms are noticed. Mumps is predominantly a childhood disease, and in 85% of cases, it affects children under the age of 15 years. It is more frequent in boys than in girls. Young adults may also be affected and have a more aggressive clinical course. Mumps is often preceded by a viral infection in the oral cavity or the nose, leading to viremia and hematogenous infections of the salivary glands.

Infection can be complicated by orchitis, pancreatitis, meningoencephalitis, and neurosensorial hearing loss. Laboratory studies could reveal leukopenia with relative lymphocytosis, and an elevation of serum amylase is observed as well. Serologic diagnosis can be made using a complement-binding reaction or a fourfold increase in antibody titer, usually at the end of the second week. Apart from vaccination, no effective treatment for mumps is available.

Human immunodeficiency virus

HIV can affect head and neck systems in 5% to 10% of infected patients. The clinical manifestations include xerostomia that can mimic Sjögren syndrome, parotid gland enlargement, and lymphadenopathy. Parotid HIV is a very well described clinical entity which may present as a painless gland enlargement with or without lymphoepithelial cysts. Given that the parotid gland possesses intraglandular lymph nodes, these are prone for HIV involvement, leading to reactive lymphadenopathy and sometimes to CD8 lymphocytic infiltration of the gland parenchyma, which results in cyst formation. Another condition that can occur in HIV-positive patients is benign lymphoepithelial lesion (BLLs) of the parotid glands; however, BLLs can progress to lymphoma or carcinoma. These cysts can be evaluated by ultrasound-guided fine-needle aspiration that can confirm diagnosis if cystic fluid is positive for amylase. The management of these cystic lesions consists of observation, serial drainage, or sclerotherapy. Clinicians should maintain solid tumors in the differential diagnosis as well.

Cytomegalovirus

CMV sialadenitis is rare and usually presents as pain and swelling of the salivary gland. The diagnosis is usually based on an elevated complement fixation titer of antibodies to CMV, a positive CMV titer, and detection of CMV in the salivary gland. Other viruses that produce sialadenitis are coxsackievirus, infectious mononucleosis, measles, echovirus, influenza A, parainfluenza, HIV, lymphocytic choriomeningitis virus, adenovirus, human herpesvirus 6, parvovirus B19, and Epstein–Barr virus. Most of these viral infections have a self-limiting condition which produces lifelong immunity. Chronic hepatitis C virus (HCV) infection has been associated with mild lymphocytic sialadenitis.

Miscellaneous infectious causes of sialadenitis

Actinomycosis

Actinomyces are branching, gram-positive, microaerophilic, non–acid-fast bacteria that can affect the salivary glands in 10% of cervicofacial actinomycosis cases, with the parotid gland being most frequently involved. Human actinomycosis is primarily caused by *Actinomyces israelii*, and many other species have been described such as *A. odontolyticus*, *A. naeslundii*, *A. meyeri*, *A. viscosus*, *A. propionicus*, *A. pyogenes*, and *A. eriksonii*.

The hallmark of actinomycosis is the tendency to invade the salivary glands following a tissue injury or mucosal breach, and they can usually spread without respecting anatomical barriers, which can lead to multiple fistulous tracts. As a result, odontogenic infections or salivary gland trauma are common preexisting events. The infection can take three forms of clinical presentation, the first being acute suppurative infection. The second is chronic in nature, has indolent induration, and may be misdiagnosed as a neoplasm. The third form is subacute and is manifested by a slightly tender mass attached to the mandible. Diagnosis is usually made by culturing the organism from an appropriate specimen, ideally from biopsy culture to avoid contamination. Findings of sulfur granules in histologic examination are also pathognomonic of this condition. Treatment is the same as that utilized for cervicofacial actinomycosis, including prolonged courses of antibiotics (preferred high-dose penicillin for 4 to 6 months) which are adjusted according to susceptibility testing combined with surgical intervention if indicated.

Cat-scratch disease

Cat-scratch disease (CSD) is frequently reported as a major cause of regional lymphadenopathy among children and adolescents, and it can by contiguity evolve to the salivary glands and lead to sialadenitis, mostly of the parotids. It occurs about 2 weeks following

skin inoculation by the bacteria *Bartonella henselae*, which is a gram-negative bacterium considered to be the etiologic agent in most cases. A probable diagnosis is made based on typical clinical presentation, such as proximal lymphadenopathy to inoculation site arising after recent contact with cats and fleas. Laboratory testing, including serology and polymerase chain reaction (PCR), confirm the clinical impression. Previously, antibiotics therapy in localized CSD was controversial because it is considered a self-limited disease. However, the current trend and practice is to treat all patients with CSD, even those who are immunocompetent, in an effort to prevent systemic complications since the pathogen can disseminate to vital organs and to shorten the course of the disease. For localized infection, single-drug therapy is suggested (e.g., azithromycin). For disseminated disease, a combination therapy is preferred, including two of the following medications: rifampicin, azithromycin, doxycycline, Bactrim, or gentamicin.

Tuberculous sialadenitis

Tuberculous involvement of the salivary glands is exceedingly rare and primary tuberculous infection is very unusual. Salivary glands can be involved by the hematogenous route of *Mycobacterium tuberculosis* from a distant source, such as primary pulmonary tuberculosis, or through contiguous infection by ascending lymphatic spread from cervical lymph nodes to the intraglandular lymph nodes. Two types of tuberculous sialadenitis have been described: the circumscribed or nodular form, which is more common, and the diffuse or infiltrative involvement of gland parenchyma. The pathogenesis of the former is related to lymphatic spreading to intraglandular lymph nodes and usually leads to unilateral parotid swelling, whereas the latter is related to the hematogenous route of infection.

Tuberculous sialadenitis can manifest as an acute or a chronic form producing a tumor-like lesion. Disseminated tuberculosis secondary to pulmonary tuberculosis can affect mainly the submandibular and cervical lymph nodes chain, resulting in tuberculous cervical lymphadenitis, also known as *scrofula*. Diagnosis is ideally made by the QuantiFERON-TB TB Gold test, followed by fine-needle aspiration for acid-fast bacilli cultures. Management is similar to pulmonary tuberculosis treatment, and entails combination therapy including isoniazid, rifampicin, ethambutol, and pyrazinamide. The duration of therapy depends on clinical response but usually varies between 6 and 9 months.

Nontuberculous mycobacterium sialadenitis

Atypical mycobacteria can involve the salivary glands, mainly the parotid and submandibular. The infection occurs commonly in children, but adults can also be infected, especially those in the immunocompromised state. *Mycobacterium avium intracellulare* and *M. scrofulaceum* are the main reported causative organisms. The diagnosis relies principally on culture taken from excisional biopsy of the salivary glands or lymph node. Treatment is mainly medical management, keeping surgical intervention, excision, and drainage as an adjunctive tools for medical therapy.

Parasitic salivary gland infection

Parasitic sialadenitis is extremely rare. *Paragonimus* trematodes and *Filariasis* worms have been reported to involve the salivary glands, mainly in highly endemic countries (paragonimiasis in China; filariasis in Africa and Central America). The diagnosis is made by salivary gland biopsy and other supportive laboratory findings such as peripheral eosinophilia. *Filariasis* therapy consists of antiparasitic medications, including ivermectin, diethylcarbamazine, or albendazole, combined with surgical excision of the affected area; praziquantel is administered for paragonimiasis.

Granulomatous sialadenitis

Granulomatous sialadenitis is a rare condition that may be related to infectious or noninfectious causes, localized or systemic etiologies. This condition can arise secondary to reactive regional lymph nodes and can lead to salivary parenchymal involvement. It is reported that obstructive sialadenopathy secondary to calculi or other causes (e.g., tumor with rupture of ducts and leakage of ductal contents, particularly mucin) plays a crucial role in developing a granulomatous inflammation with multinuclear foreign-body giant cells. The parotid gland is commonly involved; condition presents as painless firm nodules with noncaseous granulomas on histologic examination. Different types of granulomatous diseases affect the salivary glands, such as tuberculosis, syphilis, tularemia, toxoplasmosis, cat-scratch disease, blastomycosis, and coccidiomycosis. Xanthogranulomatous sialadenitis of the parotid gland presenting as B-cell lymphoma has also been reported. Other noninfectious etiologies include sarcoidosis, Wegener's granulomatosis, Churg-Strauss granulomatosis, or Crohn's disease. Treatment is directed against the etiology responsible for this clinical entity.

Lacrimal system infection

The lacrimal apparatus incorporates the lacrimal gland and the nasolacrimal drainage system. The lacrimal gland is responsible for producing tears, and each gland is characterized by approximately 12 to 14 lacrimal ductules. Tears on the ocular surface are drained through superior and inferior canaliculi to form a common canaliculus before entering the lacrimal sac followed by the nasolacrimal duct. The canaliculi and the lacrimal sac are prone to infections and can lead to three different types of infections: canaliculitis, dacryocystitis, and dacryoadenitis.

Canaliculitis

Canaliculitis is a clinical entity characterized by inflammation of the upper and lower canaliculus and is frequently associated with lacrimal outflow obstruction. Infection affects mainly the lower eyelid rather than the upper eyelid, and women are more susceptible than

men, which can be possibly related to the female's higher rate of dry eyes with punctal plug or cosmetics usage. For the most part, primary canaliculitis is a unilateral disease and is idiopathic in nature. However, a few predisposing factors, such as diverticulum or outflow obstruction, are described. Canaliculus blockage enhances bacterial overgrowth.

This disorder can manifest clinically as epiphora or unilateral conjunctivitis with itchiness, burning sensation, redness, and mucopurulent discharge from the punctum, and it is also associated with excessive tears. The causes of canaliculitis range from bacteria to viruses and fungi. According to a Kaliki et al. study, *Staphylococcus* spp. is the most common organism, followed by *Streptococcus* spp. and *Actinomyces* spp., whereas in other reports *Actinomyces israelii* is the most common cause reported for canaliculitis. Other organisms less frequently reported include *Fusobacterium*, *Enterobacter cloacae*, *Lactococcus lactis*, *Eikenella corrodens*, *Nocardia*, *Candida albicans*, *Pityrosporum pachydermatis*, *Aspergillus*, and *Mycobacterium chelonae*. Viruses like herpes simplex, adenovirus, and varicella zoster can also be involved.

The diagnosis is usually made clinically, but dacryocystography and biomicroscopy might support the diagnosis of canaliculitis. Gram stain and culture on appropriate media of exudative secretions help in identifying the causative organism. Treatment approach consists of systemic and topical antibiotics and punctal dilatation with canalicular expression combined with canalicular antibiotic irrigation. Although conservative treatment provides improvement, it is associated with high recurrent rates of infection among 33% of patients. Therefore, punctoplasty with canalicular curettage is highly efficient, and canaliculotomy may be indicated specifically as a method to prevent recurrence. Antibiotic treatment is outlined in Table 9.2. Delay in diagnosis may lead to chronic conjunctivitis, corneal infection, or canalicular stenosis.

Dacryocystitis

Dacryocystitis is an infection of the lacrimal sac and nasolacrimal duct, which can present either as an acute process or as a chronic infection. It constitutes the most common infection of the lacrimal apparatus and usually arises from functional or anatomic nasolacrimal duct obstructions. In the neonate period, it is often attributed to dacryocystocele and presents in the form of a duct cyst. In older infants and children, nasolacrimal duct obstruction may occur as a consequence of ethmoidal sinusitis or facial fracture. It also is common in adults older than 40, with obstruction occurring at the opening of the nasolacrimal duct into the inferior meatus secondary to nasal polyps or thickening mucosa. Dacryocystitis can be subdivided into acute and chronic forms.

Acute dacryocystitis

Acute dacryocystitis is considered a medical urgency which manifests as a rapid onset of pain, swelling, and erythema, along with tenderness and induration of the lacrimal sac below the medial canthal tendon. The microbiologic spectrum encompasses *Staphylococcus aureus, Streptococcus pneumonia, Streptococcus pyogenes, Haemophilus influenza, Escherichia coli, Proteus species*, and *Pseudomonas aeruginosa*. Anaerobes, including *Peptostreptococcus* and *Propionibacterium*, have been detected. In addition, fungal infections such as *Candida* or *Aspergillus* are reported and are associated with dacryoliths. Dacryocystitis can worsen and progress to preseptal or orbital cellulitis, meningitis, or sepsis, hence it should be treated with systemic antibiotics, warm compresses, and anti-inflammatory medications.

Chronic dacryocystitis

Chronic dacryocystitis may be asymptomatic. The patient can present with epiphora or mucopurulent drainage from the lacrimal punctum, and, in patients with tear deficiency, epiphora could be subclinical. The cause of infection is mainly secondary to mixed bacterial organisms, with *Streptococcus pneumonia* and *Staphylococcus* spp. being most common. The treatment consists of systemic antibiotics and removal of the obstruction if present; thus, dacryocystorhinostomy is indicated if chronic dacryocystitis is associated with nasolacrimal duct obstruction. The surgery may be performed either transcutaneously or through the nasal mucosa.

Dacryoadenitis

Dacryoadenitis is a condition characterized by an inflammation of the lacrimal gland that could be related to a variety of infectious and noninfectious etiologies. The route of infections can be secondary to hematogenous seeding or ascending contamination through the ductules. The microorganisms responsible

TABLE 9.2 **TREATMENT OF LACRIMAL SYSTEM INFECTION**

	Antibiotic treatment	Surgical treatment
Canaliculitis	Topical antibiotic drops plus antibiotic irrigation of canaliculi (Pen G) plus intravenous/oral Pen V or macrolides	Punctoplasty with canalicular curettage or Canaliculotomy
Acute dacryocystitis	Systemic antibiotics such as amoxicillin-clavulanate or guided by culture results	Decompression of the nasolacrimal duct and transcutaneous pus aspiration
Chronic dacryocystitis	IV antibiotics	Intranasal or transcutaneous dacryocystorhinostomy
Acute dacryoadenitis Chronic dacryoadenitis	Systemic antibiotic Directed toward specific cause	Incision and drainage if no improvement Rarely required

for infection include bacteria, viruses, fungi, and parasites. The most commonly encountered bacteria are *Staphylococcus* spp., *Streptococcus* spp., *Haemophilus influenza, Neisseria gonorrhoeae, Chlamydia trachomatis, Mycobacteria tuberculosis, M. leprae, Treponema pallidum, Lymphogranuloma venereum,* and *Bartonella henselae*. Among viral species, mumps, measles, influenza, Epstein–Barr virus, herpes zoster, herpes simplex are most often implicated. *Phycomycetes, Schistosoma haematobium*, and *Onchocerca volvulus* are reported as fungal and parasitic microorganisms. This clinical entity has also been associated with *Acanthamoeba* keratitis, Wegener's granulomatosis, sarcoidosis, and Sweet's syndrome. Another entity, known as lacrimal gland ductulitis secondary to *Actinomyces* infection, has been described in a group of patients complaining of chronic mucopurulent conjunctivitis.

Dacryoadenitis typically exhibits symptoms of localized tenderness and swelling of the lacrimal gland and is usually unilateral in nature with signs of eyelid swelling and ptosis. Clinically, patients with acute dacryoadenitis complain of severe pain in the lacrimal gland region, edema, redness, and swelling, whereas in chronic dacryoadenitis only minimal eyelid edema and mild tenderness can be observed. Management of dacryoadenitis includes symptomatic treatment with local hot compresses or systemic antibiotics in cases of bacterial illness. In viral dacryoadenitis, the treatment is supportive unless the patient has herpes simplex or herpes zoster infections; the treatment then is valacyclovir for 1 week. The standard treatment for acute idiopathic inflammatory dacryoadenitis is oral corticosteroids. Some patients might benefit from intralesional steroid injection. If symptoms persist, irradiation or cyclosporine may be an option. Surgical drainage is necessary for abscess formation.

Deep neck infections

Jeremy D. Gradon

Introduction

Infections of the deep spaces of the neck are becoming more common. Hospital admissions for such infections in the United Kingdom more than doubled between 1996 and 2005. These infections are often life-threatening, and even stable-appearing patients are at grave risk for sudden clinical decompensation. Clinical severity is related to both the anatomic nature of the space involved, due to the numerous adjacent critical structures, and the nature of the hosts themselves (Figure 10.1). The elderly and diabetics are more likely to have complicated infections than their counterparts. Mortality rates range from 7% to as high as 40% for deep neck structure infections.

Patients with deep neck infections are frequently either diabetic, HIV-infected (irrespective of antiretroviral therapy status), or immunocompromised in some other way. In addition, a history of injection drug use (IDU), neutropenia, or exogenous steroid therapy is common. A dental source is frequently present. On rare occasions, deep neck space infection may complicate congenital abnormalities or cancers of the head and neck. Cases complicating traumatic airway intubation have also been reported. An example of a deep neck infection with associated necrotizing fasciitis is shown in Figure 10.2.

Deep neck infections are usually polymicrobial, reflecting the oral cavity source of most of these infections. When associated with IDU, community-acquired methicillin-resistant *Staphylococcus aureus* (MRSA) is the most likely organism encountered. The microbiology of these infections is shown in Box 10.1. The increasing prevalence of multidrug-resistant gram-negative rods, especially in the nosocomial setting, complicates therapy. Wound botulism as a complication of deep neck infection may occur in IDUs.

Attempts to devise an algorithm-based approach to help with clinical management decision-making have been made. Factors considered important include the presence/absence of airway obstruction, depth of neck involvement, ability to open mouth, ability to swallow, and any recent antibiotic usage. A scoring system reflecting these factors has been proposed (see Gallo et al. in the "Suggested reading" list).

Relevant anatomy of the deep neck spaces

The deep neck spaces are bound by a variety of anatomic landmarks and are anatomically distinct. However, all have the potential for communicating with each other, and thus infection may spread from one region to another during the course of the illness. Thus, involvement of multiple anatomically distinct deep neck spaces may occur concurrently.

It is important to delineate the various spaces clinically and radiologically so that appropriate management can be provided. The main spaces are as follows:

- The submandibular space (composed of two spaces separated by the mylohyoid muscle: the sublingual space, which is superior, and the submaxillary space, which is inferior).

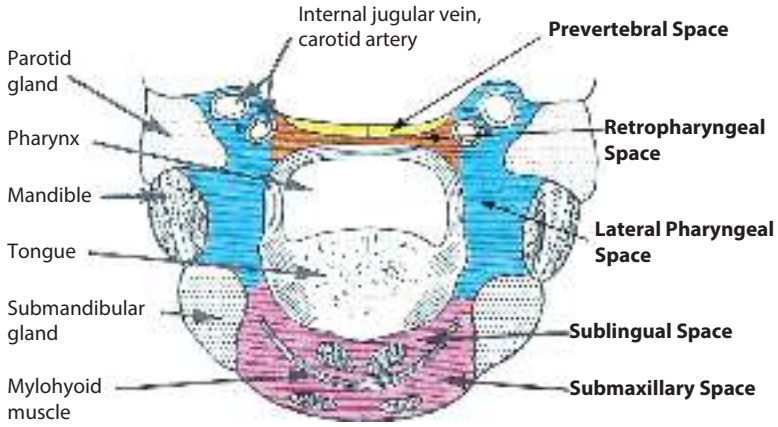

FIGURE 10.1 Oblique section of top of neck. Note contiguity of spaces and resultant potential for spread.
Adapted with permission from Hollingshead WH. *Anatomy for surgeons. Vol. 1: The head and neck*, 2nd ed. New York: Harper & Row; 1968.

- The lateral pharyngeal spaces (anterior and posterior)
- The retropharyngeal spaces (including the retropharynx, the prevertebral space, and the "danger space").

FIGURE 10.2 Recurring deep neck abscess of lateral pharyngeal space caused by *Nocardia asteroides* in an HIV-infected patient with a CD4 count of 86/mm^3.

Radiologic testing in deep neck infections

CT and MRI are excellent diagnostic tools for deep neck infections. However, it must be appreciated that these patients are critically ill with a risk for acute airway obstruction at any time in their clinical course. Thus, appropriately trained personnel must accompany these patients when they go for such scans. Equipment must be brought along to allow immediate airway protection should acute airway obstruction develop in (or on the way to) the radiology department.

In the postoperative setting, rim enhancement (>50%) of fluid collections in the neck seen on CT scanning correlates with abscess formation.

Submandibular space infections (Ludwig's angina)

This bilateral infection of the submandibular space most commonly arises from infection of the posterior two molar teeth. There is the

BOX 10.1

Pathogens encountered in deep neck space infections

Common

Viridans and other streptococci
Staphylococcus aureus (including MRSA)
Prevotella, Fusobacterium, Bacteroides, Porphyromonas

Rare

Moraxella
Haemophilus spp.
Pseudomonas spp.
Actinomyces spp.

BOX 10.2

Management of deep neck space infections

NEVER LEAVE THE PATIENT UNATTENDED out of a monitored unit.
Protect the airway—experienced otolaryngology evaluation is essential.
CT or MRI of mouth, neck, mediastinum to evaluate for drainable collections, airway compression, vascular complications, or mediastinal involvement
Dentist/oral surgery evaluation for a (removable) dental source of infection
Correct underlying medical issues: maximize glycemic control, correct neutropenia, taper steroids (if feasible), etc.

rapid onset of fever, mouth pain, and drooling of oral secretions. Soft-tissue spread of infection causes woody induration of the submandibular space and a stiff neck. Because the tongue may be displaced upward and backward, acute airway obstruction may develop. Tracheal compression due to surrounding edema is another cause of airway failure in this infection. Fatalities continue to be reported in this condition. Management is outlined in Boxes 10.2 and 10.3 and complications in Box 10.4.

BOX 10.3

Antibiotic therapy[a]

Nonimmune compromised host[b]

Penicillin G 3 million units IV q4h plus IV metronidazole 500 mg q6h
or
Ampicillin-sulbactam 3 g IV q6h
or
Clindamycin 600 mg IV q8h plus moxifloxacin 400 mg IV q24h

Immune-compromised host[b]

Meropenem 500 mg–2 g IV q8h plus vancomycin 1 g IV q12h
or
Piperacillin–tazobactam 4.5 g IV q6h plus vancomycin 1 g IV q12h

[a] These antibiotic recommendations are only examples of appropriate regimens. Multiple other combinations of antibiotics providing polymicrobial coverage for both aerobes and anaerobes are appropriate as well.

[b] In the setting of injection drug use, HIV infection, or the recent use of antibiotics (within ≤3 months), add anti-MRSA coverage with either vancomycin, ceftaroline, daptomycin, or linezolid.

BOX 10.4

Complications of deep neck space infections

Submandibular space infection

Acute airway obstruction
Aspiration pneumonia
Tongue necrosis
Carotid artery erosion
Jugular vein thrombosis
Spread to the lateral pharyngeal space

Anterior lateral pharyngeal space

Spread of infection to the parotid gland

Posterior lateral pharyngeal space

Carotid artery erosion
Suppurative jugular vein thrombosis
Cranial nerve palsies (IX–XII)

Retropharyngeal space

Respiratory distress
Spread to cervical vertebrae

Danger space

Spread of infection to mediastinum
Spread of infection to the pleural space

Prevertebral space

Spread of infection along the length of the vertebral column

Lemierre's syndrome

Jugular venous thrombosis
Septic pulmonary emboli
Empyema
Septic arthritis

Lateral pharyngeal space infections (anterior and posterior)

These are the most common forms of deep neck space infection. Infections of the lateral pharyngeal spaces can result from preexisting submandibular space infections or may develop secondary to dental, salivary gland, lymph node, or retropharyngeal space infections. IDU, with the patient attempting to access deep neck (jugular) veins with nonsterile needles, is the most common cause of lateral pharyngeal space infections in the urban setting.

Patients present with fever, neck pain, and rigors. If the anterior portion of the lateral pharyngeal space is involved, then trismus may develop. This may mimic the cephalic form of tetanus.

However, posterior lateral pharyngeal space infection is not associated with either trismus or visible neck swelling. Management is outlined in Boxes 10.2 and 10.3 and complications in Box 10.4.

Retropharyngeal space infections

The retropharyngeal space

Patients present with fever, sore throat, dysphagia, systemic toxicity, and neck stiffness. Inspection of the retropharynx will frequently demonstrate bulging or swelling of the retropharyngeal soft tissues. On occasion, the lesion may penetrate the posterior pharynx and pus may be visible on the anterior wall of the retropharynx. Infection may occur as a complication of local pharyngeal infection or be due to hematogenous seeding from a distal site. The infection may be due to dental infection, follow direct spread from acute cervical vertebral osteomyelitis, or follow penetrating trauma to the area. Diagnosis can be difficult, resulting in management delay and development of deep structure complications. The differential diagnosis is shown in Box 10.5.

The "danger space"

The "danger space" is an anatomical potential space that connects the deep neck spaces with the mediastinum. Access to the mediastinum is via the pretracheal fascia to the parietal pericardium and posterior mediastinum via the "danger space" from the retropharynx. As a result of this connection, acute bacterial mediastinitis may develop as a consequence of deep neck space infection. Other predisposing factors for mediastinal extension of a deep neck infection include older age, involvement of two or more deep neck spaces, and diabetes.

In addition, postoperative mediastinal infections may track up to the retropharynx and present as an apparent primary neck infection.

The prevertebral space

This fascial plane runs from the base of the skull to the coccyx along the anterior borders of the vertebrae. Thus, infection may spread from the retropharyngeal space to the whole length of the vertebral column. Management is outlined in Boxes 10.2 and 10.3 and complications in Box 10.4.

BOX 10.5

Differential diagnosis of retropharyngeal space infections

- Bacterial meningitis
- Cervical vertebral osteomyelitis
- Pott's disease
- Calcific tendonitis of the neck muscles
- Inflammatory tumor/neoplasm
- Mediastinal infection with spread via the "danger space"

BOX 10.6

Management of Lemierre's syndrome

- IV antibiotics (as shown in Box 10.3)
- Drainage of metastatic abscesses (other than septic pulmonary emboli) *Rarely*: ligation and resection of involved jugular vein (for unrelenting sepsis)
- No clear role for anticoagulation

Lemierre's syndrome

Lemierre's syndrome is an eponym describing internal jugular vein septic thrombophlebitis. It is the most common vascular complication of parapharyngeal space infection. The most commonly encountered cause is the anaerobe *Fusobacterium necrophorum*. Other causative bacteria include *Bacteroides*, MRSA, anaerobic streptococci, and other assorted mouth flora.

This infection classically affects young adults and is preceded by a sore throat followed by fever, systemic toxicity, and tenderness to palpation along the angle of the jaw and sternocleidomastoid muscle. Trismus is not present. As a consequence of this endovascular infection, bacteremia develops, with associated septic pulmonary emboli, empyema formation, and septic arthritis.

Routine screening of throat swabs for *Fusobacterium* in 15- to 24-year-olds presenting with pharyngitis has been suggested but is not a standard of care at present.

Lemierre's syndrome can also develop as a complication of attempts to access the jugular vein either for intravenous line placement or for purposes of IDU. The management of Lemierre's syndrome is outlined in Box 10.6.

Carotid artery erosion

This may occur as a complication of almost any deep neck space infection. Initially, this entity may be difficult to recognize due to the tight fascia binding the carotid artery. Once a false aneurysm has developed the patient may develop "herald bleeding" from the nose, mouth, or ears. Once major bleeding occurs death is common. Treatment involves urgent vascular surgical repair, and the risk of stroke is high. Successful cases of treatment with endovascular stenting for infection-induced carotid pseudoaneurysm have been reported.

Section 3

Clinical Syndromes: Eye

11

Conjunctivitis

Elmer Y. Tu

Conjunctivitis is a nonspecific term used to describe inflammation of the ocular surface and conjunctiva from either infectious or noninfectious causes. Infectious conjunctivitis is most commonly due to exogenous inoculation of the mucous membranes lining the surface of the eye and eyelid, resulting in an activation of a local inflammatory response. The vast majority of cases are acute but it may also present as chronic or recurrent. Although most cases of acute infectious conjunctivitis are self-limited and result in few long-term sequelae, appropriate evaluation and therapy are indicated with specific presentations.

Clinical features

The hallmark of conjunctivitis is injection or hyperemia of the conjunctival vessels, resulting in a red eye as well as tearing and/or mucopurulent discharge. Conjunctivitis may also result in complaints of irritation, foreign-body sensation, mattering or crusting of the eyelids, and mild visual blurring primarily due to alterations of the tear layer. The local inflammatory response may manifest as conjunctival lymphoid follicles or vascular papillae, eyelid edema, and/ or preauricular adenopathy. Complaints of severe eye pain, photophobia, significant visual loss, or referred pain should alert the examiner to the possibility of other, more ominous, etiologies. Similarly, loss of normal corneal clarity, either diffuse or focal, proptosis, pupillary abnormalities, conjunctival scarring, or restriction of eye movement are criteria for a detailed ophthalmic evaluation (Table 11.1).

Etiology

Numerous studies have demonstrated that, regardless of the etiology, acute conjunctivitis follows a benign course and results in few sequelae even without specific antibiotic therapy. Because characteristic signs and symptoms can distinguish bacterial and viral syndromes, the diagnosis of conjunctivitis is based largely on clinical history and examination. Cultures are normally reserved for neonatal or hyperacute conjunctivitis or in patients with a course greater than 2 to 3 weeks, classified as chronic conjunctivitis. A history of contact with other patients with conjunctivitis, bilateral involvement, or exposure to groups of children is associated with the more contagious viral agents. Signs of preauricular lymph node swelling (with the exception of hyperacute or chlamydial conjunctivitis), a follicular palpebral conjunctival reaction, and clear discharge or copious tearing are also more consistent with acute viral conjunctivitis. A papillary conjunctival reaction, mucopurulent discharge, and the lack of local lymph node swelling is more suggestive of bacterial conjunctivitis. When indicated, diagnostic workup consists of conjunctival swabs for Gram and other histologic stains as well as culture.

Viral conjunctivitis

Acute conjunctivitis, defined as less than 2 to 3 weeks duration, is most commonly viral, especially in adults. Adenovirus is a commonly identified pathogen in outbreaks of acute viral conjunctivitis. Although usually associated with types 8 and 19, epidemic keratoconjunctivitis (EKC) has been associated with several other serotypes and is highly contagious, spread by direct contact from hand to eye. In addition to the classic signs of viral conjunctivitis, patients with EKC may develop an immune keratitis consisting of corneal subepithelial infiltrates approximately 2 or 3 weeks after the onset of the conjunctivitis. The corneal inflammation results in complaints of foreign-body sensation, photophobia, and, possibly, decreased vision sometimes lasting days to months. Pharyngoconjunctivitis has a similar ocular presentation but is associated with serotypes 3 and 7 and includes fever and pharyngitis. Viral cultures are reserved for tracking large outbreaks because results usually are available after symptoms have subsided. The recent introduction of an in-office, rapid, reproducible adenovirus antigen screening test should prove to be of more clinical utility. The virus may remain viable on surfaces for many days to weeks, making control of outbreaks problematic. True EKC may remain highly transmissible from patient to patient for 2 weeks or more, and, therefore, requires strict hygiene instruction as well as isolation precautions, especially during the phase of copious discharge. Acute hemorrhagic conjunctivitis associated with enterovirus 70 and Coxsackievirus A24 is a highly transmissible follicular conjunctivitis with preauricular adenopathy with the added feature of subconjunctival hemorrhages (Figure 11.1). Currently available topical antivirals are not efficacious in any of these entities, making primary treatment supportive with topical lubricants, cool compresses, and topical nonsteroidal anti-inflammatory drugs (NSAIDs). Topical corticosteroids have been used cautiously in patients with debilitating symptoms of EKC-related keratitis, but their use is controversial.

Either herpes simplex type 1 or 2 may result in a primary follicular conjunctivitis seen in children and young adults. Primary conjunctivitis is normally unilateral with a palpable preauricular lymph node associated with a classic vesicular eyelid or periorbital eruption (Figure 11.2). Systemic antivirals are indicated for primary infection. Because vision-threatening sequelae are associated with corneal involvement, topical trifluridine 1% five to nine times per day or topical ganciclovir five times per day may also be added to either treat or reduce the risk of herpes simplex virus (HSV) keratitis by

FIGURE 11.1 Self-limited acute hemorrhagic conjunctivitis.

FIGURE 11.2 Primary herpes simplex blepharitis and conjunctivitis.

shortening the duration of the HSV conjunctivitis. Recurrence is common.

Chronic viral conjunctivitis may be associated with molluscum contagiosum, usually seen in children. The chronic follicular conjunctivitis is caused by viral shedding into the eye from an eyelid or periorbital molluscum, characteristically a pearly white nodule with an umbilicated center (Figure 11.3). These lesions are typically small and multiple and spread by direct contact. Immunocompromised individuals may present with much larger lesions. Treatment of the molluscum lesion by incision and curettage of its center or excision is curative of the associated conjunctivitis.

Bacterial conjunctivitis

Most bacterial conjunctivitides are self-limited, have low morbidity, and respond well to most available topical broad-spectrum antibiotics, obviating the need for microbiologic identification. Definitive evaluation and specific treatment is, however, required in hyperacute conjunctivitis, a rapidly progressive, purulent, destructive infection, and neonatal conjunctivitis to avoid local and systemic complications more common to these two entities.

FIGURE 11.3 Molluscum contagiosum chronic follicular conjunctivitis.

Hyperacute conjunctivitis

Hyperacute conjunctivitis is usually associated with *Neisseria* species, most commonly *Neisseria gonorrhoeae* in newborns and young sexually active adults. A copious, rapidly accumulating mucopurulent discharge, intense redness, and periorbital swelling are characteristic of hyperacute conjunctivitis. It is one of the few acute bacterial conjunctivitides that develops a preauricular lymphadenopathy. Rapid corneal and conjunctival penetration can result in severe corneal ulceration and ocular destruction if left untreated. It is considered a true ocular emergency. This potential for ocular complications and systemic infection with *N. gonorrhoeae* necessitates microbiologic identification as well as systemic antibiotic therapy (see Table 11.2). Local sterile saline lavage can be symptomatically helpful. Because of a significant incidence of coinfection, systemic therapy directed against *Chlamydia* infection is recommended in these cases (see below). Less commonly, *Neisseria meningitidis* may result in hyperacute conjunctivitis in a similar, but muted, presentation. The infection may be a primary conjunctivitis but is more likely secondary to systemic meningococcemia, requiring aggressive systemic therapy to prevent systemic complications.

Neonatal conjunctivitis

Conjunctivitis occurring within the first month of life is termed neonatal conjunctivitis and is either nosocomial or contracted during passage through the birth canal. The pathogens most commonly identified include *Chlamydia trachomatis* (30–50%), *Staphylococcus aureus*, and *N. gonorrhoeae*, with *Streptococcus pneumoniae*, *Haemophilus* spp., and *Pseudomonas* also identified. Prophylaxis with a single topical application of antibiotic within the hour of delivery has drastically reduced the incidence of neonatal conjunctivitis. The original solution of 1% silver nitrate (*Crede prophylaxis*) has been largely supplanted by topical erythromycin 0.5% or tetracycline 1% ointment both for better

TABLE 11.2 **SYSTEMIC TREATMENT OF GONOCOCCAL CONJUNCTIVITIS**

Adults	**Dosage**
Ceftriaxone (drug of choice)	1 g IM, single dose
Ciprofloxacin	500 mg PO, single dose
Ofloxacin	400 mg PO, single dose
Spectinomycin	2 g IM, single dose
Children (≤ 45 kg)	**Dosage**
Ceftriaxone	125 mg IM, single dose
Spectinomycin	40 mg/kg IM (max = adult dosage), single dose
Neonates	**Dosage**
Ceftriaxone	25–50 mg/kg IV or IM (max = 125 mg), single dose

coverage for *Chlamydia* and for a lower incidence of toxicity. Signs and symptoms are not helpful in discerning between these infections, necessitating microbiologic identification to direct appropriate therapy.

Infection with *N. gonorrhoeae* causes hyperacute conjunctivitis 1 to 13 days after birth and constitutes an ocular emergency. Clinical signs, symptoms, and treatment are similar to those seen in adults as described above. The proper use of neonatal prophylaxis reduces the incidence of gonococcal conjunctivitis to less than 2% in infected children born to infected mothers.

Neonatal inclusion conjunctivitis is caused by *C. trachomatis* and presents 5 to 14 days after birth. Signs may include lid swelling, redness, water, or mucopurulent discharge. In some cases a pseudomembrane may occur. Diagnostic workup is detailed below. Ocular infection can be associated with pneumonia and/or otitis media in up to 50% of patients, necessitating both topical and systemic therapy consisting of oral erythromycin or erythromycin ethylsuccinate 50 mg/ kg/day in four divided doses.

Most other bacterial infections will respond to a topical broad-spectrum antibiotic such as erythromycin, sulfacetamide, aminoglycoside, or fluoroquinolone.

HSV may also result in ophthalmia neonatorum either as an isolated conjunctivitis/ keratitis or as part of a serious systemic neonatal infection. Prophylaxis of the mother with acyclovir or valacyclovir has been shown to reduce viral shedding during delivery. This combined with cesarean section, in the presence of active genital herpes, has reduced the incidence of HSV neonatal infection. Transmission may, however, still occur in asymptomatic individuals and should be considered in the differential of neonatal conjunctivitis. Classic vesicular lesions are usually noted on the eyelid with a concomitant follicular conjunctivitis. Dendritic lesions of the cornea indicate HSV keratitis with the potential for loss of vision secondary to corneal scarring. Intraocular involvement may lead to more serious ocular damage. Although HSV type 2 is more common, HSV type 1 has also been isolated. Superficial scraping for smear and culture is helpful but not integral to diagnosis. Treatment includes systemic antivirals as well as topical trifluridine 1% nine times per day or topical ganciclovir five times per day. Other forms of neonatal viral conjunctivitis are otherwise uncommon.

Acute bacterial conjunctivitis

Overall, the majority of acute conjunctivitis is viral, except in the pediatric population, where more bacterial pathogens are seen. Clinical features include a mild to moderate mucopurulent discharge, a papillary conjunctival inflammatory response, injection (hyperemia), and initial unilaterality. With few exceptions (see hyperacute conjunctivitis, chlamydia in this chapter), routine bacterial conjunctivitis does not result in preauricular adenopathy. Cultures and smears are not normally performed in its management, but, in prospective series, gram-positive bacteria, *S. pneumoniae*, *Streptococcus viridans, S. aureus*, and *Haemophilus* predominate. Gram-negative bacteria are seen less frequently. *S. pneumoniae* may cause a bilateral conjunctivitis with characteristic small petechial hemorrhages of the conjunctiva. Seen more commonly in children, *Haemophilus* may cause discoloration of the involved eyelid described as "violaceous" and create significant upper eyelid edema resulting in a characteristic S-shaped upper eyelid.

Treatment of acute bacterial conjunctivitis with any of a number of broad-spectrum topical antibiotics will achieve local concentrations that can easily overcome even mild to moderate resistance. The average duration of untreated acute bacterial conjunctivitis is 2 to 7 days. Topical antibiotics have been shown to shorten the overall course when administered early in the course of infection and to improve clinical and microbiologic signs of disease. Addition of antibiotics later in the course after day 4 is of limited benefit. Broad-spectrum antibiotics are administered four to six times daily for 5 to 7 days (see Table 11.3). In adults

TABLE 11.3 **COMMON TOPICAL OPHTHALMIC ANTIBIOTICS AND STEROID FORMS**

Antibiotic	Common brand names	Form	Steroid-containing combination product brand name
Sulfacetamide	Bleph-10	Drop/ointment	Blephamide, Vasocidin
Erythromycin	Generic	Ointment	None
Bacitracin	Generic	Ointment	None
Bacitracin–polymyxin B	Polysporin	Ointment	
Polymyxin B–trimethoprim	Polytrim	Drop	None
Neomycin–polymyxin B		Drop/ointment	Maxitrol, Cortisporin
Tetracycline–polymyxin B	Terramycin	Ointment	None
Gentamicin	Garamycin	Drop/ointment	Pred-G
Tobramycin	Tobrex	Drop/ointment	Tobradex, Zylet
Ciprofloxacin	Ciloxan	Drop/ointment	None
Ofloxacin	Ocuflox	Drop	None
Levofloxacin	Quixin	Drop	None
Gatifloxacin	Zymar	Drop	None
Moxifloxacin	Vigamox	Drop	None

presenting with conjunctivitis, it has been suggested that a delay in treatment for 3 to 4 days, instituted only with a lack of resolution, would significantly reduce the unnecessary use of topical antibiotics in viral or self-limited bacterial cases with no significant impact on overall outcome. Although unnecessary, the use of antibiotic–steroid combinations (Table 11.3) may speed symptomatic relief but may potentiate serious masquerading conditions and should, therefore, be used with caution if the diagnosis is in question. Because of a relationship between Haemophilus conjunctivitis and acute otitis media or other involvement, the addition of appropriate systemic antibiotics is strongly considered, especially if systemic signs are present.

Chronic bacterial conjunctivitis

Conjunctivitis persisting for greater than 2 weeks is considered chronic and requires more detailed ophthalmic examination as well as Gram and Giemsa staining and culture. Chronic or recrudescent bacterial conjunctivitis may persist because of characteristics of the causative organism or a persistent local or external reservoir of the organism not exposed to normal ocular surface defense mechanisms. Although contaminated prosthetic devices such as contact lenses may be a source for pathogen reintroduction, the most common reservoir is the eyelids in the form of blepharitis, dacryocystitis, or, rarely, dacryoadenitis.

Blepharitis, or eyelid margin inflammation, is most commonly associated with chronic colonization by *S. aureus* or epidermidis and is characterized by eyelash debris, eyelid margin thickening, and telangiectasias (Figure 11.4). Angular blepharitis refers to infection of the lateral canthus causing inflammation and irritation of the eyelid skin and is associated with *Moraxella lacunata*. Seen more commonly in alcoholics and immunocompromised individuals, it may also result in conjunctivitis and keratitis. Swabs for Gram stain demonstrate the classic "double boxcar" gram-negative organisms. A concomitant conjunctivitis may accompany any form of blepharitis. Signs and symptoms are similar to other forms of bacterial conjunctivitis and respond to lid hygiene and topical antibiotic ointment such as erythromycin, bacitracin, or sulfacetamide at bedtime.

FIGURE 11.4 *Staphylococcus aureus*-related chronic blepharoconjunctivitis.

Chlamydial conjunctivitis

Serotypes A to C are associated with trachoma, a follicular bacterial conjunctivitis that because of its chronicity results in scarring of the superior tarsus. These cicatricial changes may lead to entropion and trichiasis, inward turning eyelashes, resulting in chronic corneal trauma and scarring. Seen primarily in endemic areas of the developing world, it is one of the most common causes of blindness. Diagnostic workup consists of conjunctival swabs/scrapings for culture or direct immunofluorescence. Courses of systemic erythromycin, doxycycline 100 mg twice daily for 7 days, or a single 1-g oral dose of azithromycin are effective and curative, but because of its endemic nature, whole community programs are required to prevent recurrent reinfection. Alternatives include erythromycin, ofloxacin, and levofloxacin.

Adult inclusion conjunctivitis is also caused by *C. trachomatis* (serotypes D through K). The conjunctivitis is concurrent with, but may occur independent of, active genital infection. Transmission to the eye is by direct contact with contaminated secretions. Nonspecific symptoms of tearing, foreign-body sensation, photophobia, and eyelid edema are presenting complaints. *Chlamydia* causes a follicular conjunctivitis with preauricular lymphadenopathy, but unlike trachoma, the lower eyelid is normally more involved. As in trachoma, systemic azithromycin or doxycycline is effective but also requires appropriate evaluation and treatment of sexual contacts.

Miscellaneous causes

In addition to *Neisseria* spp. and *Chlamydia* spp., several other forms of conjunctivitis may be related to systemic infection. Parinaud's oculoglandular syndrome is the association of a follicular conjunctivitis, conjunctival granuloma, and an ipsilateral lymphadenopathy. Cat scratch disease caused by *Bartonella henselae* is the most common cause of Parinaud's and is transmitted by contact with an infected cat. The conjunctival granuloma may be single or multiple and is surrounded by intense inflammation accompanied by ipsilateral head, neck, or axillary lymphadenopathy. Other causes of Parinaud's include tularemia, sporotrichosis, tuberculosis, syphilis, and coccidioidomycosis (Table 11.4). Evaluation should include a detailed history of exposures and appropriate serologic tests and systemic cultures. Treatment is directed toward the underlying process.

Chronic use of any topical ophthalmic medication may result in ocular medicamentosa. Signs and symptoms include tearing, redness, photophobia, and irritation, masquerading as an infectious conjunctivitis. Although it is most commonly associated with over-the-counter vasoconstrictors, it is also seen with topical antibiotics and may cause a self-perpetuating conjunctivitis until medication use is discontinued. Other etiologies should be considered in chronic conjunctivitis, including neoplasm, allergy, toxicity, autoimmune disease, and unusual pathogens.

TABLE 11.4 **CAUSES OF PARINAUD'S OCULOGLANDULAR SYNDROME**

Disease	Agents
Cat scratch disease	*Bartonella henselae*
Tularemia	*Francisella tularensis*
Sporotrichosis	*Sporotrichum schenckii*
Tuberculosis	*Mycobacterium tuberculosis*
Syphilis	*Treponema pallidum*
Coccidioidomycosis	*Coccidioides immitis*
Paracoccidioidomycosis	*Paracoccidioides brasiliensis*
Actinomycosis	*Actinomyces israelii, A. propionicus*
Blastomycosis	*Blastomyces dermatitidis*
Infectious mononucleosis	Epstein–Barr virus
Mumps	Paramyxovirus
Pasteurellosis	*Pasteurella multocida (septica)*
Yersinia infection	*Yersinia pseudotuberculosis Yersinia enterocolitica*
Glanders	*Burkholderia mallei*
Chancroid	*Haemophilus ducreyi*
Lymphogranuloma venereum (LGV)	Chlamydial LGV agent L, L_2, L_3
Rickettsiosis (Mediterranean spotted fever)	*Rickettsia conorii*
Listerellosis	*Listeria monocytogenes*
Ophthalmia nodosa (noninfectious)	Lepidoptera (caterpillars) Tarantula hairs

Keratitis

Elmer Y. Tu, Francis S. Mah, and Jules Baum

Keratitis is an ocular emergency that can lead to severe visual disability and requires prompt diagnosis and treatment. Sequelae can vary in severity from little or no visual loss to corneal scarring, perforation, endophthalmitis, and loss of the eye. Although the corneal surface is awash with microorganisms of the normal flora, an intact corneal epithelium and ocular defense mechanism serve to prevent infection in the normal eye. Although some organisms such as *Neisseria gonorrhoeae*, *Neisseria meningitidis*, *Corynebacterium diptheriae*, *Listeria*, and *Shigella* can penetrate an intact epithelium, all others require damage to the epithelial layer to invade the cornea. Several risk factors predispose the cornea to infection. Dry eyes from Sjogren syndrome, Stevens–Johnson syndrome, or vitamin A deficiency can result in bacterial keratitis. Prolonged corneal exposure from ectropion, lagophthalmos, or proptosis can lead to secondary infection. Entropion and trichiasis resulting in epithelial defects put the cornea at risk. Neurotropic keratopathy from cranial neuropathy, prior herpes simplex, or zoster infections predispose to secondary infections. Some systemic conditions such as chronic alcoholism, severe malnutrition, immunosuppressive drug use, immunodeficiency syndromes, and malignancy can impair immune defenses and allow infection by unusual organisms. Prior ocular surgery such as penetrating keratoplasty or refractive procedures is also a risk factor. Trauma is a common predisposing factor of bacterial keratitis, especially for patients at the extremes of age and in developing countries. Injury to the corneal surface and stroma allows invasion of normal flora as well as organisms harbored by foreign bodies.

Contact lens wear is the most common established risk factor for bacterial keratitis in developed countries. All types of contact lenses have been linked to infection, with extended-wear soft lenses conferring greater risk than daily wear hard or soft lenses. Corneal changes from contact lens use include an induced hypoxic and hypercapnic state promoting epithelial cell derangement and allowing bacterial invasion. Contact lenses also induce dry eye and corneal hypesthesia. Overnight rigid gas-permeable lens use for orthokeratology has also been associated with bacterial keratitis, but with a disproportionately high incidence of *Acanthamoeba* keratitis.

Although there are geographic variations in the order of incidence, the most common pathogenic organisms associated with bacterial keratitis include *Staphylococcus* species, *Streptococcus* species, *Pseudomonas aeruginosa*, and enteric gram-negative rods. A 5-year review of bacterial keratitis isolates from Pittsburgh showed a change in distribution with a decrease in gram-positive organisms, whereas gram-negative isolates remained stable (Figure 12.1). In South Florida, an increase in gram-positive isolates with a decrease in gram-negative isolates over a 30-year period has been reported. *Pseudomonas aeruginosa* is commonly associated with contact lens-related bacterial keratitis, causing up to two-thirds of cases, although a decline in the frequency of *P. aeruginosa* isolates in these patients has been noted. Nontuberculous mycobacteria are being reported with increasing frequency as a cause of infectious keratitis after laser *in situ* keratomileusis (LASIK). Although the reported incidence of infection after LASIK is low, this condition is a management challenge requiring proper diagnosis and treatment. Bacterial colonization of the eyelid and conjunctiva is normal and helps reduce opportunities for pathogenic strains from gaining a foothold. Host defense mechanisms can be overcome, however, and this leads to serious ocular morbidity if the pathogen is not treated properly. Although the clinical manifestations of corneal infections may be characteristic of certain pathogens, further laboratory evaluation with cultures and antibiotic susceptibility testing provides a definitive diagnosis and more focused treatment after empirical therapy has been initiated.

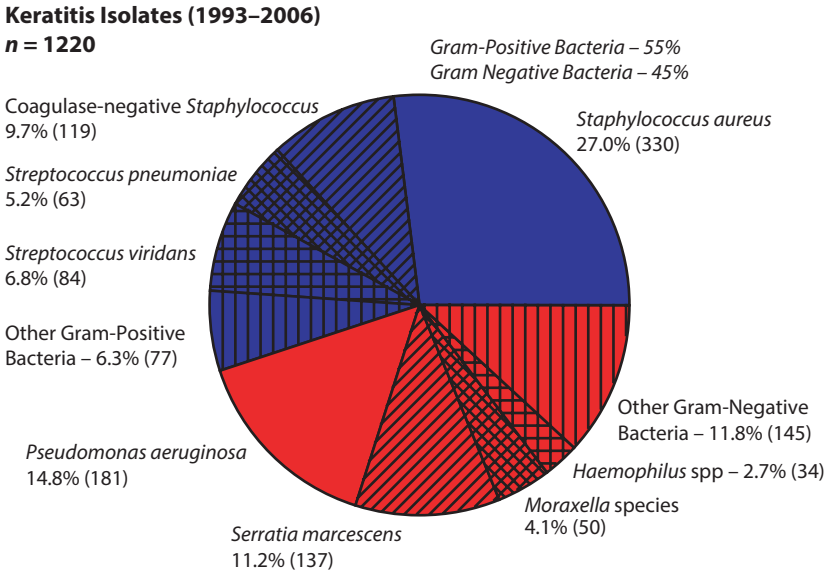

FIGURE 12.1 Keratitis isolates (1993–2006).

Clinical features

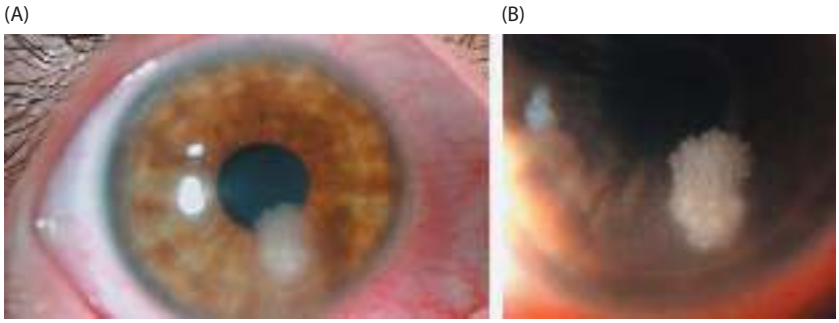
The presenting symptoms, clinical history, and exam findings may suggest an infectious keratitis but are seldom pathognomonic for a particular organism. The presenting signs of bacterial keratitis vary depending on the virulence of the organism, duration of infection, structural status of the cornea, and host inflammatory response.

Common presenting symptoms include pain, decreased vision, tearing, and photophobia. Eyelid edema, conjunctival hyperemia with a papillary reaction, and chemosis are typical findings. A corneal epithelial defect with adherent mucopurulent exudate and underlying stromal infiltrate is a hallmark sign for infectious keratitis (Figure 12.2). Multiple focal infiltrates can be seen with contact lens use or with polymicrobial infections. Migration of inflammatory cells causes a diffuse cellular infiltration adjacent to and within the ulcerated stroma. Ananterior chamber reaction can range from mild cells and flare to a marked hypopyon (Figure 12.3). A cornea damaged from prior disease can present with less distinct signs and symptoms. Pre-existing corneal scars, epitheliopathy, or inflammation confuse the picture as does prior use of antibiotics and corticosteroids. On examination, all ocular abnormalities should be documented in detail to help track the clinical course on subsequent visits. Repeat measurements of the size of the epithelial defect, the depth of the stromal infiltrate, and the severity of inflammation can be used to assess the effectiveness of treatment.

Nontuberculous mycobacterial keratitis has been reported with increasing frequency after LASIK, including several clusters of cases. In two recent reviews of post-LASIK corneal infections, *Mycobacterium* represented the most common etiologic organism. The isolated subtypes include the fast-growing *Mycobacterium chelonae*, *Mycobacterium abscessus*, *Mycobacterium fortuitum*, and *Mycobacterium mucogenicum*, as well as the slow-growing *Mycobacterium szulgai*. Non-tuberculous keratitis after LASIK is characterized by a delayed onset with an indolent course. Time of onset from fast-growing organisms averaged 3.4 weeks after the procedure, whereas the slow-growing *M. szulgai* can present 6 to 24 weeks after surgery. Symptoms can range from a mild foreign-body

FIGURE 12.2 Infectious keratitis.

FIGURE 12.3 Hypopyon.



FIGURES 12.4 (A and B) Infectious crystalline keratopathy.

sensation to pain, redness, photophobia, and decreased vision. The infiltrate, which can be multiple, begins in the interface and spreads to adjacent stroma of the flap and stromal bed. Anterior perforation through the flap can occur with progression of infection. The location can be central, paracentral, or peripheral. In addition to a focal infiltrate, a cracked windshield appearance of infectious crystalline keratopathy has been reported (Figures 12.4A and B).

Diagnostic techniques

Currently, routine culture of corneal infections is not the usual practice in the community. A small peripheral ulcer may be treated empirically, but a large, purulent, central ulcer that extends to the middle to deep stroma should be cultured. In addition, ulcers that are atypical or clinically suspicious for fungal, mycobacterial, or amebic infections or are unresponsive to initial broad-spectrum antibiotics warrant cultures. Topical anesthesia with proparacaine hydrochloride is preferred because it has fewer antibacterial properties than other topical anesthetics that might interfere with culture yields. A sterile platinum spatula is used to scrape the leading edge as well as the base of the ulcer while carefully avoiding contamination from the lids and lashes. Organisms such as *Streptococcus pneumoniae* are more readily recovered from the ulcer edge, whereas other organisms such as *Moraxella* are characteristically recovered from the base. The scrapings are inoculated onto solid media (blood, chocolate, and Sabouraud's agar) by streaking a row of Cs. New material is recovered for each row. Scrapings are also placed on microscope slides and stained with Gram and Giemsa stains. Special stains include Ziehl–Neelsen acid-fast stain for *Mycobacterium*, *Actinomyces*, and *Nocardia*. Acridine orange is a fluorescent dye that may be helpful in identifying bacteria when yields are low, but this stain does not yield classification information that Gram stain provides.

In vivo confocal microscopy may be helpful in atypical, nonbacterial corneal infections where the organisms are larger and not as amenable to culture or identification. In cases of deep stromal suppuration that is not readily accessible or a progressive microbial keratitis unresponsive to therapy, a corneal biopsy may be warranted. A round 2-mm to 3-mm sterile disposable skin trephine is used to incise the anterior corneal stroma, and lamellar dissection is performed with a surgical blade. The specimen is then ground in a mortar with trypticase soy broth and plated on media.

Treatment

Routes of administration

The topical application of drugs with eyedrops is the preferred method of treatment of bacterial keratitis. Increased drug penetration can be achieved by higher concentrations, more frequent applications, and by the typical presence of an epithelial defect. Fortified antibiotics are made by mixing the powdered drug or diluting the parenteral form with artificial tears or balanced salt solution. These freshly prepared solutions remain stable for up to a week without significant loss of activity. Although ointments prolong corneal contact time and lubricate the ocular surface, peak corneal concentrations may be limited when compared with solutions. They also retard the absorption of antibiotics delivered in eyedrop form. Ointments can be used as adjunctive therapy at bedtime in less severe cases.

The need for other routes of antibiotic administration in bacterial keratitis is rare. Subconjunctival injections may not have a therapeutic advantage over topical solutions. However, they may be indicated in certain clinical situations such as imminent perforation or spread of infection to adjacent sclera, especially when patient compliance is an issue. Soft contact lenses and collagen shields can act as drug depot/ delivery devices and aid in sustaining high corneal drug levels. These "bandage" contact lenses may also provide protection to promote reepithelialization. Systemic therapy is indicated for gonococcal infections as well as for young children with severe *H. influenzae* or *P. aeruginosa* keratitis. Systemic antibiotics are also indicated for perforations and scleral involvement.

Empiric therapy

Because bacterial keratitis can rapidly progress and threaten vision, treatment should begin when an infectious process is suspected to limit further damage in an effort to preserve vision. Topical broad-spectrum antibiotics are initially used and later modified according to culture results, antibiotic susceptibilities, and clinical response. For severe cases, combination therapy with fortified β-lactam (cefazolin 50 mg/mL) and aminoglycoside (tobramycin or gentamicin 14 mg/mL) (Figure 12.5) provides adequate coverage of both gram-positive and -negative organisms that cause bacterial keratitis. Vancomycin (50 mg/mL) can be substituted for cefazolin in cases of penicillin allergy or resistance in *Staphylococcus* species. Because of

FIGURE 12.5 Topical aminoglycosides are combined with β-lactam therapy.

a high prevalence of methicillin resistance in some centers, vancomycin instead of cefazolin is utilized as a first-line agent. A loading dose is achieved with a drop every 5 minutes for five applications. Antibiotic is then continued every 30 minutes to 1 hour around the clock for several days and then rapidly tapered once control of the infection has been achieved.

Single-agent therapy with fluoroquinolones has previously been shown to be as effective as combination therapy in treating bacterial keratitis. The widespread systemic use of the second (ciprofloxacin and ofloxacin) and third (levofloxacin) generation fluoroquinolones has, however, led to the emergence of resistance in several bacterial species, including *Pseudomonas aeruginosa*. The fourth-generation fluoroquinolones, gatifloxacin and moxifloxacin, have been developed to improve coverage of gram-positive and atypical mycobacterial pathogens. They require two mutations to establish resistance and, therefore, are more effective against gram-positive organisms that already have a single mutation and are resistant to older generation fluoroquinolones. Unfortunately, large surveys have noted that the vast majority of methicillin-resistant *Staphylococcus aureus* is also resistant to all currently available topical ophthalmic fluoroquinolones.

Regardless of the susceptibility profile, a favorable response to empiric therapy merits continuing the treatment. Positive signs of clinical improvement include decreased pain and discharge, consolidation of the stromal infiltrate, decreased anterior chamber reaction, and corneal reepithelialization. Culture and antibiotic susceptibility results can be used to focus therapy against the offending organism or to discontinue unnecessary drugs. Clinical improvement may not be seen during the first 2 days due to increased inflammation and suppuration from bacterial exotoxins. Toxicity from topical medications can also mask changes. A lack of improvement or clinical worsening after 48 hours may warrant repeat cultures, although concomitant antibiotic therapy will decrease yields. Topical therapy can be tapered as the clinical picture improves.

Management of nontuberculous mycobacterial keratitis after LASIK can be challenging and requires aggressive treatment. The flap should be lifted for smears and culture as well as for soaking of the stromal bed and flap with antibiotics. Fortified amikacin, clarithromycin, and azithromycin are the drugs of choice. Fourth-generation fluoroquinolones have also been shown to be effective against mycobacterial keratitis. Combination therapy is recommended due to emergence of resistance on monotherapy. Lack of clinical improvement warrants repeat culture and tailoring of antibiotics accordingly. Flap amputation may also be necessary to allow increased antibiotic penetration.

Adjunctive therapy

Bacterial keratitis is often associated with severe pain. Pain control with analgesics may provide not only comfort but also better compliance with the difficult regimen of around-the-clock topical drop instillation. Cycloplegic agents should also be used to decrease discomfort from ciliary spasm and to prevent synechiae formation. Cyanoacrylate glue can be used to reinforce an area of corneal thinning, a descemetocele, or a small perforation. A "bandage" contact lens is placed after the glue hardens. This procedure allows for further treatment of the infection and inflammation while postponing surgery. A corneal patch graft is an alternative for small perforations, whereas larger necrotic perforations require a therapeutic penetrating keratoplasty. Surgical interventions are most successful after patients have received therapeutic dosing of antibacterial drugs prior to surgery.

Corticosteroids may play a role in treating bacterial keratitis with their potential for reducing the host inflammatory response and resultant corneal scarring but this must be balanced by their potential to inhibit corneal wound healing. Other adverse effects may include potentiation of microbial replication, recrudescence of infection, steroid-induced glaucoma, and cataract formation. The use of corticosteroids prior to the initiation of effective antimicrobial therapy is associated with a significantly poorer outcome in bacterial keratitis and their use in eyes with pre-existing corneal disease increases the risk of the development of ulcerative keratitis. The only prospective, randomized trial of corticosteroid administration in treated bacterial keratitis failed to show any increase in adverse events with corticosteroid use, but also did not demonstrate a visual benefit at 3 months. General guidelines for the use of corticosteroids include: (1) consider use only in those patients with vision-threatening infections in or around the central cornea, (2) corticosteroids should be used only after establishing effective antibiotic therapy with an appropriate response of the infection, (3) continue use of concomitant antibiotics, and (4) do not use steroids if the infection is not responding appropriately to topical antibiotics or if there is suspicion for an atypical or nonbacterial pathogen.

Herpetic keratitis is the most common cause of corneal blindness in developed nations. Herpes simplex virus (HSV) can manifest as a blepharitis, conjunctivitis, epithelial keratitis, stromal keratitis, limbitis, endotheliitis, uveitis, or retinitis. As elsewhere, in

immunocompetent individuals, the infection is usually self-limited, but once established in any facial dermatome will become latent in the trigeminal ganglia. Recurrences may occur for a patient's lifetime in any dermatome including the eye and periocular region and visual loss is strongly associated with the number of recurrences and location within the cornea. Pediatric patients have a high rate of corneal scarring, increasing in severity with the age of first onset. Both HSV-1 and HSV-2 have been detected with HSV-1 marginally more common in eye infections. There is often a history of labial or genital herpes as well as a history of a recurrent, nonspecific red eye or frank vesicular lesions in the periorbital region.

HSV keratitis may be bilateral in a minority of cases (<10%) but is usually unilateral. The initial corneal infection may be minimally symptomatic and is characterized by a dendritic epithelial lesion with terminal bulbs which stain with Rose Bengal but may also be geographic. This usually will leave a ghost imprint on the anterior stroma. Subsequent recurrences may be either epithelial, stromal, endothelial or some combination thereof. Stromal HSV keratitis appears inflammatory with either a diffuse stromal edema and interstitial keratitis or a disciform keratitis reminiscent of *Acanthamoeba* keratitis. Isolated corneal edema may be characteristic of associated endotheliitis and elevated intraocular pressure seen with HSV trabeculitis. Most patients will have some loss of corneal sensation which may lead to an unstable epithelium and dry eye.

Treatment for the initial and recurrent episodes may be either topical or systemic. Currently available topical agents include trifluridine and ganciclovir as well as acyclovir, which is available outside of the United States. Significant toxicity can be seen with trifluridine and treatment with any topical agent should be limited to 7 to 10 days after which a reassessment should be done as to whether findings are either still due to active infection or due to the complications of neurotropic keratitis or medication toxicity. Systemic therapy consists of acyclovir, valacyclovir, or famivir in the same doses used for dermatologic therapy and is as effective as topical therapy without the local side effects. Treatment has been shown to reduce the duration of the infection by 1 to 2 days but has no preventive effect in reducing recurrences or progression to stromal keratitis. However, long-term maintenance oral antiviral therapy has been shown to reduce the number of recurrences of herpetic eye disease. Corticosteroids may be used in stromal keratitis to reduce pain and discomfort while the patient is on effective antiviral therapy.

Other viruses in the herpes family can also cause keratitis, including herpes zoster (HZV), Epstein–Barr, and cytomegalovirus. Of these, HZV is the most commonly recognized and like HSV may cause a retinitis, uveitis, epithelial keratitis, and stromal keratitis initially occurring within 3 months of an episode of Vth nerve zoster. Clinical findings are similar to HSV, but the pseudodendrites are lacking in terminal bulbs and keratitis may be treated with corticosteroids, which are a contraindication in HSV epithelial keratitis. The neurotropic keratitis seen with HZV is often more profound than with HSV. As in HSV, initial episodes should be treated with dermatologic treatment doses of oral antivirals for zoster. Subsequent "recurrences" are largely inflammatory, but some epithelial lesions may require topical antivirals for resolution. Vaccinations for HZV should be approached with caution in a zoster ophthalmicus patient for fear of reactivation, which has been reported. In other patients, however, vaccinations should prove to partially protect from episodes of shingles.

Acanthamoeba keratitis is a rare opportunistic infection that affects an estimated 18 to 20 patients per million contact lens wearers per year in the United Kingdom and more recently in the United States where there are approximately 36 million contact lens users. Acanthamoebae are ubiquitous protozoa found in both soil and water that exist in two forms: trophozoites (the active form) and cysts (the inactive form). In stressful environments, trophozoites transform into cysts within hours that are resistant to extremes of temperature, pH, and desiccation. Because the cysts are notoriously difficult to kill, the infestation of the corneal stroma is very difficult to eradicate. Indeed, only one class of commonly compounded ophthalmic medications, the biguanides (polyhexylmethylbiguanide [PHMB], chlorhexidine, pentamidine), has cystocidal activity.

The initial report of *Acanthamoeba* keratitis in 1973 occurred in a non contact lens wearer who sustained eye trauma. The infection remained rare until the mass market introduction of soft contact lenses was followed by an outbreak of infection in wearers in the late 1980s, largely attributed to nonsterile homemade saline contact lens care solutions. More than 85% of all acanthamoeba infections are in contact lens wearers with additional risk factors of ocular trauma, corneal transplantation, and exposure to contaminated lake water, sea water, or hot tubs. Starting in 2003, an alarming increase in the rate of *Acanthamoeba* keratitis has been observed, prompting the Centers for Disease Control and Prevention (CDC) and academic centers to attempt to identify a cause which persists despite the identification and recall of an at-risk contact lens solution, AMO Complete Moisture Plus, in 2007.

Acanthamoeba infection presents with similar nonspecific symptoms as bacterial keratitis. Pain that is out of proportion to clinical findings is classic but not universal. Early corneal infection manifests as epithelial involvement, including elevated epithelial lines that may appear as dendritic, punctuate epithelial erosions, microcysts, and epithelial haze (Figure 12.6). Stromal findings,

FIGURE 12.6 Epithelial haze.

FIGURE 12.7 Ring infiltrates.

which occur later in the infection, include single or multiple stromal infiltrates and nummular keratitis. Ring infiltrates or satellite lesions usually suggest advanced disease (Figure 12.7). Tropism of the *Acanthamoeba* organism for corneal nerves causes radial keratoneuritis, the reason for the extreme pain (Figure 12.8).

Diagnosis is typically delayed because the clinical appearance mimics other etiologies. Early infections are commonly treated as bacterial keratitis, especially because many practitioners rely on empiric treatment with broad-spectrum topical fluoroquinolones. Early disease is commonly misdiagnosed as herpes simplex, whereas later disease can be confused with fungal keratitis characterized by severe pain and a minimally necrotic deep stromal infiltrate. A significantly poorer prognosis is associated with deeper corneal involvement, which is increasingly likely with this delay in diagnosis.

FIGURE 12.8 Radial keratoneuritis.

Treatment of *Acanthamoeba* keratitis may last weeks to years, involves toxic medications, and may be unsuccessful in curing the infection if the infection involves the deep cornea or involves a resistant pathogen. A combination of topical antiamebic agents, including biguanides (e.g., PHMB and chlorhexidine), and diamides (e.g., propamidine) are typically used. Second-line agents include azole and triazole antifungals, specifically voriconazole (oral and/or topical) or clotrimazole, and topical neomycin. Monotherapy with a biguanide alone can be curative. Most of these medications are not available commercially in the United States and they must be either compounded (biguanides, topical azole and triazole antifungals) or imported (diamidines) by a specialty pharmacy before use. Medications are often used for months, starting with hourly dosages and tapering off as the clinical situation improves. The use of steroids is controversial; it likely has no role in an appropriately resolving *Acanthamoeba* keratitis, but may be necessary in patients with extraocular inflammatory manifestations such as scleritis or dacryoadenitis.

Fungal infections of the cornea are more common in hot, humid environments, such as India or Florida, where fungal keratitis accounts for 40% and 16% of all cornea infections, respectively. Fungi are ubiquitous in the environment and can be broadly divided into yeast (*Candida* species) and molds (filamentous fungi, e.g., *Fusarium* and *Aspergillus*). Yeast infections are more common in temperate climates while filamentous fungi predominate in more tropical environments. However, trends in the United States show an increasing frequency of filamentous fungal keratitis over the last decade not only with *Fusarium* spp., which remains the single most common corneal pathogen, but also with drug-resistant, uncommon molds such as *Paecilomyces*, *Scedosporium*, and *Alternaria*. The epithelial barrier is the most important defense mechanism against all forms of infectious keratitis, including fungi. By far the most important risk factor for fungal keratitis is ocular trauma, especially when the trauma involves contact with soil or vegetable matter. Other risk factors include ocular surface disease such as neurotropic keratitis and chronic use of steroids. Patients with atopic disease, immunocompromised patients, or those hospitalized in intensive care units are also at increased risk for fungal keratitis. Although contact lens wear has not been considered a major risk factor for fungal keratitis, a cluster of *Fusarium* keratitis cases in otherwise healthy soft-contact lens wearers was noted throughout the world in 2006 (Figure 12.9). Multiple studies around the world found a strong association with the use of a contact lens cleaning solution Renu with MoistureLoc, which was withdrawn from the market in April 2006. This resulted in a substantial reduction of the number of reported cases of *Fusarium* keratitis in contact lens wearers to near the baseline incidence prior to the solution's market introduction.

Clinical signs of fungal infection include nonspecific signs of any corneal infection. Specific clinical features that should raise suspicion include infiltrates with indistinct or "feathery" edges, multifocal infiltrates, satellite lesions, immune rings, and endothelial plaques (Figure 12.10). The patient history is an important clue to the diagnosis as patients typically have a history of outdoor trauma and a waxing and waning course of symptoms and signs that have been unresponsive to empiric management. Severe pain and elevated intraocular pressure are common. Early diagnosis is critical for

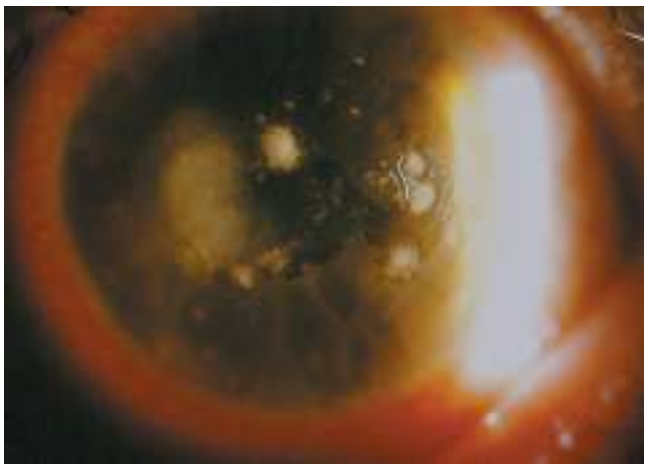


FIGURE 12.9 Fungal keratitis.

successful treatment because ophthalmic topical antifungals have variable penetration into the deep corneal stroma and corneal fungal pathogens have a propensity to proliferate vertically and to penetrate an intact Descemet's membrane, leading to endophthalmitis. The diagnosis of fungal keratitis is often delayed because it is uncommon, resulting in a low index of clinical suspicion, and because the organism can be difficult to recover if it has spread deep into the cornea. In vivo confocal microscopy can be a powerful tool in detecting filamentous fungal pathogens. Culture and vital staining is the gold standard of diagnosis, but is often negative.

Treatment of fungal keratitis is also challenging because currently available antifungal medications have a limited spectrum of activity and often have poor penetration into the cornea. The most widely used topical antifungal medications are the polyenes, amphotericin B, and natamycin (Pimaricin). Natamycin is the only commercially available antifungal topical medication in the United States. Earlier-generation azole compounds have been used topically (clotrimazole and miconazole) and systemically (ketoconazole, fluconazole, and itraconazole). Of the newer triazoles, voriconazole has been used extensively for both topical and systemic treatment of fungal keratitis. Unfortunately, multiple case series and a randomized trial have demonstrated its inferiority to natamycin as a primary empiric agent in this disease. Voriconazole, posaconazole, and the echinocandins (caspofungin and micafungin) remain useful as either adjunctive or secondary agents, however, in ulcers resistant to natamycin and/or amphotericin B, especially if in vitro sensitivities suggest susceptibility. Treatment of fungal keratitis is prolonged and often lasts for weeks to months. The use of a topical steroid is contraindicated because it can worsen disease and interferes with the efficacy of certain antifungal agents.

Iritis

Alice Lorch and Ann-Marie Lobo

Definition of uveitis

The uveal tract in the eye is the darkly pigmented, vascular, "middle layer" of the eye. It sits between the inner retinal layer and outer corneal–scleral layer, and is composed of the choroid, ciliary body, and iris. Uveitis is inflammation of the uveal tract. Uveitis can be classified according to anatomic structures involved: the iris or anterior ciliary body (anterior uveitis or iritis) the posterior ciliary body or anterior vitreous (intermediate uveitis), or choroid (posterior uveitis). Posterior uveitis can also include inflammation of the retina (retinitis), retinal blood vessels (vasculitis), and optic nerve (optic neuritis.) Many of the inflammatory and infectious etiologies of uveitis can cause both anterior and posterior uveitis, known as panuveitis. Therefore, anterior uveitis can be isolated or a harbinger of posterior uveitis and all patients with uveitis should have careful evaluation of both chambers. Only anterior uveitis, or iritis, will be discussed in this chapter, as intermediate and posterior uveitis are discussed elsewhere.

Anterior uveitis is most commonly idiopathic, but can be diagnosed as either inflammatory or infectious in etiology. Anterior uveitis can also be due to reactive inflammation from mild trauma or corneal disease. Neoplasias such as retinoblastoma or lymphoma can present as anterior uveitis, with tumor cells in the anterior chamber. Finally, iritis can be drug-related: cidofovir, diethylcarbamazepine, pamidronic acid, interleukin-3 and interleukin-6, oral contraceptives, quinidine, rifabutin, streptokinase, and sulfonamides are among medications that have been implicated in the past.

Infectious causes are generally either bacterial or viral, but can be related to protozoa or worms. Again, many of these diseases present with anterior segment findings but also have posterior involvement on further examination.

Clinical presentation

Anterior uveitis can present with sudden onset or chronic signs and symptoms. Classic symptoms of acute iritis are eye pain, redness, photophobia, and blurred vision. Examination is significant for conjunctival injection, described as ciliary flush when at the corneal limbus, without discharge. Slit-lamp examination reveals white blood cells floating in the anterior chamber; when white cells are layered forming a visible white line, this is referred to as a hypopyon (Figure 13.1). The presence of a hypopyon should always raise concern for an infectious endophthalmitis in patients with a history of recent surgery, trauma, or possible endogenous source (i.e., fungemia.) Anterior uveitis with hypopyon is otherwise most commonly seen in patients with HLA-B27-related disease or Behçet's disease. Keratic precipitates are another common finding in anterior uveitis; these are deposits of white blood cells on the posterior cornea. Keratic precipitates can be "fine," indicating a nongranulomatous disease such as Fuch's iridocyclitis, HLA-B27-related disease, or juvenile idiopathic arthritis. In granulomatous disease, such as sarcoidosis, syphilis, tuberculosis, or toxoplasmosis, keratic precipitates are large and yellowish, described as "mutton fat." White blood cells can also deposit

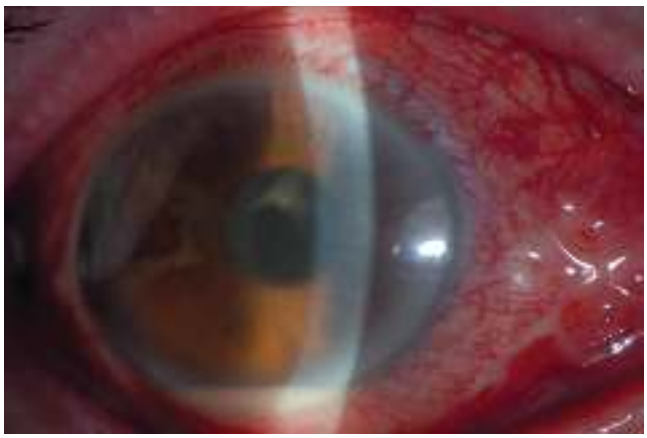

FIGURE 13.1 Slit-lamp photograph of a hypopyon in a patient with infectious endophthalmitis after cataract surgery.

on the iris, particularly in granulomatous uveitis; these are called Busacca nodules if in the iris stroma and Koeppe nodules if at the pupillary margin. Chronic iris inflammation can lead to adhesions between the iris and lens, known as posterior synechiae; these can lead to the appearance of a small or irregular pupil.

Diagnostic tests

Laboratory testing is pursued for patients with anterior uveitis that is recurrent, bilateral, or if there are concerns for a particular systemic disease. A large number of cases of anterior uveitis are classified as "idiopathic" when results of serologies are negative. These cases are thought to be due to an underlying unknown autoimmune or viral condition. Newer diagnostic modalities may help both in distinguishing between known etiologies of uveitis and in making a diagnosis in cases otherwise designated as "idiopathic."

Molecular diagnostic tests have enabled the use of small quantities of ocular fluid samples to be tested for certain infections. Anterior chamber paracentesis is a safe procedure that can be performed by an ophthalmologist at the slit lamp to obtain a small-volume sample of aqueous for testing. Aqueous samples can be tested for antibodies to determine the Goldmann–Witmer coefficient, a ratio of the total immunoglobulin in aqueous compared with that in the serum. A ratio greater than three indicates the true presence of antibodies in ocular fluid (and not just spillover from serum due to leaky inflamed blood vessels). Polymerase chain reaction (PCR), a technique used to amplify small amounts of DNA or RNA for microbial identification, can be used to identify specific viruses in intraocular fluid. Real-time PCR can quantify virus in a small volume of intraocular fluid. PCR does not have high sensitivity for all viruses and so must be used in conjunction with clinical suspicion and other diagnostic tests. Currently, PCR is used to detect herpesviruses (including herpes simplex virus [HSV] type 1 and 2, cytomegalovirus [CMV], Epstein–barr virus [EBV] and varicella-zoster virus [VZV]), toxoplasmosis, and bacterial 16S rRNA.

Infectious etiologies (Box 13.1)

Endophthalmitis

Patients with inflammation or hypopyon in the anterior chamber after intraocular surgery or trauma should be suspected of having endophthalmitis rather than anterior uveitis. Endophthalmitis can be acute, presenting with decreased vision and pain soon after surgery; these infections are generally due to staphylococcus or streptococcus infections. Delayed-onset endophthalmitis after cataract surgery can be due to *Proprionibacterium acnes*. Classically, patients with *P. acnes* endophthalmitis have white plaques on the posterior lens capsule. Endophthalmitis can also be endogenous; this is seen in patients with indwelling catheters, intravenous drug users, or others with risk of bacterial or fungal seeding of the blood. Candidemia can lead to a panuveitis with fluffy white lesions in the retina or vitreous. Endophthalmitis, whether exogenous or endogenous, must be treated immediately by an ophthalmologist with injection of antimicrobial agents into the vitreous or vitrectomy to prevent vision loss.

Herpesviruses

Herpesviruses, including HSV-1 and HSV-2, CMV, or VZV, are the most common type of infectious anterior uveitides. HSV anterior uveitis can be seen in patients with prior or concurrent HSV keratitis; however, simultaneous keratitis is not necessary for diagnosis. Herpes zoster ophthalmicus is caused by involvement of VZV in the ophthalmic branch of the trigeminal nerve. Diagnosis of herpetic uveitis can be made definitively by PCR of an aqueous sample, but treatment, with antiviral agents and topical steroids, is usually initiated based on clinical appearance. Characteristic findings of herpetic uveitis are unilateral disease and sectoral iris atrophy. Herpetic uveitis is one of the few uveitic processes that can be associated with increased intraocular pressure (others include

- Leprosy
- Chikungunya
- Leptospirosis
- Toxoplasmosis
- HIV

sarcoidosis and toxoplasmosis.) Like the HSV virus, CMV can also cause anterior uveitis associated with high intraocular pressure and iris atrophy.

The herpesviruses can cause devastating vision loss if there is posterior involvement. Acute retinal necrosis (ARN) is a rapidly progressive necrotizing retinitis that can lead to retinal ischemia and retinal breaks and requires immediate and aggressive therapy. ARN is most commonly seen in immunocompetent patients, although it also can be seen in the immunocompromised. The initial presentation of ARN can be anterior uveitis and so it is essential that all patients with anterior uveitis receive a dilated fundus examination. Progressive outer retinal necrosis (PORN) is a retinitis similar to ARN that develops primarily in immunocompromised patients and is most commonly associated with VZV. As described above, PCR of ocular fluids can be used to identify herpetic viruses. Treatment of both ARN and PORN is with intravenous antiviral medications (acyclovir, ganciclovir) and potentially intravitreal antiviral medications (ganciclovir, foscarnet).

Syphilis

Syphilis usually produces a granulomatous uveitis (although nongranulomatous presentations have been reported) that can involve all parts of the eye. Congenital syphilis presents with interstitial keratitis accompanied by anterior uveitis that presents in teenage years with "salt-and-pepper" fundus changes. In acquired syphilis, the onset of ocular involvement is in secondary or tertiary disease, and is most commonly iritis. Other common presentations of ocular syphilis include posterior placoid chorioretinitis, retinal vasculitis, vitritis, and papillitis and so a dilated fundus exam is essential for complete diagnosis.

Patients with suspected ocular syphilis should have indirect (rapid plasmin reagent [RPR] or Venereal Disease Research Laboratory [VDRL]) and direct serum testing (fluorescent treponemal antibody [FTA-ABS]). Patients with positive serum tests should undergo lumbar puncture for diagnosis of neurosyphilis. Screening for HIV also should be performed. Ocular syphilis is treated the same as neurosyphilis, with intravenous penicillin G. Topical steroids and mydriatics can be used as an adjunct to systemic treatment. Systemic steroids can be used to prevent a Jarisch–Herxheimer reaction at the time of treatment.

Bartonella species (cat scratch disease)

Bartonella (including *Bartonella henselae* and *Bartonella quintana*) is spread via contact with a contaminated cat. Patients can present with Parinaud's oculoglandular syndrome, which is a constellation of granulomatous conjunctivitis and regional lymphadenopathy. *Bartonella* can also cause a neuroretinitis that clinically presents with optic nerve edema and a "star'-like pattern of exudates in the macula (referred to as a macular star). Anterior uveitis alone is rare, but patients can present with a panuveitis with neuroretinitis. Diagnosis is confirmed by serologies as other infections can also present with neuroretinitis. Treatment with antimicrobial agents, including doxycycline and rifampin, is based on the severity of disease.

Tuberculosis

The diagnosis of ocular tuberculosis (TB) can be very difficult since many patients may have no history of systemic TB. Recent exposure to TB or a positive tuberculin skin test in a patient with chronic granulomatous uveitis should raise suspicion. The recently introduced interferon-gamma release assay (Quantiferon-Gold) can distinguish between exposure to *Mycobacterium tuberculosis* and to atypical mycobacteria or the bacille Calmette–Guérin vaccine; however, this test cannot distinguish between latent and active TB. Aqueous and vitreous cultures are often falsely negative and PCR testing is unreliable. The most characteristic eye findings are granulomatous anterior uveitis with multifocal choroiditis and occasionally choroidal tubercles. Treatment is with an antituberculous multidrug regimen (isoniazid, rifampin, pyrazinamide, ethambutol) and systemic steroids.

Lyme disease

Lyme disease results from tick-borne transmission of *Borrelia burgdorferi* and ophthalmic symptoms can vary and include unilateral or bilateral anterior uveitis, intermediate uveitis, oculomotor palsies, and scleritis. Patients generally present in Stage 2 disease, and may have systemic symptoms of headaches, arthritis, meningitis, or peripheral neuropathies. Presenting ocular complaints can include blurred vision, photophobia, eye pain, or diplopia. Patients should be screened in high-prevalence areas of the Northeastern and Midwestern United States, in the habitat of the bacteria's vector, the *Ixodes* tick. Serologic testing is performed using screening ELISA followed by a confirmatory Western blot. Treatment for ocular involvement is equivalent to that for neurologic involvement in Lyme disease, most commonly with intravenous ceftriaxone. Topical steroids and mydriatics can be used as an adjunct to systemic treatment.

Rare diseases

Brucella is a rare cause of uveitis; this bacterium is harbored in the genitourinary tract of sheep and cows and transmitted via direct contact or airborne spread from contaminated animals, meat, or dairy products. *Brucella* produces a granulomatous uveitis and is treated with topical steroids and mydriatics. Traditional systemic therapy includes doxycycline with either rifampin or streptomycin.

Whipple's disease, primarily a disease of malabsorption of the gastrointestinal tract, is caused by *Tropheryma whipplei*. Patients generally present with a chronic nongranulomatous anterior uveitis but can also have vitritis and sheathing of the retinal vessels. Definitive diagnosis is made by jejunal biopsy. Treatment includes an initial course of either IV ceftriaxone or IV streptomycin with penicillin G followed by a prolonged course of trimethoprim–sulfamethoxazole for systemic disease; periocular or systemic steroids can often make the uveitis worse.

The majority of patients with ocular leprosy present with bilateral, chronic and relapsing iridocyclitis. Examination can reveal prominent corneal nerves with a "beaded" appearance. Iris "pearls," or aggregations of bacilli, are pathognomonic for the disease; these are white spots along the pupil margin that can coalesce and become pedunculated, falling into the anterior chamber and leaving an atrophic appearance to the iris. Involvement of the posterior segment is rare but there have been reports of white lesions in the peripheral fundus, also resembling "pearls." Treatment is for systemic disease, with dapsone and rifampin for paucibacillary disease and the addition of clofazimine for multibacillary disease.

Chikungunya is a viral disease spread by *Aedes* mosquitoes, initially discovered in Africa but with outbreaks in Asia and India. The disease is characterized by persistent fever, arthritis, and skin rash. The most common ocular manifestations are iridocyclitis and retinitis. Treatment is with systemic and topical anti-inflammatory medications.

Leptospirosis is transmitted via bacteria in the urine of infected animals; it is active as long as it is moist and so outbreaks commonly occur in tropical environments. Patients can present with a nongranulomatous hypopyon anterior uveitis or panuveitis with vitritis and retinal vasculitis. Leptospirosis is treated with systemic antibiotics, although evidence for their efficacy has not been conclusive. IV penicillin G is generally used in severe cases, although doxycycline and third-generation cephalosporins have also been tried.

Of note, toxoplasmosis is the most common infectious uveitis in the world and can present with anterior chamber inflammation, but findings are predominantly posterior uveitis and as such it is not discussed in detail in this chapter.

Human immunodeficiency virus

HIV can cause a nongranulomatous uveitis as part of seroconversion or in association with a high viral load. Patients with HIV anterior uveitis often have fine keratic precipitates and no retinal findings. The inflammation does not respond to topical steroids but does respond well to highly active antiretroviral therapy. The association between HIV and anterior uveitis is more frequently due to the increased susceptibility of HIV patients to infections such as syphilis or CMV.

Summary

Anterior uveitis can be caused by a variety of infectious or inflammatory diseases. Diagnosis of a particular infection is made based on clinical history as well as ocular and systemic exam findings. All patients with anterior uveitis should also have a thorough examination of the posterior segment for signs of intermediate or posterior uveitis. Ocular inflammation after surgery or in the setting of disseminated infection should always raise the concern for infectious endophthalmitis, which must be treated emergently by an ophthalmologist. Emerging diagnostic techniques might enable more rapid diagnosis of known infectious causes or the discovery of novel infectious etiologies of uveitis in the future.

Retinitis

Hillary C. Stiefel and Daniel M. Albert

This chapter discusses the most clinically important forms of infectious retinitis: cytomegalovirus retinitis (CMVR), acute retinal necrosis (ARN), progressive outer retinal necrosis (PORN), ocular toxoplasmosis, and syphilitic retinitis. Additional infectious etiologies of retinitis (including Zika virus and tuberculosis) are well described in the literature but beyond the scope of this chapter. For information on endophthalmitis, including bacterial and fungal etiologies, please see the dedicated chapter in this text.

CMV retinitis

CMVR is the most common and clinically significant opportunistic ocular infection seen in immunocompromised patients, including those with AIDS as well as patients with compromised immunity following organ transplantation or chemotherapy for systemic malignancy. With the extensive use of highly active antiretroviral therapy (HAART) in HIV-positive patients, there has been a marked decrease in the incidence of CMVR in these patients (23 per 10,000 HIV/AIDS cases in the pre-HAART era to 8 per 10,000 HIV/AIDS cases in the post-HAART era). Rarely, CMVR may occur in apparently immunocompetent individuals due to relative immune dysfunction related to advanced age, diabetes, and use of steroids or other immunosuppressive agents.

CMVR usually begins as a unilateral condition but progresses to involve the contralateral eye in approximately 20% of cases. The onset may be insidious, with 50% of patients being asymptomatic. In patients known to have HIV or to be immunosuppressed, CMV retinitis has traditionally been diagnosed via the recognition of pathognomonic clinical exam findings, with the diagnosis confirmed by positive blood cultures for CMV. In recent years, aqueous and/or vitreous fluid analysis for viral DNA by polymerase chain reaction (PCR) has become an indispensable tool in the initial diagnosis of suspected infectious retinitis. Real-time quantitative PCR can also be used to monitor patients while on therapy or to ensure that viral DNA concentration is not increasing in the setting of refractory disease, which may occur in patients with viral strains that develop antiviral drug resistance.

During the initial stage of active CMVR, three patterns of retinal lesions have been described: (1) fulminant/edematous pattern consisting of large areas of retinal hemorrhage in a background of confluent retinal necrosis (Figure 14.1), (2) indolent/granular pattern consisting of granular satellite lesions with little or no hemorrhage, and (3) exudative pattern, also known as frosted branch angiitis, with extensive vascular sheathing. In each of these clinical patterns, vitreous inflammation is minimal or absent. Following the active retinitis, the second stage of CMVR is characterized by widespread necrosis and retinal tears. Visual loss may be severe if the macula or optic nerve is involved. Without treatment, CMV retinitis will become bilateral in 80% of cases and eventually will result in blindness from retinal atrophy, retinal detachment, or optic nerve involvement.

Successful treatment of CMVR depends on the restoration of immune function. In HIV/AIDS patients, the use of HAART lowers the progression of CMV retinitis and incidence of vision loss. To halt progression of the retinitis and improve visual outcomes, treatment with a virostatic agent that competitively inhibits CMV DNA polymerase is also required. The current, recommended systemic treatment options for CMVR

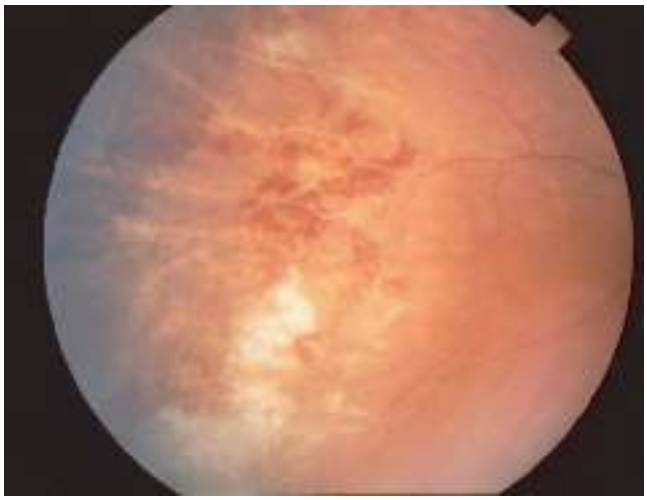

FIGURE 14.1 Photo of the peripheral fundus showing an area of retinal necrosis associated with retinal hemorrhages, representing an active chorioretinal lesion due to cytomegalovirus retinitis.

include ganciclovir, valganciclovir, and foscarnet (see Table 14.1). The choice of the antiviral agent and its route of delivery should be based on the potential medication side effects and the effectiveness of prior treatments.

Ganciclovir may be administered intravenously, orally, or intravitreally. Intravenous (IV) ganciclovir can be used as induction therapy for 14 days, followed by maintenance therapy by either an IV or oral route. In patients with impaired renal function, the full dosage of ganciclovir cannot be tolerated and requires reduction. The most common side effect of ganciclovir is neutropenia, which arises in 20% to 40% of patients and is reversible on discontinuation of the drug. A sustained-release ganciclovir implant placed directly into the vitreous cavity of the eye was previously available but was removed from the market in 2014.

The introduction of valganciclovir, a prodrug of ganciclovir with good penetration into the vitreous, has considerably advanced the treatment of CMVR by providing an oral treatment option. It has become the mainstay CMVR treatment for induction and maintenance therapy. It is usually dosed orally for 3 to 6 weeks, followed by prophylactic dosing. A treatment response equivalent to IV ganciclovir has been demonstrated, and the adverse effects of the two drugs are similar.

Foscarnet is an alternate treatment option for CMVR. It is typically administered intravenously for 3 weeks as induction therapy, followed by maintenance therapy indefinitely. The most common side effect of foscarnet is nephrotoxicity, which occurs in 25% of patients and is reversible with early cessation of the drug. Because foscarnet undergoes renal elimination and is nephrotoxic, careful monitoring of renal function is necessary. However, it is often effective in the treatment of ganciclovir-resistant retinitis and remains an important treatment option.

Intravitreal therapy should be considered in addition to systemic therapy if the retinal disease threatens the fovea. Either intravitreal foscarnet or intravitreal ganciclovir is generally used in such cases. Given the high concentration of drug delivered via intravitreal injection, this mode of therapy may also be beneficial in patients with recurrent disease or in whom there are concerns for relative drug resistance.

There may be differences between the treatment of CMVR seen in HIV patients versus non–HIV-related CMVR, which has recently been termed *chronic retinal necrosis*. In the non-HIV patient

TABLE 14.1 **THERAPY FOR VIRAL RETINITIS**

Drug	Regimen	Side effects	Viral coverage	Condition
Ganciclovir	**IV:** 500 mg q12h × 14 days **IVt:** 2–5 mg/0.1 mL, 3×/wk	Granulocytopenia, thrombocytopenia, anemia	HSV1, CMV>>VZV, HSV2	CMVR, ARN, PORN
Valganciclovir	**Oral:** 900 mg BID × 3–6 wks **Prophylactic dose:** 450 mg PO BID	Granulocytopenia, anemia, headache, GI symptoms, renal dysfunction	HSV1, CMV>>VZV, HSV2	CMVR, ARN, PORN (not initial tx; maintenance only)
Foscarnet	**IV:** 40–60 mg/kg q8h ×3 wks **IVt:** 2.4 mg/0.1 mL q3–4d	Nephrotoxicity, seizures/ headache, GI symptoms	HSV1, HSV2, VZV > CMV	ARN, PORN, CMVR
Acyclovir	**IV:** 1,500 mg/m^2/d divided q8h ×14 days followed by **Oral:** 800 mg 5×/d × 4–6 wks **Prophylactic dose:** 400 mg PO BID–TID	GI symptoms, hypersensitivity reactions, renal and/or CNS dysfunction	HSV1, HSV2, VZV, EBV >> CMV	ARN, PORN
Valacyclovir	**Oral:** 1–2 g q8h × 6 wks **Prophylactic dose:** 1 g PO BID	GI symptoms, hypersensitivity reactions, renal and/or CNS dysfunction	HSV1, HSV2, VZV >> CMV	ARN, PORN (not initial tx; maintenance only)
Famciclovir	**Oral:** 500 mg q8h	Headache, GI symptoms, rash	HSV1>HSV2>VZV	ARN, PORN (not initial tx; maintenance only)

Abbreviations: IV = intravenous; IVt = intravitreal; CMVR = cytomegalovirus retinitis; ARN = acute retinal necrosis; PORN = progressive outer retinal necrosis; HSV = herpes simplex virus; ZVZ = varicella zoster virus; BID = twice daily; TID = three times daily; GI = gastrointestinal; CNS = central nervous system; tx = treatment; wks = weeks; mos = months

with this more indolent, granular retinitis, intravitreal therapy alone may potentially be used to induce regression of retinitis while reducing systemic medication side effects.

The initial response to any antiviral therapies usually occurs 1 to 2 weeks after the initiation of the induction regimen and is evidenced by termination of the extension of the retinal lesions and gradual atrophy of the involved retina. Ophthalmologists should examine patients' fundi every 2 to 3 weeks to monitor the effectiveness of the antiviral therapy. Recurrence of CMV retinitis occurs in 30% to 50% of patients receiving maintenance doses of systemic antiviral therapy. The treatment of recurring CMVR is reinduction for 2 weeks followed by indefinite maintenance therapy. In the era of HAART therapy, HIV-positive patients with CMV retinitis having a sustained CD4+ T-cell count >100 cells/mm^3 for 3 to 6 months can terminate maintenance therapy. However, maintenance therapy needs to be restarted if the immune status is compromised (CD4+ T-cell count 50–100 cells/ mm^3). Furthermore, these patients should undergo ophthalmic screening at 3- to 6-month intervals, depending on the patient's underlying immune status.

Complications of CMVR can include retinal detachment, which in one study occurred at a median interval of 1.5 months from the time of initial diagnosis. Retinal detachment is generally repaired using vitrectomy surgery with silicone oil instillation.

Acute retinal necrosis

ARN is a necrotizing retinitis most often associated with infection by the varicella-zoster virus (VZV) or, less commonly, the herpes simplex virus (HSV) types 1 and 2. In addition, rare reports of CMV and Epstein–Barr virus (EBV) causing ARN have appeared in the literature. Although initially described only in immunocompetent patients, recent cases have been reported in immunosuppressed individuals, including those with AIDS.

Clinically, ARN presents as patchy or confluent areas of white retinal necrosis in the far periphery (Figure 14.2), which may spread to the posterior pole rapidly within days. The onset of ARN typically is unilateral, although bilateral involvement may occur in up to 30% of patients, usually within several weeks of onset. In addition, moderate to severe vitritis and occlusive retinal vasculitis (arteritis and phlebitis) are seen. Anterior uveitis, ischemic vasculopathy involving the optic nerve, and macular edema may be associated findings. The active phase of inflammation generally lasts several weeks and is followed by a convalescent phase. As many as 52% of patients with ARN develop retinal breaks and subsequent rhegmatogenous retinal detachments. Retinal detachments may occur from 9 days to 5 months after the onset of retinitis.

FIGURE 14.2 Photo of the peripheral fundus showing confluent white areas of retinal necrosis with occlusive retinal vasculitis and retinal hemorrhages suggestive of acute retinal necrosis.

Early initiation of appropriate antiviral medication is paramount in the treatment of ARN. This serves to eliminate active viral infection in the involved eye and reduces the risk of involvement of the fellow eye. Historically, patients were hospitalized in order to receive IV acyclovir for 14 days followed by oral acyclovir for 4 to 6 weeks. In recent years, however, there has been a shift toward outpatient management using oral and intravitreal antivirals. Oral valacyclovir and famciclovir are both prodrugs that are active against VZV and HSV and can be used as alternate induction agents because they have greater bioavailability and achieve systemic concentrations similar to that of IV acyclovir. Valganciclovir is another oral treatment option. These antiviral medications are generally slowly tapered after complete resolution of retinitis is observed.

Intravitreal injection of antiviral agents can also be given in cases of severe or refractory viral retinitis. Early administration of intravitreal antivirals also provides an opportunity for vitreous sampling (akin to a "tap and inject" procedure for endophthalmitis), allowing for PCR-based analysis to help identify the causative agent. Intravitreal foscarnet has been used to treat ARN caused by HSV and VZV. Intravitreal ganciclovir may assist in treatment of necrotizing herpetic retinitis in immunocompetent patients.

Systemic or ocular corticosteroids are often used to treat intraocular inflammation and associated intraocular sequelae but should only be added after initiation of antiviral therapy. The use of prophylactic retinal laser to decrease the rate of retinal detachment in patients with viral retinitis has been an issue of great debate. Several studies have reported this to be of benefit when applied posterior to areas of active retinitis, while others have found no decrease in the risk of retinal detachment. Without prospective randomized controlled studies, this question may not be definitively answered.

Progressive outer retinal necrosis

PORN is a necrotizing retinitis that occurs in immunocompromised individuals (e.g., AIDS patients with low CD4 counts or posttransplant patients). It is rapidly progressive, highly destructive, and almost exclusively caused by infection with VZV. Extensive multifocal retinal lesions tend to begin at the posterior pole and spread toward the peripheral area, with rapid coalescence of satellite lesions (Figure 14.3). There is minimal vitritis, relative sparing of the retinal vasculature, and often little to no pain or photophobia, distinguishing this clinical presentation from that of ARN. The condition often starts in one eye, with the other eye frequently becoming involved in weeks to months. PORN tends to have a worse visual prognosis than ARN. There is a high risk of profound vision

loss secondary to retinal necrosis and retinal detachment, with two-thirds of patients progressing to no light perception (NLP) vision.

Early initiation of aggressive systemic and intravitreal antiviral therapy is essential in the treatment of PORN. Systemic antiviral therapy includes IV foscarnet, IV ganciclovir, or IV acyclovir, although PORN may have a poor response to acyclovir alone. Better visual outcomes have been associated with combination therapy using IV ganciclovir and foscarnet, intravitreal ganciclovir combined with IV acyclovir or foscarnet, or intravitreal ganciclovir with foscarnet. After response to treatment, patients may be given maintenance dosing of oral valacyclovir, valganciclovir, or famciclovir.

Ocular toxoplasmosis

Ocular toxoplasmosis accounts for 30% to 50% of all cases of posterior uveitis and is caused by the obligate intracellular parasite *Toxoplasma gondii*. Infection may be congenital through transplacental transmission or acquired through contact with cat excreta or by ingestion of oocysts from undercooked meat. Most cases of ocular toxoplasmosis occur as a result of reactivation of congenital ocular lesions.

Symptoms of active infection include blurred vision and vitreous floaters. Most commonly, ocular toxoplasmosis presents as a white-yellow area of focal necrotizing retinitis adjacent to an old atrophic chorioretinal scar (Figure 14.4). Inflammation of the vitreous is typically present over the area of active retinitis, and granulomatous iridocyclitis or optic nerve swelling may also be present. Occasionally, toxoplasmosis can cause massive vitreous inflammation resulting in a "headlight in the fog" appearance. In HIV-positive individuals, the appearance of toxoplasmosis can be different from that seen in immunocompetent patients, often being much more diffuse, hemorrhagic, and potentially unassociated with scars from earlier infections. The various complications associated with larger lesions include rhegmatogenous or exudative retinal detachment, macular edema, retinal vessel occlusions, subretinal neovascularization, and epiretinal membranes.

Not all active retinal lesions require treatment when present in immunocompetent individuals. Small peripheral lesions, which often are self-limited and not visually threatening, can be observed. Without treatment, active lesions generally heal in 2–4 months. Medical therapy is indicated when the toxoplasma lesions involve or threaten the macula or optic nerve or when visually disabling vitreous inflammation is present.

The goal of treatment for ocular toxoplasmosis is to halt the infectious process and reduce scarring of the retina and vitreous (Table 14.2). The combination of pyrimethamine, sulfadiazine, and corticosteroids is considered the "classic" therapy for ocular toxoplasmosis. Pyrimethamine requires weekly complete blood counts and may be administered with folinic acid, 5 mg orally twice weekly, to reduce the incidence of bone marrow suppression. Prednisone at a dosage of 60 to 80 mg/d is often added to the treatment regimen after 3 days of antibiotic treatment and rapidly tapered based on clinical response and patient tolerance. Steroids should never be used in the treatment of ocular toxoplasmosis without the concurrent use of antibiotic agents.

A variety of other antibiotics have also been found to be effective in treating toxoplasmosis, greatly expanding the traditional treatment options. Clindamycin has been suggested in combination with sulfadiazine and pyrimethamine for severe ocular toxoplasmosis infections. Alternatively, intravitreal clindamycin has been used as local therapy in combination with dexamethasone. Trimethoprim-sulfamethoxazole is also usually effective and well-tolerated as an alternative treatment. Oral atovaquone has also been demonstrated to be effective as a single agent and has been shown in animal models to be active against the bradyzoite form of *T. gondii*. Maintenance therapy with pyrimethamine–sulfadiazine is useful in severely immunocompromised patients.

Syphilitic retinitis

Syphilis, caused by the spirochete *Treponema pallidum,* is known as the "great mimic" or "imitator" given its varied manifestations in the

TABLE 14.2 **TREATMENT OF OCULAR TOXOPLASMOSIS**

Drug	Dose	Side effects
Pyrimethamine[a]	75–100 mg PO loading dose, then 25–50 mg/d PO × 4–6 wks	Bone marrow suppression, hypersensitivity reaction, photosensitivity
Sulfadiazine[a]	2–4 g PO loading dose, then 1 g PO QID × 4–6 wks	Bone marrow suppression, hypersensitivity reaction crystalluria
Trimethoprim-sulfamethoxazole	160 mg/800 mg PO BID × 6 wks	Bone marrow suppression, hypersensitivity reaction
Atovaquone	750 mg PO QID × 3 mos	Hypersensitivity reaction
Clindamycin[b]	**Oral:** 300 mg QID × 4–6 wks **IVt:** 1.5 mg/0.1 mL weekly × 4 wks	**Oral:** Diarrhea, pseudomembranous colitis **IVt:** Risks of IVt injection
Dexamethasone	**Ivt:** 400 µg/0.1 mL given with IVt Clindamycin.	**IVt:** Risks of IVt injection, elevated IOP, cataract

[a]These antibiotics are used in combination as "classic therapy," along with oral prednisone and folinic acid.
[b]Oral clindamycin is used in combination with classic therapy for severe ocular toxoplasmosis infections.
Abbreviations: IVt = intravitreal; BID = twice daily; QID = four times daily; PO = by mouth; IOP = intraocular infection; wks = weeks; mos = months

eye. While the most common presentation is uveitis, other findings can include vitritis, retinal vasculitis, retinitis, papillitis, and scleritis. The prevalence of syphilis worldwide has increased over the past 10 to 15 years, especially in men who have sex with men and patients co-infected with HIV.

Retinitis caused by syphilis usually presents in one of two ways: (1) a punctate inner retinitis with dew-drop like collections along the surface of the retina (Figure 14.5) or (2) a more diffuse yellowish or grayish outer retinitis which can form consolidated lesions (with the latter termed *acute syphilitic posterior placoid chorioretinitis*). The retinitis is often associated with vasculitis, vitreous inflammation, and anterior segment inflammation.

Misdiagnosis can lead to a delay in appropriate treatment and subsequent vision loss, particularly if the ocular condition is erroneously treated as a noninfectious uveitis upon presentation. For this reason, maintaining a high index of suspicion and ordering appropriate diagnostic testing is paramount. Testing should include both treponemal tests (FTA-ABS or MHA-TP) and nontreponemal tests (VDRL or RPR). Newer testing, including PCR assays and rapid specific treponemal tests, may be available in some clinical settings. All patients with syphilitic eye disease should undergo a lumbar puncture to aid in the diagnosis of possible neurosyphilis and guide therapy. While ocular syphilis is always a sign of tertiary syphilis, the presence of optic neuritis and retinitis specifically are considered diagnostic of neurosyphilis. Thus, treatment of syphilitic retinitis requires a 14-day course of IV aqueous penicillin G at 3 to 4 million units every 4 hours. Therapeutic success may be gauged by improvement in clinical findings and seroconversion or low titers on subsequent nontreponemal (VDRL or RPR) testing. Once the infection has been treated, treatment with corticosteroids may be used for any residual ocular inflammation. If left untreated, syphilitic retinitis can lead to worsening inflammation, secondary glaucoma, retinal necrosis, and optic atrophy. With early diagnosis and appropriate therapy, however, patients with syphilitic retinitis can have good visual outcomes.

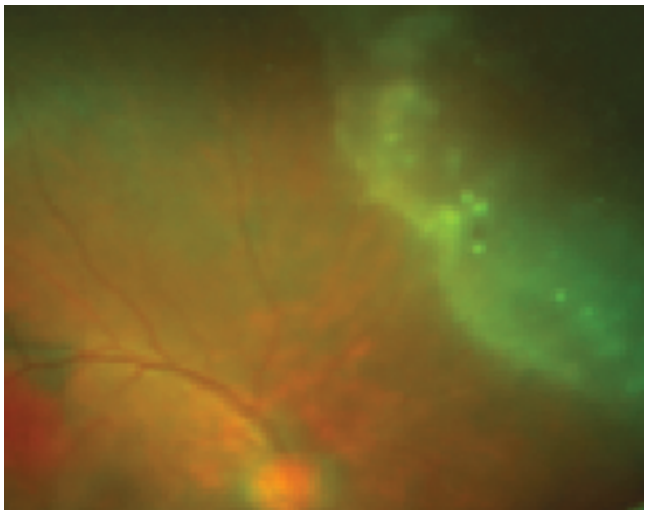

FIGURE 14.5 Fundus photo showing an area of retinal whitening with a discrete, scalloped border and numerous yellowish white precipitates characteristic of syphilitic punctate inner retinitis with dewdrop-like collections along the surface of the retina.

Endophthalmitis

Roy D. Brod, Harry W. Flynn, Jr., and Lili G. Kaplan

Introduction

Endophthalmitis is a vision-threatening inflammation of the inner eye fluids and tissues. Infectious endophthalmitis results from either exogenous or endogenous entry of microbes into the eye. In reported clinical series, exogenous endophthalmitis is much more common than endogenous (or metastatic) endophthalmitis. By far the most common cause of exogenous infection is intraocular procedures. Until recently, cataract surgery was the most frequently performed type of intraocular procedure, accounting for the greatest number of exogenous endophthalmitis cases. Intravitreal injection has now surpassed cataract surgery as the most frequently performed intraocular procedure and consequently is a significant contributor to the total number of exogenous endophthalmitis cases reported. Exogenous endophthalmitis can also occur after other types of intraocular surgery, including secondary lens implantation, glaucoma filtering surgery, vitrectomy surgery, and corneal transplantation. Organisms may also enter the eye during penetrating trauma, intraocular injection of medication, and from contiguous spread into the eye from an infected corneal ulcer. Gram-positive bacteria are the most common cause of exogenous endophthalmitis.

Incidence

Postoperative endophthalmitis cases from the University of Miami (Bascom Palmer Eye Institute) over an 8-year period (2002–2009) demonstrated the incidence of nosocomial endophthalmitis after cataract surgery to be 0.025%. In another retrospective series of endophthalmitis cases occurring after intravitreal medication injection from Bascom Palmer Eye Institute (2005–2017) the rate of endophthalmitis was 0.013%. Endophthalmitis occurs after open-globe injuries in 3% to 30% of patients depending on the nature of the injury and following glaucoma filtering surgery in 0.45% to 1.3% of cases. The rate of development of *Candida* endogenous endophthalmitis in patients with documented candidemia has been reported to range from 2.8% to 45%. Endogenous bacterial endophthalmitis is less common than fungal infection with an incidence of 2% to 11% in patients with septicemia.

Clinical features

Most cases of acute-onset endophthalmitis post-cataract surgery present within 2 weeks of intraocular surgery (Figure 15.1). Symptoms may start as early as 12 hours after the surgery. The classic symptoms include marked visual loss and ocular pain in 75% of cases. The loss of vision is typically profound, and vision is reduced out of proportion to the usual postoperative course. The presenting signs often include lid edema, conjunctival injection and swelling, conjunctival discharge, corneal edema, anterior chamber inflammation,

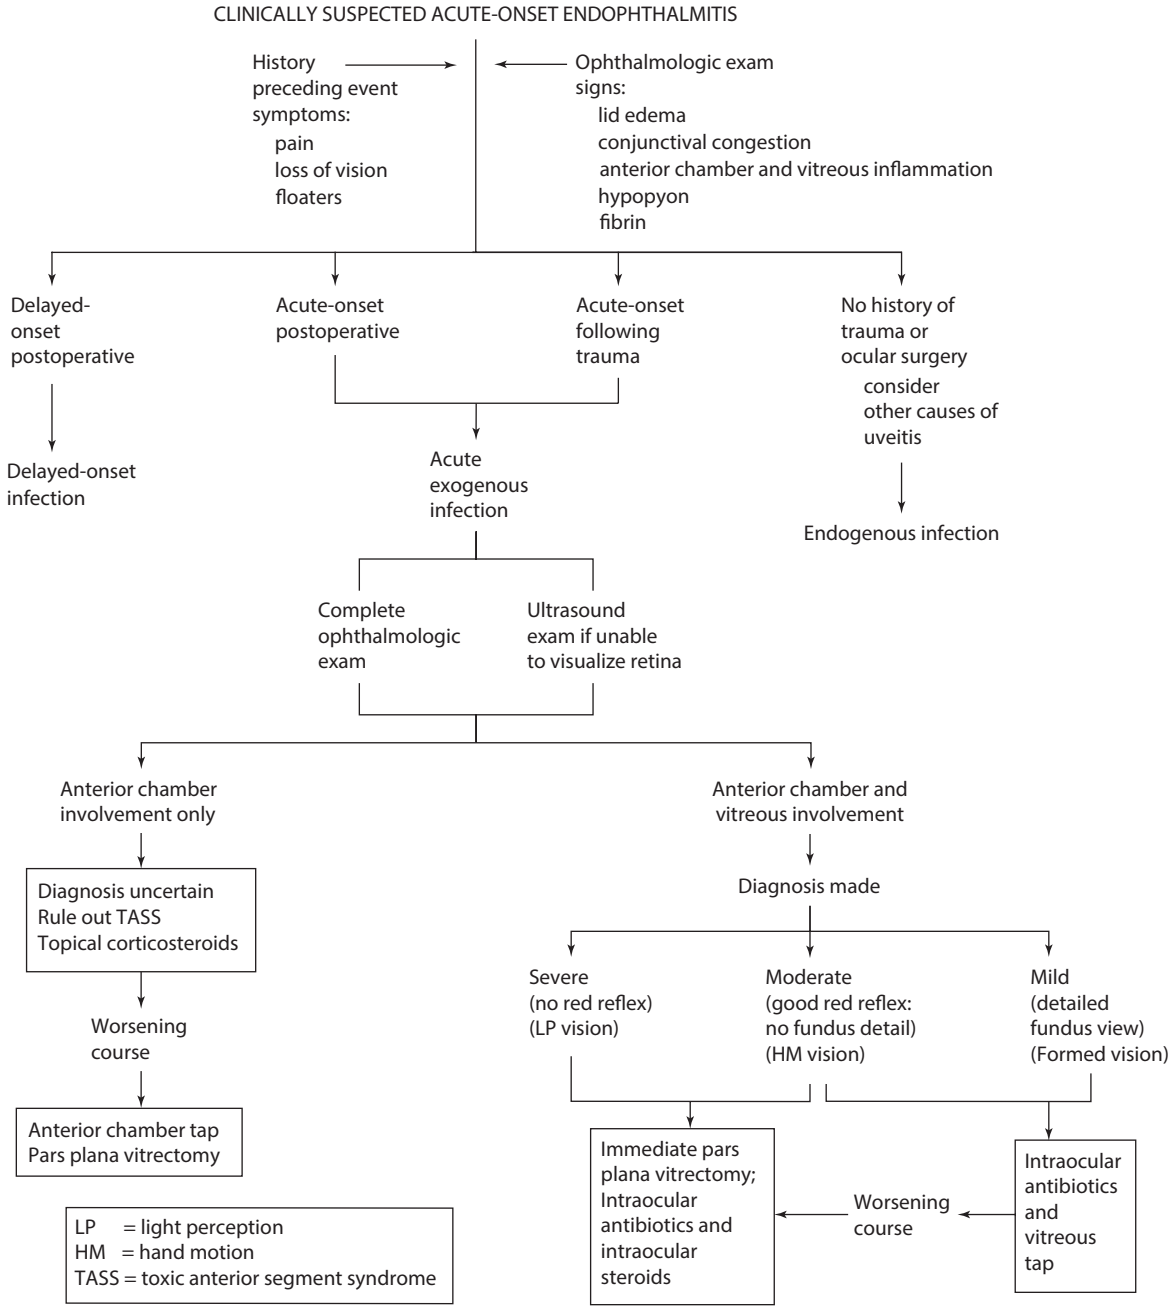

FIGURE 15.1 Algorithm for management of acute-onset endophthalmitis.

fibrin formation, and vitreous inflammatory response. In most cases, a layer of inflammatory cells (hypopyon) can be visualized in the inferior portion of the anterior chamber (Figure 15.2). Redness and purulent discharge from the conjunctiva and lid margins are also commonly seen. A severe intraocular inflammatory response will often obscure a view of the posterior pole and may cause loss of the red reflex. In these cases echographic exam of the eye may be useful in ruling out posterior segment complications such as retinal detachment and retained lens fragments.

In the Endophthalmitis Vitrectomy Study (EVS), the coagulase-negative staphylococci were the most commonly cultured organisms (68%) among patients with confirmed growth. Other gram-positive organisms were cultured in 22% of patients and included *Streptococcus* and *Staphylococcus aureus*. Gram-negative organisms were isolated in 6% of the cases in the EVS, and more than one species was confirmed in 4% of the cases. Fortunately, the coagulase-negative staphylococci are one of the least virulent causes of acute-onset postoperative endophthalmitis. *S. aureus*, *Streptococcus* spp., and the gram-negative organisms usually produce a more rapidly progressive and fulminant inflammation often leading to severe visual loss.

Another subgroup of post-cataract surgery endophthalmitis is the delayed-onset category (Figure 15.3). These patients present 6 weeks or more after cataract surgery with a slowly progressive,

FIGURE 15.2 Hypopyon (layering of white blood cells in the anterior chamber) in an eye with acute-onset post–cataract surgery endophthalmitis.

often milder, inflammatory response. The inflammation can be isolated to the anterior segment or involve both the anterior segment and vitreous. The intraocular inflammation may respond initially to topical steroid therapy but usually recurs as the topical steroids are tapered. A common cause of delayed-onset postoperative endophthalmitis is *Propionibacterium acnes*. This is a ubiquitous, gram-positive, non–spore-forming pleomorphic bacillus. Clinical features of intraocular infections caused by this organism include granulomatous inflammation with large keratitic precipitates (clumps of inflammatory cells) on the corneal endothelium. A characteristic diagnostic feature is the presence of white intracapsular plaque, which has been shown to be composed of organisms mixed with residual lens cortex (Figure 15.4). Because *P. acnes* is a slow-growing anaerobic organism, it is important for the microbiology laboratory to be instructed to keep these anaerobic cultures for at least 2 weeks. Other organisms responsible for delayed-onset

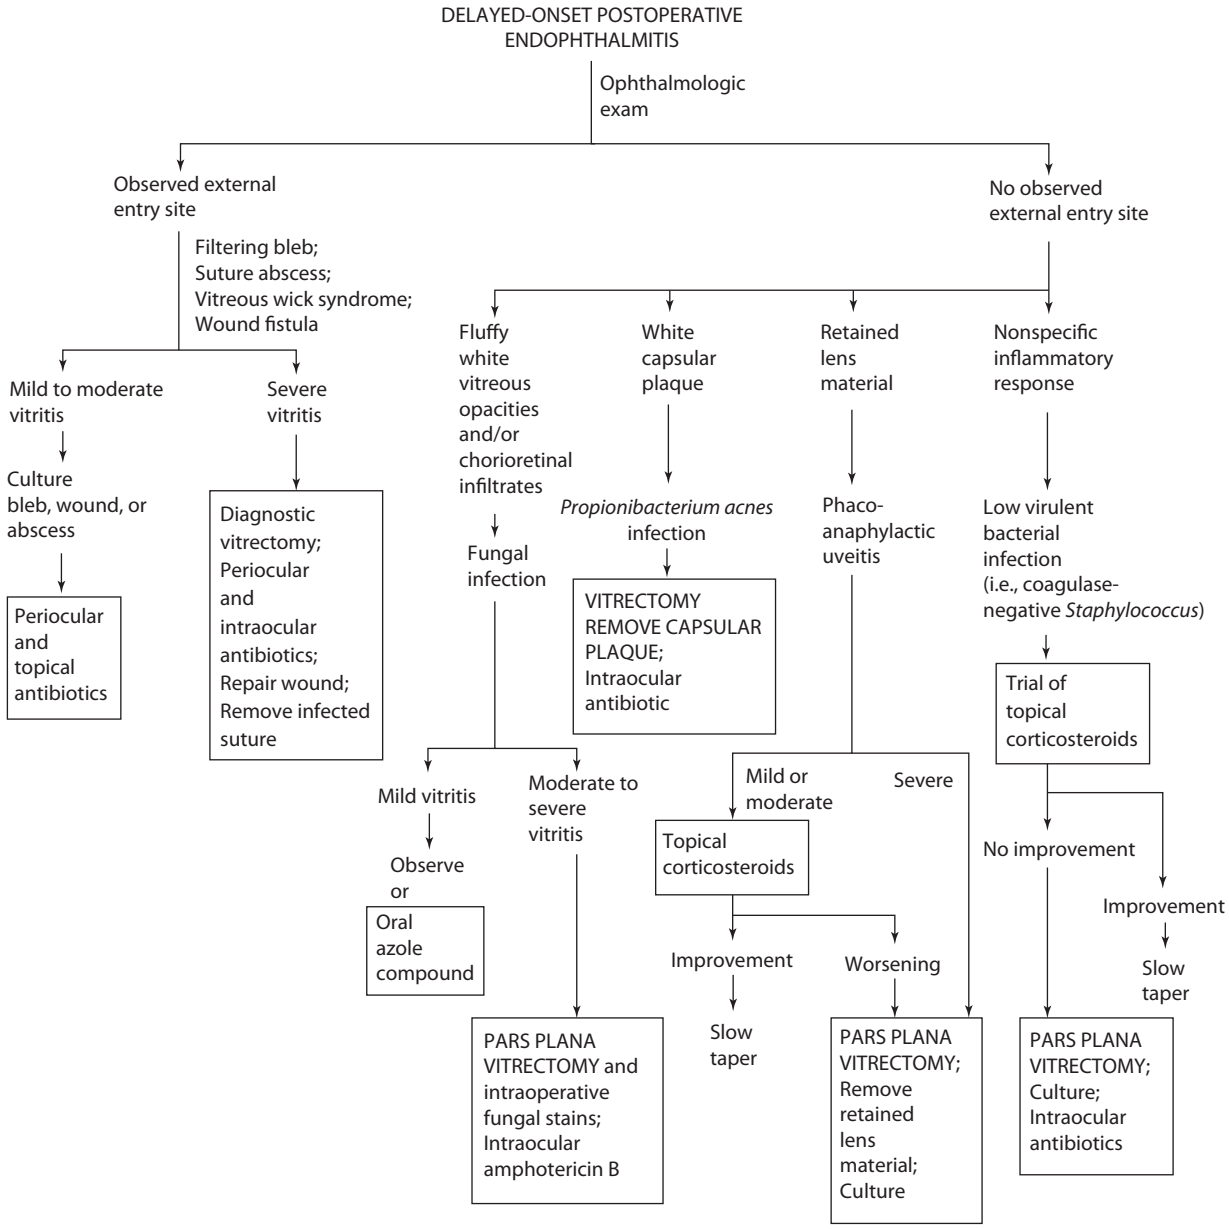

FIGURE 15.3 Algorithm for management of delayed-onset endophthalmitis.

FIGURE 15.4 White capsular plaque in a patient with *Propionibacterium acnes* endophthalmitis.

TABLE 15.1 **EXOGENOUS ENDOPHTHALMITIS CATEGORIES AND MOST FREQUENTLY ASSOCIATED ISOLATES**

Exogenous endophthalmitis categories	Most frequent isolates
Acute-onset postoperative	Coagulase negative staphylococcus
Delayed-onset postoperative	*Propionibacterium acnes*
Conjunctival filtering bleb associated	*Streptococcus*
Open globe-associated	*Bacillus* spp.
Associated with microbial keratitis	Fungi
Associated with intravitreal injections	*Staphylococcus* and *Streptococcus*

postoperative endophthalmitis include *Candida*, *Staphylococcus epidermidis*, and *Corynebacterium* species.

Delayed-onset endophthalmitis associated with conjunctival filtering blebs may present months or even years after glaucoma filtering surgery. The organisms enter the eye directly through the thin wall of the conjunctival bleb, which may develop purulent material initially (Figure 15.5). The presenting symptoms and signs are similar to acute-onset postoperative endophthalmitis. Streptococcal species are the most common organisms isolated. *Haemophilus influenzae* is also a common cause of this category of endophthalmitis. Because these organisms are more virulent than those causing acute-onset postoperative endophthalmitis, the visual outcomes are generally worse. Optic nerve damage from the preexisting glaucoma may also be a factor in poor visual outcomes. Fewer than half of the eyes achieve 20/400 or better vision. The treatment is similar to that for acute-onset postoperative endophthalmitis.

Endophthalmitis after open-globe trauma should be suspected whenever a greater than expected inflammatory response is observed. Because the organisms (e.g., *Bacillus* spp. and *Streptococcus* spp.) causing open globe-related endophthalmitis are, in general, more virulent than organisms causing postoperative endophthalmitis, the final visual outcome is often poor. The associated trauma to the eye and the frequent delay in diagnosis also contribute to a poor visual prognosis. A high index of suspicion and early diagnosis are important because even traumatized eyes infected with virulent organisms can sometimes be salvaged when treatment is promptly initiated. Prophylactic antibiotic treatment from high-risk injuries (rural setting, injuries involving vegetable matter or soil, contaminated eating utensils, retained foreign bodies) should be administered. The management of open globe-related endophthalmitis is similar to other endophthalmitis categories and often includes vitrectomy and intravitreal, subconjunctival, and topical antibiotics and steroids.

Endogenous endophthalmitis results from hematogenous spread of organisms to the eye (Table 15.1). Fungi are a more common cause than bacteria, and *Candida albicans* is the most common fungus isolated. The classic ocular finding is white vitreous opacities attached to each other by inflammatory vitreous bands in a configuration termed "string of pearls" (Figure 15.6). The second most frequently encountered fungus is *Aspergillus* spp. *Streptococcus* spp., *S. aureus*, and *Bacillus* spp. are the most common cause of endogenous bacterial endophthalmitis. These patients are frequently debilitated or immunocompromised with indwelling catheters, although endogenous endophthalmitis can occur in drug abusers and rarely in otherwise healthy patients after dental procedures or childbirth. The infection may be caused by a transient bacteremia or fungemia, in which case blood cultures may be negative. Sepsis with deep organ involvement may also be

FIGURE 15.5 Purulent material in a filtering bleb in an eye with endophthalmitis 6 months following glaucoma filtering surgery.

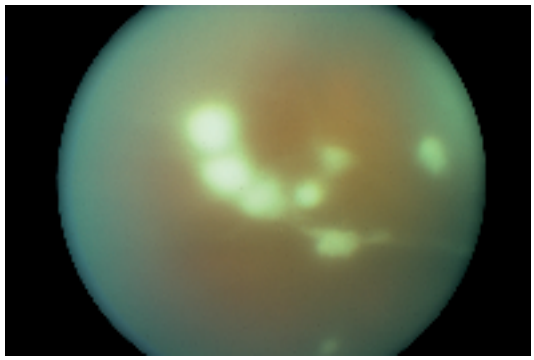

FIGURE 15.6 White inflammatory vitreous opacities in a "string of pearls" configuration in a patient with endogenous *Candida* endophthalmitis.

FIGURE 15.7 Infectious corneal ulcer associated with endophthalmitis.

present. When the source of infection is not apparent, a systemic workup is indicated.

Endophthalmitis can occur from direct spread of organisms into the eye from an infected corneal ulcer (Figure 15.7). Factors predisposing to the development of endophthalmitis associated with microbial keratitis include corticosteroid use and systemic immune dysfunction, as well as local ocular factors such as prolonged wear of contact lenses or contaminated lens solutions. Visual outcomes are poor due to the unusual and virulent nature of the infecting organisms.

Endophthalmitis may also occur following intravitreal injection of medications. The greater utilization of this route of therapy to treat various retinal diseases has increased the prevalence of this subgroup of endophthalmitis. Despite the growing number of intravitreal injections administered, endophthalmitis remains an uncommon complication. It has been reported after intravitreal injection of most medications, including vascular endothelial growth factor (VEGF) inhibitors and triamcinolone acetonide (IVTA). The incidence of endophthalmitis resulting from intravitreal injections ranges from 0.01% to 0.1% of injections. Since many patients receive multiple injections to treat a chronic retinal disease, an individual patient's risk approaches 1%. The clinical findings in intravitreal injection-related endophthalmitis may be similar to other forms of infectious endophthalmitis and include iritis, vitreitis, hypopyon, pain, red eye, and decreased vision. The median time to presentation is earlier in post-intravitreal injection cases (3 days) compared with postoperative cases, in which it is approximately 11 days. This may in part be related to the preponderance of more virulent organisms (streptococcal species) in the post-injection cases compared with postoperative cases. Hypopyon occurs less frequently in post-intravitreal injection cases (20%) compared with postoperative cases (64%). A sterile inflammatory uveitis may also occur after intravitreal drug injections and must be distinguished from true infection. The noninfectious cases usually present earlier following the injection (median 1.5 days but highly variable), and the external inflammatory signs such as redness, eyelid edema, and purulent discharge are usually less apparent. In addition, pain is much less common in noninfectious cases. Characteristics that may increase the risk of infection include blepharoconjunctivitis, poor patient cooperation, immunosuppression, decreased ocular barrier function (presence of filtering bleb), contamination during compounding the drug or drawing up the medication, and poor sterile injection techniques.

Diagnosis

Two important factors in the diagnosis of exogenous endophthalmitis include clinical recognition and microbiologic confirmation. Endophthalmitis should be suspected in any eye that has a marked inflammatory response out of proportion to that usually seen in the typical clinical course. Because of the potential for significant visual loss, diagnostic tests are usually performed concurrently with treatment.

The clinical diagnosis is confirmed by obtaining aqueous fluid and vitreous specimens. Although vitreous specimens are more likely to yield a positive culture than simultaneously acquired aqueous specimens, both are important because either one can be positive without the other. Aqueous cultures are obtained by needle aspiration. Vitreous cultures can be obtained using needle aspiration or using an automated vitrectomy instrument, which simultaneously cuts and aspirates the vitreous. Vitreous obtained by needle aspiration can be directly inoculated onto appropriate culture media including chocolate agar, 5% blood sheep agar, thioglycollate broth, or Sabouraud agar. A specimen obtained during vitrectomy can be concentrated by filtration though a 0.45-μm filter and is then placed on culture media. An alternative method for processing the vitrectomy specimen involves inoculating approximately 10 mL of the diluted vitrectomy specimen into standard blood culture bottles. The culture technique has been shown to yield a similar rate of culture positivity when compared with the traditional membrane filter technique. Gram stains are usually performed on aqueous and vitreous samples. In suspected fungal cases, cultures should be held at least 2 weeks, and additional information may be obtained using the Giemsa, Gomori's methenamine silver, and periodic acid–Schiff stains.

Treatment

Endophthalmitis can lead to rapid intraocular tissue destruction and irreparable damage. The mainstay of treatment for bacterial endophthalmitis is intraocular antibiotic therapy. The unique properties of the eye, including the fact that it is an enclosed cavity as well as the presence of a blood–ocular barrier, make intraocular injection of antibiotic an ideal way of achieving rapid and high antibiotic concentrations within the eye (Table 15.2).

Systemic antibiotics were traditionally used to supplement intravitreal antibiotic injections in the management of endophthalmitis but are less frequently used today. The EVS randomized patients received ceftazidime and amikacin versus no systemic antibiotic therapy, but all patients received intravitreal antibiotics. The results

TABLE 15.2 **TREATMENT FOR ACUTE-ONSET PRESUMED BACTERIAL POSTOPERATIVE ENDOPHTHALMITIS**

Route	Drug	Dose
Intravitreal	1. Vancomycin	1.0 mg/0.1 mL
	2. Ceftazidime	2.25 mg/0.1 mL
	or amikacin	0.4 mg/0.1 mL
	3. Dexamethasone	0.4 mg/0.1 mL
Subconjunctival (optional)	1. Vancomycin	25 mg/0.5 mL
	2. Ceftazidime	100 mg/0.5 mL
	3. Dexamethasone	10–24 mg/1.0 mL
Topical (optional)	1. Vancomycin	50 mg/mL
	2. Ceftazidime	100 mg/mL
	3. Steroids and cycloplegics	
Systemic (optional)	1. Vancomycin	1.0 g IV q12h
	2. Ceftazidime	1.0 g IV q12h
	(or fourth-generation fluoroquinolone for appropriate organism)	

of that study demonstrated there was no beneficial effect on final visual outcome or media clarity when these systemic antibiotics were used.

In addition to intravitreal antibiotics as the recommended treatment for suspected endophthalmitis, intravitreal dexamethasone (0.4 mg/0.1 mL) may also be used in acute-onset endophthalmitis. Although both animal studies and small retrospective clinical trials have shown improved endophthalmitis treatment results when intravitreal steroids were combined with intravitreal antibiotic injection, definitive proof of the value of intravitreal steroids is not available. The EVS protocol did not utilize intravitreal steroids, but EVS patients were placed on oral prednisone (60 mg/d) for 5 to 10 days. In addition to intravitreal dexamethasone, we also consider a 10 to 24 mg subconjunctival injection of dexamethasone at the time of initial treatment.

Vitrectomy surgery (Figures 15.1, 15.3, and 15.8) has often been recommended for more severe cases of endophthalmitis (e.g., initial visual acuity of light perception only and rapid onset within 2 days of surgery, more severe intraocular inflammation). Theoretical advantages of vitrectomy include the rapid removal of infecting organisms, intraocular toxins, vitreous opacities, and membranes that may lead to traction retinal detachment, and a more rapid clearing of the vitreous cavity. Vitrectomy also allows for collection of a greater volume of material for culture and the potential for enhanced distribution of intravitreal antibiotics.

The management of endogenous fungal endophthalmitis depends on the specific fungus isolated and the severity of infection (Figure 15.8). When a diagnosis of endogenous fungal endophthalmitis is suspected, a workup to look for other organ involvement is recommended. This should usually be done in conjunction with an internist or infectious disease subspecialist. The use and type of systemic antifungal therapy depends on the presence or absence of systemic fungal infection. When the infection is limited to the choroid and retina, systemic therapy alone may be adequate. Fluconazole or voriconazole may be used instead of amphotericin B as the systemic drug of choice for treating *Candida* endophthalmitis not associated with significant systemic involvement. Both fluconazole and voriconazole are systemically less toxic than amphotericin B and have better intraocular penetration. When moderate to severe vitreous involvement is present, a pars plana vitrectomy and intravitreal injection of amphotericin B (5–10 μg) or voriconazole (100 μg) is usually recommended. Eyes with minimal vitreous involvement may be treated with an intravitreal antifungal agent without vitrectomy.

Endogenous *Aspergillus* endophthalmitis more often occurs in immunocompromised patients, patients with *Aspergillus* endocarditis or pulmonary disease, or patients with a history of intravenous drug abuse. This organism has a propensity to involve the macular area, resulting in macular abscess and a layering of white blood cells under the retina or internal limiting membrane (Figure 15.9). A combination of local ocular therapy and systemic antifungal therapy (amphotericin B or voriconazole) is often recommended for treatment of this virulent organism.

Prevention

Because the ocular surface and adnexa are the primary sources of bacteria in exogenous endophthalmitis cases, the rate of postoperative endophthalmitis could theoretically be reduced by minimizing the eyelid and ocular surface flora, and this has been demonstrated in published clinical series. The administration of topical 5% povidone-iodine solution to the ocular adnexa and conjunctival surface significantly reduces the conjunctival bacterial colony count. Reduction of conjunctival organisms may also be enhanced with the addition of 1 to 3 days of topically applied, broad-spectrum antibiotics. Additional preventive measures include covering the eyelashes completely with a sterile plastic drape (Figure 15.10); meticulous surgical technique, including ensuring a water-tight wound closure; and aseptic technique. Minimizing excessive pooling of fluid around the wound may also be helpful.

The role of prophylactic intracameral antibiotics either as a single injection or added to the irrigating solution during the surgery is controversial. A multicenter European study demonstrated a significant reduction in the risk of developing endophthalmitis after cataract surgery when intracameral cefuroxime was administered at the time of surgery. In the EVS, 10 enrolled patients with endophthalmitis had a history of receiving intraocular antibiotics in the irrigating fluid during the cataract surgery. In addition, the potential for intraocular toxicity and development of resistant organisms limit the potential value of this method of prophylaxis. The use of intracameral vancomycin for prevention of endophthalmitis has dropped significantly due to reported cases of severe retinal toxicity known as *hemorrhagic occlusive retinal vasculitis* (HORV) developing 1 to 14 days after the vancomycin administration. Postoperative topical antibiotics are

commonly used, but again are unproved in reducing the incidence of postoperative endophthalmitis.

Periocular and retro-orbital infections

Miriam B. Barshak and Marlene L. Durand

Periocular infections are infections of the soft tissues surrounding the globe of the eye. These include infections of the eyelids, lacrimal system, and orbit.

Eyelid infections

Each eyelid contains a fibrous tarsal plate that gives structure to the lid. Within each tarsal plate are 20 to 25 vertical meibomian glands that secrete sebum at the lid margins. Glands of Zeis, smaller sebaceous glands adjacent to the lid-margin hair follicles, also secrete sebum. Sebum prevents ocular surface drying by slowing the rate of tear film evaporation.

Hordeolum

An internal hordeolum is an acute infection of a meibomian gland and presents as a tender, swollen nodule within the lid, pointing either to the skin or conjunctival surface. An external hordeolum (stye) is an acute infection of a gland of Zeis and points to the lid margin. Both are usually caused by *Staphylococcus aureus* and respond to frequent warm compresses and topical bacitracin or erythromycin ointment.

Chalazion

A chalazion is a nontender nodule within the lid that points to the conjunctival surface and is due to a sterile granulomatous reaction to inspissated sebum within a meibomian gland. Most chalazia resolve spontaneously within 1 month, but intralesional triamcinolone or incision and curettage (I&C) may be used if conservative measures fail. A recent meta-analysis by Avcinena et al. reported that a single I&C was more effective than a single intralesional corticosteroid injection at resolving the chalazion (78% vs. 60%), but the benefit was less clear when comparing a single I&C (78% success) with two steroid injections (73%). Of note, I&C causes more pain and has a longer recovery time than do intralesional injections.

Recurrences of chalazia are common in patients with chronic blepharitis, and *Demodex* mite infestations of the lashes and lids have been implicated in both conditions. A study from China by Liang et al. reported that *Demodex* eyelid infestations, especially due to *D. brevis*, were more common in patients with than without chalazia (69% vs. 20%) and that patients with *Demodex* tended to have recurrent chalazia. Another study from China, by Yam et al., found benefit in using tea tree oil and shampoo to treat eyelids that were both *Demodex*-infested and had recurrent chalazia, although the study was small, had a short follow-up period, and had no control group. Persistent or recurrent chalazia should be biopsied to exclude squamous cell carcinoma.

Marginal blepharitis

Marginal blepharitis is a diffuse inflammation of the lid margins and is classified as anterior or posterior, with the former associated with seborrheic dermatosis or microbial colonization and the latter with meibomian gland dysfunction. Recurrent blepharitis may be treated with gentle lid scrubs and topical bacitracin; an oral tetracycline may be helpful if there is associated rosacea. Unusual causes of blepharitis have included *Pseudomonas*, *Capnocytophaga*, herpes simplex virus, crab lice, and *Demodex* mites. *Demodex* infestations, characterized by cylindrical dandruff around the lashes, have been associated with chronic blepharitis, and treatment with tea tree oil lid scrubs have been helpful in some studies (e.g., see Koo et al. in the "Suggested reading" list).

Infections of the lacrimal system

Tears are mainly produced by the lacrimal gland, which is located beneath the upper outer rim of the orbit. Tears flow medially across the eye; collect via the puncta, canaliculi, lacrimal sac, and lacrimal duct; and drain into the nose beneath the inferior nasal turbinate.

Dacryocystitis, or infection of the lacrimal sac, is the most common infection of the lacrimal system and results from obstruction of the lacrimal duct. Patients often give a history of chronic unilateral tearing (epiphora). Acute dacryocystitis presents as a painful, red swelling near the nasal corner of the eye (Figure 16.1). The most common bacteria involved are *S. aureus* and streptococci, although gram-negative bacilli such as *Escherichia coli* may be present in up to 25% of cases. Treatment requires systemic antibiotics and often incision and drainage of the lacrimal sac abscess. A dacryocystorhinostomy is often performed to treat the underlying chronic duct obstruction once the acute infection has subsided.

Dacryoadenitis, or infection of the lacrimal gland, is uncommon. Patients present with swelling in the lateral portion of the upper lid. Acute infection is most often due to *S. aureus* or streptococci, but Epstein–Barr virus may cause acute dacryoadenitis in mononucleosis. Chronic dacryoadenitis is usually seen as part of Sjögren's syndrome, sarcoidosis, or other inflammatory conditions, although *Mycobacterium tuberculosis* may rarely cause chronic dacryoadenitis. Tumors cause 25% of cases of chronic lacrimal gland enlargement.

Canaliculitis is usually a chronic infection of the canaliculi due to *Actinomyces israelii*, which forms concretions ("sulfur granules"). Staphylococci and streptococci are other etiologies. Treatment is usually office curettage of the concretions and/or topical antibiotic eyedrops. (See also Chapter 9, "Salivary and lacrimal gland infections.")

FIGURE 16.1 Acute dacryocystitis. Note swelling below the nasal corner of the right eye.

Preseptal and orbital infections

Although both preseptal and orbital infections may present with a similar external appearance of swollen, red eyelids, the distinction is important because orbital infections are usually much more serious. The barrier between the preseptal and orbital soft tissues is the orbital septum, a fibrous membrane that arises from the periosteum of the orbital rim and extends to the tarsal plates of the lids. Preseptal infections (sometimes called "periorbital") almost never extend beyond the orbital septum and into the orbit. Patients with either preseptal or orbital cellulitis present with swollen, red lids (Figure 16.2). The lids may be swollen shut, but it is essential to open them and examine the eye in order to determine if there are any "orbital signs." There are three orbital signs: decreased vision, proptosis (which may only be measurable and not obvious), and limitation in extraocular movement. Patients with orbital infections have at least one of these three findings, while patients with preseptal cellulitis have none. Both preseptal and orbital cellulitis occur more often in children than in adults. Sinusitis, especially ethmoid sinusitis, is the etiology of most orbital infections in any age group. The ethmoid sinus is separated from the orbit by the lamina papyracea, a

FIGURE 16.2 Lid swelling and erythema, shown here are features of both preseptal and orbital cellulitis; opening the eyelids is necessary to distinguish these entities.

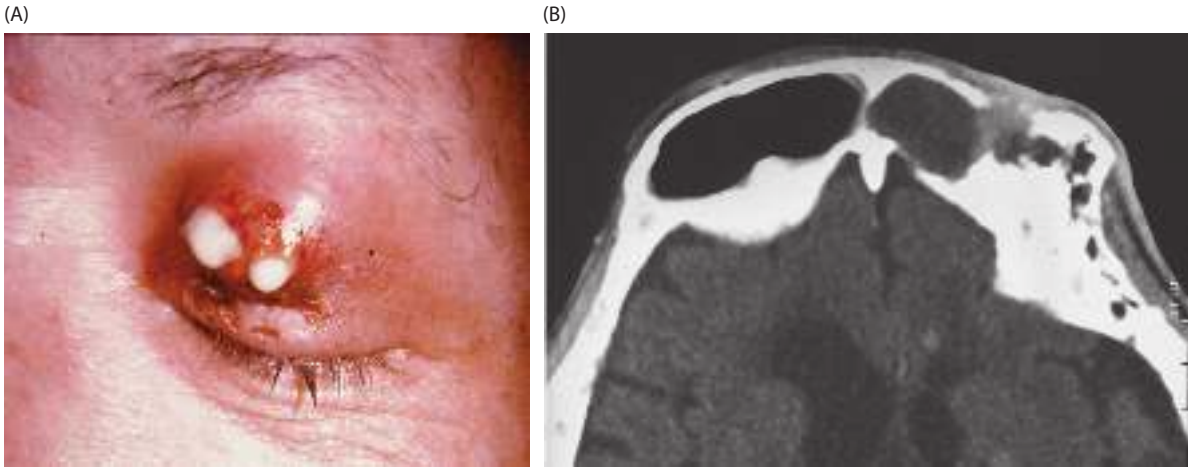

FIGURE 16.3 (A) Purulent drainage in upper lid from frontal sinusitis (superinfection of chronic frontal sinus mucocele). (B) CT of patient shown in A. Chronic frontal sinus infection led to erosion of the floor of the frontal sinus, which is also the roof of the orbit.

paper-thin bone. Frontal sinusitis may also lead to orbital infections, often from acute bacterial superinfection of a previously undiagnosed mucocele that has eroded the frontal sinus floor (orbital roof) through chronic pressure (Figure 16.3A, B).

Preseptal cellulitis is similar to facial cellulitis and is an infection of the superficial lid skin and preseptal soft tissues. It presents as unilateral redness and swelling of the eyelids but with normal vision and extraocular movements. There is no proptosis. The etiology is ethmoid sinusitis in many cases, and the bacterial etiology in sinogenic cases is presumed to be due to the usual sinus pathogens, *Streptococcus pneumoniae* and *Haemophilus influenzae*, in addition to *Staphylococcus aureus*. Some cases of preseptal cellulitis are due to superinfection of a break in the lid skin (e.g., insect bite, rash, and abrasion), and these cases are usually caused by *S. aureus* (including methicillin-resistant *S. aureus* [MRSA]) or group A streptococci. A third etiology of preseptal cellulitis is bacteremic seeding. This is now very rare, although it was more common in the pre-Hib vaccine era when most cases were due to *H. influenzae* bacteremia. The entity is usually seen only in young children (e.g., under age 3) and is now caused by *S. pneumoniae*, group A streptococci, other streptococci, or occasionally nontypeable *H. influenzae*. These children should be hospitalized for treatment with intravenous (IV) antibiotics directed against the cause of the bacteremia. Preseptal or orbital cellulitis has been described as a rare manifestation of bacteremia due to *S. pneumoniae* in adults with lupus erythematosus or hematologic disorders. *Pseudomonas* bacteremia has also caused preseptal or orbital cellulitis in neutropenic cancer patients.

Orbital cellulitis is an infection of the soft tissues of the orbit. Orbital cellulitis was the most common diagnosis in admissions to US hospitals for primary ophthalmic conditions according to a recent study by Iftikhar et al., accounting for >14% of such admissions. Patients with orbital cellulitis present with unilateral eyelid swelling and erythema, eye pain, and some degree of ophthalmoplegia or proptosis or both. There is often pain with eye movement. The proptosis may not be obvious and should be measured with a Hertel's exophthalmometer. A difference of 2 mm or more between the eyes signifies proptosis. Vision may be decreased, and there also may be an afferent pupillary defect signifying optic nerve involvement. Fever and leukocytosis are usually present in pediatric cases but may be absent in adults. Nearly all cases of orbital cellulitis in children and most in adults are caused by sinusitis, and many patients give a history of recent sinusitis symptoms. Occasional cases in adults are caused by extension of infection from acute dacryoadenitis, dacryocystitis, endophthalmitis, peribulbar anesthesia, or penetrating orbital trauma. As noted earlier, pneumococcal and *Pseudomonas* bacteremia may rarely cause preseptal or orbital cellulitis in patients with certain risk factors. Diagnosis of orbital cellulitis is by physical examination and CT scan of the orbit. The CT scan shows inflammation in the orbital soft tissues (e.g., fat "stranding") but no abscess. Treatment is with IV broad-spectrum antibiotics directed against *S. aureus*, *S. pneumoniae* and other streptococci, anaerobes, and *H. influenzae*. Sinus drainage surgery is occasionally necessary as well. In neonates with community-acquired orbital cellulitis, MRSA is an important cause and is associated with bacteremia.

Several studies have evaluated the use of adjunctive corticosteroid treatment in children with orbital cellulitis. A study by Chen et al. found that children who received IV corticosteroids (dexamethasone 0.3 mg/kg/d q6h for 3 days) and antibiotics at the time of admission had significantly shorter hospital stays than those who received only antibiotics, whether or not surgical intervention was undertaken. A study by Davies et al. measured C-reactive protein (CRP) daily among patients with orbital cellulitis and added oral prednisone at 1 mg/kg/d for 7 days once the CRP was below 4 mg/dL. The corticosteroid treatment was associated with a shorter hospital stay, although there were only seven patients in the non-corticosteroid group. There were no cases of vision loss in either study.

Orbital subperiosteal abscess presents like orbital cellulitis, although symptoms are usually more severe. Because the ethmoid sinus is the source of infection in nearly all cases, the purulent collection is usually beneath the medial orbital periosteum. The periosteum bulges into the orbit, which may limit medial rectus

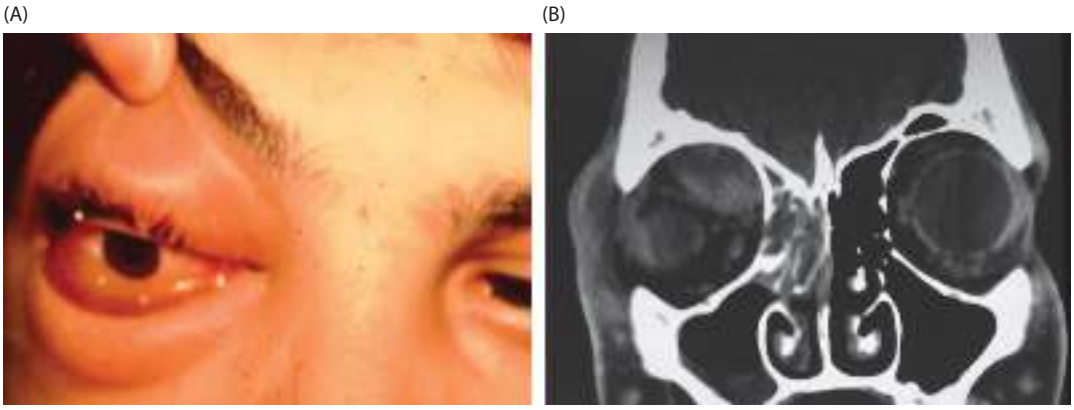

FIGURE 16.4 (A) Orbital abscess causing eye to look "down and out." (B) CT of patient in A. Note abscess in superomedial right orbit.

movement and cause the eye to look "down and out." Orbital CT scan demonstrates the collection. Most cases in older children and adults require prompt surgical drainage of the abscess in addition to IV antibiotics, while children <9 with normal vision and small, medial abscesses may respond to medical therapy alone. A study by Ryan et al. of 68 children with subperiosteal abscesses found that only one-third required surgery, and those requiring surgery were older (8 vs. 6 years) and had larger abscesses (>10 mm on CT). Broad-spectrum IV antibiotics (e.g., vancomycin, metronidazole, and ceftriaxone) should be given initially in all cases until culture results are available. Most cases of subperiosteal abscess are caused by a mixture of anaerobes and aerobes, with aerobes including one or more of the following: *S. aureus*, *Streptococcus anginosus* (*milleri*) group, group A streptococci, *H. influenzae*, or *Moraxella catarrhalis*.

Orbital abscess has clinical and microbiologic features identical to those of orbital subperiosteal abscess. The abscess is usually medial or superomedial in the orbit, which may cause the eye to look in the "down and out" directions (Figure 16.4A). An orbital CT scan reveals the collection (Figure 16.4B). Treatment is immediate surgical drainage and broad-spectrum IV antibiotics. Delay in drainage of the abscess may lead to permanent loss of vision.

Retro-orbital infections

Cavernous sinus thrombophlebitis (CST) is a very rare complication of orbital infections or of infections in the midface "danger triangle" (upper lip to root of the nose). The two cavernous sinuses are venous plexuses that are connected by intercavernous sinuses; involvement of one sinus can rapidly spread to the opposite side. Cranial nerves III, IV, V1, V2, and VI run through the cavernous sinus. Patients with CST typically present with headache, unilateral orbital cellulitis, and hypesthesia in the distribution of V1 and V2 (forehead and cheek). They sometimes then develop similar findings in the opposite eye. Diagnosis is by clinical findings supported by MRI and MR venography (MRV). The most common bacterial etiology is *S. aureus*, including MRSA, but streptococci (especially *S. anginosus* group), anaerobes, and gram-negative bacilli may be present depending on the origin of infection. Treatment is with broad-spectrum IV antibiotics. The value of anticoagulation is unknown (see also Chapter 77, "Intracranial suppuration").

Invasive fungal sinusitis usually presents with orbital cellulitis, orbital apex syndrome, and/or cavernous sinus involvement. At presentation, there may be hypesthesia of cranial nerve V divisions V1 and V2 due to orbital apex or cavernous sinus involvement. Mucormycosis should be suspected in any patient with risk factors who presents with symptoms and signs of orbital cellulitis. Risk factors include diabetes (often poorly controlled), hematologic malignancies, solid organ or hematopoietic cell transplantation, immunosuppression including chronic corticosteroid use, and deferoxamine therapy. Clinical findings include ophthalmoplegia, proptosis, and lid edema (Figure 16.5), and, in contrast with bacterial orbital cellulitis, lid erythema may be faint or absent rather than "hot" looking. While patients with bacterial orbital cellulitis complain of pain in their involved eye and orbit, patients with mucormycosis may complain that the most prominent pain is in the temple and forehead. Hypesthesia of the cheek and forehead is often present, and the periorbital skin, including the forehead, may be indurated. *Aspergillus* infections of the orbit and cavernous

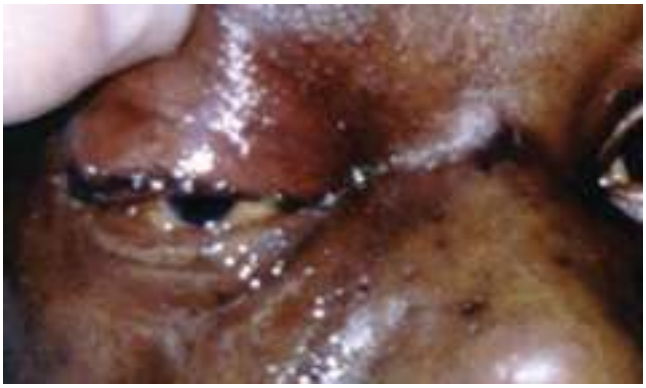

FIGURE 16.5 Rhinocerebral mucormycosis in a diabetic patient. The lids are swollen but less erythematous than they would be in typical acute bacterial orbital cellulitis.

sinus usually arise from invasive sphenoid sinus aspergillosis. Patients may present subacutely, with gradual onset of proptosis, ophthalmoplegia, and visual loss over days to weeks. There may be minimal lid swelling and erythema. The orbital apex may be involved first, leading to an orbital apex syndrome. The optic nerve and cranial nerves III, IV, VI, and V1 run through the orbital apex, so patients with this syndrome usually present with unilateral blindness, ptosis, proptosis, a fixed dilated pupil, and ophthalmoplegia. Invasive aspergillosis and mucormycosis are further discussed in Chapters 173 and 174.

Section 4

Clinical syndromes: Skin and lymph nodes

17

Fever and rash

John W. Sensakovic and Leon G. Smith

Fever and rash is one of the common symptom complexes presenting in medical practice. Because of the wide range of diseases that can present with this complex, the patient presenting with fever and rash is also one of the most challenging clinical syndromes.

Although both infectious and noninfectious disease processes can present with fever and rash, infectious causes are considered here. Nevertheless, noninfectious causes such as drug reactions, systemic vasculitis, serum sickness, erythema multiforme, toxic epidermal necrolysis, and Sweet's syndrome are often in the differential diagnosis.

The approach to the patient with infectious fever and rash should begin with the appreciation that causes include common infections that are often benign, serious emergent infections that can be rapidly fatal, and unusual infections that can pose a diagnostic challenge. Key features in the history and physical can be particularly important. These include childhood diseases and immunization history, seasonal diseases, travel history and geography, exposure, sexual history, and medication usage, as well as prodromal and accompanying symptoms. Physical examination, with particular attention to the characteristics of the rash, can be key, along with vital signs to assess severity of the illness, and particular attention to meningeal signs, lymph nodes, mucous membranes, conjunctiva, and joint examination. Features of the rash to consider include characteristics and distribution of the lesions, timing of onset of rash in relation to fever, and changes in morphology of the lesions.

When faced with the patient with fever and rash, the physician must be acutely aware of those several very serious infections that are commonly fulminant and that can be rapidly fatal. Thus, the physician must quickly address a series of important issues simultaneously (Box 17.1). These include the question of contagious potential to the medical staff, the need for rapid resuscitation in those patients who can present in shock, the rapid recognition of and therapeutic intervention for those infections that tend to be fulminant, and the need for a thorough evaluation and workup for the extensive list of diagnostic possibilities that can present with fever and rash.

Emergent conditions presenting with fever and rash

Rapid recognition and therapeutic intervention are essential in certain diseases presenting with fever and rash to minimize as much as possible the associated morbidity and mortality. The major conditions involved include meningococcemia, Rocky Mountain spotted fever, staphylococcal toxic shock syndrome, streptococcal toxic shock-like syndrome, bacteremia or endocarditis with septic emboli, and the rapidly spreading cellulitis (Table 17.1 and Box 17.2). All of these conditions can present with fever and rash in a fulminant, rapidly progressive form, requiring expedient therapeutic intervention, often on an empiric basis, before confirmation of the diagnosis, if the associated mortality rates are to be minimized.

BOX 17.1

Major issues in patients with fever and rash

Contagious potential
Resuscitation
Rapid therapy
Diagnostic evaluation
Clinical setting
Severity of illness
Nature of rash
Petechial
Cellulitic
Vesiculobullous Maculopapular

Generally, the most serious and rapidly progressive of these are associated with a petechial rash. These 1- to 2-mm purple lesions do not blanch with pressure, often coalesce to form larger ecchymotic areas, and usually are in the presence of leukocytosis and thrombocytopenia. Meningococcemia, Rocky Mountain spotted fever, and bacteremia/endocarditis with septic emboli are perhaps the most notable. However, other causes include gonococcemia, typhus, and rat-bite fever; viral infection, including dengue, hepatitis B, rubella, and Epstein–Barr virus (EBV); and noninfectious causes, including thrombotic thrombocytopenia purpura, Henoch–Schönlein purpura, vasculitis, and scurvy.

Rapidly progressive diseases with erythematous rash include staphylococcal toxic shock syndrome and streptococcal toxic shock-like syndrome, as well as the rapidly progressive cellulitis, which often have a vesicobullous component. In these conditions, as well as with necrotizing fasciitis, the patient often looks toxic out of proportion to the extent of the rash.

Meningococcemia

Of all the diseases presenting with fever and rash, meningococcemia is the one most likely to be rapidly fatal without early recognition and treatment. The ominous palpable purpura in an acutely ill, febrile patient characteristically suggests this disease. Other features that may be helpful in earlier diagnosis include sore throat, fever, muscle tenderness, and headache in the presence of significant leukocytosis and thrombocytopenia. The illness tends to occur in late winter and early spring and is well known to occur under crowded living conditions. The initial rash may be maculopapular, with the earliest petechial lesions occurring over pressure points such as the small of the back, and can easily be overlooked. The rash can progress rapidly over a few hours to the more classic, petechial form with peripheral acrocyanosis. Management requires immediate recognition, vigorous fluid replacement, and rapid therapy with aqueous penicillin or a third-generation cephalosporin, 12 to 24 million units daily intravenously (IV). Patients presenting with signs of adrenal insufficiency also require steroid replacement. The use of gamma globulin is controversial for patients with meningitis. Dexamethasone for 2 days started just before or with the first dose of antibiotics is indicated.

Rocky mountain spotted fever

Rocky Mountain spotted fever can also present with fever and petechial rash in an acutely ill patient, yet is different from meningococcemia in several respects. The illness begins with fever and severe headache, occurs between May and September in temperate-zone states, and there is a history of tick exposure in 75% of the cases. The rash appears several days into the illness, begins as a maculopapular rash on wrists and ankles, and progresses to a petechial form and spreads to palms,

TABLE 17.1 **APPROACH TO SERIOUSLY ILL PATIENTS WITH FEVER AND RASH**

Clues	Disease	Diagnosis
Multiple purpuric lesions Earliest lesions small of back Rapid progression over hours	Meningococcemia	Gram stain of pustules Blood cultures
Tick exposure, headache, fever, rash 2nd–6th days Wrists, ankles, progressing to palms, soles, trunk	Rocky Mountain spotted fever	DFA of skin biopsy Serology (CF)
Fever, rash, hypotension, menstruating female using tampons Surgical wound or skin infection	Toxic shock syndrome	Isolation of phage group I staphylococci
Fever, rash, hypotension, rapid onset of organ dysfunction	Group A streptococcal toxic shock-like syndrome	Evidence of group A streptococcal infection
Elderly or immunocompromised patient Several lesions, macular to necrotic pustules	Bacteremia with septic emboli	Gram stain of pustules Blood cultures Gram stain of buffy coat
Painful spreading lesions Local trauma	Rapidly spreading cellulitis	Clinical

BOX 17.2

Characteristics of serious rashes

Onset with or after fever
Petechial lesions
Rapid spread
Purpuric lesions
Palmar/plantar involvement

soles, and trunk. A leukocytosis with thrombocytopenia is commonly present. Therapy is doxycycline, 100 mg every 12 hours, and must be instituted early on a presumptive basis, before serologic confirmation, if mortality is to be significantly reduced. Alternative therapy is with chloramphenicol, 50 mg/ kg/day IV. In institutions where available, immunofluorescence staining of a skin biopsy specimen of the rash can yield a rapid diagnosis. A review from Duke University Medical Center cited 10 cases of illness without rash or with fleeting atypical skin eruptions, emphasizing the need for a high index of suspicion in acutely ill patients with endemic tick exposure.

Toxic shock syndrome

Toxic shock syndrome caused by the pyrogenic exotoxin of phage group 1 *Staphylococcus aureus* classically presented in a young menstruating female using a tampon. Causive strains produce staphyloccal exotoxin TSST-1. However, recently cases more commonly occur as a result of nonvaginal foci of staphylococcal infection, including surgical wound infections, infectious endocarditis nasal packing, and infected catheters. The rash tends to be diffuse and scarlatiniform in character, with associated conjunctival hyperemia and a "strawberry tongue." The rash is associated with fever, hypotension, and evidence of multisystem derangement. Therapy requires vigorous fluid replacement, removal of the infected tampon or other foreign body, or drainage of an identified infected focus, and nafcillin or oxacillin at 8 to 12 g/ day. Some experts also recommend vaginal lavage with a betadine solution as a local antibacterial agent as well as for removal of any nonabsorbed exotoxin.

Staphylococcal scalded skin syndrome can be seen in young children infected with a staphylococcal strain producing epidermolysin A or B. The result is a superficial sloughing of the skin with a painful erythema. Nikolsky's sign, "onion skin" peeling of the skin with gentle pressure, is seen.

A somewhat similar noninfectious entity, toxic epidermal necrolysis, is seen in adults. This typically is drug induced, and the sloughing of the skin occurs deeper, at the dermal–epidermal junction.

Group a streptococcal toxic shock-like syndrome

The changing epidemiology of group A streptococcal infections has been recognized as a resurgence in rheumatic fever and an increase in the frequency of invasive infections and bacteremia. In addition, the group A streptococcal toxic shock-like syndrome has been recently defined by its characteristic early onset of shock and multiorgan failure in the presence of group A streptococcal infection, often with a generalized erythematous rash that may desquamate. Most of the isolates produce pyrogenic exotoxin A, and some cases have been associated with necrotic soft-tissue infections. In group A streptococcal toxic shock-like syndrome, mortality up to 30% has been described compared to 3% with staphylococcal toxic shock syndrome.

Septic emboli

The diagnosis of septic emboli associated with bacterial bloodstream infection must be considered in any seriously ill patient with fever and rash. Such infections most commonly present in elderly or immunocompromised patients. Solitary or widely scattered purplish lesions, non-blanching and often with necrotic centers, suggest the diagnosis. The lesions often involve the digits. Ecthyma gangrenosum is one such lesion seen with *Pseudomonas aeruginosa* bacteremia. Such lesions are also seen most often in *S. aureus* bacteremia, *Candida albicans* fungemia, and infectious endocarditis. Gram stain of aspirates from the skin lesions and of the buffy coat of the blood can be rapidly diagnostic; blood cultures are confirmatory. Presumptive therapy should cover methicillin-resistant *S. aureus* as a problem; a regimen of vancomycin, 1 g IV every 12 hours, and gram-negative coverage is recommended pending culture identification.

Rapidly spreading cellulitis

The various types of rapidly spreading cellulitis associated with fever and rash are not difficult to recognize in most instances because of the painful spreading inflammatory lesion on the skin. The diagnostic difficulty involves differentiating the various types of rapidly spreading cellulitis based on probable causative organism or organisms and whether infection is confined to the surface or extends to deeper structures, including fascia and muscle. With deep extension, case adequate surgical debridement is essential, along with appropriate antibiotic therapy. "Flesh-eating" necrotizing fasciitis from group A streptococcus can be difficult to diagnose, and it is increasing in frequency.

Common infections presenting with fever and rash

The most common infections presenting with fever and rash also fortunately include conditions that are generally benign.

Many of these febrile exanthems are due to viral illnesses of children or inadequately immunized adults. Such illnesses as measles, varicella, rubella, erythema infectiosum due to parvovirus B19, and roseola infantum due to human herpesvirus type 6 (HHV-6) are typical. Kawasaki syndrome and streptococcal scarlet fever should also be considered in this age group.

In older children presenting with fever, rash, sore throat, and adenopathy, EBV infection is common. In young adults presenting in such fashion where EBV and group A *Streptococcus* have been ruled out, pharyngitis with fever and rash due to a recently described organism, *Arcanobacterium*, should be considered. This gram-positive bacillus is usually very sensitive to erythromycin.

Enteroviral infections due to Coxsackieviruses and echoviruses frequently present with febrile exanthem and should especially be considered during summer months and when accompanied with gastrointestinal symptoms.

TABLE 17.2 **RARE CAUSES OF FEVER AND RASH**

Infectious		
Viral		
Parvovirus	Hand-foot-mouth	West Nile
EBV	Herpes simplex	RSV
CMV	Herpes zoster	HHV-6
Coxsackie	HIV	Smallpox
Enterovirus (echo)	Hepatitis B and C	Vaccina
Dengue	Monkeypox	
Ebola	Rubella	
Bacteria		
Rat-bite fever	Leptospirosis	Neisseria
Mycoplasma pneumonia	Lyme	Gonorrhea
	Bartonella	Salmonella
BCG	Borrelia	
Mycobacteria		
Fungal		
Candida	Coccidiomycosis	Histoplasmosis
Sporotrichosis		
Noninfectious		
Erythema multiforme	Vasculitis's	Porphyria
Kawasaki	Sweet's syndrome	Drug reaction
Graft vs. host	Pyoderma gangrenosum	

Unusual infections that can pose a diagnostic challenge

A wide variety of less common infections that can present with fever and rash should also be considered, especially if associated with geographic or seasonal exposure (Table 17.2).

Lyme borreliosis can present with fever and a characteristic erythema migrans rash, resulting from geographic tick exposure. Diagnosis can be difficult early in the infection when serology can be negative and the rash can be atypical or missed. Follow-up serology may be diagnostic.

The recently recognized syndromes of West Nile virus infection, including West Nile fever, encephalitis, and facial paralysis, can present with fever and rash. The disease has a summer–fall prevalence and is associated most often with exposure to infected household mosquitoes. Other uncommon infections to be considered, also with geographic and seasonal occurrence, include ehrlichiosis, dengue fever, tularemia, plague, leptospirosis, and typhoid fever.

Although a wide variety of diagnostic tests and procedures can be helpful in the workup of the patient presenting with fever and rash, none of these is as important as a careful history and physical examination.

Toxic shock syndrome and Kawasaki disease

Evangelia M. Assimacopoulos, Aristides P. Assimacopoulos, Wilmara Salgado-Pabón, and Patrick M. Schlievert

Toxic shock syndrome

Staphylococcal and streptococcal toxic shock syndromes (TSS) are acute-onset multiorgan illnesses defined by criteria listed in Boxes 18.1 and 18.2. Staphylococcal TSS is caused by *Staphylococcus aureus* strains that produce pyrogenic toxin superantigens (SAgs). Human coagulase-negative staphylococci do not produce the causative toxins, though coagulase-negative strains from animals occasionally do produce SAgs. Streptococcal TSS is caused primarily by *Streptococcus pyogenes* (group A) strains but occasionally by groups B, C, and G strains. Several subsets of staphylococcal TSS exist, with two major categories being menstrual and nonmenstrual.

Menstrual TSS (Figure 18.1), which occurs within a day or two of or during menstruation, primarily has been associated with use of certain tampons, notably those of high absorbency, and is 100% associated with production of TSS toxin-1 (TSST-1) by the causative bacterium. When initially described, menstrual TSS occurred primarily in women aged 15 to 25. Presently, menstrual TSS occurs more often in younger females, particularly those aged 12 to 15; the reason for this shift in menstrual TSS to the younger age group is unclear. There are two major mechanisms that explain the association of tampons with menstrual TSS: (1) tampons introduce oxygen, which is absolutely required for production of TSST-1, into the otherwise anaerobic vagina; and (2) pluronic L-92, a surfactant present in the TSS-associated Rely tampon from the 1980s and no longer used in tampons, amplifies TSST-1 production.

Nonmenstrual TSS occurs in both males and females, adults and children, and is associated with *S. aureus* strains that produce TSST-1 or staphylococcal enterotoxins, notably enterotoxin serotypes B and C. These three SAgs are produced in amounts nearly 10^5 higher than most other SAgs. Nonmenstrual TSS occurs in association with nearly any kind of staphylococcal infection, but major forms have been identified: postsurgical, upper respiratory virus (influenza)-associated, RED syndrome (see later discussion), enterocolitis-associated, and occasionally with use of contraceptive diaphragms, sponges, and menstrual cups. Postsurgical TSS is often associated with *S. aureus* infections that do not result in pyogenic responses, and thus the infection source may be difficult to find. Influenza TSS may occur as a consequence of influenza or parainfluenza damage to the respiratory tract epithelium and superinfection with SAg-producing *S. aureus* (Figures 18.2 and 18.3); fatal cases of post-influenza TSS are almost always associated with TSST-1 *S. aureus* and not with strains producing enterotoxins B or C. This illness is highly fatal in children (as high as 90%). RED syndrome is a recalcitrant erythematous desquamating disorder in patients with AIDS that may last 70 or more days until the patients succumb. Recently, staphylococcal TSS has been associated with enterocolitis. Until enterocolitis became highly associated with *Clostridium difficile* infection, staphylococcal enterotoxins were associated with the illness. Although sometimes forgotten, staphylococcal SAgs should be considered as causes of enterocolitis with TSS symptoms when *C. difficile* cannot be isolated from patients. Finally, nonmenstrual TSS associated with use of diaphragms, sponges, and menstrual cups may be similar to menstrual, tampon-associated TSS.

BOX 18.1

Diagnostic criteria for confirmed staphylococcal toxic shock syndrome

Clinical criteria

- Temperature ≥38.9°C/101°F
- Systolic blood pressure ≤90 mm Hg for adults, <5th percentile for children, or >15 mm Hg orthostatic drop in diastolic blood pressure or orthostatic dizziness/syncope
- Diffuse macular rash
- Desquamation after 1–2 weeks
- Three of the following organ systems involved:

  Hepatic: Bilirubin, AST, ALT more than twice the ULN
  Hematologic: Platelets <100,000/mm^3
  Renal: BUN or creatinine more than twice the ULN or pyuria
  without urinary tract infection
  Mucus membranes: Hyperemia of the vagina, oropharynx, or conjunctivae
  Gastrointestinal: Diarrhea or vomiting
  Muscular: Myalgias or CPK more than twice the ULN
  Central nervous system: Disorientation or lowered level of consciousness in
  the absence of hypotension, fever, or focal neurologic deficits
  Laboratory criteria

- Negative serologies for measles, leptospirosis, and Rocky Mountain spotted fever; blood or CSF cultures negative for organisms other than *Staphylococcus aureus*

Probable case: Meets laboratory criteria and four of five clinical criteria.

Abbreviations; AST = aspartate transaminase; ALT = alanine aminotransferase; BUN = blood urea nitrogen; CPK = creatine phosphokinase; CSF = cerebrospinal fluid; ULN = upper limit of normal

FIGURE 18.1 Menstrual toxic shock syndrome (vaginal colonization): diffuse blanching erythema.

BOX 18.2

Diagnostic criteria for streptococcal toxic shock syndrome

1. Isolation of group A streptococci:

   From a sterile site for a *definite* case
   From a nonsterile site for a *probable* case

2. Clinical criteria:

   Hypotension *and* two of the following:
   Renal dysfunction
   Coagulopathy
   Hepatic involvement
   Adult respiratory distress syndrome
   Erythematous macular rash
   Soft-tissue necrosis

FIGURE 18.2 Gangrenous fingers and skin peeling with nonmenstrual staphylococcal toxic shock syndrome (pulmonary infection).

FIGURE 18.3 Same patient as in Figure 18.2 demonstrating extensive peeling and tissue damage.

Courtesy of Gary R Kravitz, MD, St. Paul Infectious Disease Associates, St. Paul, Minnesota.

Streptococcal TSS is primarily associated with group A streptococcal infections, particularly M serotypes 1, 3, and 18. The illness may or may not be associated with necrotizing fasciitis or myositis (Figures 18.4A–C). The case fatality rate is higher in cases with necrotizing myositis than when this condition is absent. Occasionally, streptococcal TSS is caused by other groups of streptococci, primarily groups B, C, and G.

Group A streptococcal strains that cause TSS produce streptococcal pyrogenic exotoxin SAgs. The major associations have been with serotypes A and C, but other family members contribute significantly. Non–group A streptococcal strains associated with TSS also produce streptococcal pyrogenic exotoxin SAgs that are related or identical to the group A streptococcal SAgs.

Major risk factors for development of streptococcal TSS include chickenpox in children, penetrating and nonpenetrating wounds, use of nonsteroidal anti-inflammatory agents, and pregnancy.

Kawasaki syndrome

Kawasaki syndrome (KS) is an acute multisystem vasculitis that occurs primarily in children <4 years of age (Box 18.3). KS shares many features with streptococcal scarlet fever and TSS except that hypotension is absent. KS is a leading cause of acquired heart disease in this age group. Coronary artery abnormalities, including aneurysms, develop in 15% to 25% of patients.

The causative agent of KS remains unclear, but studies suggest that staphylococcal and streptococcal SAgs may have important causal roles in many cases. It is noteworthy that some patients with staphylococcal TSS have also been described with coronary artery aneurysms.

FIGURE 18.4 Necrotizing fasciitis. Note the extensive edema, erythema, bullae formation, and necrosis in this patient's thigh (A and B). At the time of presentation, this patient was hypotensive with multisystem organ failure and severe pain at the site of infection. (C) Leg after extensive debridement down to and below the level of the fascia.

BOX 18.3

Clinical criteria for Kawasaki syndrome

1. Fever, usually of at least 5 days' duration
2. Four of five of the following:
   - Extremity changes, induration, edema, erythema
   - Oropharyngeal and lip changes, strawberry tongue, cracked lips
   - Cervical lymphadenopathy: at least one node >1.5 cm
   - Injected conjunctivae
   - Rash, erythematous and polymorphous
3. Other diseases excluded

Probable cases may not meet the strict definition.

Evaluation and treatment of toxic shock syndromes

Differential diagnosis of toxic shock syndrome

- Viral disease, including measles, rubella, parvovirus B19
- Spotted fever group rickettsiae
- Leptospirosis
- Drug reactions, including Stevens–Johnson syndrome
- Collagen-vascular diseases, including systemic lupus erythematosus, and Still's disease
- Scarlet and rheumatic fevers
- Syphilis
- Typhoid fever

The physician should consider myositis or necrotizing fasciitis in any patient who presents with severe local pain, especially in an extremity, and other nonspecific influenza-like or gastrointestinal symptoms. Fever, erythema, and edema are usually absent. Early intervention is life-saving for patients with necrotizing soft tissue infections, so it is important to maintain a very high index of suspicion. An elevated creatinine, elevated creatine kinase (CK), or significant bandemia may suggest the diagnosis.

Initial evaluation

Possible sources of infection or foreign bodies must be identified. The physician should perform a vaginal examination, remove any tampon, and culture for *S. aureus*. Any wounds should be unpacked and inspected. A thorough examination of the skin and soft tissues should be undertaken, paying special attention to any painful areas even if typical signs of inflammation are absent. Cultures of blood and other sites, as appropriate, should be obtained. Early surgical intervention is extremely important. MRI may be used to identify deep soft-tissue necrosis and guide surgical intervention.

Supportive care

Supportive care is of primary importance. Patients often require large amounts of intravenous (IV) fluids, vasopressors, and management of associated comorbidities, such as acute renal failure, acute (adult) respiratory distress syndrome, disseminated intravascular coagulation, or myocardial suppression.

Antibiotics

Antistaphylococcal therapy decreases the risk of recurrence of staphylococcal TSS and will treat any active infection with *S. aureus* or β-hemolytic streptococci. Nafcillin (adults: 2 g IV q4h; children: 150 mg/kg/d IV divided q6h) or cefazolin (adults: 1–2 g IV q8h; children: 50–100 mg/kg/d IV divided q8h) can be used. However, for critically ill patients, sufficiently high prevalence of methicillin-resistant *S. aureus*, or patients with an anaphylactic penicillin or cephalosporin allergy, vancomycin (adults: 1 g IV q12h; children 40 mg/kg/d IV divided q6h), daptomycin (adults: 4–6 mg/kg IV q24h; children 4–10 mg IV 24 hours, varies with age), or linezolid (adults: 600 mg IV q12h; children 10 mg/kg q8h up to age 12) can be used. Clindamycin, a protein synthesis inhibitor (adults: 900 mg IV q8h; children: 40 mg/kg/d IV divided q6–8h), should be given in addition (unless linezolid is used) as experimental data suggest that it inhibits exotoxin and M protein production. Dosage adjustments for renal failure may be required.

Once a microbiologic diagnosis has been established, the spectrum of therapy can be narrowed, using penicillin (adults: 4 million units IV q4h; children: 250,000 U/kg/d IV divided q4h) ampicillin (adults: 2 g IV q6h; children 50 mg/kg/d divided q6h), ceftriaxone (adults: 2 g IV q24h; children: 50–75 mg/kg/d IV divided q12–24h) or clindamycin alone, as appropriate. Therapy should be given for approximately 10 to 14 days unless a diagnosis, such as osteomyelitis, is made that requires extended therapy.

Intravenous immunoglobulin

Lack of neutralizing antibodies seems to be a risk factor for staphylococcal and streptococcal TSS. Human and animal studies appear to support the use of IV immunoglobulin (IVIG) in these diseases. Preparations of IVIG may vary not only by manufacturer but also by batch in their ability to neutralize superantigenic toxins. Therefore, retreatment with a different preparation may be warranted in a patient who has not responded to initial therapy. Various IV doses have been used as follows: 1 g/kg on day 1 followed by 0.5 g/kg each day on days 2 and 3, 0.4 g/kg IV once daily for 5 days, or a single dose of 2 g/kg with a repeat dose at 48 hours if the patient remains unstable.

Steroids

The clinician should not miss the patient with absolute or relative adrenal insufficiency. However, steroids are not routinely given to patients with TSS.

Surgical intervention

Any obvious source of infection should be drained. There should be a low threshold to explore other sites as expected signs of inflammation may be absent, especially in streptococcal myositis. Radionuclide white blood cell (WBC) scanning has been used to identify undrained foci of necrotizing fasciitis in a nonresponding patient.

Prevention

Up to 30% recurrence has been suggested. Elimination of staphylococcal colonization can be attempted. Avoidance of further tampon use is prudent after menstrual TSS; patients with TSST-1 associated TSS do not develop protective antibodies. Additionally, it is now well-known that approximately 20% of individuals at 12 years of age or older do not develop protective antibodies to

TSST-1 and thus always retain susceptibility. Close household contacts of an index case of streptococcal TSS should be offered chemoprophylaxis.

Treatment of Kawasaki syndrome

Differential diagnosis of Kawasaki syndrome

- Acute adenoviral infection
- Other viral exanthemata, especially measles
- Scarlet fever
- Drug reactions, Stevens–Johnson syndrome, erythema multiforme
- Spotted fever group rickettsiosis
- TSS
- Staphylococcal scalded skin syndrome
- Juvenile rheumatoid arthritis
- Leptospirosis
- Mercury poisoning

Differential diagnosis

Irritability and gastrointestinal symptoms are common. Adenoviral infection may present the most common diagnostic dilemma. Incomplete KS, more common in children <12 months of age, may be diagnosed when the patient has 5 or more days of fever and two or more criteria for diagnosis. The risk of coronary artery aneurysms increases significantly in patients not treated within 10 days.

Supportive care

Cardiorespiratory monitoring, close clinical observation, and attention to fluid balance are required.

Aspirin

The physician should give high doses of aspirin (80–100 mg/kg/d in four divided doses, maximum of 4 g/day) until 48 hours after the fever is gone and then maintain low doses (3–5 mg/kg/d in single dose) for 6 to 8 weeks or until the platelet count and sedimentation rate are normal. Consider monitoring of serum salicylate levels in nonresponders. Some prefer high doses until day 14. Aspirin therapy should be continued indefinitely in any patient with coronary artery abnormalities. Influenza or varicella exposure may prompt discontinuation of aspirin therapy for up to 14 days because of the risk of Reye's syndrome. Dipyridamole (4–9 mg/kg/d divided BID or TID) may substitute during this time in high-risk patients. Give influenza vaccination yearly while on aspirin.

Intravenous immunoglobulin

The recommended dose is 2 g/kg IV given over 12 hours. Retreatment may be necessary in those whose fever persists or recurs. Measles, mumps, and rubella vaccines should be delayed for 11 months after IVIG unless there is high risk. If so, give the vaccination on schedule and repeat 11 months later.

Steroids

IV methylprednisolone will hasten the resolution of fever and improve laboratory markers of inflammation when given in 1 to 3 pulse doses of 30 mg/kg. This should be considered for patients who fail retreatment with IVIG.

Monitoring for cardiac complications

Inpatient and outpatient serial exams are important. Obtain electrocardiogram and cardiac echo early and repeat at 6 and 8 weeks. Pediatric cardiology consultation should be obtained. Stress testing and coronary angiography have value in specific clinical situations. The patient with coronary artery lesion requires more intensive monitoring.

Evaluation of therapy

If fever or signs of inflammation persist or recur, retreat with IVIG (1–2 g/kg over 10–12 hours) and with steroids if no response to IVIG retreatment. Patients who fail to respond to IVIG and steroids could be considered for treatment with tumor necrosis factor (TNF) inhibitors such as infliximab, other immunosuppressive agents, or plasmapheresis.

Long-term management

Restrict physical activity for 6 to 8 weeks. Determine frequency of follow-up on an individual basis. It is possible to identify a group of low-risk patients who may not require intensive follow-up. Complicated management issues, such as use of warfarin, calcium channel blockers, and angiography, are beyond the scope of this text. The reader is referred to the excellent reviews of KS found in the "Suggested reading" section.

Other issues

Antibiotics are not routinely used. Pentoxifylline has been tried experimentally but is of no proven benefit.

19

Viral exanthems

Romina Bromberg, Michael Thompson, Lisa M. Chirch, and Jane M. Grant-Kels

During the early 1900s, six common childhood exanthematous infections were identified and defined by the use of numbers 1 through 6. The microbiologic agents of these infections were unknown. Over the next century, the etiologies of these exanthems were defined, and four of the six were demonstrated to be caused by viruses (Table 19.1). The first exanthem was caused by the measles virus, the third by the rubella virus, the second and fourth by bacterial toxins, the fifth by parvovirus, and the sixth by human herpesvirus 6 (HHV-6). This chapter will address the epidemiology, clinical manifestations, and diagnosis of the classic childhood viral exanthems: measles (rubeola), German measles (rubella), and exanthem subitum (roseola), and parvovirus B19 (pB19). Viral exanthems seen more often in adults (Epstein–Barr virus [EBV], HIV), as well as emerging viruses with viral exanthems are also discussed in this chapter.

Classic viral exanthems of childhood

Rubeola (measles)

Epidemiology and virology

The incidence of measles has declined substantially in the past few decades due to global increased vaccination efforts. There were 89,780 deaths in 2016, down from 550,100 deaths in 2000. Despite the fact that global measles deaths have decreased by 84% worldwide in a recent update by the World Health Organization (WHO), measles is still common in developing countries, especially in parts of Africa and Asia. Historically, measles has primarily been a disease of young children. While the incidence of measles has decreased across all age groups with increased vaccination efforts, the relative incidence of measles has increased in groups which may be less likely to have been vaccinated or have insufficient immunity, including older adults, children under the age of 1 year, and social groups that eschew vaccinations. Unfortunately, there has been a rise in cases from 2018 through 2019. In 2019 alone, there have been 10 US states affected by the measles outbreak thus far, with a total of 127 cases just in less than 2 months, from January 1 to February 14, 2019.

Rubeola is caused by an RNA virus with one serotype and is classified in the genus *Morbillivirus* in the Paramyxoviridae family. Most cases of measles occur in the late winter or spring. Humans are the only natural hosts, and transmission occurs by exposure to infectious droplets. Rubeola is one of the most highly contagious of the infectious organisms. Appropriate isolation of cases in hospital settings is critical to limit nosocomial transmission. A patient hospitalized with measles requires airborne precautions for 4 days after the onset of rash. However, if the patient with measles is immunosuppressed, airborne precautions are required until the illness completely resolves. The measles virus is labile and survives only a short time on fomites. The highest rates of transmission occur in the home, and in daycare centers, nursery schools, primary

TABLE 19.1 **CLASSIC EXANTHEMS OF CHILDHOOD**

Order	Exanthems	Agent
First	Rubeola or measles	Measles virus
Second	Scarlet fever	Streptococcal toxin
Third	Rubella or German measles	Rubella virus
Fourth	Filatov–Dukes' disease	Unknown, possibly strep. or staph. toxin
Fifth	Erythema infectiosum	Parvovirus
Sixth	Exanthem subitum or roseola	Human herpesvirus 6

and secondary schools, colleges, and universities. School outbreaks can occur despite >95% immunity among students.

Clinical and laboratory diagnosis

Clinical measles demonstrates a fairly characteristic presentation. However, given the dramatically lower incidence of illness in recent years, many contemporary providers have not seen a classic measles infection, so diagnosis may not be obvious. In addition, presentation may be atypical in immunocompromised patients.

The incubation period is 10 to 12 days. There is a prodrome of low-grade fever, malaise, and headache. This is followed or accompanied by cough, coryza, and conjunctivitis. During the prodrome, an enanthem appears on the buccal mucosa and may spread to the hard or soft palate. The typical enanthem of measles (Koplik spots) consists of punctate white or gray lesions described as grains of sand on an erythematous base. As the infection evolves, the number of Koplik spots increases and lesions coalesce. These resolve with the onset of the rash. After about 4 days of increasing prodromal symptoms, the patient develops high fever and rash. The rash (Figure 19.1) begins as erythematous macules and papules at the hairline, on the forehead, behind the ears, and on the upper neck. This characteristic morbilliform exanthem occurs in the large majority of infected individuals. The rash spreads centrifugally to the trunk and extremities over the next 3 days, blanches on pressure and may coalesce; when it resolves, it may leave brownish hyperpigmentation resulting from capillary hemorrhage (siderophages) and melanophages. The eruption may not occur at all, or it could be severe in patients who are immunosuppressed. When present, the high fever and rash persist for 2 to 4 days. As the rash fades, the coryza and conjunctivitis clear, but the cough may persist for another 5 days. Immunocompetent patients are contagious from the onset of the prodrome until approximately 4 days after the onset of the rash.

FIGURE 19.1 Measles in a boy presenting as morbilliform lesions on the face, trunk, and palms.

From https://phil.cdc.gov/Details.aspx?pid=1150

The most common complications of measles are secondary bacterial infections, including pneumonia and otitis media. Diarrhea may also occur as a complication. The risk of complications is highest for infants <1 year of age. Postinfectious encephalomyelitis occurs in approximately 1 per 1,000 measles cases within a few days of rash onset. Most patients recover, but many have persistent developmental sequelae. Acute disseminated encephalomyelitis (ADEM) is a demyelinating disease that occurs later, typically within 2 weeks of recovery. Also called postinfectious or postvaccine encephalomyelitis, ADEM may be related to an autoimmune response and carries a 10% to 20% mortality, with survivors commonly suffering neurologic sequelae. In contrast, subacute sclerosing panencephalitis (SSPE) occurs several years (classically 7–10) after natural infection and carries a very high mortality rate. This complication has become exceedingly rare with the dramatic decrease in measles cases over the past few decades due to immunization availability and utilization.

Measles can be confirmed by viral cultures of the nasopharynx, conjunctiva, blood, or urine. However, culture is technically difficult and not readily available. Sera may be obtained for measles antibody determinations both at the onset of the rash and 2 to 4 weeks later. A significant increase of measles immunoglobulin (IgG) antibody (acute and convalescent) is diagnostic. A measles-specific IgM antibody test is also available. This IgM antibody is detectable from about 3 to 30 days after the onset of the rash. Finally, isolation of measles virus RNA by polymerase chain reaction (PCR) from clinical specimens such as those just listed is diagnostic. Immunity after measles infection is lifelong, and a second attack is therefore very rare.

Treatment and prevention

Treatment of measles is usually supportive; acetaminophen or a nonsteroidal anti-inflammatory drug (NSAID) is used for pain and fever. Oral vitamin A supplementation may minimize morbidity and mortality in malnourished patients. For reasons that are not well defined, malnourished patients may suffer acute vitamin A deficiency when infected with measles. Vitamin A is necessary for the maintenance of epithelial integrity and for normal immune function. The WHO now recommends treatment with vitamin A supplementation once a day for 2 days for all children with acute measles; specific doses vary with age (200,000 IU for children 12 months and older; 100,000 IU for infants 6 to 11 months; 50,000 IU for infants under 6 months). Because measles may be complicated by secondary

bacterial infection, prophylactic antibiotics are sometimes prescribed although not generally recommended. The most common bacterial complication is pneumonia caused by *Streptococcus pneumoniae*, *Haemophilus influenzae*, or *Staphylococcus aureus*. Measles virus is susceptible in vitro to the antiviral agent ribavirin. However, ribavirin is not approved by the US Food and Drug Administration (FDA) for this indication and is associated with significant toxicity. There are anecdotal reports of successful use of intravenous and/or aerosolized ribavirin to treat severely ill, immunosuppressed patients with measles.

Measles vaccine is routinely recommended at ages 12 to 15 months. This vaccine is a live attenuated strain grown in chick embryo cells. In infants, the efficacy of this vaccine is hindered by passive maternal antibody, which is no longer present by 12 months. If the mother is immune via natural infection, not immunization, then maternal antibody can persist in the infant until 15 months. A second measles vaccine dose is recommended at 5 to 12 years of age. In areas of high measles prevalence, vaccine is given at <1 year of age to protect this particularly vulnerable population. However, due to possible interference from maternal antibody, vaccine doses administered at <1 year of age should not be counted toward vaccine requirements. Unimmunized children and adults should be given two measles doses at least 1 month apart. Following one measles vaccine dose, approximately 95% of patients will show a positive measles antibody response. This response rate increases to >99% following two doses.

Patients who are exposed to measles and have not been immunized may benefit from a measles vaccine if given within 72 hours of exposure. In addition, unimmunized patients susceptible to infection via close or household contact may receive immune globulin (IG; 0.25 mg/kg intramuscularly) within 6 days of exposure to prevent or minimize disease. Because measles inoculation is a live vaccine, it is not recommended for immunosuppressed patients (see Box 19.1 for contraindications). An exception to this rule is that vaccine should be administered to patients with well-controlled, stable HIV infection (with CD4 counts >200 cells/mm^3) because of the potentially devastating outcome of measles in this group. Severe immunocompromise or a low CD4% (<15%) would, however, be a contraindication to the live vaccine. Ensuring immunization of close contacts may confer additional protection for these patients by decreasing the chances of exposure.

International travelers should be evaluated for measles immune status and risk. Infants traveling to developing countries where measles is endemic may receive the measles vaccine as early as 6 months of age. Adults born after 1957 who have an inadequate or undocumented vaccine status may opt to have antibody testing to determine vaccination needs prior to travel.

BOX 19.1

Pregnancy
Immunodeficiency except for well-controlled HIV infection
History of anaphylaxis to eggs
History of anaphylaxis to neomycin

Rubella (German measles)

Epidemiology and virology

Rubella virus is an enveloped togavirus with a single strand of RNA at its core. In 2004, Rubella was declared eliminated (absence of endemic transmission for 12 months or more) from the United States. Fewer than 10 cases (mostly imported) have been reported annually in the United States since elimination was declared. Since the vaccine was developed in 1969, rubella incidence in the United States decreased by >99%. Although Rubella is no longer endemic in the United States, approximately 10% of US-born persons remain susceptible to infection despite vaccination. Risk of infection is highest in those who are less likely to be vaccinated, such as people born outside of the United States and social groups who reject vaccination.

Before the widespread availability of the rubella vaccine, the primary danger posed by rubella virus was the specter of infection during pregnancy, which could lead to congenital rubella syndrome in the newborn. Women born outside the United States are less likely to have received immunization; therefore, the risk of congenital rubella in the United States is highest in infants born to those women. Since 2004, 60% of rubella infections have occurred in patients aged 20 to 49 years. The median age of infection is 32 years.

Clinical and laboratory diagnosis

Rubella infection in infants and children is usually mild; up to 50% of infections in children are asymptomatic. A prodrome characterized by tender posterior auricular, posterior cervical, and suboccipital adenopathy with malaise is common among adolescents and adults with rubella. The adenopathy may persist for weeks. The rubella exanthem begins on the face, neck, and scalp and spreads centrifugally to the trunk and extremities. The rash may be associated with fever, headache, myalgias, and arthralgias. The eruption consists of pink macules and papules that range in diameter from 1 to 4 mm. The exanthem fades as it spreads; thus, it may be absent on the face when it is prominent on the trunk. The enanthem, Forchheimer's sign, occurs in 20% of patients and is characterized by petechiae or red spots on the soft palate. It occurs during the prodrome or at the onset of the exanthem. Rubella is most commonly seen during late winter and early spring.

Rubella is spread by small droplets from the respiratory mucosa. Patients are most contagious from a few days before until up to 7 days after the onset of rash. Viral shedding can occur for up to 14 days after the onset of rash. Prolonged exposure usually is necessary for transmission. The incubation period is 14 to 23 days.

Complications of rubella are unusual. The most common complication is arthritis, which occurs almost exclusively in females and increases in incidence in older age groups. Rare complications include thrombocytopenia and encephalitis. The most devastating complication is congenital rubella syndrome. The frequency of

congenital rubella is 50% if rubella infection occurs during the first 12 weeks of pregnancy. This incidence diminishes to 25% for infections occurring from 13 to 24 weeks. Congenital rubella syndrome is rare if maternal infection occurs after 24 weeks' gestation. Congenital rubella syndrome is commonly characterized by deafness, congenital cataracts, and patent ductus arteriosus. Severe involvement is often fatal, and infection can involve many organs, including the skin (described as "blueberry muffin" lesions because of bluish areas due to extramedullary hematopoiesis).

Rubella can be diagnosed by the typical exanthem and associated posterior auricular adenopathy. The virus can be isolated from nasal secretions, but most laboratories do not have the proper reagents needed for isolation. Acute and convalescent (2–4 weeks after rash) serology should show a fourfold or greater rise in IgG antibodies. A rubella-specific IgM antibody test is also available and is indicative of recent infection. The IgM antibody persists for several months after acute infection. False-positive IgM titers are associated with rheumatoid arthritis, parvovirus infection, and heterophile antibodies. Molecular diagnosis and typing using reverse transcriptase PCR may be useful in epidemic settings.

Treatment and prevention

Typical rubella infection is mild and requires no therapy. The occasional patient with severe arthralgias or arthritis should respond to therapy with NSAIDs. Arthralgias and arthritis are much more common in females. The routine administration of IG after exposure is not recommended. However, the administration of intramuscular IG may be considered if a pregnant woman is exposed in early pregnancy.

Rubella vaccine should be given with measles and mumps vaccine (MMR) in the same two-dose schedule: the first dose at 12 to 15 months and the second at 5 to 12 years of age. Contraindications for rubella vaccine are listed in Box 19.2. Because rubella is a live vaccine and can potentially infect the fetus, it should not be given during pregnancy, although the risk of fetal infection is low. In a study of 226 susceptible women who were inadvertently immunized with rubella vaccine during the first trimester, there were no congenital abnormalities in the offspring, and two offspring showed asymptomatic infection. This benign outcome may reflect the fact that this is an attenuated viral vaccine. Although immunocompromising states are relative contraindications to receipt of MMR vaccine, immunization should be considered in susceptible patients with well-controlled HIV infection (see the section on Rubeola).

BOX 19.2

Contraindications to rubella vaccine

Pregnancy
Immunodeficiency except well-controlled HIV infection
Immunoglobulin in the last 3 months

Roseola (exanthem subitum)

Epidemiology and virology

Roseola is predominantly caused by HHV-6, a double-stranded DNA virus. There are two major groups of HHV-6, variants A and B. Ninety-seven to100% of primary infections with HHV-6 are caused by variant B. Though far less common, other causes of roseola include human herpesvirus 7 (HHV-7), enteroviruses (coxsackieviruses A and B, echoviruses), adenoviruses, and parainfluenza virus type 1.

At birth, newborns usually passively acquire HHV-6 antibody. This protects the infant until about 6 months of age. From 6 to 24 months of age, about 80% of infants become infected with HHV-6, and almost all children are seropositive by 4 years. Cases of roseola occur throughout the year. The mode of transmission is unknown. It is unusual to demonstrate roseola spreading from one infant to another. After acute infection, HHV-6 can often be isolated from saliva. Saliva transmission from an asymptomatic contact to a susceptible infant may be the most common route of transmission. HHV-6 can also be isolated from both peripheral blood lymphocytes and cerebrospinal fluid.

First isolated in 1986, HHV-6 is a herpesvirus distinct from herpes simplex 1 and 2, varicella-zoster virus, cytomegalovirus, and EBV. Soon after, the isolation of HHV-7 was reported in 1990. HHV-6 may be divided into two major groups, variants A and B. Primary infection is almost always caused by variant B strains. In addition to causing roseola, HHV-6 can cause a febrile illness without rash as well as a febrile illness with lymphadenopathy, gastroenteritis, upper respiratory infection, and otitis (see Chapter 186, "Human herpesvirus 6, 7, 8"). Reactivation of HHV-6 infection in immunocompromised patients, particularly those who have undergone bone marrow transplant, has myriad manifestations, including but not limited to rash, hepatitis, pneumonia, bone marrow involvement, and encephalitis.

Clinical and laboratory diagnosis

The incubation period of roseola is 9 to 10 days; the disease has no prodrome. Clinical illness begins with a high fever (38°C to 40°C/100°F to 104°F). Febrile seizures occur in a significant number of infected children. Roseola may account for at least 10% of visits to the emergency room for infants <2 years. In addition, roseola accounts for 33% of febrile and recurrent febrile seizures seen in emergency rooms. The fever typically lasts 3 days. When the fever resolves, the exanthem usually appears, but it may also begin before the fever resolves. The exanthem is characterized by discrete, pale pink macules, varying in size from 1 to 5 mm in diameter. Around each lesion is a pale areola. Distinct from the measles and rubella exanthems, the rash commonly begins on the trunk, on the neck, and behind the ears and spreads to the proximal extremities; it rarely involves the face or distal extremities. The rash may become confluent and usually lasts for 2 to 48 hours. Before the exanthem appears, an enanthem of erythematous macules may be present on the soft palate. Vertical transmission of HHV-6 occurs in 1% to

2% of births. The significance of vertical transmission of HHV-6 is unknown.

Acute HHV-6 infection may be diagnosed by seroconversion from HHV-6 antibody negative to HHV-6 positive. A specific IgM antibody peaks 7 to 14 days after the onset of illness and usually becomes undetectable in several weeks. However, HHV-6 IgM antibody may persist in some patients and thus may be present without acute infection. Specific IgG antibody develops 2 to 4 weeks after the onset of illness and remains detectable indefinitely. Also, the IgG antibody may intermittently rise and fall, especially in association with cytomegalovirus or EBV infections. HHV-6 can be cultured from saliva and from mononuclear cells, and viral DNA can be detected in blood and cerebrospinal fluid by PCR.

Treatment and prevention

At present, no treatment or prevention strategies are available for HHV-6 infection in normal children and adults. In immunocompromised individuals, possible therapies include ganciclovir, foscarnet, and cidofovir. Because the mechanism of spread is not definitively known, only standard precautions are recommended for hospitalized patients.

Viral exanthems of adolescence and adulthood

Infectious mononucleosis

Epidemiology and virology

Infectious mononucleosis is typically caused by EBV, also known as human herpesvirus-4, an enveloped DNA virus. Infection with EBV is prominent globally, with 90 to 95% of adults testing seropositive. When EBV is acquired in childhood, it is typically mild or asymptomatic. By contrast, approximately 75% of adolescents who are infected present with symptomatic infectious mononucleosis. In developing countries, infection with EBV occurs earlier in childhood, and clinical infectious mononucleosis is rare. Disease is more common in developed countries where infection tends to occur later in adolescence or early adulthood. The peak incidence of infectious mononucleosis transpires between 15 and 24 years of age. The disease is most commonly spread by saliva but can also be transmitted via semen and blood.

Clinical findings

Symptoms of infectious mononucleosis typically present 4 to 6 weeks after infection with EBV. The prodrome consists of usually severe persistent fatigue and myalgias and typically lasts 1 to 2 weeks. Following the prodrome, patients present with cervical lymphadenopathy, fever, severe sore throat due to pharyngeal inflammation, hepatomegaly, and splenomegaly. A generalized maculopapular, urticarial, or petechial rash may also be seen in some patients. The characteristic exanthem is a maculopapular rash involving the trunk and arms. It appears shortly after the onset of symptoms, lasts for 1 to 6 days, and is identified in 3% to 15% of patients. Complications from infectious mononucleosis are rare and may include splenic rupture, hepatitis, myocarditis, and central nervous system dysfunction secondary to meningitis or encephalitis. Ten percent of patients will develop persistent fatigue that lasts for >6 months.

Another potential severe complication of infectious mononucleosis is hemophagocytic lymphohistiocytosis (HLH), a life-threatening syndrome of excessive immune activation. HLH most commonly affects infants from birth up to 18 months of age but can also be seen in adults. HLH is precipitated by a cascade of events that disturb the immune system's homeostasis. HLH can be either primary (or familial HLH) or secondary (acquired HLH), and one of the most common viral infections associated with HLH is EBV. Common clinical manifestations of HLH are fever, hepatosplenomegaly, neurological findings (seizures, altered mental status, and ataxia), cytopenias, high ferritin, and liver function abnormalities. Physicians who have a high clinical suspicion for HLH should promptly work up their patients as delay in diagnosis and treatment has serious consequences and high mortality.

Diagnosis and treatment

Infectious mononucleosis is typically diagnosed clinically. Serology may be used to confirm infection with EBV, but results and interpretation can vary. In cases with inconclusive serological results, measurement of EBV viral load by real time PCR can be useful. Patients typically have lymphocytosis with >10% atypical lymphocytes.

Treatment for infectious mononucleosis is supportive. NSAIDs may be used to manage pain. Patients should be instructed to avoid vigorous physical activity in the first month as this may increase the risk for splenic rupture. Most patients with infectious mononucleosis who are treated with amoxicillin or ampicillin will develop a maculopapular rash. The mechanism for this antimicrobial rash in EBV patients is not entirely understood. EBV causes polyclonal B-cell activation, increased immunoglobulins, and increases atypical lymphocytes ($CD8^+$ T cells). Hypersensitivity is unlikely because there are no antibodies against ampicillin and rechallenging with the drug does not cause a reaction. One possible explanation is that polyclonal antibodies may form immune complexes with drugs and deposit in the dermis, causing tissue damage. Skin biopsies of affected patients have shown $CD8^+$ T-cell infiltration, suggesting that activated $CD8^+$ T cells react with drug antigens as another possible explanation.

Parvovirus B19

Epidemiology and virology

PB19 is a single-stranded, non-enveloped DNA virus, which is part of the Parvoviridae family in the *Erythrovirus* genus. There are three genotypes within the Erythroparvovirus genus. PB19 is

the predominant parvovirus pathogen in humans and the prototype genotype 1 strain. The only known host for pB19 is humans. Productive infection and replication occur only in human erythroid progenitor cells of the bone marrow. Parvovirus gains entry into cells by binding to P antigen, which are found in high concentration on red blood cells and other cell lines (i.e., endothelial cells, cardiomyocytes, megakaryocytes). Parvovirus causes cell lysis upon viral maturity.

PB19 is a common global infection, with seroprevalence increasing with age: 15% of preschool aged children, 50% of young adults, and 85% of older adults have measurable pB19-specific IgG antibodies. In the United States, pB19 infection is most common during the winter and early spring. Epidemics typically strike every 3 to 4 years, with most occurring in children. Adults who work closely with children, such as teachers and daycare workers, are also at risk of infection.

Clinical findings

Clinical manifestations of pB19 infection are variable, ranging from asymptomatic to life-threatening disease. The clinical appearance is influenced by age and hematologic and immunologic status. The five classic presentations associated with pB19 infection are erythema infectiosum, arthropathy, transient aplastic crisis, fetal infection, and pure red blood cell aplasia in immunocompromised individuals.

Erythema infectiosum is associated with the characteristic exanthem induced by pB19 at 1 to 4 days after the onset of fever. The exanthem starts as an erythematous facial rash, also known as a "slapped cheek" rash (see Figure 19.2). After 1 to 4 days, the rash becomes maculopapular and spreads to the trunk and extremities. Central clearing of the rash may give it a reticular, lace-like appearance. The rash on the trunk and extremities persists for 1 to 6 weeks. During this time, the intensity of the exanthem may vary with exposure to sunlight or heat. Rash most commonly occurs in children; when it occurs in adults, the eruption is often less characteristic.

Arthralgias following infection with pB19 occur in 8% of children but are more common in adolescents and adults. PB19 can precipitate aplastic crises in patients with chronic hemolytic anemias, such as those due to sickle cell disease or hereditary spherocytosis. These patients less commonly develop a rash but may present with clinical symptoms of anemia, such as pallor or malaise, following a mild febrile illness.

The most severe complication of pB19 infection is fetal loss from hydrops fetalis as a result of maternal infection that can occur in 5% to 10% of infected pregnant women.

FIGURE 19.2 Right anterior-oblique view of a boy's face displaying the "slapped cheek" rash of erythema infectiosum, or Fifth disease, caused by the human parvovirus B19.

From https://phil.cdc.gov/details.aspx?pid=4508

Diagnosis and treatment

Diagnosis of pB19 can be made through serology or PCR. Detection of viral RNA or DNA through PCR is indicative of acute or persistent infection. PB19 IgM may be detected 10 days after infection and can persist for up to 4 months. PB19 IgG is present shortly after IgM and persists indefinitely.

Management of pB19 infection is primarily supportive and, in immunocompetent patients, is typically self-limited. In patients with aplastic crises from pB19, hospitalization and transfusion may be required. In fetuses with hydrops fetalis due to pB19, the administration of intrauterine erythrocyte transfusions can reduce fetal mortality. Beyond supportive red blood cell transfusion, more aggressive therapy with IVIG is generally limited to patients with chronic pB19 infection, chronic anemia, and in those who are immunosuppressed, as those with AIDS.

Hand, foot, and mouth disease

Epidemiology and virology

Hand, foot, and mouth disease (HFMD) is caused by multiple serotypes of enterovirus, a single-stranded RNA virus. Coxsackievirus A16 and enterovirus A71 cause the majority of cases of HFMD. Enterovirus A71 has been associated with major outbreaks of HFMD in Southeast Asia and the Pacific. Enterovirus A6 is emerging as a leading cause of outbreaks around the world. Viral transmission occurs via the fecal-oral route and person-to-person contact. Direct contact with vesicle fluid or oral and respiratory secretions can also lead to infection. The incubation period is typically 3 to 5 days.

Although HFMD can occur in patients of all ages, it typically impacts infants and children <5. Cases of HFMD occur worldwide, with an increased incidence in the summer and early fall.

Clinical findings

HFMD characteristically presents with low-grade fever and mouth or throat pain. Prodromal symptoms (e.g., nausea, abdominal pain, and diarrhea) tend not to occur but are sometimes seen.

Approximately 75% of patients with HFMD will present with both an oral enanthem and a cutaneous exanthem. The oral enanthem of HFMD typically occurs on the tongue and buccal mucosa and sometimes the buccal and palate mucosa. Oral lesions start out as erythematous macules that progress to vesicles before

FIGURE 19.3 Diagnostic approach for adults with fever and maculopapular rash.
From https://wwwnc.cdc.gov/eid/article/18/2/11-1147-f1

forming superficial painful ulcers. The exanthem tends to occur on the hands, feet, buttocks, legs, and arms and may be maculopapular and/or vesicular. The rash lasts 3 to 4 days and is not classically pruritic or painful, unlike the atypical perioral exanthem that can be very painful. Outbreaks of HFMD with atypical skin manifestations have also been reported. The exanthem of atypical HFMD includes diffuse vesicles, bullae, and erosions. In addition to the classical locations of HFMD (hands, feet, buttocks, oral mucosa), atypical HFMD also occurs on the torso and perioral area (see Figure 19.3).

Diagnosis and treatment

Diagnosis is typically made clinically based on oral and skin manifestations. Confirmation of specific viral etiology can be obtained via PCR testing and viral culture from vesicular fluid, although this may be of limited clinical utility.

The clinical course of HFMD is generally mild and tends to resolve within 7 to 10 days. Management is generally supportive.

HIV: Primary infection

Epidemiology and virology

HIV is a member of the Retroviridae family. Its genome is made up of two pieces of single-stranded RNA. There are two types of HIV that can cause infection, HIV-1 and HIV-2. HIV-1 is found globally and is the subtype responsible for most HIV infections in the United States. HIV-2 is primarily found in Western Africa and has a lower infectivity than HIV-1.

HIV-1 most often enters the host through the anogenital mucosa then binds to and infects dendritic CD4 cells. Fusion of HIV-infected cells with $CD4^+$ T cells leads to spread of the virus. Once the virus has entered the blood, widespread dissemination occurs.

Since the height of the HIV epidemic in the 1980s, the incidence of HIV in the United States has decreased. An estimated 1.1 million persons aged 13 and older were living with HIV infection in the United States in 2015. Additionally, the estimated number of new HIV infections in the United States in 2015 was 38,500. Estimated annual HIV infections in the United States declined 8% from 2010 to 2015. Advances in HIV therapy have led to increased survival. All populations may be affected by HIV. Incidence is highest in men who have sex with men, followed by heterosexual African American women. HIV is transmitted through contact with infected bodily fluids including semen, preseminal fluids, blood, rectal fluids, vaginal fluids, and breast milk. In the United States, HIV is primarily transmitted through sexual intercourse and the sharing of infected needles.

Clinical findings

Primary HIV infection typically presents with fever, headache, malaise, weight loss, myalgia, lymphadenopathy, diarrhea, and rash occurring 2 to 6 weeks after exposure. About 30% to 50% of patients will develop a generalized rash during the acute phase of disease. The exanthem of primary HIV is maculopapular, with characteristically small (5–10 mm), well-circumscribed, oval lesions. Vesicular, pustular, and urticarial lesions have also been less commonly described. Rash occurs on the face, collar region, and upper thorax. Affected areas may also include the scalp, extremities, palms, and soles. Patients may have oral lesions with resultant dysphagia. Onset of rash typically occurs 48 to 72 hours after onset of fever and subsides after 5 to 8 days. Because this constellation of symptoms is transient and nonspecific it may be confused with a variety of other infectious etiologies; therefore, a high degree of clinical suspicion is required

to make the diagnosis. The importance of early diagnosis cannot be overestimated as earlier diagnosis translates into immune preservation in the infected individual and decreased transmission to others.

Diagnosis and treatment

Initial diagnosis of primary HIV is now usually with a fourth-generation combination HIV-1/2 immunoassay. This assay detects both HIV-1 and HIV-2 antibodies as well as HIV p24 antigen. Most people will test positive 7 to 28 days after infection. It is important to recognize that with any screening test for HIV, there is a "window" period just after infection during which no serologic test will return positive. As such, a high clinical suspicion of acute infection should drive the clinician to request HIV RNA testing by PCR, which is the earliest test to become positive after infection. Antiretroviral therapy, now extremely effective and well-tolerated, should be started in all patients who test positive for HIV as soon as possible.

Emerging viral exanthems

West Nile virus

Epidemiology and virology

West Nile virus (WNV) is a positive-sense RNA virus that is part of the *Flavivirus* genus. WNV is primarily transmitted by the *Culex* mosquito. It is most frequently found in North America, Africa, Europe, the Middle East, and West Asia.

WNV is the leading cause of arboviral encephalitis in the United States. As of October 2018, a total of 49 states and the District of Columbia have reported WNV infections in people, birds, or mosquitoes. Of the 2,204 reported cases of WNV disease, 1,342 (61%) were neuroinvasive and 862 (39%) were non-neuroinvasive (CDC). Incidence of infection is highest in older adults. Infections peak between August and October.

Clinical findings

About 80% of patients who are infected with WNV are asymptomatic. Those who do develop symptoms typically present 3 to 14 days after infection with fever, headache, myalgias, diarrhea, nausea, and vomiting. Patients may also develop a maculopapular rash which is concentrated on the trunk. Complications from WNV may include encephalitis, central nervous system damage, and death; these occur more frequently in the elderly and in patients with hypertension or diabetes. One in 150 patients will develop severe central nervous system infection, and, out of those, 1 in 10 will die. For those patients who are pregnant, it is possible for the virus to cross the placenta and infect the fetus. However, transplacental infection appears to be rare. Rare cases of congenital infection among neonates born to women who developed symptomatic WN virus infection have been reported.

Diagnosis and treatment

WNV infection may be diagnosed using serology. Anti-WNV IgM may be detected 3 to 8 days after infection. PCR or viral culture is also used for diagnosis. Treatment for WNV is primarily supportive, including adequate hydration. NSAIDs may be used to control pain and fever. Patients with severe disease may need to be hospitalized for supportive care.

Ebola virus

Epidemiology and virology

Ebola virus is an enveloped, single-stranded RNA virus which is part of the Filoviridae family. Three species of Ebola virus have been responsible for the majority of recent outbreaks in Africa: Zaire, Bundibugyo, and Sudan Ebola virus.

Ebola virus is found primarily in Western Africa. It was first discovered in 1976. Since then, it has periodically caused outbreaks. The largest outbreak to date occurred from 2014 to 2016 and was centered in Guinea, Sierra Leone, and Liberia. It spread to several other countries including Italy, Spain, the United Kingdom, and the United States. Since 2014, a total of 28,616 suspected infections occurred, with 11,310 deaths. There were four cases of Ebola in the United States during the outbreak. Most affected individuals were travelers to West Africa and healthcare workers who cared for patients with Ebola. Since the 2014–2016 outbreak, the incidence for Ebola has dropped substantially. In 2017, there were only eight known cases of Ebola, found in the Democratic Republic of Congo. In 2018, there has been one outbreak of Ebola in the Democratic Republic of Congo, resulting in 372 cases and 194 deaths as of November 2018. People at risk for Ebola virus include travelers to endemic regions in West Africa and healthcare workers who may be exposed to Ebola virus.

Clinical findings

Onset of symptoms typically occurs 6 to 12 days after exposure to Ebola virus. The initial syndrome is marked by abrupt onset of fever, chills, and malaise. Within a few days, patients generally develop gastrointestinal symptoms such as nausea, vomiting, and diarrhea. Headache, weakness, myalgias, and high-grade fever may also occur.

Between days 5 and 7, patients may develop a diffuse erythematous maculopapular rash. Affected areas typically include the face, neck, trunk, and arms. The rash may desquamate. In the Sierra Leone outbreak, rash was described as rare; however, the eruption is generally easier to visualize in fair-skinned individuals.

Hemorrhage is frequently observed in patients with Ebola, most commonly manifested as blood in the stool, petechiae, ecchymoses, oozing from venipuncture sites, and/or mucosal bleeding. Clinically significant hemorrhage may be seen in the terminal phase of illness and in pregnancy.

Ebola infection can lead to multiorgan failure, septic shock, and ultimately may cause death. There is a high case fatality rate for Ebola, ranging from 18.5% in the United States and Europe to 74% in parts of Western Africa. In nonfatal cases of Ebola, patients

usually start to improve on day 6. They typically have a long recovery period, which can last up to 2 years.

Diagnosis and treatment

Clinicians should consider the diagnosis of Ebola virus for any person presenting with acute onset of a febrile illness who lives in or has recently been to West or Central Africa. An early diagnosis is essential to ensure implementation of proper infection control procedures and to reduce viral transmission. Laboratory diagnosis can be made using reverse transcriptase PCR. Treatment of Ebola virus infection is primarily supportive and mainly consists of volume resuscitation and pain control. There is currently no approved vaccine for prevention of Ebola virus. However, accelerated paths have been developed for introduction of vaccinations into field use during recent epidemics in West Africa.

Chikungunya

Epidemiology and virology

Chikungunya is an arthropod-borne alphavirus transmitted by mosquitos. The major mosquito vectors are *A. aegypti* and *A. albopictus*. Viral transmission can also rarely occur via maternal-fetal transmission and through blood products and organ transplantation.

While Chikungunya is endemic to parts of West Africa, outbreaks have occurred in Africa, Asia, Europe, islands in the Indian and Pacific Oceans, and, more recently, in the Americas. The first cases of Chikungunya were reported in Florida in 2014. Large outbreaks affecting 30% to 75% of populations have occurred.

Clinical manifestations

Abrupt onset of symptoms typically occurs 3 to 7 days after the mosquito bite. Typical symptoms include fever (often high-grade) and polyarthralgias (often >10 affected joints). Hands, wrists, and ankles are the most common affected joints involved. The word "*chikungunya*" is derived from an African word meaning "that which bends up" in reference to the stooped posture of infected patients due to severe arthritic symptoms.

Skin manifestations may occur in 40% to 75% of patients. A maculopapular rash typically presents 3 days after onset of illness. Affected areas include the trunk, limbs, and, less commonly, the face. Rash lasts approximately 3 to 7 days. Atypical skin manifestations such as bullous lesions and hyperpigmentation have been described.

Severe complications such as respiratory failure, renal failure, acute hepatitis, and meningoencephalitis can occur. A subset of patients will have persistent arthralgias and tenosynovitis in the months following illness.

Diagnosis and treatment

Chikungunya should be suspected in patients presenting with typical clinical manifestations and relevant epidemiological exposure. Diagnosis can be established via serologic testing and reverse-transcription PCR (RT-PCR). Immunoglobulin IgM anti-chikungunya virus antibodies are typically present 5 days after onset of symptoms.

Management of acute chikungunya virus is supportive. There is currently no antiviral therapy available.

Zika virus

Epidemiology and virology

Zika virus is a single-stranded RNA virus that is part of the *Flaviviridae* family. It is an arbovirus that is primarily transmitted by mosquitoes of the Culicidae family and the *Aedes* genus (Figure 19.4).

FIGURE 19.4 *Aedes aegypti* female.
Courtesy of CDC/Paul I. Howell, MPH; Prof. Frank Hadley Collins; https://wwwnc.cdc.gov/travel/page/world-map-areas-with-zika

TABLE 19.2 **EMERGING VIRUSES AND SKIN MANIFESTATIONS**

Virus	Onset	Characteristic
West Nile virus	3–14 days	Maculopapular rash on trunk
Ebola virus	5–7 days	Erythematous maculopapular rash. Affected areas typically include the face, neck, trunk and arms.
Chikungunya	3–7 days	Maculopapular rash. Affected areas include the trunk and limbs and sometimes the face.
Zika virus	2–14 days	Maculopapular rash. Typically originates on the trunk and then progresses to involve the lower extremities and sometimes the face and palms.

Prior to 2007, Zika infections were rare and occurred mainly in Asia and Africa. Since 2007, multiple Zika outbreaks have been reported in Southeast Asia and the Western Pacific. In 2015, Zika was first documented in the Western hemisphere with multiple large outbreaks reported in Brazil. Subsequent to 2015, Zika has spread throughout most of the Americas. In 2016, the incidence of Zika reached an all-time high in the United States with 5,168 symptomatic cases reported, of which 4,897 occurred in travelers from endemic areas and 224 resulted from presumed mosquito-borne transmission in Florida and Texas. In 2017, the incidence of symptomatic Zika in the United States fell to 433 cases. Travelers to Zika-affected regions are most at risk of contracting the infection. High-risk Zika regions include Africa, Southeast Asia, the Caribbean, the Pacific islands, and South and Central America.

Clinical findings

The majority of Zika infections are asymptomatic. When present, symptoms are typically mild. Common symptoms include fever, arthralgias, headache, and a maculopapular rash that typically originates on the trunk and then progresses to involve the lower extremities. The most serious consequence of Zika infection is the increased incidence of birth defects in infants born to Zika-infected pregnant women. These include a number of central nervous system defects including microcephaly, brain abnormalities, eye abnormalities, and neural tube defects. The incidence of birth defects in fetuses of women with laboratory evidence of Zika infection reported to the CDC's US Zika Pregnancy Registry was 5% between January 15 and December 26, 2016. For women with confirmed Zika infection in their first trimester of pregnancy, this number rose to 15%.

Diagnosis and treatment

Zika is definitively diagnosed by real-time RT PCR (rRT-PCR) for Zika virus RNA (in serum, urine, or whole blood) or Zika virus serology. The diagnostic approach depends on the timing of the clinical presentation after the onset of symptoms. There is no specific treatment for Zika virus, and management is essentially supportive care.

Conclusion

In this chapter, we have reviewed common viral infections plus emerging viral infections. Table 19.2 compares the skin lesions and rash distribution for each of the emerging viruses.

Skin ulcer and pyoderma

Joanne T. Maffei

Skin lesions are important clues to systemic diseases, and, conversely, host factors make patients susceptible to skin infections caused by certain organisms. The skin has a limited response to insults from the microbial world, forming vesicles and pustules that eventually rupture and leave exposed dermis. Accurate diagnosis and appropriate treatment depend on a detailed history that includes systemic complaints, history of exposure and travel, and the initial appearance of the skin lesions. Sound diagnosis of difficult cases also depends on appropriate cultures and histopathology. When possible, cultures should be obtained by aspirating pus or blister fluid from under intact skin; cultures from ulcerated skin are less reliable because of colonization by nonpathogenic skin flora. A Gram stain and routine culture should be done first; if the ulcer persists despite a course of antibiotics, a skin biopsy with histopathology and cultures for routine agents, acid-fast organisms, and fungal pathogens is appropriate. If the lesion has multiple thin-walled vesicles with interspersed shallow ulcers and crusts or is on a mucous membrane, a herpes polymerase chain reaction (PCR), direct fluorescent antibody (DFA) test, or viral culture should be considered.

Most superficial skin infections and ulcers can be treated empirically according to the typical clinical presentation of the lesions. A workup is required for lesions that do not respond to routine therapy, that are rapidly progressive, or that occur in an immunocompromised host.

Skin ulcers

Skin ulcers are superficial defects in the tissues of the epidermis and dermis, with surrounding inflammation. Infection, collagen vascular diseases, and malignancy can cause cutaneous ulcerations. Information on host factors, exposure history, and the clinical course of the lesions is critical to narrowing the differential diagnosis. The lesion's anatomic location also may offer clues to the cause. Facial ulcers may be caused by syphilis, herpes, or blastomycosis, whereas ulcers of the arms or hands may be caused by sporotrichosis, nocardia, atypical mycobacteria, herpetic whitlow, or cutaneous anthrax. Ulcers on the chest wall from underlying pulmonary involvement or associated with intravenous (IV) catheters may be caused by aspergillosis. Ulcers in the groin or perineum may result from sexually transmitted infections such as syphilis, chancroid, and herpes, as well as from Behçet's disease or fixed drug eruption.

Ulcers on the lower extremities result from venous insufficiency in 70% to 90% of cases and occur below the knee but never on the bottom of the foot. The patient with venous stasis ulcers has good peripheral pulses and no peripheral neuropathy. Ulcers in patients with poor peripheral pulses, an ankle/brachial pressure index <0.9, or sensory loss must be investigated further because venous stasis is not the cause. Any ulcer on the leg that does not respond to treatment for venous stasis ulcers should be further investigated by biopsy and culture, as should any ulcer that is rapidly progressive or appears on an immunocompromised host. Figure 20.1 outlines the steps in evaluating and treating leg ulcers.

A history of unusual occupation, hobby, or exposure can suggest causes of skin ulcers such as tularemia in rabbit hunters, *Mycobacterium marinum* in aquarium enthusiasts, and leishmaniasis in travelers to endemic areas of the Middle East, North Africa, and Central and South America. Host factors also may

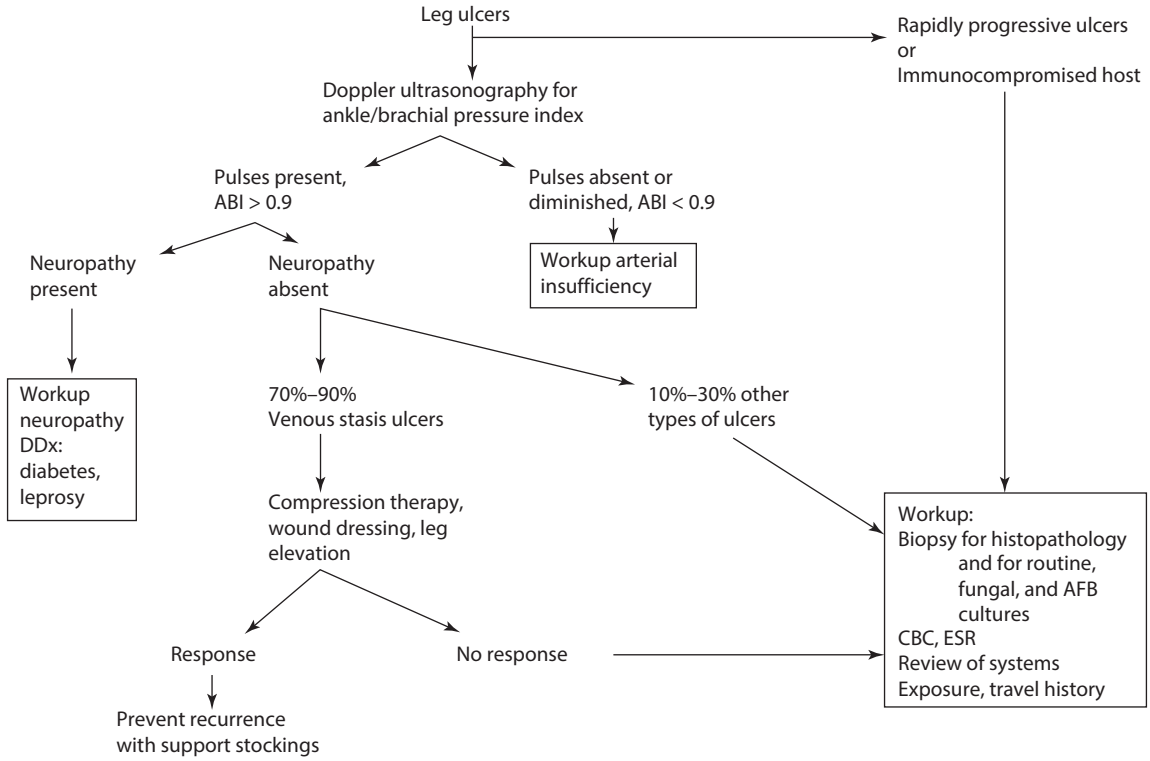

FIGURE 20.1 Algorithm for the evaluation of leg ulcers. ABI, ankle/brachial index; AFB, acid-fast bacilli; CBC, complete blood count; DDX, differential diagnosis; ESR, erythrocyte sedimentation rate.

predispose individuals to any of several types of ulcers. Patients with malignancies can be at risk for ecthyma gangrenosum caused by *Pseudomonas aeruginosa* or dense neutrophilic infiltration of the dermis that is noninfectious but responds to steroids (Sweet's syndrome, discussed later). Ecthyma gangrenosum caused by *P. aeruginosa* is a rapidly progressive (12–24 hours), necrotic ulceration with hemorrhagic bullae and skin sloughing in the setting of gram-negative sepsis and neutropenia. Empiric agents for ecthyma gangrenosum should include piperacillin-tazobactam, cefepime, imipenem, or meropenem plus an aminoglycoside such as tobramycin for high-risk cases.

Treatment of skin ulcers depends on the cause of the lesion. For venous stasis ulcers, local care with occlusive dressings on the wounds and compression bandages to aid venous return is necessary. If cellulitis or folliculitis is present, antibiotics to cover *Staphylococcus aureus* (including methicillin-resistant *S. aureus* [MRSA]), streptococci, and gram-negatives should be administered empirically pending cultures. After the ulcer has healed, compression stockings should be worn to prevent new ulcers. Therapy for other types of ulcers should address their cause; Table 20.1 outlines the clinical presentation and epidemiology of infectious ulcers.

Noninfectious ulcers

Noninfectious causes of cutaneous ulcers include drug reactions, collagen vascular diseases, and malignancy. Drugs reported to cause ulcerations include methotrexate, etretinate, and warfarin. Granulomatosis with polyangiitis (GPA) formerly known as Wegener's granulomatosis, a systemic disease with involvement of the respiratory tract and kidneys, can form necrotizing ulcerations of the skin. Biopsy of these lesions may be positive for leukocytoclastic vasculitis, granuloma, and inflammatory infiltrates. Serology for immunoglobulin G (IgG) antibodies against neutrophilic cytoplasmic components (c-ANCA) is highly specific for granulomatosis with polyangiitis. Treatment includes corticosteroids and cyclophosphamide. Behçet's disease is another systemic condition that involves recurrent oral and genital aphthous ulcerations, arthritis, and uveitis; in some cases it attacks the central nervous system. Treatment includes corticosteroids, colchicine, interferon-α, tumor necrosis factor-α (TNF-α) inhibitors, or azathioprine. Malignancy should always be considered as a possible cause of ulcers that have not responded to antimicrobial therapy because basal cell carcinoma, hematologic malignancies, and metastatic cancers may form skin ulcers.

Pyoderma

Pyoderma is a general term used to describe superficial disruption of the skin with pus formation in response to a bacterial infection. Generally caused by a single organism, pyoderma can be primary or secondary. Similar lesions can be produced by neutrophilic dermatoses such as pyoderma gangrenosum and Sweet's syndrome. Table 20.2 outlines the clinical presentation of pyoderma and suggested treatment.

TABLE 20.1 **CLINICAL PRESENTATION OF SKIN ULCERS CAUSED BY INFECTIOUS AGENTS**

Cause	Laboratory workup	Epidemiology	Clinical clues to diagnosis
Bacterial	Routine culture and Gram stain		
Bacillus anthracis (anthrax)	Gram-positive rod, biopsy for immunohistochemistry and PCR	Wool handler; Western Asia, West Africa, Eastern Europe; injection drug users (heroin); potential bioweapon	Lesions on face and arms; painless papule develops into vesicle that dries, forming black eschar that then separates from the base to form an ulcer with marked surrounding gelatinous edema; LN common; injectional anthrax—higher mortality and shock, significant edema
Corynebacterium diphtheriae (diphtheria)	Gram-positive rod	Tropical climates; rare in the United States	Ulcer with sharp margins and clean base; preexisting skin lesions may become infected
Francisella tularensis (tularemia)	Gram-negative coccobacillus, serology	Rabbits, muskrats, beavers; North America, Japan, Europe, former Soviet Union; potential bioweapon	Systemic febrile illness; tender ulcer with painful LN
Nocardia spp.	Branching, beaded gram-positive rod, modified AFB-positive	Immunocompromised patients, soil exposure	Ulcer with purulent drainage, nodular lymphangitis
Pseudomonas aeruginosa (ecthyma gangrenosum)	Gram-negative rod, may have associated bacteremia	Neutropenic or immunocompromised patients	Rapidly progressive eruption from papules to hemorrhagic vesicles or bullae that undergo central necrosis and ulceration
Polymicrobial	Mixed gram-positive and gram-negative, and anaerobes	Debilitated, immunocompromised, diabetic patients	Pressure sores, decubitus ulcers, foot ulcers
Yersinia pestis (plague)	Gram-negative coccobacillus, bipolar-staining "safety pin" morphology, serology	Rodent zoonosis transmitted to humans via fleas; Far East, India, Africa, Central and South America, potential bioweapon	Bubonic plague with classic inguinal painful LN; may have skin lesions on lower extremities; pustule, papule, vesicle, or eschar may occur at inoculation site
Spirochetes			
Treponema pallidum (syphilis)	Serology	Sexually transmitted infection	Tertiary syphilis; nodular, ulceronodular, gummas; punched-out ulcer with gummy discharge
Fungal	Fungal smear, culture		
Aspergillus spp.	Septate hyphae; serum galactomannan assay in high-risk patients	Immunocompromised, HIV-positive	Ulcers, plaques, nodules, pustules; may be associated with trauma, IV catheter sites, secondary colonization of existing wounds, or direct extension from lung to chest wall
Blastomyces dermatitidis, B. gilchristii	Broad-based budding yeast, dimorphic fungus	Sugar cane worker, HIV-positive, immunocompromised; North America, Africa	Subcutaneous nodule that enlarges and ulcerates forming a crusted, verrucous plaque; may resemble squamous cell carcinoma
Coccidioides immitis, C. posadasii	Dimorphic fungus, serology	Soil exposure, HIV-positive; Southwestern United States, Mexico, Central and South America	Usually single nodule or plaque; may form pustules, subcutaneous nodules, or abscesses
Cryptococcus neoformans, C. gattii	India ink, encapsulated yeast, mucicarmine-positive capsule, cryptococcal antigen (serum and CSF)	Exposure to pigeons, soil exposure, HIV-positive, immunocompromised	Papule with crust resembling molluscum contagiosum; also forms ulcers on skin, mouth, and genitalia; may have lung or CNS involvement

TABLE 20.1 CONTINUED

Cause	Laboratory workup	Epidemiology	Clinical clues to diagnosis
Histoplasma capsulatum	Dimorphic fungus, histoplasma antigen (urine and serum)	Bats, birds, and soil exposure; HIV-positive, immunocompromised; Eastern and Central United States in Ohio/Mississippi River Valleys, Central and South America, West Indies, Africa, Madagascar	Papule with crust resembling molluscum contagiosum; ulcerative plaques and oral ulcerations
Sporothrix schenckii	Dimorphic fungus	Rose gardening, soil exposure	Papule or pustule at inoculation site develops into subcutaneous nodules or ragged-edged ulcer with proximal nodular lymphangitis; usually on upper extremities
Mycobacterial	AFB smear, culture		
Mycobacterium marinum	AFB-positive, growth at 30°C/86°F–32°C/90°F	Water, aquarium enthusiasts	Ulcer with thin seropurulent drainage, nodular lymphangitis
Mycobacterium ulcerans (Buruli ulcer)	AFB-positive, PCR for the insertion sequence IS*2404* in swabs or tissue samples	Africa, Australia, South East Asia, South America, North America (Mexico); 2- to 3-month incubation period, usually associated with trauma	Subcutaneous nodule that ulcerates with extensive scarring and contracture formation; edematous lesion rapidly progresses to extensive ulceration, may have osteomyelitis contiguous to ulcer
Mycobacterium avium complex	AFB-positive	HIV-positive, immunocompromised; soil, water	Multiple subcutaneous nodules or ulcers; may be associated with cervical lymphadenitis drainage to skin or direct inoculation
Mycobacterium haemophilum	AFB-positive, requires iron-supplemented culture medium and incubation at 28°C/82°F–30°C/86°F	Australia, United States, Canada, France, Germany, Singapore; HIV-positive, transplantation	Papules develop into pustules which form deep ulcers, usually on extremities overlying joints; may have septic arthritis ± osteomyelitis, may have LN
Mycobacterium tuberculosis	AFB-positive, TST or interferon-γ release assay helpful if positive	Worldwide	Nodules or ulcers especially in HIV-positive patients, scrofuloderma, plaques
Viral			
Herpes simplex	PCR, DFA, viral culture	Sexually transmitted infection	Oral, perineal, genital ulcers; whitlow on hands; lesions with thin-walled vesicles; shallow painful ulcers
Parasitic			
Leishmaniasis	Punch biopsy, aspirates, or scrapings of skin for culture, histopathology, and touch prep using Wright's and Giemsa stains looking for amastigotes at base of lesion; serology; PCR of tissue aspirates, or peripheral blood	Sandfly bites, travel to endemic area (military or civilian); incubation period weeks to months, HIV-positive, immunocompromised; *Old World*: Mediterranean, Middle East, Africa, Southern Asia, India; *New World*: Latin America, Central and South America	Papule at the site of insect bite enlarges to form a nodule, which then develops into a punched-out ulcer; may have associated LN; rarely nodules form without ulceration; may involve nasal or oral mucosa (mucocutaneous); visceral involvement possible

Abbreviations: LN = lymphadenopathy; AFB = acid-fast bacilli; CNS = central nervous system; DFA = direct fluorescent antibody; PCR = polymerase chain reaction; TST = tuberculin skin test; CSF = cerebrospinal fluid.

TABLE 20.2 **CLINICAL PRESENTATION AND THERAPY OF PYODERMA**

Type of disease	Distinguishing features	Causative organism	Treatment
Primary pyoderma			
Impetigo Nonbullous impetigo Bullous impetigo	Superficial honey-colored crusts Thin vesicles and bullae, when ruptured produce varnish-like crust	*Streptococcus pyogenes, Staphylococcus aureus* Toxin-producing strains of *S. aureus*	For patients with few lesions may use topical agents for 5 days: Mupirocin topical ointment 2% TID (MSSA or MRSA) *Or* Retapamulin topical ointment 1% BID (note—for MSSA lesions only, not MRSA) For patients with many lesions or in outbreak setting use oral agents for 7 days: *For MSSA:* Amoxicillin–clavulanate 875/125 mg PO BID *Or* Dicloxacillin 250 mg PO QID *Or* Cephalexin 250 mg PO QID *Or* Clindamycin 300–450 mg PO QID *For MRSA:* Minocycline 100 mg PO BID *Or* Trimethoprim-sulfamethoxazole (TMP–SMX) 1–2 double-strength tablets (TMP 160 mg) PO BID *Or* Clindamycin 300–450 mg PO QID
Ecthyma	Ulcer with crust	*Streptococcus pyogenes*, *S. aureus*	Treat as impetigo with oral agents for 7 days
Folliculitis	Hair follicle with pustules, erythema	*S. aureus*	*Topical*: Clindamycin topical gel 1% BID *Or* Erythromycin topical solution 2% BID *Or* Mupirocin topical ointment 2% TID *Or* Benzoyl peroxide lotion *Unresponsive:* Treat as impetigo with oral agents
Gram-negative folliculitis	Usually on face in patients with acne vulgaris on chronic suppressive antibiotic therapy	*Klebsiella, Enterobacter, Proteus* species	Amoxicillin–clavulanate 875/125 mg PO BID *Or* TMP–SMX one double-strength tablet (TMP 160 mg) PO BID
Hot-tub folliculitis	Pustules and vesicles on an erythematous base in bathing-suit distribution	*Pseudomonas aeruginosa*	Self-limited in normal hosts; decontaminate and chlorinate hot tub

TABLE 20.2 CONTINUED

Type of disease	Distinguishing features	Causative organism	Treatment
Furuncle/carbuncle	Abscess formation in dermis, subcutaneous tissue that may coalesce and drain; if cellulitis or sepsis associated, needs IV antibiotics; patients may have recurrences; suggest culture to rule out MRSA or gram-negative organisms	*S. aureus* both MSSA and MRSA, now many community-acquired strains are MRSA	Careful incision and drainage, and warm compresses; for lesions >5 cm and patients with fever, add antistaphylococcal antibiotics targeting MRSA including: TMP–SMX 1–2 double-strength (TMP 160 mg) PO BID *Or* Minocycline 100 mg PO BID If associated with cellulitis or systemic inflammatory response syndrome: Vancomycin 15 mg/kg IV q12h *Or* Daptomycin 4 mg/kg IV q24h (dosed for skin/soft tissue only, not bacteremia) If recurrent, eradicate nasal carriage of *S. aureus* by: Mupirocin nasal ointment 2% BID × 7 days and Chlorhexidine 2% daily wash × 7 days Along with either: Rifampin 300 mg PO BID plus Doxycycline 100 mg PO BID × 7 days *Or* Rifampin 300 mg PO BID plus TMP–SMX 1 tab PO BID × 7 days
Neutrophilic dermatoses			
Pyoderma gangrenosum	Rapidly progressive painful ulcers, ragged violaceous edges with necrotic centers, usually on lower legs; Underlying IBD, malignancy, arthritis, monoclonal gammopathy *Biopsy:* PMN, lymphocytic infiltration, ± vasculitis	No organisms seen, culture negative	Prednisone 0.5–1 mg/kg/d *Or* Cyclosporine 4 mg/kg/d For PG associated with Crohn's disease: Infliximab Other agents used include: mycophenolate mofetil, clofazimine, azathioprine, methotrexate, tacrolimus, thalidomide, dapsone (contraindicated in G6PD-deficient patients) Localized PG: topical or intralesional corticosteroids, or tacrolimus ointment
Sweet's syndrome	Fever, neutrophilia, prompt response to steroids, painful erythematous plaques, may form bullae and ulcerate; located on head, neck, arms; 20% have associated malignancy, usually AML, elevated sedimentation rate *Biopsy*: Dense PMN infiltration of the dermis, no vasculitis	No organisms seen, culture negative	Prednisone 1 mg/kg/d, slow taper over 4–6 wk *Or* Colchicine 1.5 mg/d PO *Or* Dapsone 100–200 mg/d PO (contraindicated in G6PD-deficient patients) *Or* Potassium iodide 900 mg/d PO Alternative agents: indomethacin, clofazimine, cyclosporine
Secondary pyoderma	Preexisting lesions of dermatitis such as eczema, psoriasis, or surgical/traumatic wounds		Based on culture data. Note increasing rates of community-acquired MRSA

Abbreviations: AML = acute myelogenous leukemia; G6PD = glucose-6-phosphate dehydrogenase; IBD = inflammatory bowel disease; MSSA = methicillin-sensitive *S. aureus*; MRSA = methicillin-resistant *S. aureus*; PG = pyoderma gangrenosum; PMN = polymorphonuclear leukocytes.

Primary pyoderma

Primary pyoderma is an infection of previously healthy skin, usually caused by *S. aureus* or *Streptococcus pyogenes*.

Impetigo

Impetigo is a superficial infection of the skin involving only the epidermis (see Figure 20.2). Impetigo is highly contagious and usually occurs in young children following minor skin trauma. Nonbullous impetigo, the classic honey-colored crusts on the face or extremities, is caused by *S. pyogenes* or *S. aureus*; toxin-producing strains of *S. aureus* cause bullous impetigo (varnish-like crust). Treatment of bullous and nonbullous impetigo requires coverage of methicillin-sensitive *S. aureus* (MSSA): dicloxacillin 250 mg orally four times a day (QID), or first-generation cephalosporins such as cephalexin 250 mg orally QID for 7 days; note that the oral cephalosporins cefixime and ceftibuten have no activity against MSSA. For penicillin-allergic patients, clindamycin 300 to 450 mg orally QID is appropriate. Because most areas have seen the emergence of community-acquired MRSA, empiric therapy targeting MRSA with trimethoprim-sulfamethoxazole (TMP-SMX), one to two double-strength tablets orally twice a day (BID), or minocycline 100 mg orally BID is warranted. For patients with few lesions, topical mupirocin ointment 2% applied to the lesion three times a day (TID) for 5 days is an equally effective alternative to systemic therapy. Topical retapamulin ointment 1% applied to the lesion twice a day for 5 days is an option for MSSA lesions (not for MRSA).

Ecthyma

Ecthyma (Figure 20.3) is impetigo that extends through the epidermis, forming shallow ulcers with crusts. It occurs in immunocompromised patients and is caused by *S. pyogenes* or *S. aureus*. Gram stain and culture of the lesion must be performed to rule out MRSA or ecthyma gangrenosum, which is caused by *P. aeruginosa* sepsis. Treatment of ecthyma due to streptococci or staphylococci is the same as that for impetigo, with oral agents for 7 days. Unlike impetigo, ecthyma may heal with scarring.

FIGURE 20.2 Impetigo. This is a superficial streptococcal or staphylococcal infection that occurs just beneath the stratum corneum. It generally occurs in the paranasal or perioral area in young people. Note typical honey-colored crusts, which heal without scarring.

FIGURE 20.3 Ecthyma. This is a more serious form of impetigo in which the infection penetrates to the dermis. Scarring is common.

Reproduced with permission from Dr. Charles V Sanders from Sanders CV, Nesbitt LT, eds. *The skin and infection: A color atlas and text*. Baltimore: Williams & Wilkins; 1995: 35.

Folliculitis

Folliculitis is an inflammation of the hair follicles, usually caused by *S. aureus*. Topical therapy with mupirocin three times daily for 7 days is usually adequate. If the infection does not respond, oral therapy with agents used for impetigo should be adequate. Lesions that do not respond to antistaphylococcal antibiotics should be cultured because they may be caused by MRSA or other pathogens. Therapy should be tailored to antimicrobial sensitivities. On rare occasions, gram-negative organisms cause folliculitis, typically in association with either superinfection in patients taking long-term antibiotics for acne vulgaris or hot-tub bathing. Gram-negative folliculitis in acne patients is caused by *Klebsiella, Enterobacter*, and *Proteus* species and usually occurs on the face. Treatment depends on susceptibilities, but amoxicillin-clavulanate or TMP-SMX may be used empirically. Hot-tub folliculitis caused by *P. aeruginosa* is usually self-limiting in a normal host, and no action is necessary beyond decontaminating the water and ensuring proper chlorination.

Furuncles and carbuncles

Furuncles are skin abscesses caused by *S. aureus*; they may begin as folliculitis that extends into the surrounding dermis and subcutaneous tissue. Carbuncles comprise several furuncles that coalesce to form loculated abscesses with draining pus. If the patient is afebrile and the abscess is <5 cm in diameter, incision and drainage and warm compresses without oral antimicrobials should suffice. If the patient has fever or other components of systemic inflammatory response syndrome, or if the lesion is >5 cm, oral anti-staphylococcal antibiotics targeting MRSA should be prescribed in addition to careful incision and drainage of the abscess. In either case, cultures

of the abscess should be obtained to guide therapy in the event there is no response to the initial treatment. Some patients with recurrent furuncles and carbuncles may require elimination of nasal *S. aureus* carriage with nasal applications of mupirocin, bathing with chlorhexidine, and either oral rifampin plus doxycycline, or rifampin plus TMP-SMX.

Neutrophilic dermatoses

Pyoderma caused by neutrophilic infiltrates usually is associated with underlying disease such as cancer or inflammatory bowel disease (IBD). The main entities are pyoderma gangrenosum and Sweet's syndrome.

Pyoderma gangrenosum

The diagnosis of pyoderma gangrenosum is clinical. The lesion begins as a small erythematous papule, rapidly progressing to tender pustules that undergo central necrosis and ulceration. The border of the ulcers is ragged, violaceous, and surrounded by erythema. Distinguishing characteristics include severe pain at the ulcer site, lesions at the site of minor trauma, parchment scarring, and an associated systemic disease such as IBD, rheumatologic disease, or malignancy. Biopsy of the lesions is done to exclude infection, vasculitis, malignancy, and vascular occlusive disease because histopathologic findings are nonspecific. Central necrosis and lymphocytic and neutrophilic infiltrates with or without vasculitic changes are seen on histopathology of pyoderma gangrenosum lesions; lymphocytes and plasma cells around vessels are common findings. Pyoderma gangrenosum usually occurs on the lower extremities over bony prominences, where repeated trauma aggravates the condition (pathergy); its cause is unknown. Treatment for disseminated pyoderma gangrenosum includes prednisone 0.5 to 1 mg/kg by mouth daily or cyclosporine 4 mg/kg/d. For pyoderma gangrenosum associated with Crohn's disease, the TNF-α inhibitor infliximab is recommended as first-line therapy. Mycophenolate mofetil, clofazimine, azathioprine, methotrexate, tacrolimus, thalidomide, dapsone, and many other drugs and modalities have been used to treat pyoderma gangrenosum; response to therapy varies.

Sweet's syndrome

Sweet's syndrome is an acute febrile neutrophilic dermatosis that may be associated with a malignancy, infection (upper respiratory or gastrointestinal), IBD, pregnancy, medications, or vaccinations (BCG and influenza), or is idiopathic. Lesions are painful erythematous plaques usually on the upper extremities, head, and neck. These lesions are classically associated with fever and neutrophilia, but some patients have myalgia, arthralgia, proteinuria, and conjunctivitis. Nearly all patients with Sweet's syndrome have an elevated erythrocyte sedimentation rate. Dense neutrophilic infiltration of the dermis without vasculitis is the classic finding on biopsy, and it is important to exclude bacteria, mycobacteria, and fungi because steroids are the appropriate therapy for Sweet's syndrome. The response to prednisone 1 mg/kg/d is dramatic; constitutional symptoms improve within hours, and skin lesions improve over 1 to 2 days. Steroids should be tapered slowly over 4 to 6 weeks. Other first-line agents used to treat Sweet's syndrome include potassium iodide, colchicine, or dapsone. Alternative treatments for Sweet's syndrome include clofazimine, indomethacin, and cyclosporine.

Secondary pyoderma

Secondary pyoderma is a bacterial superinfection of skin previously disrupted by trauma, surgery, or chronic skin conditions such as eczema or psoriasis. The usual organism is *S. aureus,* which can be methicillin-resistant whether community-acquired or healthcare-associated. Empiric treatment for serious wound infections is IV vancomycin pending culture results. Mild to moderate infections can be treated with oral TMP-SMX (± rifampin) or minocycline. Secondary pyoderma caused by pressure sores and diabetic foot ulcers is usually polymicrobial and requires broad-spectrum therapy with vancomycin until MRSA is ruled out, plus piperacillin–tazobactam or a carbapenem, or a combination of ciprofloxacin and clindamycin. Table 20.2 summarizes suggested therapy for pyoderma.

Herpetic whitlow

Herpetic whitlow, a herpes simplex infection of the pulp of the finger, may occur in anyone who has mucocutaneous herpes or who comes in contact with herpetic lesions (i.e., healthcare workers). The initial lesion is a tender vesicle filled with turbid fluid. Lesions may be multiple and may ulcerate and become secondarily infected, developing purulent drainage. Axillary and epitrochlear lymphadenopathy with erythema of the proximal forearm also may occur. Diagnosis can be made by aspirating a vesicle and sending the fluid for PCR, viral culture, or performing a DFA test on the blister fluid. Treatment includes acyclovir, and surgery should be avoided.

Cellulitis and erysipelas

Katherine S. Glaser and Kenneth J. Tomecki

Skin and soft-tissue infections (SSTIs) are routinely encountered in both outpatient and inpatient settings. In 2013, the US Food and Drug Administration (FDA) redefined SSTIs as acute bacterial skin and skin-structure infections (ABSSSIs), which include cellulitis/erysipelas, major skin abscesses, and wound infections with a surface area of at least 75 cm^2. In this chapter, we focus on the clinical presentation, microbiology, and treatment of cellulitis/erysipelas. Although there are notable differences between erysipelas and cellulitis, the treatment is similar and typically based on disease severity and presence of purulence.

Erysipelas

Clinical manifestations

Erysipelas is a superficial skin infection limited to the upper dermis and superficial lymphatics; it has a distinct clinical presentation. The legs are the most commonly affected site, but erysipelas can occur anywhere on the body. Young, elderly, and immunocompromised patients are particularly susceptible to erysipelas. Conditions such as obesity, venous insufficiency, lymphedema, and defects in the skin barrier (e.g., ulcers, surgical or traumatic wounds, preexisting inflammation) are all predisposing factors that increase the likelihood of a microbial breach through the epidermis leading to development of erysipelas.

Classically, erysipelas exhibits a sharply demarcated, tender, bright red edematous plaque with raised, indurated borders (Figure 21.1). The initial insult is often clinically undetectable but can be obvious, as in cases of postoperative or traumatic wounds. Regional lymphadenopathy, lymphatic streaking, and surrounding edema can occur. Systemic symptoms such as fevers, chills, and malaise may develop abruptly and precede skin disease by hours.

Recurrence is common, especially when an underlying comorbidity such as edema is present. Other complications include bullae formation, skin sloughing, sepsis, and organ dysfunction. Overall these sequelae are uncommon in the general population and are nearly exclusive to the immunocompromised patient.

Microbiology

Most cases of erysipelas are caused by *Streptococcus* spp., predominantly group A β-hemolytic streptococci (GAS) such as *S. pyogenes*. Less often, groups B, C, D, and G are implicated. Less commonly *Staphylococcus aureus* is involved, including methicillin-sensitive (MSSA) and methicillin-resistant strains (MRSA). Gram-negative organisms, anaerobic species, and polymicrobial infections also occur, although rarely.

The bacterial source is frequently unknown, but the interdigital toe spaces can be a nidus, especially in cases of lower extremity erysipelas. In neonates and postpartum women, the vaginal canal is often the reservoir of group B streptococci. Special circumstances like intravenous (IV) drug abuse, penetrating traumas, and open wounds increase the likelihood of staphylococcal, gram-negative, and anaerobic organisms, and polymicrobial infections.

FIGURE 21.1 Erysipelas, right leg. Note the discrete, well-demarcated, raised edge of the erythematous plaque.

Diagnosis and differential diagnosis

Physical exam alone is typically sufficient to establish a diagnosis. Routine lab tests, CBC, and basic metabolic panel may reveal a leukocytosis or organ dysfunction in severe cases. Swabs for Gram stain and wound cultures are usually unnecessary and generally low yield. Skin biopsy for tissue culture and tissue aspirates are more invasive testing methods which have similarly low-yield results. Blood cultures are positive in <5% of cases, but cultures (blood, tissue aspirate, or skin biopsy) should strongly be considered in those patients with an underlying malignancy, severe systemic symptoms, or immunosuppression for whom the physical exam and implicated organisms may be atypical.

The differential diagnosis, especially in facial erysipelas, includes allergic contact dermatitis and photoallergic reactions. If present, fevers, pain, leukocytosis, and a positive culture would favor the diagnosis of erysipelas. The facial rash in systemic lupus erythematosus and dermatomyositis can appear similar but bilateral, less well-demarcated, and associated with other systemic features. Other infectious etiologies (i.e., erysipeloid) should be considered, though the location on the hands, occupation, and history of animal exposure should help to distinguish the two conditions.

Cellulitis

Clinical manifestations

Cellulitis is a type of ABSSSI that involves the deep dermis and extends into the subcutaneous tissue. Factors that predispose an individual to erysipelas can increase the likelihood of cellulitis, including peripheral vascular disease, edema, obesity, diabetes, malignancy, ulceration, trauma, IV drug abuse, and inflammatory skin disorders. In healthy patients, antecedent trauma or inflammation often produces the opportunity for microbial entry via direct inoculation. In contrast, hematogenous seeding should be suspected in immunocompromised patients.

Clinically, cellulitis presents as a unilateral, ill-defined, erythematous, firm plaque in conjunction with the four cardinal signs of inflammation: rubor, calor, dolor, and tumor (Figure 21.2). Skin manifestations are often preceded by fever, chills, and malaise. Regional lymphadenopathy and lymphangitis may also occur

Complications include focal abscess and pustule and bullae formation within the cellulitis, as well as necrosis of the skin and subcutaneous tissue. Recurrence is common and often secondary to the aforementioned predisposing conditions. Sepsis, an infrequent complication, typically occurs in children or immunocompromised individuals. Severe disease and signs of sepsis should prompt the clinician to search for systemic infection. Rarely, acute glomerulonephritis and toxic shock–like syndrome can be seen in the setting of a GAS cellulitis.

Microbiology

The most frequent causative organisms in cellulitis are *Streptococcus pyogenes* and *Staphylococcus aureus*. MRSA strains are more often implicated in purulent cellulitis, abscesses, open wounds, penetrating traumas, and IV drug abusers, in which case empiric antibiotics should include MRSA coverage. Otherwise, in uncomplicated cellulitis, MRSA incidence is low and does not necessitate specific antimicrobial coverage. Gram-negative, anaerobic, and polymicrobial infections can be seen in immunocompromised individuals. Particular clinical situations can sometimes suggest atypical causative organisms, some such examples are listed in Table 21.1.

FIGURE 21.2 Cellulitis, right leg. Note the more irregular, less defined margin of the erythematous plaque.

TABLE 21.1 **CAUSES OF CELLULITIS SPECIFIC CLINICAL SITUATIONS OR EXPOSURES**

Clinical Scenario	Likely Organism
Postsurgical cellulitis	*Staph. Aureus*
Perianal cellulitis	*Strep. Pyogenes*
Preseptal cellulitis	Staph. aureus, Strep. Pyogenes
Orbital cellulitis	*Staph. aureus, Strep. Pneumonia*
Facial cellulitis	*Haemophilus influenzae*[a,b]
Neonatal cellulitis	Strep. Agalactiae (Group B Strep)
Crepitant cellulitis	*Clostridium species*
Salt water exposure	*Vibrio vulnificus*[b]
Freswater exposure	*Aeromonas hydrophilia*[b]
Hot-tub exposure	*Pseudomonas aeruginosa*[b]
Neutropenia	*Pseudomonas aeruginosa*[b]
Soil exposure	*Clostridium species*

Human bite	*Eikenella corrodens*[b]

[a] Less common since the advent of caccines
[b]Denotes gram negative organisms

Diagnosis and differential diagnosis

Like erysipelas, the clinical presentation of cellulitis should be sufficient to make a diagnosis. Swabs for wound culture from exudates, erosions, ulcerations, abscesses, and surgical wounds can help to confirm the diagnosis and direct antimicrobial therapy. However, the results may not always identify an organism and may be difficult to interpret if pathogenic or a contaminant. Skin biopsy for tissue culture and tissue aspirates has a lower yield than do swabs. Additional laboratory studies including CBCs, anti-DNase antibody, antistreptolysin titers, and blood cultures may be helpful but none is sensitive or specific. In cases of severe sepsis or immunosuppression, cultures should be performed and interpreted cautiously.

Imaging studies may be helpful in certain patients. Conventional radiography can delineate pockets of gas in anaerobic cellulitis or suspected necrotizing fasciitis, especially with *Clostridium* spp. as the cause. This should be considered when pain is disproportionate to exam findings, skin is anesthetic, skin color is gray or dusky, palpation reveals crepitus, or disease progresses despite conventional antibiotic therapy. In the setting of periorbital cellulitis, CT helps differentiate preseptal cellulitis from orbital cellulitis, an ophthalmologic emergency. In all other cases, if the diagnosis of cellulitis is questionable, MRI with T2-weighted images can highlight skin and soft-tissue edema but is largely unnecessary.

The differential diagnosis of cellulitis, especially on the legs, includes inflammatory diseases like stasis dermatitis or atopic dermatitis or contact dermatitis, arthropod assault, erythema migrans (Lyme disease), superficial thrombophlebitis, deep venous thrombosis, lipodermatosclerosis, and vasculitides. Importantly, cellulitis virtually never occurs bilaterally, which helps distinguish it from its many mimickers.

Therapy

Systemic antimicrobial therapy is the treatment of choice for cellulitis/erysipelas. Several appropriate antimicrobial therapeutic options exist, but selection should be based on the patient population and regional variations in bacterial susceptibility. See Table 21.2 for antimicrobial options for specific organisms. In addition to antimicrobial therapy, local measures including immobilization and elevation as well as supportive measures such as warm compresses can hasten recovery and alleviate symptoms.

In 2014, the Infectious Disease Society of America (ISDA) published updated practice guidelines for the diagnosis and management of ABSSSIs. The ISDA recommended management based on

TABLE 21.2 **ANTIMICROBIAL THERAPY FOR SPECIFIC ORGANISMS**

Organism	First Line Treatment	Second Line Treatments
Strep. Pyogenes	Penicillin	Clinidamycin, Cephalosporin
Straph. Aureus (MSSA)	Nafcillin / Oxacillin (IV), Dicloxacillin (PO)	Clinidamycin, Cefazolin, Doxcycline, SMS-TMP
Staph. aureus (MRSA)	Vancomycin (IV)	Doxycycline, Clindamycin, SMX-TMP
Clostridium species	Clindamycin + Penicillin	Fluoroquinolone + Metronidazole
Haemophilus influenza	Amoxicillin, Ceftriaxone	Azithromycin, Fluoroquinolone
Vibrio vulnificus	Doxycycline + Cefotaxime	Fluoroquinolone
Aeromonas hydrophillia	Fluoroquinolone	SMX-TMP
Pseudomonas aeruginosa	Ciprofloxacin	Piperacillin-tazobactam, Ceftazidime, Carbapenem
Pasteurella multocida	Amoxicillin-Clavulanate	Cefuroxime + Clindamycin, Doxycycline
Eikenella corrodens	Amoxicillin-Clavulanate	Fluoroquinolone + Metronidazole

Abbreviations used: MSSA, methicillin sensitive staph aureus; MRSA, methicillin resistant staph aureus; IV, intravenous; PO, oral; SMX-TMP, trimethoprirm-sulfamethoxazole

the degree of severity and presence of purulence. Purulent diseases include abscesses, furuncles, and carbuncles, which are categorized separately based on the need for incision and drainage as the primary therapy. In comparison, cellulitis and erysipelas are typically nonpurulent and treated with systemic antibiotics. Mild cases include cellulitis/erysipelas without purulence or systemic symptoms. Moderate cases are typical cellulitis/erysipelas with systemic signs of infection. Severe cases are those that have progressed despite treatment with antibiotics, have ≥2 systemic signs of infection (fever, tachycardia, tachypnea, hypotension, delirium, leukocytosis), are found in immunocompromised patients, or have signs of deeper infection such as bullae, skin sloughing, or organ dysfunction.

In mild cases, oral antibiotics should be adequate treatment, whereas moderate and severe cases usually require hospitalization for IV antibiotics. In hospitalized patients, cultures with susceptibilities should be obtained and, when finalized, antibiotics de-escalated to prevent resistance. If treatment is implemented on an outpatient basis, as in the majority of cases, follow-up appointment and patient counseling on the signs of treatment failures are essential for good care. Treatment failures may occur with organism resistance, atypical bacteria, inadequate antibiotic dosing, or noncompliance. Therapeutic success including reduction in lesion size and resolution of fever, if present, should occur within 48 to 72 hours of treatment initiation. If clinical improvement does not occur in a timely fashion, physicians should obtain cultures with susceptibilities, extend the duration of antimicrobial therapy, and reassess antibiotic selection.

Most patients with typical mild cellulitis/erysipelas will respond completely to a 7-day course of empiric therapy that covers *Streptococcus* and *Staphylococcus* spp. (see Table 21.3 for oral dosing regimens). Agents targeting streptococci species include clindamycin and β-lactams (e.g., penicillin, amoxicillin, cephalexin). When MRSA coverage is indicated, as in purulent cellulitis, penetrating trauma, known MRSA colonization, or IV drug use, systemic options include doxycycline, clindamycin, or trimethoprim-sulfamethoxazole (TMP-SMX). To cover both streptococci and MRSA empirically, clindamycin is the preferred drug as monotherapy or a combination of a β-lactam with either TMP-SMX or doxycycline. For penicillin-allergic patients who are not considered to have a type 1 immunoglobulin (IgE)-mediated hypersensitivity reaction, alternative therapies include cephalosporins, tetracyclines, or TMP-SMX.

Hospitalization for IV antibiotics is uncommon but, in this setting, vancomycin is typically the treatment of choice (Table 21.4). It offers excellent coverage of gram-positive organisms including MRSA. Polymicrobial infections may occur in immunocompromised patients, and thus broader coverage for gram-negative organisms may be required. In such cases, combined treatment with vancomycin plus an extended-spectrum antipseudomonal penicillin, an extended-spectrum cephalosporin, or clindamycin plus a fluoroquinolone would be appropriate.

Though not recommended as first-line therapy, other appropriate antibiotics for use in the hospital setting with MRSA coverage include linezolid, daptomycin, tigecycline, or telavancin. Several new antibiotics have also been approved for the treatment of ABSSSIs, with the benefit of MRSA coverage: dalbavancin, oritavancin, tedizolid, and delafloxacin (see Table 21.4).

The oxazolidinones linezolid and tedizolid are excellent options for gram-positive organisms, MRSA, and vancomycin-resistant enterococci (VRE), and they are available in both IV and oral formulations that offer an opportunity for early conversion to oral therapy. Daptomycin, a cyclic lipopeptide, is bactericidal against gram-positive organisms, MRSA, and VRE and allows for daily dosing. Tigecycline offers additional coverage against gram-positive, gram-negative, anaerobic, and multidrug resistant organisms. The lipoglycopeptides dalbavancin and oritavancin have a long half-life, which allows for single-dose infusions. Telavancin, another member of the lipoglycopeptide class, is a semi-synthetic derivative of vancomycin with a similar spectrum of coverage plus activity against VRE. The new fluoroquinolone delafloxacin is available in IV and oral formulations and provides coverage against gram-positive, MRSA, and gram-negative organisms, thus permitting its use as monotherapy.

In addition to antibiotic treatment, systemic corticosteroids or nonsteroidal anti-inflammatory agents can be used to help reduce inflammation and mitigate symptoms. The degree of local

TABLE 21.3 **ORAL ANTIMICROBIAL OPTIONS FOR MIL NON-PURULENT CELLULITIS/ERYSIPELAS CASES**

Class	Medication	Dosage (Adult)*
Pencillins	Penicillin V	500 mg every 6 hours
	Amoxicillin	500 mg every 8 hours
	Amoxicillin/ Clavulante	875/125 mg every 12 hours
	Dicloxacillin	500 mg every 6 hours
Cephalosporins	Cephalexin[a]	500 mg every 6 hours
	Cefaclor[b]	250-500 mg every 8 hours
	Cefuroxime[b]	250-500 mg every 12 hours
	Cefprozil[b]	250 mg every 12 hours
	Cefdinir[c]	300 mg every 12 hours
	Cefpodoxime[c]	400 mg every 12 hours
Macrolides	Erythromycin	500 mg every 6-12 hours
	Azithromycin	500 mg on day 1, 250 mg on days 2-5
	Clarithromycin	500 mg every 12-24 hours
Tetracyclines	Tetracycline	500 mg every 6-12 hours
	Doxycycline	100 mg every 12 hours
	Minocycline	100 mg every 12 hours
Lincosamide	Clindamycin	300 mg every 6 hours
Fluoroquinolones	Ciprofloxacin	500 mg every 12 hours
	Levofloxacin	500 mg every 24 hours
Sulfonamide	Trimethoprim-Sulfamethoxazole	160-800 mg every 12 hours

Abbreviations: mg, milligrams
* All dosages for 7-14 days unless otherwise specified
[a] First generation cephalosporin
[b] Second generation cephalosporin
[c] Third generation cephalosporin

TABLE 21.4 **DOSING REGIMENS FOR SEVERE CELLULITIS/ERYSIPELAS WITH MRSA COVERAGE**

Class	Medication	Route	Dosage (Adult)
Glycopeptide	Vancomycin	Vancomycin	15 mg/kg every 12 hours
Tetracycline	Doxycycline	Oral	100 mg twice daily
Lincosamide	Clindamycin	IV/oral	IV: 600 mg every 8 hours Oral: 300-450 mg four times daily
Oxazolidinones	Linezolid[a]	IV/oral	600 mg every 12 hours
	Tedizolid[a]	IV/oral	200 mg once daily
Cyclic Lipopeptide	Daptomycin	IV	4 mg/kg every 24 hours
Cephalosporin	Ceftaroline	IV	600 mg every 12 hours
Sulfonamide	Trimethoprime-Sulfamethoxazole	Oral	1-2 double strength tablets twice daily
Glycylcycline	Tigecycline[b]	IV	100 mg loading dose then 50 mg over 1 hour every 12 hours
Lipoglycopeptides	Telavancin[c]	IV	10 mg/kg over 1 hour every 24 hours
	Dalbavancin	Iv	Single dose: 1500 mg over 30 min Two dose: 1000 mg over 30 min then 1 Week later 500 mg over 30 min
	Oritavancin	IV	Single dose: 1200 mg over 3 hours
Fluoroquinolone	Delafloxacin	IV/oral	IV: 300 mg over 1 hour every 12 hours Oral: 450 mg twice daily

[c] Requires dose adjustments in severe hepatic impairment

inflammation may worsen when antibiotics are initiated, due to the sudden destruction of organisms and an enzymatic cascade. Quicker clinical improvements occur when systemic corticosteroids are used in combination with antibiotics compared to antimicrobial monotherapy. Long-term follow-up showed no difference in recurrence rates. For this reason, anti-inflammatory agents may be very helpful adjunctive therapy in nondiabetic patients with cellulitis/erysipelas without signs of deeper infection.

When tissue necrosis is present, antimicrobial therapy alone is insufficient; immediate surgical evaluation is necessary, with early and complete surgical debridement extending beyond the areas of necrosis to reach healthy tissue. Signs of deep infection warranting debridement include gangrenous changes, severe pain or anesthetic skin, crepitus, or abscess formation with multiple sinus tracts (for additional information see Chapter 22, "Deep soft-tissue infections: Necrotizing fasciitis and gas gangrene").

Recurrence is especially common in patients with ABSSSIs of the legs who have impaired circulation or ongoing skin breakdown. In such instances, continuous antimicrobial prophylaxis may be necessary, coupled with weight reduction, leg elevation, support stockings to reduce edema, and good skin hygiene with emollients and possibly topical antifungal therapy. In general, optimizing those comorbidities that are considered predisposing factors is paramount to prevent recurrences and minimize bacterial colonization.

Deep soft-tissue infections

Necrotizing fasciitis and gas gangrene

Stephen Ash and Louis E. Kennedy

Necrotizing fasciitis (NF) and gas gangrene (GG) are serious infections of the deep soft tissue. They both carry a high morbidity and mortality. Early diagnosis and treatment is important and is the key to improving outcome. Broadly speaking, NF is an infection primarily of the fascia and deep soft tissue of the skin, whereas GG is usually an infection of the skeletal muscle.

The incidence of NF in the western world is approximately 4:100 000 with a mortality rate of 15% to 20%.

Previously, NF has been subdivided into different categories based on anatomical site, etc., but such classification is unhelpful with regards to the diagnosis and management of these dangerous conditions. More recently, NF has been classified into three etiologic types (Table 22.1).

Type I is polymicrobial with usually at least one anaerobic species present. This is more common in patients with a strong predisposition for NF, such as intravenous drug users and postoperative patients. It is more likely to be present on the trunk, abdomen, perineum, or perianally.

Type II is monomicrobial and caused by group A streptococci and is less often associated with a predisposing factor. It is more common on the head and neck, and arms and legs. Thirty percent of cases are complicated by streptococcal toxic shock syndrome.

Type III occurs in the extremities and is caused by marine vibrio or aeromonas organisms following injury in sea water.

Various other forms of NF have been described including that caused by Panton-Valentine leukocidin (PVL) staphylococcus, *Klebsiella pneumoniae*, and also a number of cases of necrotizing cutaneous mucormycosis following injuries incurred during a tornado.

Both GG and, particularly, NF are strongly associated with numerous underlying, premorbid risk factors (Box 22.1), each of which requires medical management in order to improve the prognosis of an individual patient.

Again, both conditions may be caused by one bacterial organism, or commonly, they may be polymicrobial and require treatment with broad-spectrum or multiple antibiotics.

Necrotizing fasciitis (NF)

Diagnosis of NF

NF is an uncommon, but severe infection with a fulminant course and high mortality often following a history of trauma or surgery. The patient may go into rapid decline with necrosis of soft tissue and multisystem

TABLE 22.1 **NECROTIZING FASCIITIS: CLASSIFICATION**

Type I	Polymicrobial, including anaerobes
Type II	Group A β-hemolytic streptococci
Type III	Marine vibrios and aeromonas

organ failure. The latter would appear to result from superantigenic overstimulation of the immune system and excessive production of cytokines.

NF can affect any part of the body, but has a predilection for the limbs, abdominal wall, perineum, and occasionally the neck and periorbital area. Although to begin with, there may be only slight redness, or other discoloration, and swelling, the clue to the patient having NF is often the disproportionate severity of pain as well as systemic upset. The condition is rapidly progressive, with systemic inflammatory responses, shock, and multiorgan failure. Early diagnosis is crucial in optimizing outcome. The diagnosis is predominantly clinical with surgical confirmation, but noncontrast CT and ultrasound may be of use in supporting such a diagnosis. These tests as well as plain x-ray may sometimes show gas or a localized abscess in the soft tissue. Differentiating early NF from the more common cellulitis may be difficult; one clue may be the severe pain that often accompanies early NF. Occasionally, one may find an area of anesthetic skin overlying the inflamed and indurated area, although this is usually a late feature. One report suggests tissue oxygen saturation of the affected limb may help distinguish between cellulitis and NF.

If left untreated, there is progressive discoloration and darkening of the tissue with subcutaneous hemorrhage accompanied by tachycardia, hypotension, acidosis, and fever or occasionally a fall in body temperature.

Some authorities have used a laboratory scoring system: the *L*aboratory *R*isk *I*ndicator for *NEC*rotizing fasciitis (LRINEC) to determine and assist in the diagnosis of NF. This uses a panel of hematologic and biochemical test results (C-reactive protein [CRP], serum creatinine, total white cell count, hemoglobin, blood glucose, and serum sodium) to provide a scoring system for the risk for having NF. However, recent studies strongly suggest that this system has a high specificity and high negative predictive value but limited sensitivity.

BOX 22.1

Factors predisposing to deep soft-tissue infection (necrotizing fasciitis and gas gangrene)

- Trauma, sometimes trivial and including insect bites
- Recent surgery
- Malignancy, particularly intra-abdominal and carcinoma of colon
- Diabetes mellitus
- Intra-abdominal sepsis
- Alcoholism
- Injecting drug use
- Obesity
- Malnutrition
- Recent chickenpox
- Immunocompromised states
- Chronic renal failure
- Systemic steroid use
- Peripheral vascular disease
- Old age

Treatment of NF

The principles of management of NF are outlined in Figure 22.1. Rapid *resuscitation* takes precedent, followed by the empiric administration of *broad-spectrum antibiotics.* The choice of antibiotic is further discussed below and summarized in Box 22.2. *Surgery* with exploration and excision of necrotic tissue should not be delayed. Surgery should involve thorough debridement of all nonviable and affected tissue; there is no role for an "incision and drainage" approach to surgery. Repeat surgical explorations on subsequent days should be considered.

Samples for microbiology such as blood cultures should be taken at presentation and also at the time of surgery. Administration of antibiotics should not be delayed whilst waiting for results. Treatment of *comorbidities* such as diabetes and malnutrition is important.

Some clinicians suggest considering the following three adjuvant measures to try to improve outcome, although their usefulness remains controversial:

1. The use of *hyperbaric oxygen* has been tried in many cases of NF. The current consensus is that it is of little or no value.
2. *Topical negative pressure-* or *vacuum-assisted wound* healing has been tried in patients after surgical excision to promote efficient wound healing of what is often a large surface area of tissue.
3. Because it is thought that some of the systemic proinflammatory effects of NF, mediated by cytokines, are a result of superantigenic effects of bacteria such as group A streptococci there is a hypothesis that the administration of pooled, polyvalent *intravenous immunoglobulin* (IVIG) may be beneficial in modifying this response. There is a growing amount of evidence that this is of value.

Choice of antibiotic

Possible choices of antibiotic are given in Box 22.2, and may be modified according to local policies and the circumstances around individual patients. The initial choice of antibiotic is likely to be empiric and should cover gram-positive and -negative organisms as well as anaerobic bacteria, and should be administered intravenously, as absorption from the gut is likely to be unreliable in patients with severe systemic upset. It is widely accepted that clindamycin should

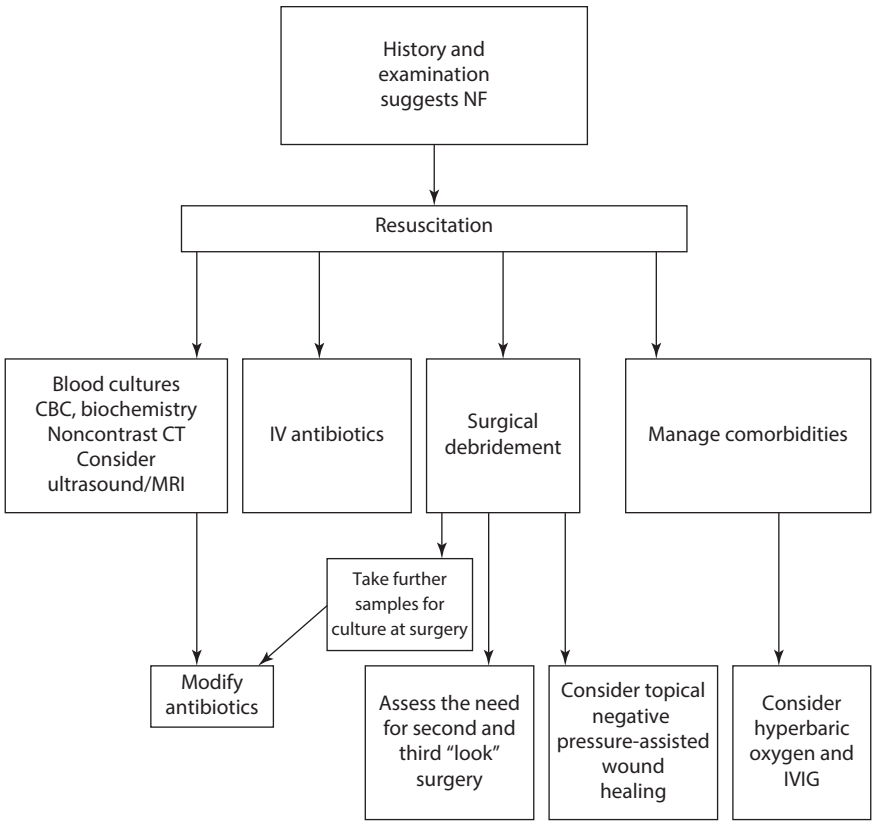

FIGURE 22.1 Management of necrotizing fasciitis. CBC, complete blood count; IV, intravenous; IVIG, intravenous immunoglobulin.

be included in any antibiotic regimen to treat NF because of its immunomodulatory effects. These effects are thought to include stimulation of opsonization and phagocytosis of bacteria, as well as reducing the production of M proteins and exotoxins from group A streptococci bacteria.

Over the past few years there have been reports of methicillin-resistant *Staphylococcus aureus* (MRSA) as the causative agent in some cases of NF, both in patients with infections acquired nosocomially and from the community. Some of the newer antibiotic agents with activity against MRSA may have use in this scenario, such as linezolid, tigecycline, and daptomycin.

BOX 22.2

Empiric antibiotic choices for necrotizing fasciitis

- Benzyl penicillin + nafcillin + metronidazole + quinolone
- Clindamycin + quinolone
- Carbapenem, eg. Meropenem (+/− fluconazole)
- Piperacillin with tazobactam
- Consider vancomycin or linezolid or daptomycin or tigecycline for possible MRSA
- *Clindamycin should be considered for inclusion in all antibiotic regimens because of its special immunomodulatory mechanisms.*

Gas gangrene (GG) (clostridial myonecrosis)

GG is most often caused by the anaerobic spore-forming bacillus *Clostridium perfringens*, an organism that causes infection of skeletal muscle following surgery or trauma. Necrosis and gas formation are characteristic features of the infection. There is rapid advancement of infection and muscle necrosis over just a few hours, if untreated.

Myonecrosis can also occur spontaneously, caused in this case by *Clostridium septicum*. This occurrence may be associated with underlying colonic abnormalities, or leukemia.

The first symptom of post-traumatic or post-surgical gas gangrene is the sudden onset of pain at the infected site. The area becomes tender and discolored, although it may be pale to begin with. Gas may be detected in the muscle on plain x-rays and also on both CT and MRI scans. However, with all but deep-seated infections, crepitus is palpable, demonstrating the presence of gas in the muscle tissue. The patient will become systemically unwell, with a bacteremia in many instances. Hemolysis may ensue, and renal failure may follow as a consequence.

Urgent surgical debridement, and antibiotic therapy are the essential mainstays of treatment and the prognosis may well be improved with the additional use of hyperbaric oxygen. Antibiotic therapy may be chosen from penicillins, clindamycin, and metronidazole. Tetracyclines and chloramphenicol can also be used. Antitoxin is no longer available.

Human and animal bites

Ellie J. C. Goldstein and Fredrick M. Abrahamian

Animal and human bites are common injuries. Patients may seek care at a hospital's emergency department, primary care physician's office, or with a specialist (e.g., orthopedics, plastic/hand surgery, infectious diseases). The bacteriology of these wounds is diverse and comprises both aerobic and anaerobic organisms originating from the oral flora of biting animal, the victim's skin flora, and occasionally environmental isolates.

Animal bites

Microbiology

An extensive number of bacterial species are isolated from infected animal bite wounds. *Pasteurella* spp., especially *P. multocida* and *P. septica*, will be present in 50% and 75% of dog and cat bite wounds, respectively. Anaerobes will be present in 50% of dog bite wounds and 67% of cat bite wounds. Streptococci are present in 46% of dog and cat bite wounds, whereas staphylococci are present in 46% of dog and 35% of cat bite wounds. *Streptococcus pyogenes*, if present, most likely is from the victim's skin flora as it is rarely isolated from dog and even less commonly from cat oral flora. *Staphylococcus aureus* is most likely also a secondary invader originating from skin flora as it is present in 20% of dog bites and only 4% of cat bites. We are not aware of dog and cat bite wound infection reports in humans due to methicillin-resistant *S. aureus*. *Capnocytophaga canimorsus* is an uncommon isolate from dog and cat bite wounds, but cases have been reported with fulminant infections often encountered in patients with asplenia, liver cirrhosis, and other immunocompromising conditions.

Wound evaluation and care

The elements of wound care are outlined in Box 23.1. If possible, wash the wound with soap and water as soon as possible after the injury. This will potentially reduce any bacterial or viral (e.g., rabies virus) inoculum. The addition of topical antiseptics or other similar remedies does not appear to affect the outcome or the incidence of infection. Washing the wound and keeping it clean and dry is sufficient for minor wounds.

If possible, the wound should be irrigated with sterile normal saline (no added iodine or antimicrobials) using an 18-gauge needle or catheter tip with a 20 mL syringe. This system functions as a high-pressure jet and reduces bacterial inoculum, whereas surface cleansing may not work as well. Tears or avulsion should be copiously irrigated, any debris removed, and necrotic tissue cautiously debrided.

Injuries to compromised hosts (Box 23.2) may lead to more extensive infections. Nerves and tendons may be injured or severed, especially when wounds involve the hand. If edema is present, develops, or is

BOX 23.1

- Cirrhosis
- Leukemia
- Lymphoma
- Myeloma
- Neutropenia
- Systemic lupus erythematosus

preexisting, elevation to reduce the edema is an important component of primary therapy. The use of a sling can be helpful, and this should be worn at the level of the heart when hand injury results in edema.

Preemptive antimicrobial therapy is often initiated for bite wounds that are extensive or located on the hands, or are associated with severe crush injury, the presence of preexisting edema, or have penetrated a joint or bony structure.

Closure of infected wounds is generally not recommended. Due to cosmetic and functional reasons, wounds to the head and neck and those overlying the joints may require primary closure. Major defects may require repair with subsequent surgeries.

Extremity elevation is vital to decreasing edema. If there is a need, tetanus immunization should be updated. Rabies prophylaxis will depend on local patterns of infection among the animals, the circumstance leading to the bite, mode of contact, and the patient's prior history of rabies immunization.

Antimicrobial selection

The preemptive selection of antimicrobials should take into account the microbiology of these wounds. Fortunately, most dog and cat bite isolates are susceptible to penicillin and ampicillin. Antimicrobial selections are outlined in Table 23.1. Of note is the relatively poor activity of cephalexin, cefaclor, cefadroxil, and erythromycin against *P. multocida*.

Patients who present >24 hours after injury without clinical signs of infection rarely require antibiotics. Patients who present for care <8 hours after injury and without signs of established infection can be given preemptive antibiotics for 5 to 7 days if they have moderate to severe wounds, especially if edema or extensive crush injury is present; are immunocompromised (including those with splenectomy, severe liver dysfunction, or chronic steroid use); have multiple deep puncture wounds, especially to the hands; have bone or joint space penetration; or have wounds adjacent to a prosthetic joint.

Follow-up is recommended within 48 hours or sooner, and the patient should be instructed to seek medical care sooner if the condition worsens.

The most common complications are septic arthritis, osteomyelitis, and residual joint stiffness. Long-standing pain should raise suspicion for complications such as septic arthritis or osteomyelitis. Although difficult to assess during the initial encounter, pain out of proportion to the injury when in proximity to a bone or joint should raise the issue of periosteum penetration.

The decision to hospitalize a patient should follow the items in Box 23.3. The course of antimicrobial therapy for cellulitis is typically 7 to 14 days, for septic arthritis 3 to 4 weeks, and for osteomyelitis 4 to 6 weeks. Abscesses should be drained, and infected wounds should be cultured. Therapeutic failure of outpatient therapy, including those listed in Box 23.4, should lead to hospitalization.

TABLE 23.1 **ACTIVITY OF SELECTED ANTIMICROBIALS AGAINST ANIMAL BITE ISOLATES**

	Pasteurella multocida	*Staphylococcus aureus*[a]	Streptococci	Capnocytophaga	Anaerobes

[a] β-lactams (with the exception of ceftaroline), fluoroquinolones, and macrolides do not have adequate activity against methicillin-resistant *Staphylococcus aureus* (MRSA); clindamycin and tetracyclines (doxycycline, minocycline) have variable but often adequate activity against MRSA.

Human bites

Human bites are either occlusional, where the teeth bite directly into flesh, or clenched-fist (closed-fist) injuries (CFIs). Most occur during fights, and the patient typically has a delayed presentation often resulting in infection.

Occlusional bites may be to any part of the body and include "love nips." Bites to children or the elderly may be the result of abuse. The most severe form of human bite wound is the CFI. Hand injuries can be severe and may result in abscess or osteomyelitis.

BOX 23.3

Hospitalization criteria for patients with bite wound infections

Signs and symptoms of systemic toxicity
Worsening infection
Septic arthritis
Osteomyelitis
Tenosynovitis

The bacteria associated with these infections include *Streptococcus anginosus*, *Streptococcus pyogenes*, *Staphylococcus aureus, Haemophilus* spp., *Eikenella corrodens*, and, in >55% of cases, oral anaerobes. Antimicrobial therapy is outlined in Table 23.2. Of note is the poor activity of cephalexin and erythromycin against *E. corrodens* and anaerobes.

CFIs injuries can be complicated by septic arthritis and osteomyelitis. Elevation and splinting are usually required, as are antimicrobials.

BOX 23.4

Causes of therapeutic failure for bite wound infections

Incorrect antimicrobial selection

Lice, scabies, and myiasis

Charlotte Bernigaud, Gentiane Monsel, and Olivier Chosidow

Arthropod infestations of humans are most commonly caused by mites, head or body lice (pediculosis), pubic lice (pthiriasis), or fly larvae (myiasis). Although many mite species may feed on human tissue, scabies are the most common mites living on human hosts. All of these arthropods can cause irritation and inflammation of the skin, but fly larvae may penetrate more deeply into the body. Diagnosis of each of these parasitic problems is dependent on accurate identification of the infesting arthropod. Lice and scabies mites are readily transmitted between close contacts, whereas myiasis is not a contagious condition.

Scabies

Scabies is a common parasitic infection caused by the mite *Sarcoptes scabiei* var. *hominis*, an arthropod of the order Acarina (Figure 24.1). The worldwide prevalence has been estimated to be about 100 to 200 million cases annually. Scabies has recently been recognized as a public health issue in the low- and middle-income countries and was added in 2017 to the list of neglected tropical disease by the World Health Organization. Tropical regions are the most affected, and young children, mostly under the age of 2, are often at risk. The morbidity of the disease is mainly due to scabies-secondary bacterial pyodermas. Scratching the skin disrupts the skin barrier, thereby providing an entry point for bacteria which can become invasive or cause post-infection complications such as post-streptococcal glomerulonephritis, acute rheumatic fever, or rheumatic heart disease. Worldwide, the risk of scabies outbreaks is particularly high in institutions (e.g., child and elderly care centers or hospitals), in underprivileged populations (e.g., refugees, homeless), and in immunocompromised individuals (e.g., HIV- or HTLV1-infected patients).

Scabies is an obligate parasite. The female mite burrows into the upper part of the epidermis and lays eggs that hatch into a larvae, which develops into a nymph that reach adulthood in 10 to 14 days. In general, transmission occurs by direct skin-to-skin contact. In severe form, such as profuse or crusted scabies, transmission may also occur through infected clothing or bedding. Skin eruption with classical scabies is attributable to both infestation and hypersensitivity reaction to the mite. Moreover, because the eruption is usually itchy, prurigo and superinfection are common. The main symptom is pruritus that typically worsens at night, and it is often associated with itching experienced by other family members in the household or among people in close physical contact with an infested individual. The lesions are commonly located in the finger webs, on the flexor surfaces of the wrists, on the elbows, in the axillae, and on the buttocks and genitalia. The elementary lesions are papules, vesicles, burrows, and nodules. In crusted scabies, clinical signs include hyperkeratotic plaques, papules, and nodules, particularly on the palms of the hands and the soles of the feet, although areas such as the axillae, buttocks, scalp, and genitalia in men and breasts in women may also be affected.

Diagnosis is based on patient history and physical examination. Recent criteria have been published for the diagnosis of scabies with three levels of diagnosis: Certainty-Confirmed Scabies, Clinical Scabies, and Suspected Scabies. The definitive diagnosis relies on the identification of the mite by light microscopy. Multiple superficial skin samples should be obtained from characteristic lesions by scraping with a

FIGURE 24.1 Scabies mite (*Sarcoptes scabiei*) female.

scalpel. The specimens are examined under a microscope, looking for mites (adults or immature forms), eggs, empty eggs, or scybala. Dermoscopy may also help diagnosing scabies in vivo. It is a useful tool that is as sensitive as skin scraping examination, and it permits the identification of a triangular or V-shaped structure corresponding to the fore portion of the mite (head and anterior legs), called the "delta-sign" (Figure 24.2). The confirmation of the diagnosis can be challenging in classic scabies as only 5 to 15 adult mites live simultaneously on the host; whereas hundreds, thousands, or even millions do in crusted scabies.

Therapy

People with scabies and their close physical contacts, even those without symptoms, should receive treatment at the same time. There are a variety of treatments available for human scabies. They can be administered either topically or orally. Topical treatment includes 5% permethrin, 10% to 25% benzyl benzoate, esdepalletrine, crotamiton, precipitated sulfur, and lindane (withdrawn from the market in most Western countries). Topical scabicides have neurotoxic effects on mites and larvae. Oral ivermectin interrupts the γ-aminobutyric acid-induced neurotransmission of many parasites, including mites. However, oral ivermectin is not approved by the US Food and Drug Administration (FDA) for scabies indication and is only licensed for scabies in some countries (e.g., Australia, Brazil, Germany, France). It is prescribed at 200 μg/kg as a single dose in patients >15 kg in weight, ideally during a meal (see below). A second dose is mandatory 7 to 10 days later due to the lack of ovicidal action of the drug. Despite the weak level of evidence (i.e., relevant and powered randomized controlled trials [RCTs]), the most recent Cochrane meta-analysis published in 2018 suggested that there was no difference in the efficacy of topical 5% permethrin compared with 200 μg/kg systemic or 1% topical ivermectin given twice and that both drugs should be considered as the most efficient treatments. The choice of agents is mostly based on the age of the patient, the presence and extent of eczematization or superinfection of the skin, the potential toxicity of the drug, and its cost and availability. Ivermectin should be routine therapy for patients who have no response to a topical scabicide, and it may be the appropriate first choice for the elderly, patients with generalized eczema or superinfection of the skin, other patients who may be unable to tolerate or comply with topical therapy, and patients included in mass drug administration programs (whether they have impetigo or not). New drugs with long plasma and skin half-lives that can be given once orally are currently under development. Drugs used in veterinary clinics, such as moxidectin, a member of the macrocyclic lactones family, or afoxolaner, a member of the isoxazolines family, are considered potential new alternatives for scabies treatment in humans.

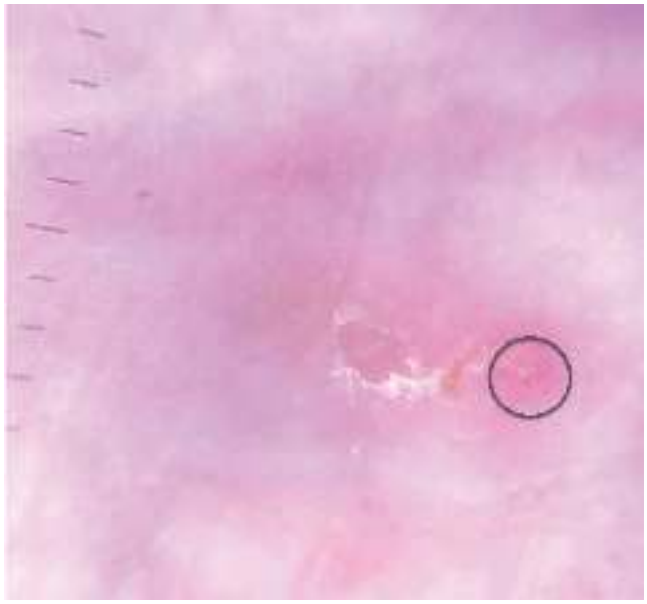

FIGURE 24.2 Visualization of scabies mite using dermatoscopy.

Patients should receive detailed information about scabies infestation and therapeutic options, including the amount of drug to be used and proper administration. Topical treatment should be applied to the entire skin surface, including the scalp, face (especially in children), all folds, groin, navel, and external genitalia, as well as the skin under the nails and reapplied again 7 to 10 days after the first treatment. Hands should not be washed during therapy (protection mandatory in infants), otherwise the treatment should be reapplied. Opinions diverge on whether the ivermectin tablets should be given with food or on an empty stomach. However, since ingestion of food increases the bioavailability of ivermectin in pharmacokinetics studies, taking the drug with food may enhance plasma concentration and penetration of the drug into the skin. The use of emollients to restore the skin barrier impaired by the infestation should be intensive, especially to reduce the itch sensation. Antihistamines (anti-H1) may help in the short term, mainly sedative antihistamines that help patients to sleep, even if histamine is not considered the main mediator implicated in scabies itch. After completion of treatment, patients should use clean clothing and bedding. If possible, potentially contaminated items should be washed at high temperature (50°C/122°F at least), kept in a plastic bag for up to 2 to 4 days in temperate climates, or frozen for at least 5 hours because mites that are separated from their human host will die within this time period. The use of insecticidal products should be restricted to unwashable

materials. Patients should be informed that itching may persist, especially in atopic individuals. After 4 weeks, the cause of itching should be reinvestigated.

Pediculosis capitis

The most common form of louse infestation is caused by the head louse, *Pediculus humanus* (designated *Pediculus humanus capitis* in the past to differentiate it from the body louse, formerly designated *Pediculus humanus humanus*, which has now been found to be genetically identical to the head louse). Since the 1970s, the prevalence has increased in many countries. Head lice predominantly infest schoolchildren (and their family close contacts) of all socioeconomic groups; transmission occurs through head-to-head contact, with the classroom being the main source of infestation. Active infestation is based on the finding of live lice. The stage of the louse most commonly seen is the nit. Each nit is oval, opaque, and white (about 0.8 × 0.3 mm) and is firmly attached individually to a single hair by the female louse. Nymphs or viable-appearing nits (louse eggs) are located about 1 mm from the scalp surface. Three immature stages (nymphs) precede the formation of the adult louse. Adult and immature lice are wingless and, as in all insects, have six legs. Each leg ends in a claw used for gripping hair. The adult lice are about 2 to 3.5 mm long and are white or cream in color (Figure 24.3).

Infested individuals may first notice itching of the scalp, most often in the postauricular and occipital regions, but pruritus occurs in a variable proportion of children. All immatures and adults require blood and, as a result of feeding, usually produce erythematous, papular lesions that are the cause of the pruritus. Some patients react to louse saliva with urticaria or lymphadenopathy. Secondary bacterial infection may occur as a result of scratching, and concomitant head louse infestation should always be considered in cases of scalp impetigo, neck or scalp eczematization, or posterior cervical lymph node enlargement in the absence of other lymphadenopathy.

Therapy

Management of head louse infestation is difficult because good comparative-effectiveness research is still lacking, and louse resistance to pyrethroid and malathion has emerged. A systematic review is in process. DNA sequencing showed that "knockdown resistance" (*kdr*) to permethrin was linked to a three-point mutation (M815I-T917I-L920F) in the louse voltage-gated sodium channel α-subunit gene, conferring nerve insensitivity. However, genetic resistance might not be predictive of clinical or parasitologic failure. It is recommended to use 1% permethrin or pyrethrin insecticide as first-line therapy. If resistance in the community has been proved or live lice are present 1 day after the completion of treatment, a switch to malathion (if available) may be necessary. Other options include wet combing, also called "bug busting," or treatment with dimethicone or other topical agents (see Table 24.1), depending on the availability of the agents in the country. All treatments should be applied twice, at a week apart, because of insufficient ovicidal activity of most drugs. Topical ivermectin has shown greater efficacy than placebo in an RCT and has been approved by FDA in 2012. An RCT published in 2010 showed that a single oral dose of ivermectin (400 μg/kg of body weight) repeated within 7 days achieved higher louse-free rates on day 15 than 0.5% malathion lotion among patients with difficult to treat head lice. The safety of such dosage of ivermectin in patients with head louse infestation remains unknown and subsequently should only be used in the case of failure of all available topical treatments (off-label).

All family members and close contacts should be screened, and only those with active signs of infestation should be treated. Dead nits may be removed with a fine-toothed comb. All materials that touched the heads of infested persons, such as hats, scarves, bedding, and cushions, should be thoroughly washed in hot water (50°C/122°F at least). Any infested materials kept in plastic bags for 3 days may be safely used. Hair grooming aids, such as brushes, combs, and curlers, should be discarded or decontaminated with an insecticidal powder.

Pediculosis pubis (pthiriasis)

Pubic louse infestation is caused by the crab louse (*Pthirus pubis*), named for its crablike appearance caused by the enlargement of the second two pairs of legs. Adult crab lice are 1 to 2 mm long and equally wide and are gray, yellow, or brown. Extreme pruritus in the inguinal region is usually the first sign of infestation. Dried serous fluid, blood, or louse feces in the pubic hair are indicative of an infestation. Heavily infested individuals may have blue or gray macules that do not blanch under pressure. Nits are usually laid on the pubic and perianal hair, but infestations of facial hair, including eyebrows, eyelashes, mustache, and beard, may occur, as do less frequent infestations of the axilla. Transmission occurs most often during sexual contact. Definitive diagnosis requires identification of the nits or lice. As with head lice, pubic lice are not known to transmit any pathogens to humans, so the sole aim of therapy is removal of the insect parasite infestation.

TABLE 24.1 **THERAPEUTIC REGIMENS FOR SCABIES, LICE, AND MYIASIS**

Infestation	Therapies of choice	Alternative therapies	Additional measures
Classical scabies	Two applications of permethrin 5% or two doses of oral ivermectin, 200 μg/kg (at day 1 and day 7–10)	Two applications of benzyl benzoate 10–25%	People in close physical contact, even without symptoms, should receive treatment (two applications/doses) at the same time Decontamination of clothes and bedding
Head lice	Two applications of topical permethrin 1% or malathion 0.5%*	Bug busting Dimethicone Topical ivermectin Two doses of oral ivermectin (failure of all available treatments, not FDA-approved) 400 μg/kg (at day 1 and day 7)	Remove nits with lice combs Wash of clothes and hats
Body lice	Decontamination of clothes and bed linen Application of permethrin 1% or malathion 0.5% for 8–24 h	Oral ivermectin 200/400 μg/kg used in indigent population to reduce reinfestation, or body lice transmitted infectious disease epidemics —not approved	Decontamination of furniture and mattresses
Pubic lice	Two applications of permethrin 1% or malathion 0.5% Shaving	Two doses of oral ivermectin, 200/400 μg/kg (repeat at 7 days)—not approved	Treatment of all hairy area of the body and all sexual contacts when necessary Decontamination of clothes and bedding
Myiasis	Mechanical or surgical removal of the maggots	One dose of oral ivermectin 200 μg/kg —not approved	Disinfection to prevent secondary infection

* Withdrawn from some western-country markets

Therapy

Pubic lice are treated with the same insecticidal creams or lotion as pediculosis capitis, with a second application after 1 week because the products have poor ovicidal activity. Resistance to pyrethrins has been shown. All hairy areas of the body should be treated at the same time (see Table 24.1). Shaving is sometimes useful when nits are plentiful. Infestations of the eyelashes should be treated with permethrin 5% cream (wash off after 10 minutes) or only with petrolatum (applied twice a day for 8–10 days), followed by mechanical removal of the nits. Oral ivermectin at the dosage of 200/400 μg/kg (repeat at 7 days) has been anecdotally used in profuse cases.

As in other louse infestations, all sexual contacts should be examined and treated when necessary. Bedding and clothes should be washed in hot water (50°C/122°F). Prepubertal children presenting with pubic louse infestations should be evaluated with regard to possible child abuse. Treatment failure is usually a result of an untreated hairy area or reinfestation from an untreated sexual contact. In addition, patients should also be screened for associated sexually transmitted diseases.

Pediculosis corporis

Body louse infestation is caused by *Pediculus humanus* (sometimes incorrectly called *Pediculus corporis*), a louse species virtually identical in morphology to the head louse, except that it is usually slightly larger, about 2 to 4 mm long. Body lice feed on blood but retreat to hide in clothing on which the nits are laid. Infestations are most commonly found in homeless individuals, refugees, and victims of war and natural disasters. Infestations are recognized by extreme pruritus in conjunction with observation of nits firmly attached to clothing fibers. The erythematous, maculopapular feeding lesions are often scratched beyond recognition, leaving only serous or bloody crusts or secondary infection. Postinflammatory pigmentation is seen in chronic cases.

Unlike head and pubic lice, body lice may act as vectors of human bacterial pathogens in those areas of the world where these organisms are endemic. Trench fever, caused by *Bartonella quintana*, is rarely fatal but may cause endocarditis. As the name implies, it was most common during World War I and re-emerged in epidemic form in Europe during World War II. The recent emergence of trench fever has been confirmed in France, the United States, and Burundi, and more recently with refugees population from the Middle East. It is becoming more prevalent in populations of alcoholic homeless and displaced persons. Symptoms include fever, myalgias, headache, meningoencephalitis, chronic adenopathies, and transient maculopapular exanthema, but it may be asymptomatic. Louse-borne (epidemic) typhus, caused by *Rickettsia prowazekii*, still occurs in parts of Africa and Central and South America. It is a serious and sometimes fatal disease that may become epidemic in crowded, unsanitary living conditions. Symptoms include fever, headache, rash, and confusion. Louse-borne relapsing fever, caused by *Borrelia recurrentis*, is also sometimes fatal but has been rarely seen in recent years, except in Ethiopia.

Therapy

Bed linen and clothes must be systematically decontaminated, and this action suffices for some physicians. Others recommend thorough washing of the body with soap followed by application of pyrethrins/pyrethroids or malathion for 8 to 24 hours (see Table 24.1). Ivermectin, used at a regimen of three doses of 200 μg/kg each, given at 7-day intervals, greatly reduced the number of body lice infesting a population of homeless men. Such treatment may be effective in limiting the viability of body lice in patients living in an institution or routinely returning to a treatment center or shelter. Depending on the geographic location of the infested individual and his or her contact with other similarly infested individuals, the physician should consider the possibility of louse-borne disease. Infested furniture, mattresses, and box springs should be discarded or fumigated to destroy lice and nits. Infested materials sealed in plastic bags for 3 days or washed at temperatures hotter than 50°C/122°F may be used safely. Antibiotics are used to treat louse-borne infectious transmitted disease.

Myiasis

Myiasis is the invasion of living vertebrate (including human) tissue by fly larvae. Various species of flies that normally deposit eggs or larvae on garbage, carrion, or corpses may occasionally deposit these stages on wounds or skin adjacent to draining infections. Other fly species deposit eggs that hatch into larvae that penetrate intact skin. Flies in the former group include various house flies, blow flies (greenbottles and bluebottles), and flesh flies. The true myiasis producers in the second group are bot flies and warble flies. Although bot fly and warble fly larvae usually infest nonhuman hosts, these larvae occasionally invade human tissues. Myiasis is most often cutaneous, but fly larvae may also invade the nose and throat, eye, ear, and intestinal and genitourinary tracts.

Dermal (furuncular) myiasis, arising in intact skin, as caused by the human bot fly (*Dermatobia hominis*) in Central and South America and the tumbu fly (*Cordylobia anthropophaga*) in Africa, appears as a painful or itchy swelling with an opening at the skin surface. Observation of the opening under low magnification will reveal the posterior end of a moving larva, on which will be two dark circular areas, the respiratory openings (spiracular plates), which allow the larva to breathe while it is feeding with its anterior end embedded in the skin. If the larva is left in the skin, it will continue to feed just below the skin surface for several days to weeks and eventually back out and drop to the ground to complete development.

Therapy

Myiasis of the nose and throat, eye, ear, or internal organs may require surgical intervention or at least the use of anesthetics for manual removal of the larvae with forceps. Invasive rhino-orbital myiasis has been treated successfully with one dose of oral ivermectin prior to surgery. However, the use of ivermectin at the dosage of 200 μg/kg is an off-label treatment in many countries and should be reserved for selected cases.

In dermal myiasis, early diagnosis and removal of the larva will relieve the irritation and discomfort caused by its movements and feeding under the skin. Direct removal involves application of a local anesthetic, followed by grasping the larva with a forceps and pulling with constant pressure to dislodge its hold, which may be strong because of the teeth or spines surrounding the anterior part of its body. Indirect methods of removal involve application of an occlusive dressing containing petrolatum or even a piece of meat or animal fat if medical supplies are not readily available. Within a few hours, the suffocating larva will back out of the opening into the dressing or embed itself in the occlusive tissue. Secondary infections are rare, and little further treatment beyond disinfection is usually needed. To prevent cutaneous myasis in an endemic area, it is necessary to use insect repellents (*Dermatobia hominis*) and not to wear clothes dried outside or to rest in sandy areas (*Cordylobia anthropophaga*). Wound myiasis, which may even occur in modern medical facilities, can be prevented by frequent changes of dressings and isolation of patients, especially immobile ones, within screened rooms. Myiasis of wounds is treated by removal of the feeding maggots, irrigation, and disinfection. Because fly larvae feed on dead tissue, secrete antibiotic chemicals, and may even expedite healing, sterile maggot therapy (with greenbottle fly larvae) has been used successfully in the treatment of persistent surgical wounds or ulcers.

Tungiasis and bed bugs

Tania F. Cestari and Simone Pessato

Tungiasis

In recent years, increased ecotourism and international travel to tropical countries has produced a growing incidence of infestations formerly limited to certain regions.

Tungiasis is a common ectoparasitic infestation that occurs mainly in the tropics, particularly where poverty and poor standards of basic hygiene exist. Despite recent progress in the treatment and prevention of tungiasis, diagnosis can present a challenge to those unfamiliar with the disorder, especially when it occurs in nonendemic countries.

Tungiasis is caused by the penetration of the female sand flea, *Tunga penetrans*, a hematophagous ectoparasite, into the epidermis of the host. The infestation is usually self-limited and presents few complications. It is known by several popular designations, including *chigoe flea, jigger flea, pico, nigua* (Mexico, Caribbean islands, Peru), *pique* (Argentina), *bicho dos pés, pulga da areia* (Brazil), *moukardan* (Sudan), *puce chique,* and *ogri eye* (South America).

In addition to humans, a wide spectrum of animal species is susceptible to an infection by *T. penetrans*. Pigs have been considered the main reservoir for human infections, but the parasite has been reported to affect cows, dogs, cats, goats, and rats as well. Recognition of infected animals and their treatment is mandatory to ensure control of outbreaks.

Epidemiology

T. penetrans is one of the few parasites that has spread from the Western to the Eastern hemisphere. Sand flea disease is common in resource-poor communities in South America and sub-Saharan Africa, with a prevalence of up to 60% in the general population. The parasite originally lived only on the American continent and came to Angola with the sand carried by travelers from Brazil. Within a few decades, it spread from Angola to sub-Saharan Africa, East Africa, and Madagascar. At present, tungiasis is endemic in many countries in Latin America (from Mexico to Northern Argentina), in the Caribbean islands, and in sub-Saharan Africa. Recent studies in Nigeria, Cameroon, and Brazil reported a similar high prevalence of tungiasis, from 45% to 51%; the higher rates occur in some communities of Brazil, Nigeria, and Trinidad and Tobago. The infestation happens mostly in underdeveloped communities in the rural hinterland, in secluded fishing villages along the coast, and in the slums of urban centers. The seasonal variation of tungiasis in endemic communities shows a highest incidence that corresponds to the peak of the dry season in the tropics.

In nonendemic areas, tungiasis is rare and usually appears on travelers returning from endemic countries. There are isolated reports of infection acquired in nonendemic regions, most likely by fleas that were imported from contaminated areas and completed their free-living life cycle at sites such as sandy beaches. Tungiasis is more common in adults. Considering the thinness of their stratum corneum and epidermis, children ought to be more susceptible; however, the infestation is rare in children living in nonendemic regions. There is no statistically significant difference between the prevalence of tungiasis in males and females considering the same chance of exposure and disease-related behavior.

Etiology

T. penetrans belongs to the genus *Tunga* of the order *Siphonaptera*; it is the smallest flea, measuring around 1 mm in length, and the only species of the genus that affect humans. The parasite development requires dry and warm soil with an optimal temperature ranging between 22°C/72°F and 31°C/88°F in the upper level of the soil. Male and female *T. penetrans* are bloodsuckers, but the male leaves its host after feeding, whereas the female burrows into soft skin regions of the body. Here, it remains for up to 5 weeks, completing its life cycle. Besides humans, various animals (domestic or wild mammals) may act as hosts for *T. penetrans.*

Clinical manifestations

About 90% of all lesions occur on the feet, and areas of soft skin, such as the interdigital spaces, the periungual regions, under the toenails, and along the medial border of the feet, are the favored sites for flea embedding. Occasionally, genital and perianal areas, thighs, hands, and other sites may be affected, especially when the infestation is massive.

The female flea burrows into the skin of its host, starting a complex five-stage sequence of structural and morphologic changes; the cycle is accompanied by different degrees of inflammatory reaction, known as the *Fortaleza classification* (Table 25.1). The clinical diagnosis of tungiasis is based on the presence of papular or nodular lesions, either single or multiple, white, gray, or yellowish in color, with a small brown-black central opening, usually localized to the feet, in a patient who recently visited endemic areas (Figure 25.1).

Dermoscopy has been shown to be helpful in confirming the clinical diagnosis of *Tunga* infestation. The exam in vivo shows an annular brown ring with a central black pore corresponding to the opening of the flea. In the central area (the abdomen), it is possible to visualize gray-blue blotches and a large number of whitish oval structures linked together forming a chain-like picture, matching the image of the eggs contained in the distended "jelly sac" and consistent with the late stage 3B of the parasite's development (Figure 25.2). After extraction of the intact parasite, ex vivo, the diagnosis is confirmed by visualization of the flea head and the abdomen full of eggs.

The histopathology of a typical lesion shows hyperkeratosis, parakeratosis, and acanthosis. The body of the flea locates in the upper dermis, and it is surrounded by a pseudocystic cavity. Inside the cavity, annular-shaped digestive and respiratory organs as well as ovaries rich in eggs may be observed. Eggs are oval or, less frequently, round, with a thickened wall and pale center. A peri-lesional, inflammatory infiltrate, mainly consisting of lymphocytes, neutrophils, and numerous eosinophils, is also present.

The differential diagnoses of tungiasis include *talon noir*, plantar or subungual warts, subungual exostoses, myiasis, abscesses, verrucae, ecthyma, tick bite, and melanocytic and nonmelanocytic skin tumors, especially melanoma.

Tungiasis is usually a self-limited condition, resolving in 4 to 6 weeks, with few complications consequent to the infestation. Colonial documents and travel reports from the early twentieth century indicate that the disease used to cause severe morbidity among the indigenous populations, such as grave inflammation in the feet, deep ulcers, gangrene, lymphangitis, and septicemia. Nowadays, the degree of morbidity depends on the intensity of infestation, hygiene conditions, and associated clinical disorders.

In economically depressed urban neighborhoods, however, poor housing conditions and inadequate healthcare lead to a high transmission potential, resulting in high parasite loads and secondary

TABLE 25.1 **BIOLOGIC CYCLE AND DEVELOPMENT OF *TUNGA PENETRANS* INFESTATION IN HUMANS**[A]

Stage/phase	Time after onset of penetration	Clinical findings: parasite	Clinical findings: host
Stage 1 Penetration	30 min–7 h (average 3 h	Penetration of the gravid flea; the abdominal segments 1–3 separate toward the cephalic direction	Penetration at an angle of 45–90 degrees; slight erythema; mild stink; tiny reddish spot
Stage 2 Hypertrophy	1–2 days	The abdominal segment enlarges and the parasite is visible	Itching and painful nodule with a central black dot; erythematous inflammatory area
Stage 3 White halo	4 days	Correspond to the maximum growth of the parasite; the lesion resembles a white pearl with a central opening from which the enlarged flea eliminates feces and eggs	Painful foreign-body reaction
Stage 4 Involution	3–4 weeks	Dark crust containing the parasite remains	The lesions may be numerous and close-set like a honeycomb; secondary infection is frequent
Stage 5 Residual scar	Days after the involution phase		Reorganization of the epidermis continued; the site occupied by the parasite is flattened and becomes indistinguishable from normal skin

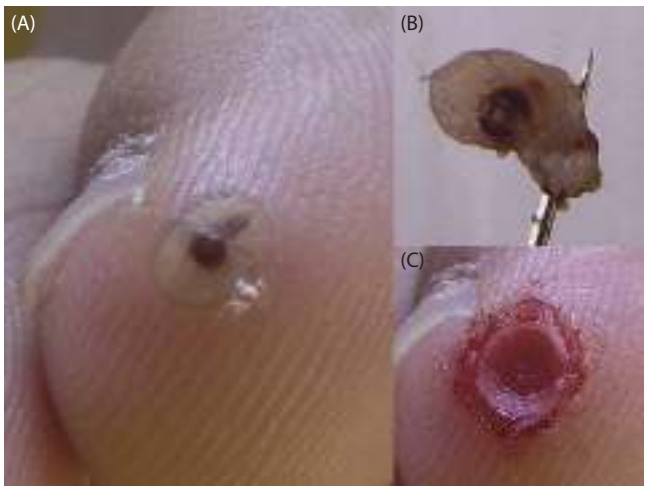

FIGURE 25.1 Tungiasis. (A) Isolated lesion on the first toe, corresponding to the parasite in its maximum growing stage and presenting as a white nodule with central opening. (B) Parasite removed with a needle after gentle debridment, showing the intact abdomen full of eggs. (C) Circular ulceration, with clean walls, after removing the female *Tunga*.

complications. The most common problems associated with tungiasis infestation are acute painful inflammation and edema, abscess formation, lymphangitis, fissures, ulcers, sepsis, tissue necrosis or gangrene, erysipelas, or even contamination by other infectious agents such as fungi, causing atrophy or loss of nails, toe deformations, and difficulty in walking and gripping. As an additional risk, clinical and epidemiologic evidence suggests that the possibility of bacterial superinfection is constant. In populations with low vaccination coverage, untreated tungiasis may provide a port of entrance for *Clostridium tetani* or *C. perfringens* bacilli, being a risk factor for tetanus.

FIGURE 25.2 Tungiasis. Dermoscopy of an isolated lesion showing the annular brown ring with a central black pore. In the surrounding area, it is possible to visualize whitish oval structures in a linear distribution corresponding to the intra-abdominal eggs (20×).

Treatment and control

Standard therapy for tungiasis consists of surgical extraction of the embedded parasite under sterile conditions, followed by appropriate care of the resulting wound. During the excision, care should be taken to prevent tearing of the flea and to avoid parts of the flea being left behind due to the risk of severe inflammation.

Topical application of kerosene, plant extracts, chlorophenothane, chloroform, 4% formaldehyde solution, turpentine, and yellow mercury oxide has been used but without controlled studies. Chemotherapeutic approaches to attempt to kill embedded fleas without mechanical extraction include administration of oral niridazole, thiabendazole, and ivermectin, none of which is completely effective.

Superinfection of the lesions may lead to pustule formation, suppuration, and ulceration. In this case, oral antibiotics should be prescribed and appropriate local care administered. Tetanus prophylaxis is recommended, especially for those individuals living in endemic areas.

The reduction of prevalence and intensity of tungiasis is possible through regular treatment of infested humans, elimination of animal reservoirs, and environmental changes. Prevention measures include paving of public areas and house floors and implementing basic hygiene measures. Animals living close to humans should also be treated using insecticidal compounds, such as collars, sprays, shampoos, or topical products. The early and late stages of the flea could be eliminated by spraying environmental insecticide on sandy areas, on beaches, and close to animal housing facilities. Biologic repellents, composed of coconut and jojoba oils (Zanzarin), may be recommended. A regular twice-daily application of Zanzarin for a period of 3 weeks reduced the rate of newly embedded fleas by 92% and reversed tungiasis-associated clinical pathology almost completely. Sanitary disposal of domestic garbage, proper vector control, correct housing of animals, wearing of protective shoes, and periodic self-examination in endemic areas are also mandatory.

Cimicidae infestation: Bedbugs

Bedbugs and their relatives belong to the family *Cimicidae* and are all blood-sucking ectoparasites of mammals or birds. The species *Cimex lectularius* is the most common. They are cosmopolitan and may be found in homes, in poultry houses, and around small caged pets or near bird and bat nests and roosts, parasitizing humans and also bats, chickens, and other domestic animals. In houses, they live in tufts, seams, and folds of mattresses, bed covers, bed frames, windows and door casings, bird nests, floor cracks, under carpets, behind loose wallpaper or wall pictures, and in furniture and luggage. Infestations of bedbugs can often be detected by their offensive odor, caused by an oily secretion produced by special glands.

Laboratory techniques have demonstrated that bedbugs could harbor some pathogenic microorganisms, including hepatitis B and hepatitis C viruses, HIV, and methicillin-resistant *Staphylococcus aureus*. However, the capacity of bedbugs to act as disease vectors is

debatable, and it appears unlikely that these insects could be a significant risk for HIV transmission. After World War II, bedbugs became uncommon. However, an increase has been observed recently and may be associated with international trade and traveling.

Epidemiology and etiology

The common bedbug is a wingless, ovoid, flat, reddish-brown, blood-sucking insect that grows up to 7 mm in length and has a lifespan from 4 months to 1 year (Figure 25.3).

Bedbugs respond to aggregation pheromones, resulting in clustering behavior, although solitary bedbugs may be found. They are nocturnal insects with chemo- and thermosensorial abilities that orient them toward human odors, being attracted by warmth and carbon dioxide. They feed on sleeping humans and hide during the day. When feeding, the insect grasps the skin with its forelegs and injects saliva containing anticoagulant, vasodilator, and anesthetic fluids. After a blood meal, female bugs lay between one and five eggs that hatch in 4 to 5 days. The female deposits eggs on rough surfaces of cracks and crevices, where nymphs could survive >260 days in case of starvation.

Clinical features

Bedbug bites are often observed in linear groups of three, the so-called "breakfast, lunch, dinner" pattern. Lesions usually occur on the face, neck, hands, and arms and can be noticed upon waking or one to several days later. The bite itself is painless and feeding is facilitated by a salivary apyrase, an anticoagulant enzyme. Lesions range from erythematous pruritic macules in previously unexposed patients, to pruritic papules, wheals, vesicles, or bullae in sensitized individuals. Exaggerated local responses occur in patients with a high degree of immunity, those sensitive to other insects, and after repeated bites. Type I hypersensitivity allergic cutaneous and asthmatic reactions have also been observed, as well as widespread bullous eruption with urticated hemorrhagic papules due to multiple bedbug bites.

The differential diagnosis of bedbug bites includes scabies, flea bites, and urticarial prurigo reactions.

Treatment and control

Many physicians are unfamiliar with bedbugs and their bites. Awareness of the possibility of infestation is important to institute correct medication and parasite control measures. Treatment of the reaction secondary to the contact with bedbugs involves the use of antihistamine or corticosteroids and topical antimicrobials for secondary bacterial infection, if necessary. Cleaning out bedbugs' hiding places and eliminating cracks and crevices, as well as the use of insecticides, will decrease the infestation of houses. Pesticides containing dichlorvos, malathion, and pyrethrins are effective, taking into account the surface being treated. Bedbug control by repellents or permethrin-impregnated bed nets has proved its effectiveness in actual use in spite of sporadic reports of resistance to pyrethroids and decrease of DEET repellency

Superficial fungal infection of skin and nails

Evelyn K. Koestenblatt and Jeffrey M. Weinberg

The vast majority of fungal infections of the skin, hair, and nails are caused by the dermatophytes and yeasts including *Candida* spp. and *Malassezia furfur*. Proper diagnosis of these conditions is essential as they can present in a fashion similar to nonfungal disease. Moreover, some fungi causing systemic infections may begin as cutaneous lesions. In most cases, potassium hydroxide (KOH) preparation, culture, and/or biopsy can provide a definitive diagnosis. Treatment of these conditions may include topical and/or systemic antifungal therapy.

The dermatophytes

The dermatophytes are organisms that are found in specific ecologic niches and consume the structural protein keratin. Those found in the soil are referred to as *geophilic* while those that are transmitted from human to human, resulting in primarily infections of the hair, skin, and nails, are termed *anthropophilic*. *Zoophilic* organisms are those that are mainly found in fur, feathers, skin, and nails of animals. Zoophilic and geophilic organisms, when transmitted to humans, tend to be much more inflammatory than anthropophilic organisms. Factors precluding a dermatophyte infection or dermatophycosis include inoculum size, host immune status, the particular organism, a suitable environment, fungal growth rate exceeding epidermal turnover, and, in certain instances, the host genetics.

The term "tinea" refers to a dermatophycosis due to one of the following genera: *Epidermophyton, Trichophyton*, or *Microsporum*. Dermatophyte infections are described by their location on the body: tinea capitis (scalp), tinea corporis (glabrous skin), tinea faciei (face), tinea cruris (groin), tinea manuum (hand), tinea pedis (feet), tinea barbae (facial hair), and tinea unguium (nails). "Onychomycosis" refers to any fungal infection (dermatophytes and nondermatophyte organisms) of the nails. Most infections in the United States are due to five species: *Trichophyton rubrum, T. tonsurans, T. mentagrophytes, Microsporum canis,* and *Epidermophyton floccosum*.

Tinea capitis

In the United States, tinea capitis (scalp ringworm) is most commonly due to *T. tonsurans* and most often seen in children. Clinically, this form of tinea capitis begins with the appearance of papules and progresses to a scaly area of irregular or well-demarcated alopecia with black dots (Figure 26.1). The black dots are due to spore-filled hairs (endothrix invasion) breaking at the surface of the scalp. This type of infection is the most common form of tinea capitis and is seen more frequently in African American and Hispanic children. An inflammatory boggy, tender, purulent mass called a *kerion* may be present, often in African American children. A short course of systemic steroids along with antifungal treatment will reduce the inflammation

FIGURE 26.1 "Black dot tinea capitis" due to *T. tonsurans*.
Courtesy of Evelyn Koestenblatt.

and discomfort as well as the chance of scarring alopecia. Other organisms causing black dot tinea, including *T. soudanense* and *T. violaceum*, are being recovered with greater frequency in the United States.

Gray patch ringworm is another form of tinea capitis, caused by the organisms *Microsporum canis* and *M. audouinii*. In this case the fungus is on the outside of the hair shaft (ectothrix invasion), causing it to have a grayish appearance. Some of these organisms produce a yellow-green fluorescence visible with a Wood's (UV) lamp. Favus or tinea favosa is generally associated with malnutrition and poor hygiene; it is rarely seen in the United States and is most frequently due to *T. schoenleinii*. Clinically, favus appears as diffuse alopecia with yellow crusts or scutula, which are made up of hyphae, neutrophils, and skin debris. Microscopically, hyphae and air spaces are seen within the hair shaft.

The most common methods for diagnosing tinea capitis are KOH preparation and fungal culture. Collection of infected hair

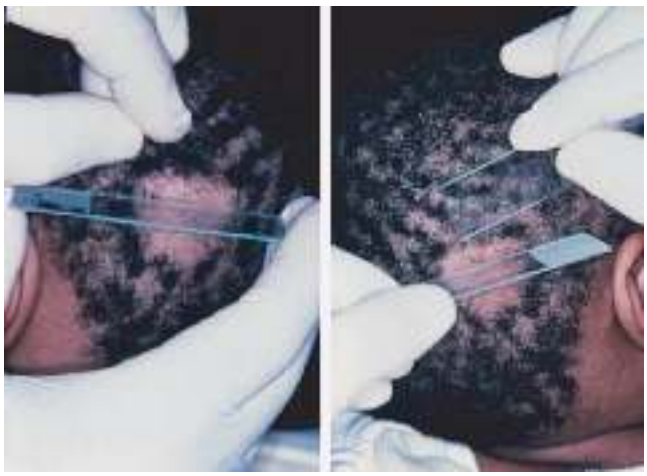

FIGURE 26.2 Tinea capitis techniques for collecting hair for KOH and culture.

TABLE 26.1 **TREATMENT FOR TINEA CAPITIS**

Griseofulvin	Terbinafine	Itraconazole	Fluconazole
20–25 mg/kg/d for 6–8 weeks (liquid microsize)	62.5 mg/d ≤20 kg 125 mg/d 20–40 kg 250 mg/d >40 kg For 2–4 weeks	5 mg/kg/d for 4–8 weeks	6 mg/kg/d for 3–6 weeks

is necessary for diagnosis of tinea capitis. The hairs may be obtained for both KOH prep and culture in two ways: a scalpel blade or glass slide may be used to scrape the area or a soft toothbrush or moist gauze can be firmly rubbed over the involved scalp (Figure 26.2). The hairs are placed onto a glass slide and mixed with 10% to 20% KOH, a coverslip is applied, and the sample is then examined under a microscope. The hairs are inspected for evidence of fungal infection with spores either inside (endothrix) or outside (ectothrix) of the hair shaft. For culture, the hairs are gently placed on the surface of the fungal media for a period of several weeks. Only the specimen should be placed inside of the media tube.

The gold standard of therapy for tinea capitis is oral griseofulvin. Topical therapy is most often unsuccessful because the medication cannot penetrate the hair follicle. Griseofulvin is usually given to children in conjunction with a fatty meal which stabilizes the gastric pH. The use of a warm compress to induce sweating and ultimately cutaneous excretion of the drug may also improve efficacy.

For patients who fail therapy with griseofulvin or cannot tolerate the medication, treatment with itraconazole (Sporanox), fluconazole (Diflucan), or terbinafine (Lamisil) is an option (Table 26.1). Terbinafine is an accepted alternative first-line agent for patients suffering from tinea capitas which is suspected or found to be caused by *Trichophyton*. Terbinafine may also be used for *Microsporum* infections but requires higher and longer dosing. In addition, brushes, combs, hats, hair ribbons, barrettes, and bed linen should be thoroughly washed. Children and caretakers of patients may be asymptomatic carriers of infection and ultimately sources for reinfection, which necessitates further evaluation and the use of 2.5% selenium sulfide or 2% ketoconazole shampoo three times a week for at least 5 minutes by all family members to reduce the spread of infectious spores.

Tinea corporis

Tinea corporis (Figures 26.3 and 26.4) refers to dermatophycosis of the glabrous skin. The infection may present as sharply demarcated annular lesions with a scaly border, bullous lesions, granulomatous eruptions, pustular lesions, psoriasiform plaques, and/or verrucous lesions. The disease is most prevalent in tropical areas but may be found across the world. In the United States, *T. rubrum* is the most common etiologic agent of tinea corporis. *T. mentagrophytes* and *M. canis* are also common. Infections caused by *M. canis* and some strains *of T. mentagrophytes* typically present with multiple lesions

FIGURE 26.3 Tinea corporis.
Courtesy of Evelyn Koestenblatt.

and are often more inflammatory and symptomatic than those caused by *T. rubrum*. Tinea corporis may also be seen in caretakers of children suffering from black dot tinea capitis due to *T. tonsurans*.

Tinea cruris

Tinea cruris refers to a dermatophyte infection of the groin, including the suprapubic areas, proximal medial thighs, perineum, gluteal cleft, and buttocks. Infection is more often seen in men than women and is commonly caused by *T. rubrum, T. mentagrophytes*, and *E. floccosum*. Women more often suffer from candidiasis than tinea cruris.

Courtesy of Evelyn Koestenblatt.

FIGURE 26.5 Moccasin type tinea pedis. Scrape the active border with a no. 15 blade for KOH preparation and culture.
Courtesy of Evelyn Koestenblatt.

Tinea pedis

Athlete's foot or tinea pedis is the most common fungal infection (Figure 26.5). The moisture, friction, maceration, heat, darkness, and occlusion present in the feet are perfect for fungal growth. *T. rubrum* is the most common etiologic agent and causes a "moccasin" distribution of scale and erythema. *T. rubrum* is associated with a familial autosomal-dominant predisposition to this type of infection. Dermatophytosis occurring between the toes is referred to as *interdigital tinea pedis*. *T. mentagrophytes*, *T. rubrum*, or *E. floccosum* may be recovered with or without bacterial organisms and/or yeast. *T. mentagrophytes* may also cause a vesicular-type tinea pedis characterized by vesicles with serous exudate on the plantar surface.

Tinea manuum

The patients commonly have dermatophycosis of both feet and one hand. Tinea manuum presents as a fine scale, with some erythema covering the surface of the palm, like the feet; *T. rubrum* is usually recovered.

FIGURE 26.6 Tinea faciei.
Courtesy of Evelyn Koestenblatt.

Tinea faciei and tinea barbae

Tinea faciei occurs in women and children generally on the upper lip and chin (involvement of similar area in men is termed tinea barbae) and is frequently acquired from pets (Figure 26.6). *T. rubrum, T. mentagrophytes*, and *M. canis* are typically recovered.

Tinea barbae or ringworm of the beard is seen in men and associated with exposure to animals (cattle, horses, cats, and dogs). The inflammatory type causes a deep, nodular, pyogenic reaction. *T. mentagrophytes* and *T. verrucosum* tend to cause this kerion-like response, whereas *T. violaceum* and *T. rubrum* usually cause a more superficial infection with scaling and alopecia. Extracted hairs are necessary for diagnosis by KOH preparation and culture. In some instances biopsy may be necessary to rule out other dermatoses. Given that the organisms affect the hair, oral antifungal therapy is necessary as topical therapies will not adequately penetrate the hair follicle.

Dermatophytid (id) reactions

The *id reaction*, or autoeczematization, is a pruritic, disseminated, papulovesicular eruption secondary to a variety of inflammatory and infectious skin disorders. Dermatophytid reactions can be seen following infections of tinea capitis, tinea corporis, tinea cruris, tinea pedis, and tinea manuum, but no fungal forms are recovered from dermatophytid lesions. Treatment involves eradication of the underlying infection with topical corticosteroids and oral antihistamines to provide symptom relief.

Treatment

The first-line therapy for tinea corporis, cruris, manuum, faciei, and pedis consists of topical antifungals. Topical antifungal agents utilized in the treatment of dermatophytosis include several classes: allylamines, benzylamines, hydroxpyridones, and imidazoles (Table 26.2).

Commonly used imidazoles include clotrimazole (Lotrimin, Mycelex), miconazole (Desenex, Micatin, Monistat), econazole (Ecostatin, Spectazole), ketoconazole (Nizoral), oxiconazole (Oxistat), sertaconazole (Ertaczo), and sulconazole (Exelderm). The allylamines are fungicidal and include terbinafine (Lamisil AT), naftifine (Naftin), and butenafine (Lotrimin Ultra, Mentax). Ciclopirox (Loprox) is fungicidal and has antibacterial, anti-inflammatory, and antifungal properties. Treatment regimens for topical medication are generally for 2 to 4 weeks twice a day. Treatment with oral antifungals may be necessary, especially when the infection is deeper, more widespread, or involves hair-bearing areas.

Onychomycosis

Onychomycosis is more than an embarrassing cosmetic problem as it can be exquisitely painful and lead to serious infections, especially in diabetic and immunocompromised populations. The dermatophytes account for approximately 90% of toenail infections, whereas yeasts account for the majority of infections affecting the fingernails. Up to 50% of nail dystrophy is due to fungal infections. There are four types of onychomycosis: (1) distal subungual onychomycosis, (2) white superficial onychomycosis, (3) proximal subungual onychomycosis, and (4) candida onychomycosis.

The most common form is distal subungual onychomycosis, most frequently caused by *T. rubrum*. The nail of the toe or the finger appears thickened, with subungual debris, discoloration, and onycholysis (separation of the nail plate from the nail bed). The infection begins at the distal and/or lateral nail fold and involves the nail bed and hyponychium.

White superficial onychomycosis involves the surface of the toenail, imparting a chalky white appearance. The most common etiologic agents are *T. mentagrophytes* or nondermatophytes such as *Acremonium, Aspergillus, Cephalosporium, Fusarium*, or *Scopulariopsis*. *T. rubrum* is most often recovered in the HIV population. For diagnosis of white superficial onychomycosis, a curette can be used to scrape the white chalky material off the surface of the nail (Figure 26.7).

Proximal subungual onychomycosis is the least common form and may be a sign of HIV infection; it begins at the proximal nail fold, causing an opaque white area near the lunula. The opaque areas grow distally along with the nail. *T. rubrum* and occasionally *T.*

TABLE 26.2 **ANTIFUNGAL TOPICAL AGENTS**

megninii are the common etiologic agents. Material for KOH and culture from proximal subungual onychomycosis can be obtained by a punch biopsy into the affected area or after deep scraping below the surface of the nail.

Candida onychomycosis is mainly due to *Candida albicans* and causes yellowing of the nails with onycholysis. Before initiation of therapy, it is important to document the presence of fungi utilizing one or more diagnostic techniques including KOH preparation, fungal culture, and nail plate biopsy with periodic acid-Schiff (PAS) stain. However, lab results are only as good as the manner in which the specimen was taken. When managing distal and lateral onychomycosis (Figures 26.8 and 26.9), it is important to trim the nail back as close to the juncture of the nail plate and nail bed as

FIGURE 26.8 Clip back the nail as closely as possible to the juncture of the nail plate and nail bed.
Courtesy of Evelyn Koestenblatt.

FIGURE 26.9 Curette small thin pieces of nail and debris for KOH preparation and culture.
Courtesy of Evelyn Koestenblatt.

possible. A curette can then be used to collect thin, small pieces of nail and debris for KOH and culture.

KOH preparation is a simple, inexpensive, and reliable way to diagnose fungal infections (Figures 26.10 and 26.11). The scraping is collected on a clean glass slide, and a couple of drops of 10% to 20% KOH are then added and mixed with the specimen. A coverslip is applied, and the slide is gently heated to promote breakdown of the keratin. The slide is microscopically examined for the presence of hyphal elements and yeast cells.

Material for culture should be gently placed on the surface of the agar using a wooden applicator stick that was premoistened with condensation from the tubed media (Figure 26.12). Sticks and blades should not come in contact with the inside of culture media tubes.

Proper diagnosis of onychomycosis is necessary because other disorders can present similarly, including psoriasis, irritant dermatitis, and trauma. Topical treatment of onychomycosis is generally insufficient to clear the infection. Naftin gel and 8% solution of ciclopirox have been used with moderate success. In the past, only 25% of patients treated with griseofulvin were disease-free after 1 year of therapy for toenail disease. Over the past several years, the emergence of itraconazole and terbinafine has allowed much shorter and more effective courses of therapy with fewer incidents of relapse.

Itraconazole has a broad spectrum of activity and shows activity against dermatophytes and nondermatophyte molds as well as yeasts and can be administered in a continuous or pulse fashion. In the continuous regimen, the dosage of itraconazole is 200 mg/d for 12 weeks for toenail disease and 8 weeks for fingernail disease. Pulse dosing of the medication involves a dosage of 200 mg twice daily for only 1 week of a given month. Toenails are treated for 3 months, whereas fingernails are treated for 2 months (Table 26.3). Unlike itraconazole, terbinafine is fungicidal, blocking cell membrane synthesis. This may account for terbinafine's higher efficacy for both mycologic and clinical cure rates as compared to other systemic antifungals. Terbinafine dosage is 250 mg/d for 12 weeks for toenails and 6 weeks for fingernails.

The combination of clipping and debridement of the affected nail with systemic antifungal therapy improves clearance of the

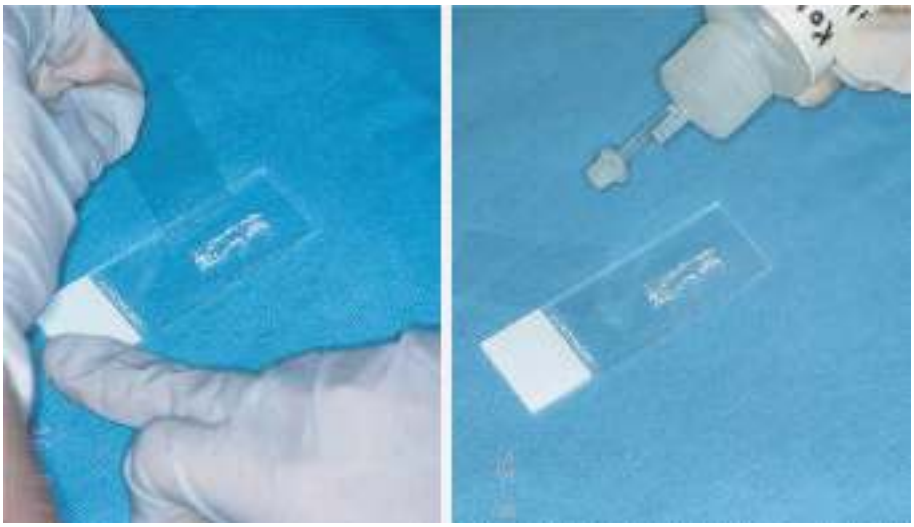

FIGURE 26.10 Method for KOH: Gather material on a clean glass slide and add a couple of drops of 10% to 20% KOH and mix with specimen. Add a coverslip.

Courtesy of Evelyn Koestenblatt.

infection. Other helpful measures include the use of white cotton socks and antifungal powder, properly fitting shoes, discarding prior fungus-laden shoes, and not walking around barefoot in public areas.

It is recommended for patients receiving either itraconazole or terbinafine to undergo liver function tests prior to and during treatment. Serious liver failure has been reported with the use of both therapies. Patients taking other medications metabolized by the cytochrome P450 pathway should not take itraconazole due to significant drug interactions. The use of itraconazole also carries a slight risk of developing congestive heart failure. Interactions have been reported in patients taking terbinafine and tricyclic antidepressants as well.

Although not approved by the US Food and Drug Administration, fluconazole is used to treat onychomycosis at a dose of 150 to 450 mg once a week for >3 months for fingernails and 6 to 12 months for toenails in those unable to tolerate other therapies.

Malassezia folliculitis

Malassezia folliculitis, previously called *Pityrosporum folliculitis*, presents with a chronic history of perifollicular erythematous and pruritic pustules and papules on the neck, torso, and upper arms. KOH preparation will reveal numerous spores and budding yeast forms. A confirmatory diagnosis in atypical locations can be made with the microscopic examination of a skin punch biopsy. Treatment is with topical antifungal therapies such as shampoos containing selenium sulfide or ketoconazole, propylene glycol 50% in water, or ciclopirox olamine cream. For more serious disease systemic oral therapies are warranted. For refractory cases, topical photodynamic therapy with methyl aminolevulinate has shown some efficacy.

FIGURE 26.11 Heat slide gently and press coverslip to flatten scale.

Courtesy of Evelyn Koestenblatt.

FIGURE 26.12 Specimen should be placed on the surface of the culture media with a wooden applicator stick.
Courtesy of Evelyn Koestenblatt.

Malassezia furfur (formerly *Pityrosporum ovale*) has also been associated with seborrheic dermatitis. Although the etiology of seborrhea is not known, *Malassezia*'s involvement may be due to its lipase degradation of sebum into inflammatory fatty acids such as arachidonic acid and to its activation of the alternative complement pathway. Whether its contribution is through immune response activation or as an irritant is still unknown. Indirect evidence supports its involvement in the pathogenesis because antifungal azole therapies have been shown effective in the treatment of seborrheic dermatitis.

Pityriasis versicolor

Pityriasis versicolor is also known as *tinea versicolor* but this is a misnomer as it is due to yeast, not a dermatophyte. The etiologic agent is *Malassezia furfur*. The skin lesions appear as sharply demarcated, superficial macules that may be hyper- or hypopigmented with fine scaling; they are located on the trunk, shoulders, neck, upper arms, back, abdomen, and, rarely, the face. Predisposing factors that cause the yeast form to convert to phialides (short hyphae with a fertile end) and spores include Cushing's disease, malnutrition, systemic steroid therapy, genetic predisposition, oral contraceptives, application of oils to the skin, immunosuppression, heat, and humidity.

Diagnosis is made by KOH preparation. Phialides and round short chains or clusters of budding thick-walled spores, commonly referred to as "spaghetti and meatballs," are seen microscopically. Culture is not generally performed as these organisms require an exogenous source of lipids for growth. Examination of the lesions with a Wood's lamp reveals a pale yellow fluorescence. A biopsy will show a thick basket-weave stratum corneum with phialides and spores.

Topical treatments are the most common therapy used. A 2.5% selenium sulfide lotion should be applied daily for 10 minutes, then washed off, for a week. To prevent recurrence the lotion may be used monthly for 3 months, and a shampoo with selenium sulfide can be used to prevent colonization of the scalp. Ketoconazole shampoo, imidazoles, triazoles, terbinafine spray, and propylene glycol are other useful topical treatments.

Oral therapies are effective but must also be continued to prevent recurrence. Itraconazole 200 mg/d for 5 to 7 days is effective, followed by 200 mg twice a day on a monthly basis for prophylaxis. Ketoconazole 200 mg/d for 10 days or single dose 400 mg repeated monthly can be effective. Fluconazole taken as a single dose of 300 to 400 mg has been shown to be effective as well.

Patients should be counseled that prophylaxis is necessary to avoid recurrence of infection and that the return to normal pigmentation takes time.

TABLE 26.3 **TREATMENT FOR ONYCHOMYCOSIS**

	Fingernails	Toenails
Itraconazole	200 mg/d for 8 consecutive weeks OR 200 mg twice a day for 1 week per month for 2–3 months	200 mg/d for 12 consecutive weeks OR 200 mg twice a day for 1 week per month for 3–4 months
Terbinafine	250 mg/d 6 weeks	250 mg/d 12 weeks
Fluconazole	150–200 mg/week for 6 months	150–200 mg/week 9–12 months

Candidiasis

Skin folds are the most common site of cutaneous candida infections. The lesions appear as erythematous, sometimes erosive, areas with satellite pustules. The intertriginous zones (submammary, inguinal creases, finger spaces) are often affected because of their predilection for moist conditions, as well as the nails, scrotum, and diaper area. Topical therapy including the azoles, nystatin, and clotrimazole are generally effective. It is also important to keep the area dry. Fluconazole and itraconazole are useful if systemic therapy is required.

Eumycetoma

Ncoza C. Dlova, Anisa Mosam, and Antoinette Chateau

Epidemiology

Although eumycetomas are endemic worldwide, they are predominantly found in the tropical regions of the world.[1] The continents most affected are Asia and Africa, with India, Pakistan, and Sudan reporting the highest number of cases. Sporadic cases have been reported in Europe and the southwestern United States.[2] Eumycetomas are caused by organisms living in soil and plants; they are spread by direct contact or by traumatic implantation through, for example, wooden splinters into the skin. They occur most often in the feet of those walking barefoot but may also occur on the back and neck. There are reported cases of inoculation following contaminated intravenous cocaine injections.[3] The disease is noted in all age groups, but it is more often seen in the age range of 20 to 40 years, with males being more commonly affected than females.[2]

Etiology

At variety of causative agents have been associated with eumycetomas, but >90% of eumycetomas reported worldwide are due to four organisms[4]: *Madurella mycetomatis* (black grain), *M. grisea* (black grain), *Scedosporium apiospermum* (white grain), and *Leptosphaeria senegalensis*.

Pathophysiology

The pathophysiology is based on the interplay between the organism, host response, and the environment.[2] The patient's immune system plays a role, and those with poor cell-mediated immunity are predisposed to developing the disease.[5] Genetics also plays a role, and a polymorphism resulting in a reduction in activity of the chitotriosidase enzyme that is normally protective against the fungus has been identified.[2] HIV-infected patients have a more intense and faster progression of the disease.[6]

Clinical features

Eumycetomas are slow-growing, painless nodules that develop on the feet. As a result of the insidious and painless nature of the disease, patients delay seeking help. The implanted organisms set up an inflammatory reaction which involves the subcutaneous tissues and causes disfigurement (Figure 27.1) The characteristic clinical diagnostic features include a triad of nodules, sinuses, and grains. The color of the grains depends on the causative organism, and this is usually black or gray-white when it is due to a fungal infection.

FIGURE 27.1 Eumycetoma in a 35-year-old black male, showing a deformed foot with multiple nodules and sinuses.

With chronicity, the foot tends to become a large mass, and resultant spread of the infection to underlying bone results in osteomyelitis.[7] Eumycetomas have the tendency of forming cysts which can be walled off, thereby preventing distant spread and thus creating a therapeutic challenge. Although the most common site is the foot, with usually unilateral involvement, the legs, hands, neck, and back may be affected. If mycetoma affects the back, it may result in vertebral collapse and resultant neurological deficit. Lymphatic spread is rare.[7]

Differential diagnosis

Several other conditions need to be taken into account because they can mimic eumycetoma (hence the need for biopsy and culture). These are

- Foreign-body granulomas
- Soft-tissue neoplasms
- Tumors (e.g., Kaposi's sarcoma)
- Other deep fungal infections (e.g., sporotrichosis; chromomycosis, conidiobolomycosis)
- Cysts
- Botryomycosis
- Leishmaniasis
- Tuberculosis

Diagnosis

Histopathology

Histologically the lesions are characterized by granulomatous inflammation with organisms within the center of the abscesses.[4] Occasionally maze-shaped structures called *clubs* are found in the vicinity of the granules.[4] The clinical presentation of mycetoma remains the same irrespective of the implicated organism, although the histologic features—namely the size, shape, and color of the granules—can be suggestive of the causative agent. Using special stains (Grocott, periodic acid-Schiff, and hematoxylin and eosin) assists in ascertaining the various types of grain. Fine-needle aspiration is an alternative to obtaining samples for cytology.[8]

Laboratory diagnosis

Direct examination, culture, and histopathology are the various methods used to identify the causative species and genus.[3] Suggestions of the etiologic agent can be drawn from the size, form, and presence or absence of clubs or pseudo-clubs. The most commonly isolated organism in eumycetoma in the world is *M. mycetomatis*, with countries like Sudan reporting up to 70% of cases.[9]

Contamination of cultures with bacteria, as well as challenges in identifying the morphology of the organism when cultures are positive, can sometimes pose a problem in diagnosing the genus and species when studying pathology specimens.[3] This has led to the introduction of various methods of molecular diagnostic techniques, such as polymerase chain reaction (PCR), including PCR restriction fragment length polymorphism (RFLP), real-time PCR, and DNA sequencing, and these have been used to identify the species of eumycetoma from lesional biopsies and environment.[10]

In the next sections, we describe a few of the common organisms.

Madurella mycetomatis

Inspection reveals oval, spherical, or lobulated black grains measuring 0.5 to 1 mm which sometimes coalesce to form 5 mm oval grains. Hyphae are light brown, ranging from 1 to 5 mm in diameter and showing reddish-brown grains on microscopy.

Culture: Initially the hyphae look white and membranous, and then later change to yellow-brown with a dark pigment that spreads into the culture medium. Growth is at 26°C/79°F to 30°C/86°F. Oval conidia (3.5–5 μm) are produced, and these are derived from the simple or branched conidiophores.

Madurella grisea

These have spherical or multilobed black grains ranging between 0.5 and 1 mm in diameter. These are soft and then develop into hard and brittle grains. Microscopically, a clear center surrounded by brown, pigmented hyphae is seen.

Culture: Slow growing gray-green hyphae with peripheral folds and short hyphae are observed with growth at temperatures between 26°C/79°F and 30°C/86°F. Occasionally a reddish-brown pigment is detected. A pigmented wall is seen around septate hyphae (1–3 μm), and there are no spores, although numerous pycnidia and chlamydoconidia are seen sometimes.

Imaging

Ultrasound and MRI have been used to determine the extent of disease and bone involvement,[11] with an increase in soft-tissue volume (93%), bone sclerosis (56%), bone cavities (32%), periosteal reaction (27%), and osteoporosis (19%) often seen.[3] Ultrasound usually reveals the "dot in circle" sign, which is considered to be typical of mycetoma.[3] CT appears to be more sensitive in picking up early bone changes in contrast to MRI.[3]

Management of Madura foot

Management of *Mycetoma* is challenging, protracted, and sometimes disappointing. A combination of surgical and medical management is the gold standard of treatment in limited disease. There are no randomize controlled trials regarding the management of mycetoma, and treatment is based on case reports.[1]

Medical management

Azoles: Imidazoles and triazoles:

Treatment is protracted, from 9 to 12 months, but may extend to up to 18 to 24 months.

- Ketoconazole 400 mg/d has been shown to be effective. This drug is however limited by its side effects, the most important being hepatotoxicity and adrenal toxicity, and others being hyperpigmentation and gynecomastia.[1]
- Itraconazole 200 mg BID is better tolerated and is thought to have greater efficacy than ketoconazole.[12] Note that there is a drug interaction of itraconazole and ketoconazole with antiretroviral therapy.
- Posaconazole 200 mg QID has been used in recalcitrant cases of mycetoma with some success.
- Voriconazole 200 mg two to three times a day has shown to be effective. Voriconazole is contraindicated in patients taking rifampicin, ritonavir, and carbamazepine.[3] Side effects such as visual disturbances, skin rashes, and elevated liver function profile frequently result in discontinuation of the drug.[3]
- Fluconazole has shown poor results.
- Newer therapies such as isavuconazole and fosravuconazole have shown excellent in vitro results, and prospective studies are ongoing.[6]

Allylamines:

- Terbinafine at a dose of 500 to 1,000 mg/d has shown a cure rate of 50%.[13]

Polyenes:

- Amphotericin B has not been shown to be effective. However there have been isolated reports of efficacy at doses ranging from 0.5 to 1.25 mg/kg/d.

Griseofulvin, a fungistatic agent, has shown poor results.[2]

A study conducted in Brazil showed improvement in patients receiving a combination of itraconazole and trimethoprim-sulfamethoxazole. The latter was thought to exert an antibacterial effect against secondary bacterial infection as well as exerting an effect on the fungi itself.[14]

Surgery

Surgery is advocated in limited disease. Antifungal therapy is used to debulk the lesion, followed by surgery, and then continuation of oral therapy. Extensive disease with bone involvement may necessitate amputation in a subset of patients.

Topical negative pressure therapy following surgery has been shown to be effective.[6]

Conclusion

Eumycetomas are a neglected disease prevalent in the tropics, particularly in India, Pakistan, and Sudan. This is a chronic, smoldering disease in which diagnosis is delayed due to initial its painless nature and the difficulty in confirming the causative organism by microbiological culture. Therapy is prolonged due to the poor response rates attributed, in part, to encapsulation and depth of inflammation.

Hence treatment of this chronic condition is expensive, and efforts need to be directed to prevention. Due to chronicity and subsequent disfigurement, many are subjected to debulking surgery and amputation. This poses a challenge in young males, who are the most frequently affected and the most productive workforce. Further research and education should be directed toward prevention, awareness, improved noninvasive diagnostic techniques, and combination therapies.

Lymphadenopathy/Lymphadenitis

Gerald Friedland and Sheela Shenoi

Fever and lymphadenopathy is a commonly encountered presentation in clinical practice. It is important to have a logical and systematic approach for the accurate diagnosis and treatment of patients with this syndrome (Figure 28.1). Careful history-taking and physical examination are essential in the initial patient evaluation, and the following questions are requisite:

1. Is the adenopathy local or generalized?
2. Is the process acute or chronic?
3. Is the cause infectious or noninfectious?
4. Is there a primary peripheral lesion?

Important elements of the history should also include the presence or absence of pain, occupational and animal exposures, geographic residence, travel history, sexual and drug use behavior, trauma, presence or absence of systemic symptoms, and/or history of underlying disease. A thorough examination must include the location of lymphadenopathy including an evaluation of all accessible lymph node–bearing areas, the size and consistency of palpated nodes, whether they are discrete or matted, and whether tenderness is present and, if so, at what level of severity.

As a general rule, a node >1 cm should be considered abnormal. Stony-hard nodes are usually a sign of malignancy. Very firm, rubbery nodes suggest lymphoma. Softer nodes are the result of infectious or inflammatory conditions, and, when suppuration is present, these nodes may tend to be fluctuant. The term *shotty* refers to small nodes that feel like "buckshot" under the skin, as found in the cervical nodes of children with viral illnesses. A group of nodes that feel connected and seem to move as a unit is said to be *matted* and can be either benign (e.g., tuberculosis [TB], sarcoidosis, lymphogranuloma venereum, and HIV) or malignant (e.g., metastatic carcinoma and lymphoma). Pain and tenderness is usually the result of an inflammatory process or suppuration within the nodes but may also represent hemorrhage into the necrotic center of a malignant node. The presence or absence of tenderness does not reliably differentiate benign from malignant nodes.

Localized lymphadenopathy

Lymphadenopathy is considered localized if no more than two contiguous lymph node groups are involved. Anatomically and clinically, the node-bearing areas are divided into five major groups: (1) the head and neck area, (2) the axilla, (3) the inguinal area, (4) the mediastinal-hilar areas, and (5) the retroperitoneal and paraaortic areas. Basic knowledge of the anatomy and areas drained by these lymph nodes can help in narrowing the differential diagnosis (see Table 28.1). Infectious local adenopathy may be acute or chronic. It is usually associated with a primary lesion. At times, the peripheral lesion may be subtle or inapparent. In patients with

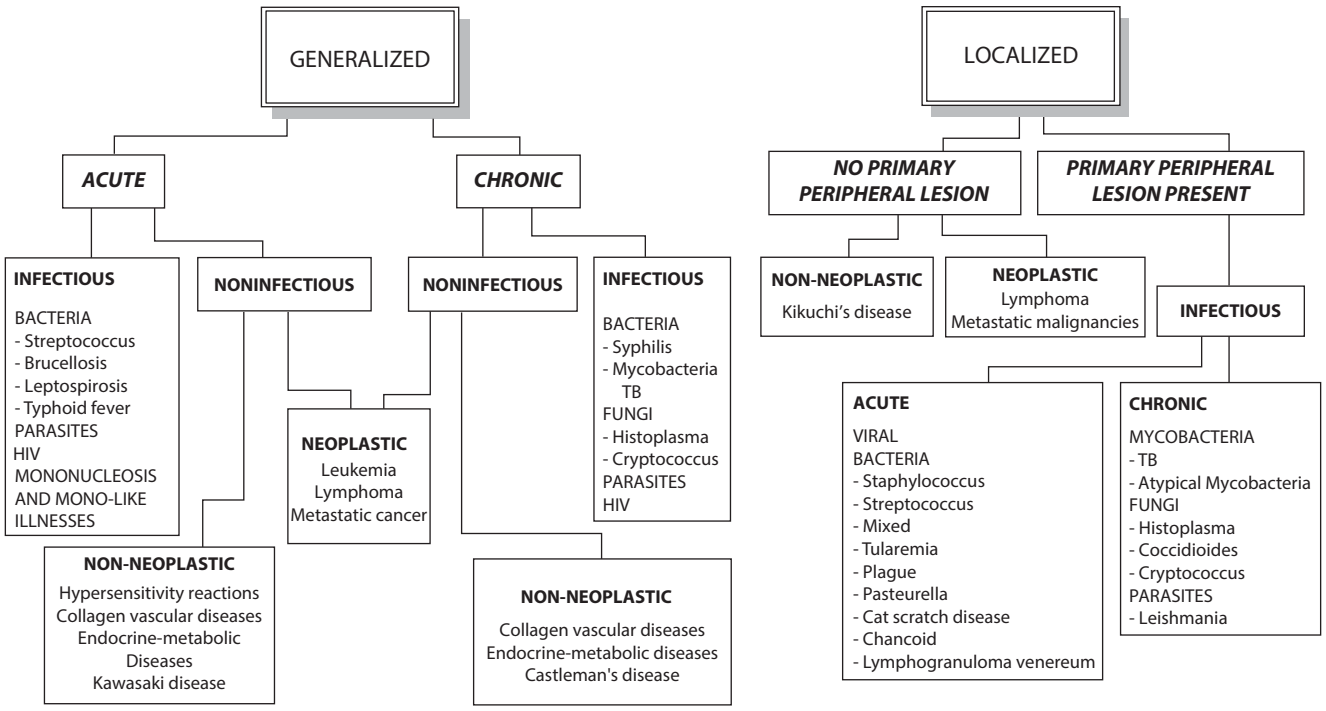

FIGURE 28.1 Differential diagnostic scheme for fever and lymphadenopathy.

TABLE 28.1 LOCALIZED LYMPHADENOPATHY: ANATOMIC AREAS DRAINED AND ASSOCIATED CONDITIONS

Lymph node area	Anatomic area	Areas drained	Associated conditions/comments
Head and neck	Occipital and posterior auricular	Scalp, face	Local infections with skin pathogens: *Staphylococcus, Streptococcus*, acute viral illnesses Children: secondarily infected insect, tick, or spider bites, dermatophyte infections (ringworm), viral infections
	Anterior auricular	Eyelids, palpebral conjunctivae, external auditory meatus, pinna	Conjunctivitis, oculoglandular syndrome (*Francisella tularensis*, *Neisseria gonorrhoeae*, *Bartonella henselae*), keratoconjunctivitis
	Tonsillar, submaxillary, submental	Pharynx, mouth, teeth, lips, tongue, and cheeks	Infections of the head, neck, sinuses, ears, scalp, pharynx, teeth, and oral mucosa
	Posterior cervical	Scalp and neck, skin of arms and pectorals, thorax, cervical, and axillary nodes	Mononucleosis, Kikuchi disease, tuberculosis, lymphoma, head and neck malignancies
Axillary		Upper extremity Thoracic wall, breasts, and back	Acute pyogenic infection, cat scratch disease, brucellosis, melanoma, breast malignancy
Inguinal		Lower extremities Abdominal wall Genitalia: penis, scrotum, vulva, vagina, perineum, and perianal region	Pyogenic infections of the lower extremities Sexually transmitted diseases: herpes simplex, syphilis, chancroid, lymphogranuloma venereum Pelvic and perianal malignancy
Mediastinal-hilar		Lungs, trachea, esophagus	Granulomatous disease (infectious and noninfectious) Malignancies
Abdominal retroperitoneal para-aortic		Abdominal viscera Retroperitoneal organs: kidneys Pelvic organs	Usually granulomatous disease: *Mycobacterium tuberculosis, Mycobacterium avium* complex Malignancies: lymphoma

FIGURE 28.2 Palpable lymph nodes in the anterior cervical area (left image) and left parasternal areas (right image).

unexplained localized lymphadenopathy and a reassuring clinical picture, a 3- to 4-week period of observation may be appropriate before considering biopsy. It is important to bear in mind and examine carefully the areas of drainage of each nodal group as this will often reveal the primary site of infection or other pathology. The lymph nodes of the head and neck are collectively called *cervical nodes* and *occipital* and *auricular nodes* and are more accurately subdivided into several anatomic and clinical areas (see Figure 28.2). The occipital and posterior auricular nodes drain large areas of the scalp and face. Adenopathy of these groups may be associated with primary infectious lesions in these areas (usually from staphylococcal and streptococcal infections) but can be a common feature of acute viral illnesses as well. In children, secondarily infected wounds from insect bites and ringworm (dermatophyte infection) are common causes. The anterior auricular nodes drain the eyelids, palpebral conjunctivae, external auditory meatus, and pinna of the ear. Conjunctivitis and anterior auricular adenopathy (the oculoglandular syndrome) is classically associated with *Francisella tularensis* via direct inoculation of the conjunctival sac but may also be seen with conjunctival infection from *Neisseria gonorrhoeae*, *Bartonella henselae* (cat scratch disease), and epidemic keratoconjunctivitis. The sternocleidomastoid muscle divides the cervical nodes into anterior and posterior sections, each with different drainage areas and resultant clinical importance. The anterior nodes, including the tonsillar, submaxillary, and submental nodes, are most commonly involved because they drain the tonsils and other structures in the pharyngeal area, including the teeth and gums. Enlargement of these nodes should prompt careful inspection of the contents of the mouth. In addition, this group also drains the external structures of the medial face including the lips, chin, cheeks, and medial aspects of the conjunctivae. The posterior cervical nodes are in the occipital triangle of the neck, posterior to the sternocleidomastoid muscle and above the inferior belly of the omohyoid muscle. The drainage of these nodes is more limited, and, if enlarged, systemic disease should be considered including infectious mononucleosis and mononucleosis-like syndromes, including HIV infection.

Kikuchi disease, or histiocytic necrotizing lymphadenitis, is a rare self-limited disorder involving the cervical lymph nodes. This condition was first recognized in Japan and has been predominantly described in females of Asian and Middle Eastern origin, commonly <40 years of age. Clinical manifestations of this entity include fever or flu-like symptoms, rash, localized and sometimes tender cervical lymphadenopathy, elevated erythrocyte sedimentation rate (ESR), and leukopenia. The involved nodes are usually rubbery or firm, discrete, and rarely >2 cm in diameter. Its etiology is still obscure, but it has been associated with Kaposi's sarcoma–associated herpesvirus (KHSV-HHV-8). This condition does not respond to antibiotics but usually resolves spontaneously in 1 to 2 months. Because of its association with systemic lupus erythematosus (SLE) and Still's disease, it is also thought to be autoimmune in origin. Recognition of this disease is important because pathologists who are unfamiliar with it commonly mistake it for other conditions that require treatment, such as malignant lymphoma and Kawasaki disease.

The inferior deep cervical nodes lie below the level of the inferior belly of the omohyoid muscle and anteroposterior to the sternocleidomastoid muscle. These nodes receive drainage from the scalp; the superior deep cervical nodes; the axillary nodes; and the nodes of the hilum of the lung, the mediastinum, and abdominal viscera. Infectious and noninfectious entities that involve these structures should be considered when these nodes are involved. Adenopathy in this area is usually subtle and not recognized clinically but may be detected with the Valsalva maneuver.

While rarely representing coccidioidomycosis, supraclavicular lymphadenopathy has been associated with malignancy in the majority of patients >40 years. The left supraclavicular (Virchow) node receives lymphatic flow from the thorax and abdomen and may indicate pathology involving the testes, ovaries, kidneys, pancreas, prostate, stomach, or gallbladder. Mediastinal and hilar adenopathies are usually detected only on radiography. These nodes are infrequently involved in acute suppurative disease. Acute suppurative mediastinal lymphadenitis, if present, can be a fulminant process, typically a complication of progressive infections of the upper respiratory tract or perforation of the esophagus or bronchial tree as a result of trauma or surgery. A useful diagnostic criterion is whether the lymphadenopathy is unilateral or bilateral. Unilateral enlargement most frequently suggests granulomatous disease of both infectious (e.g., *Mycobacterium tuberculosis* and histoplasmosis) and noninfectious (e.g., sarcoidosis) origin (see Figure 28.3) and an ipsilateral malignant pulmonary process. Bilateral hilar adenopathy is seen in approximately three-fourths of patients with sarcoidosis. When

FIGURE 28.3 Chest x-ray depicts unilateral (right) hilar lymphadenopathy (as indicated by the arrow) in a patient with pulmonary tuberculosis.

FIGURE 28.4 An example of chest CT in a patient with HIV and atypical mycobacterial pulmonary infection who presented with multiple hilar and left axillary lymphadenopathy (as indicated by the arrows).

dealing with mediastinal and hilar adenopathy, the diagnostic approach includes *M. tuberculosis* skin test (purified protein derivative [PPD]) or interferon-γ release assay (IGRA) blood test, sputum cultures (routine, fungal, acid-fast bacillus [AFB]), and lymph node culture (routine, AFB, anaerobic) as well as cytology. CT is useful in assessing the size and location of these lymph nodes. Biopsy should be considered in any node >1 cm in the absence of a primary diagnostic lesion. Tissue for histologic examination may be obtained through inferior cervical node biopsy, transbronchial lung biopsy, mediastinoscopy, or percutaneous or surgical biopsy of the hilar nodes (see Figure 28.4).

The axillary nodes drain the entire upper extremity as well as the lateral parts of the chest wall, back, and breasts. This cluster of nodes is most frequently involved in acute pyogenic infections of these drainage areas. By far, the most common etiologic organisms include staphylococci and streptococci, associated with furunculosis, cellulitis, or lymphangitis. The extremities are also often the site of zoonotic infections from other organisms acquired from the environment, including *F. tularensis* (tularemia), *Yersinia pestis* (plague), *Pasteurella multocida* (from dog or cat bites or scratches), *Erysipelothrix rhusiopathiae* (erysipeloid), and *B. henselae* (cat scratch disease). Lymphadenopathy can precede the ulcers seen with localized cutaneous leishmaniasis.

Inguinal lymphadenopathy is very common, partly due to frequency of trauma or prior infections in the lower extremities and the wide watershed drainage area. These nodes not only drain the lower extremities but also the lower abdominal wall, the genitalia, perineum, and perianal areas. Acute pyogenic bacterial infection caused by the same organisms encountered in axillary adenopathy are the usual culprits. The drainage of the perineum and the perianal area suggests that enteric aerobic and anaerobic gram-negative organisms as well as gram-positive organisms are present. Because of the drainage of the genitalia and perianal area, sexually transmitted infections often involve the inguinal nodes as well. Those most likely to present with prominent inguinal adenopathy are syphilis (secondary), lymphogranuloma venereum, chancroid, and genital herpes simplex. Initial inguinal lymphadenopathy can progress to the buboes seen with bubonic plague, although they can also be seen in the axillary, cervical, crural, and submaxillary nodes.

The abdominal and retroperitoneal nodes drain the abdominal viscera and the retroperitoneal and pelvic organs. They may receive drainage from the inguinal nodes as well. Because they are not directly accessible by physical examination, their recognition and characterization usually requires CT or MRI (see Figure 28.5).

Generalized lymphadenopathy

Generalized lymphadenopathy is present if nodes in two or more noncontiguous major lymph node–bearing areas are enlarged. It is frequently a manifestation of disseminated infection. Clues may be provided by the age of the patient, presence or absence of rash, geographic factors (e.g., dengue fever, filariasis, localized leishmania lymphadenitis, histoplasmosis, TB), occupation and dietary history (brucellosis, toxoplasmosis), and exposure to animals and their excreta or standing water (leptospirosis). Acute generalized infectious lymphadenopathy, which is most often viral, is a common feature of many childhood viral infections, including rubella, measles, and varicella. Generalized lymph node enlargement may also be seen in the prodromal period of hepatitis A and B, Epstein–Barr virus (EBV), cytomegalovirus (CMV), HIV, and toxoplasmosis. These conditions initially present with the mononucleosis-like syndrome and generalized lymphadenopathy. Bacterial pathogens are much less often the cause of generalized lymphadenopathy, except in

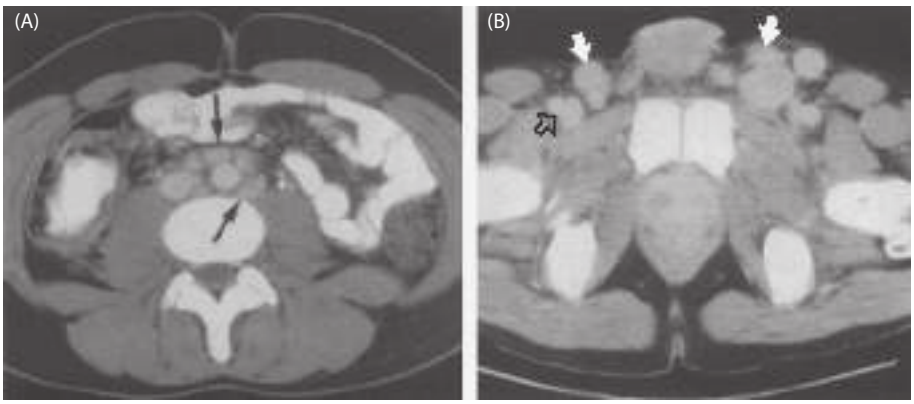

FIGURE 28.5 An example of high-attenuation lymph nodes (*solid arrows*) in the (A) retroperitoneum and (B) inguinal areas of patients with AIDS and Kaposi's sarcoma. Contrast-enhanced femoral vessels are seen on the right (*open arrow*).

brucellosis and leptospirosis. In all these infections, the nodes are typically tender, discrete, firm to touch, and without fluctuance. Acute generalized noninfectious lymphadenopathy is frequently due to hypersensitivity reactions, most commonly drug-induced. Sulfonamides, hydralazine, carbamazepine, and phenytoin are among the agents that have been most commonly implicated in such reactions. This condition rapidly disappears on withdrawal of the offending drug. Other offending medications include allopurinol, atenolol, captopril, quinine, primidone, and sulindac. Collagen vascular diseases, including rheumatoid arthritis and SLE, may also cause acute generalized lymphadenopathy and fever. Kawasaki syndrome (acute febrile mucocutaneous lymph node syndrome) is a disease of uncertain origin that is seen almost exclusively in infants and young children, and it also presents with nonsuppurative cervical lymphadenopathy that may be unilateral.

Chronic generalized infectious lymphadenopathy is less likely to be viral, except for HIV. Its presence suggests more serious diagnostic possibilities. Disseminated bacterial and fungal diseases, including TB, syphilis, histoplasmosis, and cryptococcosis, should be considered. In children, persistent lymphadenopathy and fever may suggest an immunodeficiency state, including chronic granulomatous disease. Castleman's disease, associated with HHV-8, the same etiologic agent as for Kaposi's sarcoma, also presents with fever and chronic lymphadenopathy and is discussed later in this chapter.

Chronic generalized noninfectious lymphadenopathy is most often neoplastic. Lymphoreticular neoplasms (e.g., Hodgkin's disease, non-Hodgkin's lymphoma, chronic lymphocytic leukemia) predominate. Fever, when present, may be due to the underlying malignant disease or to secondary infection. Non-neoplastic diseases (with variable frequency) cause chronic generalized lymphadenopathy and fever, and these include sarcoidosis, Still's disease, and hyperthyroidism. In patients receiving immunosuppressive therapy following a solid organ or bone marrow transplant, one should consider the diagnosis of posttransplant lymphoproliferative disorder (PTLD), which is a heterogeneous group of lymphoid proliferations, most of which are of B-cell lineage and associated with EBV. These disorders can occur months to years after transplantation and would require reduction in immunosuppressive therapy with or without antiviral therapy.

Lymphadenopathy and HIV infection

Lymphadenopathy is a common and important finding in people with HIV infection. Acute retroviral infection is a mononucleosis-like syndrome that occurs 2 to 10 weeks after exposure to HIV. Acute bilateral generalized lymphadenopathy, which may be accompanied by fever, sore throat, maculopapular rash, headache, mucosal ulcerations, myalgias, and malaise, is a common feature; occasionally signs and symptoms of meningitis are seen due to early neural invasion of the virus. Since HIV antibody tests are negative during the first 6 weeks and sometimes longer, during the early stage of HIV primary infection, the diagnosis is best made by testing for HIV RNA in plasma (viral load). Titers are extremely high during the acute infection and may be assayed by the reverse transcription-polymerase chain reaction (RT-PCR) method. The mean interval between the onset and resolution of symptoms during primary HIV infection is approximately 25 days, after which patients may remain asymptomatic for years. During this time, many infected individuals exhibit persistent generalized lymphadenopathy (PGL) which may last for several years. The nodes are typically nontender and firm to rubbery in consistency. In the untreated patient, as immunodeficiency worsens, symptoms may include fevers, night sweats, weight loss, and diarrhea and herald the presence of more severe complications including opportunistic infections and malignancies, thus defining AIDS. In contrast to earlier stages in the natural history of HIV disease, lymphadenopathy is a less common finding in those with AIDS, and its presence suggests an infectious or neoplastic process involving the reticuloendothelial system. Of infectious causes, disseminated *Mycobacterium avium-intracellulare* infection, *M. tuberculosis*, histoplasmosis, CMV infection, toxoplasmosis, syphilis, and cryptococcosis are most common. Although high-grade B-cell lymphomas are common in AIDS, they are often extranodal. Kaposi's sarcoma may involve lymph nodes, occasionally without apparent skin lesions. The diagnosis of lymphadenopathy in people living with HIV is highly dependent on the geographic and social setting. In high-prevalence TB settings, TB is usually the most frequent finding, occurring in up to 60% of cases. In contrast,

in a recent retrospective, multicentered biopsy study among people living with HIV in a non-TB endemic setting, 42.9% of peripheral lymphadenopathy was attributable to malignancy, 49.5% to reactive changes, and 7.5% to infections, with only 2.8% of all cases secondary to TB. Fevers, weight loss, antiretroviral use, and lower viral loads were significantly associated with nonreactive (malignant or infectious) lymphadenopathy. Multicentric Castleman's disease, associated with HHV-8, presents with persistent fever, marked splenomegaly, generalized lymphadenopathy in >90% of patients, weight loss in 70%, and pancytopenia in 35%. These symptoms usually last >6 months and may represent acute infection with HHV-8 or reactivation of HHV-8 in the setting of immune suppression in AIDS. For more details on HIV and AIDS, please refer to Chapter 101, "Differential diagnosis and management of HIV-associated opportunistic infections."

General diagnostic approaches

In most cases of infectious lymphadenopathy, clinical and laboratory findings short of biopsy often suggest the causative agent responsible for the enlarged nodes. Some of these findings are as follows:

1. Primary site of infection (e.g., streptococcal cellulitis, staphylococcal furuncle, syphilitic chancre)
2. Associated symptoms: "B" symptoms with lymphomas, rash, serositis with SLE; arthritis with Still's disease, or rheumatoid arthritis
3. Characteristic rash (e.g., rubella, rubeola, drug eruption, acute HIV infection)
4. Characteristic physical findings (e.g., splenomegaly in mononucleosis, lymphoma)
5. Typical hematologic findings (e.g., eosinophilia [drug reactions], atypical lymphocytosis [mononucleosis syndrome], high ESR and/or C-reactive protein [CRP] [rheumatologic diseases])
6. Skin tests or IGRA (e.g., TB [though unreliable in immunocompromised hosts])
7. Serologic tests (e.g., EBV, hepatitis, syphilis, HIV, tularemia)
8. Stains, cultures, and histologic examination of material from peripheral primary lesions and pulmonary lesions (atypical mycobacteria, tuberculosis, plague, lymphoma).

Lymph node biopsy versus fine-needle aspiration biopsy

The simplicity, safety, and cost-effectiveness of fine-needle aspiration (FNA) make it a useful test for the evaluation of persistent lymphadenopathy. The advent of radiologically guided FNA makes biopsy of the nodes of the hilum and retroperitoneum accessible, thus avoiding extensive surgical procedures. The presence of a cytopathologist on site to determine the adequacy of the specimen has been shown to increase the yield of FNA considerably. However, there are limitations to the procedure. FNA is useful in the diagnosis of benign reactive processes, certain infections, or metastatic disease, yet its accuracy in the diagnosis of lymphoma and primary malignancies as well as granulomatous infections remains controversial. Technical difficulties pose an obstacle for the effective differentiation of certain malignancies. Because the chemotherapeutic agents used for treatment of patients with lymphoma are selected on the basis of the specific type of lymphoma, excisional biopsy remains necessary for definitive subclassification of lymphoma in the majority of patients. Another limitation of FNA is insufficient material for histology, special stains, and culture, particularly when mycobacterial disease or other granulomatous infections are under consideration. These additional tests are often necessary to establish the diagnosis and select appropriate therapy. This is especially important for *M. tuberculosis* and nontuberculous mycobacteria, when establishing the species and the antitubercular medication resistance pattern is critical.

The following general guidelines are intended to suggest to the clinician circumstances in which excisional biopsy is appropriate:

1. Undiagnosed chronic lymphadenopathy of 1 month in adults, 3 months in children
2. Localized nonsuppurative lymphadenopathy without an accessible or apparent peripheral lesion
3. Enlarging undiagnosed lymphadenopathy after 2 weeks of observation
4. Nontender, matted to hard lymphadenopathy or a high clinical suspicion of neoplastic disease
5. Radiologic findings or systemic signs and symptoms suggesting granulomatous or lymphoproliferative disease when noninvasive tests are unrevealing
6. Positive tuberculin test in the absence of diagnostic pulmonary TB
7. New adenopathy in immunocompromised patients; otherwise, asymptomatic patients with HIV and PGL do not need biopsies
8. Lymphadenopathy in the setting of fever of undetermined origin
9. Persistently nondiagnostic or inconclusive FNA results.

Technique

Approximately half of all lymph node biopsies lead to a specific diagnosis. Careful attention to several rules maximizes the usefulness of the invasive diagnostic procedure.

1. Discuss the differential diagnosis with the surgeon, pathologist, and the microbiology laboratory ahead of time so that any special considerations (e.g., fixation, staining, and special culture media) can be identified.
2. Select the best site. Lymph nodes frequently involved in minor inflammatory processes, such as the inguinal and submandibular nodes, should be avoided. In the presence of generalized lymphadenopathy, the inferior or posterior cervical nodes are preferred. The second choice is the axillary node.
3. The largest node in a cluster of enlarged nodes should be removed.

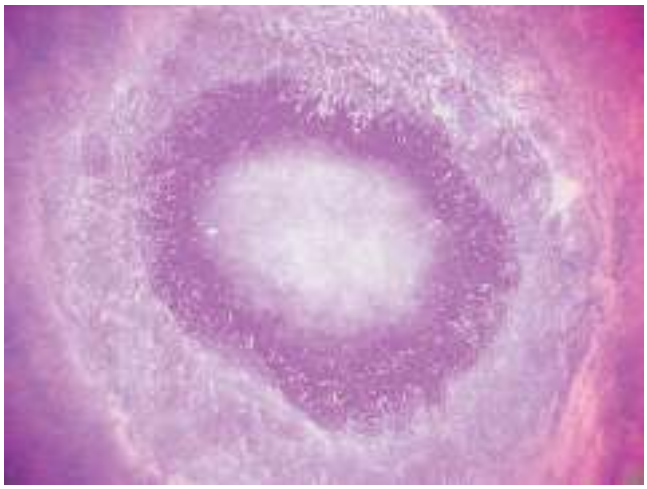

FIGURE 28.6 An example of a supraclavicular lymph node biopsy stained by hematoxylin and eosin (H&E). This is a granuloma, with extensive necrosis in the center, caused by *Mycobacterium tuberculosis*.

Courtesy of Theresa Liu-Dumlao, MD.

4. Remove nodes in their entirety with capsules intact. Dissect them, sending half of the specimen to the pathology laboratory and the other half to the microbiology laboratory for stains and culture of common pathogens, including mycobacteria, fungi, and other suspected organisms (see Figure 28.6).
5. Request that the pathologist make additional sections of the excised tissue if the node is abnormal but not diagnostic.
6. Consider a repeat biopsy and the excision of more tissue if the node is abnormal but not diagnostic and the clinical picture is unclear.

Interpretation

Entities discussed in this chapter that have a characteristic histologic pattern and for which a specific or strongly suggestive diagnosis can be made histologically are lymphoma, other neoplasms, TB, fungal disease, sarcoidosis, toxoplasmosis, and cat-scratch disease. Most noninfectious non-neoplastic disorders and most acute viral infections show nonspecific lymphadenitis or hyperplasia only. However, a significant number of patients with initially nondiagnostic lymph node biopsies and persistent lymphadenopathy will ultimately prove to have a serious underlying disease. If the biopsy is not initially diagnostic, it is essential to follow the patient carefully and consider repeat biopsy if adenopathy persists.

Section 5

Clinical syndromes: Respiratory tract

29

Bronchitis

Phillippa Poole and Mark Hobbs

Bronchial infections with viral and bacterial microorganisms cause considerable morbidity as well as economic costs incurred through healthcare and loss of productivity. These infections affect all age groups. An important consideration is whether or not an individual has underlying chronic lung disease, as that alters the etiology, clinical presentation, laboratory findings, and indications for therapy. In this chapter, we discuss acute infectious bronchitis in individuals without underlying chronic lung disease before outlining approaches when an individual has an acute exacerbation of a chronic lung disease such as asthma, chronic obstructive pulmonary disease (COPD), or non-cystic fibrosis bronchiectasis. Idiopathic pulmonary fibrosis is outside the scope of this chapter.

Acute bronchitis

Acute bronchitis is a common condition in both children and adults. It has been defined as "an acute illness, occurring in a patient without chronic lung disease, with symptoms including cough, which may or may not be productive and associated with other symptoms or clinical signs that suggest LRTI [lower respiratory tract infection] and no alternative explanation (e.g., sinusitis or asthma)." Most people will experience this at some time during their lives, and, in most cases, it is self-limiting and will not result in those affected seeking medical attention.

Nonetheless, this condition is a frequent cause of attendance to primary care providers and has been identified as a potential target for reducing unnecessary antibiotic prescribing in the community. Additionally, those who seek medical care for acute bronchitis, especially if this is frequent, should be considered for investigation into whether they have an underlying chronic airways disease or an alternative explanation for chronic or recurrent cough.

Typical symptoms of acute bronchitis are the acute onset of cough with or without sputum production or discoloration, often preceded by or associated with upper respiratory tract symptoms such as sneezing, a runny nose, or a sore throat. The cough often lasts for 7 to 10 days but may persist for several weeks. Fever and wheezing are frequently associated, as is a burning sensation in the tracheal area. Some patients may have focal signs on chest auscultation. Abnormality of vital signs or the presence of focal chest signs suggesting consolidation should prompt consideration of a chest radiograph to exclude pneumonia.

Young children under 2 years of age may present with the similar syndrome of bronchiolitis. In addition to the previously described symptoms and signs they may have a reduced oral intake and, in severe cases, may develop cyanosis or apnea. Treatment may involve the use of nebulized adrenaline or hypertonic saline.

Acute bronchitis is usually a viral illness but it may also be caused by bacterial species including *Mycoplasma pneumoniae, Chlamydophila pneumoniae*, or *Bordetella pertussis* among others. The relative frequency of implicated viral species varies with time, place, and patient age, with agents circulating in the community with epidemic-like characteristics. Common viral causes include influenza, rhinovirus, coronavirus, respiratory syncytial virus (RSV), human metapneumovirus, and parainfluenza virus. In young children with bronchiolitis, RSV and rhinovirus are the most common pathogens.

Extensive investigation for a cause of acute bronchitis is not usually necessary or beneficial. While molecular testing (polymerase chain reaction [PCR]) of upper respiratory tract secretions will often identify a viral pathogen, this finding seldom alters management. However, a positive result for a viral pathogen can provide some reassurance to the patient and clinician that antibiotics are not required. Additionally, testing for specific pathogens may be of use in selected cases, such as for epidemiological monitoring, determining whether inpatients may be co-housed in shared rooms, or investigating occupational health exposures. If whooping cough (pertussis) is suspected then confirmation of this diagnosis should be sought as it carries significant public health implications.

Antibiotic treatment is commonly requested by patients with acute bronchitis, with wide variation in prescribing practice for this condition. There is observational evidence that antibiotic use may lead to a statistically significant but clinically nonsignificant reduction in symptom duration. Given the typically benign, self-limited course of the illness and increasing rates of antibiotic resistance in common bacterial pathogens, antibiotic use for this condition should be avoided. Unnecessary treatment exposes the patient to the risk of an allergic reaction or adverse drug reaction such as gastrointestinal upset, and undermines their ability to self-manage this common condition in the future. Several methods exist for dealing with patients' expectations of receiving antibiotics. These include education or printed information outlining the uncertainties involved or the use of delayed prescriptions. This is where a prescription is given but is to be used only under specific criteria which point to bacterial infection. Where antibiotics are thought to be necessary, a macrolide or doxycycline is a suitable choice. Agents with a low barrier to resistance, such as quinolones, should generally be avoided. Symptomatic treatment may be offered, but there is little evidence it alters any outcomes. The use of neuraminidase inhibitors for influenza has become controversial due to publication bias in early trials. The benefits of these medications are unclear, but they may be appropriate in some patients with a consistent illness during an epidemic if the circulating strain is known to be susceptible and the patient has presented early in their illness.

Postviral bacterial pneumonia may occur following an episode of bronchitis and may be severe. Investigation for this with a chest radiograph should be considered in patients who have deteriorated or failed to settle as expected. If pneumonia is confirmed, antibiotic treatment is appropriate and further microbiologic investigation may be required. Consideration should be given to specific cover for *Staphylococcus aureus* in patients with post-influenza pneumonia.

Acute exacerbations of chronic airways disease

Disease definitions

Asthma and COPD are relatively common, with each affecting 5% to 10% of people worldwide. By definition, asthma is a reversible airways disease characterized by steroid-responsive airways inflammation. It occurs in people with a genetic predisposition to develop allergic reactions to aeroallergens. In contrast, COPD is a progressive disease with an enhanced inflammatory response in the airways and the lungs to noxious particles and gases, such as smoke from cigarettes or fires. COPD as a disease entity encompasses patients with emphysema and/or chronic bronchitis. The latter term describes a clinical syndrome of chronic cough or sputum for 3 months in 2 consecutive years and should not be considered indicative of chronic infection. Instead, excess mucus is produced by goblet cells which have become hypertrophic due to the abnormal inflammatory response.

Bronchiectasis (BX) is a rarer condition which results in daily production of large amounts of sputum. It has a number of causes, including infection. BX is characterized by irreversible dilation of parts of the bronchial tree resulting from destruction of the muscle and elastic tissue. The damaged airways are in turn more susceptible to mucus build-up and infection. The prevalence of BX is unknown but the condition is increasingly recognized in part because of greater use of chest CT scans.

It is increasingly recognized that chronic airways diseases may occur together: bronchial hyperreactivity may be a risk factor for COPD; there is now a defined asthma–COPD overlap syndrome; and BX may complicate severe asthma or COPD.

Common features of acute exacerbations

The role of infection in chronic airways diseases is discussed further later. All three are characterized by the occurrence of acute exacerbations (AEs) which may or may not be infective in origin. There are various definitions of AEs, but most are clinical, such as an acute worsening in the patient's shortness of breath, and/or cough, and/or sputum beyond the baseline, sufficient to warrant a change in management. AEs are more frequent in the winter months, suggesting that viruses play an important role.

The frequency of AEs increases with disease severity and correlates with poorer quality of life. In turn, AEs may have a role in accelerating decline in lung function and thus contribute to morbidity and premature mortality. In economic terms, the cost of AEs, especially hospitalizations, far exceeds that of stable chronic disease management. Costs amount to billions of dollars annually in the United States alone.

The pathologic and physiologic abnormalities of airways that predispose patients with chronic airways disease to bacterial infection include impaired mucociliary clearance, bronchial obstruction by abnormal secretions, and bronchoconstriction. In patients with COPD or BX, there are colonizing bacteria in the bronchial epithelium which may become pathogenic, as well as impaired host defenses. For example, there is reduction in bacterial phagocytosis, intracellular bactericidal activity by polymorphonuclear neutrophils, macrophage recruitment, and sputum immunoglobulin levels.

Although purulence of sputum is often equated with infection, the characteristic yellow to green color is caused by myeloperoxidase released from polymorphonuclear neutrophils and eosinophils,

reflecting the stasis of secretions in the bronchial tree. Microscopic assessment of the sputum by Gram stain and simple wet preparation reveal the two essential characteristics of bacterial infection: first, increased numbers of bacteria; second, increased bronchial neutrophilic inflammation. To be significant, the Gram stain must have bacteria in numbers >10 to 20 per oil immersion field, which is significantly above the average of 2 when a patient is stable. In addition, the majority of the inflammatory cells are neutrophils. This, when accompanied by an increase in the volume of sputum expectorated, reflects the outpouring of neutrophils into the bronchial lumen in response to bacterial infection.

Reducing the impact of acute exacerbations

To reduce morbidity and unnecessary healthcare utilization, including hospitalization, all patients with chronic airways disease at risk of AEs should use preventive approaches. Smoking cessation and influenza vaccination are essential preventive strategies for every patient with chronic airways disease. Pneumococcal vaccination has less of an evidence base to support its use, but is recommended every 5 years for those with COPD.

In airways diseases with copious sputum (usually chronic bronchitis or BX), sputum clearance techniques such as postural drainage and active cycle of breathing are safe and improve symptoms and quality of life. Physiotherapists have a role in teaching these techniques as well as in clearance of secretions in severe AEs, although this lacks evidence of effectiveness.

Education is an important component in the management of all chronic airways diseases. Patients should be taught to recognize early symptoms and seek escalation of therapy, including antibiotics where appropriate. Maintenance of physical fitness is critical. Many of these aspects are covered in pulmonary rehabilitation programs which have been shown to improve symptoms, quality of life, and healthcare utilization at all stages of COPD.

Exacerbation frequency in COPD has become an important end point in clinical trials. These have shown a reduction in AE of COPD (AECOPD) with inhaled corticosteroids and long-acting bronchodilators (β-agonists and antimuscarinics) and possibly by oral phosphodiesterase inhibitors, mucolytics, and bacterial extract immunostimulants. Combining a long-acting inhaled bronchodilator and corticosteroid leads to an even greater reduction in exacerbations. The mechanism is unclear but is likely anti-inflammatory or immunomodulatory. A current controversy is the finding that, overall, inhaled corticosteroids reduce AECOPD, yet are associated with an increase in the risk of pneumonia. The role of prophylactic antibiotics is discussed further later.

Symptoms of acute exacerbations

Patients with AEs of chronic airways disease present with similar respiratory symptoms. Among these are increased dyspnea, increased frequency and severity of cough, increased volume or purulence of sputum, or chest tightness. More general symptoms include malaise, anorexia, fatigue, chills, or fevers. A viral cause may be suspected when the patient has antecedent coryzal symptoms. The presence of rigors, high fevers, or pleuritic pain suggest coexistent pneumonia. Physical examination may reveal wheeze, accessory muscle use, decreased breath sounds, tachypnea, or tachycardia. Measures of airflow such as forced expiratory volume (FEV_1) or peak flow will be reduced from usual values. Chest radiography may assist in determining the presence of pneumonia or other conditions such as heart failure. Increasingly, patients with chronic lung diseases have other comorbidities that need to be incorporated into the differential diagnosis, such as heart failure, cancer, or pulmonary emboli.

The goals of therapy for an infective AE of chronic airways disease are the expeditious resolution of the acute infection without significant early relapses followed by a long infection-free post-treatment period. Implicit in these goals is the avoidance of further damage to the airways and lungs along with maintenance of functional status and quality of life.

Role of infection in asthma

The role of infection in causing asthma is controversial. RSV and rhinovirus are found more commonly in the airways of children with asthma, but this is not thought causal. On the other hand, viruses cause about 75% of asthma exacerbations. Most commonly, infection is with rhinovirus, but other common viral pathogens are influenza, RSV, coronavirus, human metapneumovirus, parainfluenza, or adenovirus. Bacterial infections play only a minor role. Compared with nonasthmatic controls, people with asthma infected with a common cold–causing rhinovirus show more severe lower respiratory symptoms and changes in airway physiology. This suggests the presence of abnormal airways responses to infection, such as defective interferon responses to rhinovirus. The bacteria *C. pneumoniae* and *M. pneumoniae,* primarily recognized as causative agents in "atypical" community-acquired pneumonia, may play a role in asthma.

Current treatment options for AE of asthma are limited and have developed little in recent years. Generally they consist of increased inhaled bronchodilator therapy and anti-inflammatory treatment with inhaled or oral corticosteroids. Antibiotics are reserved for situations where there is strong evidence of a bacterial lung infection. Macrolides have been shown to have anti-inflammatory, bactericidal, and possibly antiviral activity, making them attractive agents in asthma. However, clinical trials of macrolides in either acute or chronic asthma have yielded inconsistent results. Newer antiviral approaches such as either vaccination against or enhancement of the host response to respiratory viruses are under consideration.

Role of infection in COPD

An AECOPD is thought to occur as a result of the increased inflammatory burden in the airways from interactions among host, viruses, bacteria, and/or air pollution. Infections (viral, bacterial, or other) account for the majority of AECOPD, with other causes being air pollution or comorbidities such as heart failure, pneumonia, or pulmonary embolism. In a third of AECOPD no cause is found. During an infective AECOPD, the airways exhibit an increase in neutrophils, products of neutrophil activation, and oxidative stress,

some of which may result in an increased systemic acute phase response.

Depending on the study, viruses account for 12% to 48% of AECOPD, with the common viral pathogens being influenza, parainfluenza, rhinovirus, adenovirus, coronavirus, and RSV. In some AECOPD, both viruses and bacteria are found. Where viruses are detected, the AECOPD is more severe and prolonged than when they are not detected.

The same bacteria seen in an AECOPD may colonize the airways of more than half of patients while they are in a stable state. Features that suggest pathogenicity include a pure, heavy growth of organism on sputum culture or a change in organism from one known to be present in the stable state. The four most common bacterial organisms found in COPD patients and in AECOPDs are *Streptococcus pneumoniae*, *Haemophilus influenzae, H. parainfluenzae,* and *Moraxella catarrhalis*. In very severe COPD, *Pseudomonas aeruginosa* is an important consideration, particularly in patients with frequent hospitalizations, more than four courses of antibiotics per year, recent oral steroid use, or who have not been vaccinated against influenza. The atypical organisms—*Chlamydophila*, *Legionella*, and *Mycoplasma*—do not play a specific causative role in AECOPD.

In principle, the identification of a specific bacterial etiology in AECOPD allows for selection of appropriate therapy and avoids the costs and adverse effects associated with the use of unnecessary medications, including the emergence of resistant strains. Obviously, antimicrobials are not indicated for any AECOPD that is not bacterial in nature. A Cochrane review of antibiotics for AECOPD found that currently available antibiotics, as a group, do not reduce treatment failure in mild exacerbations, whereas they do in severe AECOPD. There is no evidence of an effect on mortality or length of hospital stay, with almost no data on patient-reported outcomes.

In practice, the decision to treat with antibiotics is often based on clinical and not microbiologic grounds. Sputum cultures and antibiotic sensitivity testing are rarely indicated to guide empirical treatment for mild AECOPD in the community. In part this is due to the delay in getting a helpful result. Another problem is the difficulty in obtaining adequate sputum samples, free of saliva, that reflect the bronchial pathology. A final problem is the cost and availability of the test.

In contrast, a sputum culture and antibiotic sensitivity testing should be considered if the patient is having frequent AECOPDs treated with antibiotics; if the AECOPD is severe, especially where artificial ventilation is needed; or if the AECOPD does not respond to the initial choice of antibiotic. If gram-negative bacilli (other than *Haemophilus*-like organisms) or gram-positive cocci resembling staphylococci are noted on Gram stain, culture and sensitivity should be performed. There is increasing interest in procalcitonin-guided antibiotic therapy in AECOPD, but whether it offers clinical benefit is uncertain.

A useful heuristic is to treat empirically with antibiotics those AECOPDs which have no other cause and that have all three of the following: increased dyspnea, increased volume, and increased purulence of sputum. In addition, antibiotics are recommended for most exacerbations in those with severe COPD.

Antibiotics for AECOPD should be chosen with the following in mind:

- coverage of all common pathogens in AECOPD;
- local resistance patterns;
- risk factors for *P. aeruginosa;*
- route of delivery, with oral preferred where possible;
- a dosage regimen that favors compliance;
- minimization of undesirable side effects, interactions with other medications, and costs;
- duration appropriate to treat the infection. This is usually 5 to 7 days unless there is coexistent underlying disease such as bronchiectasis.

Empirical oral treatments for infective AECOPDs suggested by global guidelines come from most of the major antimicrobial classes (i.e., penicillins, tetracyclines, quinolones, macrolides, cephalosporins, and sulfonamides). Oral antibiotics should suffice in most cases without pneumonia. The increase in β-lactamase-producing *H. influenzae* and *M. catarrhalis* and the rising incidence of penicillin-resistant *S. pneumoniae* have forced a shift to newer antibiotics or combinations, such as a penicillin with a β-lactamase inhibitor such as clavulanic acid. Of the new quinolones, moxifloxacin appears to have the best efficacy and safety profile. If pseudomonas is suspected, a quinolone is the antibiotic of choice. In an AECOPD, parenteral therapy should only be needed if the patient is severely unwell. Switching from parenteral to oral therapy should be considered as early as possible as it is cost-effective and permits earlier discharge from hospital. Antiviral therapy is not indicated for usual AECOPD.

In the United States, by far the most commonly used antibiotic for bronchitis is azithromycin, followed by amoxicillin and clarithromycin. This is despite concerns about the cardiotoxicity of azithromycin in patients at high risk of QT prolongation. Macrolide resistance in *S. pneumoniae* is a growing concern, with prevalence proportional to the amount of macrolide use in the population.

Thirty years ago the use of prophylactic antibiotics for chronic bronchitis was common, including cyclical treatment, but concerns about effectiveness and antibiotic resistance led to a decline in the use of this approach. Recently there has been renewed interest in whether prophylactic antibiotics prevent AECOPD. In part this is due to the observation that, in addition to antibacterial effects, macrolides may be anti-inflammatory and immunomodulatory. Both continuous and pulsed approaches (several days per week or month) have been trialed. In one placebo-controlled study of 250 mg/d azithromycin for a year in more than 1,000 patients with at least moderate COPD, there was a 40% reduction in the number of patients with an AECOPD and a 20% reduction in the total number of AECOPDs. However, this benefit came at an increased risk of adverse effects including hearing impairment and an increase in antibiotic resistance in the colonizing organisms. A recent Cochrane systematic review found no data on efficacy of prophylactic antibiotics used for >1 year. Because of ongoing safety concerns to both individual patients and to society, prophylactic antibiotics in COPD should be reserved for the small portion of

patients with moderate to severe COPD and high morbidity from frequent bacterial AECOPD.

Role of infection in bronchiectasis

BX is the end result of a number of disease processes, several of which are noninfective, such as cystic fibrosis (CF), cilial or connective tissue diseases, immune deficiency syndromes, or abnormal immunologic responses to *Aspergillus* spp. Infection does play a role in the development of some cases of BX (e.g., recurrent respiratory infections in childhood including with respiratory viruses, *Bordetella pertussis,* or tuberculosis).

Regardless of the cause, few studies have assessed the microbiologic pattern of airway colonization in established BX. Bacteria found in the airways during stable BX include *S. pneumoniae*, *H. influenza*e, *M. catarrhalis, S. aureus*, gram-negative enteric bacilli, *Mycoplasma pneumoniae*, and nontuberculous mycobacteria. *P. aeruginosa* is particularly a problem in BX of early onset or where there is severely reduced lung function. Colonization with *P. aeruginosa* is associated with an increased rate of exacerbations and hospitalizations, and with an increased risk of death. Therefore some respiratory physicians will attempt to eradicate new *P. aeruginosa* colonization when detected.

Unfortunately, little is known about the microbiologic etiology of AE in BX (AEBX). Despite the lack of evidence, general recommendations for AEBX have been made, which include:

- considering periodic surveillance of colonization;
- providing antibiotic treatment for patients with exacerbations;
- obtaining a sputum sample for culture before starting antibiotic treatment in most cases and particularly in those requiring hospitalization;
- for empirical antibiotic treatment, stratifying patients according to the potential risk of *Pseudomonas* spp. infection;
- adjusting or modifying empirical antibiotics according to sputum culture results.

Prolonged antibiotic therapy has shown only a small benefit in modifying the outcome of purulent BX. Nebulized antibiotics are not recommended for non-CF BX, in contrast to the situation with CF BX.

As in COPD, there is interest in the use of prophylactic treatment of patients with BX using either continuous or pulsed regimens, with the main aim to reduce exacerbation frequency. While this approach does reduce exacerbations significantly in BX, it has no effect on lung function decline or quality of life. Moreover, there is the potential for harm through adverse effects and in terms of driving antibiotic resistance, as discussed earlier in the COPD section. At present, this approach is not recommended in routine practice.

The isolation of nontuberculous mycobacteria from the patient with bronchiectasis may reflect either colonization or active infection. Depending on the species identified and imaging appearances, further investigation and management may be required, but this topic is outside the scope of this chapter.

Croup, supraglottitis, and laryngitis

Irmgard Behlau

Croup

Croup is a clinical syndrome characterized by a seal-like barking cough, hoarseness, inspiratory stridor, and often some degree of respiratory distress. The term *croup* is usually used to refer to acute laryngotracheobronchitis. Other croup-like syndromes can include spasmodic croup and bacterial tracheitis (Table 30.1). Other potential infectious causes of stridor include supraglottitis (epiglottitis), peritonsillar abscess, retropharyngeal abscess, and rarely, diphtheria, whereas noninfectious etiologies include angioneurotic edema, foreign-body obstruction, hemangioma, trauma, neoplasm, subglottic stenosis, or extrinsic compression. Croup is primarily a disease of children between the ages of 1 to 6 with peak incidence between 6 months and 3 years. The parainfluenza viruses (1, 2, and 3) are the most frequent cause with outbreaks occurring predominantly in the winter months. Other occasional causes include respiratory syncytial virus (RSV), influenza, and adenovirus with rare cases secondary to *Mycoplasma*, *Corynebacterium diphtheriae*, and herpes simplex virus (HSV). In adults, the causes are also predominantly viral, including reported cases of influenza, parainfluenza, RSV, HSV, and cytomegalovirus (CMV). In either children or adults, most likely secondary bacterial infections with *Haemophilus influenzae* type b (Hib), staphylococci, *Moraxella catarrhalis*, and *Streptococcus pneumoniae* can be seen.

Croup usually follows a relatively mild upper respiratory infection. Its onset is commonly abrupt and occurs in the late evening and night. Viral infection with associated inflammation of the nasopharynx spreads inferiorly to the respiratory epithelium of the larynx and trachea. The subglottic region in children is normally narrow and surrounded by a firm ring of cartilage. Small swelling of this narrow subglottic area will significantly restrict air flow and produce audible inspiratory stridor, while the impairment of the mobility of the vocal cords will produce hoarseness.

Rapid, objective, and calm assessment of severity must be done to determine management and without respiratory compromise. The presence of chest wall retractions and stridor at rest are most critical (Table 30.2). Anteroposterior radiologic examination of the soft tissues of the neck (with medical monitoring) may be useful when the diagnosis is in question. The classic steeple sign is produced by the cone-shaped narrowing of the proximal 1-cm subglottic area of the trachea, at the conus elasticus to the level of the true vocal cords. It is produced by edema with elevation of the tracheal mucosa and the loss of the normal lateral convexities (shoulders) of the air column (Figure 30.1). Direct visualization of the airway can be attempted if the symptoms are not typical and the child is stable. If intubation appears imminent or there is a strong suspicion of epiglottitis, this should be performed under anesthesia. In croup, the supraglottic region appears normal.

Therapy

Management includes corticosteroids, nebulized budesonide, and nebulized epinephrine. Oxygen or heliox are often used as supportive treatment. No clear data exist on the benefits of mist or humidified air.

TABLE 30.1 **COMPARISON OF CROUP-LIKE SYNDROMES**

Characteristic	Spasmodic croup	Laryngotracheobronchitis	Bacterial tracheitis	Supraglottitis
Age range	6 mo–3 yr	0–6 yr (peak, 6 mo–3 yr)	1 mo–6 yr	Infants ≤2 mo, older children, and adults
Etiology	? Viral ? Airway reactivity	Parainfluenza virus (1, 2, 3) Influenza Respiratory syncytial virus Adenovirus	*Staphylococcus aureus* *Haemophilus influenza* *Corynebacterium diphtheriae*	*Haemophilus influenzae* (Hib/non-b) *Streptococcus pneumonia* Group A streptococcus *Haemophilus parainfluenzae*
Onset	Sudden	Insidious	Rapid deterioration	Sudden
Clinical manifestations	Afebrile Nontoxic Barking cough Stridor Hoarse	Low-grade fever Nontoxic Barking cough Stridor Hoarse	High fever Toxic Barking cough Stridor Hoarse	High fever Toxic Nonbarking cough Muffled voice Drooling Dysphagia Sitting, leaning forward
Endoscopic findings	Pale mucosa Subglottic swelling	Deep-red mucosa Subglottic swelling	Deep-red mucosa Copious tracheal secretions	Cherry-red epiglottis Arytenoepiglottic swelling
Complete blood count, differential	Normal	Mild leukocytosis Lymphocytosis	Normal to mild leukocytosis Marked Bandemia	Marked leukocytosis Bandemia
Radiographic findings	Subglottic narrowing	Subglottic narrowing	Subglottic narrowing Irregular tracheal border	Large epiglottis Thick arytenoepiglottic folds
Therapy	Mist Calm ?Racemic epinephrine ?Steroids	Corticosteroids Racemic epinephrine Nebulized budesonide Intubation (if necessary)	Intubation Antibiotics	Intubation Antibiotics
Response	Rapid	Transient	Slow (1–2 wk)	Variable (hours–days)
Intubation	Rare	Occasional	Usual	Usual

Analgesics improve sore throat and overall comfort. Antitussives, decongestants, and "prophylactic" antibiotics are not beneficial.

Due to the sustained anti-inflammatory effects of corticosteroids, they have been shown to improve the status of not only severe croup but also mild to moderate croup. Dexamethasone in doses of 0.15 to 0.6 mg/ kg has been shown to be beneficial and decreases the need for hospitalizations and unscheduled medical visits even in mild croup. Oral, intramuscular, and intravenous routes of administration are all effective, with nebulized dexamethasone possibly less effective. Nebulized budesonide, 2 mg, has been shown to be as effective as dexamethasone but is often reserved for patients with intractable vomiting or for simultaneous administration with epinephrine in severe respiratory distress because it is substantially more expensive and more difficult to administer. The combination of oral dexamethasone and nebulized budesonide is no better than either alone. For the management of outpatient croup, oral prednisolone, 2 mg/kg/day as two divided doses per day, may be considered as an alternative, but comparison studies have been limited to oral dexamethasone.

Owing to the rapid onset of action, the use of nebulized racemic epinephrine has markedly reduced the need for intubation, even in hospitalized patients, to less than 2%. L-epinephrine (1:1000) is as effective as racemic epinephrine. Improvement occurs within minutes, but symptoms can recur within 2 hours; therefore, patients must be observed in the emergency room for 3 hours.

The administration of oxygen should be reserved for children with significant respiratory distress and hypoxia (oxygen saturation on room air ≤92%). Heliox, a lower density gas that is a mixture of oxygen (20%–30%) and helium (70%–80%), has been proposed to help reduce the need for intubation in the severely ill child by improving laminar gas flow through a narrowed airway. There remains insufficient evidence to advocate its general use.

If intubation is deemed necessary, an endotracheal tube one to two sizes smaller than would be used for the same-size healthy child will be needed to prevent pressure necrosis and resulting subglottic stenosis. For those children who appear to have a secondary bacterial infection, antibiotic therapy similar to that recommended for epiglottitis should be considered to treat the possibility of a secondary

TABLE 30.2 **RECOMMENDED TABLE ALGORITHM FOR THE MANAGEMENT OF CROUP (LARYNGOTRACHEOBRONCHITIS)**

Condition	Treatment
Mild	
No stridor	Analgesics, hydration as needed
No chest wall retractions	Single dose of oral dexamethasone (0.6 mg/kg body weight)
No respiratory distress at rest	Educate parents (illness, when to seek medical assessment)
Moderate	
Stridor at rest	Above including oral dexamethasone, 0.6 mg/kg
Mild chest wall retractions	Observe in emergency room
No agitation or significant respiratory distress	If improved with no stridor or retractions, educate, home If no or minimal improvement by 4 h, hospitalization
Severe	
Stridor may decrease with worsening airway obstruction	Nebulized racemic epinephrine 2.25% (0.5 mL/2.5 mL saline) or L-epinephrine 1:1000 (5 mL), may repeat
Significant respiratory distress	Oral or parenteral dexamethasone 0.6 mg/kg, may repeat
Severe chest wall retractions	If contraindications to oral medication, consider nebulized budesonide 2 mg with epinephrine
Agitation or lethargy	
Decreased air movement	Humidifed oxygen (≤92% room air 0_2 sat, consider heliox)
Possibly cyanosis	ICU care, intubation as necessary

bacterial process. Table 30.2 outlines therapy recommendations depending on the clinical state of the patient.

Acute Supraglottitis (Epiglottitis)

Supraglottitis is characterized by inflammation and edema of the supraglottic structures, including the epiglottis, arytenoepiglottic folds, arytenoids, and false vocal cords; paradoxically, the epiglottis may be spared.

In children, acute supraglottitis is typically characterized by a fulminating course of severe sore throat, high fever, dysphagia, drooling, low-pitched inspiratory stridor, and airway obstruction, which, if left untreated, can lead to death. The child appears toxic and prefers an airway-preserving posture—sitting upright, jaw protruding forward, while drooling. In adults, the presentation is more variable; most adults have mild illness with a prolonged prodrome. In immunocompromised patients, there may be a paucity of physical findings.

Courtesy of Drs. A Weber and HD Curtin, Department of Radiology, Massachusetts Eye and Ear Infirmary, Boston, Massachusetts.

Definitive diagnosis is made by examination of the epiglottis and supraglottic structures. No attempt should be made to visualize the epiglottis in an awake child; therefore, a severely ill child must be examined in the operating room at the time of control of the airway. In children, the epiglottis is typically fiery red and extremely swollen, but occasionally the major inflammation involves the ventricular bands and arytenoepiglottic folds, and the epiglottis appears relatively normal. In adults, awake indirect laryngoscopy may be performed, but only when it is possible to establish an artificial airway. In adults, the supraglottic structures may appear pale with watery edema. If indirect laryngoscopy is unavailable, lateral neck radiographs are also useful for evaluating supraglottitis (Figure 30.2), but they are not as sensitive and should never delay protecting the airway. The classic appearance is of an enlarged epiglottis bulging from the anterior wall of the hypopharynx with straightening of the cervical spine from the usual mild lordosis. Computed tomography (CT) imaging may help to diagnose complicating conditions such as a parapharyngeal abscess (Figure 30.3).

The epidemiology of acute supraglottitis has changed dramatically since the introduction of the Hib vaccines in the mid to late 1980s. Supraglottitis, which most commonly had affected children 2 to 7 years of age, is now rarer in young children than adults, is primarily a disease of older children and adults, and is increasingly being caused by other microbial pathogens. The incidence of invasive Hib has decreased more than 99% compared to the pre-vaccine era. The organisms typically involved, in addition to Hib, are *S. pneumoniae*, *Staphylococcus aureus*, β-hemolytic streptococci, *H. influenzae* type non-b, *Haemophilus parainfluenzae*, rarely in adults *Pasteurella multocida*, and possibly increasing reports of *Neisseria meningitidis* since 1995. There are very rare reports of children developing Hib epiglottitis despite vaccination. The role respiratory tract viruses play as primary pathogens remains unclear. There have been reports of HSV type 1 and varicella as primary pathogens in immunocompromised

hosts. Noninfectious causes include thermal and corrosive injury, lymphoproliferative disorders, and graft-versus-host disease.

Therapy

Treatment of acute supraglottitis is directed at establishing an airway and administering appropriate antibiotics. Children with epiglottitis should routinely have an artificial airway established; observation cannot be routinely recommended because the mortality rate is 6% to 25% and increases to 30% to 80% for those who develop obstruction. Most deaths occur within the first hours after arrival. The use of a "prophylactic airway" has reduced the mortality rate to less than 1%. The management of the airway in adult supraglottitis reflects the greater variability of clinical presentation and course. It has a range of mortality rates from 10% to 32%. Vigilant airway monitoring and continuous staging are needed for adults whose disease may progress to respiratory compromise. A formal written "acute airway obstruction protocol" should be followed. Factors associated with airway obstruction include symptomatic respiratory difficulty, stridor, drooling, shorter duration of symptoms, enlarged epiglottis on radiograph, and *H. influenzae* bacteremia.

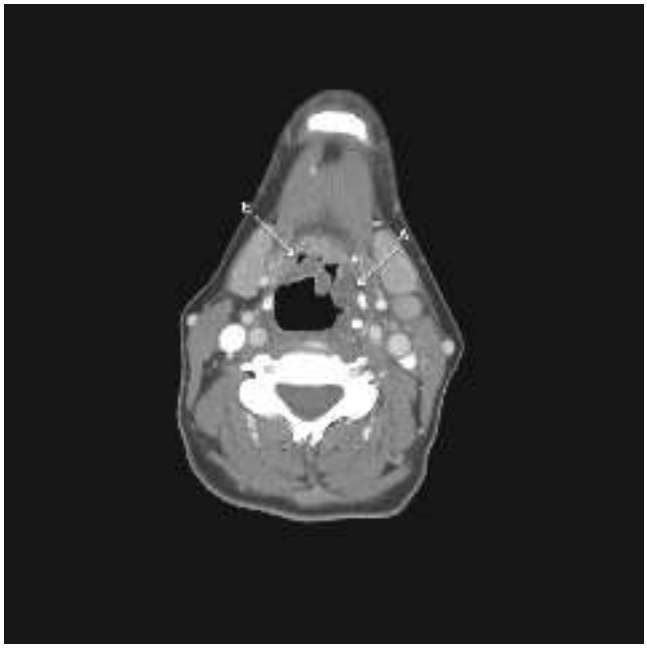

FIGURE 30.3 CT scan of the neck in an adult with acute supraglottitis due to group A β-hemolytic streptococci. Findings include an edematous epiglottis (E), narrowing of the larynx, and also a hypoattenuating area (A) at the level of the hyoid body suggestive of early abscess formation.

Courtesy of Drs. RL Reichle and PA Rogoff, Department of Radiology, Mount Auburn Hospital, Cambridge, Massachusetts.

An endotracheal tube is preferred over a tracheotomy for the following reasons: (1) ease of removal of the tube 2 to 3 days after the edema has subsided, thereby shortening the hospital stay; (2) no surgery; and (3) mortality and complication rates equal to or lower than those for tracheotomy.

Antibiotic therapy should include coverage for *H. influenzae*, *S. pneumoniae*, group A β-hemolytic streptococci, other streptococci, *H. parainfluenzae*, and *S. aureus*. Second- and third-generation cephalosporins are first-line agents. Pediatric dosages are intravenous cefuroxime, 150 mg/ kg, 3 doses per day; cefotaxime, 150 mg/ kg, 3 doses per day; ceftriaxone, 50 mg/ kg/day; or ampicillin–sulbactam, 200 to 400 mg/ kg, at 4 doses per day. The recommended adult dosages are intravenous ceftriaxone, 2 g/ day; cefotaxime, 2 g every 4 to 8 hours; or ampicillin/sulbactam 1.5 to 3 g every 6 hours. Antibiotic therapy should be continued for 10 to 14 days. In patient populations with a significant prevalence of community-acquired methicillin-resistant *S. aureus* (MRSA) or penicillin-resistant *S. pneumoniae*, clindamycin, 30 to 40 mg/kg divided in 3 doses (max 2400 mg/day) or vancomycin, 40 to 60 mg/kg/ day in 3 to 4 doses in children or 2 g/ day in adults adjusted for renal function should be considered. Duration of therapy is usually 7 to 14 days, depending on patient response.

Steroids are commonly used for supraglottitis to theoretically decrease inflammation. There has been no evidence for any significant benefit, and in adults, there is no indication that steroids prevent the need for airway intervention. With epiglottitis being so uncommon and therefore all studies being small, it will be difficult to evaluate any beneficial role. The use of steroids remains controversial.

Prevention

Prophylaxis is indicated for supraglottitis secondary to Hib. Rifampin, 20 mg/ kg, not to exceed 600 mg/day, daily for 4 days is recommended for: (1) all household contacts (except pregnant women) when there is a child younger than 12 months irrespective of vaccine status or there is a child younger than 4 years of age with incomplete vaccination; (2) day-care and nursery school classroom contacts (including adults) (a) if two or more cases of invasive disease have occurred within 60 days and unvaccinated or incompletely vaccinated children attend or (b) with one case and susceptible children 2 years or younger who attend for 25 hours or more per week (susceptible children should be vaccinated); if

children are older than 2 years, rifampin prophylaxis need not be given irrespective of vaccination status. (3) The patient should receive prophylaxis before discharge if treated with ampicillin or chloramphenicol to prevent reintroduction of the organism into the household. Prophylaxis is not needed for those treated with the aforementioned recommended cephalosporins because they eradicate Hib from the nasopharynx.

Since the introduction of conjugated vaccines for infants beginning at 2 months of age, the incidence of supraglottitis resulting from Hib in this age group has declined by 99%, along with other invasive forms of Hib. There have been isolated rare reports of supraglottitis in children who have been vaccinated, but in general, we are seeing a near-eradication of Hib supraglottitis in young children. Supraglottitis caused by Hib occurs now primarily in undervaccinated children, infants too young to have completed the primary series of vaccinations, and older children and adults who have never been immunized.

Laryngitis

The larynx rests in the hypopharynx and consists of: (1) the supraglottic larynx, which includes the laryngeal inlet formed by the epiglottis anteriorly and the arytenoepiglottic folds bilaterally merging inferiorly into false cords, and (2) the glottic larynx, which consists of the true vocal cords.

Acute laryngitis often presents with hoarseness, odynophagia, and localized pain, which may also be referred and manifests as otalgia. Obstruction of the airway is uncommon in adults but more common in young children, especially if associated with tracheal inflammation as in croup, and must be distinguished from acute supraglottitis. Examination of the larynx reveals erythema, edema, secretions, and occasionally superficial mucosal ulcerations. The presence of exudate or membrane on the pharyngeal or laryngeal mucosa should raise the suspicion of streptococcal infection, mononucleosis, or diphtheria; granulomatous infiltration may be compatible with tuberculosis, sarcoidosis, fungal infection, or syphilis.

The respiratory viruses such as influenza virus, parainfluenza virus, rhinovirus, and adenovirus are most often isolated in cases of laryngitis (90%). *M. catarrhalis* has been isolated from the nasopharynx of 50% to 55% and *H. influenzae* from 8% to 15% of adults with laryngitis. It remains unclear whether these may represent a secondary bacterial invasion. Group A and G streptococci, *Chlamydia pneumoniae*, and *Mycoplasma pneumoniae* have also been associated with acute laryngitis. Laryngeal diphtheria is very rare and usually results from extension of pharyngeal involvement. It may occur in previously immunized persons.

Fungal infections such as histoplasmosis, coccidioidomycosis, blastomycosis, and cryptococcosis may cause laryngitis. Candidiasis is most often seen in immunosuppressed patients. *Treponema pallidum*, HSV, and herpes zoster virus may also be causes of acute laryngitis. Laryngeal tuberculosis is very rarely seen in the United States since the advent of effective antimycobacterial therapy. It is associated with a large tuberculous load, and patients often have very active pulmonary involvement. Sarcoidosis, Wegener's granulomatosis, and rhinoscleroma may be considered causes of laryngitis.

Therapy

Because most cases of acute laryngitis are viral in etiology and self-limited, treatment usually consists of resting the voice and inhaling moistened air. The role of empiric antibiotic therapy of laryngitis has been examined by prospective double-blinded studies. Penicillin V had no effect on the clinical course. Patients treated with erythromycin (0.5 g twice a day for 5 days) had a marked reduction of *M. catarrhalis* carriage in the nasopharynx and reported a significant improvement of subjective voice disturbances after 1 week and cough after 2 weeks; however, there was no difference in laryngoscopic examination and voice evaluation. Because acute laryngitis in adults is self-limiting and subjective symptoms are spontaneously reduced after 1 week in most cases, empiric antibiotic treatment does not seem warranted as a general policy.

Antimicrobial therapy is indicated only in those patients with a bacterial infection or super-infection; therapy is directed toward the believed causative agent. Usual duration is for 10 to 14 days. The use of corticosteroids should be avoided due to their ability to mask vocal cord pathology.

Immunosuppressed patients who present with hoarseness or patients whose hoarseness has persisted longer than 10 to 14 days should have a laryngoscopic examination to exclude other more atypical causes such as HSV, bacterial, fungal, mycobacterial, and malignant etiologies of laryngitis.

Atypical pneumonia

Thomas M. File, Jr.

The term "atypical pneumonia" was first coined more than 60 years ago to describe cases of pneumonia caused by an unknown agent(s) and which appeared clinically different from pneumococcal pneumonia. It was initially characterized by constitutional symptoms often with upper and lower respiratory tract symptoms and signs, a protracted course with gradual resolution, the lack of typical findings of consolidation on chest radiograph, failure to isolate a pathogen on routine bacteriologic methods, and a lack of response to penicillin therapy. In the 1940s an agent that was believed to be the principal cause was identified as *Mycoplasma pneumoniae.* Subsequently other pathogens have been linked with "atypical pneumonia" because of similar clinical presentations, including a variety of respiratory viruses, *Chlamydia pneumoniae, C. psittaci,* and *Coxiella burnetii*. Less common etiologic agents associated with atypical pneumonia include *Francisella tularensis, Yersinia pestis* (plague), and the sin nombre virus (Hantavirus pulmonary syndrome), although these agents are often associated with a more acute clinical syndrome. In addition, although presently exceedingly rare, inhalation anthrax is included in part because of the concern for this pathogen as an agent of bioterrorism. Finally, pneumonia caused by *Legionella* spp., albeit often more characteristic of "pyogenic" pneumonia, is also included since it is not isolated using routine microbiologic methods.

Although the original classification of atypical and typical pneumonia arose from the perception that the clinical presentation of patients was different, recent studies have shown that there is excessive overlap of clinical manifestations of specific causes that does not permit empiric therapeutic decisions to be made solely on this basis. Thus, the designation of "atypical pneumonia" is controversial in relationship to scientific and clinical merit and many authorities have suggested that the term "atypical" be discontinued. However, the term remains popular among clinicians and investigators and remains prevalent in recent literature regardless of its clinical value. Moreover, options for appropriate antimicrobial therapy for the most common causes are similar, and this is considered by some to provide justification to lump these together.

M. pneumoniae, *C. pneumoniae,* and *Legionella pneumophila* are the most common causes of atypical pneumonia. Results of recent studies indicate they cause from 10% to 30% (depending on population assessed and methodology of diagnosis) of cases of community-acquired pneumonia (CAP). However, these pathogens have not been identified often in clinical practice because until recently there have not been specific, rapid, or standardized tests for their detection. The "other" causes of atypical pneumonia occur with much less frequency.

Treatment of atypical bacterial in the spectrum of CAP has been controversial and is related to several issues, including the relevance of terminology, imprecise diagnostic methods at present, and perceived contradictory results of published evidence. However, limitations of clinical trial methodology limit our interpretation of the actual benefit of providing coverage since many atypical pneumonias are eventually self-limited. Studies evaluating the time to clinical recovery and the use of earlier end points for evaluation suggest that appropriate therapy provides a benefit if an atypical pathogen is a pathogen. Recent critical reviews of the evidence for therapy of atypical pneumonia concluded that available evidence does support treatment.

Clinical manifestations

Although the diagnosis of these specific pathogens is difficult to establish on clinical manifestations alone, there are several generalizations which may be helpful.

Mycoplasma pneumoniae

M. pneumoniae is a common cause of respiratory infections that range from unapparent infection, URI, and, tracheobronchitis to pneumonia. Respiratory droplets with a usual incubation period of several weeks transmit infection from person to person. Only 3% to 10% of infected persons develop pneumonia. Although commonly perceived as a cause of CAP predominantly in young healthy patients, the incidence of *M. pneumoniae* pneumonia increases with age, highlighting the importance of this pathogen in the elderly as well. *M. pneumoniae* is primarily transmitted from person to person via respiratory droplets. The incubation period after exposure averages 2 to 3 weeks.

M. pneumoniae pneumonia is considered the "classic" atypica pneumonia. Many of the pathogenic features are believed to be immune-mediated rather than induced directly by the bacteria (antibodies produced against the glycolipid antigens of *M. pneumoniae* may cross-react with human red cells and brain cells). Constitutional symptoms including headache, malaise, myalgias, and sore throat are frequently present. Cough is typically initially dry, may be paroxysmal and frequently worse at night, and may become productive of mucopurulent sputum. The physical findings often are minimal, seemingly disproportionate to the patient's complaints. Auscultation of the lungs usually reveals variable scattered rales or wheezes. Bullous myringitis, first described in volunteer subjects infected with *M. pneumoniae*, has been infrequent in naturally occurring infection and is not a diagnostic sign. Chest radiograph findings are variable. Most common is peribronchial pneumonia.

The course of *M. pneumoniae* pneumonia is usually mild and self-limiting. However significant pulmonary complications may occur and include pleural effusion, pneumatocele, lung abscess, pneumothorax, bronchiectasis, chronic interstitial fibrosis, respiratory distress syndrome, and bronchiolitis obliterans. Extrapulmonary manifestations including mucocutaneous disease (including mild maculopapular rashes, erythema multiforme, and mucositis), neurological involvement (i.e., aseptic meningitis, meningoencephalitis, cerebral ataxia, Guillain–Barré syndrome, and transverse myelitis), hemolytic anemia (associated with cold agglutinins), myo-pericarditis, polyarthritis, hepatitis, and pancreatitis. A recent study of patients with *M. pneumoniae* requiring ICU care observed an ICU mortality of 11%.

Chlamydia pneumoniae

Pneumonia caused by *C. pneumoniae* may be sporadic or epidemic. *C. pneumoniae* infections are often acquired early in life. Transmission is by person to person via respiratory secretions, with an incubation period of several weeks. Reinfections or recrudescent processes, both referred to as *recurrent infection*, may occur throughout one's lifetime. Most adults who are hospitalized with *C. pneumoniae* pneumonia have recurrent infection.

The clinical manifestations of C. pneumoniae pneumonia remain somewhat unclear because of the lack of a gold standard of diagnosis and the contributing effect of co-pathogens. The majority of infections are asymptomatic. For symptomatic infection the onset is usually insidious. A biphasic pattern of illness has also been reported, with upper respiratory tract symptoms preceding the onset of pneumonia by 2 to 6 weeks. Infections often present initially with sore throat, hoarseness, and headache as important nonclassic pneumonic findings. A subacute course is common, and fever is low grade. Cough is prominent but unproductive and, if not treated early and effectively, may last for weeks or even months. Chest radiograph findings are nonspecific. Patients with primary infection are usually younger and tend to have higher fever. For older patients with reinfection, the presence of comorbid illness and the requirement for supplemental oxygen therapy are often the reason for hospital admission.

Legionella pneumophila

Legionellosis is primarily associated with two clinically distinct syndromes: *Legionnaires' disease* (LD), a potentially severe pneumonia, and *Pontiac fever*, a self-limited, non-pneumonic illness. Many of the clinical features of Legionnaires' disease are more typical of pyogenic (bacterial) pneumonias. However as LD has become increasingly recognized, less severely ill patients are seen earlier in the course of disease and thus clinical manifestations of unusual severity are now less specific. *Legionella* is not spread person to person but usually by exposure to water. Outbreaks may be associated with infected water sources. The incubation period is 2 to 10 days. Although there are many species, most prevalent is *L. pneumophila* serogroup 1.

The onset of LD is often acute, with high fever, myalgias, anorexia, and headache which often precedes the cough. Temperature often exceeds 40°C/104°F. Gastrointestinal symptoms are prominent, especially diarrhea. Hyponatremia and elevated lactate dehydrogenase levels (LDH) are common abnormal laboratory studies observed in our experience. Radiographic findings are varied and nonspecific; however, the most common findings are patchy unilobar infiltrates, which can progress to consolidations.

The index of suspicion for *Legionella* infection should be particularly high during known outbreaks, which are often associated with contamination of water supplies in large facilities such as hospitals, hotels, or apartment buildings. Other epidemiologic factors that should heighten suspicion for *Legionella* infection include known or potential exposure to a contaminated water source (e.g., hot tubs, birthing pools, fountains) and exposure to soil or potting mix in areas where the incidence of *L. longbeachae* is high.

Other causes of atypical pneumonia

Several of the less common causes of the atypical pneumonia syndrome are zoonotic infections transmitted from animals to humans. In such cases epidemiological clues may be very important, and, while specific manifestations cannot be considered "diagnostic" of a specific etiology, there are general findings that are characteristic of these diseases (Table 31.1).

TABLE 31.1 **COMMON CHARACTERISTICS AND THERAPY FOR THE "OTHER" ATYPICAL PNEUMONIAS**

Pathogen	Epidemiological or underlying condition	Clinical features	Recommended therapy
Chlamydia psittaci	Exposure to birds	HA, pharyngeal erythema, splenomegaly, Horder spots (see text)	Doxycycline *Alternatives*: Macrolide or respiratory fluoroquinolone (e.g., levofloxacin or moxifloxacin)
Coxiella burnetii (Q fever)	Exposure to farm animals (especially parturient)	HA prominent, liver involvement	Doxycycline (in combination with hydroxychloroquine if endocarditic) *Alternatives*: Macrolide or respiratory fluoroquinolone
Francisella tularensis[a] (Tularemia)	Exposure to rabbits	HA, chest pain prominent	Streptomycin or gentamicin (acceptable and preferred) considered as drug of choice Fluoroquinolone or doxycycline effect for most cases (especially if nonsevere)
Yersinia pestis[a] (Pneumonic plague)	Exposure to infected animals (rodents, cats, squirrels, chipmunks, prairie dogs)	For inhalation, acute onset with rapidly severe pneumonia; blood tinged sputum	Streptomycin, gentamicin (acceptable and preferred) Tetracycline, doxycycline
Bacillus anthracis[a]	Woolen mill worker	Biphasic (see text); hallmark radiographic finding-mediastinal widening	Ciprofloxacin plus one of the following for initial therapy: Meropenem, clindamycin, or linezolid; switch to monotherapy when clinically appropriate—see text and refer to Hendricks et al.
Viruses			
Influenza	Influenza in community (avian-poultry exposure)	Influenza pneumonia usually follows tracheo-bronchitis	Oseltamivir (orally), zanamivir (via inhalation), peramivir (IV); beloxavir (orally)
Adenovirus		Pharyngitis prominent	No approved antiviral
Respiratory Syncytial Virus	Adults: Cardiopulmonary disease, COPD	Bronchospasm	No antiviral agent currently recommended (ribavirin possibly for selected cases; see text)
Hantavirus Pulmonary Syndrome	Exposure to rodent excreta	Febrile prodrome/ followed by noncardiogenic pulmonary edema with shock; thrombocytopenia	Supportive care
MERS-CoV	Travel to Arabian peninsula	Severe respiratory syndrome	Supportive care

[a] Potential infectious agent for biological warfare.
Abbreviation: HA = Headache

Coxiella burnetii may be associated with exposure via any mammal, but most commonly cattle, goats, sheep, and pets, including cats and dogs. Infected mammals shed *C. burnetii* in their urine, feces, milk, and placenta. The mode of transmission is either aerosol or by tick bite. High concentrations of the organism can be found in birth products of infected animals. The incubation period is approximately 3 weeks. The acute disease (Q fever) is often a self-limiting "flu-like" illness characterized by fever, headache, myalgias, cough, and arthralgia. Pneumonia is commonly accompanied by granulomatous hepatitis. Radiological findings include lobar or segmental alveolar opacities, which may be multiple. Other manifestations may include maculopapular or purpuric rash, aseptic meningitis or encephalitis, hemolytic anemia, endocarditis, pericarditis, pancreatitis, or epididymo-orchitis. Occasionally *C. burnetii* is associated with chronic Q fever, which is defined as infection lasting for >6 months and in which endocarditis is the predominant manifestation.

Pneumonia due to *C. psittaci* usually occurs after exposure to infected birds. Infection in birds is usually asymptomatic or may cause illness associated with ruffled feathers or ocular or nasal discharge. The organism is shed in feces, urine, and respiratory secretions. Humans are usually infected by inhalation of organisms in dried feces or in bird feather dust, which may occur during cage cleaning. The onset is often insidious, with nonproductive cough, fever, and headache, but may be abrupt. Headache may be severe and associated with photophobia. The incubation period is usually 5 to 15 days. Clinical clues include pharyngeal erythema, splenomegaly (which tends to occur toward the end of the first week), and a rarely

seen specific rash (Horder's spots, a pink blanching maculopapular eruption resembling the rose spots of typhoid fever).

Francisella tularensis can cause primary tularemia pneumonia. Human infection occurs following contact with infected animals (hares or rabbits most common) or the bite of invertebrate vectors (most commonly ticks but also mosquitoes, horseflies, fleas, and lice). In one reported outbreak of tularemia pneumonia, a significant risk factor was grass mowing (presumably airborne transmission from close contact to rabbit habitats). Pneumonia may also occur from hematogenous spread after vector-borne (e.g., tick) infection. The incubation period following infection with *F. tularensis* is 3 to 5 days. The onset is usually abrupt, with high fever, chills, cough (usually nonproductive, occasionally with hemoptysis), pleuritic chest pain, and diaphoresis. Other than pneumonia *Tularemia* may also be associated with other clinical syndromes including ulceroglandular, oculoglandular, and typhoidal forms.

Hantaviruses comprise a genus of enveloped viruses within the family Bunyaviridae and are associated with two severe, acute febrile illnesses: *hemorrhagic fever* with renal syndrome and *hantavirus pulmonary syndrome* (HPS). Hantaviruses are shed in the urine, feces, or saliva of acutely infected reservoir rodents; transmission to humans occurs via the aerosol route. Many patients describe encountering living or dead rodents or visible evidence of rodent infestation prior to illness. Typically the incubation period is 3 weeks after exposure. The clinical illness of HPS typically begins with a prodromal phase characterized by nonspecific manifestations such as fever, myalgias, headache, nausea, vomiting, abdominal pain, and cough. This phase typically lasts 3 to 8 days and is followed by the cardiopulmonary phase, which starts suddenly with tachypnea and shortness of breath and is followed by respiratory failure and shock. Chest radiograph shows noncardiogenic bilateral interstitial edema during this phase. Characteristically, the patient is hemoconcentrated and manifests significant thrombocytopenia.

Yersinia pestis, which causes plague pneumonia, is primarily a zoonotic infection of rodents and wild and domestic animals (most often cats); humans are considered incidental hosts. Transmission occurs via bites of rodent fleas, scratches or bites from infected domestic cats, direct handling of infected animal tissues, or inhalation of respiratory secretions from infected animals. Infection is found in the United States mainly in the southwestern and Pacific coastal areas. Incubation is usually 2 to 3 days. The disease may have an abrupt onset and usually begins with a painless cough with shortness of breath. Untreated pneumonic plague has a 40% to 90% mortality.

In the natural setting, *inhalation anthrax* is exceedingly uncommon and is classically referred to as *wool sorters disease* because of the association with workers in woolen mills who may inhale *Bacillus anthracis* spores. However, its potential use as a biological weapon has brought increased interest to this pathogen. In the 2001 outbreak of probable bioterrorism-associated anthrax conducted through the US postal system, nine cases of inhalation anthrax were identified and resulted in four deaths. The incubation is variable, often less <1 week, but it can be 6 weeks or longer. Initial symptoms are nonspecific with fever, malaise, chest pain, and nonproductive cough. This may be followed by brief improvement and then severe respiratory distress, shock, and death. Widened mediastinum (associated with hemorrhagic mediastinitis) without parenchymal infiltrates found on radiographic imaging (CT scan is most sensitive) is characteristic of inhalation anthrax. The diagnosis is often established with positive blood cultures that may initially be dismissed as "contaminants."

In addition to inhalation anthrax syndrome, pneumonic plague and pneumonic tularemia are possible agents of bioterrorism. Clustered cases occurring without the expected epidemiologic exposures to animals, insects, or environmental activities should raise the possibility of a bioterrorism event. Specific epidemiological, clinical, and microbiological clues should lead to early suspicion and rapid activation of the health alert system since laboratory confirmation of the agent could be delayed.

Pneumonia caused by respiratory viruses

Viruses account for an important number of pneumonias in adults, especially during the winter months and among the elderly. Recent studies suggest that approximately one-quarter to one-third of adults hospitalized for pneumonia had a virus as sole etiology. Of interest, many of the emerging infections have been associated with newly identified viruses (many zoonotic): Middle East respiratory syndrome-novel coronavirus (MERS-CoV) and avian influenza A viruses (H5N1 and H7N9). Influenza and RSV are the most commonly identified viral pathogens; others include parainfluenza virus, rhinovirus, coronavirus, and human metapneumovirus. Influenza should be considered during periods of peak activity within a community and is often associated with sudden fever, myalgias, and cough. RSV is a more common cause of pneumonia in immunocompetent adults than previously appreciated. Characteristics include seasonal occurrence (winter) and association of bronchospasm. MERS-CoV is a novel coronavirus identified in the fall of 2012 in Saudi Arabia; it is different from the coronavirus previously associated with severe acute respiratory syndrome (SARS). Most persons infected developed a severe acute respiratory illness and about a third died. MERS-CoV is a zoonotic virus; available evidence suggests infection occurs through contact with camels, although transmission from person-to-person and to healthcare providers has occurred. A few cases from travelers have been reported in the United States. Clinicians are advised to consider this in patients with compatible illnesses who have traveled to the Arabian Peninsula or neighboring countries.

A strain of avian influenza (influenza A H7N9) was identified in China in 2013. Most people infected have had contact with poultry, and available evidence suggests there is no ongoing spread from person to person. Symptoms begin with high fever and cough. While mild cases have been seen, most patients have severe respiratory illness with a mortality rate of approximately 40%.

Diagnosis

Laboratory tests used for the diagnosis of the etiologic agents associated with atypical pneumonia are listed in Table 31.2. Until

TABLE 31.2 **DIAGNOSTIC STUDIES FOR PATHOGENS ASSOCIATED WITH ATYPICAL PNEUMONIA**

Pathogen	Rapid test	Standard culture or microbiologic test(s)	Serology,[c] other tests
M. pneumoniae	PCR [95]*	Throat or NP swab [90] (requires 7–10 days for preliminary growth)	ELISA, CF [75–80] (IgM may be present after 1 week but can persist 2–12 months) Diagnostic criteria: Definite: 4-fold titer rise Possible: IgG ≥1:64 (CF) IgM ≥1:16 (ELISA) Cold Agglutinin [50] [<50% specificity; takes weeks to develop)
C. pneumoniae	PCR [80–90]	Throat or NP swab-requires cell culture technique, rarely done [50–90]	CF or MIF (latter not as available) (IgM may take up to 4–6 weeks to appear in primary infection) Diagnostic criteria: Definite: 4-fold titer rise Possible: IgG ≥1:512 IgM ≥1:32
Legionella pneumophila	Urine Antigen (serogroup 1) [60–70] PCR[a]	Sputum, bronchoscopy [75–99] (selective media required, 2–6 days)	IFA[c] ELISA [40–75] Diagnostic criteria: Definite: 4-fold titer rise Possible: IgG or IgM ≥1:512 (titer of a:256 has positive predictive value of only 15%)
C. psittacosis	PCR[a]	Usually not done (considered laboratory hazard)	CF (Presumptive IgG ≥1:32) MIF for IgM
Coxiella burnetii	PCR[a]	Usually not done (considered laboratory hazard)	IFA (current reference method)
Viruses Influenza RSV Adenovirus	Rapid Antigen Detection (EIA)[b], PCR Antigen Detection (IF or EIA; mainstay of diagnosis), PCR PCR PCR	Virus isolation Virus isolation Virus isolation	CF or HAI, ELISA ELISA ELISA
Francisella tularensis	PCR (not available in general laboratories)	Culture (selective media; considered laboratory hazard)	ELISA preferred; passive hemagglutination
Yersinia pestis	Gram Stain, morphology, gram-negative coccobacillus exhibiting bipolar staining ["safety pin"]; PCR	Culture (considered laboratory hazard)	ELISA, IF
Bacillus anthracis (Inhalation Anthrax)	PCR	Culture (may be dismissed as *Bacillus* contaminant)	

Numbers in brackets ([ ]) indicate % sensitivity of test.
[a] In selected laboratories; reagents are not FDA-cleared.
[b] Low sensitivity for 2009 influenza A N1N1.
[c] Paired sera generally required.
Abbreviations: ELISA = enzyme-linked immunosorbent assay, CF = complement fixation, HAI = Hemaggluination inhibition; IF = Immunofluorescence; MIF = microimmunofluorescence, IFA = indirect fluorescence Ab

recently serologic tests were the most common means of laboratory diagnosis for most pathogens associated with atypical pneumonia but are less valuable given the requirement for measurement during acute and convalescent specimens. However, advancements in molecular testing methods have produced new potentials for diagnosis and more rapid identification of these pathogens. Nucleic acid amplification tests (NAATs), such as polymerase chain reaction (PCR), are becoming available with marked expansion of diagnostic capability for infectious diseases. There are several commercially available and/or institutionally developed NAATs for the atypical pathogens. Tests approved by the US Food and Drug Administration (FDA) are available for *Mycoplasma*, *Chlamydia*, and *Legionella* (as part of multiplex PCR) and most respiratory viruses. Present evidence suggests testing for atypical pathogens in patients admitted for CAP is poorly standardized in real life and does not mirror atypical prevalence in different settings.

Although the isolation of *M. pneumoniae* on specialized media is possible, culture requires 2 to 3 weeks and the organism is fastidious. As a result, most clinical laboratories do not attempt to culture this organism. Cold agglutinins, which are immune-mediated, are often positive in patients with *M. pneumoniae*. *C pneumoniae* can be cultured on cell lines, but this is rarely used by standard laboratories. *Legionella* can be readily isolated from respiratory specimens but requires specialized media-buffered charcoal yeast extract agar (BYCE). A urinary antigen test is available for *L. pneumophila* serogroup 1, which represents the most common cause of *Legionella* pneumonia in the United States; sensitivity for *L. pneumophila* serogroup 1 is approximately 70 to 80%, with a specificity close to 100%.

Several of the other causes of atypical pneumonia can be isolated by culture, including *Francisella, Yersinia, C. psittaci,* and *Bacillus anthracis*. Since these agents can be potentially transmitted from laboratory isolates, if there is a clinical suspicion the laboratory should be notified to optimize growth conditions and take proper precautions to reduce the risk of infection among laboratory personnel. Blood cultures are often positive for *Yersinia* infection. For *C. psittaci*, *Coxiella,* and *F. tularensis,* serology is the primary means of diagnosis.

For most respiratory viruses, PCR is now the most sensitive diagnostic approach. PCR was vital for epidemiology during the 2009 influenza H1N1 pandemic because commercially available rapid influenza detection tests (RIDTs) were found to be relatively insensitive (sensitivity ranging from 10% to 70% depending in part on the method used).

Antimicrobial therapy

Antimicrobial agents generally considered effective for these atypical pathogens are included in Tables 31.1, 31.3, and 31.4. Since most cases of atypical pneumonia are treated empirically, clinicians need also to consider the possibility of other standard pathogens (i.e., *S. pneumoniae, H. influenzae*) when deciding on antimicrobial therapy.

TABLE 31.3 **AUTHOR'S RECOMMENDATION FOR ANTIMICROBIAL THERAPY OF *M. PNEUMONIAE* AND *C. PNEUMONIA* (ADULT DOSES[a])**

Antimicrobial	Dose	Duration (days)
Clarithromycin (Biaxin)	500 mg BID	7
Azithromycin (Zithromax)[b]	500 mg initially then 250 mg/d (alternative 500 mg/d)	5 (3)
Dirithromycin (Dynabac)	500 mg/d	7
Doxycycline[b]	100 mg BID	7
Omadacycline	100 mg BID IV for 2 days then Daily; can switch to 300 mg PO	7
Levofloxacin (Levaquin)[b]	500 mg/d 750 mg/d	7 5 (data limited)
Moxifloxacin (Avelox) [b]	400 mg/d	7
Gemifloxacin (Factive)	320 mg/d	5
Delafoxacin[c]	300 mg IV, q12h for at least 6 doses with	5–7
Lefamulin[c]	potential to switch to 450 mg oral tablet 150 mg IV BID or 350 mg PO	5–7

[a] Oral except where noted.
[b] Also can be administered intravenously in equivalent dose.
[c] Completed phase 3 study.

Mycoplasma and *Chlamydia*

Appropriate treatment (especially for *M. pneumoniae*) reduces the morbidity of pneumonia and shortens duration of symptoms. Erythromycin and tetracyclines (e.g., doxycycline) have been considered effective therapy. The newer macrolides (clarithromycin and azithromycin) have good in vitro activity against these organisms, and have shown good results in clinical studies. Although resistance to the macrolides is relatively low in the United States (<10%), the prevalence of macrolide-resistant *Mycoplasma* in Asia is very high (up to 70–90% in some areas). The newer fluoroquinolones (i.e., levofloxacin, moxifloxacin, gemifloxacin) are bactericidal and have been shown to be effective in clinical trials.

Legionella

There is little debate concerning the need for therapy in *Legionella* pneumonia. Therefore, empirical therapy should be included in treatment of severe CAP. Macrolides initially have been considered the treatment of choice for Legionnaires' disease. However, intracellular models as well as animal models of *Legionella* infection indicate that the systemic fluoroquinolones and the newer macrolides (especially azithromycin) show superior activity compared with erythromycin. Several observational studies suggest that quinolones produce superior clinical responses compared with macrolides. The addition of rifampin to erythromycin has been suggested for patients who are severely ill; however, there is no convincing laboratory data to show that adding rifampin to fluoroquinolones or the more active macrolide therapy improves bacterial killing. I prefer the newer fluoroquinolones because of greater activity in vitro against *S. pneumoniae* (including drug-resistant strains) and other common causes of CAP that need to be considered for empirical therapy (Table 31.4). Doxycycline has also been shown to be effective in limited, well-documented cases for *L. pneumophila*, but *L. longbeachae* is often resistant. Oral therapy for less serious cases or for step-down from intravenous (IV) therapy includes the oral macrolides and fluoroquinolones as well as doxycycline.

More recently FDA-approved antimicrobials or those in late-stage development with activity against *Mycoplasma* and *Chlamydia* as well as *Legionella* include delafloxacin, omadacycline, and lefamulin.

The duration of therapy for optimal response of *C. pneumoniae* and *M. pneumoniae* has not been well established. In initial descriptions of *C. pneumoniae* pneumonia, observers found that respiratory symptoms frequently recurred or persisted after short courses (5–10 days) of erythromycin or tetracycline. In recent recommendations, the usual duration of therapy for *C. pneumoniae* or *M. pneumoniae* using more recently approved agents has been 7 to 10 days (shorter for azithromycin because of its longer half-life); however, recent studies (mostly with the fluoroquinolones) have suggested that a minimum of 5 days may be adequate for immunocompetent patients if the patient has had a good clinical response within 48 to 72 hours. Similarly, the usual duration of therapy for Legionnaires' disease of immunocompetent adults has been 7 to 14 days; one recent study showed good efficacy of 750 mg/d of levofloxacin for 5 days. For therapy of immunocompromised patients or more severe disease, longer duration is recommended.

Therapy for other pathogens associate with atypical pneumonia

For details, please see Table 31.1.

C. psittaci. The tetracyclines (e.g., doxycycline 100 mg orally twice daily) are generally considered the drugs of choice, with the macrolides as appropriate alternatives. The newer fluoroquinolones are active in vitro and in animal models but their efficacy for human infection is unknown.

C. burnetii. Doxycycline is the preferred agent; macrolides or fluoroquinolones are alternatives. Prolonged therapy (e.g., 18

TABLE 31.4 **PARENTERAL THERAPY FOR SERIOUS *LEGIONELLA* INFECTIONS**[a]

Preferred antimicrobial	Alternative antimicrobial
Fluoroquinolone Levofloxacin (Levaquin) 500 mg IV q24h [750 mg/d for 5 days possible for immunocompetent patients]	Doxycycline 100 mg IV q12h
Moxifloxacin (Avelox) 400 mg IV q24h	
Azithromycin (Zithromax) 500 mg IV q24h	-- -- -- -- -- -- -- -- -- -- -- -- -- -- -- --
-- -- -- -- -- -- -- -- -- -- -- -- -- -- -- --	
Newer Agents Delafloxacin** 300 mg IV, q12h Omadacycline 100 mg q12h IV for 2 days then daily Lefamulin[b] 150 mg IV q12h	

[a]Requiring hospitalization or in immunocompromised patients; can change to PO when clinically stable and can tolerate PO.
[b]Not FDA-approved at time of submission.

months) with hydroxychloroquine in combination with doxycycline is the preferred treatment regimen for Q fever endocarditis.

F. tularensis. Aminoglycosides are the drug of choice for severe infection. The traditional choice of therapy for pneumonic tularemia is streptomycin (10 mg/kg q12h up to 2 g/d for an adult); however, gentamicin (3–5 mg/kg/d) is more available and less toxic; treatment is for 7 to 14 days. An oral fluoroquinolone (ciprofloxacin, levofloxacin) or doxycycline (100 mg IV or PO BID) has often been used with good success in nonsevere ambulatory pneumonia and is easier to administer.

Hantavirus pulmonary syndrome. Treatment options are limited. Ribavirin has in vitro activity but clinical observations of efficacy are inconclusive. Optimal cardiopulmonary and fluid management is critical for appropriate management.

Y. pestis. Pneumonic plague has a mortality approximating 100% if untreated. Aminoglycosides are the preferred agents for plague, with doxycycline and tetracycline as alternatives. Streptomycin (similar dose/day as for tularemia) has been considered the drug of choice, with 10 days being the minimum recommended course of therapy; however, as with tularemia, gentamicin is now considered acceptable and preferred. Doxycycline is an alternative for those intolerant of gentamicin. Close contacts of patients with pneumonic plague should receive tetracycline (500 mg QID) or doxycycline (100 mg BID) for 5 to 7 days for prophylaxis.

Inhalation anthrax. The mortality rate remains high if treatment is not initiated prior to the development of clinical symptoms. Initial therapy of inhalation anthrax should include at least two agents effective against *B. anthracis,* which can be switched to monotherapy once the patient has stabilized and possible susceptibility test results are known. A commonly recommended initial regimen is ciprofloxacin (400 mg IV q8h) plus clindamycin (900 mg IV q8h) or linezolid (600 mg IV q12h). Adjunctive use of antitoxin should be administered as soon as possible. If anthrax is a concern as an agent of bioterrorism, it is important to provide prophylaxis to the population at risk. The preferred regimens are ciprofloxacin (500 mg PO BID), levofloxacin (500 mg/d), or doxycycline (100 mg PO BID). Amoxicillin 500 mg TID for an adult is acceptable if the associated *B. anthracis* strain has an amoxicillin MIC of 0.125 μg/mL or less. Prophylaxis should be continued for 60 days.

Influenza. Because of the high rates of resistance in the United States, amantadine and rimantadine are not recommended for treatment of seasonal influenza. A neuraminidase inhibitor (oseltamivir, zanamivir, or peramivir) is the recommended antiviral treatment. Peramivir is available for IV administration when oral therapy is unsuitable. Recently beloxavir, a selective inhibitor of influenza cap-dependent endonuclease, has been approved for seasonal influenza. Although there are no randomized clinical trials, oseltamivir is can be considered for the treatment of avian influenza A (including H5N1 and the newly described H7N9). There does appear to be a mortality benefit for H5N1 based on an analysis of a registry of 300 patients. While no data are available regarding treatment of persons with H7N9 influenza, laboratory testing indicates that most strains are susceptible to oseltamivir but resistant strains have been identified.

RSV. The routine use of ribavirin is not recommended for infants and children with RSV. The benefit of ribavirin therapy for adults has not been established; however, it has been shown to reduce morbidity and mortality in adult bone marrow transplant recipients who develop RSV infections.

MER-Cov. No specific antiviral therapy is presently available.

Community-acquired pneumonia

Keyur S. Vyas

Community-acquired pneumonia (CAP) continues to cause significant morbidity and mortality worldwide. In developed countries, most episodes occur in those elderly who have one or more chronic underlying diseases. Children are more commonly affected in the developing world. Morbidity and mortality from CAP remains high worldwide despite advances in antibiotic and intensive care therapy. Making the clinical diagnosis of pneumonia is usually not difficult; deciding which patients should be admitted to the hospital and selecting appropriate therapy, however, can be challenging.

Diagnosis and treatment

Pneumonia is suspected when one or more of the following is present: cough, purulent sputum, dyspnea, pleuritic pain, fever, chest auscultation findings consistent with pneumonia, leukocytosis, or a new pulmonary infiltrate on imaging. Once the diagnosis is suspected, the physician must decide whether hospitalization is necessary and. if so, whether intensive care unit (ICU) admission is appropriate.

A number of risk factors predict a complicated course (Box 32.1). Multiple scoring systems have been proposed to assess disease severity and predict mortality to assist in determining if hospitalization is necessary; two such systems are the CURB-65 score from the British Thoracic Society and the Pneumonia Severity Index (PSI) from the Pneumonia Patient Outcomes Research Team (PORT). The PSI assigns points for 19 variables based on age and comorbidities similar to those listed in Box 32.1. Patients are then assigned to one of five risk categories. Patients in risk groups I and II can be managed as outpatients, whereas risk groups III–V should be hospitalized. The CURB-65 criteria include confusion, blood urea nitrogen (BUN) (>20 mg/dL), respiratory rate (>30 breaths/minute), blood pressure (systolic ≤90 mm Hg or diastolic ≤60), and age (≥65 years). Patients with 0 to 1 of these findings can be managed as outpatients. Those with a score of 2 should be admitted to hospital, whereas those with 3 or more should receive ICU care. The PSI gives a more accurate prediction of which patients can be safely managed outside the hospital. The CURB-65 is less cumbersome and easier to use in the outpatient setting. Various biomarkers have been proposed to assist in risk stratification, with procalcitonin (PCT) being the most widely studied and increasingly used in clinical practice. PCT is elevated in bacterial infections compared to nonbacterial processes. Its utility in determining the need for initiation of antibiotics is debatable; however, studies have shown it to be a useful adjunct in guiding de-escalation and discontinuation of antibiotics, especially as part of antibiotic stewardship efforts. Risk stratification guides and biomarker measurements are useful adjuncts to assist the clinician's judgment, which remains the ultimate decision-making tool.

Accurate history, including occupation; travel; exposure to animals, birds, and insects; sick contacts; recent dental work; and history of alcohol or drug abuse may suggest a causative agent (Table 32.1). Bacteria and respiratory viruses cause the majority of CAP, with a minority of cases caused by fungi, such as the endemic mycoses. Geographic variations affect the spectrum and proportion of causative agents. A significant

BOX 32.1

Predictors of a complicated course in patients with community-acquired pneumonia

Suspicion of high-risk cause (*Staphylococcus aureus*, gram-negative bacilli, aspiration, or postobstructive process)
Age >50 years
Prior episode of pneumonia
Consolidation, multilobe involvement, or pleural effusion on chest radiograph
Abnormalities on physical examination:
- Temperature ≤95°F (35°C) or >104°F (40°C)
- Systolic or diastolic blood pressures ≤90 mm Hg or ≤60 mm Hg,
- Respectively
- Respiratory rate ≥30 breaths/minute
- Heart rate >125 beats/minute
- Extrapulmonary areas of infection

Laboratory factors
- Abnormal renal function (BUN >20 mg/dL or serum creatinine >1.2 mg/dL)
- Sodium ≤130 mg/dL
- Glucose ≥250 mg/dL
- Hematocrit ≤30%
- WBC count ≤4,000/mm^3 or >30,000/mm^3
- Metabolic acidosis (pH ≤7.35)
- PaO_2 ≤60 mm Hg breathing room air

Comorbid conditions
- Renal insufficiency
- Congestive heart failure
- Liver disease
- Diabetes mellitus
- Altered mental state
- Neurologic disease
- Alcoholism
- Immunosuppression
- Malignancy
- Splenectomy
- No responsible person in the home to assist the patient

Abbreviations: BUN = blood urea nitrogen; WBC = white blood cell.

TABLE 32.1 **RELEVANT CLINICAL HISTORY RELATED TO SPECIFIC PATHOGENS**

Anaerobes (oral)	Alcoholism, aspiration, lung abscess, recent dental work, endobronchial obstruction
Bordetella pertussis	Cough ≥2 weeks with whoop or vomiting after cough
Burkholderia cepacia	Bronchiectasis
Chlamydia pneumoniae	COPD, smokers, biphasic illness
Chlamydia psittaci	Bird exposure
Coccidioides immitis	Travel to Southwest United States
Coronaviruses (SARS and MERS)	Travel to or residence in East Asia or the Middle East or with outbreak in other countries
Coxiella burnetii	Farm animal or pregnant cat exposure, hepatosplenomegaly
Francisella tularensis	Exposure to wild mammals, esp. rabbits and ticks in endemic areas
Haemophilus influenzae	COPD, smokers, HIV, postinfluenza
Hantavirus pulmonary syndrome	Pulmonary edema, hemoconcentration, thrombocytopenia esp. after travel to Southwest United States
Histoplasma capsulatum	Bat or bird droppings, cave exploration
Influenza	Seasonal outbreak. Travel to or residence in Asia: avian influenza
Klebsiella pneumoniae	Alcoholics
Legionella spp.	Hotel or cruise ship
Moraxella catarrhalis	COPD, smokers
Mycobacterium tuberculosis	Alcoholics, HIV, elderly, injection drug use
Mycoplasma pneumoniae	Prominent cough, hyperreactive airways, hemolytic anemia
Pneumocystis jirovecii	HIV, chronic corticosteroid use
Pseudomonas aeruginosa	COPD, bronchiectasis
Staphylococcus aureus	Postinfluenza, endobronchial obstruction, injection drug use
Streptococcus pneumoniae	Most common through all age groups, alcoholics, postinfluenza

Bacillus anthracis (anthrax), *Yersinia pestis* (plague), and *Francisella tularensis* (tularemia) would be the most likely bacterial bioterrorism agents to cause pneumonia.
Abbreviations: COPD = chronic obstructive pulmonary disease; SARS = severe acute respiratory syndrome; MERS = Middle East respiratory syndrome; HIV = human immunodeficiency virus.
Adapted from Infectious Diseases Society of America and American Thoracic Society Consensus Guidelines 2007.

proportion of cases may be polymicrobial, most commonly bacteria in combination with either atypical bacteria or respiratory viruses. A causative agent is identified in only about half of cases of CAP even with extensive testing. Most cases are treated empirically without identification of a specific cause, especially in the outpatient setting.

Streptococcus pneumoniae is the most commonly identified bacterial pathogen in all treatment settings, followed by atypical bacterial agents (*Chlamydia pneumoniae and Mycoplasma pneumoniae),* and *Haemophilus influenzae*. The incidence of pneumonia due to *S. pneumoniae* is falling in North America compared to Europe, likely due to increased use of pneumococcal vaccines and decreased rates of smoking. *Staphylococcus aureus* causes only 1% to 3% of cases of CAP but is associated with significant morbidity and mortality, especially in younger adults. Respiratory viruses are a significant cause of CAP in up to a third of cases. There are no unique clinical features of any pathogen that allow a specific identification by history alone.

HIV disease should be a diagnostic consideration in most patients hospitalized with CAP.

Laboratory studies (Box 32.2 and Table 32.2) may be useful in diagnosis and management. The extent of the evaluation should depend on the severity of illness and the likelihood that test results will influence therapy. Diagnostic studies are usually unnecessary for patients treated on an outpatient basis because empiric antimicrobial choices adequately treat most common bacterial etiologies. Hospitalized patients should have, at a minimum, routine laboratory studies including a CBC with differential, a chest radiograph, and arterial blood gases, especially if hypoxic. Blood cultures are diagnostic in up to 14% of patients hospitalized for CAP. They are most useful in patients with severe CAP (Table 32.2). The Gram stain and culture of expectorated sputum is most useful in patients with severe CAP (Table 32.2). The sputum specimen should be grossly purulent, obtained by deep cough (or tracheal aspirate), and processed in <2 hours. Minimum criteria for a specimen suitable for culture are <10 squamous epithelial cells or >25 polymorphonuclear neutrophils (PMNs) per low-power field. Sputum studies can be diagnostic for *Legionella*, mycobacteria, fungi, and *Pneumocystis jirovecii* (Box 32.2). Molecular diagnostic tests such as polymerase chain reaction amplification assays may be performed on nasopharyngeal or lower respiratory tract specimens for many pathogens including *S. pneumoniae, Mycoplasma pneumoniae, Chlamydia pneumoniae, Bordetella pertussis*, and respiratory viruses. A parapneumonic pleural effusion is a common complication of pneumonia, and cultures obtained by thoracentesis will often give a positive result. The incidence of pleural effusion with pneumonia depends on the etiologic agent, accompanying approximately 95% of *Streptococcus pyogenes* infections but only 10% of *S. pneumoniae* infections. Sampling of the lower respiratory tract via bronchoalveolar lavage, bronchoscopic protected specimen brushings, or quantitative endotracheal aspirates may be useful in cases of nonresolving pneumonia. Transthoracic needle aspiration and lung biopsy should only be considered in severely ill patients not responding to therapy for whom less invasive techniques are nondiagnostic.

Urinary antigen tests (UAT) may be useful in *Legionella* spp. and *S. pneumoniae* infections. Both tests have a >90% specificity. The *S. pneumoniae* UAT may yield a diagnosis even after starting antibiotics. The *Legionella* UAT is positive in 74% of cases due to serogroup I, which causes most cases of community-acquired Legionnaires' disease in the United States. Serologic studies may aid in the confirmation of atypical bacterial causes of CAP but are rarely helpful in antibiotic choice. A fourfold rise in serologic titer, which often takes several weeks, is necessary for confirmation. Cross-reactivity among some organisms lessens the specificity of serology. A definitive microbial cause is identified in only a minority of patients even after extensive testing.

BOX 32.2

Routine studies useful in the diagnosis and management of patients hospitalized with community-acquired pneumonia

Chest radiograph (posterior and lateral)
Arterial blood gas values (for hospitalized patients). Pulse oximetry should be obtained for patients judged suitable for outpatient therapy.
Complete blood count with differential
Chemistry panel, including electrolytes, glucose, blood urea nitrogen, and creatinine
Aminotransferases
Blood culture (2 sets drawn 10 minutes or more apart)
Not necessary for all patients. See Table 32.4.
Pleural fluid gram stain, culture, leukocyte count with differential, pH
Sputum studies (for pneumonia unresponsive to usual antibiotics, see Table 32.4):
- Acid-fast stain and culture
- Fungal stains and culture
- *Legionella* spp. Culture
- Immunofluorescent antibody, Gomori's methenamine silver, or
- Giemsa stain for *Pneumocystis jirovecii* (*carinii*)
- A Gram stain (from an appropriately obtained specimen, examined by an expert within 2 h of collection before the patient has received antibiotics)

Urinary antigen
- *Streptococcus pneumoniae*
- *Legionella* spp.

Serology (for patients with appropriate epidemiologic history)
- HIV serology
- *Legionella* spp.
- *Francisella tularensis*
- *Mycoplasma pneumoniae*
- *Chlamydia (pneumoniae and psittaci)* spp.
- *Coxiella burnetii*

Abbreviation: HIV = human immunodeficiency virus.

Recommendation for empiric selection of antimicrobial agents

Delay in antibiotic therapy for CAP increases morbidity and mortality. Empiric selection of antimicrobials is necessary in most cases. Selection of appropriate antibiotics is facilitated by categorizing patients by age and severity of illness, comorbidities, and epidemiologic factors. Some microbes cause disease in all ages and types of patients; others are common only in patients with certain comorbidities (Boxes 32.3 to 32.6).

Among patients with mild pneumonia not requiring hospitalization (Box 32.3), *S. pneumoniae* is the most common bacterial pathogen. The atypical pneumonias (*M. pneumoniae* and *C. pneumoniae*) are also common and are generally benign, with systemic complaints often more prominent than respiratory ones. Fever, headache, and myalgia are frequent. Leukocytosis is rare, and chest infiltrates consist primarily of segmental lower lobe or hilar infiltrates. *M. pneumoniae* is more common among patients

<30 years of age but is recognized with increasing frequency in older persons. *M. pneumoniae* is characterized by a prominent cough, often occurs in slowly evolving epidemics, and can precipitate reactive airway disease, especially in children. *C. pneumoniae* is a common cause of mild, often biphasic illness, initially with upper respiratory symptoms and pharyngitis with development of pneumonia 2 or 3 weeks later. Reinfection is common. Macrolides such as azithromycin and clarithromycin are the drugs of choice for treating outpatient pneumonia in low-risk patients. However,

BOX 32.3

Guidelines for empiric antibiotic therapy for community-acquired pneumonia in outpatients younger than 50 years with no comorbid illness

Common pathogens

Streptococcus pneumoniae
Mycoplasma pneumoniae
Chlamydia pneumoniae
Respiratory viruses

Antibiotics

Macrolide[a]
Azithromycin, 500 mg PO day 1, then 250 mg/d
Clarithromycin, 250 mg PO BID
If macrolide intolerant:
Doxycycline 100 mg PO BID

[a] If >25% *S. pneumoniae* macrolide-resistant (minimal inhibitory concentration [MIC] ≥16 μg/mL) in a community: levofloxacin 750 mg PO daily, or moxifloxacin 400 mg PO daily.

BOX 32.4

Guidelines for empiric antibiotic therapy for community-acquired pneumonia in patients older than 50 years or with comorbid illness not requiring hospitalization

Common pathogens

Streptococcus pneumoniae
Legionella spp.
Haemophilus influenzae
Moraxella catarrhalis
Other gram-negative bacilli
Respiratory viruses

Antibiotics

Fluoroquinolone as a single agent
Levofloxacin 750 mg PO daily
Moxifloxacin 400 mg PO daily
Or
Macrolide[a]
Azithromycin, 500 mg PO day 1, then 250 mg/d
Clarithromycin, 250 mg BID
And
β-lactam
Amoxicillin 1 g TID
Amoxicillin-clavulanate 2 g BID
Ceftriaxone, cefpodoxime, cefuroxime

[a] Doxycyline 100 mg BID may be substituted in macrolide-intolerant patients.

BOX 32.5

Guidelines for empiric antibiotic therapy for community-acquired pneumonia in patients requiring hospitalization (not intensive care)

Common pathogens

Streptococcus pneumoniae
Mycoplasma pneumoniae
Chlamydia pneumoniae
Haemophilus influenzae
Legionella spp.
Aspiration
Respiratory viruses

Antibiotics

Fluoroquinolone[a]
Levofloxacin 750 mg IV/PO daily
Moxifloxacin 400 mg IV/PO daily
Or
Macrolide[b]
Azithromycin, 500 mg PO day 1, then 250 daily
Clarithromycin, 250 mg BID
And
β-lactam
Cefotaxime, ceftriaxone, ampicillin, ertapenem

[a] Second regimen should be substituted if fluoroquinolones have been used in the previous 3 months.

[b] Doxycyline 100 mg BID may be substituted in macrolide-intolerant patients.

Guidelines for empiric antibiotic therapy for community-acquired pneumonia in patients requiring intensive care hospitalization

Common pathogens

Streptococcus pneumoniae
Legionella spp.
Staphylococcus aureus[a]
Haemophilus influenzae
Pseudomonas aeruginosa
Enterobacteriacae spp.
Gram-negative bacilli
Aspiration
Respiratory viruses

Antibiotics[a]

β-lactam[b]
Ceftriaxone, cefotaxime, or ampicillin–sulbactam
And
Azithromycin or respiratory fluoroquinolone

[a] If *S. aureus* infection is suspected, either vancomycin or linezolid should be added to the preceding regimen.

[b] If *P. aeruginosa* is a likely organism, an antipseudomonal β-lactam (piperacillin–tazobactam, cefepime, imipenem, or meropenem) should be substituted for the β-lactams listed earlier. Either ciprofloxacin or levofloxacin should accompany the antipseudomonal β-lactam or the combination of an aminoglycoside with azithromycin.

mycoplasma resistance to macrolides is a growing problem, particularly in Asia. Doxycycline can be used for those who are macrolide intolerant.

Patients who are >50 or have comorbid illnesses (Box 32.4) are more likely to require hospitalization. Some can be managed as outpatients but will require close follow-up, preferably within 3 days. Gram-negative organisms, such as *Haemophilus influenzae* and *Moraxella catarrhalis*, are more common, particularly in persons who smoke or have chronic obstructive pulmonary disease (COPD). A respiratory fluoroquinolone, such as levofloxacin or moxifloxacin, is an acceptable choice for these patients unless they have received a fluoroquinolone in the previous 3 months or are allergic to them, in which case a macrolide plus a β-lactam should be given.

Patients hospitalized with pneumonia of moderate severity require empiric therapy to cover the organisms listed in Box 32.5. The first antibiotic dose should be given as soon as the diagnosis is made.

Empiric antimicrobial therapy for hospitalized patients should include either a respiratory fluoroquinolone alone or a macrolide combined with a β-lactam antibiotic. If fluoroquinolones have been used in the previous 3 months, the latter regimen is preferred. Ertapenem is as efficacious as ceftriaxone but has not been extensively studied. It is useful when a broader spectrum agent is necessary to cover anaerobes and gram-negative organisms, but it is not active against *Pseudomonas aeruginosa*. Ceftaroline, the first cephalosporin with methicillin-resistant *S. aureus* (MRSA) activity, is noninferior to ceftriaxone for CAP requiring hospitalization. Tigecycline, a glycylcycline with MRSA and anaerobic activity, is noninferior to levofloxacin in hospitalized patients with CAP. Neither ceftaroline nor tigecycline has activity against *Pseudomonas*. Given the efficacy and safety of current antibiotics for CAP, the use of these newer agents should be limited to specific circumstances when standard antibiotics are not appropriate. When the etiologic agent and its sensitivity are known, the antibiotic regimen should be as narrow and as cost-effective as possible.

Severe pneumonia causes increased mortality, ranging from 50% to 70% in some studies, especially during the first 7 days. Severe pneumonia manifests as hypoxia, tachypnea, multilobe involvement or consolidation, and signs of septic shock. These patients should receive ICU care. Organisms listed in Box 32.6 may cause more severe disease, although the severity of the pneumonia and ultimate outcome is more a function of the immune response of the host. Initial antimicrobial therapy should include either a macrolide or fluoroquinolone plus a β-lactam. Several retrospective studies indicate that the combination of a β-lactam plus macrolide may result in better outcomes especially in cases of severe CAP, although current guidelines do not include the obligatory addition of macrolides in this setting. Persons requiring ICU monitoring should have blood cultures drawn and sputum studies for Gram stain and culture. Empiric antibiotic choices should take into account organisms on

the Gram stain. Gram-positive cocci in clusters suggests *S. aureus,* which is often seen as a complication of influenza. MRSA is commonly found in the community and may cause a severe necrotizing pneumonia. For persons admitted to the ICU with severe pneumonia and clusters of gram-positive cocci in the sputum or cavitary lesions in the lung, initial therapy should include either vancomycin or linezolid. If vancomycin is used, strong consideration should be given to the addition of clindamycin. Linezolid and clindamycin have been shown in vitro to decrease bacterial toxin production. When a patient admitted to the ICU has severe structural defects of the lung (COPD or bronchiectasis) and gram-negative organisms in the sputum, initial antibiotics should have antipseudomonal activity (see Box 32.6).

Although rare, tularemic pneumonia should be considered in patients with exposure to wild mammals, especially rabbits, and ticks. Intravenous gentamicin should be given when tularemic pneumonia is considered. *Coxiella burnetii* causes an atypical pneumonia often accompanied by hepatosplenomegaly. It is endemic in many hot, dry areas. The most common reservoirs are sheep, goats, cattle, and ticks. Tetracycline or doxycycline is the recommended therapy. *Chlamydia psittaci* is an atypical pneumonia that should be considered in patients with exposure to birds, especially parrots. Splenomegaly and an atypical pneumonia suggests psittacosis, which is treated with tetracycline or doxycycline. *Mycobacterium tuberculosis* should be considered early when pneumonia does not respond to usual antibiotics. Fungal infections, such as blastomycosis, histoplasmosis, cryptococcosis, and coccidioidomycosis, may also present as a CAP and should be considered in persons with soil exposure or residence in or travel to endemic areas.

Viruses are responsible for up to one-third of the cases of CAP. Influenza A and B viruses are common worldwide and cause yearly seasonal epidemics. Influenza A viruses can also cause pandemics such as that caused by the 2009 novel H1N1 virus. Influenza can cause a primary viral pneumonia or predispose to secondary bacterial pneumonia, especially due to *S. aureus* or *S. pneumoniae*. Avian influenza virus infections such as H5N1 and H7N9, while limited in number, are important due to the very high case fatality rates (~50%), typically due to overwhelming pneumonia. Other viruses associated with CAP include parainfluenza, rhinoviruses, adenoviruses, and coronaviruses. Human metapneumovirus (hMPV) most commonly occurs in late winter or early spring in young children and adults >65 years, with symptoms ranging from mild disease to severe pneumonia. hMPV may cause exacerbations of asthma. Human bocavirus and parechovirus types 1, 2, and 3 cause lower respiratory tract infection in children. Respiratory syncytial virus (RSV) can cause CAP in adults, particularly those who are immunocompromised. Two novel human coronaviruses (CoV) have been implicated in severe respiratory infection. Severe acute respiratory syndrome (SARS) caused by the SARS CoV, was first identified in 2002, in China and Southeastern Asia, resulting in >8,000 infections worldwide with a 10% case fatality rate before the last cases were seen in the summer of 2003. In 2012, a severe respiratory illness with a high case fatality rate was identified in Saudi Arabia and Jordan. This Middle Eastern respiratory syndrome (MERS) is due to a novel coronavirus, MERS-CoV. As of April 2019, >2,400 cases with a case fatality rate of 34% have been identified, with the majority of cases occurring on the Arabian Peninsula. Treatment for all these viruses, except for influenza, is supportive. The neuraminidase inhibitors, oseltamivir, zanamivir, and peramivir decrease the duration of illness and may reduce complications seen with influenza and the spread of influenza to other patients. They should be given within the first 48 hours of symptom onset; however, patients requiring hospitalization or at high risk for complications from influenza, including pregnant women, persons with immunocompromise, or persons with underlying chronic medical illnesses, should be treated even if they present beyond 48 hours of symptom duration. Baloxavir is a cap-dependent endonuclease inhibitor used to treat influenza. Studies show similar efficacy to oseltamivir, but there are concerns for the development of resistance. The adamantanes, amantidine and rimantidine should not be used to treat influenza due to widespread resistance.

Therapeutic response

Antibiotic choices should generally not be altered during the first few days of therapy unless there is marked deterioration or cultures indicate the need for a change. Usually 48 to 72 hours are required for significant clinical improvement. Fever usually lasts 2 to 4 days but may last longer, especially in persons with bacteremia. The white blood cell count generally returns toward normal after 4 days, and blood cultures become negative 24 to 48 hours after starting treatment. Duration of therapy should be individualized according to the infecting organism, response to treatment, and the overall health of the patient. Antibiotic therapy for 5 to 7 days is generally sufficient, especially in persons treated as outpatients or those inpatients who have timely response to therapy. Routine prolongation of therapy beyond 8 days is not usually beneficial. Because of its long tissue half-life, azithromycin may be given for a shorter durations. Patients with pneumonia caused by *S. pneumoniae* should usually receive antibiotics for 72 hours after the resolution of fever. Persons who are bacteremic, immunocompromised, or develop lung abscess or empyema may require longer courses. When the patient is hemodynamically stable, improving clinically, and tolerating oral intake, transition to oral antimicrobials should be considered. It is not necessary that the patient be afebrile, but the fever curve should be improving. Persons with *S. aureus* pneumonia should receive at least 2 weeks of treatment unless a hematogenous source is suspected, in which case therapy should be continued for a minimum of 4 weeks.

Resolution of abnormal radiographic findings lags behind clinical improvement and is slower in elderly patients, smokers, and those with comorbidities or multilobe involvement. Multiple chest radiographs in the hospital are unnecessary except for intubated patents and those with clinical deterioration. Patients who are >40 years of age or are smokers should be followed until complete radiographic resolution of the infiltrate is demonstrated with follow-up chest radiographs obtained between 7 and 12 weeks after completion of therapy. If abnormalities have not resolved or greatly improved, the possibility of an occult neoplasm should be considered.

There are a number of reasons for failure in the treatment of CAP. The serum level of the chosen antibiotics may not be high enough. Some antibiotics, such as the aminoglycosides, may not achieve high

enough concentrations in the lung tissue. The etiologic agent may be resistant to the antibiotics, or less likely, resistance may develop during therapy. Initial improvement followed by recurrent fever may be due to the development of thrombophlebitis, empyema, lung abscess, or drug fever. Lack of clinical improvement should raise suspicion for alternative etiologies, such as viruses, mycobacteria, fungi, or parasites. Choice of antibiotic, dosage, and route of administration should be re-evaluated in this setting. Clinicians must always keep in mind the possibility of noninfectious mimics of pneumonia, such as pulmonary infarction, organizing pneumonia, carcinoma, pulmonary edema, atelectasis, sarcoidosis, hypersensitivity pneumonitis, and drug-induced pulmonary disease.

Nosocomial pneumonia

Cheston B. Cunha and Burke A. Cunha

Introduction

Nosocomial pneumonia (NP) may be defined as pneumonia that occurs after 5 or more days in hospital. NP is synonymous with hospital-acquired pneumonia (HAP). The subset of NP/HAP patients on ventilators are referred to as *ventilator-associated pneumonias* (VAP). NP occurring early (i.e., <5 days after admission) actually represents incubating community-acquired pneumonia (CAP) that has become clinically manifest early after hospital admission. For this reason, the respiratory pathogens causing "early NP" are the usual CAP pathogens (e.g., *Streptococcus pneumoniae*). With true NP (≥5 days after admission), the respiratory pathogens acquired in hospital are aerobic gram-negative bacilli (GNB). The most important, but not the most common, NP pathogen is *Pseudomonas aeruginosa*; some other GNB are also important NP pathogens (e.g., *Klebsiella pneumoniae*) (Box 33.1).

In this chapter, the term "NP" is used rather than a designation of the clinically meaningless healthcare-associated pneumonia (HCAP). Nursing home-acquired pneumonias (NHAP) are not the same as NP. First, the pathogens differ. NHAP pathogens are the same as CAP pathogens (e.g., *S. pneumoniae, Haemophilus influenzae*). Even though the respiratory secretion and urine/feces of nursing home/chronic care facility residents may be colonized by "hospital organisms" (e.g., GNB), these organisms are not NHAP pathogens (i.e., they do not cause NHAP). Pathogens aside, the NHAP mean length of stay (LOS) is approximately 7 days, which is the same LOS (~7 days) as for hospitalized CAP. This is in marked contrast to the NP LOS (~14 days). For these reasons, it is clinically important to differentiate NHAP from NP and not combine them as HCAP.

Mimics of nosocomial pneumonia

Because the definition of NP is based on epidemiologic rather than pathologic criteria, there are many noninfectious disorders that fit the epidemiologic definition of NP. In intensive care unit (ICU) patients, there are many mimics of NP with fever, leukocytosis, hypoxemia, and pulmonary infiltrates on chest x-ray (CXR). Many of these mimics of NP have pulmonary infiltrates but are disorders unassociated with fever/leukocytosis. In such patients with mimics of NP, the fever/leukocytosis are due to unrelated extrapulmonary processes (e.g., drug fever, phlebitis, cerebrovascular accidents, myocardial infarction, gastrointestinal bleed, adrenal insufficiency). Patients with acute respiratory distress syndrome (ARDS) often have fever/leukocytosis, hypoxemia, and pulmonary infiltrates that are unrelated to NP but rather are due to drug-induced pancreatitis mimicking NP. Other mimics of NP may have fever. In such cases, the diagnosis is usually suggested by associated extrapulmonary signs/symptoms (e.g., systemic lupus erythematosus [SLE] with pneumonitis. Before fever, leukocytosis, hypoxemia, and pulmonary infiltrates are ascribed to NP, the clinician should carefully rule out the many mimics of NP based on nonpulmonary

BOX 33.1

Clinical diagnosis of nosocomial pneumonia[a]

Appearance of new pulmonary infiltrates after 5 or more days in hospital with:

- Otherwise unexplained new fever (>38°C/100°F)
- Otherwise unexplained leukocytosis (± left shift)
- Otherwise unexplained pulmonary infiltrates (*consistent* with bacterial pneumonia)[b]

[a] Definition does *not* include positive respiratory secretion cultures in ventilated patients.

Positive blood cultures (excluding blood culture skin contaminants (e.g., methicillin-sensitive *Staphylococcus aureus* [MSSA], methicillin-resistant *S. aureus* [MRSA]) or secondary to extrapulmonary infections (e.g., central venous catheter infection, *P. aeruginosa*, *K. pneumoniae*, *Enterobacter* spp., *Acinetobacter baumannii.*

[b] See Table 33.2 (Mimics of nosocomial pneumonia).

findings from the history, physical examination, and relevant laboratory tests (Table 33.1). In ventilated patients, mimics of NP may also have positive respiratory secretion cultures. All too often, the clinical diagnosis of NP is based on "guilt by association" (e.g., fever/leukocytosis, hypoxemia, infiltrates on CXR, and positive respiratory secretion cultures).

Since a definitive diagnosis of NP is problematic (i.e., lung biopsy), some degree of overtreatment is unavoidable. If mimics of NP are excluded and the presumed diagnosis is NP, empiric monotherapy should be directed against the most important NP pathogens (e.g., *P. aeruginosa*) and not based on respiratory secretion cultures.

Respiratory secretion colonization versus infection

In intubated patients, respiratory secretions rapidly become colonized by nosocomial GNB. Nosocomial GNB colonization in the ICU occurs as a function of time. Antimicrobial therapy, if not chosen carefully, may not only promote colonization of respiratory secretions with GNB, but also colonization with *Staphylococcus aureus*, such as methicillin-sensitive *S. aureus* (MSSA) or methicillin-resistant *S. aureus* (MRSA). The common GNB colonizers of respiratory secretions (e.g., *Enterobacter* spp.*, Citrobacter freundii, Burkholderia cepacia, Stenotrophomonas maltophilia*) are relatively avirulent and rarely, if ever, cause NP. Until proved otherwise, if these organisms are cultured from respiratory secretions of ventilated patients, they should be considered as "colonizers" and not treated with antibiotics (Box 33.1). Respiratory secretions of ventilated patients are also commonly colonized by bona fide NP pathogens (e.g., *P. aeruginosa, K. pneumoniae*, *Serratia marcescens*). In contrast, *Acinetobacter baumannii* is a common colonizer of respiratory secretions but is rarely a cause of sporadic NP. Unless part of an outbreak/cluster, respiratory secretion cultures positive for *A. baumannii* should be regarded as colonization and the cause of NP until proved otherwise. Similarly, nosocomial Legionnaires'

TABLE 33.1 **RADIOGRAPHIC MIMICS OF NOSOCOMIAL PNEUMONIA**

Fever *plus* leukocytosis plus CXR infiltrates *plus* positive respiratory secretion cultures ≠ NP

Bronchiolitis obliterans organizing pneumonia (BOOP)[a]	Aspiration (chemical)[a]
Sarcoidosis[a]	Phantom tumor (localized CHF)[a]
SLE pneumonitis	Bronchogenic carcinoma[a]
Rheumatoid lung[a]	Metastatic carcinoma[a]
Pulmonary infarcts	Lymphoma
Goodpasture's syndrome	Radiation pneumonitis[a]
Wegener's granulomatosis	Lung contusion
Acute respiratory distress syndrome (ARDS)	Pulmonary hemorrhage
Drug-induced pulmonary disease	Mucus plug[a]
Noncardiogenic (neurogenic) pulmonary edema[a]	
Cardiogenic pulmonary edema (LVF)[a]	

Abbreviations: NP = nosocomial pneumonia; SLE = systemic lupus erythematosus; LVF = left ventricular failure; CHF = congestive heart failure.
[a] The disorders listed may mimic NP; many are afebrile disorders and may be associated with leukocytosis/left shift. Fever may be present with disorders listed, not typically afebrile infection, but search should prompt for a nonpulmonary cause of the fever. ARDS is in the ICU and commonly due to acute pancreatitis (drug-induced), and the patient is febrile secondary to pancreatitis not ARDS.
Diagnosis of NP should not be based on "guilt by association." Similarly, positive respiratory secretion's culture should be considered as colonization, not NP, until proved otherwise. Other clues to the clinical nonsignificance of positive respiratory secretion cultures are growth of non-NP pathogens, *Stenotrophomonas maltophilia, Burkholderia cepacia*, or colonizing pathogens (e.g., *Enterobacter* spp.*, S. aureus, Citrobacter* spp.) or multiple organisms, pathogens that are significant only if in a cluster/outbreak (e.g., *Acinetobacter* spp.).
Adapted from Cunha BA, ed. *Pneumonia Essentials*, 3rd ed. Sudbury, MA: Jones & Bartlett; 2007.

disease occurs in clusters/outbreaks and only rarely occurs as sporadic NP. Gram-positive cocci (e.g., enterococci) or *S. aureus* (either MSSA/MRSA) are common colonizers of respiratory secretions of ventilated patients receiving certain broad-spectrum antibiotics (e.g., ciprofloxacin, imipenem, ceftazidime). However, group D streptococci rarely, if ever, cause NP. In intubated patients with presumed NP, organisms cultured from respiratory secretion are often considered a cause of NP and are covered/treated. There is little to no relationship between respiratory secretion cultures and distal lung parenchymal NP pathogens. The clinical and pathologic features of *S. aureus* (MSSA/MRSA) CAP have well-described clinical parameters to evaluate potential MSSA/MRSA NP. *S. aureus* (MSSA/MRSA) CAP (virtually always associated with influenza or influenza-like illness) patients are critically ill, cyanotic, and have a fulminant necrotizing/hemorrhagic pneumonia with rapid cavitation in <72 hours (like *P. aeruginosa* NP). This is in contrast to the intubated patient with MSSA/MRSA cultured from respiratory secretions, without the clinical/radiologic characteristics of a necrotizing/hemorrhagic pneumonia. Unless the patient has MSSA/MRSA tracheobronchitis, MSSA/MRSA in respiratory secretions represents colonization and not MSSA/MRSA NP. Furthermore, adding MSSA/MRSA coverage in the empiric treatment of NP has no effect on outcomes (Table 33.2).

Without invasive diagnostic tests (e.g., lung biopsy), the definitive diagnosis of NP remains elusive. The epidemiologic diagnosis of NP is based on fever/leukocytosis, hypoxemia, and new-onset pulmonary infiltrates compatible with bacterial pneumonia. Obviously, there are many noninfectious mimics of NP with the same clinical presentations. *P. aeruginosa* and *S. aureus* in particular have readily recognizable clinical presentations (e.g., fulminant necrotizing/hemorrhagic pneumonias). When either of these two organisms is responsible for pneumonia (e.g., CAP due to *S. aureus* [+ influenza] or NP due to *P. aeruginosa*), such patients acutely deteriorate clinically with high spiking fevers accompanied by cyanosis and, on CXR, rapid cavitation (≤72 hours) after infiltrate appearance. Fulminant necrotizing/hemorrhagic pneumonia due to either *P. aeruginosa* NP or *S. aureus* (CAP + influenza) is frequently fatal. The clinical presentation of *P. aeruginosa* NP or *S. aureus* CAP (+ influenza) is distinctive and reflects the underlying lung pathology. The epidemiologic definition of NP is, but should not be, based on nonspecific clinical findings and respiratory secretion cultures. In intubated ICU patients in the United States with presumed NP, respiratory secretion cultures often are positive (>25%) for MSSA/MRSA. If MSSA/MRSA were actual pathogens in >25% of NP, this would be readily apparent in very high mortality/autopsy findings, which is not the case. MSSA/MRSA remains a rare cause of NP. In a ventilated patient, if either MSSA/MRSA or *P. aeruginosa* are cultured from respiratory secretions and the patient's clinical status has not dramatically deteriorated and there is no cyanosis and no rapid cavitation (≦72 hours) on CXR, then the pathogens represent colonization and not NP due to either of these pathogens. However, both *P. aeruginosa* or *S. aureus* may cause tracheobronchitis (purulent respiratory secretions with a negative CXR), which should be treated to preserve respiratory function.

TABLE 33.2 **NOSOCOMIAL PATHOGENS AND RESPIRATORY SECRETION COLONIZERS**

Nosocomial pneumonias: respiratory pathogens	Respiratory secretions: common colonizers
Common pathogens	**Common colonizers**
Pseudomonas aeruginosa	*Staphylococcus aureus* (MSSA/MRSA)
Klebsiella pneumoniae	*Pseudomonas aeruginosa*
Uncommon	*Acinetobacter baumannii*
Serratia marcescens	*Enterobacter* spp.
Escherichia coli	*Stenotrophomonas* (*Xanthomonas*) *maltophilia*
Rare	*Burkholderia* (*Pseudomonas*) *cepacia*
Acinetobacter baumannii [a]	*Citrobacter freundii*
Legionella spp.[a]	

[a] Nosocomial pneumonias due to these organisms are virtually always part of a cluster/outbreak.
Abbreviations: MRSA = methicillin-resistant *Staphylococcus aureus;* MSSA = methicillin-sensitive *Staphylococcus aureus.*

Optimal empiric monotherapy for nosocomial pneumonia

Until there are better methods to accurately diagnose NP, some overtreatment is understandable and clinically prudent. Because some overtreatment is unavoidable due to difficulties in diagnosis, clinicians use antibiotics as selectively as possible to empirically treat presumed NP. In ventilated patients optimal empiric monotherapy should have a high degree of anti-*P. aeruginosa* activity (e.g., meropenem, cefepime). In addition to an appropriate spectrum for NP (e.g., anti-*P. aeruginosa*), the antibiotic selected should have a "low resistance potential" to prevent the emergence of multidrug-resistant (MDR) GNBs as well as not promoting selection of *S. aureus* in respiratory secretions. The antibiotics often used in the therapy of NP that are most likely to result in the emergence of MDR GNBs are ceftazidime, imipenem, and ciprofloxacin. In addition, ceftazidime and ciprofloxacin are likely to select out MSSA/MRSA in respiratory secretions. Further proof of the unimportance of including MRSA coverage in NP empiric therapy is that MRSA coverage does not improve outcomes. MRSA coverage is not necessary for the empiric therapy of NP (Boxes 33.2 and 33.3).

For NP, well-selected monotherapy is optimal and double-drug therapy offers no advantage. When antibiotics had relatively little *P. aeruginosa* activity, double-drug therapy was used. Because currently available antibiotics have a high degree of anti-*P. aeruginosa* activity, optimal empiric monotherapy is effective. In bona fide *P. aeruginosa* NP, double-drug therapy is preferred.

If MDR *K. pneumoniae* or MDR *P. aeruginosa* strains are the cause of NP, meropenem remains useful against most non–metallo

BOX 33.2

Nosocomial pneumonia: selection of antibiotic empiric therapy

Key factors in empiric antibiotic selection for NP

1. High degree of activity against *Pseudomonas aeruginosa* (and other GNB NP pathogens). MSSA/MRSA coverage unnecessary.
2. Penetrates lung parenchyma in therapeutic concentrations
3. "Low resistance" potential (avoid ciprofloxacin, ceftazidime, imipenem)
   Carefully selected antibiotics that:
   - Do not increase **prevalence** of MSSA/MRSA
   - Do not increase **prevalence** of VRE
   - Do not increase **potential** for *Clostridium difficile* diarrhea/colitis
4. Good safety profile

Unimportant factors in NP antibiotic selection for NP

1. MSSA/MRSA coverage
2. Penetration into epithelial cells, alveolar macrophages (except for *Legionella* spp.)

Abbreviations: NP = nosocomial pneumonia; GNB = gram-negative bacteria; MSSA = methicillin-sensitive *Staphylococcus aureus*, MRSA = methicillin-resistant *Staphylococcus aureus*; VRE = vancomycin-resistant enterococci.

β-lactamase-producing GNBs. For meropenem-resistant strains, effective antimicrobial therapy is relatively limited (e.g., colistin).

Nosocomial pneumonia unresponsive to appropriate antibiotic therapy

Empiric therapy of NP is usually given for 1 to 2 weeks. After 2 weeks of therapy, lack of CXR improvement suggests an alternate diagnosis rather than ineffective antimicrobial therapy or the development of antibiotic resistance.

After 2 weeks of optimal anti-*P. aeruginosa* NP therapy, ventilated patients with fever, leukocytosis, hypoxemia, and persistent pulmonary infiltrates on CXR may have herpes simplex virus-1 (HSV-1) NP. In a patient without preexisting cardiopulmonary disease, otherwise unexplained "failure to wean" off a ventilator after 2 weeks of appropriate antimicrobial therapy for NP should suggest the possibility of HSV-1 NP. HSV-1 NP is an underrecognized clinical entity. If HSV-1 NP is suspected, diagnostic bronchoscopy should be performed. Herpetic vesicles in the oropharynx/airways are indicative of NP severity rather than lower respiratory tract infection (i.e., HSV-1 NP). HSV-1 cultured from respiratory secretions suggests colonization, not infection. Bronchoalveolar lavage (BAL) fluid should be obtained for cytologic diagnosis. Viral cytopathic effects in distal respiratory epithelial cells are diagnostic of active infection (not viral colonization/reactivation). Cowdry type A inclusion bodies (CPEs) in respiratory epithelial cells from BAL specimens are diagnostic of HSV-1 NP. If HSV-1 CPEs are present in BAL specimens, empiric therapy with acyclovir should be initiated (Box 33.4). Rapid improvement in oxygenation (e.g., decreased FiO_2/decreased A-a gradient) follows after 3 to 5 days of acyclovir therapy. Patients can then be weaned off the ventilator over the next several days.

Importantly, cytomegalovirus (CMV) in normal hosts, unlike HSV-1, is not a common cause of NP. The diagnosis of CMV NP is based on demonstrating CMV CPEs in BAL cellular specimens. Elevated CMV immunoglobulin M (IgM) titers/positive CMV PCR are not diagnostic of CMV NP. CMV PCR positivity reflects CMV reactivation in peripheral white blood cells, not infection in the lungs or elsewhere.

BOX 33.3

Empiric therapy of nosocomial pneumonia

Gram-negative nosocomial pneumonia

Preferred empiric therapy[a]

Nosocomial pneumonia
Preferred therapy coverage directed primarily against *P. aeruginosa* (MRSA coverage unnecessary)
Meropenem 1 g (IV) q8h × 2 weeks
Levofloxacin 750 mg (IV) q24h × 2 weeks
Cefepime 2 g (IV) q8h ± amikacin 1 g (IV) q24h × 2 weeks[b]

Alternative therapy
Piperacillin/tazobactam 4.5 g (IV) q6h *plus* amikacin 1 g (IV) q24h × 2 weeks

Specific therapy

MDR *Klebsiella pneumoniae*
Tigecycline 200–400 mg (IV) × 1 dose, then 100–200 mg (IV) q24h × 2 weeks
Colistin 1.7 mg/kg (IV) q8h × 2 weeks ± rifampin 600 mg (IV) q24h × 2 weeks
Polymyxin B 1.25 mg/kg (IV) q12h × 2 weeks

MDR *Acinetobacter baumannii*
Tigecycline 200–400 mg (IV) × 1 dose, then 100–200 mg (IV) q24h × 2 weeks
Ampicillin/sulbactam 3 g (IV) q6h × 2 weeks
Colistin 1.7 mg/kg (IV) q8h ± rifampin 600 mg (IV) q24h × 2 weeks
Polymyxin B 1.25 mg/kg (IV) q12h × 2 weeks

MDR *Pseudomonas aeruginosa*
Colistin 1.7 mg/kg (IV) q8h ± rifampin 600 mg (IV) q24h × 2 weeks
Polymyxin B 1.25 mg/kg (IV) q12h × 2 weeks

Abbreviation: MDR = multidrug resistant.

[a] Doses are for adults with normal renal function.

[b] Note that therapy of NP with piperacillin–tazobactam requires a higher than usual dose plus a second drug (e.g., amikacin). Do not use piperacillin–tazobactam at the usual dose 3.375 mg (IV) q6h or as monotherapy for NP.

BOX 33.4

Nosocomial HSV-1 pneumonia

Symptoms

"Failure to wean" off respirator (in patients *without preexisting lung disease*)
In immunocompetent hosts

Signs

Low-grade fevers
Unexplained hypoxemia (*with normal/near normal CXR*)
CXR unchanged after 2 weeks of optimal NP antibiotic therapy

Laboratory tests

Leukocytosis (± left shift)
Otherwise unexplained ↓ pO_2 or ↑ A-a gradient (>30)
HSV serology: unhelpful
Diagnostic bronchoscopy:
HSV vesicles:
Usually no HSV vesicles in respiratory passages
If present, HSV vesicles in respiratory tract (reflective of HSV severity/reactivation) not HSV
NP
Viral culture:
± HSV-1 virus cultured from respiratory secretions (Dx of colonization *not* infection)
Cytology:
HVS-1 intranuclear inclusion bodies (Cowdry type A). CPEs are Dx of infection not colonization/reactivation.

Empiric therapy

Acyclovir 10 mg/kg (IV) q8h × 7–10 days
(Results in clinical improvement in 3–5 days) (↓ FiO_2, ↓ A-a gradient)

Abbreviations: CSX = chest x-ray, HSV = herpes simplex virus.

Aspiration pneumonia

Jean Gibb and Matthew Bidwell Goetz

Introduction

Aspiration is the inhalation of oropharyngeal or gastric contents into the respiratory tract. Three major syndromes may develop as a consequence of aspiration: chemical pneumonitis, bronchial obstruction secondary to aspiration of particulate matter, and bacterial aspiration pneumonia. Less commonly, interstitial lung disease occurs in persons with chronic aspiration. Which of these consequences emerges is determined by the amount and nature of the aspirated material as well as by the integrity of host defense mechanisms. Aspiration is the main means of bacterial contamination of the lower airways.

The term "aspiration pneumonia" is used to refer to the infectious consequences of inhalation of relatively large volumes of material (macro-aspiration). Although healthy persons frequently aspirate small volumes of pharyngeal secretions during sleep, the development of pneumonia after such micro-aspiration is normally prevented by mechanical (e.g., cough and mucociliary transport) and immunological responses. Pneumonia arises when these host defenses fail to limit bacterial proliferation either because of micro-aspiration of highly virulent pathogens to which the host lacks specific immunity (e.g., *Streptococcus pneumoniae* or enteric gram-negative bacteria) or because of macro-aspiration of lower or higher virulence organisms.

Aspiration may be clinically obvious, as when acute pulmonary complications follow inhalation of vomited gastric contents. Such acute chemical pneumonitis is often referred to as *Mendelson's syndrome*. On the other extreme, so-called *silent aspiration*, as occurs in persons with neurological impairment who lack cough responses, is often followed by the indolent onset of infectious pneumonia consequent to the inhalation of the composite of aerobic and anaerobic microorganisms normally resident in the oropharynx.

In evaluating patients who have aspirated, it is important to bear in mind that there are considerable variations in the subsequent clinical course. Although aspiration of gastric contents is inevitably accompanied by aspiration of the oropharyngeal flora, the initial chemical pneumonitis may resolve without further consequences. In the setting of risk factors for the development of aspiration pneumonia, it may result in the emergence of infection within several days if high-virulence organisms have colonized the oropharynx, or in the delayed emergence of mixed aerobic/anaerobic pneumonia caused by normal oral flora.

Risk factors

The risk for aspiration pneumonia is mediated by anatomic, microbiologic, immunologic, age-related, and comorbidity-related risk factors. First, inability to mechanically clear airways with cough and normal oropharyngeal reflexes provides extended incubation time for proliferation of bacteria in the large and small airways. This loss in structural control affects patients with cerebrovascular and other neurologic disorders, alcoholism, substance use disorders that result in sedation, general anesthesia, seizures, disorders of the gastrointestinal tract, and uncontrolled postoperative pain (see Box 34.1). Because these factors contribute to the risk of pneumonia in both hospitalized and community dwelling patients, such risk factors should be

BOX 34.1

Risk factors for aspiration

Altered level of consciousness
- General anesthesia
- Narcotic and sedative drugs
- Drug overdose and ethanol toxicity
- Metabolic encephalopathies (electrolyte imbalances, liver failure, uremia, sepsis)
- Hypoxia and hypercapnia
- CNS infections
- Dementia
- Seizure

Abnormal glottic closure
- Anesthetic induction or postanesthetic recovery
- Postextubation
- Structural lesions of the central nervous system (tumors, cerebrovascular accident, head trauma)
- Seizures
- Infection (e.g., diphtheria, pharyngeal abscess)

Gastroesophageal dysfunction
- Alkaline gastric pH
- Gastrointestinal tract dysmotility
- Esophagitis (infectious, postradiation)
- Hiatal hernia
- Scleroderma
- Esophageal motility disorders (achalasia, megaesophagus)
- Tracheoesophageal fistula
- Ascites (increased intra-abdominal pressure)
- Intestinal obstruction or ileus
- Diabetes (functional gastric outlet obstruction)

Neuromuscular diseases
- Guillain-Barré syndrome
- Botulism
- Muscular dystrophy
- Parkinson's disease
- Polymyositis
- Amyotrophic lateral sclerosis
- Multiple sclerosis
- Myasthenia gravis
- Poliomyelitis
- Tardive dyskinesia

Mechanical factors
- Nasogastric or enteral feeding tubes
- Upper endoscopy
- Emergency and routine airway manipulation
- Surgery or trauma to the neck and pharynx
- Tumors of the upper airway
- Tracheostomy
- Endotracheal tube
- Zenker's diverticulum

Other factors
- Obesity
- Pregnancy

considered for presentations of aspiration pneumonia in both outpatient and inpatient settings.

Second, disturbance of the normal oropharyngeal or gastric flora contributes to the risk for pneumonia following an aspiration event by increasing colonization of the oropharynx by relatively low-virulence bacteria. The presence of gingivitis, dental plaque, and decayed teeth combined with poor oral hygiene or decreased salivary flow (e.g., due to tube feedings or anticholinergic medications) are associated with this altered oropharyngeal microbiome.

Other iatrogenic interventions or sequelae, including enteral feeding, gastroparesis, or small bowel obstruction, increase colonization of gastric contents by pathogenic microorganisms and contribute to the risk of hospital-acquired pneumonia, especially in patients with altered consciousness, impaired swallowing, and similar comorbid risk factors. While some studies indicate that decreased gastric acidity increases the risk of aspiration pneumonia, recent studies in ICU patients have not demonstrated this association. Moreover, replacement of normal oral flora by more virulent microorganisms such as *Staphylococcus aureus, Pseudomonas aeruginosa*, and *Klebsiella pneumoniae* as a consequence of alcoholism, malnutrition, diabetes, and other severe comorbidities or prior antimicrobial therapy also increases the risk of pneumonia following an aspiration event.

Pulmonary clearance defects at the mucociliary level (e.g., secondary to tobacco smoking or influenza) and impairment of normal humoral and cellular host defenses, particularly those conditions that decrease immunoglobulin production (e.g., hematological malignancies) or result in severe neutropenia also increase the risk of developing pneumonia after aspiration. Not surprisingly, risk factors for aspiration leading to pneumonia are often cumulative.

Clinical epidemiology

Between 2002 and 2012, >1.5 million patients were admitted with a diagnosis of aspiration pneumonia to hospitals in the United States (ICD-9-CM procedure code 86.70, 96.71, or 86.72). These hospitalizations accounted for >55,000 deaths over a 10-year period, with a total cost of more than $9 billion. Aspiration syndromes predominantly affected those older than age 65, and >75% of patients hospitalized with sequelae of aspiration had two or more identified risk factors. Swallowing disorders due to neurologic diseases affect 300,000 to 600,000 people each year in the United States. Nearly 40% of stroke patients with dysphagia aspirate and develop pneumonia. Overall, aspiration accounts for approximately 0.5% of all hospitalizations, 3% to 4% of inpatient mortality, and 5% to 23% of all cases of community-acquired pneumonia. As a corollary, aspiration pneumonia is the second most frequent principal cause of pneumonia among US Medicare patients hospitalized for pneumonia.

Among nursing home patients, aspiration pneumonia accounts for up to 30% of cases of pneumonia, occurs at a rate three times that of age-matched patients in the community, and markedly increases the risk of death. Among such patients, difficulty swallowing food, use of tube feedings, requiring assistance with feeding, delirium, and use of sedative medications are the most frequent risk factors for aspiration pneumonia. While the debilitated elderly are at particularly high risk, prior silent aspiration is also common in apparently healthy elderly patients with community-acquired pneumonia.

Aspiration complicates the course of approximately 10% of persons admitted to hospitals for overdosage with sedative or hypnotic agents. Aspiration is the greatest contributor to airway-related mortality in anesthesia-associated airway events; in 2014, the rate of anesthesia-associated fatal aspiration in the United Kingdom was 1 in 350,000. Patient characteristics independently associated with an increased risk of aspiration following general anesthesia include male sex, nonwhite race, age >60 years, dementia, chronic obstructive pulmonary disease, renal disease, malignancy, moderate to severe liver disease, and emergency surgery.

Clinical course and diagnosis

Aspiration of gastric contents results in acute inflammation of the major airways and lung parenchyma. Animal models demonstrate maximal hypoxemia within 10 minutes of aspiration. In these models, the severity of lung injury is greatest when the pH is <2.5, but gastric materials can cause severe pulmonary injury even at higher pH. Local injury results in complement activation as well as release of tumor necrosis factor (TNF-α), interleukin (IL-8), and other pro-inflammatory cytokines which in turn are primarily responsible for the acute nonobstructive complications of chemical aspiration.

Acute clinical symptoms and signs of chemical pneumonitis following aspiration of gastric contents include respiratory distress, fever, cough, reflex bronchospasm, leukocytosis, and pulmonary infiltrates; up to a third of patients who experience aspiration develop acute lung injury or acute respiratory distress syndrome (ARDS), manifested by capillary permeability, proteinaceous edema, hypoxemia, and loss of lung compliance. Life-threatening hypoxemia may develop as a consequence of atelectasis, pulmonary capillary leak, and direct alveolar damage. However, in contrast to the course of gastric aspiration, more modest aspiration of normal oral flora (i.e., mixed aerobic/anaerobic bacteria) may be clinically silent and only later recognized when pneumonia develops.

Following an aspiration event, acute respiratory symptoms often improve with supportive therapy alone. Alternatively, patients may initially improve for several days but then worsen with the onset of recurrent symptoms and signs; this saddleback pattern of illness following an aspiration event often indicates the development of a secondary bacterial pneumonia.

The distinction between progressive chemical lung injury and the presence of bacterial pneumonia is important to avoid unnecessary antibiotic use, especially because pneumonia fails to develop in approximately half of all aspiration events. Furthermore, given the differences in microbial etiology of aspiration pneumonia versus other cases of community-acquired pneumonia, it is important to consider aspiration in persons with pneumonia who have the risk factors listed in Box 34.1 even if an aspiration event has not been witnessed.

Many of the clinical and laboratory manifestations of aspiration pneumonitis overlap with those of bacterial pneumonia and challenge the clinician to distinguish the host response to proliferating microorganisms from host response to the noninfectious inflammatory cascade. Early acute findings are easily attributable to chemical pneumonitis rather than bacterial infection if they follow witnessed vomiting and aspiration of gastric acidic contents. Furthermore, as a general rule, the clinical manifestations of aspiration pneumonia, including fever and respiratory symptoms such as productive cough, dyspnea, and pleuritic pain, are much less dramatic than those of chemical pneumonitis. In elderly patients who are at greatest risk for aspiration, the signs and symptoms of pulmonary infection may be particularly muted and overshadowed by nonspecific complaints such as general weakness, decreased appetite, altered mental status, or decompensation of underlying diseases. Pneumonia following silent aspiration events is often indolent; patients often do not develop fever, malaise, weight loss, and cough for 1 to 2 weeks or more after aspiration. This is an especially common presentation for patients who present with mixed aerobic/anaerobic lung abscesses or empyemas after an aspiration event.

Routine laboratory studies do not distinguish between aspiration pneumonitis and pneumonia. If the event is not witnessed, detection of pepsin A in tracheal aspirate may be used as a marker for gastric aspiration pneumonitis; of note, pepsin C, a normal product of pneumocytes, is present in patients without aspiration. Although procalcitonin distinguishes bacterial pneumonia from viral lower respiratory infections, procalcitonin results have not been shown to discriminate between aspiration pneumonitis and bacterial aspiration pneumonia.

Radiographic evaluation is necessary to establish the diagnosis of pneumonia because there is no combination of historical data, physical findings, or laboratory results that reliably confirms the diagnosis. Limitations of chest radiography for the diagnosis of pneumonia include poor specificity in patients with the ARDS and decreased sensitivity in persons with previous structural lung disease, very early infection, severe dehydration, or profound granulocytopenia. Otherwise, the failure to detect an infiltrate essentially rules out the diagnosis of pneumonia. While spiral CT of the chest provides a more sensitive means of detecting infiltrates than chest radiography, such infiltrates may not actually represent pneumonia. Patients with chronic aspiration may exhibit atelectasis, bronchiectasis, consolidation, and ground-glass opacities in the absence of an acute aspiration or a clinical acute bacterial pneumonia. Esophagography and CT are especially useful in determining whether recurrent aspiration disease is due to a tracheoesophageal or tracheopulmonary fistula.

Radiologic findings do not distinguish between chemical pneumonitis and aspiration pneumonia save for the fact that radiological abnormalities have more rapid onset and resolution with chemical pneumonitis. Pneumonia complicating aspiration most often involves the posterior segment of the right upper lobe, the superior segment of the right lower lobe, or both, as well as the corresponding segments on the left. Manifestations of mixed aerobic/anaerobic infection include necrotizing pneumonia, lung abscess, and empyema (Figures 34.1–34.5). Foreign body aspiration typically occurs in children and manifests as obstructive lobar or segmental overinflation or atelectasis. An extensive, patchy bronchopneumonic pattern may be observed in patients following massive aspiration of gastric contents.

Although the utility of routine sputum examination in uncomplicated pneumonia is much debated, cultures of sputum and two

FIGURE 34.1 Mixed aerobic–anaerobic lung abscess following aspiration.

FIGURE 34.3 Chest x-ray showing increased parenchymal opacity in the right mid and lower lung field and bilateral pleural effusions in a patient presenting with progressive shortness of breath and a nonproductive cough for 1 month.

blood (two sets) should be obtained in patients who are medically unstable. Pleural fluid should also be cultured when present, and efforts to obtain sputum should be pursued before initiation of antimicrobial therapy in hospitalized patients who develop pneumonia after an aspiration event. Sputum samples must be carefully collected, transported, and processed in order to optimize the recovery of common aerobic bacterial pathogens such as *S. pneumoniae*. Since anaerobic cultures are not performed for sputum specimens, the presence of mixed bacterial flora on the sputum Gram stain should be used to diagnose polymicrobial infection typical of the mixed aerobic-anaerobic infections. Inspection of the sputum Gram stain is also necessary to ensure that materials being cultured are not unduly contaminated by saliva. Bronchoscopic sampling of the lower respiratory tract (with a protected specimen brush or by bronchoalveolar lavage) and quantitative culture are particularly useful in critically ill patients with hospital-acquired aspiration pneumonia. Such interventions are especially warranted in persons who do not respond to initial antimicrobial therapy.

Unfortunately, despite extensive evaluation, the microbial cause of pneumonia can be identified only 40% to 60% of hospitalized patients. In recent data, only 38% of patients with community-acquired pneumonia admitted to the hospital had an identifiable pathogen, and the incidence of viral pathogens was higher than that of bacterial pathogens. Pathogen detection has improved up to 89% in some studies with use of targeted polymerase chain reaction (PCR) for common bacterial and viral respiratory pathogens, but the utility of PCR for anaerobic flora or polymicrobial infection remains unclear. Nevertheless, identification of the infecting microorganism serves to verify the clinical diagnosis of infection and facilitates the use of specific therapy instead of unnecessarily broad-spectrum antimicrobial agents.

FIGURE 34.2 Mixed aerobic–anaerobic empyema following aspiration.

FIGURE 34.4 CT scan correlating with chest x-ray shown in Figure 34.5; interpreted as showing large loculated fluid and foci of gas in the right mid and lower hemithorax; interpreted as loculated fluid versus lung.

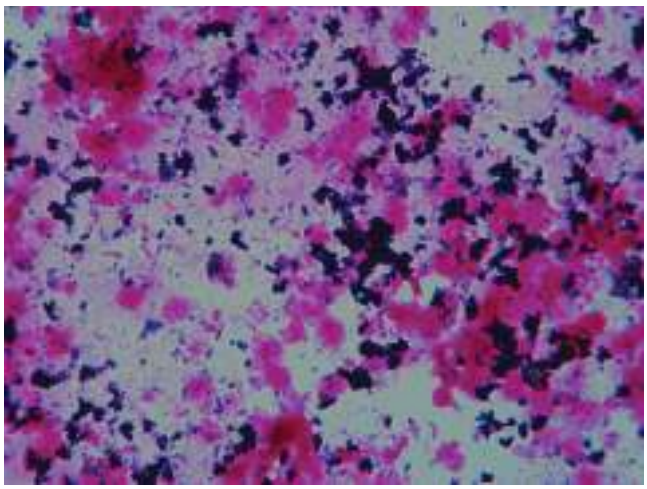

FIGURE 34.5 Gram stain of aspirated material from lung abscess shown in figure showing mixed bacteria flora with gram-positive cocci, gram-negative cocci, and gram-negative rods; the mixture of organisms is highly suggestive of a mixed aerobic–anaerobic infection.

Microbiology

The microbial etiology of aspiration pneumonia is complex and variable. The distribution of responsible pathogens differs in persons with community- versus hospital-acquired illness and varies with the presence or absence of previous antimicrobial exposure, comorbidities, or odontogenic disease.

While some studies show a decreased prevalence of anaerobic bacteria as causes of aspiration pneumonia, the adequacy of anaerobic culture techniques is often uncertain, leaving in doubt whether the true frequency of anaerobic infection has been underestimated. Methods to recover anaerobes in the laboratory are laborious and time-intensive; these are not performed in the majority of current clinical settings for routine sputum culture. In many studies performed during the 1970s, bacteriologic specimens were obtained by percutaneous transtracheal sampling or thoracentesis, and rigorous laboratory methods were used to optimize the recovery of anaerobic bacteria. Although typical causes of bacterial pneumonia such as *S. pneumoniae* were often recovered, these studies demonstrated that viridans streptococci and anaerobic organisms including *Peptostreptococcus, Bacteroides, Prevotella,* and *Fusobacteria* were the predominant pathogens in aspiration pneumonia.

Significant involvement of anaerobes in pulmonary infection is well described in patients with dysphagia or altered mental status and infection in dependent pulmonary anatomy—primarily lower, posterior lobes. Anaerobes are clinically recognized by the presence of purulent sputum and an identifiable odor, the product of volatile short-chain fatty acids by anaerobic microbes. These organisms are frequently implicated in lung abscesses and empyema. Even if viable organisms are not present, presence of *Bacteroides* capsular material alone may contribute to abscess formation. Well-performed studies continue to demonstrate anaerobes in up to 20% of nursing home patients with aspiration pneumonia; increased rates are found in patients with greater levels of debility. Conversely, the frequency of anaerobic infection is somewhat less in edentulous patients.

In communities with high rates of childhood or adult immunity to due to the use of protein-conjugate pneumococcal vaccines, viral etiologies of community-acquired pneumonia are more commonly identified than are bacterial etiologies. When bacterial pathogens are identified in patients with community-acquired pneumonia, *S. pneumoniae, L. pneumophila, M. pneumoniae*, and *C. pneumoniae* predominate and enteric gram-negative organisms are exceedingly rare.

Aerobic bacteria, particularly *S. aureus*, enteric gram-negative bacilli (i.e., *Enterobacteriaceae*) and occasionally *P. aeruginosa*, are more common causes of aspiration pneumonia in persons who develop disease after prior antibiotic exposure, while hospitalized, or in a nursing home setting. Studies in patients receiving care in intensive care units (ICUs) indicate that *S. aureus* and *Enterobacteriaceae* can be isolated from lower respiratory tract specimens from up to 40% of patients with hospital-associated pneumonias, many of which are due to aspiration. *P. aeruginosa* is most common in persons who have received prior intensive antimicrobial therapy or who have underlying bronchiectasis, cystic fibrosis, or severe immunological compromise. Data regarding the frequency of gram-negative pneumonia in patients with less severe aspiration pneumonia (i.e., those not requiring treatment in an ICU) are very sparse. Methicillin-resistant *S. aureus* nasal colonization in the nares carries a poor positive predictive value for the development of methicillin-resistant *S. aureus* (MRSA) pneumonia, but its absence has excellent negative predictive value and should be considered in the de-escalation of antibiotic therapy. Finally, polymicrobial infection, usually with a combination of aerobes and anaerobes, is common in patients with aspiration pneumonia.

Clinical management

Although corticosteroids have long been used in the treatment of acute chemical pneumonitis caused by aspiration, this treatment cannot be recommended. Prospective studies have failed to show a benefit in animal models of acid lung injury or in patients with either aspiration pneumonitis or the ARDS.

Antibiotic use is not warranted in most patients who acutely develop fever, leukocytosis, and pulmonary infiltrates following aspiration as these consequences are caused by chemical irritation and inflammation rather than by established infection. Many patients with chemical pneumonitis improve without any specific antimicrobial therapy. Retrospective data have demonstrated that in settings of witnessed macroaspiration, prophylactic antibiotics fail to decrease mortality or transfers to ICU-level care or prevent bacterial aspiration pneumonia. Prophylactic antibiotics carry the potential to select more resistant pathogens and generate a need for escalation in the spectrum of antibiotic therapy in those do develop aspiration pneumonia. While available studies do not preclude the possibility that there may be some benefit to early antibiotics in selected populations, such as persons with acute life-threatening complications of aspiration (i.e., patients requiring

invasive mechanical ventilation) or those who have aspirated heavily colonized gastric contents (e.g., in the setting of small bowel obstruction), neither are there any data showing that the benefits outweigh the harms. Antibiotics should generally be administered to patients whose symptoms do not improve within 48 to 72 hours or in whom new or progressive signs of pulmonary infection later emerge.

The need to select antibiotics with robust anaerobic activity in the treatment of aspiration pneumonia in patients with aspiration pneumonia is controversial. Vigorous anti-anaerobic therapy may not offer meaningful benefit to patients with simple pneumonia, especially if therapy is not unduly delayed. However, effective anti-anaerobic therapy should be given to persons with aspiration events manifesting as necrotizing pneumonias, lung abscesses, or empyemas. Because of the emergence of β-lactamase–mediated resistance among anaerobes, empirical treatment for complicated aspiration pneumonia likely to involve mixed aerobic-anaerobic flora requires the use of a β-lactam/β-lactamase inhibitor, clindamycin, or metronidazole combined with a penicillin, ampicillin, or an appropriate cephalosporin; if highly resistant aerobic gram-negative organisms are present, monotherapy with a carbapenem also provides excellent anti-anaerobic therapy (Table 34.1). Because of the very frequent concomitant presence of aerobes, metronidazole monotherapy should not be given.

Considering the range of pathogens and antimicrobial resistance, initial therapy of aspiration pneumonia that develops in nursing home or hospitalized patients must be carefully selected. Although monotherapy may be reasonable for immunocompetent patients with mild to moderate diseases who are known or likely to be infected by susceptible strains of *Proteus, Morganella*, *K. pneumoniae*, or *E. coli*, broad-spectrum multidrug therapy is often necessary to ensure coverage of drug-resistant pathogens. The choice of a particular combination must depend on the severity of infection, presence or absence of immunocompromise, and hospital-specific patterns of antimicrobial resistance and rates of isolation by specific microorganisms. Therapy should be made more specific when the pathogen(s) has been identified and susceptibilities are known. Again, the absence of MRSA in nasal surveillance specimens greatly reduces the risk of MRSA pneumonia being present.

With appropriate antimicrobial therapy, 50% of patients treated for aspiration pneumonia defervesce within 2 days of initiation of antibiotic therapy and 80% do so within 5 days. Prolonged fever is more common in patients with lung abscess or with infections by aggressive pathogens such as *P. aeruginosa*.

Prevention

Precautions should be taken to minimize the possibility of aspiration in hospitalized patients. Avoidance of the recumbent position and hypopharyngeal suctioning prevent aspiration by intubated patients. Guidelines from the American College of Chest Physicians and the American Gastroenterology Association provide specific recommendations regarding the evaluation of patients who are at risk for aspiration due to dysphagia. These guidelines recommend a multidisciplinary approach to patient evaluation and note the need to design and test therapy on an individual patient basis. Patients with documented aspiration during swallowing studies have a 4- to

TABLE 34.1 **SUGGESTED EMPIRIC THERAPY FOR INPATIENTS WITH ASPIRATION PNEUMONIA**

Suspected pathogens	Preferred agent	Alternative agents
Mixed aerobic/anaerobic flora	β-lactam plus metronidazole, β-lactam/β-lactamase inhibitor[a]	Clindamycin, moxifloxacin, ertapenem
Enterobacteriaceae	β-lactam/β-lactamase inhibitor[a], cefepime, carbapenem[b]	Third-generation cephalosporin[c] or fluoroquinolone[d], both ± aminoglycoside[e]
P. aeruginosa	Anti-pseudomonal β-lactam[f] ± aminoglycoside, carbapenem + aminoglycoside	Ciprofloxacin + aminoglycoside, ciprofloxacin + anti-pseudomonal β-lactam[e]
S. aureus, methicillin-sensitive	Anti-staphylococcal β-lactam[g] or first-generation cephalosporin[h]	Vancomycin, linezolid, trimethoprim-sulfamethoxazole
S. aureus, methicillin-resistant	Vancomycin	Linezolid, quinupristin/dalfopristin

Therapy should be modified when the identity and susceptibility of the responsible pathogen(s) is determined.
[a] Piperacillin/tazobactam is the preferred β-lactam/β-lactamase inhibitors for the treatment of nosocomial pneumonia due to Enterobacteriaceae. Ampicillin/sulbactam lacks adequate activity against many nosocomial enteric gram-negative bacilli.
[1b] Ertapenem, imipenem, and meropenem have equivalent activity against *Enterobacter* spp. mixed aerobic/anaerobic flora. Only imipenem and meropenem have activity against *P. aeruginosa*
[c] Third-generation cephalosporins: cefotaxime, ceftriaxone, and ceftazidime.
[d] Levofloxacin and ciprofloxacin generally have equivalent activity against *Enterobacter* spp. and *P. aeruginosa*. High resistance rates, particularly for nosocomial isolates, limit the empiric usefulness of these agents in many settings.
[e] Addition of an aminoglycoside should be strongly considered in seriously ill patients to ensure adequate breadth of antimicrobial therapy.
[f] Antipseudomonal β-lactams: ceftazidime, cefepime, imipenem, meropenem, or piperacillin-tazobactam.
[g] Antistaphylococcal β-lactams: nafcillin, oxacillin.
[h] Antistaphylococcal first-generation cephalosporins: cefazolin, cefadroxil, cephalexin.

10-fold increased risk of pneumonia depending on the magnitude of aspiration. Patients with risk factors for aspiration including neurologic disease, esophageal dysfunction, altered mental status, and known dysphagia have demonstrated higher 1-year mortality and higher risk for hospital readmissions compared to patients without risk factors; identifying and addressing risk factors has potential to reduce aspiration incidence.

Placement of gastrostomy tubes in persons with dysphagia is not superior to the use of a nasogastric tube for preventing aspiration. The failure of this intervention is likely related to ongoing aspiration of oral secretions and the observation that aspiration of gastric contents still occurs in persons fed by gastrostomy tubes. Nonetheless, decreased local irritation, fewer mechanical problems, and improved nutrition justify the use of gastrostomy tubes in selected patients. Monitoring the residual volume of tube feedings is often recommended as a measure to reduce incidence of aspiration in patients receiving tube feeds. However, in mechanically ventilated patients, the absence of gastric volume monitoring has not demonstrated an increase in ventilator-associated pneumonia.

Good periodontal care decreases the burden of pathogenic bacteria in oral secretions and thereby may prevent aspiration pneumonia. Studies have demonstrated direct correlation between implementation of oral hygiene initiatives and incidence of non–ventilator-associated hospital-acquired pneumonia. Data are mixed regarding the use of chlorhexidine oral care for the prevention of ventilator-associated pneumonia; there may be some benefit in short-term intubation (on the order of 2–3 days), but results for more critically ill patients intubated for longer periods are less obviously beneficial and in some instances trend toward harm. In contrast to the evidence to support good periodontal care, prophylactic antibiotic use is not recommended for patients in whom aspiration is suspected or witnessed.

Lung abscess

Amee Patrawalla and Lisa L. Dever

Lung abscess is a chronic or subacute lung infection initiated by the aspiration of contaminated oropharyngeal secretions. The result is an indolent, necrotizing infection in a segmental distribution, usually dependent and limited by the pleura. Except for infections with unusual organisms such as *Actinomyces*, the process does not cross interlobar fissures, and pleural effusion is uncommon. The resultant cavity is usually solitary, with a thick, fibrous reaction at its periphery. So defined, lung abscess is almost always associated with anaerobic bacteria, although the majority of infections are polymicrobial, with microaerophilic and aerobic bacteria present.

In contrast, *necrotizing pneumonia* is an acute, often fulminant, infection characterized by irregular destruction of alveolar walls and therefore multiple cavities. This infection spreads rapidly through lung tissue, frequently crossing interlobar fissures, and is often associated with pleural effusion and empyema. The duration of illness before recognition is usually only a few days. Causative organisms include *Staphylococcus aureus, Streptococcus pyogenes, Klebsiella pneumoniae, Pseudomonas aeruginosa*, and, less commonly, other gram-negative bacilli, *Legionella* spp., *Nocardia* spp., and fungi.

Diagnosis

The focus of this discussion will be the diagnosis and therapy of anaerobic lung abscess. Diagnosis can usually be made from the clinical presentation and chest radiograph findings. Many patients have conditions such as seizure disorders, neuromuscular diseases, alcoholism, or other causes of impaired consciousness that predispose them to aspiration of oropharyngeal secretions. Obstructing tumors and foreign bodies may also predispose to lung abscess. Additionally, patients with impaired local and systemic host defenses are at greater risk. Gingival disease and poor dental hygiene, which promote higher concentrations of anaerobic organisms in the mouth, are common. Patients usually give a several-week history of fever and cough; putrid sputum occurs in fewer than 50% of patients. Hemoptysis may also occur. With chronic infection, patients will often experience weight loss and anemia, mimicking malignancy. Chest radiographs show consolidation in a segmental or lobar distribution with central cavitation, and air–fluid levels are often present (Figure 35.1 and 35.2). Chest tomography can further define the extent and location of the abscess (Figure 35.3). The lung segments most commonly involved are those that are dependent when the person is supine (i.e., posterior segments of the upper lobes and superior segments of the lower lobes).

The microbiologic diagnosis of lung abscess is hampered by contamination of specimens by the normal anaerobic flora of the mouth, prior antimicrobial therapy, and difficulties inherent in culturing and identifying anaerobic bacteria. Although the Gram stain of sputum may be helpful in suggesting an etiologic diagnosis, routine sputum cultures are of no value because all contain anaerobic organisms. Techniques that have been used to obtain uncontaminated lower airway specimens for anaerobic cultures include transtracheal needle aspiration, transthoracic needle aspiration, and open lung biopsy. Using these techniques, early investigators demonstrated anaerobic bacteria in virtually all untreated patients. These invasive techniques are seldom warranted in the clinical management of patients today. Quantitative cultures of bronchoalveolar lavage or

FIGURE 35.1 Chest radiograph showing a large lung abscess with air–fluid level in the right upper lobe.

other bronchoscopically obtained lower airway specimens, such as those obtained with a protected specimen brush, may prove useful in the occasional patient suspected of having lung abscess but are not needed in most. Transthoracic fine needle aspiration guided by either ultrasound or CT has been used increasingly for diagnostic purposes. Although generally safe in experienced hands, serious complications such as pneumothorax and bacterial contamination can result and greatly prolong the recovery period.

Anaerobic organisms most commonly recovered from lung abscesses are listed in Box 35.1. Multiple anaerobic organisms are commonly present along with aerobic or microaerophilic

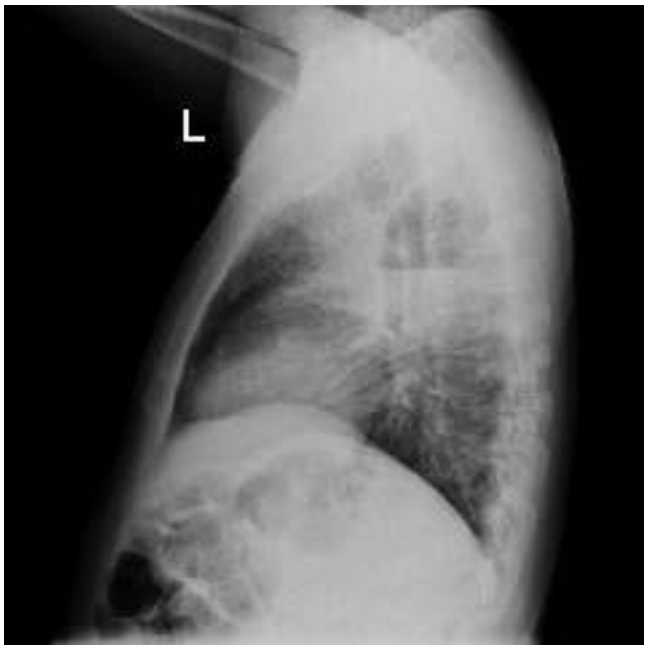

FIGURE 35.2 Corresponding lateral chest radiograph confirming that the large lung abscess with air–fluid level is located in the right upper lobe.

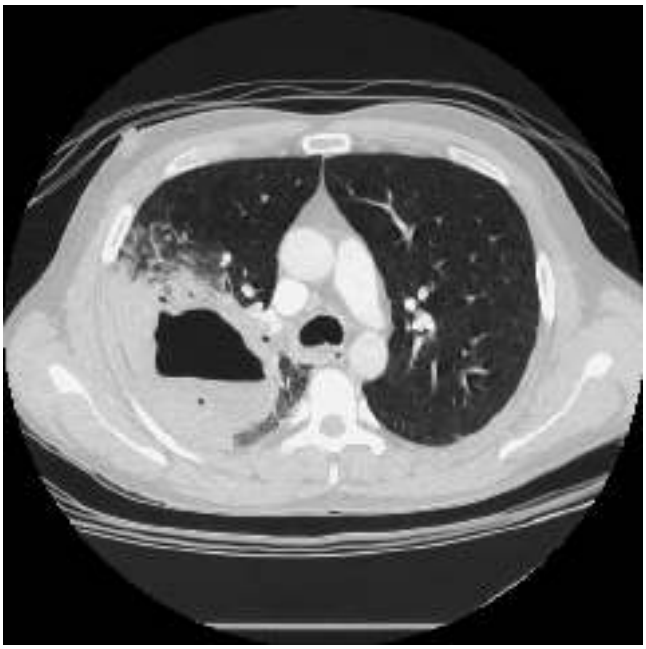

FIGURE 35.3 CT scan of the chest further defines the location and extent of the lung abscess measuring 8 × 6 cm.

organisms. The viridans streptococci, particularly the *Streptococcus milleri* group, appear to be significant pathogens. *K. pneumoniae* was the most common pathogen in a retrospective review of 90 cases of community-acquired lung abscess from Taiwan. *K. pneumoniae* was recovered from 30 patients (33%), compared to 28 patients with anaerobic organisms. In an observational hospital-based study

Actinomyces spp.

in India, *K. pneumoniae* was isolated from sputum cultures in 23 of 46 patients (50%) with lung abscess; anaerobic cultures were not obtained. In a retrospective single-center retrospective study of pediatric lung abscess, *S. aureus* and streptococcal species were the most common single pathogen identified, but in more than half of the patients no organism was recovered. The most likely explanation for these findings is lack of anaerobic cultures, prior antibiotic therapy, and geographic location. Other than determination of β-lactamase production, susceptibility testing of anaerobic organisms is usually not required.

Therapy

Most lung abscesses are treated empirically. Table 35.1 provides therapeutic options for intravenous treatment of lung abscess. Selection of agents should be guided by the spectrum of pathogens suspected or isolated from appropriately collected specimens. Historically, penicillin has been the antibiotic of choice because of its good in vitro activity against most anaerobic and microaerophilic bacteria present in the oral cavity. Two randomized clinical trials found that clindamycin is superior to penicillin, with time to resolution of symptoms and failure rate significantly lower in clindamycin-treated patients. Failure of penicillin therapy was associated with the isolation of penicillin-resistant *Bacteroides* spp. in one of these studies. Although increasing resistance of anaerobes and gram-positive bacteria to clindamycin has been reported, it is still preferred over penicillin for treatment of lung abscess when anaerobes or microaerophilic streptococci are likely to be predominant pathogens.

Although the combination of metronidazole and penicillin has been used successfully for the treatment of anaerobic pulmonary infections for decades, it should not be used if staphylococci or aerobic gram-negative bacilli may be part of the infectious process. Metronidazole has excellent bactericidal activity against virtually all gram-negative anaerobes but lacks activity against microaerophilic streptococci, as well as *Actinomyces* spp., and should not be used as a single drug agent in the treatment of lung abscess.

A number of other agents have good in vitro activity against anaerobic organisms, including β-lactamase producers, and may pose less risk for the development of *Clostridium difficile*-associated disease than clindamycin. These agents include second-generation cephalosporins, carbapenems, β-lactam/β-lactamase inhibitor combination drugs, and newer fluoroquinolones. In addition, these drugs are attractive for the treatment of lung abscess because of their activity against many of the aerobes that may be present in mixed infections. Ampicillin-sulbactam was found to be as effective as clindamycin with or without an added cephalosporin in the treatment of aspiration and lung abscess in a prospective trial. Drugs that have little or no anaerobic activity should not be used in the treatment of lung abscess. These include aminoglycosides, aztreonam, and the older fluoroquinolones, levofloxacin and ciprofloxacin. Although a number of newer antimicrobials have a suitable spectrum of activity in vitro, it is unlikely that any will ever prove to be more efficacious than current therapy in prospective clinical trials. This is because of the difficulties inherent in conducting trials in this condition—no single institution sees large numbers of patients with lung abscess, it is difficult to isolate anaerobic organisms from uncontaminated respiratory specimens for accurate diagnosis and susceptibility testing, and the patients' response to treatment varies widely but is often slow, which can lead to the erroneous conclusion of treatment failure if that decision is made too early.

TABLE 35.1 **INTRAVENOUS ANTIBIOTIC THERAPY OF ANAEROBIC LUNG ABSCESS**[a]

Antibiotic	Intravenous dosage	Frequency
Clindamycin	600 mg	q8h
Penicillin G plus	2–3 million U	q4h q6h
Metronidazole	500 mg	
Alternative regimens with broader-spectrum activity[b]		
Ampicillin–sulbactam	3 g	q6h
Piperacillin–tazobactam	3.375 g	q6h
Cefoxitin	2 g	q6h
Ertapenem	1 g	q24h
Imipenem	500 mg	q6h
Meropenem	1 g	q8h
Moxifloxacin	400 mg	q24h

[a] All dosages are for adults with normal renal function.
[b] Includes activity against gram-negative aerobic bacilli.

Duration of therapy

The duration of therapy for lung abscesses must be individualized, but extended therapy is usually required. Parenteral therapy is recommended initially in seriously ill patients and should be continued until the patient is afebrile and clinically improving. A prolonged course of oral antibiotics follows initial parenteral therapy. Less severely ill patients can be treated effectively with oral antibiotics alone. Options for oral therapy are provided in Table 35.2. Therapy should be continued until there is complete resolution or at least stabilization of chest radiographic lesions—this may require 6 to 8 weeks of therapy. Relapses may occur when therapy has been

TABLE 35.2 **ORAL ANTIBIOTIC THERAPY OF ANAEROBIC LUNG ABSCESS**

Antibiotic	Dosage (mg)	Frequency
Clindamycin	300	QID
Penicillin G plus	750	QID
Metronidazole	500	QID
Amoxicillin/clavulanate	875	BID
Moxifloxacin	400	Daily

All dosages are for adults with normal renal function.

discontinued before resolution of chest radiographic findings, even when patients are clinically asymptomatic.

Other therapy

The majority of patients with lung abscesses respond to appropriate antimicrobial therapy and spontaneous drainage of the abscess through the tracheobronchial tree. Bronchoscopy may be required in those who have unchanged or increasing air–fluid levels and who remain septic after 3 to 4 days of antibiotic therapy. However, it rarely results in direct drainage of the abscess cavity and may lead to spillage of purulent material into the airways. In patients failing to respond to medical therapy and in those with large abscess cavities (>6–8 cm diameter), drainage may be accomplished percutaneously, endoscopically, or surgically. Percutaneous catheter drainage, guided by CT or ultrasound, is the approach that has gained the most popularity in recent years. Although there are no controlled trials evaluating the role of this procedure in the treatment of lung abscess, a review of the literature suggests that in appropriately selected patients this approach is safe and effective. The safety of this approach, however, depends critically on the degree of synthesis of the two pleural surfaces. If the visceral pleura has not been firmly adhered to the chest wall, a pyopneumothorax results, often with bronchopleural fistula—a true disaster that is to be avoided. Successful drainage through pigtail catheters placed directly in abscess cavities using a flexible bronchoscope, in some instances with use of a laser to perforate the abscess cavity, has been described. Most recently endobronchial ultrasound has been used in endoscopic drainage of lung abscesses. It must be remembered that the gross appearance of the bronchial orifice and the results of cytological examinations may falsely suggest the presence of an underlying malignancy because of intense and long-lived inflammation. However, lung abscesses in adults >50 years of age are frequently associated with carcinoma of the lung, either because of cavitation of the neoplasm or cavitation behind a proximal bronchial obstruction. Such patients should be followed to resolution with great care. Thoracotomy or video-assisted thorascopic surgery for resection of lung abscess (most commonly a lobectomy), is required in fewer than 15% of patients. Surgery is generally reserved for patients who have failed medical therapy and other attempts at drainage and may have additional complications such as empyema, bronchopleural fistula, or suspicion of malignancy.

Empyema and bronchopleural fistula

Charlotte E. Bolton and Dennis J. Shale

Infection of the pleural space leading to empyema formation, and the importance of clearing infection and pus from this space, has been recognized since ancient times. Historically, empyema was associated with pneumococcal pneumonia, with *Streptococcus pneumoniae* causing up to 70% of pleural space infections. With effective antibiotic treatment for community-acquired pneumonia, the incidence of empyema due to pneumococcus has decreased and the spectrum of causative organisms has widened, with *S. pneumoniae*, *Streptococcus Milleri* group, and *Staphylococcus aureus* now accounting for up to approximately 65% and an increasing isolation rate for anaerobes and gram-negative organisms. However, parapneumonic effusions occur in 30% to 60% of pneumonia cases, and, when empyema occurs, it is associated with an overall mortality of 20% with a further 20% requiring surgical intervention. Importantly, a reported increase has occurred in recent times with the young and elderly at the greatest risk of empyema.

Parapneumonic effusions are classified as simple or uncomplicated, complicated, and empyema, based on the appearance and biochemical characteristics of aspirated fluid, which supports the clinical impression of a continuum of disease (Table 36.1).

This classification also has clinical utility in that, during the early acute phase, with free flowing fluid, treatment is simpler than in the more chronic fibropurulent stage associated with multiple loculations and the need for greater interventional therapy. Empyema may be defined as the presence of organisms and numerous host defense cells, neutrophils, in the pleural fluid, or, more narrowly, as pus apparent to the naked eye. Bronchopleural fistula (BPF) may be caused by an empyema or may be associated with empyema formation following surgery, penetrating lung injuries, or a lung abscess.

Etiology

Empyema occurs most commonly in association with bacterial pneumonia, either in a community-or hospital-acquired setting. In a study in 434 pleural infections in the United Kingdom using standard culture and nucleic acid amplification techniques a causative organism was identified in 74%. Of the 336 isolates in the community-acquired setting 52% were of the genus *Streptococcus*, approximately 20% were anaerobes, 10% were staphylococcal, and 10% were gram-negative organisms. In the hospital-acquired infections (60 isolates) *Staphylococcus* was the major genus isolated (35%) of which 71% were methicillin-resistant forms; 23% were gram-negative organisms; 18% were *Streptococcus*; and 8% were anaerobes. Other organisms isolated included *Actinomyces* spp., *Enterococcus* spp., and *Mycobacterium tuberculosis*. This large study supports smaller studies suggesting the spectrum of organisms in pleural infections differs from that in pneumonia. Local events such as thoracic surgery, rupture of the esophagus, hepatic or subphrenic abscesses, and all penetrating injuries may introduce organisms, especially gram-negative or anaerobic organisms, into the pleural space. Ameba may enter the pleural space from an amebic abscess in the liver. Tuberculous empyema is a modest problem in the developed world, but is still seen in reactivation of tuberculosis in the elderly. However, in developing countries, with rapid urbanization, continued population increase, and greater levels of human immunodeficiency virus infection, there is an increasing incidence of tuberculous empyema.

TABLE 36.1 **CLASSIFICATION OF PARAPNEUMONIC EFFUSIONS AND EMPYEMA**

	Appearance	Biochemistry and bacteriology	Risk category for poor outcome
Simple/uncomplicated parapneumonic	Clear fluid	pH >7.2	1 and 2
		LDH ≤1000 IU/L	Very low or low
		Glucose >3.3 mmol/L	
		Negative Gram smear or culture	
Complicated parapneumonic	Clear fluid or turbid	pH ≤7.2	3
		LDH >1000 IU/L	Moderate
		Glucose ≤3.3 mmol/L	
		Positive Gram smear or culture likely	
Empyema	Frank pus	Positive Gram smear or culture likely	4
		Biochemistry unnecessary	High

Pleural space infections may cause a BPF or may occur secondary to a BPF. Lung resection surgery remains the major cause of BPF, occurring in 3% to 5% of these operations.

Clinical features

There are no specific clinical features to differentiate simple from uncomplicated parapneumonic effusions. The main features are fever, chest pain, sputum production, appropriate physical signs of an effusion, and peripheral blood leukocytosis. Progression to an empyema is usually indicated clinically by the persistence or recurrence of fever and features of systemic upset with a lack of resolution of physical signs, because differentiation of consolidation from a small- to medium-volume effusion may not be possible. Other physical features include dyspnea with large effusions, rapid-onset finger clubbing, lethargy, and marked weight loss. Purulent sputum may indicate the development of a BPF. However, more insidious onset may occur with the presentation occurring over weeks to months after the original pneumonia or injury.

Investigations

A chest radiograph usually shows collection of fluid, although a localized, loculated collection may resemble an intrapulmonary mass. Differentiation between these possibilities may be resolved by the addition of a lateral chest radiograph to the standard posteroanterior film or by ultrasound or computed tomographic (CT) scanning. Ultrasonography is superior to CT in identifying septations in a loculated collection and also defines pleural thickening. Increasingly bedside ultrasound is used to guide a percutaneous diagnostic aspiration, increasing the diagnostic yield and patient safety. However, it is occasionally difficult to distinguish between empyema with a BPF and a lung abscess. In this setting, the use of CT scanning may guide both investigation and management approaches.

Aspirated material should be collected under anaerobic conditions and a portion submitted for anaerobic culture and a sample in a blood culture bottle can increase the anaerobic yield. Routine bacterial and mycobacterial culture should be undertaken with cytologic examination. If appropriate, fungi and parasites should be sought. Other investigations including pH, glucose concentration, and lactate dehydrogenase (LDH) activity of the fluid may be of use if there is little evidence of purulence to the naked eye. A meta-analysis of pleural fluid biochemistry, based on user characteristics, demonstrated that pH, especially ≤7.2, was a guide to the need for tube drainage and that glucose or LDH determination conferred no extra benefit; however, if pH assessment is unavailable, a glucose ≤60 mg/dL (3.3 mmol/L) is an alternative guide. Pleural fluid pH is measured in nonpurulent samples taken into a heparinized syringe and determined in a blood gas analyzer. There is no need to determine the pH of purulent samples. Litmus paper assessment is not an alternative. It should be remembered that lidocaine can lower the pH of samples and hence the sampling syringe should not be contaminated by this.

Generally, percutaneous pleural biopsy is not helpful and potentially harmful, although the diagnosis of tuberculosis is often made only from such material.

The literature on the value of individual investigations in guiding management is very limited. The American College of Chest Physicians (ACCP) analysis of risk of a poor outcome is based on pooled data, a small number of randomized controlled trials, and expert consensus but provides a framework to guide management of treatment (Table 36.1).

Therapy

There has been a paucity of evidence on which to base therapeutic decisions, which reflects the wide breadth of the condition in terms

TABLE 36.2 **MANAGEMENT OPTIONS FOR PLEURAL SPACE INFECTION**

Therapeutic option	Comment
Observation and antibiotics	Acceptable option for small-volume category 1 or 2 low-risk collections
Therapeutic thoracentesis	Repeated treatment used in complicated effusions and empyema. Small studies suggest benefits, but no comparison with tube drainage
Tube thoracostomy	Most commonly used drainage method. Combined with antibiotics can improve clinical and radiologic status in 24–36 hours
Fibrinolysis	Probably not of value in most complicated effusions. Can be used in patients unfit for required surgical intervention
Medical or surgical thoracoscopy	Allows complete drainage and inspection of the pleural space. Small studies suggest leads to more rapid resolution of effusion
Decortication	Allows removal of all pus, tissue debris, and connective tissue. Is major surgery and requires the patient to be fit for surgery. Appropriately used, will reduce management period. Not for routine management of residual pleural thickening
Open drainage	An alternative option to decortication for patients unfit for surgery, but leads to a prolonged recovery period

of clinical feature and pathology. However, the recent ACCP and the British Thoracic Society (BTS) UK guidelines have both reviewed evidence and graded it to develop management recommendations. These documents represent current good practice, but both emphasize the need for more robust studies in the area of the management of pleural space infections.

Management options are summarized in Table 36.2 with summary notes. All patients with a pleural effusion in the presence of sepsis or pneumonia require diagnostic aspiration. Patients with parapneumonic effusion or empyema require antibiotics, usually, commenced empirically and subsequently guided by culture results. Many will have received antibiotics already, and negative cultures do not indicate cessation of antimicrobial therapy.

Small or insignificant effusions, the maximal thickness of which is ≤10 mm on ultrasound scanning or decubitus radiograph, simple or uncomplicated (category 1), may not need thoracentesis and are unlikely to need tube drainage. However, if the volume increases up to 50% hemithorax, simple or uncomplicated (category 2), or a positive Gram stain or culture is reported, further thoracentesis is recommended, though in a very small effusion such results are often false positives. In these categories the risk of a poor outcome is low, and they equate to the former simple or uncomplicated parapneumonic effusions.

Larger effusions occupying more than 50% hemithorax with evidence of loculation or parietal pleural thickening or with a pH ≤7.2 or evidence of infection in the pleural space (category 3) require closed tube drainage and carry a moderately high risk of a poor outcome. Generally, such drainage is effective, though negative low-pressure high-volume suction may be needed if flow is slow and will hasten the obliteration of the pleural space. In the past large-bore tubes were recommended for drainage, but more recently narrow-bore tubes placed with imaging guidance have been shown to be just as effective and to be better tolerated by patients. Tube drainage is contraindicated in patients with a neoplasm causing airway obstruction, which is the only indication for bronchoscopy in empyema. Full characterization of this category, which corresponds to the complicated parapneumonic effusions in other classifications, requires more extensive investigation to develop an appropriate management plan (Table 36.2). Effective antibiotic choice and closed tube drainage should lead to radiologic and clinical improvement within 24 to 36 hours. Failure to respond requires further investigation, including imaging to assess tube position, any residual collection, or the formation of loculation, and should include either ultrasound or contrast-enhanced CT scanning as loculation and parietal pleural thickening are indicators of a poor outcome. A slow response to lack of improvement will allow an empyema to form and may require surgical intervention, while increasing the risk of prolonged morbidity and a higher mortality.

The presence of pus defines an empyema (category 4), which carries a high risk of a poor outcome and requires closed tube drainage and antibiotic treatment. Frequently in empyema, the chest tube can become blocked, requiring saline flushes to maintain patency. As many infections will be of mixed organisms, antibiotic coverage for both anaerobic and nonanaerobic organisms is required. Surgical options are likely to be needed in this group. It requires a cautious and balanced decision so that surgery is not contemplated too late, a widely reported problem, when the patient's condition may reduce the chance of a satisfactory outcome. Medical or surgical thoracoscopy has been reported to reduce the time to recovery and to be as effective as formal surgical intervention, but the design of comparisons is inadequate to make firm recommendations other than that surgical options should be pursued if there is evidence of continuing sepsis and a collection after 7 days of antibiotic treatment and drainage.

Decortication aims to remove pus and fibrous tissue lining the pleural cavity but is a major surgical procedure and is unsuitable for debilitated patients, who should be considered for fibrinolytic therapy or open drainage. Decortication has the benefit of a quicker resolution of the empyema over methods of open drainage, which have a median healing period of 6 to 12 months. In general, decortication is not needed for residual pleural thickening from the successful management of categories 3 or 4, unless it persists for longer than 6 months or where there is extensive pleural thickening or respiratory symptoms secondary to restrictive effects.

The evidence for using fibrinolytic agents has been inconclusive due to small, often open, studies. A recent double-blind study in 454 patients with complicated pleural infection and at category 3 or 4 risk compared streptokinase with placebo, with all other treatment options as per routine. The primary end point of death or surgical drainage at 3 months was no different between treatment groups, $p = 0.43$. Similarly, secondary end points of death rate, requirement for

BOX 36.1

Management of bronchopleural fistula (BPF)

Small BPF

- Some may close spontaneously:
- Without empyema
  - Transbronchoscopic fibrin glue
  - Transbronchoscopic tissue glue
  - Transbronchoscopic vascular occlusion coils/Amplatzer devices
  - Transbronchoscopic laser/tetracycline/gel foam
  - Thoracoscopic sealing
- With empyema
  - Antibiotic/tube drainage and attempted closure of BPF

Large BPF

- Typically associated with empyema:
  - Surgical options include decortication or open drainage of empyema and occlusion of the BPF by direct closure or well-vascularized muscle or omental flaps

surgery, radiographic outcome, and length of hospital stay were also no different between the streptokinase or placebo groups, whereas serious adverse events were increased in the streptokinase group, relative risk 2.49 (95% confidence interval 0.98–6.36). Important contraindications include BPF, coagulation disorders, and allergy.

Currently fibrinolytic therapy is not recommended for routine care of infected pleural effusions but remains an option for the patient unfit for surgery or in the absence of free flowing pus. Treatment with streptokinase 250 000 international units twice daily for 3 days or urokinase 100 000 international units daily for 3 days has been recommended. The latter is less likely to produce allergic side effects. Early clinical studies comparing the use of streptodornase (DNase) with tissue plasminogen activator and in combination in complicated parapneumonic effusions and empyema suggest this combination is effective and reduces the need for surgery and the length of hospital stay.

This classification of empyema has the value of matching a spectrum of clinical status to a plan of escalating therapeutic options but remains only a guide based on limited evidence. Patients may move in either direction along this spectrum, so careful and repeated assessment of the patient's status is required, particularly soon after a therapeutic intervention is made, to ensure a continuing appropriate management response.

The aim with BPF, whether in the setting of trauma, neoplasm, or empyema, is to deal with the air leak and any new or residual empyema. Air in the pleural cavity indicates the presence of a BPF and need for tube drainage. The air leak may be dealt with either by surgical or by nonsurgical intervention, largely depending on the size and duration of the BPF (Box 36.1).

Pleural space infections demand major management decisions of physicians. There are various approaches to the patient with empyema and BPF, and the heterogeneity of the response means that the management of this problem should be individualized to the patient. There is considerable literature relating to such problems, but most studies until recently have been too small to demonstrate clear beneficial options.

Clinical syndromes: Heart and blood vessels

37

Endocarditis

John L. Brusch

Definition and pathogenesis

The term *infective endocarditis* (IE) describes an infection of the endothelial surface of the heart, most commonly that of a valve. Cases may be categorized in several ways: as acute (ABE) or subacute (SBE) on the basis of the speed of their clinical progression, or by pathogenic organism (e.g., *Staphylococcus aureus*), or by location (e.g., right- or left-sided), or by the nature of the infected material (native tissue vs. prosthetic), or by the mechanism of acquisition, such as intravenous (IV) drug abuse. When approaching a case of possible IE, it is quite helpful to generate a profile of disease process using the preceding characteristics especially when it comes to empirically choosing the initial antibiotic regimen.

Pathogenesis

All varieties of IE share the same basic pathogenesis: a bloodstream infection that delivers the organisms to the surface of the valve. Then, they must be able to firmly adhere.

Most microorganisms cannot directly attach to normal endothelium. They require a preexistent platelet fibrin thrombus or nonbacterial thrombotic endocarditis (NBTE). This results from a variety of valvular abnormalities that cause turbulent blood flow across a high- to low-pressure gradient and denude epithelium from surfaces impacted by the turbulence. The damaged endothelium loses its anticoagulant properties. A sterile nidus of platelets and fibrin form over this area and gradually develop into NBTE.

Over time, the transient *Streptococcus viridans* bacteremias of daily living, which occur after injury to mucosal surfaces in the oropharynx, genitourinary tract, or gastrointestinal tract, stimulate the formation of agglutinating antibodies that cause the streptococcus to clump together; these are not bactericidal. When these antigen–antibody clumps reach a critical mass, they are able to adhere to the NBTE by means of their ability to produce an extracellular dextran, glucan, and adhesive matrix of molecules (MSCRAMMs) that attach to the fibronectin-platelet units found within the thrombus. There, they multiply and stimulate further deposition of platelets and fibrin. This is amplified by activation of the extrinsic clotting pathway as well as by cytokine and fibronectin production. Streptococci may actually produce biofilms within this vegetation. All of these factors quite effectively thwart the body's defenses as well as interfere with antibiotic effectiveness because of the reduced metabolic state of the pathogens and limited penetration into the thrombus itself. The concentration of bacteria within the thrombus may be $>10^{10}$ colony-forming units per gram of tissue.

Complications may arise through local bacterial spread or through embolization of fragments of the vegetation. The endovascular location of the lesions causes multiorgan bacterial seeding as well as organ damage through immune complex deposition.

S. aureus does not require any preexisting NBTE to initiate valvular infection. It has the ability to directly enter endothelial cells (endotheliosis). In doing, it shuts off the anticoagulation effect of the cells. Microthrombi appear on the valve surface and enlarge, as just described.

Epidemiology

Since the 1960s, the mean age of patients with IE has increased from 58.6 to 60.8 years (1998–2009). The overall incidence of IE in the United States increased from 11/100,000 population to 15/100,000 population from 2000 to 2011. These increases have been driven primarily by the proliferation of various types of intravascular devices as well as the aging of the population. Approximately 50% of the cases are seen in those >60 years of age. Males are disproportionately affected.

S. aureus, both methicillin-sensitive (MSSA) and methicillin-resistant (MRSA), have become the most common cause of acute IE, IV drug abuse IE (IVDAIE), prosthetic valve IE (PVIE), and intravascular device-associated valvular infections. Approximately 17% of these infections are caused by *S. viridans*. Coagulase-negative staphylococci (CoNS) and enterococci each account for 11% of cases.

Native valve endocarditis

In most cases of native valve endocarditis (NVE), there is an identifiable predisposing cardiac lesion. Mitral valve prolapse with regurgitation is the most common underlying cardiac abnormality in patients with IE in the United States. Rheumatic heart disease remains the most common underlying valvular abnormality in developing countries. Other recognized predisposing cardiac lesions are ventricular septal defects, subaortic and valvular aortic stenosis, tetralogy of Fallot, coarctation of the aorta, Marfan syndrome, and pulmonary stenosis.

As mentioned earlier, overall cases of IE have increased significantly since 2005. The rate of increase in prior years had been initially attributed to the "graying" of the population and, more recently, to the growth of intracardiac/intravascular device placement. In addition, it has become recognized that the increasing incidence may well be associated with 2005 recommendations to forego antibiotic prophylaxis in those at moderate risk of developing IE associated with various procedures. In response, there has been a significant growth of IE in moderate-risk individuals (75%) and a greater growth in those patients at high risk (177%). In part, this rise may be attributable to the decrease in recommended antibiotic prophylaxis. About 70% of cases of NVE are due to *S viridans*, *S. bovis,* and enterococci. *S. aureus* has surpassed the *S. viridans* group streptococci as the leading overall cause of SBE. In data published from the International Collaboration of Endocarditis-Prospective Cohort Study (ICE-PCS), *S. aureus* was the most commonly identifiable pathogen among the 1,779 cases of definitive IE (31.4%). *S. aureus* accounts for 25% of NVE. It is currently the most aggressive form of native valve infection with a higher mortality rate and greater incidence of embolic and/or central nervous system (CNS) events (Figures 37.1–37.3). Enterococcal IE accounts for 10% of cases. It typically occurs in elderly men and young women with underlying genitourinary disease. In recent years, both enterococci and staphylococci have become major pathogens in infections originating from intravascular catheters. HACEK group (*Haemophilus* spp., *Aggregatibacter* spp., *Cardiobacterium hominis,*

FIGURE 37.1 Splinter hemorrhage of nails in patient with *Staphylococcus aureus* infective endocarditis.

Eikenella corrodens, and *Kingella* species) gram-negatives account for <10% of community-acquired IE. Fungi rarely cause IE on a native valve (2%) except in IV drug abusers (13%).

Prosthetic valve endocarditis

The overall incidence of prosthetic valve endocarditis (PVE) is 1% to 4% during the first 12 months following valve surgery. PVE accounts for 20% to 30% of total cases of IE. The causative organisms

FIGURE 37.2 Embolic lesions in a patient with *Staphylococcus aureus* infective endocarditis.

FIGURE 37.3 Embolic lesions in a patient with *Staphylococcus aureus* infective endocarditis.

differ in early and late PVE. Infection within 60 days of valve insertion is considered to be early PVE that is usually caused by CoNS (25–30%) or *S. aureus* (15–20%). During this time, infection of the valve is caused by contamination of the operative field or through healthcare-associated bloodstream infection (HCBSI). Sites of bacterial adherence are the sutures, sewing ring, and cardiac annulus. As the implanted valve gradually becomes coated (conditioned) with tissue proteins, fibronectin, and fibrinogen, this facilitates microorganisms "sticking" to the valvular structures.

The intermediate postoperative phase occurs 60 to 365 days after implantation. The sewing ring has become "endothelialized" by cells that do not express the antithrombotic properties of normal endothelium, especially at the sewing cuff of the valve. During the intermediate period, the profile of pathogens becomes increasingly similar to that of NVE except that CoNS continues to be a significant cause of PVE.

The 1-year postoperative date marks the beginning of the late phase of PVE. At this time, the percentage of PVE caused by CoNS stabilizes at 10%.

In a prospective study of patients with prosthetic valves and *S. aureus* bacteremia conducted at Duke University Medical Center, 26 of 51 patients (51%) developed PVE. The risk of endocarditis in this study was independent of the type of valve (mechanical vs. bioprosthetic), location (mitral vs. aortic), or onset of bacteremia after prosthetic valve implantation. The remaining cases of PVE are caused by gram-negative aerobic organisms, enterococci, diphtheroids, and streptococci. Fungal endocarditis may develop in patients with prolonged hospitalization with indwelling central venous catheters and long-term antibiotic use. Organisms that cause late PVE closely resemble those of NVE, although staphylococci remain predominant.

Nosocomial endocarditis

Nosocomial infective endocarditis (NIE) describes IE diagnosed after 48 hours of hospitalization and up to 4 weeks following a hospital-based procedure. The term "healthcare-associated infective endocarditis" (HCIE) describes cases of IE acquired outside the hospital. Patients with either NIE or HCIE are more likely to be diabetic, to be on hemodialysis, or to have been subjected to intravascular catheters or inserted intracardiac devices, and are more likely to have persistent *S. aureus* bloodstream infection. IE can occur as a complication of nosocomial bacteremia.

Since the mid-1980s, the increased use of intravascular devices and invasive diagnostic procedures, with their consequent complications, has increased the risk of HCIE. Colonized intravascular catheters now account for up to two-thirds of HCIE. The most common pathogens isolated in this type of infection are CoNS (15%), enterococci (14%) streptococcal species (8%), gram-negatives (5.8%), culture-negative (4.7%), and *Candida* species. Only 25% of patients with NIE will have fever or chills.

The upsurge of intravascular catheter-related bloodstream infections (CRBSIs) is directly related to an increase in the acute IE caused by *S. aureus*. In the past two decades, CRBSIs have increased >100%. The risk for this type of infection significantly increases 3 to 4 days after the insertion of the catheter.

During the first 15 days after insertion, skin flora makes up the greatest source of infection for these devices. After this time, contamination of the upper portion of the catheter by healthcare providers is a major source and leads to colonization of the hub and resultant intraluminal contamination. The risk of contamination/infection of the system is directly related to the length of time that the catheter remains in place and to the degree of manipulation of the hub. Rarely is a contaminated infusate the source of infection. Shortly after insertion, the catheter's extraluminal wall becomes coated with a fibrin-platelet thrombus that becomes covered by endothelial cells. This structure essentially becomes an NBTE, which can become infected as skin bacteria, commonly *S. aureus*, migrate down the insertion tract. *S. aureus* in the infected thrombus may enter the bloodstream as well as the endothelium of the adjacent vein, multiply there, and then re-enter the bloodstream, resulting in a sustained *S. aureus* bacteremia. This may or may not lead to valvular infection. This process may explain persistent *S. aureus* bloodstream infection with negative transesophageal echocardiogram (TEE).

The Infectious Disease Society of America has updated its CRBSI guidelines with key recommendations regarding *S. aureus* bloodstream infection (Box 37.1). *S. aureus* in blood should rarely, if ever, be considered a contaminant, and a low threshold should be maintained regarding suspicion of IE in this setting.

Long-term catheters should be removed in the setting of endocarditis. TEE should be performed (at least 5–7 days after the onset of bacteremia or fungemia) for patients with CRBSI who have a prosthetic heart valve, pacemaker, or implantable defibrillator.

Infective endocarditis in the intravenous drug abuser

IVDAIE accounts for at least 25% of total cases of IE, and this number is rising. The incidence of hospitalization for IV drug abuse has reached 12%, and HIV infection is four times higher in this population (40–90%). Those with CD4 counts of less 350 are eight

BOX 37.1

Catheter-related bloodstream infections (CRBSIs) with *Staphylococcus aureus*

Catheter removal recommended

Long-term catheters should be removed from patients with CRBSI associated with any of the following conditions: endocarditis, severe sepsis, bloodstream infection that continues despite >72 h of appropriate antimicrobial therapy, suppurative thrombophlebitis, or infections due to S. aureus, Pseudomonas aeruginosa, fungi, or mycobacteria.

S. aureus specific recommendations

In addition to catheter removal, patients should receive 4–6 weeks of antimicrobial therapy, or a minimum of 14 days of therapy if they meet the following criteria: the patient is not diabetic or immunosuppressed; if the infected catheter is removed; if the patient has no prosthetic intravascular device (e.g., pacemaker or recently placed vascular graft); if there is no evidence of endocarditis or suppurative thrombophlebitis on TEE and ultrasound, respectively; if fever and bacteremia resolve within 72 h after initiation of appropriate antimicrobial therapy; and if there is no evidence of metastatic infection on physical examination and sign or symptom-directed diagnostic tests.

times more likely to develop IVDAIE. The tricuspid valve is involved in 30% to 70% of cases; 13% involve both right and left sides of the heart. *S. aureus* causes up to 70% of cases. The contributions of other pathogens are as follows: streptococcal species, 8%; enterococcal species, 2%; fungal species, 2%; gram-negative anaerobes, 5%; and polymicrobials, 9%. The polymicrobial infections include various combinations of *Pseudomonas* sp., *S. aureus,* and *S. pneumoniae.* Polymicrobial IE most likely reflects poor injection techniques such as using contaminated water, sharing needles, and licking needles for good luck before injection.

Endocarditis in IV drug abusers involves mainly normal valves. Only 20% to 30% of the patients have an underlying valvular abnormalities. As discussed, *S. aureus* can produce its own sterile valvular thrombus. It is postulated that organisms that cannot do so produce an NBTE through contaminant particulate matter contained within the injected material. The tricuspid valve is predominantly involved in IVDAIE, but aortic and mitral valves may also be damaged. Although *S. aureus* is known to be the most common causative organism in patients with IE associated with IV drug abuse, a variety of microorganisms and fungi, including unusual and fastidious organisms (e.g., the HACEK group) and gram-negative organisms (e.g., *Pseudomonas* spp. from water sources used), are not uncommon in IV drug abusers, particularly in the patients who are not meticulous in their injection practices.

Right-sided IV drug abusers will commonly present with pleuritic pain, hemoptysis, cough, or empyema caused by septic pulmonary emboli. Left-sided disease (30% of cases) may lead to cerebral mycotic aneurysms (especially with *P. aeruginosa*), renal failure, and septic arthritis.

Polymicrobial infections may also occur. Because of the higher incidence of right-sided lesions and the generally younger age of the affected group, prognosis for recovery in treated IVDAIE is better than in the general population. However, valvular damage sustained in the course of the infection confers an extremely high risk of recurrent IE in those patients who continue to use IV drugs.

Diagnosis of infective endocarditis

Recognizing the clinical presentations of valvular infection is the first step toward arriving at a successful diagnosis. SBE makes itself manifest in markedly different ways than does acute disease. Untreated subacute disease may extend over a year. It often presents with non–cardiac-related symptoms such as renal failure, musculoskeletal complaints, and peripheral stigmata that are primarily immune complex-mediated. Fevers may not be consistently present and are usually low-grade. Because of the need for underlying preexisting valvular abnormalities, a cardiac murmur is almost always present. Often, there will be no change in the nature of the murmur during the disease process.

ABE is a rapidly progressing disease with very high-grade fever course. Congestive heart failure (CHF) develops early on. Occasionally, patients will have a more extended course prior to the correct diagnosis when they have been given antibiotics aimed incorrectly at misdiagnosed infections. This can result in a state of "muted" disease. These antibiotics simply dampen the symptoms of ABE but do not have any significant effect on the valvular infection.

The diagnosis of IE has been become more challenging due to a variety of factors, including increasing numbers of cases among the immunosuppressed with attenuated signs and symptoms of the disease as well as an increase in "nonclassic" organisms" for IE, such as CoNS. In addition, rheumatological diseases and lymphomas are quite effective mimics. Among patients with *S. aureus* CRBSI, there is a growing challenge in determining the significance of a noncontinuous bacteremia, as well as the challenge of interpreting the significance of a continuous bacteremia in the setting of a negative TEE.

Documentation of a continuous bacteremia is the major criteria for diagnosing IE. Such a bloodstream infection denotes that the source is an endovascular one.

Blood culture caveats:

1. Drawing one set of blood cultures is worse than drawing none. One cannot determine whether a positive culture is a contaminant or represents a continuous bacteremia.
2. The venipuncture site must be appropriately prepared with application of chlorhexidine, which is allowed to dry before the venipuncture is performed. Failure to do so is the major cause of contamination of blood cultures with CoNS.
3. An adequate volume of blood must be obtained:10 mL of blood per blood culture bottle. Inadequate volumes are the major cause of false-negative blood cultures.

4. Blood cultures should not be drawn from an intravascular catheter except in the setting of ruling out catheter infection.
5. No patient is too ill to delay initiation of antibiotic therapy for a few minutes to obtain two or three sets of blood cultures. They can be drawn in quick succession as long as the skin is appropriately prepared and the appropriate blood is drawn through different venipunctures.
6. Unless the patient has recently been on antibiotics or there is concern for CoNS PVE, no more than three sets of blood cultures need to be drawn. This exception for CoNS recognizes the fact that IE with this pathogen does not always have a continuous bacteremia.

Therapy

A vegetation consists of microorganisms in high density (10^{10} organisms/g of tissue) and in a reduced metabolic state inside an acellular lesion with impaired host defenses. Eradication of IE is thus almost totally dependent on the efficacy of the antimicrobial therapy. To achieve this end, certain principles of therapy are critical:

1. Parenteral antibiotics are usually required to provide a predictably high serum antibiotic level and thus optimize penetration of the antibiotic into tissue. There is growing evidence that in patients who are responding to 2 weeks of IV therapy, oral administration of well-absorbed antibiotic such as linezolid or levofloxacin can be effective.
2. Bactericidal rather than bacteriostatic antibiotics should be used to compensate for impaired host defenses in the vegetation. A major exception to this rule is the bacteriostatic antibiotic, linezolid.
3. Prolonged therapy is required for complete eradication of microorganisms.

In a patient with suspected IE but in whom culture results are not available, empiric antimicrobial therapy should be directed against staphylococci, streptococci, and enterococci unless epidemiologic data points at alternative etiologies. Nafcillin or oxacillin, 2 g IV every 4 hours, and gentamicin, 1 mg/kg IV every 8 hours, may be used as initial therapy. Vancomycin, 15 mg/kg every 12 hours, should be used if the patient is allergic to penicillin. Vancomycin should also be the drug of choice in suspected nosocomial endocarditis because of the high incidence of MRSA and coagulase-negative *S. epidermidis* (CoNS) in such a setting (see Figures 37.4 and 37.5).

Viridans streptococci and *Streptococcus bovis*

Antibiotic selection for therapy of streptococcal endocarditis is based on the minimal inhibitory concentration (MIC) of the isolated organism to penicillin (Table 37.2). Viridans streptococci and *S. bovis* are generally highly susceptible to penicillin (MIC ≤0.12 μg/mL) and can be treated with aqueous penicillin G or ceftriaxone for 4 weeks. The addition of gentamicin can shorten therapy to 2 weeks, but such therapy should be reserved for patients with NVE of <3 weeks duration with normal renal function and without intracardiac or extracardiac complications. The same regimen applies to the therapy of streptococcal PVE, but the duration of treatment is prolonged to 6 weeks. For streptococci with moderate resistance to penicillin (MIC 0.12 to ≤0.5 μg/mL), the addition of gentamicin for the first 2 weeks is always recommended to prevent

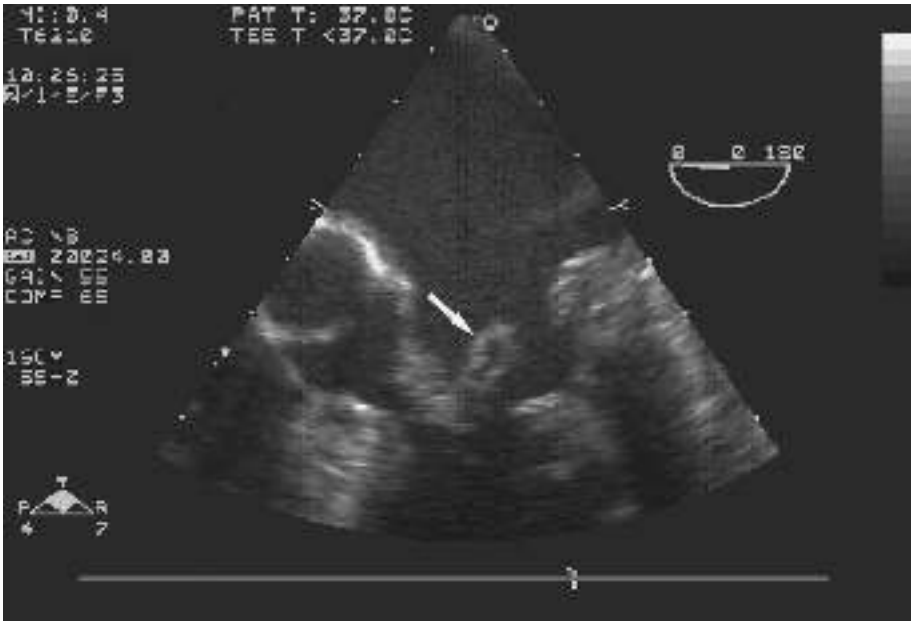

FIGURE 37.4 Transesophageal echocardiogram of a patient with *Haemophilus parainfluenzae* infective endocarditis showing large vegetation in mitral valve chordae apparatus (*arrow*).

TABLE 37.1 MODIFIED DUKE CRITERIA FOR DIAGNOSIS OF INFECTIVE ENDOCARDITIS

Definitive infective endocarditis

Pathologic criteria

Microorganism demonstrated by culture or histology of vegetation or emboli or intracardiac abscess

Histopathologically proven at autopsy or surgery

Clinical criteria

2 major; 1 major and 3 minor criteria; or 5 minor criteria

Possible infective endocarditis

1 major and 1 minor or 3 minor criteria[a]

Rejected

Alternative diagnosis, resolution of syndrome with ≤4 days of antibiotic; no histopathologic evidence with ≤4 days of antibiotic therapy; does not meet criteria for "possible" IE.

Major criteria	Minor criteria
Positive blood cultures	Predisposing heart condition or IV drug use
Typical microorganism for IE from 2 separate blood cultures, as follows:	Fever (38°C/100°F)
Viridans streptococci, *Streptococci bovis*, HACEK group, *Staphylococcus aureus*[a], or community-acquired enterococci with no primary focus	Vascular phenomena Immunologic phenomena
Persistently positive blood cultures with microorganism consistent with IE: At least 2 positive blood cultures drawn 12 h apart All of 3 or a majority of 4 or more separate blood cultures: first and last sample at least 1 h apart	Positive blood cultures but short of major criteria or serologic evidence of infection; excludes single positive blood cultures with coagulase-negative staphylococci and organism consistent with IE
Single blood culture positive for *Coxiella burnetii* or positive serology: antiphase 1 IgG ab titer 1:800[a]	Echocardiogram consistent with IE but short of major criteria was eliminated[a]
Endocardial involvement by showing vegetation; or abscess; or new prosthetic valve dehiscence; or *de novo* valvular regurgitation in echocardiogram. TEE recommended for prosthetic valve, "possible IE" cases, or complicated IE with intracardiac abscess[a]	

Abbreviations: TEE = transesophageal echocardiogram; IE = infective endocarditis; IgG = immunoglobulin G; ab = antibody.

Abbreviations: MIC = minimal inhibitory concentration; PCN = penicillin.
[a] Combination therapy has not demonstrated superior cure rates compared to monotherapy

relapse. IE caused by highly penicillin-resistant viridans streptococci (MIC 0.5 μg/mL) and by *Abiotrophia* and *Granulicatella* spp. (formally known as nutritionally variant streptococci) are difficult to treat and should be treated with the same regimen as recommended for enterococcal endocarditis. Vancomycin is to be administered only for patients with significant penicillin allergies. IV penicillin G and IV ampicillin are currently less frequently used because of their multiple dosing schedules(q4–6h).

It is important to make note of the possibility of surgical therapy for the treatment of *S. anginosus*. This is a group of *S. viridans* that behaves more like *S. aureus*. They may cause both intracardiac and extracardiac abscesses (brain abscesses). Frequently these sites require surgical drainage. Their antibiotic sensitivity pattern is like that of the other groups of *S. viridans.*

Staphylococci

Most penicillin resistant strains of *S. aureus* I don't produce beta-lactamases or are intrinsically methicillin resistant. Nafcillin or cefazolin should be administered for 6 weeks (Table 37.3). Vancomycin should be used only in cases of serious β-lactam allergy (immunoglobulin E [IgE]-mediated hypersensitivity) or if a MRSA isolate is suspected or documented; otherwise increasing rates of MRSA, both hospital and community isolates, obligate the use of vancomycin as empiric antibiotic therapy. In cases of vancomycin failure or difficulty achieving therapeutic levels due to fluctuating renal function, alternatives linezolid and daptomycin should be considered. In cases of uncomplicated right-sided endocarditis with MSSA, the treatment course of nafcillin/oxacillin may be limited to 2 weeks. It is important to be aware of the presence of *S. lugdunensis*. This is a coagulase-negative staphylococcus that is capable producing suppurative complications similar to those of *S. aureus*.

In PVE, the most common causative agents are *S. aureus* and coagulase-negative *S. epidermidis* (see Table 37.3). Both species are commonly resistant to β-lactam antibiotics; thus, until sensitivity to methicillin can be confirmed, vancomycin should be used as the primary therapy of endocarditis. Bacteriologic

failures are common, and surgical valve replacement may be necessary.

Enterococci and vancomycin-resistant enterococcus

Enterococci are intrinsically resistant to the bactericidal effect of penicillin or vancomycin. Therefore, for the treatment of endocarditis, the addition of aminoglycoside is needed to promote bactericidal effect. Cephalosporins are inactive against enterococci and cannot substitute for penicillin in this setting. The emergence of enterococci highly resistant to penicillin, aminoglycosides, and vancomycin has seriously compromised the efficacy of available treatment; therefore, all enterococcal isolates in cases of suspected IE should be subjected to in vitro sensitivity testing.

Patients with prosthetic valve infection should have therapy prolonged for a minimum of 6 weeks. Some gentamicin-resistant enterococcal strains are quite sensitive to streptomycin. There is a good deal of evidence that a combination of ampicillin (12 g per 24 hours) with ceftriaxone (2 g BID) is very effective in IE due to *Enterococcus faecalis* strains that are both susceptible to and highly resistant to gentamicin and in patients who cannot tolerate the potential side effects of an aminoglycoside. In my opinion, this combination is the preferred therapy for these patients. For enterococci that are highly resistant to ampicillin and highly resistant to aminoglycosides, treatment is based on vancomycin alone. In such cases, the input of an infectious disease consult is needed to arrive at an appropriate therapeutic choice.

Vancomycin-resistant enterococcus (VRE) now accounts for 15% of infections in critical care units; isolates of *Enterococcus faecium* are much more common than *E. faecalis*. There is no standard regimen for VRE endocarditis. From compassionate use data, linezolid resulted in a cure rate of 77% in VRE IE (Table 37.4).

Other treatment considerations

Gram-negative organisms of the HACEK group grow slowly on standard culture medium, although most will grow within 6 days. Because β-lactamase-producing HACEK organisms have emerged, ampicillin can no longer be recommended. At this time, third- or fourth-generation cephalosporins or ampicillin-sulbactam should be the regimen of choice. Fluoroquinolones (ciprofloxacin, levofloxacin, gatifloxacin, or moxifloxacin) may be used as an alternative regimen in patients who cannot tolerate β-lactam therapy (Box 37.2).

Enterococci PCN- and vancomycin-resistant, native valves or prosthetic valves

E. faecium	***E. faecalis***
	Ceftriaxone,2 g q24h IV/IM ≥8 wk, plus ampicillin 12 g q24h IV ≥8 wk (preferred)
	Or
Linezolid, 600 mg IV/PO q12h ≥8 wk	Imipenem–cilastatin, 2 g q24h IV ≥8 wk, plus ampicillin 12 g q24h IV ≥8 wk

[a] Prosthetic valve or intracardiac material; recommended therapy for 6 weeks.
[b] Substitute gentamicin with streptomycin, 15 mg/kg q24h IV/IM divided in 2 doses 4–6 wk, whenever enterococci are gentamicin-resistant but streptomycin-sensitive.

BOX 37.2

Antibiotic therapy for endocarditis caused by HACEK microorganisms[a]

Native and prosthetic valve

Ceftriaxone 2 g/24 h IV/IM 4 wk
Or
Ampicillin 12 g/24 h IV 4 wk
Or
Ciprofloxacin 500 mg/12 h PO or 400 mg q12h IV for 4 wk (need close monitoring)

[a] *Haemophilus parainfluenzae, H. influenzae, H. aphrophilus, H. paraphrophilus, A. actinomycetemcomitans, C. hominis, E. corrodens, K. kingae*, and *K. denitrificans*.

Most streptococci other than *S. viridans* or enterococci (pneumococcus, group A to G streptococci) remain susceptible to penicillin, but empiric therapy must allow for possible resistance. Although pneumococcal endocarditis is rare (≤1%), its aggressive fulminant course and the increasing incidence of penicillin and cephalosporin resistance have mandated vancomycin with or without ceftriaxone as the empiric regimen. Non–group A strains of streptococci may need gentamicin in addition to penicillin to achieve synergistic killing. Enterobacteriaceae and *Pseudomonas aeruginosa* are uncommon causes of endocarditis. Therapy should be determined by in vitro susceptibility testing.

Treatment of PVE is generally longer than that of NVE. If infection occurs within a year after surgery, empiric therapy should particularly target *S. epidermidis* and *S. aureus*. Animal models demonstrate rapid sterilization of vegetations with the addition of rifampin (Table 37.3). Thus, when PVE is clinically suspected, the combination of vancomycin, gentamicin, and rifampin should be initiated empirically. Rifampin is the key part of this combination since it is most likely the only one able to penetrate into the biofilm of the infected valve. The purpose of the other two antibiotics is to prevent resistance developing to the rifampin. For staphylococcal infection, nafcillin or oxacillin should be substituted for vancomycin if susceptibility results allow. If the pathogen is resistant to all available aminoglycosides, a fluoroquinolone may be used as an alternative. Duration of aminoglycoside use is similar to recommendations for infection of native valves.

Due to the higher mortality and valvular complications of PVE, especially when due to *S. aureus*, surgery is more frequently considered than in native valve infection.

Fungal endocarditis is poorly responsive even to standard-treatment amphotericin B or newer agents (for ≥6 weeks). Surgical valve replacement is usually necessary. In patients with hemodynamically stable valves and candida or aspergillus infections susceptible to imidazoles, long-term suppression with fluconazole (*Candida albicans*) or itraconazole (*Aspergillus* spp.) may be the preferred therapeutic choice. In PVE, valve replacement is usually mandatory regardless of the fungal organism.

Culture-negative endocarditis

The most common cause of culture-negative endocarditis (see NIE) currently is prior antimicrobial treatment before obtaining appropriate blood culture. In addition this condition is often caused by fastidious or difficult to culture organisms, including fungi, *Rickettsia*, *Mycobacteria*, *Chlamydia, Legionella*, *Coxiella burnetii*, and *Bartonella*.

Traditionally, serological studies have been the diagnostic modality of choice in CNIE but recent molecular advances (16S ribosomal RNA PCR) and epidemiology may also be helpful (Table 37.5).

Oral antibiotic regimens have seldom been used to treat IE because of concern about achieving adequate levels in the vegetation by the oral route and . I have employed linezolid orally to finish up the last 2 weeks of therapy in the situation where the patient was doing well but essentially "ran out" of venous access. With newer agents, such as the quinolones and linezolid, the serum concentration after oral administration is equivalent to that seen with parenteral dosing. These agents have been used for the oral treatment of highly susceptible gram-negative pathogens. A 4-week oral regimen of ciprofloxacin plus rifampin has been used to treat uncomplicated right-sided endocarditis in IV drug abusers. A recent study examined partial oral antibiotic treatment of left-sided endocarditis due to *Streptococcus* spp., enterococci, and CoNS. The criteria excluded any patients with ongoing signs of significant inflammation, fever, or

TABLE 37.5 **ANTIBIOTIC THERAPY FOR CULTURE-NEGATIVE ENDOCARDITIS**

Native valve	Prosthetic valve
Ampicillin–sulbactam 12 g/24h IV 4–6 wk	**Early infection (≤1 yr)**
Plus	Vancomycin 30 mg/kg q24h IV divided in 2 doses 6 wk
Gentamicin 1 mg/kg IV/IM q8h for 4–6 wk	*Plus*
Or	Gentamicin 1 mg/kg IV/IM q8h 2 wk

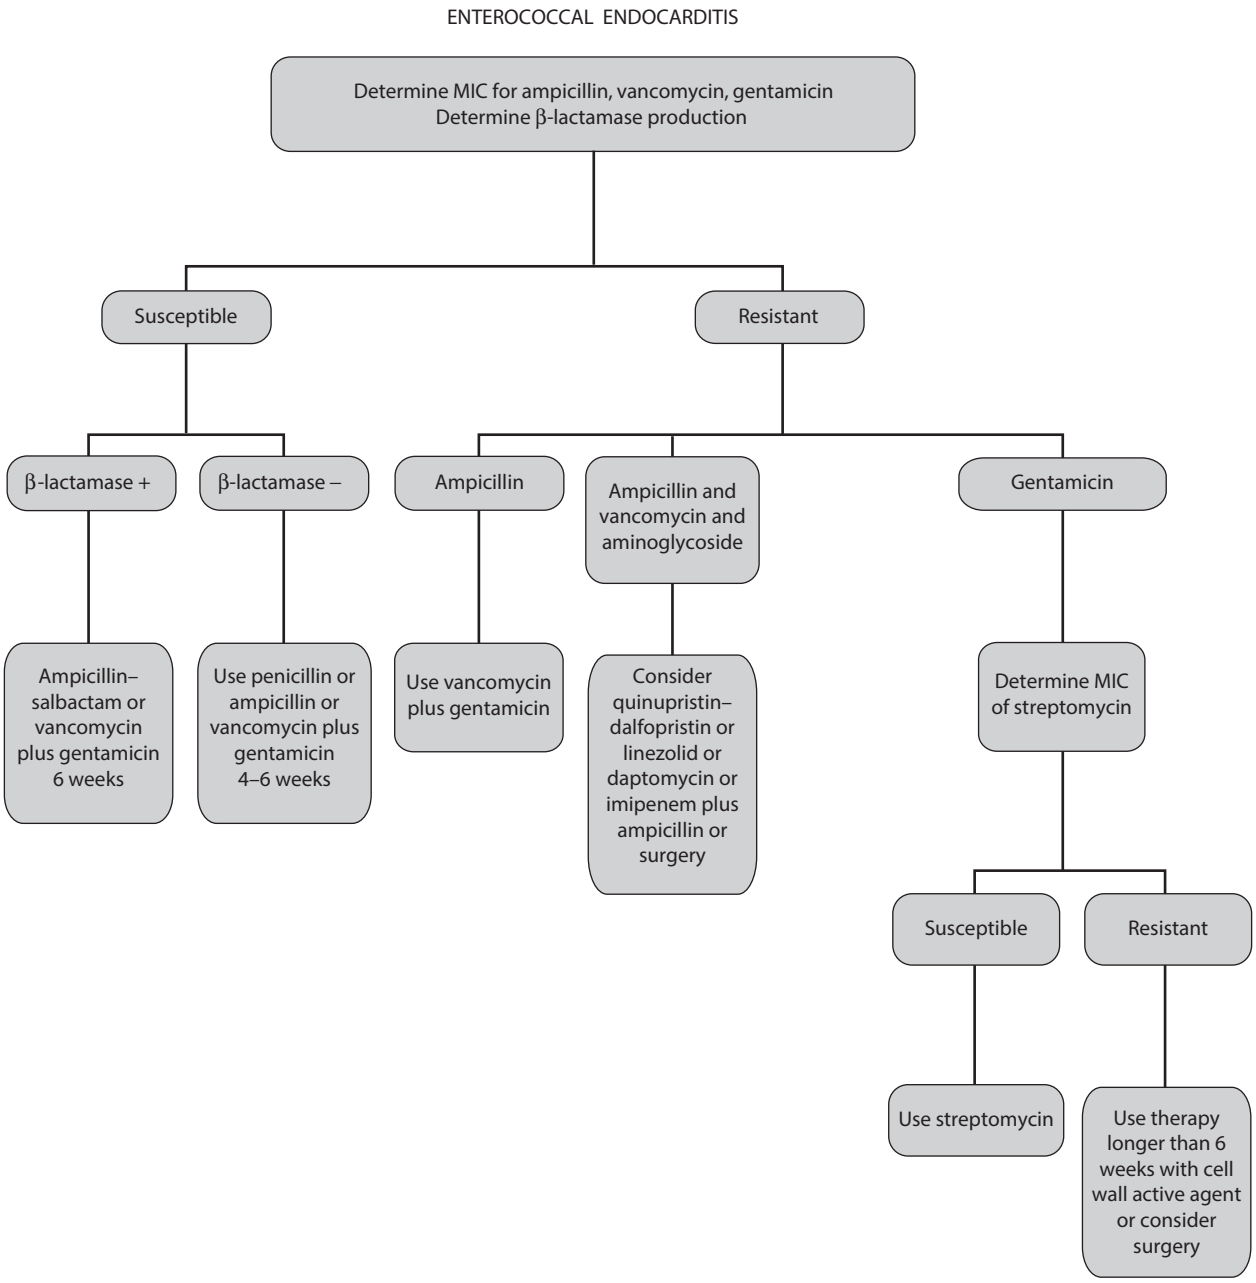

FIGURE 37.6 Algorithm for the treatment of HACEK endocarditis.

abscess formation, and the pharmacokinetics of the oral antibiotic matched those when it was given intravenously. Outcomes in the partially orally treated group were equivalent to those who remained continuously on IV-administered agents.

Prophylaxis

The American Heart Association's (AHA) most recent guideline in April 2007 made substantial changes in recommending preventive antibiotics. These recommendations were prompted by a growing amount of evidence that suggests that the risks of prophylactic antibiotics outweigh the benefits for most patients, especially those at low to moderate risk of developing procedure-related IE. (The risk of developing IE is very low, with 1 in 114,000 adults in the United States with prosthetic valves developing IE and 1 in 142,000 adults with rheumatic heart disease developing disease after dental procedures.) In addition, the data show that IE is much more likely to result from random bacteremias associated with daily activities than from dental, gastrointestinal, or genitourinary instrumentation. There is no compelling evidence to connect a significant risk of developing IE from the bacteremia of invasive and dental procedures. The 2007 AHA and updates guidelines consider only cardiac conditions with the highest risk of adverse outcome from endocarditis for which prophylaxis should be recommended (Box

BOX 37.3

Cardiac conditions warranting endocarditis prophylaxis

Prophylaxis recommended

Prosthetic heart valves
Previous history of endocarditis
Certain congenital heart conditions, including
- unrepaired or incompletely repaired cyanotic congenital heart disease, including those with palliative shunts and conduits
- a completely repaired congenital heart defect with prosthetic material or device, whether placed by surgery or by catheter intervention, during the first 6 months after the procedure
- any repaired congenital heart defect with residual defect at the site or adjacent to the site of a prosthetic patch or a prosthetic device

Valvular disease in cardiac transplant recipients

Prophylaxis no longer recommended

Mitral valve prolapse
Rheumatic heart disease
Bicuspid valve disease
Calcified aortic stenosis
Congenital heart conditions such as ventricular septal defect, atrial septal defect, and hypertrophic cardiomyopathy

BOX 37.4

Procedures warranting endocarditis prophylaxis

Prophylaxis recommended

All dental procedures that involve manipulation of gingival tissue or the periapical region of teeth or perforation of the oral mucosa
Tonsillectomy and/or adenoidectomy
Invasive respiratory procedures to treat infection
Surgical procedures involving infected skin and soft tissues

Prophylaxis not recommended

Injection of local intraoral anesthetic through noninfected tissue
Taking dental radiograph
Placement of removable prosthodontic or orthodontic appliances
Adjustment of orthodontic appliances
Placement of orthodontic brackets
Shedding of deciduous teeth
Bleeding from trauma to the lips or oral mucosa
Endotracheal intubation
Bronchoscopy without biopsy
Tympanectomy tube insertion
Transesophageal echocardiogram
Gastrointestinal or genitourinary procedures
Vaginal delivery or vaginal hysterectomy
Cesarean section
Dilatation and curettage
Ear and body piercing
Tattooing

37.3). The procedures are limited to dental and invasive respiratory procedures and surgery of infected soft tissues (Box 37.4). The antibiotic regimens are listed in Box 37.5.

Since 2007, there has been a 64% fall in prescription rates for antibiotic prophylaxis for moderate-risk individuals and a 20% decrease in patients at high risk. Well before these changes, there was a gradual increase in the cases of IE; this was attributed to aging of the general population and to increased rates of invasive procedures and intravascular device placement. However, several recent studies have demonstrated a rise in IE that exceeds these historical changes. There has been a moderate increase in IE among those of moderate risk but a significant increase (177%) among patients at high risk. It is not yet clear what is causing this. However, these figures compel a re-examination of prophylactic recommendations, one that should be more focused on prophylaxis in the placement of intravascular devices.

Surgical indications in the management of infective endocarditis

In certain cases of IE, surgery is associated with improved patient outcomes. Some of these indications are strongly supported by evidence. Other indications are more relative and have conflicting evidence, but expert opinion often favors surgical intervention (Table 37.6). CHF resulting from acute aortic insufficiency remains the major indication for immediate valve replacement because of the unacceptably high mortality rate in medically treated patients. Nonresponse to antimicrobial therapy may mandate valve removal

BOX 37.5

American Heart Association recommended prophylactic regimens

Single dose 30–60 minutes before procedure
Oral
Amoxicillin 2 g
Unable to take oral medications
Ampicillin 2 g IV/IM or cefazolin/ceftriaxone[a] 1 g IV/IM
Allergic to penicillin
Clindamycin 600 mg or azithromycin/clarithromycin 500 mg or cephalexin 2 g
Allergic to penicillin and unable to take oral medications
Clindamycin 600 mg IV or cefazolin/ceftriaxone[a] 1 g IV/IM

[a] Use only if non-IgE-mediated allergic reaction.

TABLE 37.6 **INDICATIONS FOR SURGICAL INTERVENTION IN NATIVE AND PROSTHETIC VALVE INFECTIVE ENDOCARDITIS (IE)**

Surgery usually recommended	Surgery to be considered
Congestive heart failure from acute aortic insufficiency	Large (10 mm) anterior mitral leaflet vegetation
Infective endocarditis caused by organism that may respond poorly to antimicrobial therapy (e.g., fungal or *Brucella* spp.)	Increase in vegetation size despite adequate treatment (after 4 weeks of antibiotic)
Persistent bacteremia after 1 week of adequate antibiotic therapy	Periannular extension on infection or myocardial abscesses
More than one embolic event occurring within the first 2 weeks of antibiotic therapy	IE caused by resistant enterococci species when effective bactericidal therapy is not available
Presence of echocardiography finding consistent with local cardiac complications such as valve dehiscence, large perivalvular abscess, rupture, or perforation of a valve Heart block	Uncontrolled infection caused by highly antibiotic-resistant pathogens despite optimal therapy (enterococci or gram-negative bacilli)
Staphylococcus aureus prosthetic valve endocarditis complicated by perivalvular abscess or dehiscence (reduces mortality rates)	
PVE or left-sided IE caused by gram-negative bacteria such as *Serratia marcescens, Pseudomonas* spp.	

Abbreviations: PVE = prosthetic valve endocarditis.

if no alternative source for the continued bacteremia or fungemia is found. Fungal endocarditis on a prosthetic valve almost always requires valve replacement. With aggressive pre- and postoperative antibiotic therapy, valve replacement with a mechanical prosthesis during active IE is a safe procedure. The risk of relapse of endocarditis in a newly implanted prosthetic valve is minimal. There is no strong evidence supporting the superiority of early versus later surgical treatment in NVE patients with indications for surgical intervention.

Treatment duration after surgery depends on culture data from the operating room; if operating room cultures are sterile, the antibiotic duration does not change. If operating room cultures are still positive, antibiotic therapy is considered to start at the time of surgery and should continue to completion following the NVE guidelines for the particular organism and not those for PVE. Similarly, those individuals with NVE who receive a prosthetic valve are treated for NVE, not for PVE.

Local cardiac complications of IE may require surgical intervention. TEE may detect valvular dehiscence, rupture, fistula, perforation, perivalvular extension of abscess, a large abscess, or a large vegetation (10 mm) on an anterior mitral valve leaflet. Because large vegetations tend to embolize, valve replacement or vegetectomy may be indicated in a patient with suspected or documented recurrent central nervous system or large-vessel emboli. The incidence of stroke from embolic events in patients receiving appropriate antimicrobial therapy in a recent European study was 4.82/1,000 patient days in the first week of therapy and fell to 1.71/1,000 patient days in the second week.

Anticoagulation should never be considered in patients with embolic complications of IE because of the significant risk of intracerebral hemorrhage. Maintenance anticoagulation in a patient with a prosthetic valve should be continued regardless of the diagnosis of endocarditis because of the risk of mechanical thrombosis. It may be prudent to monitor these patients on 2 weeks of heparin therapy following current guideline recommendations.

Acute pericarditis

Richard A. Martinello and Michael Cappello

Introduction

The pericardium serves to protect the heart from physiologic changes in intracardiac pressure related to respiration and postural change, and it may also augment the mechanical function of the cardiac chambers. The pericardium is composed of a visceral layer that directly adheres to the epicardium and an outer parietal layer. These two layers are separated by 10 to 35 mL of serous fluid. *Pericarditis* refers to the inflammation of these tissues. It may be acute, recurrent, or chronic, and it can be due to a wide array of etiologies.

Epidemiology and etiologic agents

Both infectious and noninfectious processes have been identified as causes of pericarditis (inflammation of the pericardium). Most cases are caused by viruses, are self-limited, and the specific pathogen is often unidentified. Purulent pericarditis, due to bacterial or fungal pathogens, is less common and the incidence is much lower than during the pre-antibiotic era. In one recent series, pericarditis was diagnosed in 5% of adults presenting for emergency care due to chest pain that was not associated with myocardial infarction. While pericarditis can affect patients across the spectrum of age, an analysis of US Medicare recipients (patients ≥65 years) cared for and diagnosed with pericarditis found that, between 1999 and 2012, the rate of hospitalization for pericarditis remained stable at about 26 cases/100,000 person years, with a modest decrease in the 30-day and 1-year all-cause observed mortality over this time period.

Most episodes of pericarditis occur in the spring and summer, coincident with the peak prevalence of enteroviral infections. During the winter months, influenza virus is a frequent cause of pericarditis, whereas pericarditis due to bacterial or atypical pathogens occurs throughout the year. There are no clinical features that allow a differentiation between viral and idiopathic causes of acute pericarditis. Approximately 15% of episodes of viral and idiopathic pericarditis are associated with concomitant myocarditis.

In areas of the world where the incidence of infection with *M. tuberculosis* remains high, tuberculosis is responsible for >50% of cases of acute pericarditis. Tuberculosis should be considered in persons who have spent significant time in endemic countries, including international adoptees, immigrants, and refugees. Patients with HIV infection are more likely to experience nonpulmonary manifestations of tuberculosis, such as pericarditis, and have been shown to experience higher rates of mortality due to tuberculous pericarditis than their non-HIV counterparts.

Pericarditis may also develop following cardiothoracic surgery. This may be due to a bacterial surgical site infection or postpericardiotomy syndrome, a noninfectious inflammatory condition that generally develops days to 6 months following cardiac surgery. In immunocompromised hosts, the range of potential pathogens that can cause pericarditis is quite broad and includes viruses, bacteria, fungi/yeasts, and parasites (Box 38.1) Cases of pericarditis associated with COVID have been published, though the characteristics of the relationship between infection with SARS-CoV-2 and pericarditis remain unclear. Acute pericarditis can also be

due to noninfectious causes (Box 38.2). Very rarely, pericarditis has been observed within weeks of vaccination, particularly after vaccination against smallpox, though whether other vaccinations may cause pericarditis is uncertain.

Pathogenesis

Microbial pathogens may gain entry into the pericardial space by direct extension from the chest (e.g., in the context of pneumonia or mediastinitis), through direct extension from the heart itself (e.g., endocarditis), through hematogenous or lymphatic spread (bacteremia or viremia), or via direct inoculation (e.g., surgery, trauma). The presence of an adjacent or otherwise concurrent infection as well as a history of recent surgery or trauma may provide significant clues to specific pathogens. For example, purulent pericarditis due to *N. meningitidis* has been diagnosed in patients with concurrent bacterial meningitis. In a review of 162 children with purulent pericarditis, all but 10 patients had at least one additional site of infection, suggesting that isolated cardiac disease occurs infrequently in those with purulent pericarditis. In cases where either *S. aureus* or *H. influenzae* type B was the responsible pathogen, pneumonia, osteomyelitis, and cellulitis were the most frequently identified additional sites of infection. Tuberculous pericarditis, however, usually occurs in the absence of identifiable pulmonary disease, thus suggesting that the pathogenesis involves the spread of mycobacteria from adjacent mediastinal lymph nodes into the pericardium.

The inflammatory response in the pericardial space leads to extravasation of additional pericardial fluid, polymorphonuclear white blood cells, and monocytes. During bacterial or fungal pericarditis, the inflammatory process may be sufficient to lead to loculation and fibrosis. Significant fibrosis may lead to constrictive pericarditis, which is manifest by signs and symptoms associated with compromised ventricular filling. The rapid accumulation of exudative fluid, as is often seen in purulent pericarditis, frequently leads to hemodynamic changes. Cardiac tamponade occurs when the pressure caused by an increased fluid volume within the pericardial space prevents adequate right atrial filling and leads to reduced stroke volume, low-output cardiac failure, and shock. If the accumulation of pericardial fluid occurs more slowly, as is common with viral pericarditis, large amounts may be present without hemodynamic effect.

Symptoms and clinical manifestations

Chest pain is the most common presenting symptom of acute pericarditis. Due to the relationship between the phrenic nerve and pericardium, pain resulting from inflammation of the pericardium may be retrosternal with radiation to the shoulder and neck or may localize between the scapulae. Often, the pain is worsened by swallowing or deep inspiration, or it is positional and worsened when the patient is supine but lessened by leaning forward while sitting. Dyspnea is also a common presenting symptom. If pericarditis has resulted from contiguous spread of bacteria or fungi from an adjoining structure, the signs and symptoms of the primary infectious process may predominate. Purulent pericarditis due to a bacterial pathogen tends to be more acute and severe in nature, whereas viral pericarditis is typically of lesser severity. Symptoms of tuberculous pericarditis tend to be insidious in presentation.

In infants, the presenting signs and symptoms of pericarditis may be nonspecific and include fever, tachycardia, and irritability. Older children may complain of chest and/or abdominal discomfort. A study by Carmichael et al. in 1951 showed that more than half of patients diagnosed with "nonspecific" pericarditis of presumed viral origin described a respiratory illness preceding the diagnosis of pericarditis by 2 to 3 weeks.

On physical exam, nearly all patients with pericarditis, regardless of cause, will have tachycardia. Those with bacterial pericarditis are also likely to have fever and tachypnea as well as possible evidence of at least one additional site of infection (e.g., pneumonia, surgical site infection, osteomyelitis, etc.). Perhaps the most characteristic physical finding in acute pericarditis is the presence of a friction rub on cardiac auscultation. The rub may be confused with a high-pitched murmur, particularly when it is only present in systole. Pericardial friction rubs may have as many as three components corresponding with atrial systole, ventricular systole, and rapid ventricular filling during early diastole. A rub may be best appreciated with the patient leaning forward or in the knee-chest position. Although more than one component of a pericardial rub may be present, all three components were noted in fewer than 50% of patients in one case series.

The presence of a pulsus paradoxus or jugular venous distention suggests the possibility of cardiac tamponade, which may require emergent intervention. This is most frequently seen in the presence of a large or rapidly accumulating pericardial effusion but can also result from constrictive disease due to long-standing pericarditis with fibrosis.

Diagnosis

An acutely enlarged cardiac silhouette on chest radiograph, particularly in the absence of increased pulmonary vascularity, suggests the presence of pericardial effusion. However, there may be no radiographic abnormalities detected in patients with small but rapidly accumulating effusions, as well as in those with constrictive disease.

Although the pericardium is not involved in the electrical activity of the heart, pericarditis is associated with classic electrocardiographic (EKG) changes, which are likely due to concomitant inflammatory changes in the epicardium and outer myocardium. Electrocardiographic changes may be present in 50% of patients with acute pericarditis, and the specific changes evolve over time. Elevation or depression of the ST and/or depression of the PR segments may occur early in the disease process (Figure 38.1). Over subsequent days, the ST segment returns to baseline. Late EKG changes in pericarditis may include flat or inverted T waves. These EKG changes can be differentiated from those due to myocardial infarction as it is uncommon for T-wave inversions to be detected until the ST segment changes resolve. Large pericardial effusions may result in reduced voltage or electrical alternans due to beat-to-beat variation in the position of the heart within the pericardial fluid.

Echocardiography is the diagnostic study of choice for detecting excess pericardial fluid and is recommended for all patients in whom pericarditis is suspected. In patients with post-sternotomy pericarditis, CT scan and cardiac MRI are both extremely useful for identifying mediastinal fluid collections and potential abscesses. Pericarditis occurs concurrently with myocarditis in approximately 20% to 30% of patients, and myocarditis can be noted by the presence of elevated troponins and/or myocardial edema on cardiac MRI.

Pericardiocentesis is the most specific means of determining the etiology of pericarditis, although the overall diagnostic yield may be low. Drainage of pericardial fluid should be performed when there is evidence for cardiac tamponade or a suspicion of tuberculous, neoplastic, or purulent pericarditis. The fluid should be transported quickly to the microbiology laboratory for Gram, acid-fast, and silver stains, as well as culture for bacteria (aerobic and anaerobic), fungi, mycobacteria, and viruses, as indicated. Pericardial fluid should also be analyzed for cell count and differential, glucose, total protein, and red blood cell count, and cytology may be considered. When tuberculous pericarditis is suspected, biopsy of the pericardium for histology and polymerase chain reaction (PCR) is useful, and an adenosine deaminase level should be measured in the pericardial fluid. The interferon-γ release assay has been shown to have both favorable sensitivity and specificity when studied in countries with modest to high rates of tuberculosis.

FIGURE 38.1 (A) Electrocardiogram (EKG) in acute pericarditis. ST segment elevation is noted with an upward concave appearance in all leads except I, aVR, and aVL. PR segment depression is noted in I, II, III, aVF, and the precordial leads. (B) EKG from the same patient as in A, but 3 days later. Note that PR segment depression persists in II, III, and aVF. Some ST elevation persists but has markedly diminished compared with the initial EKG

Courtesy Dr. Thuy Le.

For patients in whom a viral etiology is suspected, swabs from the nasopharynx, throat, and rectum may be obtained for PCR or culture as these sites are more likely to yield a positive result for enterovirus than the pericardial fluid itself. However, extensive testing to identify the etiology of viral pericarditis has not been found, in general, to be clinically useful. In the setting of pneumonia, sputum or tracheal aspirates can be cultured for bacteria, and diagnostic studies for respiratory viruses, including influenza A or B, should be obtained. Acute and convalescent antibody titers may be measured for the common enterovirus serotypes and other pathogens.

In patients with purulent pericarditis, blood cultures are frequently positive. These patients should be carefully evaluated for other infectious processes, including pneumonia, osteomyelitis, and meningitis. A positive bacterial culture from one of these alternative sites is strongly suggestive of the identity of the pericardial pathogen.

The diagnosis of tuberculous pericarditis can be particularly challenging. Although a study by Strang et al. found cultures of pericardial fluid to be positive in 75% of suspected cases, results may not be available for weeks. In this setting, pericardial biopsy may yield a more rapid diagnosis of *M. tuberculosis* infection, particularly if the characteristic granulomatous changes are present. Cigielski et al. have recently shown that a PCR-based assay was nearly as sensitive as culture (81% vs. 93%) for detecting *M. tuberculosis* in pericardial biopsy specimens. The obvious advantage to PCR is the speed with which results can be obtained, although false-positive results may occur more frequently than with culture.

Treatment

Urgent drainage of pericardial fluid should be considered in any patient with a possible diagnosis of purulent pericarditis or if hemodynamic compromise is identified. The outcome in these patients is generally poor without drainage even when appropriate antibiotics are administered. Likewise, purulent infections contiguous with the mediastinum should be drained. Intrapericardial fibrinolysis for persons with purulent pericarditis may prevent future complications of constrictive or persistent pericarditis.

If the Gram stain of pericardial fluid does not suggest an etiologic agent in the setting of purulent pericarditis, then empiric antibiotic coverage should be initiated while awaiting the results of cultures. The antibiotic(s) for empiric coverage should be chosen according to whether the patient has evidence for a contiguous site of infection, history of recent cardiothoracic surgery, trauma, or other relevant risk factors. In patients with community-acquired purulent pericarditis and no history of antecedent surgery or trauma, empiric treatment directed at *S. aureus* (oxacillin, nafcillin, or vancomycin) and common respiratory pathogens (ceftriaxone) would be appropriate.

If a viral etiology is suspected, nonsteroidal anti-inflammatory drugs (NSAIDs) are used as first-line therapy and have been found to relieve chest discomfort in 85% to 90% of patients. Typically, ibuprofen (1,600–3,200 mg/d in divided doses) is the drug of choice due to its low incidence of adverse events compared with other NSAIDs. Some experts favor the use of aspirin (650–975 mg q6–8h) in patients who have experienced a recent myocardial infarction because evidence from animal studies has led to concern that other NSAIDs may impair scar formation. Indomethacin should be avoided in persons with coronary artery disease as it has been shown to decrease coronary artery blood flow.

As the signs, symptoms, and pathological findings in pericarditis are often primarily due to the inflammatory response, pharmacological management is directed toward modifying inflammation in addition to addressing an infectious cause if one is present and treatable. Randomized trials have shown that colchicine (0.5–0.6 mg once daily if <70 kg, twice daily if >70 kg), in addition to an NSAID, effectively decreases the incidence of both the persistence of symptoms and the incidence of primary and secondary recurrent pericarditis. Colchicine is generally continued for 3 months. Markers of inflammation (i.e., erythrocyte sedimentation rate [ESR] and c-reactive protein [CRP]) may be followed to assess disease progression and help guide tapering of NSAIDS. It is recommended that NSAIDs be tapered once the patient's signs and symptoms have resolved for at least 24 hours and the inflammatory markers have normalized. Evidence supporting the use of systemic corticosteroids is limited and there is concern that their use, especially higher doses, may be associated with greater rates of relapse; use should only be considered in persons with persistent symptoms despite full doses of NSAIDs or in persons in whom NSAIDs are contraindicated (e.g., third trimester of pregnancy) or not tolerated despite acid suppressive therapy. For persons with recurrent pericarditis and those for whom NSAIDs and colchicine are unable to control symptoms, a progressive escalation of anti-inflammatory medications (i.e., corticosteroids, azathioprine, intravenous immunoglobulin, and anakinra-a recombinant IL-1 receptor antagonist given daily by subcutaneous injection) may be considered.

It is recommended that patients avoid strenuous activity during the initial weeks after diagnosis of acute pericarditis, but patients may then reintroduce activities after complete resolution of symptoms. Typically, competitive athletics should be avoided for 3 months.

Tuberculous pericarditis should be treated with four active antimicrobial agents until susceptibilities are known. The recommended duration of therapy for pericarditis caused by *M. tuberculosis* is 6 to 12 months, with the longer durations reserved for patients who improve more slowly. The use of corticosteroids as an adjunct does not appear to decrease mortality, although some investigators have concluded that there may be some benefit in reducing the occurrence of constrictive pericarditis. Likewise, it is not clear that there is a role for routine pericardial drainage or pericardiectomy in the treatment of tuberculous pericarditis.

Complications

Increased intrapericardial pressure due to an accumulating effusion may result in cardiac tamponade. Tamponade should be suspected if the patient's hemodynamic status is unstable, heart sounds are diminished, jugular venous pressure is raised, or if pulsus paradoxus is present. Echocardiography may note significant variation in blood flow across the mitral and tricuspid valves with respiration and collapse of the right-sided chambers during diastole. Drainage of the pericardial effusion is essential in the setting of purulent pericarditis or in the presence of tamponade. Patients with purulent pericarditis should be treated with a combination of both antimicrobial therapy and drainage. High mortality rates have been observed for patients with purulent pericarditis who have received only medical or surgical management in isolation.

A minority of patients may experience recurrent pericarditis involving reaccumulation of the pericardial effusion, fever, and chest pain. These episodes may relapse and remit for several years and are most commonly diagnosed in patients with prior viral pericarditis. Recurrent episodes are rarely complicated by either tamponade or constriction and are effectively treated with NSAIDs with or without colchicine or corticosteroids. Pericardiectomy, pericardial window placement, or other surgical procedures may be considered for those with the most recalcitrant signs and symptoms who fail aggressive medical management.

Constrictive pericarditis occurs due to the development of a thickened fibrous exudate within the pericardium, and the pericardium itself may calcify. The reduced compliance of the pericardial sac may impair diastolic filling and result in hemodynamic compromise. Constrictive pericarditis has most commonly been associated with antecedent tuberculous pericarditis, cardiac surgery, and radiation-induced pericarditis, though patients with a history of prior pericarditis of any etiology are at risk for developing constrictive disease. Constrictive pericarditis typically presents within 3 to 12 months of the initial episode, though the time interval may be days to years. Less severe cases may be managed medically by careful

monitoring of the patient's fluid status, but pericardiectomy remains the definitive therapy.

Myocarditis

Lori Blauwet and Andrew Rosenbaum

Definition

Myocarditis is a rare, potentially deadly and often underdiagnosed cause of acute or chronic heart failure that primarily affects children and younger adults. The incidence is estimated at 22 per 100,000 people. Historically, the diagnosis of myocarditis was confirmed by histologic analysis of endomyocardial biopsy (EMB) specimens with findings of an inflammatory cellular infiltrate of the myocardium with or without myocyte necrosis and/or degeneration of adjacent myocytes. The type of inflammatory infiltrate, its distribution in cardiac tissue, and the degree of myocardial injury help construct the differential diagnosis.

Clinically, myocarditis is defined by the time course and severity of illness. Acute myocarditis is the presence of an acute cardiomyopathy with myocardial inflammation. The presentation is highly variable. Chronic myocarditis is subdivided into two entities. *Chronic active myocarditis* has variable symptomatology, is accompanied by impaired cardiac function, and is marked by relapses of symptomatology and histology. *Chronic persistent myocarditis* is described by persistent symptoms, evidence of ongoing myocardial immune infiltrate on biopsy, but without ventricular dysfunction.

Fulminant myocarditis is described as acute onset of severe heart failure/cardiogenic shock or life-threatening arrhythmias due to myocarditis. *Cardiac sarcoidosis* is an uncommon form of inflammatory myocarditis distinguished histologically by non-necrotizing interstitial granulomas. Idiopathic *giant cell myocarditis* (GCM) is another rare form of inflammatory myocarditis that is characterized histologically by multinucleated giant cells, myocyte necrosis, and a lymphocytic inflammatory infiltrate.

Etiology

Most cases of myocarditis are triggered by infection or exposure to a toxin, although some cases are thought to be due to primary immunologic abnormalities in the patient (Box 39.1A,B). Viral infection is the most common cause of myocarditis in North America and Europe, with adenoviruses and enteroviruses (especially coxsackievirus B3 [CVB3]) historically being the most common culprits. However, parvovirus B19, cytomegalovirus, Ebstein–Barr virus, herpes simplex virus 1 and 2, human herpesvirus 6 (HHV 6), and hepatitis C are commonly observed. With the development of new molecular techniques such as polymerase chain reaction (PCR) and in situ hybridization, data suggest that PVB19 and HHV 6 are the most common viruses detected. Whether geographical differences account for the varying distribution of viral species implicated in myocarditis or whether these differences are more likely due to temporal epidemiologic differences as well as differences in diagnostic procedures also remains unclear.

At least one cardiotropic viral genome has been identified in 75% of EMBs performed for myocarditis. Two or more viruses are not infrequently found during PCR examination of myocardial tissue, but it is unclear whether this represents concurrent, past viral infection, or innocent bystander. Some studies have suggested that PVB19 is not a pathological agent in adult myocarditis because persistent low-level titers

BOX 39.1

A. Infectious etiologies of myocarditis

Viral
- **Adenovirus**
- Arborvirus
- Chikungunya virus
- **Enterovirus**
  - Echovirus
  - Coxsackie A
  - **Coxsackie B**
  - Polio
- Flavivirus
  - Dengue
  - Yellow fever
- Hepatitis B virus
- **Hepatitis C virus**
- Herpes viruses
  - Cytomegalovirus
  - Epstein–Barr
  - Herpes simplex
  - **Human herpesvirus 6**
  - Varicella-zoster
- **Human immunodeficiency virus**
- Influenza A and B
- Lassa fever virus
- Measles virus
- Mumps
- **Parvovirus** (especially *Parvovirus B-19*)
- Rabies
- Respiratory syncytial virus
- Rubeola
- Rubella
- Vaccinia
- Variola (*smallpox*)

Bacterial
- Actinomyces
- Burkholderia pseudomallei (*melioidosis*)
- Brucella
- Campylobacter jejuni
- Chlamydia (especially *Chlamydia pneumonia* and *Chlamydia psittacosis*)
- Clostridium
- **Corynebacterium diphtheriae** (*diphtheria*)
- Francisella tularensis (*tularemia*)
- Haemophilus influenzae
- Gonococcus
- Legionella pneumophila (*Legionnaire's disease*)
- Listeria monocytogenes
- **Mycobacterium** (*tuberculosis*)
- Mycoplasma pneumoniae
- Neisseria meningitidis
- Salmonella
- Staphylococcus aureus
- **Streptococcus A** (*rheumatic fever*)
- **Streptococcus pneumoniae**
- Tetanus
- Vibrio cholera

Spirochetal
- **Borrelia burgdorferi** (*Lyme disease*)
- Borrelia recurrentis (*relapsing fever*)
- Leptospira
- Treponema pallidum (*syphilis*)

Rickettsial

Coxiella burnetii (*Q fever*)
- Rickettsia prowazekii (*typhus*)
- Rickettsia rickettsii (*Rocky Mountain spotted fever*)
- Rickettsia tsutsugamushi (*scrub typhus*)

Fungal
- Aspergillus
- Blastomyces
- Candida
- Coccidioides
- Cryptococcus
- Histoplasma
- Mucor species
- Nocardia
- Sporothrix schenckii
- Strongyloides stercoralis

Protozoal
- Balantidium
- Entamoeba histolytica (*amebiasis*)
- Leishmania
- Plasmodium falciparum (*malaria*)
- *Sarcocystis*
- **Toxoplasma gondii** (*toxoplasmosis*)
- Trichinella spiralis
- **Trypanosoma cruzi** (*Chagas disease*)
- Trypanosoma brucei (*African sleeping sickness*)

Helminthic
- Ascaris
- Echinococcus granulosus
- *Heterophyes*
- Paragonimus westermani
- Schistosoma
- Strongyloides stercoralis
- Taenia solium (*cysticercosis*)
- Toxocara canis (*visceral larva migrans*)
- Trichinella spiralis

- **Hypereosinophilic syndrome with eosinophilic endomyocardial disease**
- Kawasaki's disease
- **Sarcoidosis**

Other

- Heat stroke
- Hypothermia
- Transplanted heart rejection
- Radiation

of PVB19 are fairly common and may not be related to myocardial injury.

Myocarditis can also be triggered by bacterial and protozoal infections. The most common nonviral pathogens which that directly infect the heart or activate inflammatory mechanisms are *Corynebacterium diphtheriae* (diphtheria), *Streptococcus A* (rheumatic fever), *Borrelia burgdorferi* (Lyme disease), and *Trypanosoma cruzi* (Chagas disease). Chagas disease is the most common etiology of myocarditis in Latin America. Bacterial myocarditis, typically associated with a neutrophilic infiltrate, is rare.

Numerous medications and environmental exposures can have toxic effects on the myocardium. In particular, several chemotherapy drugs are known to be potentially cardiotoxic. Type I chemotherapy agents (e.g., the anthracyclines) cause permanent

damage to the myocardium, while type 2 agents such as tyrosine kinase inhibitors (including trastuzumab) cause acute myocardial damage which is usually reversible once the offending drug is discontinued. Myocarditis caused by the immune checkpoint inhibitors, agents used to promote T-cell response against cancers, is often fulminant. Drug-induced hypersensitivity reactions can induce hypersensitivity eosinophilic myocarditis. The most common drugs include allopurinol, antimicrobials, antipsychotics, antiepileptics, and anti-inflammatories. Myocardial damage due to hypersensitivity reaction is usually reversible once the causative agent is withdrawn. Eosinophilic-lymphocytic myocarditis has also been associated with smallpox, tetanus, meningococcal C, and hepatitis B vaccines.

Systemic diseases, particularly Churg–Strauss syndrome, hypereosinophilic syndrome, Loeffler's endocarditis, and malignancies including T-cell lymphoma and cancer of the lung and biliary tract, have also been associated with eosinophilic myocarditis. Acute necrotizing eosinophilic myocarditis is a rare but fulminant form of myocarditis with acute onset and high mortality.

Pathogenesis

The pathogenesis of myocarditis in humans is not completely understood. Much of our understanding of the pathophysiology of myocarditis has been derived from murine models of enteroviral infection, particularly Coxsackievirus B3, which suggests that viral myocarditis is characterized by three stages (Figure 39.1). Stage I involves viral entry into the cardiomyocyte via endothelial cell receptors. Group B coxsackieviruses and some adenoviruses use the coxsackievirus-adenovirus receptor (CAR) to transport their viral genomes into myocytes. In addition to CAR, coxsackieviruses use decay-accelerating factor (DAF) and adenoviruses use special integrins ($\alpha_{v\beta3}$ and $\alpha_{v\beta5}$) as co-receptors for viral entry. Differential binding to DAF increases viral virulence in coxsackievirus B infections. Viral infection does not occur in the absence of CAR expression on myocytes.

Stage I also involves acute myocardial injury due to a combination of direct viral injury to the myocytes and the innate immune response, which is initially triggered by interferon release and involves upregulation of multiple inflammatory mediators including cytokines, nitric oxide, toll-like receptors, and complement and exposure of intracellular antigens such as cardiac myosin. Viruses that evade the innate immune response replicate, producing proteins that lead to myocyte apoptosis and necrosis.

Stage II begins approximately 4 to 5 days post viral infection, when the acquired immune response arises. Lasting several weeks to several months, this subacute phase is characterized by an antigen-specific response mediated primarily by T lymphocytes. Virus-specific T-killer cells are targeted to infected cells and destroy these host cells through secretion of cytokines or perforins. B lymphocytes produce antibodies directed against viral antigens and autoantibodies directed against endogenous cardiac proteins that may augment myocardial damage.

In most patients with myocarditis, viral clearance and downregulation of the immune system occurs during stage III, resulting in complete myocardial recovery without sequelae. In some patients, however, the virus is not cleared and cardiac-specific inflammation persists, resulting in chronic myocardial damage which leads to myocardial remodeling and the development of dilated cardiomyopathy (DCM). CVB3 myocarditis is associated with high titers of autoantibodies targeted at heart-specific proteins, suggesting a role for autoimmunity in those who progress to chronic myocarditis. In animal models, exposure to concealed proteins, such as α-myosin heavy chain, results in development of autoimmunity. Progression to DCM may also involve an underlying genetic substrate.

Epidemiology

Due to varying clinical presentations and infrequent utilization of EMB, the diagnosis of myocarditis is often missed, making it difficult to estimate the true incidence of this disease. Autopsy studies have estimated the incidence of myocarditis to range from 0.12% to 12%, depending on the population studied. The Myocarditis Treatment Trial showed that biopsy-proven myocarditis occurred in 9.6% of adult patients with unexplained heart failure. An analysis of hospital dismissal ICD-9 codes estimated that between 0.5% and 4% of heart failure cases are due to myocarditis.

Myocarditis has a slightly greater prevalence in men compared to women. Most trials and registries have a female to male ratio of 1:1.5 to 1:1.7. This sex difference may be at least partially explained by sex hormones. Estrogenic hormones have been shown to protect against viremia and viral infectivity of cardiomyocytes while also decreasing the potentially harmful inflammatory response in female mice. Testosterone, on the other hand, has been shown to inhibit anti-inflammatory responses in male mice.

Clinical presentation

The clinical presentation of acute myocarditis in adults varies by clinical scenario. Typically, but not always, a viral prodrome including fever, myalgias, arthralgias, rash, and respiratory or gastrointestinal symptoms precedes the onset of acute myocarditis by several days to several weeks. Patients with myocarditis may present with chest pain, dyspnea, palpitations, fatigue, edema, syncope, and/or decreased exercise tolerance. The presence of pleuritic chest pain, particularly in the setting of pericardial effusion, may indicate myopericarditis. Cardiac arrhythmias are common.

Patients with fulminant myocarditis usually present with severe heart failure symptoms that rapidly lead to cardiogenic shock, whereas patients with cardiac sarcoidosis tend to present in a more indolent manner with chronic DCM and either high-grade atrioventricular block (AVB) or new ventricular arrhythmias. Patients with GCM tend to present with acute heart failure symptoms that inexorably progress to probable early death or transplant despite guideline-directed heart failure therapy.

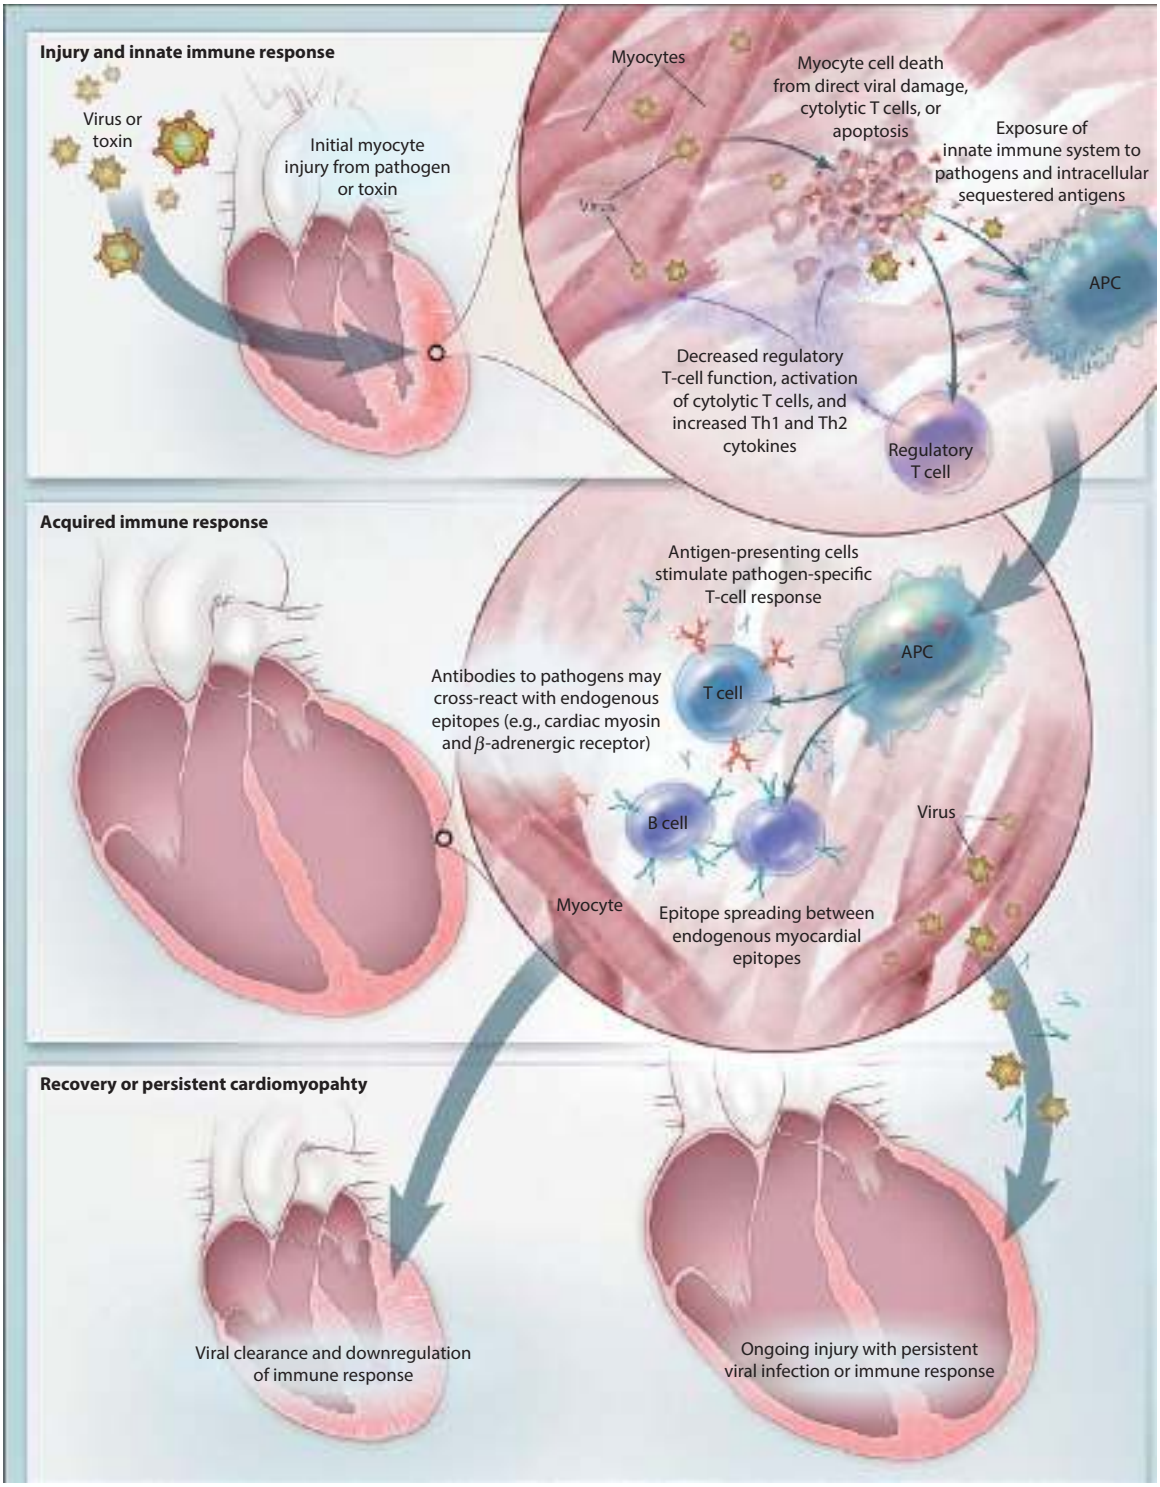

FIGURE 39.1 Pathogenesis of viral myocarditis. The current understanding of the pathogenesis of viral myocarditis is based on murine models. In these models, myocarditis progresses from acute injury to chronic dilated cardiomyopathy (DCM) in three distinct stages. During stage I, viral entry into cells results in direct myocardial injury, exposure of host antigens such as cardiac myosin, and activation of the innate immune system. The acquired immune response is the dominant feature in stage II, whereby activated T lymphocytes, antibodies, and autoantibodies induce significant myocardial inflammation. In most patients, stage III involves viral clearance, downregulation of the immune system, and complete myocardial recovery. In some patients, however, stage III is characterized by the persistence of viral genomes and cardiac-specific inflmmation in the myocardium, leading to chronic DCM.

Diagnosis

The first step in diagnosing myocarditis is to exclude more common causes of cardiac dysfunction such as atherosclerosis or valvular heart disease. There are no laboratory, electrocardiographic (EKG), or echocardiographic findings specific for myocarditis. When acute myocarditis is suspected, initial laboratory testing usually includes assessment of serum cardiac biomarkers. Troponin T, troponin I, and/or CK-MB may be elevated. Serum markers of inflammation including C-reactive protein, erythrocyte sedimentation rate, and leukocyte count are frequently elevated, but these are nonspecific. Serologic testing of suspected viral agents is not recommended as the viruses that cause myocarditis are common and positive serology does not necessarily establish causality. Evaluation for the presence of HIV, Lyme disease, or Chagas disease should be dictated by individual risk. Testing for noninfectious causes of heart failure including autoimmune disease, infiltrative myocardial diseases such as amyloidosis and hemochromatosis, and thyroid dysfunction may be warranted.

Most myocarditis patients have nonspecific changes on their initial EKG, including sinus tachycardia, ST-segment, or T-wave abnormalities that may mimic acute myocardial infarction or acute pericarditis, AVB, and partial or complete bundle branch block. Nonsustained ventricular or supraventricular arrhythmias are fairly common. The presence of Q waves or a QRS duration of >120 ms is associated with increased risk of cardiac death or heart transplantation. Chest x-ray may show cardiomegaly, pulmonary venous congestion, interstitial infiltrates, and/or pleural effusions.

The most common echocardiographic findings in patients with acute myocarditis are a dilated left ventricle with reduced left ventricular ejection fraction (LVEF). New regional wall abnormalities may be present, either in a coronary or noncoronary distribution. Decreased right ventricular function is less common than decreased left ventricular function but is a strong predictor of poor prognosis.

Cardiac MRI has become a routine noninvasive test that may be highly sensitive and specific for diagnosing acute myocarditis, particularly when both T1 and T2 weighted images are obtained. Both the typical T1 and T2 weighted changes observed in acute myocarditis decrease with time, so it is important to obtain cardiac MRI testing as soon as possible after symptom onset as sensitivity wanes as the disease moves to a chronic phase. Cardiac MRI has also been shown to be helpful in guiding EMB and provides prognostic information. Coronary angiography may be indicated if the patient's history and clinical presentation is suspicious for ischemic heart disease.

Histological or immunohistological evidence of an inflammatory infiltrate with or without myocyte necrosis on myocardial biopsy specimens remains the gold standard for the diagnosis of myocarditis. The Dallas criteria, proposed in 1986, define *active myocarditis* as the presence of both inflammatory cells and adjacent myocyte necrosis, and *borderline myocarditis* as the presence of inflammatory cells without associated myocardial injury. The Dallas criteria have been criticized due to interreader variability in interpretation, low sensitivity due to sampling error, discrepancy with other markers of viral infection, and immune activation in the myocardium and lack of prognostic value. Immunohistochemical stains that detect cellular surface antigens such as anti-CD3, anti-CD4, and anti-CD28 (T lymphocytes), anti-CD8 (macrophages), and Class I and II anti-human leukocyte antigens may have greater sensitivity than the Dallas criteria and may have prognostic value. The Marburg criteria, proposed in 1997, state that a clear-cut infiltrate of ≥14 leukocytes/mm^2 (quantitated by immunohistochemistry), including up to 4 monocytes/mm^2 and CD3 positive T lymphocytes at >7 cells/mm^2, and myocyte necrosis or degeneration must be present to diagnose acute myocarditis. Chronic myocarditis is defined as an infiltrate of ≥14 leukocytes/mm^2 without myocyte necrosis or degeneration. Fibrosis may or may not be present in either acute or chronic myocarditis.

Outside of a few tertiary medical centers, EMB is not routinely performed in adult patients with suspected myocarditis due to perceived risk and the cost of the procedure. EMB is strongly indicated in adult patients with either of the following two clinical scenarios: (1) new unexplained heart failure symptoms of <2 weeks' duration coupled with a normal or dilated left ventricle and hemodynamic compromise, or (2) new unexplained heart failure symptoms of 2 weeks to 3 months duration with a dilated left ventricle and ventricular arrhythmias, high-grade AVB, or failure to respond to guideline-directed heart failure therapy within 1 to 2 weeks. These clinical scenarios suggest the diagnosis of either necrotizing eosinophilic myocarditis (scenario 1) or GCM (scenarios 1 or 2), both of which have a poor prognosis that may be modified with immunosuppressive treatment. EMB may be considered in adults who present with other clinical scenarios, including patients with (1) DCM of any duration with suspected allergic reaction and peripheral eosinophilia, (2) unexplained heart failure of any duration associated with anthracycline therapy, or (3) unexplained heart failure associated with restrictive cardiomyopathy. However, European guidelines have recently broadened criteria for consideration of EMB to any patients with clinically suspected acute myocarditis. EMB is considered reasonable in the setting of unexplained cardiomyopathy in children as biopsy results may help to identify those who will likely respond to medical treatment and thus decrease the need for cardiac transplantation. EMB is usually obtained transvenously from the right ventricle and carries a less than 1:1,000 risk of major complications when performed by experienced operators.

A three-tiered classification for diagnosing acute myocarditis has recently been proposed (Table 39.1). A patient may be classified with *subclinical acute myocarditis* if (1) they are asymptomatic, (2) other causes of acute cardiomyopathy are excluded, and (3) they have had a recent trigger for myocarditis such as a viral illness plus one or more of the following: (a) an otherwise unexplained troponin elevation, (b) EKG changes suggestive of acute myocardial injury, or (c) echocardiographic or cardiac MRI evidence of cardiac dysfunction. Patients who meet the criteria for subclinical acute myocarditis and also present with symptoms consistent with acute myocarditis can be classified as having *probable acute myocarditis*. If histology or immunohistology results are consistent with myocarditis, then the patient has *definite myocarditis*, even if asymptomatic.

TABLE 39.1 **MYOCARDITIS DIAGNOSTIC CLASSIFICATION**

Classification	Patient presentation	Criteria	Histologic classification	Biomarker, ECG, and/or imaging findings consistent with myocarditis	Treatment
Possible subclinical acute myocarditis	Asymptomatic	1 or more of the following required: 1. Troponin elevation 2. ECG findings suggestive of acute cardiac injury 3. Echocardiographic or cardiac MRI findings consistent with abnormal cardiac function	Absent	Present	Unknown
Probable acute myocarditis	Symptomatic	1 or more of the following required: 1. Troponin elevation 2. ECG findings suggestive of acute cardiac injury 3. Echocardiographic or cardiac MRI findings consistent with abnormal cardiac function	Absent	Present	Per clinical syndrome
Definite myocarditis	Symptomatic or asymptomatic	Histologic or immunohistologic evidence of myocarditis	Present	Present or absent	Per clinical syndrome

Treatment

Guideline-directed medical therapy

There are no guidelines to direct therapy for patients with subclinical acute myocarditis. If the LVEF is <40%, then it would be reasonable to consider either an angiotensin-converting enzyme inhibitor (ACE-I) or angiotensin II receptor blocker (ARB) and a β- blocker, with regularly scheduled clinical follow-up in accordance with heart failure treatment guidelines.

Therapy for adult patients who present with heart failure symptoms and are diagnosed with probable or definite myocarditis consists of guideline-directed heart failure therapy including sodium and fluid restriction as well as treatment with diuretics and an ACE-I or an ARB. β-blocker therapy should be added once acute heart failure symptoms have resolved. The potential benefit of calcium channel blocker therapy in patients with viral myocarditis patients has not been established. Digoxin should be used with caution in patients with viral myocarditis as administration of high-dose digoxin to mice with viral-induced myocarditis increased mortality. Nonsteroidal anti-inflammatory medications should be avoided as use of these medications in mouse models of viral myocarditis results in augmented inflammation and increased mortality. Strenuous exercise should be avoided for 6 months after acute infection as mouse models have shown this type of activity to be deleterious. Patients who present with severe heart failure symptoms may require intravenous (IV) vasodilators or inotropes, while patients in cardiogenic shock may require mechanical circulatory support with intra-aortic balloon pumps, extracorporeal membrane oxygenation, or left ventricular/biventricular assist devices. Cardiac transplantation is reserved for patients who do not respond to guideline-directed heart failure therapy and mechanical circulatory support.

Antiviral therapy

As myocarditis is most often caused by viral infection, it would seem reasonable that elimination of viral translation, transcription, and proliferation with the use of antiviral medications that target viral attachment to host-cell receptors, virus entry, or virus uncoating such as Pleconaril or soluble CAR-Fc, would be effective in early stages of the disease, but, unfortunately, most patients present several weeks after viral infection. These agents are therefore likely providing little benefit to patients with acute viral myocarditis. Anecdotal evidence has suggested a role for nucleoside analogues, such as ganciclovir, in the treatment of HHV-6 related myocarditis, but clinical trials are lacking. Similarly, a small study called the PreTopic study evaluated telbivudine, another nucleoside analog, in treatment of parvovirus and found an improvement in symptoms and reduction in viral load.

Immunosuppressive therapy

Treatment of acute viral myocarditis with immunosuppressive drugs has not shown to be beneficial in adults. Results from the Myocarditis Treatment Trial showed that myocarditis patients

treated with prednisone plus either azathioprine or cyclosporine had similar changes in LVEF and transplant-free survival compared to patients treated with placebo. Immunosuppression in patients with GCM, cardiac sarcoidosis, necrotizing eosinophilic myocarditis, and myocarditis associated with connective tissue disorders, however, is warranted because immunosuppression has been shown to improve outcomes in patients with these disorders. Several small case control studies have shown that immunosuppressive treatment may be effective in children with acute myocarditis, but randomized controlled trials in this regard are lacking.

The Tailored Immunosuppression in Inflammatory Cardiomyopathy (TIMIC) trial randomized 85 adult patients with chronic myocarditis without persistent viral genomes to either prednisone and azathioprine or placebo. Patients in the immunosuppression group experienced significant improvement in LVEF and quality of life, while none of the patients in the placebo group had sustained improvement in either of these outcomes, indicating that immunosuppression may be efficacious in patients with chronic myocarditis/DCM.

Immunomodulatory therapy

Small studies using IV immunoglobulin (IVIG) in adult myocarditis patients have shown mixed results. The IMAC trial randomized 62 patients with recent onset cardiomyopathy and LVEF of <40% to either treatment with IVIG or placebo. Patients in the IVIG and placebo groups had identical survival and improvement in LVEF at 1 year. In contrast, a small retrospective study assessing the efficacy of high-dose IVIG (2 g/kg) in children with presumed acute myocarditis demonstrated a trend for improved survival in the IVIG compared to historical controls. High-dose IVIG has been utilized in one small series for CMV myocarditis and was associated with greater clearance of the virus.

Interferon-α and interferon-β therapy in mice with viral-induced myocarditis reduces myocyte injury, decreases inflammatory cell infiltrates, and results in elimination of cardiac viral load. A small case series of patients with chronic DCM and persistent enteroviral or adenoviral genomes in their myocardium showed that treatment with interferon-β eliminated viral genomes and improved LVEF compared to placebo. The subsequent Betaferon in patients with Chronic viral Cardiomyopathy (BICC) trial randomized 143 patients to treatment with interferon-β-1b or placebo. The interferon-β-1b group had significantly reduced cardiac enteroviral load, increased LVEF, and decreased left ventricular volumes compared to the placebo group. Whether these results can be extrapolated to treatment of other viruses (e.g., PVB19 or HHV 6) remains unclear.

The European Study of Epidemiology and Treatment of Cardiac Inflammatory Disease (ESETCID) is an ongoing randomized, double-blind, placebo-control trial evaluating a pathogen-guided treatment approach involving high-dose IVIG for CMV myocarditis, α-interferon for enterovirus, and immunosuppression for virus-negative myocarditis.

Natural history and prognosis

Natural history and prognosis in acute myocarditis varies by clinical scenario. Patients with acute lymphocytic (viral) myocarditis who present with mild symptoms and normal or near normal LVEF usually spontaneously improve without consequences, although approximately 15% of these patients may develop recurrent myocarditis. In contrast, the Myocarditis Treatment Trial revealed that symptomatic adult patients who presented with an LVEF <45% have a 1-year mortality of 20% and a 2-year mortality of 56%. The Intervention in Myocarditis and Acute Cardiomyopathy (IMAC) trial enrolled 62 patients with recent-onset heart failure due to myocarditis or idiopathic DCM and a baseline LVEF of <40%, randomizing them to conventional heart failure therapy plus/minus IVIG. Overall, LVEF improved from a mean of 25% at baseline to a mean of 41% at 6 months and 42% at 12 months, regardless of treatment arm. Transplant-free survival was 92% at 1 year and 88% at 2 years. The IMAC-2 trial enrolled 373 patients with recent-onset nonischemic DCM and showed that recovery differed between sexes. Mean LVEF in men increased from 23% at baseline to 39% at 6 months, while mean LVEF in women with non-peripartum cardiomyopathy increased from 24% at baseline to 42% at 6 months. Women with peripartum cardiomyopathy had the greatest myocardial recovery, with mean LVEF increasing from 24% at baseline to 45% at 6 months. There were no deaths at 4 years.

Future directions

Although EMB remains the gold standard for the diagnosis of myocarditis, it is an invasive test with associated risks of major complications. Molecular diagnostics may help provide improved characterization of inflammation and organisms if present, including translational activity to determine if the organism is pathogenic. The development of a sensitive and specific noninvasive test that can provide both diagnostic and prognostic information is sorely needed. Effective therapy specifically targeted for viral myocarditis is lacking. Use of selected antiviral and antimicrobial therapies may be beneficial, but adequately powered randomized controlled trials are needed to determine their efficacy. Other potential therapies that remain to be assessed include cell-based therapies targeted toward T cells in order to modulate the immune response to viral infection. Prevention of myocarditis is yet another area that warrants further research. Vaccinations against many viruses, including measles, mumps, and polio, have made myocarditis secondary to these diseases quite rare, which raises the possibility that vaccination development and usage against cardiotropic viruses such as enterovirus, adenovirus, PVB19, HHV-6, and HIV may decrease the incidence of myocarditis in the future.

Mediastinitis

Ravi Karra and Keith S. Kaye

The mediastinum is the space in the thorax between the lungs; it houses the heart, great vessels, esophagus, trachea, thymus, and lymph nodes. The connective tissues of the mediastinum are continuous with the long fascial planes of the head and neck, one reason why mediastinitis was primarily a complication of pharyngeal infections until the advent of thoracic surgery. By virtue of its deep position within the thorax, the mediastinum is a relatively protected organ space. There are four major portals of entry into the mediastinum: (1) direct inoculation of the mediastinum following sternotomy (i.e., postoperative mediastinitis [POM]); (2) spread along the long fascial planes of the neck (i.e., descending mediastinitis); (3) rupture of mediastinal structures, such as the esophagus; and (4) contiguous spread of infection from adjacent thoracic structures.

Postoperative mediastinitis

Postoperative mediastinitis (POM) is classified as an organ/ space infection by Centers for Disease Control and Prevention (CDC) criteria and is a dreaded complication of median sternotomy. POM classically presents as a febrile illness with sternal wound dehiscence and purulent drainage, usually 2 to 4 weeks after sternotomy. Occasionally POM presents as a more chronic, indolent infection months to years after sternotomy. Sometimes, only superficial signs of infection are present, making POM difficult to diagnose. Frequently, a high index of clinical suspicion is required to differentiate POM from a more superficial sternal wound infection.

Pathogenesis

Infection most often occurs as the result of direct inoculation of host bacteria into the mediastinum during surgery. Bacteria that colonize the skin and oral mucosa, such as coagulase-negative *Staphylococcus* (CoNS) and *Staphylococcus aureus* are the most common causes of POM. Gram-negative bacilli, a less common cause of POM, are believed to spread to the mediastinum from the abdomen. Infrequently, pathogens such as *S. aureus* might be introduced into the mediastinum by a member of the surgical team or by contaminated operative instruments. Whether bacterial contamination develops into full-blown infection is a combination of three major factors: (1) inoculum of bacterial contamination, (2) the degree of local tissue and vascular damage, and (3) host immunity. Larger inoculum and greater perioperative tissue damage both increase the risk for infection. Decreased host immunity increases susceptibility to the development of POM, contributing to an elevated risk for mediastinitis after cardiac transplantation.

Epidemiology and outcomes

Despite advances in surgical techniques and the use of preoperative prophylactic antibiotics, rates of POM in the modern era remain around 1.0%. The high number of median sternotomies performed annually makes POM a frequently encountered problem.

Risk factors for the development of POM comprise three categories: (1) host-related factors, (2) hospital-related factors, and (3) technical or operative factors. Host-related factors include diabetes, obesity, advanced age, prior sternotomy, chronic obstructive pulmonary disease, and New York Heart Association (NYHA) class III or IV heart failure. Hospital factors include prolonged postoperative mechanical ventilation and prolonged postoperative stay in an intensive care unit. Operative factors include mobilization of an internal mammary artery, increased duration of surgery, and surgical complexity. Complex surgeries are simultaneous coronary artery bypass grafting and valve repair, "repeat" or "redo" median sternotomy, and surgical re-exploration following initial sternotomy.

POM is associated with significant attributable morbidity and mortality. Estimates of postoperative mortality range from 11.8% to 14% in patients with POM compared to 2.7% to 5.5% in uninfected operative controls. Some series report mortality rates as high as 40%. Risk factors for mortality in the immediate postoperative period are related to the patient (advanced age and postoperative bacteremia), the hospitalization (e.g., mechanical circulatory support and prolonged postoperative mechanical ventilation), technical factors (prolonged operative duration, surgical re-exploration, blood transfusion), and the specific pathogen. POM due to methicillin-resistant *S. aureus* (MRSA) is associated with particularly adverse clinical outcomes. Patients with POM are not only at increased risk for mortality during the immediate postoperative period but also carry a two- to four-fold increased risk for death for up to 10 years following cardiothoracic surgery. Risk factors for long-term mortality in patients with POM include age >65 years, serum creatinine >2.0 mg/dL prior to surgery, infection with MRSA, delay of sternal closure more than 3 days following therapeutic debridement for POM, and failure to treat POM with effective antimicrobial agents within 7 days of therapeutic sternal debridement.

Descending necrotizing mediastinitis

Mediastinitis arising from the migration of pathogens from head or neck infection, as opposed to direct inoculation of the mediastinum, is classified as descending necrotizing mediastinitis. Pharyngeal infections cause nearly 50% of all descending necrotizing mediastinitis. However, virtually any infection of the head and neck can spread into the mediastinum. If infections of the head and neck are treated with appropriate antimicrobial agents, descending necrotizing mediastinitis can be prevented. In the modern age of antibiotics, descending mediastinitis is becoming increasingly rare.

Pathogenesis

Spread to the mediastinum can occur via each of the three spaces of the head and neck: the pretracheal space (suppurative thyroid and tracheal infections), the perivascular space (oropharyngeal infections), and the retrovisceral space (oropharyngeal infections). Negative intrathoracic pressure during inspiration acts to draw infection into the mediastinum from these spaces. The retropharyngeal space houses the "danger" space, so named because it extends from the base of the skull all the way to the diaphragm. Spread within the retropharyngeal space is involved in the pathogenesis of approximately 70% of cases of descending mediastinitis. Infections of the perivascular space can also be complicated by thrombophlebitis of the jugular vein (Lemierre's disease) and direct extension of infection into the carotid artery. (See Chapter 10, Deep neck infections.)

Epidemiology and outcomes

The microbiology of descending necrotizing mediastinitis reflects the bacteria that usually colonize or infect the head and neck. Often, descending necrotizing mediastinitis is a polymicrobial infection involving anaerobes. Common anaerobes include *Fusobacterium*, *Prevotella*, *Vellionella*, *Peptostreptococcus*, and other oral anaerobes. *Streptococcus* spp. are common pathogens. *Actinomyces* can also cause descending mediastinitis.

Patients with descending necrotizing mediastinitis often present with fevers, signs of an underlying head and neck infection, and sometimes sepsis. However, in immunocompromised patients, obvious clinical signs and symptoms may not be readily apparent. Signs of associated neck infection can provide clues to the presence of descending mediastinitis and include trismus, pain of the oropharynx, pain on movement of the neck, dysphagia, hoarseness, stridor, and occasionally erythema of the overlying skin. Overall, the diagnosis of descending necrotizing mediastinitis requires a high degree of clinical suspicion. Early recognition and treatment is important, as this syndrome can be rapidly fatal, with an estimated mortality rate of 15% in spite of therapy.

Mediastinitis originating from mediastinal structures

Mediastinitis can also occur as a result of direct spillage of bacteria from mediastinal structures. Perforation of any of the organs or vessels housed in the mediastinum, most commonly the esophagus, can lead to mediastinitis. Perforation of the esophagus can occur after heavy emesis (as in Boerhaave's syndrome); following ingestion of sharp objects; or following procedures involving the esophagus such as endoscopy, myotomy, or esophageal stenting. Mediastinitis can develop following tracheal perforation, which sometimes occurs as a complication of endotracheal intubation and bronchoscopy. Rare cases of mediastinitis have been reported as a consequence of spread of infection from the aorta following surgical repair or central venous line placement.

In mediastinitis originating from mediastinal structures, particularly Boerhaave's syndrome, patients often present with chest pain and fever. If mediastinitis is suspected, special attention in the history should be focused on recent procedures involving the trachea or esophagus or episodes of heavy retching.

Mediastinitis from contiguous thoracic infections

If untreated, pulmonary infections due to bacteria, fungi, and *Mycobacteria* can cause secondary mediastinitis by contiguous spread. Mediastinitis caused by bacterial pathogens usually presents as an acute infection. Mediastinitis due to tuberculosis or histoplasmosis tends to have a subacute or chronic course compared to bacterial infection. These infections can lead to granulomatous mediastinitis or immune-related deposition of collagen within the mediastinum and resultant fibrosing mediastinitis.

Evaluation of suspected mediastinitis

It is important to obtain a history of predisposing events, such as median sternotomy, head and neck illness, or endoscopy or bronchoscopy.

Patients with mediastinitis classically present with chest pain and fever. The chest pain is sometimes pleuritic in nature. On exam, patients with mediastinitis usually display signs of severe systemic illness such as hypotension and sepsis. In some instances, patients may not present with overwhelming systemic signs and symptoms of infection. Often, a high degree of clinical suspicion is needed to differentiate POM from superficial infection.

Mediastinitis may present differently depending on the type of infection present in a given case. For example, patients with POM classically present within 3 weeks of surgery with erythema or frank purulent drainage at the sternal incision site. If the sternum is firmly depressed on either side of the incision, a sternal "click" is sometimes elicited, representing sternal instability from damage of underlying tissue planes. Unfortunately, acute signs and symptoms of POM might not be present and sometimes patients present with only mild signs of infection, such as small amounts of drainage or erythema from a median sternotomy site. In contrast, patients with descending necrotizing mediastinitis often have signs of head and neck infection, making evaluation of the head and neck a critical component of the physical exam. Sometimes, in cases of dental abscess, fluctuant masses are present at the base of the teeth. Other signs include tonsillar exudates, pharyngeal inflammation, or cervical lymphadenopathy. Neck tenderness may represent tracking of infection from the head or neck to the mediastinum. "Hamman's crunch," present in some cases of mediastinitis, refers to crunching sounds on cardiac auscultation with each heartbeat and is indicative of air in the mediastinum. Patients with mediastinitis secondary to spread of infection from adjacent organs often have signs or symptoms associated with infection of the adjacent organ space (e.g., findings of pulmonary consolidation in cases of pneumonia).

When considering mediastinitis, diagnostic evaluation includes complete blood count, white blood cell differential, blood cultures, C-reactive protein, and imaging. Chest x-ray may show a widened mediastinum (most commonly seen in cases of descending necrotizing mediastinitis). Rarely, chest x-ray might demonstrate pneumomediastinum. Chest computed tomography (CT) and magnetic resonance imaging (MRI) are the most useful radiographic tests. CT and MRI commonly demonstrate fluid in the mediastinum and pneumomediastinum. While remaining sensitive for POM, chest CT or MRI are less specific, as postoperative inflammation can be difficult to differentiate from infection or abscess.

Prevention and treatment of suspected mediastinitis

Postoperative mediastinitis

In patients undergoing sternotomy, preoperative antibiotic prophylaxis is recommended. First- or second-generation cephalosporins can be administered within 60 minutes prior to surgery. In patients or institutions with high rates of MRSA or in patients with a penicillin allergy, vancomycin can be considered as part of the prophylactic regimen in combination with agents active against gram-negative bacilli. Organized programs to preoperatively decontaminate the nasopharynx and the nares of patients with chlorhexidine prior to surgery have been shown to reduce the incidence of postoperative infection, including deep sternal infections. More recently, implementation of a program consisting of preoperative chlorhexidine baths and mupirocin treatment of the nares for patients with *S. aureus* colonization was shown to reduce rates of deep surgical site infections, including mediastinitis. Other approaches such as use of implantable antibiotic sponges at the time of surgery or vaccination against *S. aureus* have proven to be less effective.

Optimal treatment of POM involves a combination of definitive surgical debridement and appropriate antimicrobial therapy. In POM, the most common pathogens are gram-positive cocci (*Staphylococcus* spp. and *Streptococcus* spp, ~70% of cases) and gram-negative bacilli (~12% of cases). Therefore, initial antimicrobial therapy typically includes two agents: one with activity against aerobic gram-positive cocci and one with activity against aerobic gram-negative bacilli. Gram-positive coverage usually includes a β-lactam (such as nafcillin or cefazolin) or glycopeptides (such as vancomycin). At institutions where MRSA is a notable POM pathogen, vancomycin should be used for empiric gram-positive therapy. Empiric coverage for gram-negative pathogens usually involves treatment with a fluoroquinolone, aminoglycoside, or extended-spectrum cephalosporin. *Pseudomonas* is a rare pathogen in mediastinitis and, therefore, antipseudomonal drugs are not typically required for empiric therapy. Antimicrobial therapy should be tailored based on culture results from the sternum and/ or mediastinum; and blood. Results from sternal culture specimens, ideally obtained in the operating room, are usually available within 3 to 5 days after they are submitted.

Immediate surgical debridement, including removal of sternal wires, is needed to confirm the diagnosis of mediastinitis (by demonstrating the presence of pus in the mediastinum), to obtain tissue for microbiologic culture, and to remove purulent material and devitalized or grossly infected tissue. Sternectomy, including

removal of the avascular costal cartilage, usually is necessary due to concurrent sternal osteomyelitis. After initial debridement and sternectomy, various therapeutic operative approaches can be implemented. Historically, the sternum was left open and packed until granulation tissue visibly developed. However, this approach was associated with considerable morbidity and mortality, often due to superinfection of the open mediastinum. Utilization of negative pressure wound therapy (NPWT, Wound Vacs) for mediastinitis may improve outcomes. Several series demonstrate shorter hospital stays, faster time to complete sternal closure, and even decreased mortality with NPWT compared to an open sternum. The preferred approach for sternal closure following sternectomy is to use a muscle flap, usually derived from the pectoralis or omentum, with the use of fenestrated drains in the mediastinum. Closure of the sternum with a muscle flap typically occurs either immediately after sternectomy and debridement or soon afterward. Delayed closure is associated with adverse outcome. Occasionally, the sternum is closed primarily without use of a muscle flap.

Descending necrotizing mediastinitis, mediastinitis originating from mediastinal structures, and mediastinitis from contiguous thoracic infections

In descending necrotizing mediastinitis, empiric antimicrobial therapy should provide activity against gram-positive cocci, anaerobes, and gram-negative rods. When the infection is restricted to the upper mediastinum, transcervical drainage is recommended. However, when infection includes the lower mediastinum, thoracotomy and open drainage is often necessary.

Mediastinitis following rupture of a mediastinal viscus requires open surgical drainage and repair of the perforated viscus. In the case of Boerhaave's syndrome, antibiotics with activity against aerobic gram-negative bacilli and anaerobes should be used. For example, an extended-generation cephalosporin in combination with metronidazole or clindamycin would be a reasonable empiric regimen. Other single-drug regimens might include a β-lactam/β-lactamase inhibitor combination such as piperacillin–tazobactam; or a carbapenem. Surgical intervention is guided by the degree of infection and the perforation. Large collections of infection require drainage, and large esophageal tears require local esophagectomy and repair.

Mediastinitis secondary to spread of a contiguous thoracic infection should be empirically treated with broad-spectrum antibiotics with activity against pulmonary pathogens such as *Streptococcus pneumoniae*, *S. aureus*, and gram-negative bacilli. In cases of suspected aspiration pneumonia, anaerobes should also be covered. An appropriate empiric regimen might include a third-generation cephalosporin or aztreonam in combination with vancomycin and either clindamycin or metronidazole. Definitive therapy requires debridement of the mediastinum and drainage of infected thoracic collections, usually via chest tube. Antibiotic regimens should be tailored based on intraoperative culture results.

Fibrosing mediastinitis due to either mycobacterial infection or fungal infection is a therapeutic challenge. Empiric therapy for *Mycobacterium tuberculosis* includes the standard four-drug regimen (e.g., isoniazid, rifampin, pyrazinamide, and ethambutol). For the treatment of fungal infections, itraconazole, sometimes in combination with amphotericin for histoplasmosis, is used. However, the utility and effectiveness of antimicrobial therapy in the treatment of fibrosing mediastinitis due to these pathogens remains unclear. Surgical debridement is primarily used to relieve vascular and airway obstruction.

Vascular infection

Susan E. Beekmann and David K. Henderson

Diagnosis and treatment of vascular infections are complex and depend on a variety of factors, including the location of the infected tissue, the microbiology of the infection, and patient-specific factors such as anatomy and immune status. Purulent or suppurative thrombophlebitis is inflammation of a peripheral or central venous wall because of the presence of microorganisms. Endarteritis (or infective arteritis) and mycotic aneurysms are infections of the arterial walls; arterial aneurysms or pseudoaneurysms are usually present because endarteritis may be difficult to diagnose unless an aneurysm is present. The term *mycotic aneurysm* is a misnomer that refers to any arterial aneurysm of infectious cause, fungal or bacterial, and may also include secondary infections of preexisting aneurysms or pseudoaneurysms. Vascular graft infections present an even wider spectrum of disease that depends on the type and location of the graft. Management of infections located on vascular prostheses is further complicated by the fact that prosthesis excision can jeopardize a patient's life and organ function, and alternative grafting techniques, including ex situ bypass, autologous reconstruction, and a variety of other graft materials, must be considered. Finally, endovascular repair of aneurysms has resulted in a variety of infectious complications of endovascular stents, stent-grafts, and other intra-arterial devices.

Purulent phlebitis of peripheral and central veins

Pathogenesis and diagnosis

Septic thrombophlebitis is characterized by inflammation with suppuration of the vein wall. The various anatomic sites of this serious condition determine the clinical significance and manifestations. Superficial suppurative thrombophlebitis is most often a complication of indwelling intravenous (IV) catheters or IV substance use. Suppurative thrombophlebitis due to IV catheters occurs more commonly with plastic than with steel cannulas. Irritation of the vein wall and subsequent development of purulent thrombophlebitis occurs more often with polyethylene catheters than with Teflon or Silastic catheters and is higher in lower extremity cannulation. Central vein thrombosis is a relatively common complication of central venous catheterization, occurring in as many as one-third of patients in some autopsy and clinical series. Peripherally inserted central venous catheters are also associated with increased risk of symptomatic thrombosis. Suppurative thrombophlebitis of the thoracic central veins results from the bacterial or fungal contamination (sepsis) of these, often asymptomatic, thrombi. The second major type of septic thrombophlebitis occurs by invasion from adjacent primary nonvascular infections and includes Lemierre's syndrome (internal jugular vein septic thrombophlebitis caused by anaerobic gram-negative organisms) as well as other entities discussed elsewhere. Lemierre's syndrome, although rare, usually follows an oropharyngeal infection and occurs most often in previously healthy patients aged 16 to 25 years.

Diagnosis of peripheral suppurative thrombophlebitis may be difficult if local findings of inflammation are absent, as often occurs in lower extremity cannulization. Local findings, including swelling, erythema, induration, and/or a palpable cord, are much more common in suppurative thrombophlebitis of the upper

extremities. Bacteremia is present in as many as 90% of patients with peripheral suppurative thrombophlebitis, and gross pus within the vein may be apparent in half of the patients. Suppurative thrombophlebitis of the thoracic central veins should be considered in any septic patient with a central venous catheter when bacteremia (or fungemia) fails to resolve after removal of the catheter and institution of appropriate antimicrobial therapy. Diagnosis can be established by venography with the demonstration of thrombi in a patient with bacteremia or fungemia. CT with contrast is also likely to be diagnostic; presence of gas in the venular lumen is typical of this condition. MRI may be even more sensitive for diagnosis. Fluorodeoxyglucose positron emission tomography (FDG-PET) may be useful, particularly in neutropenic patients suspected to have infection. In Lemierre's syndrome, the course is described by the triad of pharyngitis, a tender/swollen neck, and noncavitating pulmonary infiltrates. Septic pulmonary emboli occurred in 97% of cases in two series. Oropharyngeal findings alone, however, are not diagnostic, and a tender and/ or swollen neck occurs in only about 50% of patients. CT with contrast, ultrasound, or MRI can document this syndrome.

Therapy

Treatment of superficial suppurative thrombophlebitis traditionally has consisted of surgical excision plus parenteral antimicrobials. Currently available literature, most of which is derived primarily from burn center studies, strongly recommends vein excision, indicating that patients treated with antibiotics alone had much higher mortality rates than patients who underwent surgical exploration. Other studies suggest that local incision and drainage of the involved site plus appropriate antimicrobial therapy may be sufficient in many nonburn cases. Patients who fail less radical surgery should then be referred for extensive surgical excision with total removal of all involved veins and drainage of contiguous abscesses.

In recently published reviews, Enterobacteriaceae caused more than half of all cases of suppurative thrombophlebitis, followed by *Pseudomonas aeruginosa*, *Staphylococcus aureus*, and *Candida* spp. Initial empiric treatment might include vancomycin and either an aminoglycoside or a third- or fourth-generation cephalosporin with antipseudomonal activity to cover the Enterobacteriaceae, *Pseudomonas*, and *S. aureus* (both methicillin-resistant and methicillin-sensitive) until a culture of the infected material can be performed. Blood cultures should always be drawn before antibiotics are initiated and will very frequently yield the invading pathogen. Empiric antibiotic choices should be tailored for known resistance patterns within hospitals and in geographic areas and may be adjusted based on Gram stain results. For example, a Gram stain of venular material showing gram-negative rods should result in discontinuation of vancomycin. Therapy with an appropriate antibiotic(s) should be continued once culture results are available. Treatment of superficial suppurative thrombophlebitis caused by *Candida albicans* is controversial because most of these infections can be cured by vein excision alone. Nonetheless, fluconazole, 400 to 800 mg/d, may be used, and amphotericin B or fluconazole is mandatory in the immunosuppressed patient or if metastatic complications occur.

Treatment of central suppurative thrombophlebitis consists of catheter removal and parenteral antibiotics. The addition of full-dose anticoagulation is more controversial, although one review concluded that the administration of heparin in these settings may be beneficial. Empiric antibiotic treatment is the same as for peripheral suppurative thrombophlebitis, with the potential addition of an antipseudomonal penicillin. The antibiotics appropriate for the organisms identified from cultured material should be continued for at least 2 weeks after catheter removal. A minimum of 4 weeks of antimicrobial treatment is recommended after catheter removal when *S. aureus* is involved. Amphotericin B to a total dosage of at least 22 mg/kg ± 5-fluorocytosine is recommended for suppurative thrombophlebitis of the great central veins caused by *Candida* spp.; for the intrinsically resistant species, including *C. glabrata* and *C. krusei*, echinocandins may be an acceptable alternative. Lemierre's syndrome should be treated with a prolonged course of either clindamycin or metronidazole. Surgical treatment is usually not necessary.

Arterial infections (mycotic aneurysms and arteritis)

Pathogenesis and diagnosis

Mechanisms of arterial infection include (1) embolomycotic aneurysm secondary to septic microemboli (most commonly in the setting of infective endocarditis), (2) extension from a contiguous infected focus, (3) hematogenous seeding during bacteremia originating from a distant site, and (4) trauma to the vessel wall with direct contamination, with the latter mechanism occasionally associated with iatrogenic manipulation of the artery (e.g., cannulation). Normal arterial intima is quite resistant to infection, but congenital or acquired malformation or disease (e.g., atherosclerosis) lowers resistance to infection, and hematogenous seeding of a previously damaged arteriosclerotic vessel currently constitutes the most common mechanism of infection (Figure 41.1). Mycotic aneurysms complicate infective endocarditis in approximately 5% to 10% of cases, with about half of these aneurysms involving the brain. Brain MRI with angiography may be more sensitive than CT scans for neurologic manifestations of infective endocarditis, including cerebral mycotic aneurysms.

Staphylococcus spp. and *Salmonella* spp. are the two most commonly cultured organisms in mycotic aneurysms, with staphylococci most commonly infecting preexisting aneurysms and *Salmonella* most common in causing aortitis of the non-aneurysmal aorta. When aneurysms are associated with endocarditis, gram-positive organisms account for at least 80% of pathogens.

Clinical manifestations depend to a large extent on the site of the aneurysm (Table 41.1), although mycotic aneurysms are often clinically unsuspected. Most infected aortic aneurysms occur in elderly atherosclerotic men rather than women (4:1 ratio), but symptoms are nonspecific and may overlap with those of uninfected aneurysms. Fever and continuing bacteremia despite seemingly appropriate

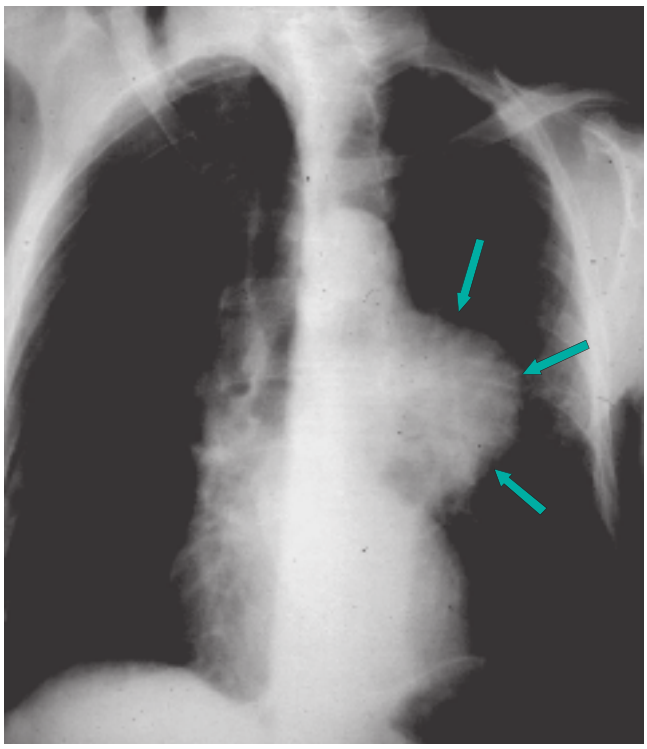

FIGURE 41.1 Infected atherosclerotic aneurysm of descending thoracic aorta (*arrows*): blood cultures grew *Salmonella*.
Courtesy of David Schlossberg, MD.

antimicrobial therapy are suggestive of an infected intravascular site. CT scan is considered the optimal initial imaging technique, with multiple newer imaging modalities including MRI, FDG-PET, and single-photon emission computed tomography (SPECT) emerging as increasingly feasible and helpful, although costly, adjunctive imaging techniques.

A variety of intra-arterial prosthetic devices are now being used in cardiovascular medicine, including arterial closure devices, prosthetic carotid patches, coronary artery stents, and endovascular stents and stent-grafts. Infections of these devices remain either uncommon or extremely rare, but infectious complications associated with the placement of these devices are often devastating. *S. aureus* has been implicated in as many as three-quarters of these cases and has been the primary pathogen, even in late-onset infections. Blood cultures should be obtained from all patients who have a history of endovascular stent placement and local or systemic signs of infection.

Therapy

Despite improved prognosis for infected aneurysms of the thoracoabdominal vessels associated with earlier diagnosis and treatment, the case fatality rate for aortic aneurysms infected with gram-negative organisms is extraordinary and may be as high as 75%. Currently accepted management is IV antibiotic therapy, excision and debridement of the artery or aneurysm, and extra-anatomic vascular reconstruction along an uncontaminated path where possible. As a general principle, antibiotic therapy alone is insufficient without surgical resection of the infected tissue. Despite this axiom, surgical management of asymptomatic intracranial mycotic aneurysms does depend on their size and location because small lesions may resolve with antibiotic therapy alone. A reasonable approach would be to monitor by MRI every 2 to 3 weeks for 2 months, although this approach may carry a higher risk of rupture and bleeding. Surgery is indicated if the infected vessel is accessible or the lesions increase in size and should be considered if the lesions fail to decrease in size.

Basic principles of grafting in this situation include the use of autogenous rather than synthetic grafts and insertion only in clean, noninfected tissue planes. Use of cryopreserved allografts allows in situ reconstruction, and these grafts are increasingly used, particularly for cases involving the thoracic or suprarenal aorta. Direct (in situ) reconstruction with synthetic or autologous grafts has become increasingly common, and short- and mid-term outcomes of this approach appear to be acceptable. At surgery the aneurysm must be sectioned, Gram-stained, and cultured; appropriate antibiotic therapy must be individualized and based on culture and sensitivity results. Bactericidal antibiotics should be continued for 6 to 12 weeks postoperatively, and some authors recommend indefinite antibiotics with in situ graft placement.

Endovascular aneurysm repair (EVAR) or endoluminal stenting for mycotic aneurysms is an additional alternative that reduces hospital stay and frequency of surgical complications but that raises significant concern because of the potential for persistent infection. In many cases, these endovascular stents are short-term solutions (i.e., "bridge" repairs) until definitive surgical repair can be performed, and chronic oral antimicrobial therapy is required. Nonetheless, endovascular grafts may now be used preferentially in patients with limited life expectancy and multiple comorbidities for whom conventional surgical methods carry extremely high risk. As technology has continued to advance, a shift toward EVAR has occurred. More recent data indicate better short-term survival in comparison with open repair and a similar incidence of serious infectious complications. Gram-positive organisms are the most common cause of infections (primarily staphylococci), and infected endografts are increasingly being diagnosed with FDG-PET and CT scan. A lifelong follow-up strategy for patients treated with EVAR is vital given the potentially devastating consequences of infection, including higher mortality rates with recurrent or new infection.

Vascular graft infections

Pathogenesis and diagnosis

Reported incidence of vascular graft infections ranges from 0.8% to 6% and varies with the site of graft placement and the graft material selected for insertion. For example, procedures requiring an inguinal incision have an incidence of infection that is two to three times higher than procedures not requiring an inguinal incision; use of a vascular prosthesis results in significantly higher infection rates than autologous reconstruction. Surgical site infections, longer procedure times, and mycotic aneurysms also are independent determinants of graft infections. Most contamination likely occurs

TABLE 41.1 **DIAGNOSIS AND MANAGEMENT OF MYCOTIC ANEURYSMS**

Site	Clinical presentation	Imaging	Microbiology	Management
General				
All infected aneurysms	Fever common (70–94%) Malaise, weight loss Pain (100%) Rapidly expanding mass Leukocytosis (65–85%) Positive blood cultures (50–75%)	*Findings:* Aneurysm with lack of intimal calcification Perianeurysmal fluid/gas collection *Studies:* CT angiography, MRI Ultrasonography (if accessible) Radionuclide-tagged WBC scans	*Staphylococcus* 50–60% (at least 66% *S. aureus*) *Salmonella* 30–40% *Streptococcus* *Escherichia coli* IVDU: *S. aureus*, *Pseudomonas* spp. *Enterococcus* spp., *Streptococcus* *Viridans*	*Surgical:* Wide debridement, irrigation with antibiotic solution of involved tissues, complete resection of aneurysm if possible *Antibiotic:* Empiric treatment with IV antibiotics for 6–12 wk after surgery based on culture results of resected tissue Follow-up blood cultures Consider chronic suppressive oral antibiotic therapy when extra-anatomic bypass is not performed (i.e., for in situ repairs)
Specifics				
Aorta Infrarenal abdominal aorta[a] Ascending aorta and arch (secondary to endocarditis)	Abdominal or back pain (65–90%) Palpable abdominal lesions (about 50–65%) Vertebral osteomyelitis (lumbar/thoracic)	Frontal, lateral abdominal x-ray studies Abdominal ultrasound	*Salmonella* spp. have predilection for suprarenal aorta *Staphylococcus* predominates in infrarenal aorta	Extra-anatomic arterial reconstruction (axillofemoral or aortofemoral) If risk too high, in situ reconstruction with cryopreserved allograft
Visceral artery Superior mesenteric,[a] splenic, hepatic, celiac, renal	Colicky abdominal pain Jaundice (hepatic artery) Hemoptysis or hemothorax (celiac artery)	Ultrasound may exclude other causes (e.g., pancreatic masses)	*Bacteroides fragilis* reported from supraceliac aorta and celiac artery	Complete excision may be hazardous; careful drainage and longer term antibiotic therapy may be necessary
Iliac	Thigh pain, quadriceps wasting, depressed knee jerk Arterial insufficiency of extremity			Excision and arterial ligation; reconstruction usually can wait until infection has resolved
Arm Radial artery[a] Humeral artery Axillary artery	Pain over site of lesion About 90% palpable May appear as cellulitis, abscess; distal embolic lesions; skin changes common		Gram-positive including *Staphylococcus* and *Streptococcus*	Proximal ligation of the vessel, resection of the aneurysm, and appropriate drainage should be followed by antibiotic therapy.
Leg Femoral artery[a]	Pain over site of lesion About 90% palpable Pulsatile mass, decreased peripheral pulses Possible local suppuration, distal embolic lesions; petechiae, purpura		*S. aureus* incidence as high as 65%	Excision and arterial ligation; reconstruction usually can wait until infection has resolved Autogenous grafting may allow reconstruction through the bed of the resected aneurysm if anastomoses performed in clean tissue planes
Intracranial Peripheral middle cerebral artery[a]	Usually clinically silent May appear as severe unremitting headache Usually secondary to endocarditis	Multislice CT angiography (CTA) or magnetic resonance angiography (MRA) equivalent MRI in endocarditis	*S. aureus 2° endocarditis* *Viridians group streptococci* *Enterococcus* spp. *Pseudomonas* spp. *Candida albicans*	Clipping or embolization may decrease mortality, but nonoperative management may be acceptable when lesions are small or inaccessible

[a] Most common site or manifestation.
Abbreviations: CT = computed tomography; MRI = magnetic resonance imaging; WBC = white blood cell; IV = intravenous; IVDU = intravenous drug user.

at the time of implantation, although hematogenous seeding and retrograde infection from superficial wound infection, as well as bacteria harbored in atherosclerotic plaques may account for some late graft infections. Prophylactic systemic antibiotics at time of graft placement have been associated with a decrease in vascular graft infections. Prophylactic antibiotics should be considered mandatory with placement of vascular grafts.

Staphylococci remain the most prevalent pathogens, with *S. epidermidis* infections often presenting months to years after the operation and *S. aureus* most commonly causing early infections (Table 41.2). More than 70% of infections involving vascular grafts of the groin and lower extremities develop within 1 to 2 months of surgery, whereas 70% of intra-abdominal graft infections do not manifest until months or years after surgery. An aortoenteric fistula can be the presenting sign in 25% to 30% of aortic graft infections, while systemic symptoms, including fever, leukocytosis, elevated inflammatory markers, and bacteremia, are much more variable.

Appropriate imaging of the infected area is vital to diagnosis because the extent of local infections may not be recognized if imaging techniques are inadequate. Angiography often is unhelpful in the diagnosis of vascular graft infections, but it is useful for identifying aortoenteric fistulas as well as for guiding the surgical procedure. An anatomic imaging study should be performed. Ultrasound can be used for extracavitary vascular graft infections and superficial grafts, including dialysis shunts; a CT with contrast or an MRI with contrast and fat saturation should be performed for deeper grafts.

TABLE 41.2 **DIAGNOSIS AND MANAGEMENT OF VASCULAR GRAFT INFECTIONS**

Site	Clinical presentation	Microbiology	Imaging	Management
General				
Any infected vascular graft	*Early (≤4 mo):* Immediate postoperative infections rare; usually associated with wound sepsis Fever, leukocytosis, bacteremia Anastomotic bleeding (most common with gram-negative organisms) Wound healing complication *Late:* Systemic signs few or absent; WBC count often normal Tenderness, erythema of skin over prosthesis Anastomotic false aneurysm Graft-enteric erosion, fistula	Coagulase- negative staphylococci *Staphylococcus aureus* *Pseudomonas* *Streptococcus* *Escherichia coli*	*Findings:* Perigraft fluid, gas collection; abnormal appearance of perigraft soft tissues; abscess; pseudoaneurysm formation *Studies: Anatomic imaging study:* 1. CT with contrast, or 2. MRI with contrast and fat saturation; or, for superficial grafts: 3. Ultrasonography *Radioisotope studies that may be useful:* 1. WBC-labeled indium scan, or 2. Tc99-HMPAO-labeled WBC, if available 3. FDG-PET/CT	*Surgical:* Wide debridement, irrigation with antibiotic solution of involved tissues (commonly used but efficacy data not available), graft excision when possible with ex situ bypass reconstruction Consider thorough debridement with myocutaneous flap for patients with a patent graft, intact anastomoses, absence of hemorrhage, and sterile blood cultures *Antibiotic:* Empiric treatment with IV antibiotics for 4–6 wk after surgery based on culture results of resected tissue Follow-up blood cultures Consider 3–6 mon of follow-up oral therapy. Consider chronic suppressive oral antibiotic therapy if infected graft not removed
Specific				
Aortoiliac	Higher incidence in months 8–15 First symptoms, fever, slightly increased WBC count Later, abdominal, back pain, false aneurysm formation Finally, hemorrhage Aortoenteric fistula (30% of aortic graft infections)	*E. coli S. aureus* *Streptococcus* Coagulase- negative staphylococci	MRI more sensitive than CT for aortal graft infection	Place axillofemoral or bifemoral graft, then remove entire aortic graft Close arteriotomy sites with monofilament sutures, irrigate with antibiotic solution (no efficacy data)

TABLE 41.2 CONTINUED

Site	Clinical presentation	Microbiology	Imaging	Management
Aortofemoral	*False aneurysm in groin site* *Wound infection or abscess* *In inguinal incision* *Pulsatile mass at groin site*	*S. aureus* *S. epidermidis* *Proteus spp.* *E. coli Streptococcus* *Other gram-negative bacilli*	Ultrasonography can be useful in femoral area	May be possible to remove only infected part of graft (one limb), although continued infection likely without removal of entire graft Extra-anatomic bypass when possible
Axillofemoral	Same as for aortofemoral	Same as for aortofemoral	Same as for aortofemoral	Remove entire graft Intra-abdominal graft may suffice for revascularization; high amputation and death rates
Femoropopliteal	Higher incidence in first 3 mo Small sinus tract, abscess, cellulitis in inguinal incision	*S. aureus* *Streptococcus* *S. epidermidis* Other gram- negative bacilli		Remove entire graft Nonviable limbs must be revascularized or amputated; delay amputation as long as possible to allow maximum development of collaterals

Abbreviations: WBC = white blood cell; MRI = magnetic resonance imaging; CT = computed tomography; IV = intravenous.

If doubt about infection still exists, radioisotope imaging can be performed using either indium-111–labeled leukocytes or, if available, technetium-99 hexamethylpropylene-amine oxime (HMP AO)-labeled leukocytes. Other nuclear medicine techniques, including FDG-PET imaging and SPECT/CT, are being investigated for diagnosis of suspected vascular graft infections and appear promising. These studies, although sensitive, are limited by low specificity, particularly in the early postoperative setting (i.e., in the period up to 12 weeks following surgery). Imaging findings that suggest the presence of graft infection include the presence of fluid around the graft ≥3 months postimplantation, air (perigraft gas volume on serial CT images), the definition of abnormal tissue planes, extensive soft-tissue swelling, anastomotic aneurysms, and the identification of pseudoaneurysms, especially when more than one is apparent.

Therapy

Conventional gold standard treatment after vascular graft infection is defined as intensive antibiotic therapy and graft excision with extra-anatomic bypass revascularization if distal ischemia is present. Revascularization should be delayed, if possible, to establish potential collateral circulation and to decrease bacterial levels (i.e., a two-stage procedure). Vascular graft material does appear to affect outcome, with autogenous (often the femoral vein) and cryopreserved allografts having the best overall success rates.

Although antibiotic treatment and local wound care are unsuccessful when used alone, a subset of patients may be managed without removal of the entire graft or with in situ grafting. Criteria for complete graft preservation include the following (at a minimum): a patent graft, intact and uninvolved anastomoses, absence of hemorrhage, and sterile blood cultures. Partial graft excision may be attempted with intact anastomoses but occluded grafts, whereas bacteremia, systemic sepsis, or involvement of anastomoses mandate complete graft removal. Diabetic patients and those receiving long-term systemic steroid therapy should be considered at highest risk for continued infection without graft removal and extra-anatomic bypass. Likelihood of successful graft preservation appears to be highest with early, low-grade infections (e.g., early coagulase-negative staphylococcal infection) and lowest with gram-negative infections and *S. aureus*. Muscle flap coverage after aggressive perigraft debridement should be considered a vital component during attempts to salvage grafts. The optimal therapy of infected vascular grafts remains removal of the entire graft and revascularization where necessary through uninfected tissue planes.

If a new graft must be placed in the infected field (in situ grafting), use of autogenous artery or vein grafts may decrease susceptibility to infection. In the absence of available autologous vessels, cryopreserved arterial allografts may be used or prosthetic conduits (including rifampin-bonded or silver-coated synthetic grafts) if necessary. Parenteral antibiotics should be administered for 4 to 6 weeks after the infected graft is removed, and some authorities have recommended administering oral antibiotics for an additional 1 to 3 months. Because of the risk of reinfection regardless of the treatment chosen, surveillance ultrasound examination should be performed every 6 to 12 months for life.

Infections of cardiovascular implantable devices

M. Rizwan Sohail, Daniel C. DeSimone, and James M. Steckelberg

Cardiovascular implantable electronic devices (CIED) include permanent pacemakers (PPM), implantable cardioverter-defibrillators (ICD), and cardiac resynchronization therapy (CRT) devices. The reported risk of CIED infection ranges from 1% to 10% and depends on the complexity of the device and host comorbid conditions. Once infected, complete device removal and systemic antibiotic therapy are necessary to achieve cure.

Earlier versions of CIEDs required surgical placement of epicardial leads, which was facilitated by sternotomy, and generators were mostly placed in the abdominal area. However, in contemporary practice, most device leads are placed percutaneously via the subclavian vein and the device generator resides in a subcutaneous pocket in the pectoral area. Use of epicardial leads is now reserved for special situations where transvenous lead placement is not possible or deemed high risk due to active or recent bloodstream infection.

Risk factors for CIED infection

Purported risk factors for CIED infection include procedure, device, and host-related elements. Several comorbid conditions including diabetes mellitus, renal failure, chronic anticoagulation, long-term corticosteroid therapy, and malignancy have been associated with increased risk of CIED infection. Procedure-related risk factors include generator or lead exchange or revision, lack of antibiotic prophylaxis at the time of implantation, prolonged surgery, and postoperative hematoma at the generator pocket. Device-related risks comprise the presence of multiple leads (>2), abandoned leads, epicardial leads, other hardware (central venous catheters, prosthetic vascular grafts, etc.), and complexity of device (CRT > ICD > PPM).

Microbiology of CIED infections

Staphylococcal species (coagulase-negative staphylococci and *Staphylococcus aureus*) are the predominant organisms responsible for CIED infection. Device infections that present early (within 4 weeks of implantation) are generally related to device or wound contamination at the time of surgery. *S. aureus* is the most common microorganism encountered in this situation. However, pocket infection with coagulase-negative staphylococci can present weeks or months after device implantation. In contrast, the majority of late-onset CIED lead infections are caused by hematogenous seeding of device leads from remote sources of bloodstream infection. In published series, up to 40% of the patients who present with *S. aureus* bacteremia have underlying CIED lead infection, even when the generator pocket has no obvious inflammatory signs. Therefore, transesophageal echocardiography (TEE) is recommended in patients with CIEDs and positive blood cultures with *S. aureus*. In contrast, hematogenous seeding of CIED leads with gram-negative bacteria is an exceedingly rare complication, and routine use of TEE is not recommended in these cases. Moreover, gram-negative bacteria are also an uncommon cause of CIED pocket infections but may be seen in patients with multiple comorbid conditions and those with long-term central venous catheters (e.g., hemodialysis

populations). Mycobacterial or fungal CIED infections are exceedingly rare and the subject of case reports.

Clinical presentation and diagnosis

CIED infections primarily manifest in two distinct ways: local infection, limited to the generator pocket, or systemic infection involving CIED leads, heart valves, or both. Pocket infection is the most common manifestation of device infection, and these patients typically present with inflammatory changes at the pocket site that may include localized pain, erythema, drainage, or cellulitis around the pocket site. Occasionally, erosion of the device generator or leads through the skin is the sole manifestation of chronic smoldering infection. Systemic findings may or may not accompany local infections.

Systemic symptoms and signs such as fever, chills, rigors, malaise, or diaphoresis are hallmarks of CIED lead infection or endocarditis. Blood cultures are typically positive in these cases but could be negative, especially if drawn after administration of antibiotics. Patients with CIED lead infection or endocarditis could present with evidence of septic emboli to the lungs or other organs, especially if left-sided heart valves are also involved.

Diagnosis of CIED pocket infection is relatively straightforward based on inflammatory changes at the generator pocket site. However, blood cultures should be obtained in all cases prior to initiating antibiotic therapy even if systemic symptoms are not overt. In cases where blood cultures are reported positive, echocardiography should be performed to look for evidence of CIED lead or valvular vegetations. TEE is preferred because it has a sensitivity of about 95% for the detection of lead or valve vegetation compared with a sensitivity of <50% with transthoracic echocardiography (TTE). Occasionally, additional testing such as 18-FDG position emission tomography (PET) combined with CT (PET-CT), MRI, or Indium -111 leukocyte scanning may be necessary to evaluate CIED infection and associated complications such as deep abscesses or metastatic foci of infection in the spine, brain, or other organs.

A particularly challenging aspect of diagnosing CIED infection is the cases where blood cultures are positive for staphylococci (especially *S. aureus*) but there are no inflammatory changes at the generator pocket and TEE shows no clear evidence of vegetations on CIED leads or heart valves. Whether these devices should be left in place or taken out is a complex decision, and PET-CT may be helpful in guiding decision-making. Based on published series, the following factors increase the likelihood that the CIED is seeded with *S. aureus*: (1) no other identifiable source of infection, (2) persistently positive blood cultures for 72 hours or longer, (3) community-onset *S. aureus* bacteremia (SAB), and (4) SAB within 3 months of device implantation. If any of these factors is present, we favor removal of the CIED. In the absence of any of these features, it may be reasonable to treat for 2 to 4 weeks depending on the presumed source of SAB and closely follow-up for any evidence of relapse of infection. If the patient has relapse of SAB, the CIED should then be removed.

Management

For patients who present with systemic manifestations of infection, it is reasonable to start empiric antibiotic therapy once blood cultures have been obtained. However, for cases where infection is limited to the generator pocket without any systemic signs and the device extraction is planned within 24 to 48 hours of presentation, it is prudent to wait until pocket and device cultures are submitted at the time of explantation and then start empiric therapy. Empiric coverage should include antimicrobials with activity against *S. aureus* and coagulase-negative staphylococci. Until sensitivities are known, vancomycin is a reasonable choice as it is active against methicillin-resistant staphylococci. If vancomycin cannot be clinically tolerated, daptomycin or linezolid are reasonable second-line agents. Once culture data are available, antimicrobial therapy should be tailored accordingly.

In cases where infection appears to be limited to cellulitis or superficial surgical site infection (infected incision or stitch abscess), a 7- to 10-day trial of antibiotic therapy may be reasonable before extraction is considered. However, complete removal of all hardware (CIED generator and all leads) is generally required for eradicating infection involving generator pockets or device leads. In our institutional experience and that of others, conservative management of the device (antimicrobial therapy alone without device removal) is almost always associated with treatment failure and is the single most important predictor of relapse of infection. Based on these data, the most recent guidelines from the American Heart Association (AHA) recommend complete removal of the device for CIED infection (Class 1A recommendation). Duration of antimicrobial therapy for various CIED infection syndromes is summarized in Figure 42.1.

In contemporary practice, most device leads are removed percutaneously using a transvenous approach. For CIED leads that were implanted relatively recently (weeks or months), removal by applying countertraction may be adequate. However, this procedure can be very difficult and can result in avulsion of the tricuspid valve, arteriovenous fistulas, or retention of the lead tip, especially if leads have been in place for a longer period of time (months to years). In these cases, use of a laser sheath is more appropriate. In this approach, a laser sheath is slid over the length of the electrode and used to excise the implanted lead, allowing the entire lead to be withdrawn with little trauma. However, expertise in lead removal via laser sheath is usually limited to high-volume referral centers.

Percutaneous lead extraction also appears safe in patients with lead vegetations. However, some experts recommend surgical removal of leads via cardiotomy in patients who have lead vegetations >5 cm due to concern for clinically significant pulmonary emboli. Failure of the transvenous approach or the need to remove epicardial patches are other indications for open surgical procedures.

For patients who present with bloodstream infection, blood cultures should be repeated after device removal. Once blood cultures obtained after device removal are reported negative and the infected pocket has been adequately debrided, it is reasonable

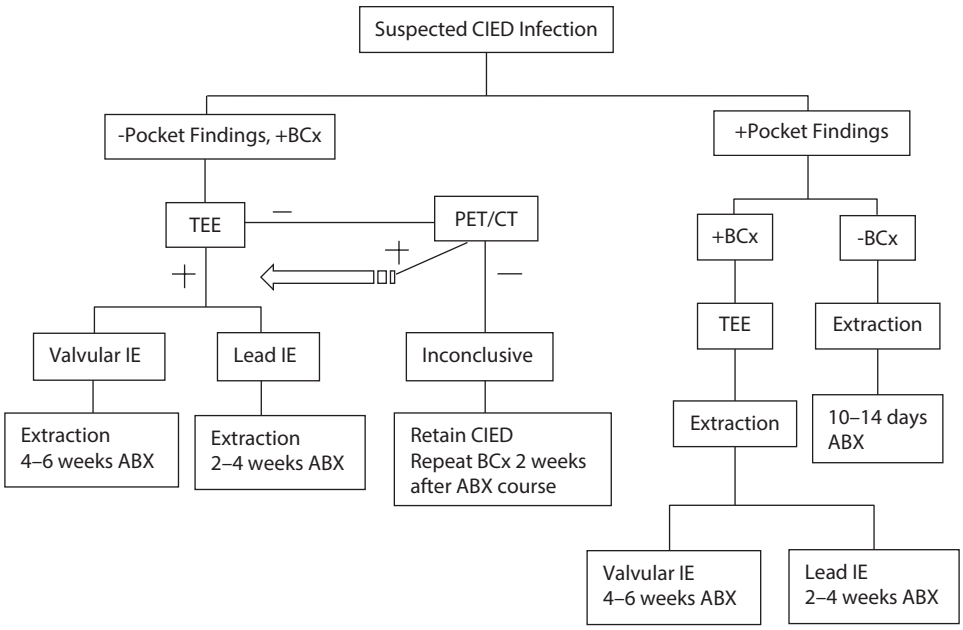

FIGURE 42.1 **CIED** - Cardiovascular implantable electronic device, **BCx** - Blood culture, **TEE** - Transesophageal echocardiogram, **ABX** - Antibiotics, **PET/CT** - Positron emission tomography/computed tomography, **IE**-Infective endocarditis

to implant a new device. However, a longer interval (up to 2 weeks or more) is usually recommended in the setting of CIED infection complicated by right-sided valvular endocarditis.

Limited data suggest that same-day reimplantation may be reasonable in patients who present with CIED infection limited to the generator pocket and in whom physical examination, laboratory parameters, and blood cultures do not show any evidence of systemic involvement.

The new CIED system (when required) should be implanted at a distant site. However, it is worth noting that a significant proportion of patients (up to 30% in some studies) do not require ongoing device therapy. Therefore, it is critical that the need for ongoing CIED therapy be assessed prior to implantation of a new device (preferably even before removal of the infected device).

Prevention

Preventing CIED infections is fundamental due to the morbidity and mortality associated with device infections. Because most early-onset infections result from pocket or device contamination at the time of surgery, meticulous attention to aseptic techniques during surgery is essential. Efficacy of antistaphylococcal antimicrobial prophylaxis before CIED implantation has been demonstrated in randomized clinical trials. In general, cefazolin 1 g is administered intravenously within an hour prior to starting the device implantation procedure. However, for patients who are allergic to cephalosporins, vancomycin is a reasonable alternative. For patients with known colonization with methicillin-resistant staphylococci, vancomycin should be administered in addition to cefazolin. This is because vancomycin is inferior to β-lactam antibiotics in preventing infection due to methicillin-susceptible staphylococci. Some implanters continue antibiotic prophylaxis for 24 to 48 hours or longer. However, there are no good data to support the added benefit of this practice.

Optimal management of host comorbidities (diabetes, renal failure, heart failure, etc.) is also important to minimize the risk of CIED infection. Another issue is optimal management of anticoagulation therapy to minimize the risk of pocket hematoma in patients who are on long-term oral anticoagulants for prosthetic heart valves or secondary prevention of venous thromboembolism. Earlier practice was to hold the oral anticoagulation therapy and "bridge" the perioperative period with unfractionated heparin. However, more recent clinical trials have demonstrated that continuation of oral anticoagulation is associated with a lower incidence of pocket hematomas compared with "bridge" therapy with heparin.

Guidelines from the AHA issued in 2010 do not recommend antimicrobial prophylaxis for patients with CIEDs undergoing dental or other procedures associated with transient bacteremias.

VAD infection

Ventricular assist devices (VADs) are increasingly being used in patients with end-stage heart failure as both a bridge to

transplantation and as myocardial surrogate (destination) therapy. VADs are undergoing rapid evolution, and most recent devices use continuous flow pump mechanisms, which improve the device function and lower the risk of infection. However, infection remains a major complication of VAD therapy, with reported risk varying from 25% to 60%.

Purported risk factors for VAD infection include length and complexity of the implantation procedure, hemorrhage at the surgical site, malnutrition, diabetes, obesity, and presence of central venous catheters. Moreover, friction-related trauma at the driveline exit site may result in cutaneous migration of microbes along the driveline and is a well-established risk factor for late-onset driveline infection. Use of an abdominal binder can minimize movement at the exit site and reduce the risk of driveline infection.

VAD infections can present as local driveline or pocket infections that result in pain, erythema, swelling, or purulence at the exit site. More severe infections can involve pump or cannula infection, bloodstream infection, or endocarditis (Figure 42.2). The majority of VAD pocket or pump infections, with or without bacteremia, occur within 30 days of device implantation, though late infections have been reported.

The most common pathogens responsible for VAD infection include *S. aureus*, *Staphylococcus epidermidis*, *Enterococcus* spp., *Pseudomonas aeruginosa*, and *Candida* spp. VAD infections due to gram-negative pathogens are mostly of nosocomial origin and are difficult to eradicate or suppress due to multidrug resistance of the organisms.

Driveline exit site infections are usually managed with wound debridement and a short course (typically 2 weeks) of antimicrobial therapy. If local VAD infection is complicated by bloodstream infection, then treatment is prolonged to 4 weeks or longer. However, management of VAD pump or cannula infection presents a major challenge. Unlike other prosthetic devices where removal of the infected hardware is the cornerstone of management, VADs cannot be easily removed or replaced because these patients cannot survive without a device. Therefore, a 4- to 6-week course of intravenous antimicrobial therapy followed by chronic suppression, targeted at the causative pathogen and guided by antimicrobial susceptibility testing, is typically prescribed. Occasionally, VAD may be replaced due to uncontrolled infection despite appropriate antimicrobial therapy. However, suppressive antibiotic therapy should be continued as the new device is placed in an actively infected pocket.

Clinical syndromes: Gastrointestinal tract, liver, and abdomen

43

Acute viral hepatitis

Kalyan Ram Bhamidimarri and Paul Martin

Acute viral hepatitis is a systemic infection with predominant hepatic involvement and remains a significant cause of morbidity and mortality in the United States despite the availability of effective vaccines against two major infections (hepatitis A and B) that cause acute viral hepatitis. There are five major hepatotropic viruses (A, B, C, D, and E) and several non-hepatotropic viruses that cause acute hepatitis characterized by acute hepatic inflammation and necrosis. Acute viral hepatitis typically runs its course in 6 months or less, in contrast to chronic hepatitis, which persists for longer. However, with modern serologic, molecular diagnostic testing and efficacious therapeutic options the time course is less important in distinguishing acute from chronic viral hepatitis. The clinical illness produced by these viruses can range from asymptomatic or clinically inapparent to a fulminant and fatal acute infection. A major distinction between hepatitis A and hepatitis B, C, D, and E is that the former causes acute hepatitis only, in contrast to the latter four which cause acute and chronic hepatitis. Nonhepatotropic viral infections, such as herpes simplex virus (HSV), Epstein–Barr virus (EBV), cytomegalovirus (CMV), and parvovirus B19, can present with prominent hepatic dysfunction, although they are usually multisystem disorders. Hepatitis G, human herpesviruses, adenovirus, coronavirus, and TT virus (TTV) have also been implicated in causing hepatic dysfunction, but their clinical significance remains dubious.

Hepatitis A virus

The hepatitis A virus (HAV) is an RNA virus identified in 1973; it is transmitted predominantly via the fecal–oral route and is a common cause of acute viral hepatitis worldwide. Community outbreaks due to contaminated water or food were common prior to 1995, but person-to-person transmission is now frequently responsible since 2016. Inhabitants in low-socioeconomic areas, homeless individuals, international travelers, intravenous (IV) drug users, and men who have sex with men (MSM) are at particular risk of HAV infection. The epidemiology of HAV in the United States has changed drastically over the past few decades with a significant reduction in incidence rates prior to 2011, and it had plateaued until 2016. However, >8,000 outbreaks were reported in 12 US states as of October 2018. The incidence of HAV, once predominantly higher (up to 20% reported in 1980s) among persons with IV drug use (PWIDs) and the homeless, has surged in the past 3 years. Unsafe sanitary conditions, poor hygiene in congregated living facilities (sheltered or unsheltered), contaminated paraphernalia among PWIDs, and high-risk sexual behavior accounted for most of the cases transmitted from person to person. California, Kentucky, Michigan, and Utah were four states that reported large sustained within-state transmission but eight other states including Florida also had a public health advisory due to increased incidence of HAV. The infection was reported across all demographic groups, but men aged 30 to 49 years (median age 37 years) accounted for 68% of the cases. In underdeveloped countries, HAV infection typically occurs in childhood and is subclinical (age ≤6 years, 70% are asymptomatic), with most of the population infected before adulthood acquiring life-long immunity. HAV infection occurring in older children and adults is more likely to be symptomatic, with increased morbidity and even mortality (Figure 43.1).

The average incubation period of HAV infection is 28 days (range 15–50 days), with peak fecal viral shedding and infectivity occurring 3 weeks before and 1 week after the onset of clinical symptoms, which may include anorexia, fever, malaise, fatigue, nausea, vomiting, diarrhea, and right upper quadrant discomfort. In acute HAV infection, these symptoms tend to occur 1 to 2 weeks before the onset of jaundice. Replication of HAV occurs exclusively within the cytoplasm of the hepatocyte, where the virus causes a noncytopathic infection. Hepatocellular damage is due to the host's immune response as the infected hepatocytes are cleared and is clinically observed by marked reduction of HAV RNA. Acute liver failure is rare and occurs in about 0.5% of infected individuals, more frequently in adults than in children. Recent acute HAV outbreaks have been associated with increased rates of hospitalizations (72% vs. 42% prior to 2016), of which 3% had confirmed or probable hepatitis B virus (HBV), and 22% had confirmed or probable hepatitis C virus (HCV) and concomitant alcoholic liver disease. The recent case fatality rate of acute HAV was also higher at 3% compared to previously reported 0.3% to 1.8% and could have been prevented by HAV vaccination. Prompt referral of patients who develop acute liver failure cases to a transplant center is indicated. It is well known that patients with chronic liver disease are at increased risk of hepatic decompensation and death from acute HAV, which has led to the recommendation that HAV-naïve patients with chronic liver disease should be vaccinated against HAV. Based on the recent reports, the Advisory Committee for Immunization Practices (ACIP) unanimously voted for HAV vaccination in another identified risk group: the homeless population. Most infected individuals recover uneventfully although the illness can occasionally be bimodal or relapsing. Chronic infection with HAV does not occur, but a protracted cholestatic phase may be present with persistent jaundice and pruritus before the eventual recovery.

Extrahepatic manifestations of HAV include acute pancreatitis, acalculous cholecystitis, autoimmune hemolytic anemia, aplastic anemia, reactive arthritis, effusions, mononeuritis multiplex, and Guillain–Barré syndrome. HAV-related acute kidney injury has been reported in cases from Asia, possibly mediated by immune complexes or interstitial nephritis.

Routine diagnosis of acute HAV infection is made by detection of immunoglobulin M (IgM) anti-HAV antibody in serum (Table 43.1), which becomes detectable 5 to 10 days before the onset of symptoms and persists for 3 to 12 months after infection. IgG anti-HAV antibody develops early in infection and persists indefinitely. The presence of IgG anti-HAV in the absence of IgM anti-HAV reflects immunity either from prior infection or from vaccination. Testing for HAV polymerase chain reaction (PCR) and genotypes is not routinely recommended or available. However, HAV PCR, genotyping, and viral sequencing are of epidemiological value. Three HAV genotypes 1a, 1b, and 3a are common in the North and South Americas and a significant epidemiologic shift is noteworthy. A CDC report by the US Centers for Disease Control and Prevention (CDC) that genotype 1a, which was the predominant strain prior to 2017, has been replaced with genotype 1b, which now accounts for 96% of cases in recent outbreaks.

Therapy

Acute HAV infection is self-limited without chronic sequelae. About 85% of acute HAV cases have clinical and biochemical recovery within 3 months, and nearly all have complete recovery by 6 months from the time of initial infection. Treatment is largely supportive and includes adequate nutrition and hydration, avoidance of hepatotoxic medications, steroids, and abstinence from alcohol (Table 43.2). Because acute HAV is more likely to lead to hepatocellular failure in adults, especially in those with underlying chronic liver disease, these patients require close follow-up until symptoms resolve.

Universal precautions to prevent transmission among close contacts, good personal hygiene, and immunization are recommended. Passive prophylaxis with intramuscular polyclonal immunoglobulin before and after exposure is safe and efficacious. Pre-exposure prophylaxis with immunoglobulin should be reserved for nonimmune patients at risk for HAV who are allergic to

TABLE 43.1 **DIAGNOSTIC TESTING FOR VIRAL HEPATITIS**

Type	Diagnostic tests	Comments
Hepatitis	IgM anti-HAV	Acute infection
A virus (HAV)	IgG anti-HAV	Resolved infection, immunity
Hepatitis	HbsAg	Indicates infection
B virus (HBV)	IgM anti-HBc	Acute infection
	HBeAg, HBV DNA	Indicates replication
	Anti-HBs	Indicates immunity
	IgG anti-HBc	Current or prior infection
Hepatitis	Anti-HCV	Indicates infection
C virus (HCV)	HCV RNA	Indicates infection/viremia
Hepatitis D virus (HDV)	IgM anti-HDV	IgM anti-HBc positive Indicates coinfection
	Anti-HDV	IgG anti-HBc positive Indicates superinfection
		Indicates infection
	HDV RNA and HDV antigen	Research tools at present
Hepatitis	IgM anti-HEV	Acute infection
E virus (HEV)	IgG anti-HEV	Resolved infection
EBV	EBV IgM and PCR	Indicates infection
CMV	CMV IgM and PCR	Indicates infection

HAV vaccine. Postexposure prophylaxis with immune globulin is recommended for the following high-risk groups in whom protective antibody titers should be generated quickly: (1) close household and sexual contacts of an index patient with documented acute HAV, (2) staff and patients of institutions for the developmentally disabled with outbreaks of HAV, (3) children and staff of daycare centers with an index case of HAV, (4) those exposed to protracted community outbreaks, and (5) travelers and military personnel who plan to visit

TABLE 43.2 **THERAPY OF ACUTE VIRAL HEPATITIS**

Type	Major focus	Comments
Hepatitis A	Symptomatic therapy	Recognition of ALF and promptly refer to transplant center
Hepatitis B	Symptomatic therapy. Oral agents for acute severe HBV	Observe for ALF
Hepatitis C	Pegylated interferon +/− ribavirin	Treatment efficacious in acute HCV
Hepatitis D	Consider anti-HBV agents in severe cases	Clinically more severe than HBV alone
	Prevention: HBV vaccine	
Hepatitis E	Ribavirin monotherapy is effective	FHF common in pregnant women.
		Transmission can be enteric or zoonotic. Can become chronic in immunocompromised
EBV	Symptomatic therapy	Risk factor for PTLD
CMV	Immunocompetent: monitor	
	Immunocompromised: ganciclovir, foscarnet, or cidofovir	

Abbreviations: CMV = cytomegalovirus, EBV = Epstein–Barr virus, FHF = fulminant hepatic failure, PTLD = posttransplantation lymphoproliferative disease.

countries endemic for HAV. The recommended dose of immune globulin for passive immunity is currently five times higher than in previous years as immunoglobulin titers are now low in the donor pool. Active immunization with an inactivated HAV vaccine has been available in the United States since 1995. The vaccine is highly immunogenic and most immune-competent individuals (>95%) develop protective antibodies within 4 weeks of receiving the first dose and almost 100% protection after the second vaccine dose. HAV vaccine is superior to passive immunization even for postexposure prophylaxis. It is also important to note that although the two-dose HAV vaccine series given 6 months apart is recommended, a single dose of HAV vaccine has durable efficacy for up to 11 years or even life-long in several reports. Single-dose HAV vaccine is not only expected to confer personal protection but also would contribute to herd immunity for a reasonable duration and is expected to reduce the large-scale person-to-person outbreaks. Therefore, completion of the two-dose vaccine series should not be a deterrent for initiation of vaccination, especially in the homeless. Various public health departments have increased their effort in educational campaigns to augment public awareness and ensure vaccination of those at high-risk as necessary.

Hepatitis B virus

HBV is the most common cause of chronic viral hepatitis worldwide and is also a major cause of acute viral hepatitis, especially in developing nations. There are an estimated 257 million people chronically infected with HBV worldwide. In the Far East and sub-Saharan Africa, up to 20% of the population has serologic evidence of current or prior HBV infection. In the United States, although HBV infection is less frequent, the prevalence of chronic HBV is much higher in certain immigrant communities, including Asian Americans. After acute HBV infection, the risk of chronic infection varies inversely with age. Thus, children younger than 5 have a high risk of chronicity after acute HBV infection (>90%), whereas an immunocompetent adult has a ≤10% likelihood.

HBV is a DNA virus transmitted predominantly by a parenteral route or through intimate contact with an infected subject. In Asia and other hyperendemic areas, vertical transmission is an important transmission route, whereas sexual and percutaneous transmission predominates in the Western world. The incubation period is 45 to 160 days. The typical course of a patient with acute HBV infection is illustrated in Figure 43.2. Typically, elevated alanine aminotransferase (ALT) levels and clinical symptoms appear earlier than jaundice. However, not all patients with acute HBV infection develop jaundice. About 70% of patients with acute HBV infection develop subclinical or anicteric hepatitis, and only 14% to 30% develop icteric hepatitis. Paradoxically, the patient with anicteric and clinically less severe acute HBV infection is more likely to become chronically infected than the individual with more symptomatic acute infection because a brisk immune response causes more hepatic dysfunction but also a greater likelihood of ultimate clearance of HBV infection. The symptomatic patient should be reassured that full recovery is likely but should be warned to report back if symptoms such as deepening jaundice, severe nausea, or somnolence develop because these symptoms may herald acute hepatic failure. Approximately 1% to 4% of acute HBV can present with acute liver failure (ALF), of which approximately 20% to 80% can result in death or liver transplantation. A recent study from China that evaluated 293 hospitalized patients with acute HBV reported that total bilirubin of five times the upper limit of normal, low prothromin time activity (PTA <20%), and grade III–IV hepatic encephalopathy were independent predictors of ALF and

prognosticated the risk of death or liver transplantation. Like acute HAV, acute HBV infection may be more severe in patients with underlying chronic liver disease.

The diagnosis of acute HBV hepatitis is made by detection of hepatitis B surface antigen (HBsAg) and IgM anti-hepatitis B core antibody (anti-HBc IgM) in the serum (Box 43.1). Resolution of HBV infection is characterized by loss of HBsAg. Development of the corresponding neutralizing antibody to HBsAg, anti-HBs, indicates resolution of infection. IgM anti-HBc declines and becomes undetectable whereas IgG ("total") anti-hepatitis B core antibody (anti-HBc IgG) persists after resolution of infection. Detection of IgG anti-HBc distinguishes immunity acquired from prior infection from vaccination in a patient with detectable anti-HBs.

The rate of progression of acute to chronic HBV is typically quoted to be around 5% to 10%. Some studies have proposed a specific HBV genotype as a determinant of likelihood of chronicity, but this remains to be confirmed. A recent study from Northern Ireland reported that subjects >50 years had a higher rate of progression from acute to chronic infection when compared to those <50 years (36.36% vs. 16.28%, p = 0.0068). It appears from the study that older individuals had lower rates of clearance of acute HBV than younger peers. Individuals who are immunocompromised or have another chronic condition such as renal failure are more likely to develop chronic infection. Children <5 years and the elderly also have a greater likelihood of becoming chronically infected. The absence of a brisk immune response during acute HBV infection, implied by a relative absence of symptoms, with modest aminotransferase elevation in an anicteric patient, indicates that infection is more likely to become chronic. Chronic HBV infection is suggested by HBsAg positivity for >6 months with the absence of IgM anti-HBc. However, in severe reactivation of chronic HBV infection (spontaneous or iatrogenic due to administration of corticosteroids or chemotherapy to an infected patient), IgM anti-HBc may reappear in serum although usually in low titers. The presence of HBeAg and HBV DNA in the serum suggests ongoing active viral (wild-type) replication or a "high replicative state" in patients with chronic infection. The absence of these markers of active replication in a chronically infected patient with no clinical evidence of liver disease is referred to as the *nonreplicative* or *inactive carrier state*.

BOX 43.1

Initial serologic workup of suspected acute hepatitis

IgM anti-HAV
HBsAg (if positive, then IgM anti-HBc, HBV DNA, HBeAg)
Anti-HCV antibody (if positive, then HCV RNA)
Consider testing for HEV, HSV, CMV, and EBV if A, B, and C tests are negative. Testing for other viruses is at clinician's discretion.

Therapy

Interferon-α, pegylated interferon-α 2a, lamivudine, adefovir dipivoxil, entecavir, telbivudine, and tenofovir are currently approved therapies in the United States for the treatment of chronic HBV infection. Interferon, entecavir, and tenofovir are the currently recommended first-line agents in the treatment of chronic HBV infection. Interferon's side effects have limited its use, with the introduction of well-tolerated oral agents. Given the high rate of spontaneous resolution of acute HBV in otherwise healthy adults, antiviral therapy is generally not recommended. Treatment with oral agents should be initiated in acute severe cases of HBV or in those who are immunosuppressed. Early referral to a transplant center is highly recommended for patients with severe liver injury suggested by hepatic encephalopathy, worsening coagulopathy, or ascites. Posttransplant outcomes for HBV are now excellent for HBV. There has been a very low rate of recurrence of viral infection posttransplant with current immune-prophylaxis regimens using an oral antiviral agent with high-dose hepatitis B immunoglobulin (HBIG). However, indefinite HBIG therapy is both cumbersome and expensive. Accordingly, transplant programs are evaluating the use of alternative schedules of HBIG administration and combinations of antiviral agents to prevent allograft reinfection. Therapy for chronic HBV infection is discussed in Chapter 44, "Chronic viral hepatitis."

The highly effective recombinant HBV vaccine is recommended for newborns, infants, adolescents, healthcare workers, hemodialysis patients, household contacts and sexual partners of HBV-infected individuals, international travelers to endemic areas, injection drug users, MSM or heterosexuals with multiple sexual partners, patients with chronic liver disease, and those who are potential organ transplant recipients. Postexposure prophylaxis should consist of a combination of HBV vaccination and passive protection with HBIG.

Hepatitis C virus

The HCV is a single-stranded RNA virus. It is estimated that about 170 million people in the world are chronically infected with HCV. Acute HCV is typically subclinical, with <25% of patients developing jaundice, and thus acute illness usually escapes medical attention. If symptomatic, acute HCV is less likely to lead to chronicity. HCV infection is usually transmitted parenterally. In the past, this was often by contaminated blood products. Now, most HCV infection is contracted by sharing contaminated needles among IV drug abusers or by other percutaneous or high-risk practices such as tattooing or possibly intranasal cocaine use, although the latter is controversial. Sexual and maternal–neonatal transmission can occur, but these are generally less efficient routes of transmission although maternal HIV coinfection appears to increase the risk of perinatal transmission. Sexual transmission of HCV is also recognized in MSM, especially those coinfected with HIV. There is a rising incidence of acute HCV in HIV-infected MSM. There is a high clustering of sexually transmitted infections (STI) as well in this cohort, which reflects high-risk practices. Acute HCV infection

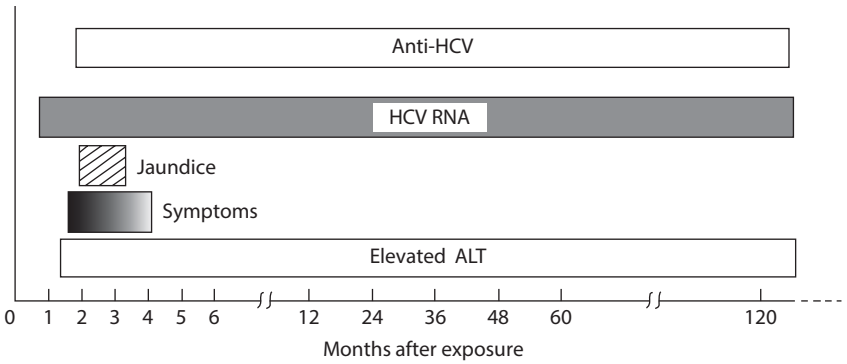

FIGURE 43.3 Typical course of acute hepatitis C progressing to chronic hepatitis C.

anti-HCV, antibody to the hepatitis C virus; HCV, hepatitis C virus.
Adapted from Martin P, Friedman LS, Dienstag JL. Diagnostic approach to viral hepatitis. In Thomas HC, Zuckerman AJ, eds. *Viral hepatitis*. Edinburgh: Churchill Livingstone, 1993: 393–409.

results in a high rate of chronicity, up to 85% in some series. Figure 43.3 illustrates the course of a patient with acute HCV infection progressing to chronicity. The incubation period is 14 to 180 days, after which elevation of ALT levels occurs and symptoms may appear, although, as noted, the acute illness is frequently subclinical. Fulminant hepatic failure due to acute HCV infection is very rare but may be more common in patients with underlying chronic HBV infection.

Routine diagnosis is made by detection of antibodies in serum to HCV (anti-HCV) by enzyme-linked immunosorbent assay (ELISA) testing. The recombinant immunoblot assay (RIBA) test was formerly used to enhance specificity as a supplemental test in ELISA-positive individuals. However, it has generally been supplanted by PCR testing to confirm viremia. Fluctuating ALT levels are characteristic of chronic HCV infection. Perhaps a fifth of chronically infected patients have ALT levels regarded as within the normal range, although this reflects a lack of sensitivity of aminotransferases in detecting lesser degrees of necro-inflammatory activity in the liver rather than an absence of liver injury. PCR techniques vary in their sensitivity in detecting HCV RNA. The more sensitive transcription-mediated amplification (TMA) technique can detect even minute quantities of HCV RNA (0.9–5.2 copies/mL).

Therapy

Acute HCV infection is most typically recognized in a healthcare worker after a needle-stick injury or, rarely, in someone who develops a hepatitis flare. A small subset of patients, especially those with a favorable IL28B genotype (C/C), can have spontaneous clearance of the virus. Therefore, acute hepatitis C patients should be closely monitored and those with persistent viremia beyond 12 weeks should be offered treatment. Delaying antiviral therapy for 2 to 4 months after acute HCV infection does not compromise efficacy. This short delay allows spontaneous resolution of HCV without embarking on unnecessary treatment that is expensive. Direct-acting antivirals (DAAs) have revolutionized HCV therapy. Treatment of HCV during the acute phase is highly effective, and sustained virologic response can be anticipated in up to 95% of treated patients. A recent study from the Netherlands where acute HCV is frequent, reported a 70% reduction of acute HCV cases due to widespread use of DAAs. Modeling and cost effectiveness studies also support the treatment of acute HCV as a preventive measure to curtail the person-to-person transmission among high-risk groups. Therapy of chronic HCV infection is discussed in more detail in Chapter 44, "Chronic viral hepatitis." The World Health Organization (WHO) declares an ambitious target of HCV eradication via micro-elimination by 2030.

An HCV vaccine is not yet available because of the virus' heterogeneity and the lack of seroprotective capability of HCV antibodies. There is no benefit from γ-globulin administration following a needle-stick exposure to HCV. Universal precautions are mandatory because the risk of HCV transmission to healthcare workers is substantial, averaging about 3% particularly with hollow-bore needles. Routine screening by blood banks for HCV has reduced the risk of transmission by transfusion to a negligible level.

Hepatitis D virus

The hepatitis delta virus (HDV) is an incomplete RNA virus that depends on HBsAg to complete its replicative cycle. It is estimated that 5% of chronic HBV patients worldwide are coinfected with HDV. HDV is transmitted parenterally in developed countries, whereas in other areas of high endemicity (Mediterranean basin), transmission is through intimate contact. Immigration from highly endemic areas is implicated in the recent increase in prevalence in Western Europe. HDV has been called by several names: "black vomiting fever," Bangui fever in Africa, Santa Marta hepatitis in Colombia, and Labrea hepatitis in Brazil. HDV may be transmitted simultaneously with HBV (coinfection) or acquired in chronic HBV carriers (superinfection). Most cases of coinfection are self-limited, but patients are more likely to develop fulminant hepatitis than with HBV monoinfection. If HDV is acquired by

superinfection, infection tends to become chronic, with higher rates of progression to cirrhosis than with HBV alone. HBV viral load is typically suppressed by active HDV infection.

The diagnosis of HDV coinfection is made if serum IgM anti-HDV, HBsAg, and IgM anti-HBc are simultaneously present in serum. HDV superinfection is denoted by IgM anti-HDV, HBsAg, and IgG anti-HBc with absent IgM anti-HBc. During the acute infection, HDV serologies are often insensitive, and repeat testing may be required in cases with high clinical suspicion (see Table 43.1). HDAg (direct immunofluorescence) or HDV RNA (reverse transcriptase assay) testing in the serum or on liver tissue can be performed, but these techniques are not widely available for clinical use.

Therapy

There is no specific treatment for acute HDV infection as most patients have spontaneous resolution after the flare. Among hepatotropic viruses, HDV is the only infection without satisfactory oral treatment options. Interferon is the only effective therapy against HDV but is contraindicated during an acute flare due to risk of acute hepatic failure. Antiviral agents against hepatitis B are generally not useful because HBV is usually suppressed, but they can be tried in patients who are at risk of fulminant liver failure. Liver transplantation is the only option for patients with acute liver failure from HDV coinfection. Control of HBV with antiviral agents plus or minus HBIG prevents HDV recurrence in the graft. Vaccination against HBV prevents HDV infection. Newer agents against HDV are currently being investigated.

Hepatitis E virus

The hepatitis E virus (HEV) is an RNA virus first identified in 1980 as an enterically transmitted hepatitis virus similar to HAV. Currently, there are four genotypes identified. Genotypes 1 and 2 are predominant in developing countries with enteric transmission, whereas genotypes 3 and 4 are predominant in developed countries and have zoonotic transmission (consumption of contaminated uncooked meat, especially pork). The incubation period is 15 to 60 days, with high infection rates in adults between the ages of 15 and 40. Antibodies against HEV have been found in up to 20% of the general population in developed countries and may account for 3% of cases of putative drug-induced liver injury presenting with acute liver failure.

HEV infection is usually acute and self-limited, but chronic HEV progressing to cirrhosis has been increasingly recognized especially in genotype 3 and immunocompromised subjects. A unique feature of this disease in developing nations is that fulminant hepatic failure occurs more frequently in pregnant women during the third trimester and carries a high mortality rate (15–25%). HEV is diagnosed by IgM and IgG anti-HEV antibodies and HEV RNA. HEV RNA, although diagnostic of active infection, could be a fleeting presence during an acute phase of HEV infection and may be undetectable in up to 40% of infected individuals.

Therapy

Acute HEV infection is self-limited and treatment is mainly supportive. Pregnant women should not travel to areas endemic for HEV. Acute severe hepatitis can be treated with ribavirin monotherapy (dose 600–1,000 mg/d) for 3 to 6 months, which can result in rapid clinical improvement. Ribavirin is teratogenic, however, and thus contraindicated in pregnancy. Interferon is contraindicated in severe hepatitis as it can exacerbate the ALT flare, leading to fulminant hepatic failure. Chronic HEV in immunosuppressed transplant recipients can be treated with lowering of immunosuppression, ribavirin monotherapy or pegylated interferon monotherapy, or a combination of these. HEV vaccines are currently in the developmental phases, with promising preliminary results.

Herpes simplex virus

HSV is a capsulated double-stranded DNA virus. Infection can rarely lead to acute liver failure (1–2% of all acute liver failure cases). Acute severe hepatitis is associated with high mortality rates of 75% to 90% and is commonly seen in immunocompromised patients, pregnant women (late trimester), neonates, and, rarely, in immunocompetent individuals.

Clinical features of HSV can vary from mild asymptomatic anicteric hepatitis to fulminant hepatic failure or severe HSV sepsis (pneumonitis, esophagitis, encephalitis) resulting in multiorgan failure. Newborns presenting with systemic infection, herpes neonatorum, have high rates of brain injury and a 25% mortality rate. Mucocutaneous lesions are found only in 50%, with their absence often resulting in diagnostic delay. Most cases of acute HSV hepatitis reflect acute infection rather than viral reactivation. Fever, flu-like symptoms, and leukopenia are typical. Serologies are usually nondiagnostic, and thus diagnosis rests on detection of viremia by HSV PCR and/or liver biopsy. Presence of viral Cowdry type A nuclear inclusion bodies, positive HSV immunohistochemical stains, HSV PCR, and electron microscopy if liver biopsy is performed aid in confirming the diagnosis.

Early treatment with high-dose acyclovir (10 mg/kg IV TID) is highly effective. Delay in treatment can result in lowered efficacy, and thus empiric treatment is recommended in cases with typical features of HSV hepatitis. Foscarnet can be used if there is concern about acyclovir resistance. Patients with fulminant liver failure should be carefully evaluated for liver transplantation although the 1 year posttransplant survival rate is around 43%, usually due to disseminated and uncontrolled HSV infection. Indefinite antiviral therapy is indicated to prevent recurrence following spontaneous resolution or transplant.

Epstein–Barr virus

EBV is the causative agent for infectious mononucleosis, with asymptomatic liver enzyme and lactate dehydrogenase elevations up

to three times the upper limits of normal occurring in 80% to 90% of cases. Clinical manifestations include fever, pharyngitis, lymphadenopathy, abdominal pain, hepatosplenomegaly, and, rarely, jaundice. The serum aminotransferases typically rise over 1 to 2 weeks, and, in most patients, the disease is self-limited with resolution of symptoms and normalization of enzymes over the subsequent 4 to 6 weeks. Severe hepatitis and fulminant hepatic failure are rare but have been reported.

Leukocytosis (predominance of lymphocytes and monocytes) and mild thrombocytopenia is common. EBV IgM antibodies peak early and can persist for months, after which EBV IgG develops. Although the Monospot is sensitive in detecting heterophile antibodies, it is not specific for EBV infection. EBV DNA quantification can be accomplished through PCR assays on blood or plasma. Liver biopsy is not usually indicated although in situ hybridization or PCR of the biopsy sample may be used to confirm the diagnosis. Treatment is largely supportive as no specific treatment exists. Acyclovir has been used without effect on symptoms or outcome. EBV may rarely cause chronic infection in immunocompetent patients. EBV infection is an important factor in the development of posttransplantation lymphoproliferative disease (PTLD) in transplant recipients.

Cytomegalovirus

CMV infection frequently involves the liver, most commonly with asymptomatic elevation of serum transaminases. It can be a result of a primary infection or reactivation of latent infection in an immunocompromised host. In immunocompetent children and adults, primary CMV infection is usually subclinical but may cause an illness that can mimic mononucleosis. The clinical course is typically mild and self-limited, but CMV has been implicated in hepatic granulomata, cholestatic hepatitis (mimicking primary sclerosing cholangitis), and even rare cases of fatal hepatic necrosis. CMV can be severe and even life-threatening in patients with impaired cellular immunity, due to disseminated infection.

Antibody testing is of low utility in immunocompromised patients and therefore CMV PCR is the most reliable and specific diagnostic test. Liver biopsy may be indicated and confirmatory in an immunocompromised patient or a transplant recipient when the characteristic multinucleated giant cells and owl-eye inclusions can be identified. No definite therapy is required in immunocompetent patients with mild CMV infection. In immunocompromised patients, effective therapies include ganciclovir or, alternatively, foscarnet or cidofovir if ganciclovir fails. Therapy should be continued until patients become aviremic and preferably maintained during the intense immunosuppressive period.

Parvovirus B19

Human parvovirus B19 is a small nonenveloped single-stranded DNA virus which is a rare (probably underdiagnosed) cause of acute hepatitis and liver failure in immunocompetent individuals. It is a common infection of childhood called *erythema infectiosum* or *fifth disease,* with up to 50% of adolescents developing parvovirus antibodies by age 15. The virus is transmitted via respiratory droplets, blood products, and solid organ transplantation. Adults can present with acute upper respiratory viral syndrome, arthropathy, and varying severity of bone marrow suppression and liver injury. Rare hematologic manifestations include pure red cell aplasia, pancytopenia, and hematopoietic failure, which are thought to be due to viral interaction with P-antigen. Although most case reports describe a lesser degree of elevation of transaminases (<2,000), levels of ALT >9,000 have also been reported. The pathogenic mechanisms involved in liver injury are unclear but may be due to caspase-mediated apoptosis from direct viral invasion. Diagnostic workup includes serum parvovirus B19 IgM, IgG, DNA, and liver biopsy. Bone marrow biopsy can show characteristic red cell aplasia and giant pro-normoblasts. There is no standard treatment, but there are several case reports describing the use of supportive treatments, including IV immunoglobulin (IVIG), tacrolimus, cyclosporine, mycophenolate mofetil, azathioprine, steroids, and plasmapheresis, with varying outcomes. Patients with fulminant hepatic failure require liver transplantation although there are limited data on the outcomes and hematopoietic recovery posttransplant. Recurrence of pure red cell aplasia after transplantation is approximately 10%, and prolonged courses of IVIG appear to be beneficial.

Miscellaneous viruses

Nonhepatotropic viruses such as hepatitis G (HGV), Zika, Ebola/Marburg, TTV, human herpesvirus (HHV-6, HHV-8), varicella zoster virus (VZV), adenovirus, and coronavirus can all cause acute hepatic inflammation resulting in mild to modest increase in transaminases. HGV, also known as GBV-C, is a single-stranded RNA virus which is mainly transmitted parenterally and has some genomic similarity to HCV. HGV is lymphotropic but not hepatotropic, and thus some authors debate its inclusion as a hepatitis virus. HGV coinfection in HIV-positive patients is associated with favorable outcomes, including lower levels of HIV viremia, higher CD4 count, better response to antiretroviral therapy, lower transmission rates, and 2.5-fold reduction in mortality compared to those who are not coinfected with HGV. TTV is a single-stranded DNA virus first isolated in 1997 as a cause of posttransfusion hepatitis, but current data suggest that TTV does not play a significant role in the genesis of acute or chronic liver disease. HHV-6 is associated with hepatic artery thrombosis, encephalitis, and sepsis, and HHV-8 is associated with development of Kaposi's sarcoma, especially in immunocompromised transplant recipients. Outbreaks of Ebola and Marburg viruses have been reported in individuals who traveled to West Africa. Icteric-hemorrhagic fevers with acute hepatitis have been reported with Dengue, Hanta, and yellow fever viruses, which typically present with multiorgan dysfunction and failure. Zika and Chikungunya viruses have not been associated with severe hepatitis to date. Similar to HGV and TTV, other

viruses such as Sanban, Yonban, and SEN viruses do not cause clinical hepatitis, and their role in human pathogenesis is controversial.

Chronic viral hepatitis

Michelle E. Freshman and Lawrence S. Friedman

Chronic hepatitis is defined as necroinflammation of the liver of more than 3 to 6 months' duration, demonstrated by persistently elevated serum aminotransferase levels and associated with characteristic histologic findings. The causes of chronic hepatitis include hepatitis B, C, and D viruses (HBV, HCV, and HDV) as well as noninfectious disorders, including nonalcoholic steatohepatitis, autoimmune hepatitis, hepatitis following alcohol or medication exposure (e.g., isoniazid or nitrofurantoin), Wilson disease, α_1-antitrypsin deficiency, and, rarely, celiac disease. Hepatitis A virus does not cause chronic hepatitis, but hepatitis E virus may rarely lead to chronic hepatitis in immunosuppressed persons or transplant recipients. Chronic hepatitis is characterized on the basis of etiology; grade of portal, periportal, and lobular inflammation (minimal, mild, moderate, or severe); and stage of fibrosis (none, mild, moderate, severe, cirrhosis).

In the absence of advanced cirrhosis, patients are often asymptomatic or have mild, nonspecific symptoms. Infection caused by HBV may be associated with arthritis-dermatitis and, rarely, polyarteritis nodosa, glomerulonephritis, or mixed cryoglobulinemia. HCV is a more common pathogenetic factor in mixed cryoglobulinemia as well as membranoproliferative glomerulonephritis and may be related to lichen planus, autoimmune thyroiditis, lymphocytic sialadenitis, idiopathic pulmonary fibrosis, sporadic porphyria cutanea tarda, and monoclonal gammopathies. HCV infection confers a 20% to 30% increased risk of non-Hodgkin B-cell lymphoma and may induce insulin resistance (which in turn increases the risk of hepatic fibrosis); moreover, the risk of type 2 diabetes mellitus and cardiovascular disease is increased in persons with chronic hepatitis C. Hepatic steatosis is a particular feature of infection with HCV genotype 3 and may also occur in patients infected with other HCV genotypes who have risk factors for fatty liver. On the other hand, chronic HCV infection is associated with a decrease in serum cholesterol and low-density lipoprotein levels.

Chronic hepatitis B

Chronic hepatitis B affects 248 million people worldwide (Figure 44.1). Two billion persons overall have been infected; endemic areas include Southeast Asia (excluding Japan), China, and sub-Saharan Africa. In the United States, up to 2.2 million (predominantly males) have HBV infection. Chronic hepatitis B may be identified as a continuation of acute hepatitis B or by repeated detection of hepatitis B surface antigen (HBsAg) in serum, often in a person with elevated serum aminotransferase levels (Table 44.1).

Five phases of chronic HBV infection are recognized (Figure 44.2 and Table 44.2), historically designated as the immune tolerant phase, immune active (or immune clearance) phase, inactive HBsAg carrier state, reactivated chronic hepatitis B phase, and HBsAg-negative phase. Revised nomenclature for the five stages are hepatitis B e antigen (HBeAg)-positive chronic HBV infection, HBeAg-positive chronic hepatitis B, HBeAg-negative chronic HBV infection, HBeAg-negative chronic hepatitis B, and the HBsAg-negative phase (functional cure).

In *HBeAg-positive chronic HBV infection*, HBeAg and HBV DNA are present in serum and indicative of active viral replication, and serum aminotransferase levels are normal, with little necroinflammation in the

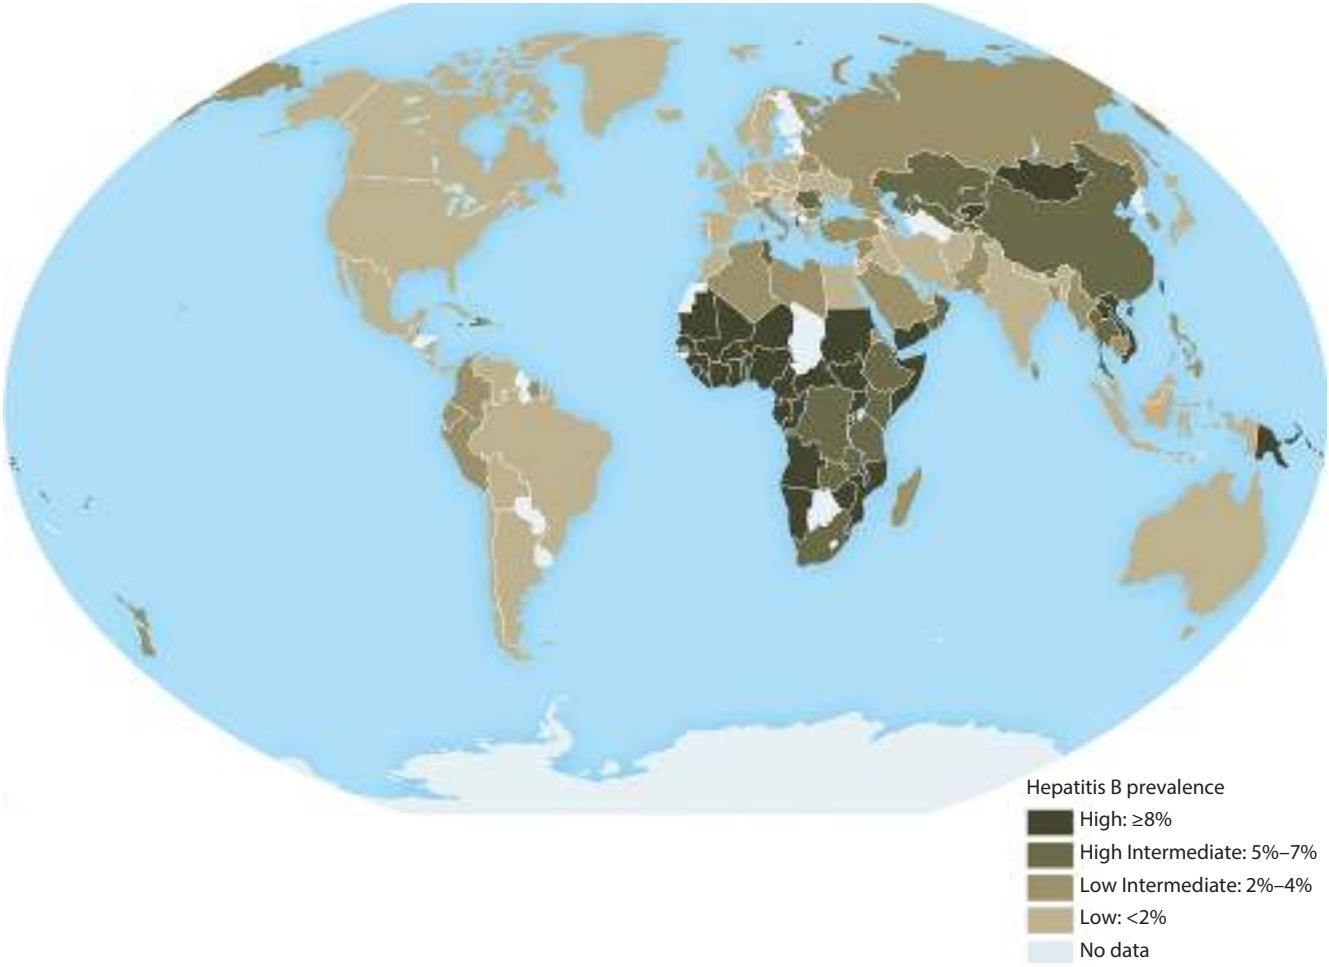

FIGURE 44.1 World map showing the prevalence of the chronic hepatitis B virus infection in low- (very light brown, <2%), low intermediate- (light green, 2–4%), low intermediate- (darker green, 5–7%), and high- (darkest green, ≥8%) prevalence areas.
Adapted from Centers for Disease Control website. https://wwwnc.cdc.gov/travel/yellowbook/2018/infectious-diseases-related-to-travel/hepatitis-b

liver. This phase is common in infants and young children whose immature immune system fails to mount an immune response to HBV.

Persons with HBeAg-positive chronic HBV infection and those who acquire HBV infection later in life may enter an immune active phase, or *HBeAg-positive chronic hepatitis B*, in which aminotransferase levels are elevated and necroinflammation is present in the liver, with a risk of progression to cirrhosis (at a rate of 2–5.5% per year) and of hepatocellular carcinoma (at a rate of >2% per year in those with cirrhosis); low-level immunoglobulin M antibody to hepatitis B core antigen (immunoglobulin M (IgM) anti-HBc) is present in serum but below the detection assay of the standard serologic assay in about 70%. Seroconversion with the loss of HBeAg and the appearance of anti-HBe occurs at the end of this phase. For those persons who seroconvert after age 40, the risk of cirrhosis and hepatocellular carcinoma is greater than in those who seroconverted at a younger age.

Persons with *HBeAg-negative chronic HBV infection* have experienced biochemical improvement following immune clearance. This improvement coincides with disappearance of HBeAg and reduced HBV DNA levels ($<10^5$ copies/mL, or <20,000 international units [IU]/mL) in serum, appearance of antibody to hepatitis B e antigen (anti-HBe), and integration of the HBV genome into the host genome in infected hepatocytes. In the research setting, detection in serum of a hepatitis B core-related antigen correlates with intrahepatic covalently closed circular DNA, a marker of transcriptional activity. Patients in this phase are at a low risk for cirrhosis (if it has not already developed) and hepatocellular carcinoma, and those with persistently normal serum aminotransferase levels infrequently have histologically significant liver disease, especially if the serum HBsAg level (not generally measured in practice) is low.

HBeAg-negative chronic hepatitis B ("reactivation") may result from infection by a pre-core mutant of HBV or spontaneous mutation of the pre-core or core promoter region of the HBV genome during the course of chronic hepatitis caused by wild-type HBV. HBeAg-negative chronic hepatitis B accounts for <10% of cases of chronic hepatitis B in the United States, up to 50% in southeast Asia, and up to 90% in Mediterranean countries, reflecting in part differences in the frequencies of HBV genotypes. In reactivated chronic hepatitis B, there is a rise in serum HBV DNA levels and possible progression to cirrhosis (at a rate of 8–10% per year),

TABLE 44.1 **INTERPRETATION OF SEROLOGIC TESTS FOR HEPATITIS B VIRUS (HBV) INFECTION**

	Susceptible	Immune due to vaccination	Immune due to natural infection	Acute infection	Chronic infection	Various interpretations[a]
HBsAg	–	–	–	+	+	–
Anti–HBc	–	–	+	+	+	+
IgM anti–HBc	–	–	–	+	–[b]	–
HBeAg	–	–	–	+	±	–
Anti–HBe	–	–	±	–	±	±
Anti–HBs	–	+	+ ≥10 mIU/mL[c]	–	–	–

[a] (1) Recovering from acute HBV infection, (2) chronically infected with an undetectable level of HBsAg in serum, (3) susceptible with a false-positive anti-HBc result, (4) distantly immune and the test is not sensitive enough to detect a very low viral levels of anti-HBs in serum.
[b] IgM anti-HBc may be positive (in low titers) in some persons with chronic hepatitis B.
[c] Threshold level of anti-HBs antibody concentration considered adequate for immunization protection.
Anti-HBc, antibody to hepatitis B core antigen; anti-HBe, antibody to hepatitis B e antigen; anti-HBs, antibody to hepatitis B surface antigen; HBeAg, hepatitis B e antigen; HBsAg, hepatitis B surface antigen; IgM anti-HBc, IgM antibody to hepatitis B core antigen; mIU/mL, milli-international units per milliliter.

particularly when additional mutations in the core gene of HBV are present. Risk factors for reactivation include male sex and HBV genotype C as well as immunosuppression. Treatment of HCV infection with direct-acting antiviral agents (see later discussion) has been reported to lead to instances of HBV reactivation. For persons who have serum HBsAg concentrations of 1,000 IU/mL or more, the risk of cirrhosis and hepatocellular carcinoma is increased.

In persons with either HBeAg-positive or HBeAg-negative chronic hepatitis B, the risk of cirrhosis and of hepatocellular carcinoma correlates with the serum HBV DNA level. Other risk factors include advanced age, male sex, alcohol use, cigarette smoking, HBV genotype C, and coinfection with HCV or HDV. HIV coinfection is also associated with an increased frequency of cirrhosis when the CD4 count is low.

Occasional infected persons reach the *HBsAg-negative phase*, or functional cure, in which anti-HBe remains the only serologic marker of HBV infection, serum ALT levels are normal, and HBV DNA is undetectable in serum but remains present in the liver. HBsAg seroclearance (0.7–2.3%) is associated with a negligible risk of cirrhosis in noncirrhotic patients and a substantially decreased risk of hepatocellular carcinoma, including in persons with cirrhosis.

TABLE 44.2 **FIVE PHASES OF CHRONIC HEPATITIS B VIRUS (HBV) INFECTION AND ASSOCIATED BIOCHEMICAL, SEROLOGIC, AND HISTOLOGIC FINDINGS**

Phase (New terminology)	Phase (Old terminology)	ALT	HbeAg	Anti–HBe	HBV DNA (IU/mL)	Liver histology	Natural history
HBeAg-positive chronic HBV infection	Immune tolerant	Normal	+	–	≥20,000	Minimal inflammation	Low risk of progression to advanced liver disease
HBeAg-positive chronic hepatitis B	Immune active (Immune clearance)	Elevated (fluctuating)	+	+/–	≥20,000 (fluctuating)	Variable inflammation +/– fibrosis	Associated with hepatitis flares
HBeAg-negative chronic HBV infection	Inactive HBsAg carrier state	Normal	–	+	<2,000	Minimal inflammation and liver damage	Low risk of advanced liver disease HBsAg loss in 1% per year; 10–20% have reactivation of HBV replication after many years
HBeAg-positive chronic hepatitis B	Reactivated chronic hepatitis B	Elevated	–	+	2,000–20,000 (may be higher)	Inflammation and often significant fibrosis	High risk of progression to advanced liver disease
HBsAg-negative phase	HBsAg-negative	Normal	–	+/–	Undetectable	Minimal inflammation if prolonged viral suppression	Low risk of advanced liver disease if prolonged viral suppression

Abbreviations: ALT = serum alanine aminotransferase level, anti-HBe = antibody to hepatitis B e antigen, HBeAg = hepatitis B e antigen, HBsAg = hepatitis B surface antigen, IU = international units.

Treatment

Patients with active viral replication (HBeAg, HBV DNA [$\geq 10^5$ copies/mL, or ≥20,000 IU/mL], and elevated aminotransferase levels in serum) may be treated with a nucleoside or nucleotide analog or with pegylated interferon, although interferon is rarely used now (Figure 44.3). Nucleoside and nucleotide analogs are preferred because they are better tolerated and can be taken orally. For patients who are negative for HBeAg, the threshold for treatment is a serum HBV DNA level of 10^4 copies/mL, or 2000 IU/mL (Figure 44.3). If the threshold HBV DNA level for treatment is met but the serum ALT level is normal, treatment may still be considered in patients older than 35 to 40 years if liver biopsy or a noninvasive assessment of liver fibrosis demonstrates a fibrosis stage of 2 of 4 (moderate) or higher. For those who do not meet standard criteria but are positive for HBeAg, are older than 30 years of age, have a family history of hepatocellular carcinoma, or have extrahepatic manifestations, the European Association for the Study of the Liver advocates treatment. Therapy is aimed at reducing and maintaining the serum HBV DNA level at the lowest possible levels, normalization of the serum ALT level, and histologic improvement. An additional goal in HBeAg-positive patients is seroconversion to anti-HBe, and some responders eventually clear HBsAg (see Figure 44.2 and Box 44.1). Although nucleoside and nucleotide analogs generally have been discontinued 6 to 12 months after HBeAg-to-anti-HBe seroconversion, some patients (especially Asian patients) serorevert to HBeAg after discontinuation, have a rise in HBV DNA levels and recurrence of hepatitis activity, and require long-term therapy, which also is required when seroconversion does not occur and in patients with cirrhosis (at least until HBsAg clears and possibly indefinitely).

BOX 44.1

Goals of therapy for chronic hepatitis B virus (HBV) infection

Sustained suppression of HBV replication
HBV DNA undetectable in serum
HBeAg to anti-HBe seroconversion
HBsAg to anti-HBs seroconversion

Remission of liver disease
Normalization of serum ALT levels
Improvement in liver histology

Improvement in clinical outcome
Prevention of liver failure and hepatocellular carcinoma
Improved survival

Abbreviations: ALT = serum alanine aminotransferase level, anti-HBe = antibody to hepatitis B e antigen, anti-HBs = antibody to hepatitis B surface antigen, HBeAg = hepatitis B e antigen, HBsAg = hepatitis B surface antigen.

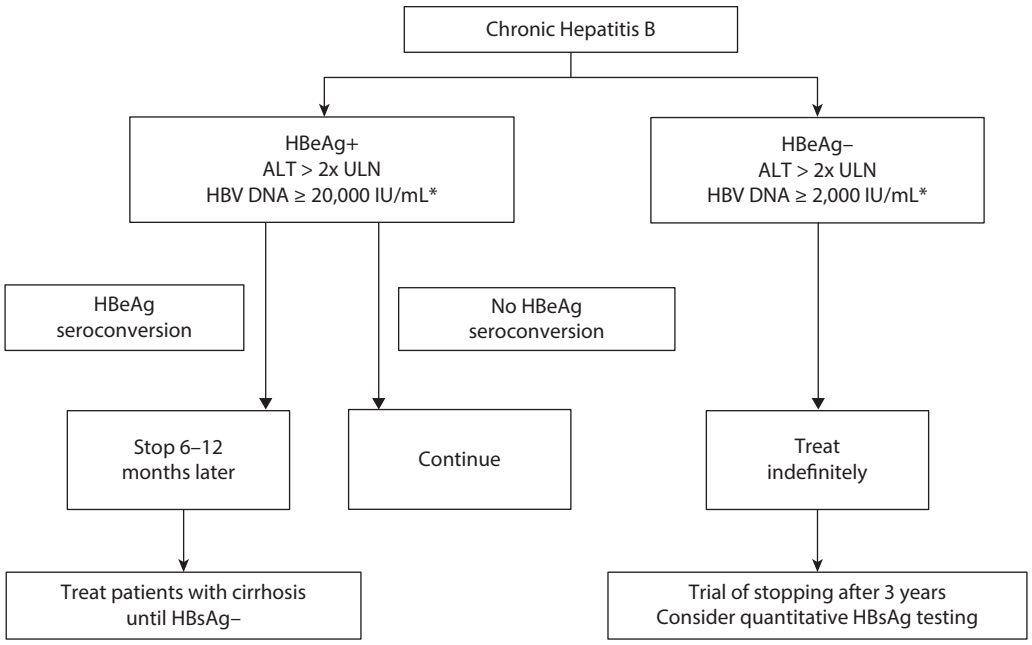

FIGURE 44.3 Indications for treatment and treatment endpoints in HBeAg-positive and HBeAg-negative persons. The following patients not fulfilling treatment indications can be considered for treatment: HBeAg-positive and >30 years of age, family history of hepatocellular carcinoma, and extrahepatic manifestations. Fibrosis stage can be assessed by noninvasive methods or liver biopsy.

ALT, alanine aminotransferase; HBeAg, hepatitis B e antigen; HBV, hepatitis B virus; ULN, upper limit of normal.

Patients with HBeAg-negative chronic hepatitis B also generally require long-term therapy because relapse is frequent when therapy is stopped; a low serum HBsAg level identifies patients at low risk for relapse and in whom HBsAg is more likely to clear if therapy is stopped after 3 years than if therapy is continued indefinitely.

The available nucleoside and nucleotide analogs—entecavir, tenofovir, lamivudine, adefovir, and telbivudine—differ in efficacy and rates of resistance (Table 44.3); however, in HBeAg-positive patients, they all achieve an HBeAg-to-anti-HBe seroconversion rate of about 20% at 1 year, with higher rates after more prolonged therapy (Box 44.2). The preferred first-line oral agents are entecavir and tenofovir. Entecavir is rarely associated with resistance unless a patient is already resistant to lamivudine. The daily dose is 0.5 mg orally for patients not resistant to lamivudine and 1 mg for patients who previously became resistant to lamivudine. Suppression of HBV DNA in serum occurs in nearly all treated patients (>95%), and histologic improvement is observed in 70% of patients after at least 5 years of treatment. Entecavir has been reported infrequently to cause lactic acidosis when used in patients with decompensated cirrhosis.

Tenofovir disoproxil fumarate, 300 mg/d orally, is equally effective and is used as a first-line agent or when resistance to a nucleoside analog has developed. Like entecavir, tenofovir has a low rate of resistance when used as initial therapy. Long-term use may lead to an elevated serum creatinine level and reduced serum phosphate level (Fanconi-like syndrome) that is reversible with discontinuation of the drug. Tenofovir alafenamide, 25 mg/d orally, is an alternative formulation of tenofovir that was approved by the US Food and Drug Administration (FDA) in 2016 and may be associated with a lower rate of renal and bone toxicity than tenofovir disoproxil fumarate.

The first available nucleoside analog was lamivudine, 100 mg/d orally, which is no longer considered first-line therapy in the United States but may be used in countries in which cost is a deciding factor. By the end of 1 year of therapy with lamivudine, however, 15% to 30% of responders experience a relapse (and occasionally frank decompensation) as a result of a mutation in the polymerase gene (the YMDD motif) of HBV DNA that confers resistance to lamivudine. The rate of resistance reaches 70% by 5 years of therapy. Adefovir dipivoxil has activity against wild-type and lamivudine-resistant HBV but is the least potent of the oral antiviral agents for HBV and is rarely if ever used now. The standard dose is 10 mg orally once a day for at least 1 year. As with lamivudine, only a small number of patients achieve sustained suppression of HBV replication with adefovir, and long-term suppressive therapy is often required. Resistance to adefovir occurs in up to 29% of patients treated for 5 years. Patients with underlying kidney dysfunction are at risk for nephrotoxicity from adefovir. Telbivudine, given in a daily dose of 600 mg orally, is more potent than either lamivudine or adefovir but, like them, is associated with resistance, particularly in patients who are resistant to lamivudine. Elevated serum creatine kinase levels are common in patients treated with telbivudine (see Table 44.3).

Nucleoside and nucleotide analogs are well tolerated even in patients with decompensated cirrhosis (for whom the treatment threshold may be an HBV DNA level of $<10^4$ copies/mL and therapy should be continued indefinitely) and may be effective in

TABLE 44.3 **DRUGS USED TO TREAT CHRONIC HEPATITIS B VIRUS (HBV) INFECTION AND THEIR ADVANTAGES AND DISADVANTAGES**

Agent/Dose	**Entecavir** (nucleoside analog) 0.5 mg/d (1.0 mg/d in lamuvidine-resistant patients)	**Tenofovir disoproxil** (nucleotide analog) 300 mg/d	**Tenofovir alafenamide** (nucleotide analog) 25 mg/d	**Adefovir dipivoxil** (nucleotide analog) 10 mg/d	**Lamivudine** (nucleoside analog) 100 mg/d	**Telbivudine** (nucleoside analog) 600 mg/d	**Peginterferon alfa-2a** 180 μg SC weekly for 48 weeks
Advantages	Oral Negligible side effects More potent than other oral agents; little resistance (requires ≥3 mutations to confer resistance)	Oral Negligible side effects More potent than other oral agents; no in vivo resistance seen after 8 years of use	Oral Negligible side effects; more potent than other oral agents; low chance of resistance; approved for ESRD +/- dialysis; pregnancy risk unknown	Oral Negligible side effects Effective against lamivudine-resistant mutants	Oral Negligible side effects Has been used in pregnancy and prior to chemotherapy	Oral Negligible side effects Effective against lamivudine-resistant mutants	Finite duration Durable response No resistant mutants HBsAg-to-anti-HBs seroconversion, common in responders
Disadvantages	Indefinite duration of therapy in incomplete responders Risk of lactic acidosis in patients with decompensated cirrhosis; hepatomegaly 10% cross-resistance with lamivudine; 94% undetectable at 5 years; for nucleoside-naïve patients, 1.2% resistance at 5 years	Indefinite duration of therapy in incomplete responders Renal toxicity in higher doses; caution in underlying kidney dysfunction; risk of Franconi syndrome Risk of lactic acidosis, hepatomegaly, gastrointestinal distress, rash, itching, osteopenia Negligible resistance as initial therapy (1 treatment naïve case, 2018)	Indefinite duration of therapy in incomplete responders Renal toxicity much less likely than TD; caution in new onset kidney dysfunction; risk of Franconi syndrome Risk of lactic acidosis, hepatomegaly, gastrointestinal distress, rash, itching; reduced BMD, much less so than TD (long-term data unavailable) Presumed negligible resistance as initial therapy	Indefinite duration of therapy in incomplete responders Risk of lactic acidosis, hepatomegaly Renal toxicity in higher doses; hypophosphatemia (Franconi-like syndrome); pancreatitis Risk of lower bone mineral density, SJS, TEN Resistant mutants (29% at 5 years); relatively weak agent when used alone; used as add-on to lamivudine or telbivudine	Indefinite duration of therapy in incomplete responders Nausea, headaches; malaise and fatigue Risk of lactic acidosis, pancreatitis High rate of resistant mutants (>70% by 5 years); considered for hepatic decompensation or HCC	Indefinite duration of therapy in incomplete responders Risk of elevated CK level Some cross-resistance with lamivudine (up to 25% in HBeAg-positive and 11% in HBeAg- negative patients at 2 years)	Injection Side effects (see Table 44.6) Up to 60% sustainability of response over 4 years of therapy in patients with HBeAg-negative chronic hepatitis B; not appropriate for decompensated cirrhosis; 20-50% clearance of HDV

Abbreviations: Anti-HBs = antibody to hepatitis B surface antigen, BMD = bone mineral density, CK = creatine kinase, ESRD = end-stage renal disease, HBeAg = hepatitis B e antigen HBsAg = hepatitis B surface antigen, HCC = hepatocellular carcinoma, SC = subcutaneously, SJS = Stevens-Johnson syndrome, TD = tenofovir disoproxil, TEN = toxic epidermal necrolysis.

BOX 44.2

Features of therapy with nucleoside and nucleotide analogs for chronic hepatitis virus (HBV) infection

HBeAg to anti-HBe seroconversion in 12–21% at 1 year
HBeAg to anti-HBe seroconversion increases over time
Serum ALT level predicts HBeAg loss
HBeAg-negative patients are more likely than HBeAg-positive patients to become HBV DNA-negative, but response is much less durable, typically requires ongoing therapy
Liver histology improves
Degree of viral suppression varies among drugs
Rate of serum HBsAg loss is low (<1%) after 1 year
Resistance profiles vary

Abbreviations: ALT = serum alanine aminotransferase level, anti-HBe = antibody to hepatitis B e antigen, anti-HBs = antibody to hepatitis B surface antigen hepatitis B virus, HBeAg = hepatitis B e antigen, HBsAg = hepatitis B surface antigen.

patients with rapidly progressive hepatitis B ("fibrosing cholestatic hepatitis") following organ transplantation. Combined use of a nucleoside and nucleotide analog or of peginterferon and a nucleoside or nucleotide analog has not been shown convincingly to have a substantial advantage over the use of one drug alone.

Nucleoside analogs are also recommended for inactive HBV carriers (and those positive only for anti-HBc) prior to the initiation of immunosuppressive therapy (including rituximab or an anti-tumor necrosis factor antibody) or cancer chemotherapy to prevent reactivation. In patients infected with both HBV and HIV, antiretroviral therapy, including two drugs active against both viruses (e.g., tenofovir plus lamivudine or emtricitabine), has been recommended when treatment of HIV infection is indicated. Tenofovir, telbivudine, and lamivudine have been shown to be safe in pregnant women. Antiviral therapy has been recommended, beginning in the third trimester, when the mother's serum HBV DNA level is ≥200,000 IU/mL to reduce levels at the time of delivery. Prophylactic tenofovir disoproxil fumarate has been shown to be cost-effective if the rate of compliance with hepatitis B vaccination in a population is at least 98%.

Peginterferon alfa-2a is still an alternative to the oral agents in selected cases. A dose of 180 μg subcutaneously once weekly for 48 weeks leads to sustained normalization of aminotransferase levels, disappearance of HBeAg and HBV DNA from serum, and appearance of anti-HBe in up to 40% of treated patients and results in improved survival. A response is most likely in patients with a low baseline HBV DNA level and high aminotransferase levels and is more likely in those who are infected with HBV genotype A than with other genotypes (especially genotype D) and who have certain favorable polymorphisms of the interferon lambda (*IFNL3*), also known as the interleukin 28B (*IL28B*) gene. Moreover, many complete responders eventually clear HBsAg and develop antibody to hepatitis B surface antigen (anti-HBs) in serum and are thus cured. Relapses are uncommon in complete responders who seroconvert from HBeAg to anti-HBe. Peginterferon may be considered in order to avoid long-term therapy with an oral agent, as in young women who may want to become pregnant in the future. Patients with HBeAg-negative chronic hepatitis B have a response rate of 60% after 48 weeks of therapy with peginterferon, but the response may not be durable once peginterferon is stopped. A rapid decline in serum HBsAg titers predicts a sustained response and ultimate clearance of HBsAg. The response to peginterferon is poor in patients with HIV coinfection. Interferon is associated with a variety of side effects and is contraindicated in persons with decompensated cirrhosis.

New treatments with novel modes of action and the potential to increase the chance of a functional cure are under study. These include HBV entry inhibitors, agents that target covalently closed circular DNA, inhibitors of gene expression, and compounds that target nucleocapsid assembly.

Chronic hepatitis D

HDV (the delta agent) is a defective RNA agent that only infects (either concurrently or sequentially) persons also infected with HBV. Acute hepatitis D infection superimposed on chronic HBV infection may result in severe chronic hepatitis, which may progress rapidly to cirrhosis and may be fatal. HBsAg is required only for assembly but not replication of HDV.

Among HBV carriers, the estimated rate of HDV coinfection worldwide is as high as 13%. Unlike HBV, perinatal exposure is not a significant route of HDV transmission. The prevalence of HDV infection is reported to be highest in the Mediterranean region, the Middle East, central and northern Asia, west and central Africa, Taiwan, and the Amazon basin, particularly in the western Amazon region of South America, where the frequency of coinfection is 32%. Highly endemic regions include Cameroon, the Central African Republic, and Gabon. Patterns of immigration and intravenous (IV) drug use appear to be contributing to increasing rates of HDV in the Mediterranean region, whereas improved hepatitis B vaccination rates and the use of barrier protection against sexual transmission have been mitigating factors. In survey data among HBsAg-positive persons who inject drugs in Baltimore and San Francisco, HDV infection rates have been as high as 50% and 36%, respectively.

Chronic HDV infection is diagnosed by the detection of IgM and IgG anti-HDV in serum. IgM anti-HDV is often detectable in high titers in patients with chronic HDV infection, and levels tend to parallel the activity of liver disease; therefore, it is frequently regarded as a marker of serious liver damage. A decline in IgM anti-HDV levels may indicate either a decline in disease activity or resolution of HDV infection. In patients in whom HDV infection resolves, IgG anti-HDV may remain detectable in serum, but levels are low. IgG anti-HDV is not a protective antibody. The presence of HDV RNA in serum distinguishes chronic hepatitis D from recovery. In the late phase of chronic HDV infection, declining serum HDV RNA levels may be accompanied by an increase in serum HBV DNA levels (Table 44.4).

The majority of patients with chronic HDV infection demonstrate an initial active hepatitis that progresses rapidly to cirrhosis, after which the hepatitis becomes inactive and runs a more indolent course. Patients with long-standing chronic hepatitis D and B often have inactive cirrhosis and are at risk for decompensation and hepatocellular

TABLE 44.4 **SEROLOGIC MARKERS IN HEPATITIS D VIRUS (HDV) INFECTION**

Serologic marker	Acute HBV-HDV coinfection	Acute HDV superinfection	Chronic HDV infection
HbsAg	Positive	Positive	Positive
IgM anti-HBc	Positive	Negative	Negative
HDAg	Positive (early and transient)	Positive (early and transient)	Negative
Total anti-HDV	Weakly positive (transient low titers)	Positive (with rising titers)	Positive (with high sustained titers)
IgM anti-HDV	Weakly positive (transient low titers; may be the only marker of infection)	Positive (with rising titers)	Positive (with high sustained titers)
HDV RNA	Positive (early and transient)	Positive (early and persistent)	Positive (usually persistent)

Abbreviations: Anti-HDV = antibody to HDV, HBsAg = hepatitis B surface antigen, HDAg = hepatitis D antigen.
From Ghany MG. Hepatitis D. In: Feldman M, Friedman LS, Brandt LJ, eds., Wilcox CM, Chung RT, Rubin DR, assoc. eds. *Sleisenger and Fordtran's Gastrointestinal and Liver Disease: Pathophysiology/Diagnosis/Management*, 11th ed. Philadelphia: Elsevier 2021;1283-91.

carcinoma. Of the eight known HDV genotypes, some are associated with a more severe outcomes (e.g., HDV genotypes 1, 3, and 4), whereas for others (e.g., HDV genotypes 5–8) natural history data are lacking. HDV genotype 3, which has been associated with outbreaks of severe acute hepatitis and an increased rate of acute liver failure and death, may be more responsive to peginterferon therapy than other genotypes (see later discussion). Durable suppression of HDV RNA has been shown to be associated with a reduced risk of liver-related complications (hepatic decompensation, hepatocellular carcinoma, liver transplantation, and liver-related death; see later discussion).

Treatment

In persons with chronic hepatitis D, peginterferon alfa-2b, 1.5 μg/kg/wk for 48 weeks, may lead to normalization of serum aminotransferase levels, histologic improvement, and elimination of HDV RNA from serum in 20% to 50% of patients, but subsequent relapse may occur and tolerance is poor. Nucleoside and nucleotide analogs are generally not effective in treating chronic hepatitis D; prenylation inhibitors (e.g., lonafarnib) and HBV-HDV–specific receptor blockers (e.g., bulevirtide) are under study, as are a variety of targeted immune system inhibitors.

Chronic hepatitis C

Chronic hepatitis C develops in up to 85% of patients with acute hepatitis C. It is clinically indistinguishable from chronic hepatitis due to other causes and may be the most common type. Worldwide, 71 million people (about 1% of the population), are infected with HCV, with 1.8% of the US population infected, although most are unaware they have it. In 2005, the peak prevalence (about 2.7%) in the United States was in persons 55 to 64 years of age. As a result, it is recommended that all persons born between 1945 and 1965 be tested for anti-HCV. Coincident with the aging of the population with untreated hepatitis C, disease-related mortality has accelerated since 2003; however, this trend is likely to slow by 2030 due to effective treatment options (see later discussion). In the United States, Australia, and other developed countries, peak prevalence is in persons 40 to 49 years of age, and analysis of risk factors suggests that most HCV transmission occurred between the mid-1980s and the mid-1990s, through injection drug use. The frequency of HCV infection in persons who inject drugs (PWID) ranges from 57% to 90%, and the majority of PWID become anti-HCV positive within 6 months of initiating injection drug use with shared needles.

In approximately 40% of cases with chronic HCV infection, serum aminotransferase levels are persistently normal. The diagnosis is confirmed by detection of anti-HCV by enzyme immunoassay (EIA). In rare cases of suspected chronic hepatitis C but a negative EIA, the diagnosis is made by detection of HCV RNA through polymerase chain reaction (PCR) testing.

Progression to cirrhosis occurs in 20% of affected persons after 20 years, with an increased risk in men, those who drink >50 g of alcohol daily, and those who acquire HCV infection after 40 years of age. The rate of progression of hepatic fibrosis accelerates after age 50, and cirrhosis has been predicted to develop in most patients with chronic hepatitis C by about 65 years of age, irrespective of the age at infection. Blacks have a higher rate of chronic HCV infection, but lower rates of fibrosis progression and response to therapy, than whites. Immunosuppressed persons—including patients with hypogammaglobulinemia or HIV infection with a low CD4 count or those receiving immunosuppressants—appear to progress more rapidly to cirrhosis than immunocompetent persons with chronic hepatitis C. Tobacco and cannabis smoking and hepatic steatosis also appear to promote progression of fibrosis, but coffee consumption appears to slow progression. Persons with chronic hepatitis C and persistently normal serum aminotransferase levels usually have mild chronic hepatitis with slow or absent progression to cirrhosis; however, cirrhosis is present in 10% of these patients. Serum fibrosis testing (e.g., FibroSure) or elastography (by ultrasound or magnetic resonance to measure liver stiffness) may be used to suggest the absence of fibrosis or presence of cirrhosis. Overall, chronic hepatitis C is responsible for approximately 25% of cases of hepatocellular carcinoma worldwide.

Treatment

The introduction of direct-acting and host-targeting antiviral agents has rapidly expanded the therapeutic armamentarium against HCV (Table 44.5 and Table 44.6). Standard therapy for HCV

TABLE 44.5 **RECOMMENDED FDA-APPROVED ORAL DIRECT-ACTING ANTIVIRAL AGENTS FOR HCV INFECTION (IN ALPHABETICAL ORDER WITHIN CLASS).**[a]

NS 3/4A Protease Inhibitors			
Glecaprevir	[a–f]	300 mg orally once daily	Used with pibrentasvir +/− ribavirin
Grazoprevir	[a, d]	100 mg orally once daily	Used with elbasvir[d]
Paritaprevir	[a, d]	150 mg orally once daily	Used with ombitasvir and dasabuvir; ritonavir (100 mg) boosted[c]; for genotype 1b with cirrhosis and genotype 1a, used with ribavirin. Used in combination with omitasvir, ritonavir boosting, and ribavirin for genotype 4.[f]
Simeprevir	[a, d]	150 mg orally once daily	Used with sofosbuvir
Voxilaprevir	[a–f]	100 mg orally once daily	Used with sofosbuvir and velpatasvir[g]
NS5A Inhibitors			
Daclatasvir[h]	[a–f]	60 mg orally once daily	Used with sofosbuvir (genotypes 1–6, +/− ribavirin depending on presence of cirrhosis) or with asunaprevir (not available in US)
Elbasvir	[a–f]	50 mg orally once daily	Used with grazoprevir
Ledipasvir	[a, d–f]	90 mg orally once daily	Used with sofosbuvir
Ombitasvir	[a, d]	25 mg orally once daily	Used with paritaprevir (ritonavir boosted) +/− dasabuvir and +/− ribavirin as per paritaprevir above
Pibrentasvir	[a–f]	120 mg orally once daily	Used with glecaprevir +/− ribavirin
Velpatasvir	[a–f]	100 mg orally once daily	Used with sofosbuvir.[j] May be used with sofosbuvir and voxilaprevir.
NS5B Nucleos(t)ide Polymerase Inhibitor			
Sofosbuvir	[a–f]	400 g orally once daily	Used alone (genotypes 2 and 3) or with simeprevir (genotypes 1,3, 4) or with velpatasvir (all genotypes) or with velpatasvir and voxilaprevir (all genotypes).
NS5B Non-Nucleos(t)ide Polymerase Inhibitor			
Dasabuvir	[a, d]	250 mg orally twice daily	Used with paritaprevir (ritonavir boosted) and ombitasvir +/− ribavirin as per paritaprevir above

[a] Regimen approved by the FDA as of early 2019.
[b] The preferred regimen and duration of treatment may vary depending on HCV genotype, presence or absence of cirrhosis or chronic kidney disease, or nonresponse to prior therapy for HCV infection. In selected cases, testing for resistance-associated substitutions may be considered.
[c] Marketed as Mavyret (AbbVie).
[d] Marketed as Zepatier (Merck).
[e] Marketed as Viekira Pak and Viekira XR (AbbVie).
[f] Marketed as Technivie (AbbVie).
[g] Marketed as Vosevi (Gilead Sciences).
[h] Approved by the FDA for use with sofosbuvir in HCV genotypes 1 and 3 infection.
[i] Marketed as Harvoni (Gilead Sciences).
[j] Marketed as Epclusa (Gilead Sciences).

infection from the late 1990s to the early 2010s was a combination of peginterferon plus ribavirin, and ribavirin continues to be used occasionally in some all-oral regimens. Sustained virologic response rates (negative HCV RNA in serum at 24 weeks after completion of therapy) for peginterferon plus ribavirin were 45% in patients with HCV genotype 1 infection and 70% to 80% in those with genotype 2 or 3 infection. Response of genotype 1 infection to peginterferon plus ribavirin was associated most strongly with the CC genotype of the *IFNL3* gene, with sustained response rates as high as 80%, compared with 40% for the CT genotype and 30% for the TT genotype. Higher rates of response were achieved in persons infected with HCV genotype 1 when a first-generation direct-acting antiviral agent—boceprevir or telaprevir (agents no longer available in the United States), nonstructural (NS) 3/4A serine protease inhibitors—was added to peginterferon plus ribavirin. Sustained response rates were as high as 75% for HCV genotype 1 with a standard three-drug regimen. With the addition of the protease inhibitor, the treatment duration for HCV genotype 1 infection

TABLE 44.6 **PREFERRED FDA-APPROVED ORAL DIRECT-ACTING ANTIVIRAL TREATMENT REGIMENS FOR INITIAL AND RETREATMENT OF HEPATITIS C VIRUS INFECTION**[1]

Regimen	Indication	Duration of Treatment in Noncirrhotic Treatment-Naïve Patients (weeks)
Glecaprevir and pibrentasvir	Genotypes 1–6 and DAA-experienced genotype 1	8
Sofosbuvir and velpatasvir	Genotypes 1–6, and DAA-experienced genotypes 1b and 2	12
Sofosbuvir, velpatasvir, and voxilaprevir	DAA-experienced genotypes 1–6	–

[1]Based on the American Association for the Study of Liver Diseases/Infectious Diseases Society of America Guidance. In late 2020, two preferred regimens were recommended: glecaprevir and pibrentasvir for 8 weeks (genotypes 1–6) and sofosbuvir and velpatasvir for 12 weeks (genotypes 1, 2, 4, 5, 6), with sofosbuvir, velpatasvir, and voxilaprevir as a rescue regimen for rare nonresponders to first-line therapy. See HCV Guidance: Recommendation for testing, managing, and treating hepatitis C. http://www.hcvguidelines.org, accessed December 18, 2020.

could be shortened to 24 weeks, depending on the rapidity of clearance of HCV RNA from serum—so-called *response-guided therapy*. Treatment with peginterferon-based therapy was associated with frequent, often distressing, side effects, and discontinuation rates were as high as 15% to 30%.

After the introduction of all-oral regimens, the criterion for a sustained virologic response was shortened from 24 weeks to 12 weeks following the completion of treatment. The definition of clearance of HCV RNA requires use of a sensitive real-time reverse transcriptase-PCR assay to monitor HCV RNA during treatment (the lower limit of quantification should be ≤25 IU/mL, and the limit of detection should be 10–15 IU/mL).

Several types of direct-acting antiviral agents have been developed (see Table 44.5). HCV protease inhibitors ("–previrs") generally have high antiviral potency but differ with respect to the development of resistance (although resistance-associated substitutions in the HCV genome tend not to persist after therapy, after these agents are stopped). Examples include glecaprevir and voxilaprevir. Some of the compounds show better response rates in HCV genotype 1b than in genotype 1a infection. Simeprevir is less effective in patients with genotype 1a and a nonstructural protein Q80K mutation than in those without the mutation. Drugs in this class are contraindicated in persons with decompensated cirrhosis.

NS5A inhibitors ("–asvirs"), such as ledipasvir and velpatasvir, are characterized by high antiviral potency at picomolar doses. The cross-genotype efficacy of these agents varies.

HCV polymerase inhibitors ("–buvirs") are categorized as nucleoside or nucleotide analog and non-nucleoside polymerase inhibitors. Nucleos(t)ide analogs are active against all HCV genotypes and have a high barrier to resistance. Sofosbuvir has been the sole available agent in this category. Non-nucleos(t)ide polymerase inhibitors, such as dasabuvir, are the weakest class of compounds against HCV because of a low barrier to resistance. Drugs in this class are generally more active against HCV genotype 1b than HCV genotype 1a. They have been developed to be used only in combination with the other direct-acting antiviral agents, mainly protease inhibitors and NS5A inhibitors.

In late 2019, the American Association for the Study of Liver Diseases and the Infectious Diseases Society of America recommended two preferred combination regimens: glecaprevir plus pibrentasvir for 8 weeks for genotypes 1–6 and sofosbuvir plus velpatasvir for 12 weeks for genotypes 1, 2, 4, 5, or 6 (see Table 44.6). The combination of glecaprevir and pibrentasvir is approved for 8 weeks in treatment-naïve, noncirrhotic or compensated cirrhotic and treatment-experienced noncirrhotic patients, including those coinfected with HIV, and for 12 weeks in treatment-experienced, compensated cirrhotic patients. Sofosbuvir and velpatasvir should also be administered for 12 weeks in treatment-experienced compensated cirrhotic patients. Additional modifications may be required in patients with genotype-3 treatment-experienced compensated or decompensated cirrhosis. The combination of glecaprevir and pibrentasvir is also a pangenotypic option for patients with chronic kidney disease, including those receiving dialysis. The combination of sofosbuvir, velpatasvir, and voxilaprevir is recommended as "rescue" therapy in patients with nonresponse or relapse following treatment with an NS5A-containing regimen. Other "rescue" regimens are under study, including grazoprevir, ruzasvir (an NS5A inhibitor), and uprifosbuvir (an NS5B polymerase nucleotide inhibitor), with or without ribavirin, for patients who have not responded to NS5A-containing therapy. Where available, testing for resistance-associated substitutions may be helpful in some cases before re-treatment. Use of any regimen containing a protease inhibitor is contraindicated in patients with decompensated cirrhosis.

Overall treatment rates are still less than 20% and lowest among Hispanics and persons with Medicaid or indigent care insurance. The cost of direct-acting antiviral agents has been high (although declining), and lack of insurance coverage has often been a barrier

to their use. Additional factors to consider in the selection of a regimen are the presence of cirrhosis or kidney dysfunction, prior treatment, potential drug interactions (of which there are many) (see Table 44.7), and the likelihood that a patient may require liver transplantation in the future. Certain cytochrome P450/P-glycoprotein inducing agents, such as carbamazepine, phenytoin, and phenobarbital, contraindicate the use of all HCV direct-acting antiviral regimens. HCV genotype 1 is now easy to cure with oral direct-acting agents, with expected sustained virologic response rates well above 90%, and virtually all HCV genotype 2 infection is curable with all-oral regimens. HCV genotype 3 infection, particularly in association with cirrhosis, has been the most challenging to treat, but the newest regimens achieve a high rate of cure. Interferon is now rarely required, and the need for ribavirin has decreased also. Other agents that have been studied include NS3/4A protease inhibitors (eg, danoprevir); polymerase inhibitors (eg, mericitabine); virus entry, assembly, and secretion inhibitors; microRNA-122 antisense oligonucleotides (eg, miravirsen); cyclophilin A inhibitors (eg, alisporivir); interferon lambda-3; and therapeutic vaccines.

Patients with HCV-HIV coinfection have been shown to respond well to treatment of HCV infection. Moreover, in persons coinfected with HCV and HIV, long-term liver disease–related mortality increases as HIV infection–related mortality is reduced by antiretroviral therapy. Occasional instances of reactivation of HBV infection, as well as herpesvirus, have occurred with direct-acting antiviral agents for HCV infection, and all candidates should be prescreened for HBV infection, with the initiation of antiviral prophylactic therapy in those who are positive for HBsAg when treatment of HCV infection is begun. Antiviral therapy of HCV is beneficial in the treatment of HCV-associated cryoglobulinemia; an acute flare of cryoglobulinemia may first require treatment with rituximab, cyclophosphamide plus methylprednisone, or plasma exchange. Antiviral therapy can be used in patients who have undergone liver transplantation, thereby expanding the donor pool to include HCV-positive persons. There are insufficient safety data regarding the use of direct antiviral agents in pregnancy; therefore, they are not recommended during pregnancy.

Prognosis

The sequelae of chronic hepatitis secondary to hepatitis B include cirrhosis, liver failure, and hepatocellular carcinoma. The 5-year mortality rate is 0% to 2% in those without cirrhosis, 14% to 20% in those with compensated cirrhosis, and 70% to 86% following decompensation. The risk of cirrhosis and hepatocellular carcinoma correlates with serum HBV DNA levels, and a focus of therapy is to suppress HBV DNA levels <300 copies/mL (60 IU/mL). In patients with cirrhosis, even low levels of HBV DNA in serum increase the risk of hepatocellular carcinoma compared with undetectable levels. HBV genotype C is associated with a higher risk of cirrhosis and hepatocellular carcinoma than other genotypes. Antiviral treatment improves the prognosis in responders, prevents (or leads to regression of) cirrhosis, and decreases the frequency of liver-related complications (although the risk of hepatocellular carcinoma does not become as low as that of inactive HBV carriers, and hepatocellular carcinoma may even occur after clearance of HBsAg). A risk score (PAGE-B) based on a patient's age, sex, and platelet count has been reported to predict the 5-year risk of hepatocellular carcinoma in white patients taking entecavir or tenofovir. Emerging therapies are likely to provide a functional cure, achieved through HBsAg seroclearance, through a combination of drug therapies used to isolate the viral components in the covalently closed circular DNA that remain in hepatocytes indefinitely without foreseeable eradication by available antiviral agents.

Chronic hepatitis C is an indolent, often subclinical disease that may lead to cirrhosis and hepatocellular carcinoma after decades. The overall mortality rate in patients with transfusion-associated hepatitis C may be no different from that of an age-matched control population. Nevertheless, mortality or transplantation rates clearly rise to 5% per year once cirrhosis develops. A risk score combining age, sex, platelet count, and AST-to-ALT ratio is useful for estimating survival. There is some evidence that HCV genotype 1b is associated with a higher risk of hepatocellular carcinoma than other genotypes. Antiviral therapy has a beneficial effect on mortality and quality of life, is cost-effective, appears to retard and even reverse fibrosis, and reduces (but does not eliminate) the risk of decompensated cirrhosis and hepatocellular carcinoma in responders with advanced fibrosis. Even patients who achieve a sustained virologic response remain at an increased risk for mortality compared with the general population. An increased risk of death from extrahepatic cancers has been described in this group, as well as in patients who achieve suppression of HBV infection. Although mortality from cirrhosis and hepatocellular carcinoma due to hepatitis C is still substantial, the need for liver transplantation for chronic hepatitis C has declined, and survival after transplantation has improved. The risk of mortality from drug addiction is higher than that for liver disease in patients with chronic hepatitis C. HCV infection appears to be associated with increased cardiovascular mortality, especially in persons with diabetes mellitus and hypertension. Statin use has been reported to be associated with improved virologic response to antiviral therapy and decreased progression of liver fibrosis and frequency of hepatocellular carcinoma.

Prevention

Chronic hepatitis B and D

Strict isolation of patients with chronic hepatitis B is not necessary. Thorough hand-washing by medical staff who may contact contaminated utensils, bedding, or clothing is essential. Medical staff should handle disposable needles carefully and not recap them. Screening of donated blood for HBsAg, anti-HBc, and anti-HCV has reduced the risk of transfusion-associated hepatitis markedly. All pregnant women should undergo testing for HBsAg. HBV-infected persons should practice safe sex. Immunoprophylaxis of the neonate reduces the risk of perinatal transmission of HBV infection; as noted earlier, when the mother's serum HBV DNA level is ≥200,000 IU/mL (or the mother's serum HBsAg level is >4–4.5 log10 IU/mL), antiviral treatment of the mother should also be initiated in the third trimester and is particularly important if

the initial vaccine injection of the neonate may be delayed. HBV-infected healthcare workers are not precluded from practicing medicine or dentistry if they follow Centers for Disease Control and Prevention (CDC) guidelines.

Hepatitis B immune globulin (HBIG) may be protective—or may attenuate the severity of illness—if given within 7 days after exposure (adult dose is 0.06 mL/kg body weight) followed by initiation of the HBV vaccine series. This approach is recommended for unvaccinated persons exposed to HBsAg-contaminated material via mucous membranes or through breaks in the skin and for individuals who have had sexual contact with a person with HBV infection (irrespective of the presence or absence of HBeAg in the source). HBIG is also indicated for newborn infants of HBsAg-positive mothers, with initiation of the vaccine series at the same time, both within 12 hours of birth (administered at different injection sites).

The CDC recommends HBV vaccination of all infants and children in the United States and all adults who are at risk for hepatitis B (including persons >60 with diabetes mellitus) or who request vaccination; the vaccine appears to be underutilized in adults for whom vaccination is recommended. More than 90% of recipients of the vaccine mount protective anti-HBs levels; immunocompromised persons, including patients receiving dialysis (especially those with diabetes mellitus), respond poorly. Reduced response to the vaccine may have a genetic basis in some cases and has also been associated with age >40 years and celiac disease. The standard regimen for adults is 10 to 20 μg (depending on the formulation) repeated again at 1 and 6 months, but alternative schedules have been approved, including accelerated schedules of 0, 1, 2, and 12 months and of 0, 7, and 21 days plus 12 months. For greatest reliability of absorption, the deltoid muscle is the preferred site of inoculation. Vaccine formulations free of the mercury-containing preservative thimerosal are given to infants under 6 months of age. A newer vaccine, Heplisav-B, which uses a novel immune system–stimulating ingredient, was approved by the FDA for adults in 2017. Immunization requires only two injections, and Heplisav-B appears to be more effective than previous HBV vaccines. When documentation of seroconversion is considered desirable, postimmunization anti-HBs titers may be checked. Protection appears to be excellent even if the titer wanes—persisting for at least 20 years—and booster reimmunization is not routinely recommended but is advised for immunocompromised persons in whom anti-HBs titers fall below 10 mIU/mL. For vaccine nonresponders, three additional vaccine doses may elicit seroprotective anti-HBs levels in 30% to 50% of persons. Doubling of the standard dose may also be effective. Universal vaccination of neonates in countries endemic for HBV has reduced the incidence of hepatocellular carcinoma, although resource allocation remains a challenge. Incomplete immunization is the most important predictor of liver disease among vaccinees. The World Health Organization's Global Strategy for Viral Hepatitis includes the elimination of hepatitis B as a global health threat by 2030. Vaccination against HBV necessarily protects against HDV infection.

Chronic hepatitis C

Testing donated blood for HCV helped reduce the risk of transfusion-associated hepatitis C from 10% in 1990 to about 1 case per 2 million units in 2011. The US Preventive Services Task Force has recommended that asymptomatic adults age 18 to 79 be screened for HCV infection. The CDC subsequently recommended screening of all persons over age 18 at least once in a lifetime and in all pregnant women (in both cases except in settings where the prevalence of HCV infection is less than 0.1%, which is unusual). Screening of all pregnant women for HCV infection has been recommended by professional societies. HCV-infected persons should practice safe sex, but there is little evidence that HCV is easily spread by sexual contact or perinatally, and no specific preventive measures are recommended for persons in a monogamous relationship or for pregnant women. Because a majority of cases of HCV infection are acquired by IV drug use, public health officials have recommended avoidance of shared needles and access to needle exchange programs for PWID. As yet, there is no vaccine for HCV. Vaccination again HAV (after prescreening for prior immunity) and HBV is recommended for patients with chronic hepatitis C, just as vaccination against HAV is recommended for patients with chronic hepatitis B.

Biliary infection

Cholecystitis, cholangitis

Raghav Chandra and Robert V. Rege

This chapter discusses the pathogenesis, diagnosis, and treatment of infections of the gallbladder and bile ducts. Bacterial disorders of the biliary tract range from simple colonization of bile with bacteria to serious, life-threatening problems requiring prompt diagnosis and treatment.

Acute cholecystitis

Acute cholecystitis is a common disorder that manifests as acute inflammation of the gallbladder. In 98% of patients, the pathogenesis of the disease involves obstruction of the cystic duct by an impacted gallstone at the gallbladder neck with resulting inflammation, Cystic ductal obstruction results in nonvisualization of the gallbladder on technetium radionucleotide cholescintigraphy (HIDA) scan. In 2% to 5% of cases, gallstones are not present, a condition termed acute *acalculous cholecystitis*. While acute acalculous cholecystitis is most often encountered in debilitated or critically ill patients who have not been fed by mouth for extended periods of time, it can occur in otherwise healthy patients as well, including children. It is believed that biliary stasis in the gallbladder lumen leads to gallbladder wall inflammation in both calculous and acalculous cholecystitis. Secondary superinfection of static bile with gram-negative and anaerobic bacteria further promotes gallbladder wall inflammation and ultimately compromise (Figure 45.1). If unchecked, the process progresses to complicated cholecystitis with gangrene or perforation of the gallbladder, which can result in rupture, fistulae, sepsis, and death. For this reason, early diagnosis and effective management of acute cholecystitis is imperative.

Bacteriology

Interestingly, bacteria are not isolated from bile in the great majority of patients undergoing operation early in the course of the disease. In a study of 509 patients who underwent cholecystectomy or cholecystostomy tube placement for acute cholecystitis, bile cultures were positive in only 34% of patients (Hadi et al., 2016). Bacteria in bile increase as the duration from the onset of symptoms increases, and the majority of patients demonstrate bacteriobilia by 3 days. The relative proportion of organisms varies in studies, but in general, the most common organisms isolated include the gram-negative bacteria including *Escherichia coli, Klebsiella, Proteus*, and *Pseudomonas*; anaerobes such as *Bacteroides* and gram-positives, particularly *Enterococcus* (Table 45.1). Polymicrobial infection is common. Anaerobic bacteria are reportedly isolated in >10% of cases, but may be more common as culturing these organisms using standard techniques is difficult. *Candida* spp. are uncommon in normal patients but are frequently encountered in immunosuppressed patients and those with underlying maligiancies.

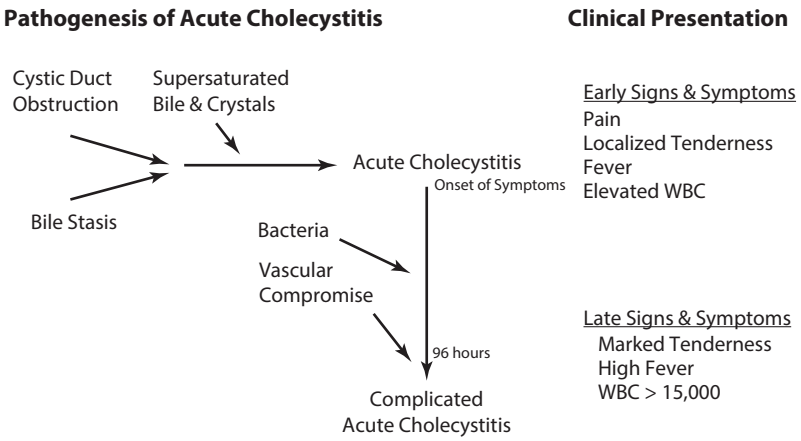

FIGURE 45.1 The pathogenesis of acute cholecystitis is illustrated on the left side of the figure, whereas differences in clinical presentation between acute cholecystitis and complicated acute cholecystitis are shown on the right. Note that bacteria do not play a primary role but result in progression of the disease to its complicated form.

Acalculous cholecystitis

While the majority of cases of acute cholecystitis are caused by secondary infection of the gallbladder after biliary obstruction from a gallstone, there are several other etiologies of cholecystitis as well. Critical illness, major abdominal surgery, malnutrition, severe burns, and immunosuppression are known risk factors for a highly aggressive infection of the gallbladder termed *acute acalculous cholecystitis*. As the name suggests, acalculous cholecystitis does not occur in the presence of gallstones. The pathophysiology of acalculous cholecystitis is multifactorial and includes systemic inflammation, biliary stasis, ischemia, and infection. Histologically, acalculous cholecystitis is characterized by gallbladder wall edema, bile infiltration into the gallbladder wall, and microvascular occlusion (Huffman & Schenker, 2010). Immunosuppressed patients, in particular, are at significantly increased risk of serious systemic infections, including cholecystitis. In these high-risk patients including those on post-transplant immunosuppression or those with acquired immunodeficiency syndrome (AIDS), acalculous cholecystitis has been associated with opportunistic infections including cytomegalovirus (CMV), *Cryptosporidium*, or *Mycobacterium avium complex* (Cacciarelli et al., 1998; Drage et al., 2009).

Diagnosis

Acute cholecystitis must be distinguished from biliary colic, and clues need to be sought to determine if complicated cholecystitis is imminent or already present. While both patients with acute cholecystitis and biliary colic experience right upper quadrant abdominal pain, the pain associated with acute cholecystitis is persistent, lasts more than 3 to 4 hours, and is associated with abdominal tenderness. Tenderness is well-localized in the right upper quadrant of the abdomen directly over the gallbladder and increases when the patient inspires as the gallbladder strikes the examiner's hand (Murphy's sign). The maneuver can be duplicated with the ultrasound probe (sonographic Murphy's sign). Diffuse right upper quadrant tenderness is suggestive of a liver problem, and severe tenderness or peritonitis is indicative of complicated cholecystitis or another upper abdominal cause of pain.

Systemic signs of inflammation, including low-grade fever and moderately elevated white blood cell (WBC) count, are usually present. The presence of dark urine, acholic stool, or jaundice raises the concern of common bile duct stones (choledocholithiasis). Conversely, if these findings are accompanied by painless jaundice, malignant ductal obstruction should be suspected. Back pain and epigastric tenderness should also heighten the clinician's suspicion of choledocholithiasis or biliary pancreatitis.

TABLE 45.1 **COMMON BACTERIA IN BILE**

Gram-negative	Gram-positive	Anaerobes	Fungi
Escherichia coli	*Enterococcus*	*Bacteroides* spp.	*Candida* spp.
Klebsiella spp.	*Streptococcal* spp.	*Clostridium* spp.	
Proteus spp.			
Pseudomonas spp.			
Enterobacter spp.			

Approximately 65% of patients are colonized with a single species of bacteria; 35% are polymicrobial. Gram-negative bacteria are cultured from nearly 75% of patients.

Physical examination can, however, be misleading. Some patients exhibit few signs and symptoms of acute cholecystitis, which may delay the diagnosis and underestimate the severity of the disease. Such patients are more likely to be elderly, male, and have a history of cardiac disease. Furthermore, while leukocytosis is common, WBC counts >15,000 suggest severe disease (gangrene or perforation of the gallbladder). A high index of suspicion for complicated cholecystitis must be maintained for such patients, as they may present with minimal symptoms prior to decompensation. Laboratory testing should include CBC with differential, liver function tests, serum amylase, and serum lipase. The latter three tests may suggest choledocholithiasis or biliary pancreatitis when abnormal. Ultrasound of the abdomen reliably demonstrates gallstones in the majority of patients. A typical clinical presentation, coupled with a "positive" ultrasound for stones suffices for the diagnosis. More specific findings of acute cholecystitis including gallbladder wall thickening and pericholecystic fluid are less frequent and suggest more severe disease. A HIDA scan may be helpful in patients without gallstones or atypical presentation. Nonvisualization of the gallbladder is specific for acute cholecystitis (the gallbladder is visualized in only about 2% of patients with acute cholecystitis); demonstration of the gallbladder argues strongly against acute cholecystitis.

Treatment

All patients should be evaluated and prepared for operation, which may be required at any time if the disease progresses. Intravenous (IV) fluid resuscitation and antibiotics should be started, and patients should be placed on bowel rest. Antibiotics must cover the spectrum of bacteria just outlined, and complicated cholecystitis and immunosuppressed patients may require broader coverage (Box 45.1). Antibiotic coverage must include gram-negative rods, gram-positive organisms, and anaerobes. The Tokyo 2018 guidelines recommend piperacillin/tazobactam for most cases of acute cholecystitis and cholangitis for both community-acquired and healthcare-associated disease. For severe community-acquired or healthcare-associated disease, addition of vancomycin to cover *Enterococcus* is also recommended. Vancomycin-resistant *Enterococcus* (VRE), particularly in the hospital setting, may require initiation of daptomycin or linezolid. If there is concern for extended-spectrum β-lactamase–producing organisms, imipenems are advised (Gomi et al., 2018).

BOX 45.1

Summary of antibiotic regimens for acute cholecystitis and acute cholangitis

Acute cholecystitis
Cefoxitin 1–2 g IV q6–8h
Ampicillin-sulbactam (Unasyn) 3 g IV q6h
Acute cholangitis
Single agents
Ciprofloxacin 400–800 mg IV q12h
or
Piperacillin-Tazobactam (Zosyn) 3.375 g IV q6h
or
Imipenem 500 mg IV q6h
Multidrug therapy
Ampicillin 2 g IV q6h + gentamicin 5–7 mg/kg IV q24h
or
Ceftazidime 1–2 g IV q8–12h + Ampicillin 2 g IV q6h + Metronidazole 500 mg IV q6h

Some physicians recommend medical treatment with a delay of 6 weeks to definitive operation. Their rationale is that elective operation is safer than an emergent procedure and that conversion to open rates will be lower than after the acute attack resolves. Although most patients have some response to medical therapy, it is not clinically safer than surgery, nor does it reduce the rate of conversion. It may play a role in a few selected patients with severe, potentially reversible comorbidities which preclude an operative approach. If such patients fail medical therapy, they can be salvaged with percutaneous drainage of the gallbladder through placement of a cholecystostomy tube. Cholecystectomy may be performed electively later, but it is arguable whether all patients require cholecystectomy after nonoperative therapy.

Early laparoscopic cholecystectomy is the definitive treatment for most patients with acute cholecystitis. It is safe in the hands of experienced biliary surgeons, avoids the progression of the disease (which can be observed in as many as 30% of medically treated patients), and has conversion rates similar to elective cholecystectomy (<5%). As the duration of symptoms surpasses 96 hours, conversion rates rise because complicated cholecystitis develops. Although laparoscopic cholecystectomy can still be performed in the majority of these patients as well, the operation is more difficult and morbid. If laparoscopic surgery is attempted late in the disease, surgeons should convert to open operation liberally if marked inflammation or fibrosis is encountered.

It is my preference to admit a patient with acute cholecystitis to the hospital and perform operation within 72 hours from onset of symptoms. The patient is treated with medical therapy (IV antibiotics and fluids) until operation. Patients with early disease often spend <24 hours in the hospital. Those with severe or late disease require urgent or emergent intervention and continued medical therapy postoperatively. Patients who are poor operative risks are the exception; medical therapy and/or percutaneous cholecystostomy tube drainage is a consideration.

After laparoscopic cholecystectomy, patients with mild to moderate disease should discontinue antibiotic therapy. For patients with severe disease, antibiotic therapy should be continued for up to 7 days (Gomi et al., 2018).

Acute cholangitis

Acute cholangitis refers to inflammation and infection of the intra- and extrahepatic biliary tree. Bacterial infection is the most common etiology, but cholangitis can result from parasitic infections, autoimmune diseases, and chemical irritants. *Toxic cholangitis* manifests when bacteria in bile gain access to hepatic sinusoids and are rapidly disseminated, resulting in sepsis, multisystem organ failure, and death.

Pathogenesis

The pathogenesis of acute cholangitis involves a combination of factors including ductal obstruction, injury to the biliary epithelium, and the presence of bacteria in bile. Most patients harboring bacteria in bile do not have an infection, and, in fact, asymptomatic colonization of bile with bacteria increases with advancing age. Bacteriobilia is a risk for acute cholangitis once biliary obstruction develops or if the epithelium is injured, as might occur during an invasive biliary procedure. This is the rationale for prophylactic antibiotic coverage during biliary tract invasive procedures.

Most cases of cholangitis in the United States are secondary to partial or complete biliary obstruction, usually by gallstones which have migrated from the gallbladder into the common bile duct and have caused an obstruction. Normal biliary intraductal pressure is between 7 and 12 mm H_2O. Increased intraductal pressure behind the impacted gallstone disrupts epithelia and intracellular junctions between epithelial cells in the proximal biliary tree. When intraductal pressures increase beyond 25 mm H_2O, the resulting weakening of the lumen wall results in translocation of bacteria systemically into the venous system, termed *cholangiovenous reflux* (Kimura et al., 2007; Ahmed, 2018).

Non-gallstone etiologies of acute cholangitis include benign strictures, stenosis, iatrogenic injury, external compression from gallstones at the neck of the gallbladder (Mirizzi's syndrome), pancreatic cancer, gallbladder cancer, or duodenal lesions (cancer, duodenal or Lemmel's diverticulum). Cholangitis can also occur with malignant biliary obstruction caused by a primary bile duct cancer (cholangiocarcinoma). Patients with malignant obstruction usually present with painless jaundice and sterile bile, though bacteriobilia can be found in 20% of cases. Patients with colonized bile are at higher risk for cholangitis after procedures in the biliary tract. Expectedly, the incidence of iatrogenic cholangitis is rising as the volume of endoscopic and radiological bile duct procedures performed continues to increase. Prophylactic antibiotics and adequate drainage are therefore recommended to minimize the risk of bacterial cololnization of sterile bile during such invasive diagnostic tests.

Microbiology

Causative organisms of acute cholangitis are similar to those isolated from acute cholecystitis, and the most commonly identified pathogens include *E. coli, Klebsiella*, and *Enterococcus*. However, infections from these pathogens are significantly more severe, and blood cultures more often positive, when patients have cholangitis compared to those who have bacteriobilia. Some studies show differences in the incidence of causative organisms between benign and malignant causes of ductal obstruction. Indeed, multiple studies show that patients with malignant obstruction have a higher incidence of bile colonized with *Candida* spp. (Table 45.1). Other infectious etiologies associated with cholangitis include parasitic infections (*Clonorchis sinensis, Ascaris lumbricoides*, and *Opisthorchis* spp.) and AIDS cholangiopathy, often secondary to the similar organisms that can cause opportunistic cholecystitis (*Cryptosporidium*, CMV) (Kimura et al., 2007; Yusuf & Baron, 2004; Ahmed, 2018).

Diagnosis

The classic description of patients with acute cholangitis—Charcot's triad—consists of abdominal pain, fever, and jaundice. Unfortunately, only 50% of patients present with all three signs and symptoms which may delay diagnosis. Fever and chills, present in 90% of patients, are the most consistent signs of acute cholangitis and are often high and spiking in nature. Reynolds' pentad—Charcot's triad as well as hypotension and altered sensorium—is indicative of toxic cholangitis. All five features are present in the minority of patients with toxic cholangitis, so acute and toxic cholangitis must be considered in patients who have any of these signs or symptoms.

Physical examination most often reveals right upper quadrant abdominal tenderness and jaundice. However, as many as 20% of patients with acute cholangitis have a serum bilirubin level of <2.0 mg/dL, the absence of jaundice does not exclude acute cholangitis. Physical findings are typically accompanied by leukocytosis, fever, and/or abnormal liver function tests. Septic patients may have a deceptively low white cell count as well as signs of hemodynamic instability. Ultrasound should be performed urgently to distinguish between "medical" and "surgical" jaundice; dilated bile ducts are indicative of obstruction and surgical jaundice. Endoscopic retrograde cholangiography (ERC; see "Treatment") is diagnostic but can also be therapeutic. Percutaneous transhepatic cholangiography is helpful when ERC is unsuccessful.

Treatment

Acute cholangitis requires aggressively addressing both infection and biliary obstruction. The majority of nonseptic patients respond quickly to fluid resuscitation and appropriate antibiotics. Subsequent measures need to be taken promptly to address the underlying problems causing acute cholangitis. Because toxic cholangitis is a life-threatening problem, these patients should be placed in the intensive care unit for careful hemodynamic monitoring. IV hydration should correct the hypovolemia associated with biliary obstruction, and urine output should be followed closely. Restoration of normal intravascular volumes before undergoing invasive diagnostic and therapeutic procedures is essential to ameliorate the risk of renal failure. Patients in septic shock often exhibit coagulopathy that must be corrected with vitamin K, fresh frozen plasma (FFP), and platelets.

Broad-spectrum antibiotic therapy is essential and should be instituted immediately before any diagnostic and therapeutic interventions are undertaken. Choice of an antibiotic should take into account the profile of organisms commonly cultured at the hospital, especially for hospitalized individuals undergoing invasive procedures. Coverage should be later tailored to match the sensitivities of organisms isolated from bile or blood cultures. The long-standing regimen of ampicillin and an aminoglycoside continues to provide excellent gram-negative and gram-positive coverage for the major culprits, including *Enterococcus* spp., but aminoglycoside-induced nephrotoxicity greatly limits long-term use of this agent. First- and second-generation cephalosporins, while adequate for prophylaxis for elective biliary surgery, lack the

breadth of gram-negative coverage required to treat patients with established infections. Third- and fourth-generation cephalosporins provide gram-negative coverage but do not treat *Staphylococcus* and *Enterococcus* spp. nor anaerobic bacteria effectively. Historically, triple therapy with ceftazidime, ampicillin, and metronidazole provided adequate coverage, but the trend has shifted to single-drug therapy with piperacillin/tazobactam or ampicillin/sulbactam, which is as efficacious as triple-drug therapy or ampicillin plus an aminoglycoside. Fluoroquinolones or carbapenems are good alternatives if first-choice antibiotics are ineffective. Furthermore, ciprofloxacin can be used long-term orally to suppress recurrent attacks of cholangitis. The duration of therapy for antibiotics for acute cholangitis is typically 4 to 7 days, pending adequate drainage of the biliary tree (Gomi et al., 2018).

After adequate resuscitation and antibiotic administration, the primary therapeutic objective is to relieve the obstruction of the biliary tree. This is currently accomplished using either endoscopic retrograde cholangiopancreatography (ERCP)-mediated drainage or percutaneous transhepatic cholangiography (PTC). ERCP is the first choice as it is less risky than PTC in critically ill patients. ERCP is also the gold standard for diagnosing the etiology of acute cholangitis. Effective decompression of the biliary tree can be accomplished by removal of obstructing gallstones with or without stenting of the duct. Cancers of the biliary tree can be visualized and biopsied. PTC is reserved for failure of ERCP or for patients with obstructing cholangiocarcinoma of the proximal bile duct. Adequate drainage should result in prompt improvement.

Decisions about timing of intervention depend on the severity of disease. Factors associated with the need for emergent treatment include older age, high bilirubin levels, prolonged prothrombin time, dilated common bile ducts, and the presence of liver abscesses. Literature suggests that ERCP performed within 24 hours of initial diagnosis is associated with reduced rate of recurrent cholangitis and length of stay (Alizadeh et al., 2017). Salek et al. developed scoring systems to determine mortality risk after cholangitis and identified 18 variables associated with mortality and 15 variables associated with need for early ERCP. They noted that the presence of liver abscess, total bilirubin serum levels, and prothrombin time were predictive of mortality, and alanine aminotransferase level and WBC predicted the need for urgent ERCP with good sensitivity and specificity (Salek, Livote, Sideridis, & Bank, 2009).

If appropriate, definitive procedures should be performed to treat the cause of biliary obstruction because recurrent cholangitis is common. Cholecystectomy should be performed during the index admission if choledocholithiasis was the inciting event. Curable malignancies should be resected. Benign strictures require balloon dilatation or choledochointestinal bypass, whereas unresectable tumors are either bypassed or palliated with internal drainage or external stents.

Timing of operation for patients who present with a transient episode of biliary pancreatitis (low to moderate risk of choledocholithiasis) is somewhat controversial; most stones pass from the common duct spontaneously without complication and the incidence of retained common bile duct stones is highest early after an attack and decreases with time. However, patients in whom choledocholiths do not pass are at high risk for recurrent pancreatitis, obstructive jaundice, and acute cholangitis. The timing of treatment then depends on a balance between the risk of intervention for and further complications from retained common duct stones. Low-risk patients with mild pancreatitis may be taken to the operating room for laparoscopic cholecystectomy with intraoperative cholangiography if the surgeon is prepared to perform laparoscopic common bile duct exploration. The standard of care in this country is to intervene during or shortly after the index admission.

However, patients who present with severe, complicated gallstone pancreatitis may be poor candidates for surgery. Most surgeons allow them to recover from their episode of pancreatitis before definitive intervention. The probability of developing cholangitis is low. Patients with unrelenting pancreatitis, persistently elevated liver enzymes, or jaundice are at high risk for common bile duct stones and should be evaluated for ERCP. Cholecystectomy is performed later to avoid recurrent complications of stones if the patient is an acceptable operative risk.

Pyogenic liver abscess

Patricia Wong and H. Franklin Herlong

First described by Hippocrates around 400 BC, pyogenic liver abscess is an uncommon hepatic infection, but is associated with significant morbidity and healthcare costs. With the advent of imaging techniques that allow for prompt diagnosis, potent antibiotics, and effective drainage procedures, the mortality from pyogenic liver abscess has declined dramatically over the past several decades.

Epidemiology

The epidemiology of liver abscesses has changed significantly over the years. There is increasing recognition that geography plays a significant role in the demographics, etiologic factors, and clinical presentation of pyogenic liver abscesses. In the first large published series of cases of pyogenic liver abscess in the United States in 1938, there was an incidence of 8 cases per 100 000 admissions and a mortality rate of 72%. More recent US-based population studies estimate the annual incidence to be 3.6 per 100 000 population, with a higher incidence among men than women (incidence risk ratio 1.85). Significantly higher incidence rates have been reported in Taiwan at 17.6 per 100 000 population. Reported risk factors include diabetes, underlying hepatobiliary disease, and liver transplantation. In-hospital mortality ranges from 2% to 12% in developed countries and has been reported at 5.6% in the United States. Risk factors for mortality include older age; comorbidities such as cirrhosis, chronic renal failure, and malignancy; the presence of anaerobic infection; and open surgical drainage. The significant decline in associated mortality reflects changes in the underlying source of bacterial seeding and advances in diagnostic and treatment options.

Etiology

Pyogenic liver abscesses result from seeding of the liver from biliary tract disorders (choledocholithiasis, malignant obstruction, strictures, biliary procedures), portal vein pyemia (appendicitis, diverticulitis, colon cancer, inflammatory bowel disease), direct extension (peritonitis, subphrenic abscess), hematogenous spread (pneumonia, endocarditis), or hepatic trauma (infected necrosis, bile leak, or hematoma). Rarely, abscesses develop after arterial embolization or radiofrequency ablation of hepatic tumors. Biliary tract disorders have emerged as the most common causative condition, accounting for 40% to 60% of liver abscess cases. Cholangitis from obstructing cholangiocarcinomas is more common than infections resulting from calculus obstruction.

Liver abscesses from intra-abdominal infective processes have decreased dramatically because of improvements in the diagnosis and treatment of these primary infections. No identifiable source of infection, or "cryptogenic abscess," is found in up to 25% of cases. Most liver abscesses are solitary and occur in the right lobe of the liver, likely due to its greater blood supply compared to the left and caudate lobes.

Clinical presentation

Most patients with pyogenic liver abscesses appear acutely ill with fever and right upper quadrant pain. However, in elderly, debilitated patients, clinical signs may be minimal, potentially delaying diagnosis. Many patients have tender hepatomegaly, occasionally with focal tenderness over the intercostal spaces of the right upper quadrant. However, absence of right upper quadrant findings does not exclude the diagnosis and in patients with liver transplants, denervation may prevent the pain of hepatic enlargement. Nonspecific systemic symptoms such as fatigue, malaise, nausea, and weight loss are common. Jaundice is unusual unless the abscess compresses the biliary tact. An associated pleural effusion may obliterate breath sounds at the right bases. Laboratory abnormalities frequently include leukocytosis and elevated C-reactive protein levels. A modest elevation of alkaline phosphatase is seen in up to 90% of cases. Serum aminotransferases and bilirubin are elevated in about one-half of cases. Blood cultures are positive in less than 50% of cases. No single test or combination of tests can accurately predict the outcome, size, or number of abscesses or complications.

Cultures from liver abscesses usually yield polymicrobial flora. Mixed enteric facultative and anaerobic species are the most common pathogens. A single organism indicates hematogenous spread. Enteric aerobic gram-negative bacilli, such as *Escherichia coli*, and enterococcus suggest a biliary source. Mixed enteric flora containing anaerobes such as *Bacteroides fragilis* originate from portal bacteremias. Monomicrobial *Klebsiella pneumoniae* infection is the most common cause of pyogenic liver abscesses in Taiwan and accounts for a large proportion of cases throughout Asia. These patients have a unique clinical presentation with classic symptoms but no identifiable coexisting intra-abdominal pathology and metastatic complications, such as endophthalmitis. Most patients also have diabetes mellitus. *Yersinia enterocolitica* is an unusual pathogen associated with patients with diabetes or underlying liver disease, particularly hemochromatosis.

Gram-positive organisms such as *Staphylococcus aureus* and *Streptococcus milleri* often originate from infections outside of the abdominal cavity. *S. aureus* is a common cause of liver abscess in children and trauma patients and has been associated with transarterial embolization for hepatocellular carcinoma. Species of *Candida* cause abscesses in immunosuppressed patients, particularly those receiving chemotherapy. The abscess may not be apparent until the neutrophil count rebounds (Table 46.1).

TABLE 46.1 **CLINICAL FINDINGS IN PYOGENIC LIVER ABSCESS**

Signs and symptoms	Incidence (%)
Fever	75
Chills	60
Abdominal pain	60
Weight loss	30
Hepatomegaly	50
Right upper quadrant tenderness	40
Jaundice	25
Laboratory values	
Leukocytosis	70
Elevated bilirubin	40
Elevated alkaline phosphatase	50
Elevated aminotransferases	60

Diagnosis

The diagnosis of pyogenic liver abscess is made through radiographic imaging and aspiration and culture of abscess material. Ultrasonography is the preferred initial test for diagnosing liver abscesses, with a sensitivity of 75% to 95%. Examination of the liver shows a round, focal defect with irregular walls and variable echogenicity. Abscesses may be septated or multiloculated and contain internal echoes caused by debris. Small abscesses, <2 cm in diameter, may not be detected. Contrast-enhanced computed tomography (CT) has a sensitivity of 95% and can detect abscesses as small as 0.5 cm. It can also identify associated intra-abdominal pathology. CT typically shows a fluid collection with surrounding edema or stranding. It is important to distinguish liver abscesses from tumors and cysts. Magnetic resonance imaging and tagged white blood cell scans are less effective at detecting and distinguishing abscesses from other liver lesions.

Treatment

The mainstay of treatment of pyogenic liver abscess is systemic antimicrobial therapy in combination with drainage. When pyogenic liver abscess is suspected, blood cultures should be obtained immediately, followed by initiation of broad-spectrum parenteral antibiotics before blood culture results are available, based on the most probable source of infections (Table 46.2). Initial antibiotic

TABLE 46.2 **EMPIRIC ANTIBIOTIC THERAPY FOR PYOGENIC LIVER ABSCESS**

Potential source	Suggested regimen
Biliary	PipTz 4.5 g q8h IV or
	AMSB 3.0 g q6h IV or
	ERTA 1.0 g IV qd or
	MER 1.0 g q8h IV or
	CIP 400 mg IV BID + metro 1.0 g IV then 0.5 g q6h
Intra-abdominal	IMP 500 mg IV q6h or
	MER 1 g IV q8h or
	AMP 2 g IV q6h + metronidazole 500 mg IV q6h +
	CIP 400 mg IV q12h

Abbreviations: AMP = ampicillin; AMSB = ampicillin–sulbactam (Unasyn); CIP = ciprofloxacin; ERTA = ertapenem; IMP = imipenem cilastatin (Primaxin); MER = meropenem; metro = metronidazole; PipTz = piperacillin–tazobactam.

therapy should be tailored to information obtained from the Gram stain and cultures of aspirated abscess contents and blood cultures. Anaerobic coverage should be continued if multiple organisms are recovered, regardless of whether anaerobes are isolated, since they are difficult to culture. Most abscesses require at least 4 to 6 weeks of total antibiotic therapy with 2 to 4 weeks of parental therapy.

Successful treatment of pyogenic liver abscesses with antibiotics alone is rare, and some form of drainage procedure is almost always required. Exceptions include abscesses less than 3 cm in diameter or multiple small abscesses that are not amenable to surgical or catheter drainage.

Drainage techniques include percutaneous approaches (closed aspiration or with catheter placement), surgical drainage, or drainage by endoscopic retrograde cholangiopancreatography (ERCP). Closed aspiration is a reasonable approach for single abscesses <5 cm. It is the simplest, quickest, and least costly approach with low risk of procedural complications. However, reaccumulation often requires repeat aspiration, catheter placement, or surgical intervention. Placement of a catheter into the abscess cavity under ultrasound guidance is an effective and widely used method of drainage at many centers. This technique is preferred over needle aspiration for single abscesses >5 cm, and is often used if closed aspiration is unsuccessful.

Open surgical drainage has decreased in popularity, with the trend towards percutaneous techniques. However, surgical treatment should be considered for single abscesses >5 cm, multiple or loculated abscesses, inadequate response to percutaneous drainage, viscous contents obstructing the drainage catheter, or concurrent intra-abdominal surgical pathology. Surgical intervention allows for exploration of the abdomen and liver for multiple abscesses. A laparoscopic approach to surgical drainage may also be considered.

Endoscopic abscess drainage has emerged more recently as a treatment option for patients with abscesses that communicate with the biliary tree. This is performed through ERCP with sphincterotomy, dilation, insertion of a nasobiliary catheter, or stenting. Successful endoscopic management of liver abscess complicated by biliary fistula has also been described.

Prognosis

Current mortality rates associated with liver abscesses range from 2% to 12% in developed countries. Few patients die from complications of the abscess itself, such as sepsis or peritonitis. The most important factor in determining survival is the lethality of the primary disease process.

Infectious complications in acute pancreatitis

Jodie A. Barkin and Jamie S. Barkin

Introduction

Patients with acute pancreatitis (AP) have two types of diseases, as shown in detail in Figure 47.1. Type 1 is edematous or mild, non-necrotic pancreatitis, which is usually not associated with persistent or multiorgan system failure (MOSF) that lasts >48 hours. Type 2 is necrotizing pancreatitis which is often associated with persistent organ system failure (>48 hours) and is prone to development of pancreatic infection.[1]

The overall mortality of acute pancreatitis is approximately 5% due to organ system failure secondary to systemic inflammatory response syndrome (SIRS) and infection. The sites of infection are pancreatic and peri-pancreatic, lung with pneumonia and circulating bacteremia.[2] Xue et al. reported that AP patients with infectious complications had a significantly higher severity index, incidence of complications, and mortality than did noninfected patients.

Necrotizing pancreatitis is associated with organ system failure (OSF) and higher morbidity and mortality versus edematous pancreatitis. The fluid collections resulting from edematous and necrotizing AP differ, with the defining criteria being the presence or absence of an enclosing wall and the contents—whether it is only liquid or mixed with solid necrotic debris (necrotizing).[3] Walled-off necrosis contents are a mixture of solid and liquid (edematous) necrosis whereas pseudocysts resulting from edematous pancreatitis are comprised predominantly of liquid contents. The natural history of walled-off necrosis (WON) versus pancreatic pseudocyst is different. WON has a much higher chance of becoming infected (ranging from 20% to 40%) than does pancreatic pseudocyst. WON may become symptomatic early on after AP onset, often requiring intervention, or it may remain asymptomatic. The natural course of asymptomatic WON was reported by Rana et al.[4] They found that 30% of patients developed complications or symptoms that occurred prior to 6 months following an AP episode, and these included pain, infection, rupture into the GI tract, and bleeding.

Petrov et al. reported in a meta-analysis on whether organ failure (OF) or infected pancreatic necrosis (IPN) is the main determinant of severity in acute pancreatitis.[5] They found that the absolute influence of IPN is comparable to development of, with a mortality of approximately 30%. The relative risk of mortality doubles when both OF and IPN are present. These studies emphasize the important role of infection in the outcome of patients with AP.

The usual classification of patients with AP is that early complications and mortality are associated with SIRS and that late complications (after 1–2 weeks) are related to infection. Lytras et al. reported that persistent early OF was significantly associated with the development of infected necrosis and worse outcomes.[6] This illustrates that complications are an interrelated spectrum, that infection may occur early, and that OSF may predispose to infection via increased bacterial translocation from gastrointestinal hypoperfusion.

When does pancreatic necrosis become infected, and where does the bacteria originate?

IPN in AP patients was found to occur by routine use of CT-guided fine needle aspiration (FNA) within 14 days of hospital admission. Besselink et al., in a prospective study, similarly found that infected necrosis

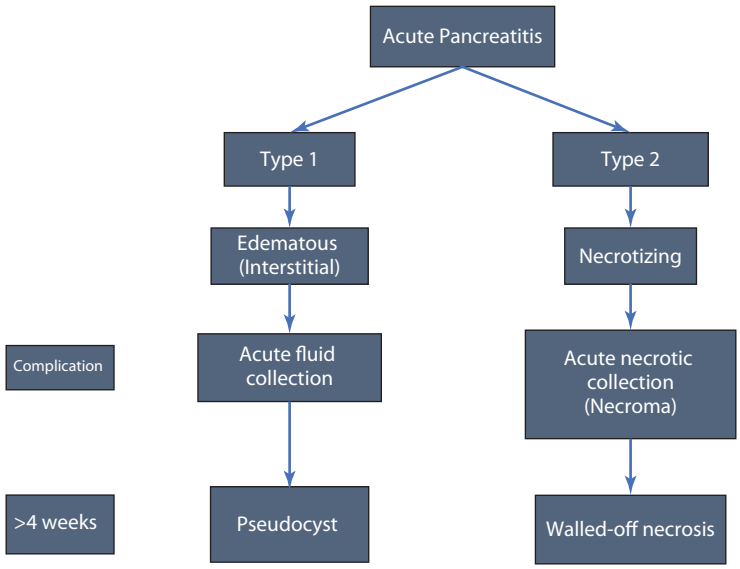

FIGURE 47.1 Types of acute pancreatitis

occurred as early as 1 week after onset of AP and peaked at week 4.[7] They also reported the importance of bacteremia, as it was found to be an independent predictor of death and was associated with an increased risk of pancreatic parenchymal necrosis becoming infected and a higher mortality rate associated with infected necrosis. Bacteremia and pneumonia are earlier events than infected necrosis. Bacteremia in patients AP originates from extra-pancreatic sources (i.e., pneumonia), as well as from the bowel. Fritz et al. showed in an animal study that bacterial translocation from the colon is less frequent than bacterial translocation from the small bowel, which is likely the main source of enteral bacteria in IPN.[8]

Extra-pancreatic infections occurred in 25% of patients with AP.[9] Urinary tract infection was the most common. Risk factors for the development of extra-pancreatic infection were use of total parenteral nutrition (TPN), severe AP disease, and presence of persistent SIRS. TPN was related to IPN because it results in intestinal barrier dysfunction, which favors bacterial translocation. AP itself affects the gut barrier function, especially in patients with organ dysfunction, which results in increased intestinal permeability.[10] Possible mechanisms include hypovolemia and SIRS. Liu et al. found that intestinal mucosal function is injured in the early phase of AP, more so in patients with organ dysfunction.[10] This allows translocation of bacteria and inflammatory and toxic products from the intestinal wall and the bowel to enter the systemic circulation.[11]

The diagnosis of infection in pancreatitis has been based on culture from pancreatic necrosis.[12] Busquets et al. expanded this concept of pancreatic infection status; they found that infection can be present by itself in intra-abdominal free fluid and peri-pancreatic fat and/or bile, or associated with pancreatic necrosis. They reported high mortality in patients with sterile pancreatitis with infected ascites who had undergone early surgical intervention. Applying the present approach of delaying surgical intervention, we should perform a diagnostic paracentesis in patients with AP and ascites to allow early diagnosis of infection.

Radiologic diagnosis of pancreatic infections

CT and MRI of the pancreas cannot accurately detect infected pancreatic collections. The only finding that is suggestive of infection is the presence of gas bubbles in the collection. However, gas bubbles within a pancreatic collection can be the result of infection or secondary to rupture of the pancreatic collection into the GI tract. Islim et al. found air bubbles in only 40% of infected pancreatic collections.[13] However, when gas bubbles are present in the appropriate clinical setting, they should be considered as evidence of pancreatic infection.

Volume replacement

AP patients can be viewed similarly to the burn patient. Their major therapeutic regimen is adequate fluid resuscitation because they have hemoconcentration. AP, especially severe AP (SAP), results in vascular leak syndrome with hypovolemia and hypotension. This frequently causes acute tubular necrosis, renal failure, intestinal ischemia, and decreased pancreatic microcirculation resulting in necrosis.[11] The majority of fluid resuscitation should be given primarily in the first 24 hours to decrease the risk of SIRS and OF. The present regime for patients with SAP is infusion of Ringer's lactate given as a 1-liter bolus, followed by 250 to 300 cc/hr for 24 hours, depending on patient comorbidities; then reassess volume status and fluid needs. During this initial period, we follow frequent measurements of urine output, respiratory and cardiac rates, blood pressure, and changes in hematocrit/blood urea nitrogen (BUN). The goal in the early phase (up to 1 week) of AP is to prevent and treat OF as outlined in Box 47.1.

Prophylactic antibiotics

The basis for prophylactic antibiotics use was to prevent infection in patients with necrotizing AP. Mortality is higher in patients with

BOX 47.1

Prevention of necrosis and recognition of infection in acute pancreatitis

Prevention of necrosis
- Volume for appropriate fluid resuscitation
- No role for prophylactic antibiotics
- Enteral nutrition early in the course

Recognition of infection (bacterial/fungal)
- Unexplained fever, leukocytosis
- Organ system failure
- Hypotension
- Increasing abdominal pain
- CT with air in pancreatic fluid collection

Petrov MS, Kukosh MV, Emelyanov NY. A randomized controlled trial of enteral versus parenteral feeding in patients with predicted severe acute pancreatitis shows a significant reduction in mortality and in infected pancreatic complications with total enteral nutrition. *Dig Surg*. 2006;23(5–6):336–44; Marik PE, Zaloga GP. Early enteral nutrition in acutely ill patients: a systematic review. *Crit Care Med*. 2001;29(12):2264–70.

necrotic versus edematous or interstitial AP (up to 20% vs. 5%).[14] Once infection complicates necrosis, mortality increases to 30% to 40%. Therefore, prophylactic antibiotics would appear to be a reasonable therapeutic approach. However, this treatment has been shown *not* to be effective in a Cochrane Database systematic review of antibiotic therapy for prophylaxis against infection of pancreatic necrosis in AP by Villatoro et al. They found no benefit of antibiotics to prevent pancreatic necrosis infection or decrease mortality.[15]

Subgroup analysis of patients who received imipenem showed a significant decrease in pancreatic infection but no significant reduction in mortality. Antibiotics should only be administered early in AP patients who have suspected biliary sepsis as well as extra-pancreatic infection (i.e., urinary tract infection and/or positive blood cultures). In addition, antibiotic treatment should be used for suspected or diagnosed pancreatic or peripancreatic infections in the later phase (1–2 weeks) after onset of disease. The role of antibiotics in this phase is to allow the organization of the necrosis as well as delay surgery, usually until 4 weeks, as this is associated with decreased mortality versus early intervention. In addition, delay and use of antibiotics may allow for application of less invasive drainage procedures. In addition, as Adler and Runzi reported, antibiotic therapy alone can effectively treat a subgroup of patients with infected necrosis.[16,17]

An initial report by Runzi et al. of nonsurgical treatment of severe AP with IPN showed 16 patients who were treated with nonsurgical therapy alone had a 12% mortality rate.[17] This placed a wedge in the concept that all patients with IPN needed immediate open pancreatic surgical drainage. The currently accepted management is that IPN can generally be managed nonsurgically with antibiotics in the initial stage and that antibiotics alone can also be definitive therapy. The second concept is that surgery can be delayed, which allows the operative intervention to be performed electively and with less invasive intervention.

Recognition of infection

Recognition of infection in patients with necrotizing pancreatitis is based primarily on clinical suspicion and imaging (Box 47.1). Infection usually occurs during the so-called second phase of disease, 1 to 2 weeks after onset of necrotizing pancreatitis, when the patient's immune system is likely suppressed, thus increasing susceptibility to infection.[18] Clinically, the patient may have persistent or new-onset sepsis without another source (i.e., pneumonia, urinary tract infection). Bacteremia is a poor prognosis factor, and patients may have clinical deterioration with OSF despite maximum support. Contrast-enhanced CT may reveal gas bubbles within the pancreatic or peri-pancreatic necrosis, and while this is highly suggestive of infected necrosis, it can be the result of a fistula between the pancreatic collection and the bowel. Laboratory findings may include leukocytosis, acidosis, and positive blood culture. Previously, Barkin et al. described CT-guided percutaneous FNA for diagnosing pancreatic infection.[19] Presently, percutaneous pancreatic aspiration by FNA is not routinely utilized because of a high rate of false-negative aspirations. The role of FNA in the diagnosis of IPN was reported by van Baal et al.[20] who found that IPN can generally be diagnosed based on clinical or imaging signs of infection. FNA may be useful in patients with unclear clinical signs and/or no imaging signs of IPN. We also utilize FNA in patients who are clinically not responding to empiric antibiotic therapy as this may be due to bacterial antibiotic resistance and/or fungal infection. The impact of antibiotic-resistant bacterial and/or fungal infections on outcome of AP was reported by Moka et al.[21] They found fungal infection in 102/556 patients, of which 28/102 had fungal infection without bacterial infection. Culture-proven IPN collection was present in 161/556 (29%). Drug resistance to tigecycline was 21% in their series. Drug resistance and rate of fungal infection increased in patients with ICU stay and increased length of hospital admission. Our approach to patients with suspected pancreatic infection is empiric antibiotics and delay of intervention. This conservative approach for IPN was summarized by Mouli et al.[22] who reported that conservative management of IPN, with intravenous (IV) antibiotics and nutritional support with or without catheter drainage, was successful for 64% of patients (with a mortality of 12%) and that only 26% of patients required necrosectomy or additional surgery for complications. Thus, the currently adopted modified conservative approach is drugs, delay, and then drain/debride.

Role of enteral nutrition to prevent infection

Enteral nutrition (EN) when compared to parenteral nutrition (PN), in patients with AP reduces mortality, multiorgan failure (MOF), infections, and operative intervention. In addition, it reduces local septic complications as well as other local complications. Subgroup analysis of EN versus TPN in patients with SAP showed a relative risk of death in the EN group of 0.18 and a relative risk for MOF of 0.46.[23]

EN likely improves intestinal barrier function and prevents bacterial translocation (see the earlier section "When does pancreatic necrosis become infected?"). EN can be administered either via nasogastric or nasojejunal feedings. In patients with SAP who are

unable to tolerate oral liquids, EN should begin early in their course, within 48 hours of admission, as it significantly reduces MOF, pancreatic infection, and mortality. Petrov, in a systemic review on timing of artificial nutrition in AP, found that EN begun within 48 hours of admission versus TPN resulted in significant reduction in risk of MOF, pancreatic infectious complications, and mortality. These benefits were not found if EN was begun after 48 hours of admission.[24]

Approach and treatment of pancreatic infection

Mowbray et al. reported the microbial spectrum seen in IPN that revealed a high frequency of polymicrobial infection with predominance of enterococci, staphylococci, and *Escheria coli* bacteria.[25] In his own population, he found that pathogens causing IPN were predominantly gastrointestinal flora (i.e., *Enterococcus faecalis* and *faecium* and *E. coli*). Almost half of their patients grew multiple organisms. The median time to drainage was 29 days. Carbapenem antibiotics provided good antimicrobial coverage against these enteric microorganisms (see Box 47.2).

Sahr et al. reported culture results at a median of 45 days (mean 87 days) from the onset of AP. In their nontransfer group of patients, there was an almost equal distribution of single microorganism and polymicrobial cultures.[26] Predominant microorganisms were *Staphylococcus* spp. and *Streptococcus* spp. In the transfer group, of whom 80% were previously treated with antibiotics, infected WON was found in 70% of patients previously treated with antibiotics versus only 20% in patients without previous antibiotics. The most common microorganisms included *Candida* spp., *Enterococcus* spp., and coagulase-negative staphylococci.

The emergence of multidrug resistant (MDR) microorganisms is a major concern in treating critically ill patients, such as those with SAP. Lee et al. found MDR organisms in 63% of their 46 patients.[27] The most frequent MDR bacteria was methicillin-resistant *Staphylococcus aureus*. Transferred patients, as in other studies, had a higher incidence of MDR infections than did primary admitted patients, in a ratio of 2:1. Mortality was not significantly different in the patients with MDR infections versus those without. Conversely, Jain et al.[28] reported that IPN due to infection with MDR organisms was an independent predictor of mortality, whereas IPN by itself was not a predictor. This is explained likely by the improved present-day management of IPN with IV antibiotics, drainage, and minimally invasive necrosectomy. In this transferred group, almost half of patients had received prophylactic antibiotics.

Fungi, especially *Candida* spp., are the most frequently isolated fungi in patients with IPN.[29] *Torulopsis glabrata* is the second most common species in IPN. Primary fungal infections, which occur in the absence of intervention, may be more likely to occur in patients receiving TPN and in elderly patients. Fungal infections are being increasingly recognized in patients with a complicated course of AP, especially in those who received antibiotics.[30] Kochhar et al. reported primary fungal infections in up to 17% of patients with IPN and in up to 32% during their disease course (secondary fungal infection).[31] Reuken et al. found fungal pancreatic infections (FPI) in 46% of aspirates. These were predominantly caused by *Candida* spp. Increased risks for FPI were having previously received antibiotic therapy and for a longer duration (9 vs. 2 days).[30] This population had a lower long-term, 1-year survival (78% vs. 95%) than those with only bacterial infection. Other studies have questioned whether antibiotic therapy predisposes to fungal infection or whether FPI is simply an indicator of increased disease severity and comorbidities. Gram-positive bacteria are more common in patients with primary candida infection, whereas gram-negative bacteria are more common in secondary infections. Mortality is higher in secondary fungal infections.[31]

The clinical presentation of fungal infection mimics bacterial infection except for a more indolent course compared to bacterial infection.29 While there are no clinical features of fungal infection in patients with AP, it has been reported to occur 22 to 33 days from admission. Diagnosis can be via culture or polymerase chain reaction assay. Treatment with fluconazole or amphotericin B is appropriate for *Candida* spp., whereas amphotericin B is appropriate for *T. glabrata*. There is controversy over whether antifungal therapy changes the outcome. Werge et al. found no significant difference in mortality (21% vs. 13%) or OF between the group treated with antifungals after the first fungal finding compared with the group not treated or treated inadequately.[32] Similar to IPN from bacteria, minimally invasive debridement should be evaluated in the presence of ongoing infection and/or deterioration of clinical parameters.

BOX 47.2

Initial approach to acute pancreatitis patients with suspected infection during the course of acute pancreatitis by clinical features and/or imaging

- Culture blood or other fluid collection—ascites, pleural
- Begin carbapenem drugs if negative culture—meropenem or imipenem
- Failure to respond to antibiotics—evaluate for fine-needle aspiration with drainage

Treatment of infected pancreatic necrosis

Debridement or necrosectomy is a foundation of therapy for organized IPN, as shown in Table 47.1 and Box 47.3. This treatment is presently based on an organ-preserving approach, combined with maximization of removal of retroperitoneal debris and exudates. Our approach has evolved from open surgery to minimally invasive surgery. The surgical odyssey for patients with SAP has evolved from simple drainage to resection of necrosis, to debridement, and now to sequestration.[33] Bradley emphasizes that delayed complications may still require surgical intervention, including gastroduodenal or common bile duct obstruction by necrotic collections, fistulization of the necrotic collections into adjacent bowel, disconnected pancreatic duct syndrome secondary to pancreatic ductal necrosis, and intraperitoneal hemorrhage.[34] Presently, intervention is primarily

TABLE 47.1 **TREATMENT OF PANCREATIC INFECTION (4 D'S)**

Drugs	Empiric antibiotics, enteral nutrition
Delay	Watch and wait for 4 weeks to allow for localization of infection in a stable patient
Drain	Drainage initial modality can be done prior to 4 weeks
Debride	Minimal invasive approach by endoscopic transluminal, percutaneous catheter drainage, video-assisted retroperitoneal dissection

Modified from Besselink MGH. *Dig Liver Dis.* 2011; 43:421–422

applied sparingly to patients with IPN because the majority of patients with necrotizing pancreatitis have sterile necrosis, which can be successfully treated conservatively.[18] The conservative approach, known as the "step-up-approach" to patients with IPN, is advocated by Besselink.[35] It is based on allowing the inflammatory process to become localized (the so-called "delay"). Use of antibiotics is associated with decreased mortality, and the role of antibiotics is to prevent systemic sepsis ("drugs"). The approach then moves to minimally invasive procedures (percutaneous or endoscopic) to drain the infection ("drain"), and, last, to debridement ("debride"), again using minimally invasive methods (i.e., video-assisted retroperitoneal dissection [VARD] or endoscopic or percutaneous catheters).[33] This step-up-approach was found, when compared to open necrosectomy, to reduce mortality (12% vs. 40%) and cost. The step-up approach applies minimally invasive techniques (MITs), that are associated with less physiologic stress when compared with open surgical procedures and therefore less morbidity and mortality.[36] The MITs include percutaneous catheter drainage, endoscopic transluminal drainage and debridement, and retroperitoneal surgical necrosectomy. Initially, minimally invasive drainage was by percutaneous drainage alone. Minimally invasive percutaneous drainage is used to control sepsis in patients with IPN. All minimally invasive procedures including endoscopic therapy can be the final therapy needed or a bridge to definitive therapy and can be successfully applied, prior to 4 weeks, with no increase in complications.[37] The goal is removal of infected material and to allow reabsorption of remaining material. Thus, surgical intervention has changed from early open surgical necrosectomy with possibly an open incision to facilitate second debridement (multiple) to delayed operation for debridement of a localized infected area.[37]

BOX 47.3

When to consider drainage/debridement

- Walled-off pancreatic or peripancreatic infection optimal >4 weeks
- Patients with severe clinical deterioration resulting in ongoing organ failure
- Minimally invasive drainage/debridement can be utilized prior to 4 weeks without increased mortality

Guo Q, Hu WP. *Ann Surg*. 2017;265:e64–e65.

This delay in postponing surgical necrosectomy until 30 days after initial hospitalization is associated with decreased mortality. The drawback to this "delayed approach" may be an increase in fungal infections and infection with antibiotic-resistant organisms.

A follow-up study on the original patient groups that were randomized to a surgical step-up approach or open necrosectomy by Hollemans et al. reported that a significantly lower proportion of patients in the step-up group died or had major complications, including decreased incisional hernias, pancreatic exocrine insufficiency, and endocrine insufficiency. No differences were found in patients requiring additional drainage procedures or pancreatic surgery or in recurrent AP. Thus, the step-up approach is superior to open necrosectomy.[38] Van Baal et al. performed a systematic review of percutaneous catheter drainage (PCD) used in patients with suspected infected pancreatitis or sterile, symptomatic collections.[39] They found in this primarily retrospective study cohort that 71% were infected. Overall, 56% of all patients undergoing PCD did not require additional surgical necrosectomy. Complications were mostly internal and external fistulas. Mortality rate in infected patients was 15%. PCD of sterile pancreatic collections can introduce infection more so than percutaneous aspiration. In addition, the authors noted that PCD is a labor-intensive and time-consuming therapy (i.e., daily lavage of the catheter by the patient and frequent need for catheter replacement by the interventional radiologist).

Liang Ji et al. evaluated the risk factors for need of surgical necrosectomy after PCD of IPN.[40] They found on CT that the mean density of the necrotic fluid collection was an independent risk factor, emphasizing that PCD does not debride necrotic debris effectively, thus favoring the initial use of endoscopic drainage and debridement for IPN. Hollemans et al. also found that increasing amounts of pancreatic necrosis and heterogeneous collections were negative predictors for successful catheter drainage in infected necrotizing pancreatitis.[41] Hollemans et al. and the previous study by Liang Ji et al. also reported that MOF was also a negative feature. Thus, the catheter sizes used for percutaneous drainage allows for drainage primarily of fluids but limits the effective debridement of necrotic material, which is an especially important limitation in patients with MOF.[40]

PCD is an especially useful drainage procedure in patients who (1) cannot tolerate the anesthesia needed for endoscopic procedures, (2) when collections are too distant (>2 cm) from the stomach for endoscopic drainage, and (3) there is no window to allow for endoscopic drainage and debridement. Percutaneous drainage is usually CT-guided, and multiple catheters may be needed. Follow-up procedures using CT imaging are needed to upsize the catheter to facilitate drainage of debris. In addition, ongoing drainage from the

pancreatic duct may require endoscopic stent placement.[42] PCD can be combined with video-assisted endoscopic debridement and/or endoscopic drainage and debridement.

Surgical laparoscopic necrosectomy

Surgical laparoscopic necrosectomy (SLN) can be applied by itself, at the later stage of disease, and/or combined with other needed surgical procedures (i.e., cholecystectomy in patients with biliary AP). Its advantages over MIP include the more likely complete removal of necrotic infected material in a single session.[43] Its disadvantages include the need for general anesthesia and pneumoperitoneum, and it is overall more invasive, thus favoring MIP.

Video-assisted retroperitoneal debridement allows debridement via direct or guided (via PCD tract) placement of a scope into a retroperitoneal collection. It avoids pneumoperitoneum and entry into peritoneum as needed for open surgery, but it requires multiple procedures. It should be regarded as a possible next step for drainage of collections that previously had undergone PCD. Its complications include bleeding and colon perforation.[43] Open necrosectomy is being utilized less frequently for IPN but has a role in patients with complications (i.e., perforation). Noninvasive modalities each have advantages, and their combined use can improve patient outcomes.

Endoscopic transluminal drainage and debridement has become the initial step-up procedure for drainage of IPN. Endoscopic step-up was compared to an open surgical step by Bakker et al.[44] Eighty percent of their study population previously had catheter drainage, accounting for their high surgical complication rate. Endoscopic transgastric necrosectomy significantly reduced postprocedural interleukin (IL-6) levels compared with surgical necrosectomy. In addition, endoscopic transgastric necrosectomy did not cause new-onset MOF, which is a major cause of morbidity and mortality in AP (0% vs. 50% surgical), and it reduced the number of pancreatic fistulas.[44] Endoscopic drainage is becoming the primary step-up drainage/debridement procedure. The follow-up article by van Brunschot et al. from the same group randomly compared endoscopic necrosectomy to percutaneous catheter drainage followed, if needed, by VARD. Endoscopic necrosectomy prevailed because the rate of pancreatic fistulas and length of hospitalization were lower in the endoscopic group. The major complications and mortality did not differ. Thus, the endoscopic approach offers an incisionless approach over PCD (followed, if necessary, by VARD) to a very difficult problem.[45] Bang et al. compared outcomes of minimally invasive surgery, laparoscopy, or VARD with or without PCD to endoscopic approaches for patients with confirmed or suspected IPN in a randomized trial.[46] Overall, there was no difference in mortality (8.8 vs. 6.3 surgery). However, no patients developed enteral or pancreatic cutaneous fistula in the endoscopic group versus 28.1% in the surgical group, and the surgical group had significantly more complications compared to the endoscopy group. The endoscopy group had better quality of life scores and lower mean total costs. Nutritional support was provided to both groups.

Khan et al. conducted a systematic review and meta-analysis to compare the safety of endoscopic drainage (ED) with minimally invasive surgery for managing IPN.[47] They reported that the rate of mortality for ED was 8.5% versus 14.2% for minimally invasive surgery. The pooled odds ratio was 0.59 in favor of ED. Development of new MOSF rates after intervention was 12% for ED and 54% for MIS. ED was associated with significantly lower rates of pancreatic fistula formation and shorter length of hospital stay. Thus, ED is the preferred invasive management strategy over minimally invasive surgery.

Conclusion

Pancreatic infection is associated with increased mortality and morbidity compared with sterile pancreatic necrosis. Overall, these patients are best managed by "a city" that comprises a multidisciplinary team of specialists, including dedicated pancreatologists, infectious disease specialists, interventional endoscopists, radiologists, nutritionists, and surgeons. This team approach will result in improved survival with decreased morbidity. Our approach is the "4 D's":

1. Drugs—antibiotics and enteral nutrition
2. Delay intervention until the acute process is localized
3. Drain by a minimally invasive procedure/s
4. Debride—may be combined with drainage, as in endoscopic necrosectomy, to improve the outcome of patients with pancreatic infections. Surgery may be needed in select patients with complications.

Esophageal infections

Uni Wong and Jean-Pierre Raufman

Esophageal infections are commonly encountered in clinical practice and contribute significant morbidity, particularly in those with pathologic or iatrogenic impaired cellular immunity. Patients with AIDS encompass a large proportion of those with infectious esophagitis. However, with the increased use of highly active antiretroviral therapy (HAART) to treat HIV/AIDS, the risk of opportunistic esophageal infections has decreased in this patient population. Others who are particularly susceptible to opportunistic esophageal infections include those receiving chemotherapy, radiation, or immunotherapy for cancer, and those receiving immunosuppressants following solid organ or bone marrow transplantation.

Candida albicans is the most common pathogen underlying infectious esophagitis, but a variety of fungal, viral, and bacterial organisms are capable of triggering infection (see Box 48.1). Regardless of the causative organism, infection results in mucosal inflammation with hallmark symptom of odynophagia (painful swallowing). Erosions, ulcerations, and fistulae may occur. Prompt recognition with identification of the pathogen and initiation of therapy is of paramount importance because esophageal infections generally respond quickly to appropriate therapy.

Fungal infections of the esophagus

Candida species

C. albicans is the fungal organism most frequently implicated in infectious esophagitis. Other *Candida* spp. (*tropicalis, parapsilosis, krusei,* and *glabrata*) rarely cause disease in the absence of severe immunosuppression. *Candida* organisms are normal components of the oral flora; colonization of the esophagus is not unusual. In fact, a population-based study revealed colonization with *Candida* organisms in up to 20% of healthy adults. Rates of colonization are even higher—up to 80%—in those receiving critical care in an intensive care unit.

Progression to infectious esophagitis requires invasion of the epithelium, usually in the setting of defective cellular immunity. HIV infection, particularly when associated with CD4 counts of $<200/mm^3$ has long been an established risk factor for *Candida* esophagitis, an AIDS-defining illness. Other risk factors include hematological malignancies, diabetes mellitus, adrenal insufficiency, alcoholism, advanced age, radiation therapy (especially for head and neck cancers), systemic chemotherapy, systemic and topical oronasopharyngeal steroids, antibiotics, and suppressants of gastric acid secretion (e.g., proton pump inhibitors). Prolonged stasis of esophageal contents, for example in the setting of achalasia or scleroderma, may also predispose to epithelial invasion by microorganisms. Surprisingly, biologicals and immunomodulatory drugs used to treat inflammatory bowel diseases and rheumatoid arthritis do not appear to increase the risk of esophageal candidiasis.

BOX 48.1

Organisms associated with infectious esophagitis

Fungi

Candida spp. (especially *C. albicans*)
Aspergillus spp.
Histoplasma capsulatum
Blastomyces dermatitidis

Viruses

Herpes simplex virus type 1
Cytomegalovirus
Varicella-zoster virus
Human immunodeficiency virus
Human papilloma virus

Bacteria

Mycobacterium tuberculosis and *M. avium*
Actinomyces israelii
Staphylococcus aureus
Streptococcus viridans
Lactobacillus acidophilus
Treponema pallidum
Idiopathic ulcerative esophagitis in AIDS

Parasite

Trypanosoma cruzi

Clinical presentations

The symptoms of *Candida* esophagitis vary depending on severity of disease and the degree of host immunocompetency. Mild disease in immunocompetent hosts may cause minimal to no symptoms. When symptomatic, odynophagia is the most common complaint. In severe cases, patients may describe dysphagia (difficulty swallowing) and experience sitophobia (fear of eating). With severe inflammation and edema, some patients may even have difficulty tolerating oral secretions or experience chest pain even in the absence of swallowing. Particularly in profoundly granulocytopenic patients, disseminated candidiasis can result in fever, sepsis, and the development of fungal abscesses in the liver, spleen and kidneys.

Esophageal candidiasis is often associated with oropharyngeal thrush, but approximately 25% of the time *Candida* esophagitis occurs in the absence of thrush. In general, thrush has positive and negative predictive values for the presence of *Candida* esophagitis, in the range of 90% and 82%, respectively. A high index of suspicion remains necessary as the absence of thrush does not preclude the diagnosis of *Candida* esophagitis.

Notably, immunocompromised patients are at high risk for esophageal coinfection. The probability of viral coinfection in the setting of *Candida* esophagitis is reported as high as 50%. Cytomegalovirus (CMV) and herpes simplex virus (HSV) infections can be seen in HIV-infected patients with CD4 counts of <200/mm^3. Therefore, if odynophagia or dysphagia does not improve within 3 to 5 days on empiric therapy for *Candida* esophagitis, esophagoscopy is warranted to evaluate for existing coinfection.

Severe complications from *Candida* esophagitis are rare but can contribute substantially to the morbidity and mortality of the underlying disease. Low-grade upper gastrointestinal bleeding can occur with friability and ulcerations in the esophagus but generally does not require blood transfusion. Other complications include mucosal scarring and stricture, mucosal sloughing with replacement by pseudomembranes, and luminal obstruction from fungus balls. The most concerning complication associated with severe *Candida* esophagitis is the formation of fistulae from the esophagus to the trachea, bronchi, or mediastinum.

Diagnosis

Candida esophagitis should be suspected in any at-risk patients complaining of odynophagia or dysphagia. In the appropriate clinical setting, empiric therapy is recommended, and symptoms are expected to improve within 3 to 5 days in uncomplicated cases. However, due to the high frequency of coinfection, further evaluation with esophagoscopy is recommended for those not responding to treatment within 3 to 5 days.

Esophagoscopy with direct brushing and biopsy of abnormal mucosa remains the most accurate method to diagnose fungal esophagitis (Figure 48.1). Endoscopic findings of *Candida* esophagitis range from scattered white or pale yellow plaques (Figure 48.2A) to dense pseudomembranes consisting of fungi, sloughed mucosal cells, and fibrin overlying severely damaged mucosa. The latter findings are usually accompanied by severe symptoms. However, the endoscopic appearance alone is insufficient to diagnose *Candida* esophagitis. Brushings from the involved mucosa can be obtained with a sheathed cytology brush, spread onto slides, and stained with the periodic acid-Schiff (PAS), silver, or Gram methods. Mycelial forms and masses of budding yeast are consistent with *Candida* infection (Figure 48.2B). Fungal cultures are generally not needed unless an unusual pathogen (e.g., a resistant *Candida* species, such as *C. glabrata*) is suspected.

Due to nonspecific findings and high rates of coinfection, radiologic studies are generally not utilized to diagnose esophageal infections. Radiologic studies are useful, however, when esophagoscopy with biopsies is contraindicated due to severe thrombocytopenia or coagulopathy, or when a complication such as perforation, stricture, or fistula (severe dysphagia or coughing during meals) is suspected. Abnormal barium esophagrams may reveal a "shaggy" esophagus, plaques, pseudomembranes, cobblestoning, nodules, strictures, fistulae, or mucosal bridges.

Treatment

When *Candida* esophagitis is suspected in at-risk patients with complaints of odynophagia or dysphagia, empiric therapy should be initiated as soon as possible; endoscopic confirmation is

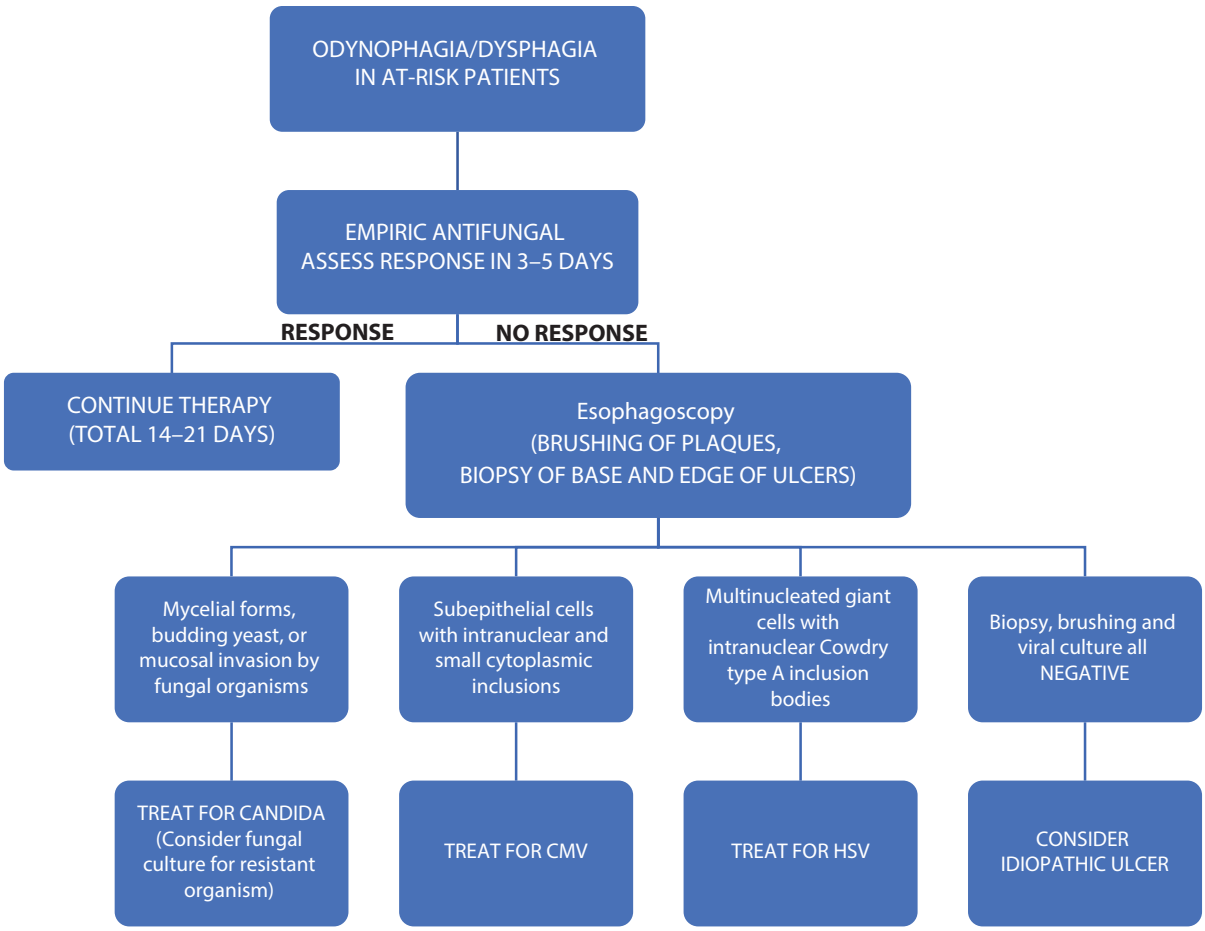

FIGURE 48.1 Suggested diagnostic approach to common esophageal infections.
CMV, cytomegalovirus; HSV, herpes simplex virus type 1.

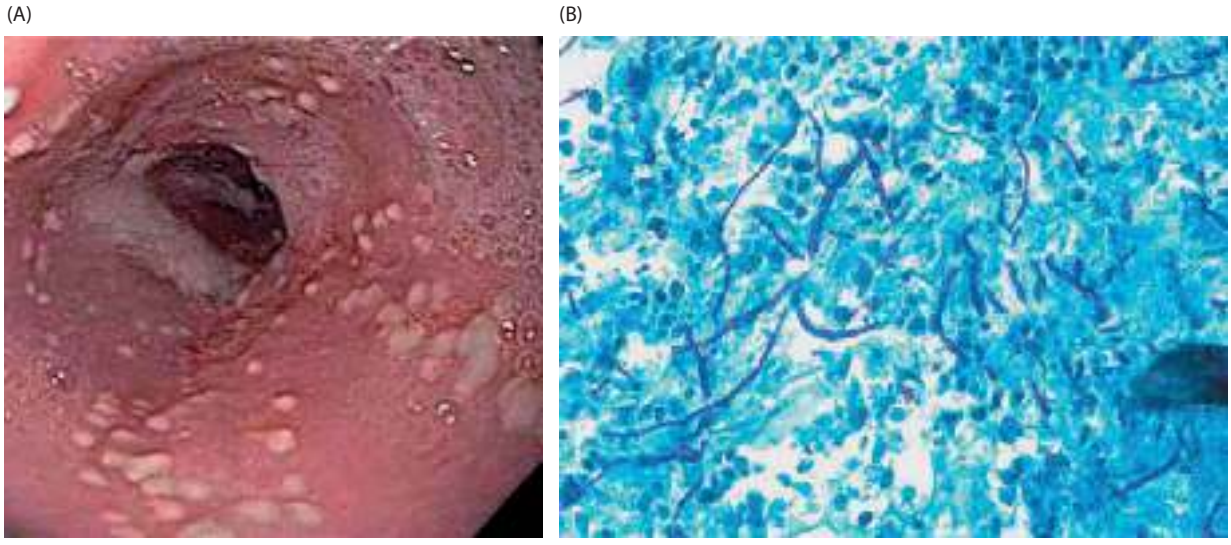

FIGURE 48.2 Endoscopic image of *Candida* esophagitis with multiple raised white plaques. (B) Biopsy revealing budding yeast cells, hyphae, pseudohyphae, and mucosal invasion by the organisms (periodic acid-Schiff 60×).
Courtesy of Harris Yfantis, MD, VA Medical Center, Baltimore, Maryland.

not required. Esophageal candidiasis always requires systemic rather than topical therapy. Treatment options include azoles, echinocandins, and amphotericin B. Azoles work by altering the fungal cell membrane permeability by inhibiting ergosterol synthesis. Echinocandins inhibit the synthesis of β(1,3)-D-glucan, an essential component of *Candida* cell walls. Amphotericin B binds irreversibly to fungal membrane sterols, thereby altering membrane permeability. If there is no response to empiric therapy within 3 to 5 days, esophagoscopy with biopsy and brushing is warranted to evaluate for coinfection.

According to the 2016 Update by the Infectious Diseases Society of America on the Clinical Practice Guideline for Management of Candidiasis, oral fluconazole remains the preferred first-line agent to treat esophageal candidiasis. Treatment with oral fluconazole (200–400 mg [3–6 mg/kg] daily) is recommended for 14 to 21 days. This is generally a safe, cost-effective approach. Toxicity is infrequent and the cost is low. Alternative therapies for those who cannot tolerate oral therapy include intravenous (IV) fluconazole (400 mg [6 mg/kg]) daily or an echinocandin such as micafungin (150 mg/d), caspofungin (70 mg loading dose followed by 50 mg/d), or anidulafungin (200 mg/d) for 14 to 21 days. Amphotericin B deoxycholate (0.3–0.7 mg/kg/d for 21 days) is a less favorable alternative due to the risk of renal toxicity. Once the patient can tolerate oral intake, switching to oral fluconazole (200–400 mg/d) is recommended.

For fluconazole-refractory infections, recommended therapies include itraconazole, voriconazole, micafungin, caspofungin, anidulafungin, and Amphotericin B deoxycholate. In randomized trials, itraconazole oral solution (200 mg/d) appears to be as effective as fluconazole but its use is limited by nausea. Absorption of the capsule form of itraconazole is unreliable compared to the solution. It is important to note that itraconazole inhibits the cytochrome p450 enzymes, thereby increasing the potential for drug interactions. In a large, randomized, double-blind, multicenter trial, voriconazole (200 mg [3 mg/kg] BID) was as effective as fluconazole; therefore, this is another alternative for fluconazole-refractory infection. Echinocandins (micafungin, caspofungin, anidulafungin) and Amphotericin B deoxycholate dosing for refractory *Candida* infection is the same as described earlier.

Patients with recurrent *Candida* esophagitis and those expected to remain on chemotherapy and/or corticosteroids should continue prophylactic fluconazole (100–200 mg three times per week). For HIV-infected persons, antiretroviral therapy (ART) is essential to minimize the risk of recurrent *Candida* infection. In addition, secondary prophylaxis should be considered in this population susceptible to frequent and severe infections until they achieve immune reconstitution on HAART. Fluconazole is generally well tolerated—the most common adverse reactions include headache, abdominal pain, nausea, vomiting, and diarrhea.

Another setting requiring special consideration is pregnancy. Imidazoles are teratogenic, and therefore fluconazole should not be used during the first trimester. Amphotericin B deoxycholate is the drug of choice to treat esophageal candidiasis during pregnancy. Echinocandins are not recommended due to lack of safety data in pregnant women.

Other fungal infections of the esophagus

Esophageal aspergillosis, histoplasmosis, and blastomycosis acquired from the environment rather than from endogenous flora are much less common than infection with *Candida* species. Blastomycosis and histoplasmosis generally invade the esophagus from paraesophageal lymph nodes. Esophageal blastomycosis and histoplasmosis are characterized by focal lesions and abscesses, whereas esophageal aspergillosis is characterized by large deep ulcers. Patients may complain of severe odynophagia if there is muscle layer involvement. Complications of esophageal stricture and tracheaesophageal fistulae are reported.

Viral infections of the esophagus

Herpes simplex virus type 1

HSV-1 is the most common herpesvirus infection of the esophagus, followed by CMV and varicella-zoster virus (VZV). HSV type 2 (HSV-2) infection of the esophagus is rare. HSV-1 esophagitis occurs most commonly in those on immunosuppressive therapy following solid organ and bone marrow transplantation, although infections in immunocompetent hosts are reported. Compared to posttransplant patients, HSV-1 infection occurs much less frequently in HIV-infected individuals (3–5%).

Most cases of HSV esophagitis result from reactivation of the virus in the root ganglia of nerves supplying the affected areas, such as the laryngeal, superficial cervical, and vagus nerves. Primary HSV esophagitis can occur through direct extension from oropharyngeal HSV infection when this double-stranded DNA virus invades the squamous epithelium of the esophagus.

As in fungal esophagitis, the presenting symptoms of HSV esophagitis are usually odynophagia and dysphagia. In some cases, symptom onset can be very abrupt. Other symptoms include chest pain, fever, nausea, and vomiting. Herpes labialis (i.e., cold sores) or oropharyngeal ulcers may precede or occur concurrently with esophageal infection. Approximately 25% of HSV esophagitis is accompanied by HSV or *Candida* infection in the oropharyngeal or genital area.

Immunocompetent hosts usually recover from HSV esophagitis within 1 to 2 weeks, although early use of antiviral therapy can hasten recovery. HSV esophagitis in immunocompromised hosts, on the other hand, can lead to esophageal hemorrhage, perforation with tracheoesophageal fistulas, food impaction, or dissemination to the liver, lungs, and central nervous system.

HSV esophagitis is usually diagnosed by endoscopy when at-risk patients fail to achieve symptomatic improvement after 3 to 5 days of empiric antifungal therapy (see Figure 48.1). In early-stage disease, vesicular herpetic lesions (round vesicles measuring 1–3 mm) may be observed in the mid to distal esophagus. More commonly, by the time endoscopy is performed, vesicles have sloughed to reveal discrete, punched-out, circumferential ulcers (usually <2 cm) with

raised edges (Figure 48.3A). On double-contrast barium studies of the esophagus, HSV esophagitis usually has a distinct appearance of volcano-like ulcers without plaques, whereas ulcerations in *Candida* esophagitis are usually seen with plaques. As disease progresses, however, the discrete HSV ulcers seen at early stages can coalesce into large lesions and can even progress to near-total denudation of the esophageal epithelium. Diffuse herpetic esophagitis can therefore lead to cobblestoning or a "shaggy" mucosa similar to the appearance of *Candida* esophagitis.

Establishing the diagnosis of HSV requires viral culture, histological or cytological examination of the endoscopic brushings, and biopsies obtained from the ulcer edges. HSV preferentially infects squamous epithelial cells, so viral cytopathic changes are most common at ulcer edges. Findings on histological examination of HSV-infected epithelial cells include multinucleated giant cells, ballooning degeneration, ground-glass nuclei and eosinophilic inclusions (Cowdry type A inclusion bodies), and margination of chromatin (Figure 48.3B). Immunohistochemical stains using monoclonal antibodies to HSV glycoproteins may also help establish the diagnosis. Viral culture is more sensitive than histological examination of the brushings and biopsy specimens and can be helpful if a resistant organism is suspected. Qualitative and quantitative polymerase chain reaction (PCR) testing has been used to detect HSV DNA from biopsy samples, although this has limited specificity and positive predictive value.

For immunocompromised patients able to take oral medications, the recommended therapy for HSV esophagitis is acyclovir (400 mg orally five times a day, renally adjusted if needed, for 14 to 21 days). Famciclovir (500 mg TID) and valacyclovir (1 g TID for the same duration) have similar efficacy as acyclovir but are more expensive. IV acyclovir (5 mg/kg q8h for 7–14 days) is recommended for those who cannot tolerate oral medications. Due to manufacturing shortages of IV acyclovir, oral acyclovir should be used to complete treatment when feasible. After 1 to 2 weeks, immunocompetent individuals usually have spontaneous resolution of HSV infection. Anecdotal reports suggest a short course of oral acyclovir (400 mg TID for 7–10 days) can accelerate recovery. Prophylaxis with oral acyclovir (or similar agent such as valacyclovir or famciclovir) should be considered in those remaining at risk for recurrent infection (e.g., undergoing treatment for organ rejection).

Resistant strains of HSV have emerged that typically exhibit cross-resistance to valacyclovir and famciclovir. With these infections, IV foscarnet (40 mg/kg TID) is recommended. Pritelivir, an investigational helicase-primase inhibitor, is currently being evaluated to treat acyclovir-resistant mucocutaneous HSV infection. Viscous lidocaine, often used for pain relief, has modest efficacy and the potential for systemic absorption and toxicity.

Cytomegalovirus

Unlike HSV esophagitis, CMV esophagitis occurs primarily in immunocompromised hosts; rare cases are reported in immunocompetent hosts. In healthy individuals with latent infection, CMV viral DNA can be detected in many tissues, including circulating leukocytes. Latent infection is responsible for the high transmission rate of the virus from CMV-seropositive donors to CMV-seronegative recipients after blood transfusion or organ transplantation. Most cases of CMV esophagitis occur in those with advanced immunosuppression, including AIDS with CD4 counts of <50 cells/mm^3 and CMV viremia. The onset of symptoms is typically more gradual with CMV compared to HSV or *Candida* esophagitis. In addition, odynophagia may be accompanied by fever, nausea, and substernal burning pain.

Endoscopy with biopsy is essential to diagnose esophageal CMV infection (see Figure 48.1). Findings can vary from superficial erosions to large, shallow, well-circumscribed ulcers, most commonly located in mid to distal esophagus. Biopsies should be targeted at the ulcer bases, where CMV-infected subepithelial fibroblasts

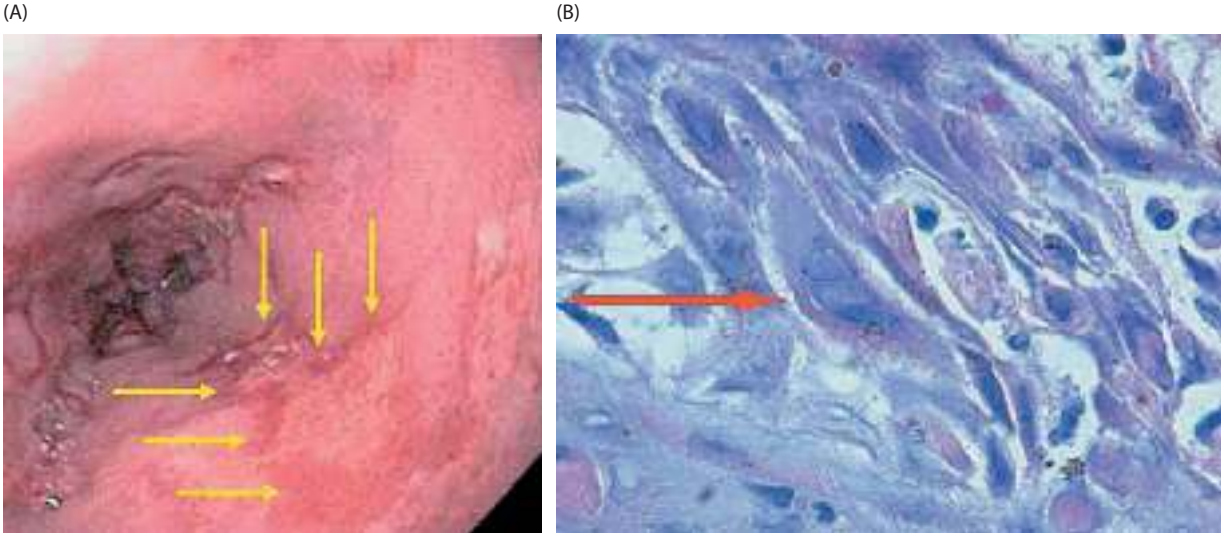

FIGURE 48.3 Endoscopic image revealing a large sharply demarcated ulcer with raised edges in mid esophagus. Ulcer borders are defined by arrows. (B) Biopsy from the ulcer margin demonstrating a multinucleated giant cell (hematoxylin and eosin stain, 100×).
Courtesy of Harris Yfantis, MD, VA Medical Center, Baltimore, Maryland.

and endothelial cells are most likely present. Superficial brushings for cytologic examination have low diagnostic yield. Histological features of CMV infection include the presence of large cells in the subepithelial layer with eosinophilic intranuclear inclusions, a "halo" around the nucleus, and basophilic intracytoplasmic inclusions (Figure 48.4A). Immunohistochemical staining and in situ hybridization can confirm CMV infection (Figure 48.4B), but viral cultures of tissue obtained from ulcer bases are most sensitive and least costly.

Detecting CMV DNA in blood or tissue and/or a positive CMV antibody does not confirm active CMV infection. In a study of patients with advanced AIDS and CMV viremia detected by PCR, fewer than half developed CMV disease after 1 year despite not receiving anti-CMV therapy. While CMV antibody positivity is not helpful in confirming disease, CMV seronegativity suggests an alternate etiology since infection often results from reactivation of latent virus.

Notably, CMV retinitis often occurs concurrently with extraocular CMV infection. Therefore, any patient diagnosed with CMV gastrointestinal disease should have formal ophthalmological screening for retinitis. An initial negative ophthalmologic exam should be repeated for any new visual symptom or followed by serial exams every 6 months until the patient's absolute CD4 cell count is restored to >50 cells/mm^3 with the use of ART.

If the index of suspicion for CMV esophagitis is high (CD4 cell count <50 cells/mm^3 and characteristic endoscopic finding) in someone with severe symptoms, empiric antiviral therapy should be considered. Both ganciclovir and foscarnet are effective treatment options for CMV esophagitis. Due to the risk of renal toxicity with foscarnet, ganciclovir (5 mg/kg IV q12h for at least 3 weeks) is the preferred option. However, foscarnet (90 mg/kg q12h for at least 3 weeks) is preferred for those with refractory leukopenia or thrombocytopenia, and/or when there is concern for ganciclovir resistance. The combination of ganciclovir and foscarnet has been used in resistant disease. Those who respond slowly may need up to 6 weeks of treatment. Maintenance therapy with valganciclovir (900 mg/d) is suggested in patients with recurrent infection until CD4 cell counts of >100 cells/mm^3 are sustained for at least 6 months on ART.

Restoration of a healthy immune system is key to prevent recurrent CMV infection. Most AIDS patients with CMV esophagitis are not on ART. For patients who are ART-naïve, ART should be initiated as long as CMV retinitis has been excluded. ART can induce immune reconstitution inflammatory syndrome (IRIS) in the eyes of patients with CMV retinitis, resulting in blindness. Therefore, in ART-naïve patients with CMV retinitis, anti-CMV therapy should precede ART by at least 2 weeks.

Varicella-zoster virus

VZV esophagitis is rarely symptomatic, and the incidence rate is uncertain. In immunocompromised individuals, VZV esophagitis can be severe but considerably minor compared to disseminated infections including varicella encephalitis, pneumonitis, and fulminant hepatitis. The clinical presentation and endoscopic finding of VZV are similar to those of HSV esophagitis. Dermatologic VZV lesions often occur concurrently with esophagitis, aiding diagnosis. VZV esophagitis may be treated with acyclovir and famciclovir. Foscarnet can be considered in acyclovir-resistant VZV infection.

Idiopathic esophageal ulcers in AIDS

HIV infection is occasionally associated with esophageal ulcers that lack an identifiable pathogen. These lesions, known as *HIV-associated* or *idiopathic esophageal ulcers*, appear as multiple, small aphthoid ulcers during seroconversion in early HIV infection that eventually become giant deep ulcers extending up to several centimeters (Figure 48.5). The latter are associated with severe, incapacitating odynophagia. The clinical, radiologic, and endoscopic appearance of these HIV-associated esophageal ulcers mimic those of CMV esophagitis but without the histological features of CMV infection. Initiation of HAART therapy is essential in healing these ulcers. Systemic and intralesional corticosteroids have been reported to provide symptomatic and endoscopic improvement.

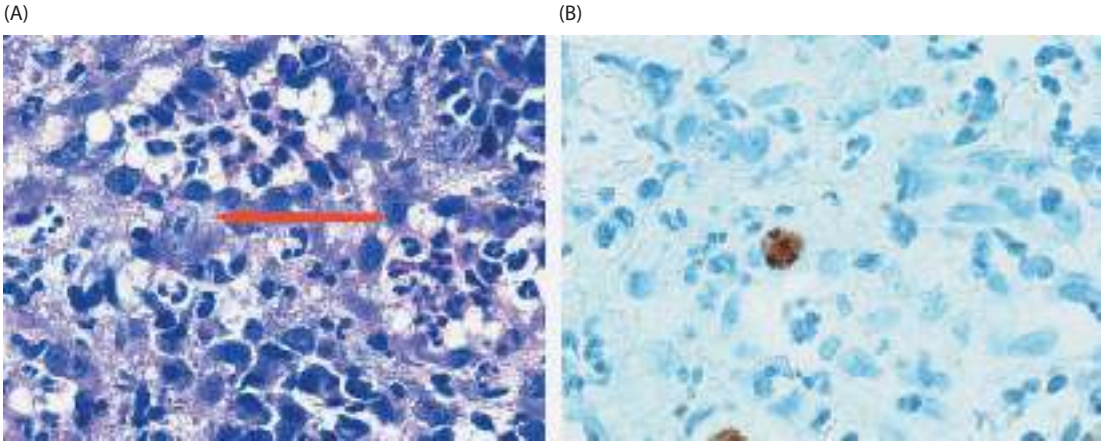

FIGURE 48.4 (A) Biopsy specimen from base of the an esophageal ulcer revealing a perinuclear "halo" suggestive of herpes simplex virus infection (hematoxylin and eosin stain, 100×). (B) Biopsy specimen revealing subepithelial cytomegalovirus by immunohistochemical staining (100×). Courtesy of Harris Yfantis, MD, VA Medical Center, Baltimore, Maryland.

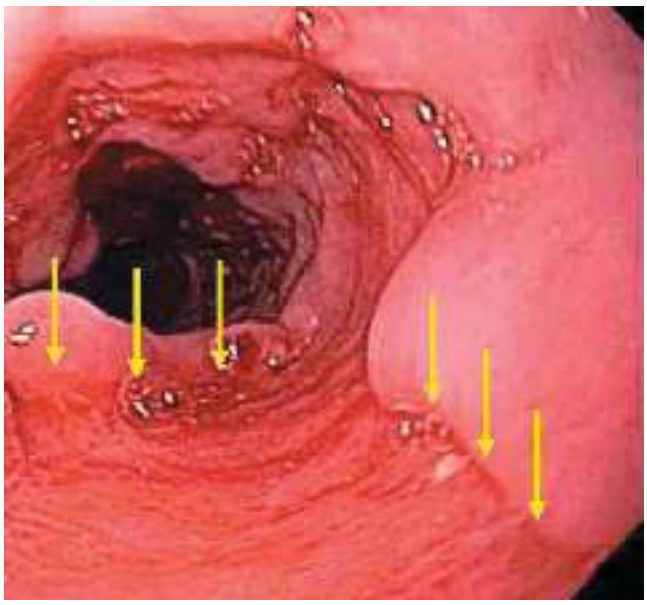

FIGURE 48.5 Endoscopic photograph of a large idiopathic esophageal ulcer crater in a patient with AIDS and odynophagia. Ulcer borders are defined by arrows.

Human papillomavirus

Human papillomavirus is a small DNA virus that infects squamous epithelia after sexual transmission. Warts and condylomata in the esophagus from HPV infection are usually asymptomatic and do not require treatment unless large lesions cause mechanical obstruction. Endoscopic findings include erythematous macules, nodules, plaques, or exophytic lesions found most commonly in the mid to distal esophagus. Diagnosis is based on histological findings of koilocytosis (atypical haloed nucleus), giant cells, or positive immunostaining.

Bacterial, mycobacterial, treponemal, and parasitic infections

Invasive bacterial infections of the esophagus account for a small proportion (11–16%) of infectious esophagitis in immunocompromised hosts. Use of gastric acid–suppressing medication, such as proton pump inhibitors, may increase risk of bacterial esophagitis. Similar to fungal or viral esophagitis, odynophagia and dysphagia are the most common presenting symptoms. Endoscopic findings are nonspecific, including mucosal friability, plaques, pseudomembranes, and ulcerations. Bacterial organisms can be detected on diagnostic biopsies. Standard therapy consists of a broad-spectrum β-lactam antibiotic combined with an aminoglycoside.

Mycobacterium tuberculosis and *avium* infections of the esophagus are rare. Esophageal involvement with tuberculosis often results from direct extension of the infection from mediastinal structures, with few cases of primary esophageal tuberculosis. Clinical presentations include odynophagia, dysphagia, weight loss, cough, chest pain, and fever. Endoscopic findings include shallow ulcers, malignant-appearing ulcerating lesions, and extrinsic compression of the esophagus from regional adenopathy. Biopsies often do not show caseating granulomas (sensitivity 25–60%) as the density of the tuberculous granulomas in the infected organ may be low. In suspected cases, deep tissue sampling of the submucosal layer is required to establish the diagnosis. Tissue biopsies and brushings should be sent for histology, routine culture, mycobacterial culture, acid-fast staining, and PCR. Mycobacteria infection of the esophagus is treated with standard multidrug therapy, guided in part by the sensitivity pattern in the community. Endoscopic stenting and surgery are sometimes needed to treat complications including fistulas and strictures.

Esophageal syphilis is extremely rare; dysphagia may occur many years after the initial infection. Classically, tertiary syphilis may be associated with gummas, diffuse ulcerations, fistulas to trachea, and stricture of the upper third of the esophagus. Diagnosis is suspected when syphilitic periarteritis is present on biopsy specimens, but immunostaining for *Treponema pallidum* should be performed for definitive diagnosis. Endoscopic and surgical interventions are warranted for strictures and fistulas, and penicillin is the antibiotic of choice for those without complications.

Trypanosoma cruzi, a protozoan endemic in parts of South and Central America, can lead to progressive destruction of nerve ganglion cells: *Chagas disease*. The esophagus and lower esophageal sphincter manifestations of Chagas disease include achalasia and megaesophagus. As a result, dysphagia is the most common presenting symptom. When compared to idiopathic achalasia, Chagas-related achalasia is associated with reduced pressure at the lower esophageal sphincter as a result of impaired excitatory and inhibitory innervation. Vasodilators including nitric oxide may improve emptying of the megaesophagus and lessen dysphagia, but their use is limited by side effects. Gastroesophageal junction myectomy and esophagectomy have been performed for refractory disease.

Gastroenteritis

Douglas R. Morgan, Vivian Chidi, and Robert L. Owen

Gastroenteritis

Gastroenteritis, broadly defined, refers to any inflammatory process of the stomach or intestinal mucosal surface. However, the term usually refers to acute infectious diarrhea, a diarrheal syndrome of less than 2 weeks' duration, which may be accompanied by fever, nausea, vomiting, abdominal pain, dehydration, and weight loss. This chapter provides an overview of the infectious enteritides. Other chapters consider food poisoning, travelers' diarrhea, antibiotic-associated diarrhea, sexually transmitted enteric infections, and *Helicobacter pylori* disease.

Gastroenteritis in high-income countries (HICs), similar to upper respiratory infections, is common and an inconvenience, but it usually does not require a physician visit, laboratory evaluation, or antibiotic treatment. In a US surveillance network with a population-based telephone survey of 12 075 adults (1998–1999), about 0.72 episodes per person-year were documented. In the 2009 US National Ambulatory Medical Care Survey, diarrhea was the second leading gastrointestinal (GI) symptom prompting an outpatient clinic visit, an estimated 4.2 million in total. The Centers for Disease Control and Prevention (CDC) estimates that known foodborne pathogens account for an estimated 14 million illnesses, 60 000 hospitalizations, and 1800 deaths. In the United States in children, it is estimated that acute diarrhea causes 300 to 400 deaths annually. Globally, gastroenteritis is the second principal cause of mortality, after cardiovascular disease. It is the leading worldwide cause of childhood death and of years of productive life lost, with approximately 12 600 deaths per day. Annual per-person attack rates range from 5 to 20 in the low- and middle-income countries (LMICs).

Pathophysiology

The GI tract is remarkably efficient at fluid reabsorption. Normally, of the 1 to 2 L of fluid ingested orally and the 7 L that enter the upper tract from saliva, gastric, pancreatic, and biliary sources, less than 200 mL of fluid are excreted daily in the feces. Thus, small increases in secretory rate or decreases in the absorptive rate can easily overwhelm the intestinal absorptive capacity. Diarrhea is generally defined as increased frequency (more than three bowel movements) or increased volume (>200 mL/day).

Intestinal infection with bacteria, viruses, and parasites that produce gastroenteritis usually follows fecal–oral transmission. Multiple host defenses are in place to protect the human GI tract (Table 49.1). The principal defenses include gastric acidity and the physical barrier of the mucosa. A gastric pH less than 4.0 will kill more than 99% of ingested organisms, although rota-virus and protozoal cysts can survive. Patients with achlorhydria or hypochlorhydria from chronic atrophic gastritis, gastric surgery, human immunodeficiency

TABLE 49.1 **HOST DEFENCES**

Host defense factor	Example disease state
Barrier	
Gastric acid	Achlorhydria (PPI, HIV, gastric surgery)
Mucosal integrity	Mucositis (chemotherapy)
Intestinal motility	
Peristalsis	Blind loop, antimotility drugs, hypomotility states (diabetes, scleroderma)
Commensal microflora	Antibiotics, age extremes
Sanitation	Contaminated water
Intestinal immunity	
Phagocytic	Neutropenia
Cellular	HIV
Humoral	IgA deficiency

TABLE 49.2 **VIRULENCE FACTORS**

Virulence factors	Examples
Inoculum size	*Shigella, Entamoeba, Giardia*
Adherence	Cholera, EPEC
Invasion	*Shigella, Salmonella typhi, Yersinia*, EIEC
Toxins	
Enterotoxin	Cholera, *Salmonella*, ETEC
Cytotoxin	*Shigella, Clostridium difficile*, EHEC
Neurotoxin	*Clostridium botulinum, Staphylococcus aureus, Bacillus cereus*

Abbreviations: EPEC = enteropathogenic *Escherichia coli*; EIEC = enteroinvasive *E. coli*; ETEC = enterotoxigenic *E. coli*; EHEC = enterohemorrhagic *E. coli*.

virus (HIV) infection, or proton pump inhibitor (PPI) use are at increased risk of developing infectious diarrhea. Disruption of the mucosal barrier, as with mucositis associated with chemotherapy or irradiation, may predispose patients to gram-negative bacteremia. Increased peristalsis in gastroenteritis propels organisms along the GI tract, analogous to the cough reflex with clearing of the lungs. The intestinal flora forms an important element of the host defense, both in terms of quantity and composition. The small intestine and colon contain approximately 10^4 and 10^{11} organisms per mL, respectively. More than 99% of the colonic bacteria are anaerobes. Their production of fatty acids with an acidic pH and their competition for mucosal attachment sites prevent colonization by invading organisms. At the extremes of age, in children and the elderly, and after recent antibiotic use, the flora is altered and the risk for gastroenteritis may be increased in some individuals. Impairment of intestinal immunity is also a risk factor for intestinal infections.

Virulence factors play a complementary role in acute infectious diarrhea. Whether an individual ingests an inoculum sufficient to establish clinical gastroenteritis is directly related to the organisms, community sanitation, and personal hygiene. Most organisms require an inoculum of 10^5 to 10^8 to establish infection. Exceptions include *Shigella* and protozoa such as *Giardia, Cryptosporidium*, and *Entamoeba*, which may cause diarrhea when only 10 to 100 organisms are ingested. Certain bacteria may produce toxins, which lead to a variety of clinical syndromes, and include enterotoxin (watery diarrhea), cytotoxin (dysentery), and neurotoxin. Botulinum toxin is the classic example of a preformed neurotoxin, but interestingly, both *Staphylococcus aureus* and *Bacillus cereus* also produce neurotoxins, which act on the central nervous system to produce emesis. Adherence and invasion factors facilitate colonization and contribute to virulence. Various forms of *Escherichia coli* express the gamut of virulence factors (Table 49.2).

Clinical syndromes

The acute infectious diarrheas can be divided into noninflammatory, inflammatory, and invasive (Table 49.3). Overall in the United States, the most common bacterial or protozoal pathogens in the acute setting are *Campylobacter*, *Salmonella*, *Shigella*, *E. coli* O157:H7, and more recently, *Clostridium difficile*. While the majority of noninflammatory episodes are viral, the more severe cases are often bacterial. The bacteria causing a noninflammatory diarrhea, such as *Vibrio cholerae* and enterotoxigenic *E. coli* (ETEC), typically secrete an enterotoxin, which affects the small intestine, producing a large volume of watery diarrhea without fecal leukocytes. Most forms of viral gastroenteritis fall into this group. The four most common enteric viral infections are norovirus, rotavirus, adenovirus, and astrovirus. The three most common parasites responsible for noninflammatory diarrhea are *Cryptosporidium*, *Giardia*, and *Cyclospora*.

The inflammatory diarrheas typically affect the colon, causing frequent small-volume stools, often with fecal white cells and either occult or gross blood. Fever, tenesmus, and bloody diarrhea are characteristic of dysentery. A pathogen is identified in about one-fifth of cases of bloody diarrhea, most commonly, enterohemorrhagic (EHEC) *E. coli* O157:H7, *Shigella*, *Campylobacter*, and *Salmonella*. Certain bacteria that cause inflammatory diarrhea produce cytotoxins. The invasive diarrheas may be considered a subset of the inflammatory diarrheas with invasion of the intestinal mucosa, and a propensity to cause bacteremia and distant disease. *Salmonella typhi* is the prototype. Typhoid bacteria are taken up and proliferate within the Peyer's patches of the distal ileum, then disseminate and multiply in the reticuloendothelial system to produce systemic disease. *E. coli* O157:H7 in human and animal studies has been shown to affect both the small and large intestines often with hemorrhage noted throughout. Both the *Shigella* and the EHEC pathogens have been associated with sequelae such as hemolytic-uremic syndrome (HUS) and thrombotic thrombocytopenic purpura (TTP).

Patients with neutropenia, particularly with an absolute neutrophil count <500/mm^3 and secondary to immunodeficiency or cytotoxic medications (e.g., bone marrow transplantation) can develop

[a] Formerly known as the Norwalk agent or calicivirus.

neutropenic enterocolitis or typhlitis (from *typhlon*, the Greek term for cecum). In these patients, cytotoxic mucosal injury and neutropenia affect host defenses and mucosal integrity to allow invasion and produce fever, abdominal pain (often right lower quadrant), watery or bloody diarrhea, and thickening of the bowel wall on computed tomography (CT) imaging.

Certain populations of patients with gastroenteritis merit surveillance because of the organisms involved, the potential for severe disease, and the possible need for intervention (Table 49.4). Foodborne disease should be considered in outbreaks of acute GI symptoms affecting two or more persons. The most common causes include *Salmonella* species, *Campylobacter*, *Shigella* species, EHEC (Shiga toxin), *B. cereus*, and the parasites *Cryptosporidium* and *Cyclospora* (see Chapter 50, Food poisoning). The microbial pathogens responsible for travelers' diarrhea are dependent upon the region visited, with some of the most common being enteroaggregative *E. coli* (EAEC), ETEC, *Salmonella*, *Campylobacter*, and *Shigella* (see Chapter 121, Travelers' diarrhea). Patients with advanced acquired immunodeficiency syndrome (AIDS), particularly with CD4 counts <50/μL, are predisposed to a number of unique infections (microsporidia, *Cyclospora*, *Cystoisospora*—formerly known as isosporiasis, cytomegalovirus) which may be chronic, and more severe manifestations of otherwise common infections *(Salmonella, Campylobacter, Cryptosporidium)*. Acute infectious proctitis, which is often sexually transmitted, leads to tenesmus, hematochezia, and rectal pain. Syphilis, gonorrhea, and chlamydia are additional organisms to consider. The incidence of sexually transmitted proctitis is decreasing in the AIDS era with safer sex practices. Other important subpopulations include patients with antibiotic-associated diarrhea, especially those from hospitals or chronic care facilities (see Chapter 51, Antibiotic-associated diarrhea). *Helicobacter pylori* is the most common chronic bacterial infection in the world, and is associated with chronic gastritis, peptic ulcer, gastric adenocarcinoma, and gastric MALToma (Chapter 138, *Helicobacter pylori* infection).

Gastroenteritis is a major cause of global mortality and morbidity among infants and children. In HICs, acute diarrheal illnesses account for an estimated 7% of pediatric ambulatory visits and hospitalizations. Peak attack rates involve young schoolchildren and their younger siblings. Most cases are caused by viral agents: rotaviruses (10% to 50%), *Norovirus* (Norwalk agent, 10% to 30%), and the enteric adenoviruses (2% to 5%). Bacterial agents cause less than 15% of disease but may cause severe disease in patients with *Campylobacter* species, *E. coli* species, *Salmonella* species, or *Yersinia* species. EHEC O157:H7 is an important cause of hemolytic-uremic syndrome in children. *Yersinia* causes a watery diarrhea in children ages 1 to 5, but it may mimic appendicitis in older children and adolescents. Important pathogens in day-care and institutional settings are the above-mentioned bacterial species, as well as *Giardia lamblia, Cryptosporidium* species, and *C. difficile*.

Patient evaluation

Most cases of acute gastroenteritis are self-limited and do not require medical attention. Physician consultation generally is advised for patients with a fever (>38.5°C [101.3°F]), dysentery (bloody stools), significant abdominal pain, dehydration, and risk factors for disease requiring intervention (e.g., elderly, pregnancy, recent antibiotic use). Initial evaluation consists of the history, physical examination, and screening stool examination. Laboratory testing and antimicrobial therapy are recommended in a limited subset of patients based on this initial evaluation, which is underscored by the

TABLE 49.4 **ETIOLOGIC AGENTS BY CLINICAL PRESENTATION**

Population	Bacteria	Viruses	Parasites	Other

fact that overall few stool cultures will be positive (1.5% to 9%), of which only a minority will have indications for antibiotic therapy.

The history should focus on the severity of disease and the risk factors for specific types of infectious diarrhea. The patient should be questioned regarding symptom duration, fever, abdominal pain, tenesmus, and dehydration. The description of the diarrhea is important: frequency, volume, and any blood, pus, or mucus. Diarrhea persisting longer than 2 to 4 weeks qualifies as chronic, with an alternate differential, and should be fully investigated. Inquiry should also be made into factors that may place the patient in a specific subgroup at increased risk for significant infection. Examples include advanced age (over 70), pregnancy, recent international travel or camping, recent antibiotic use, immunosuppression (e.g., HIV, prednisone therapy, chemotherapy), anal intercourse, seafood consumption, household contacts of day-care workers or children, and the potential for a common source outbreak (e.g., friends or relatives with similar symptoms). Short incubation periods of less than 6 hours, or 6 to 16 hours, suggest ingestion of an enterotoxin produced by *S. aureus* and *B. cereus*, or *Clostridium perfringens*, respectively. Vomiting may be the dominant complaint with viral infections and food poisoning (*S. aureus*, *B. cereus*, noroviruses [Norwalk-like]).

A broad differential diagnosis is initially appropriate as acute diarrhea may be the initial presentation of noninfectious and potentially life-threatening diseases. Important etiologies to consider include inflammatory bowel disease, mesenteric vascular disease, GI hemorrhage, and hyperthyroidism. Patients should be questioned regarding the use or recent initiation of medications that may cause diarrhea, such as ACE inhibitors, metformin, colchicine, diuretics, PPIs, magnesium-containing antacids, and sorbitol.

The physical examination is helpful to gauge the severity of the disease. Orthostasis, tachycardia, decreased skin turgor, and dry mucous membranes are signs of significant dehydration. The presence of fever, abdominal tenderness, and skin rash should be documented. All patients should undergo a rectal examination when rectal bleeding is reported.

Patients who present for medical evaluation may warrant a screening stool examination, based upon the history and physical exam. A fresh-cup specimen is preferred because there is evidence that swab and diaper specimens have decreased sensitivity.

The stool should be evaluated for fecal leukocytes and fecal occult blood. Some studies in the literature have questioned their utility, sensitivity, and specificity, but they can be helpful to suggest a bacterial etiology (Table 49.5). Fecal leukocytes are detected in the clinical laboratory either with staining techniques or with lactoferrin testing. Microscopic examination of the stool is facilitated by the methylene blue stain. A wet mount is prepared with two drops of methylene blue mixed with fecal mucus; 2 minutes should be allowed for adequate staining of the leukocyte nuclei before high-power microscopy of the cover-slipped slide. The presence of three or more fecal leukocytes per high-powered field in at least four fields is considered a positive examination. The fecal lactoferrin latex agglutination assay appears to be a more precise marker of fecal leukocytes. With fecal leukocytes, there is some overlap between the inflammatory and noninflammatory diarrheas. The finding on screening stool examination of either fecal leukocytes, lactoferrin, or occult blood has equal predictive values for diffuse colonic disease, positive stool cultures, and disease requiring antimicrobial therapy. The organisms most commonly associated with a positive screening test include *Salmonella, Shigella, E. coli* O157, *Campylobacter, Yersinia, Aeromonas, Vibrio*, and *C. difficile*.

The history, physical examination, and office stool evaluation are screening steps prior to further laboratory evaluation and consideration of treatment. As noted, most patients require only symptomatic therapy for a self-limited, noninflammatory infectious diarrhea. Laboratory evaluation is indicated in patients with the following findings or risks: severe or persistent disease (fever greater than 38.5°C, dehydration, grossly bloody stools, duration of more than 1 week), at-risk subpopulations (see above), and those with a positive stool screening examination (fecal leukocytes or occult blood). In these cases, the initial laboratory evaluation should include a complete blood count, serum electrolytes, and stool processed for bacterial culture. Stool cultures can identify *Salmonella, Shigella*, and *Campylobacter*, *E. coli* O157, *Yersinia* and *Aeromonas*. Many stool cultures are ordered inappropriately. The probability of a positive culture is less than 2% to 5% for patients without fever, occult blood, or fecal leukocytes. The yield increases to approximately 20% and 50%, respectively, when one or two of the three findings are present. Stool examination for ova and parasites is not cost-effective, and should be limited to patients with appropriate risk factors (e.g., appropriate travel history, day-care infant exposure, bloody diarrhea). Formed stools should not be sent for testing. Patients hospitalized for more than 3 days, who subsequently develop diarrhea are unlikely to have a bacterial or parasitic pathogen, and stool cultures are inappropriate, with *C. difficile* being the exception.

Additional laboratory or diagnostic evaluation will depend upon the clinical situation. Routine stool examination for ova and parasites is not recommended. Studies for parasites are indicated in the setting of persistent diarrhea, international or wilderness travel, AIDS, and infants attending a day-care center (or their caretakers). Fecal leukocyte-negative, bloody diarrhea has been associated with *Entamoeba histolytica, Schistosoma, Dientamoeba fragilis*, and *Balantidium coli*. The sensitivity of three ova and parasite examinations on three separate days is 95% to 98%. Stool testing for *C. difficile*, previously reserved for those with a history of antibiotic use or hospitalization, is now broadened with the current epidemic and advent of community-acquired infection. Differentiation of pathogenic and nonpathogenic strains of *E. coli* requires specific serotyping, although testing for *E. coli* O157:H7 is now commonplace. Commercial enzyme immunoassay kits are available for detection of rotavirus and enteric adenovirus and may be useful in the pediatric population and in elderly patients. Colonoscopy is rarely needed, but is appropriate where the differential includes ischemic colitis, inflammatory bowel disease, or other etiologies which require visualization or biopsy (e.g., immunocompromised patients, individuals with concern for *C. difficile* with negative stool studies). In addition, cross-sectional abdominal imaging (e.g., CT scan) may be helpful in complex presentations to help differentiate infectious and noninfectious causes of acute diarrhea and/or bleeding.

The initial evaluation of AIDS-associated diarrhea should include stool examination for culture, ova and parasites, and acid-fast stain. Specialized stool studies are required for the detection of *Cryptosporidium, Cyclospora*, microsporidiosis, and *Cystoisospora belli*. Mucosal biopsies are required for the diagnosis of cytomegalovirus (cytopathogenic effect) and *Mycobacterium aviumintracellulare* complex (MAC). Sigmoidoscopy may be considered for persistent or severe cases in patients with CD4 counts less than 100/μL and for those who have experienced weight loss. Colonoscopy/ileoscopy and upper endoscopy generally are reserved for refractory cases.

TABLE 49.5 **FECAL LEUKOCYTES**

Present	Variable	Absent
Campylobacter	*Salmonella*	Toxigenic bacteria
Shigella	*Yersinia*	ETEC, EPEC
EIEC, EHEC	*Clostridium difficile*	Viruses
	Vibrio parahaemolyticus	Parasites
	Noninfectious causes: ischemic colitis, IBD	

Abbreviations: EIEC = enteroinvasive *E. coli*; EHEC = enterohemorrhagic *E. coli*; IBD = inflammatory bowel disease; ETEC = enterotoxigenic *E. coli*; EPEC = enteropathogenic *E. coli*.

Management

Rehydration is the primary focus of initial management. This can be accomplished with oral fluids. Oral rehydration solutions (ORS) have decreased worldwide cholera mortality rates from 50% to 1%. The World Health Organization (WHO) ORS is made up of 3.5 g sodium chloride, 2.5 g sodium bicarbonate, 1.5 g potassium chloride, and 20 g glucose per liter of water. Rice-based ORS also may be used (e.g., CeraLyte). Prepared forms are available in solution (e.g., Pedialyte, Rehydrolyte) and packets (e.g., Orlyte). Various homemade alternatives are available, for example alternating a glass of fruit juice (8 oz) with honey (½ tsp) and salt (¼ tsp), with a second glass of water (8 oz) with baking soda (¼ tsp). Sport drinks such as Gatorade are reasonable for adults who are not dehydrated. The goal

is the passage of relatively dilute urine every 2 to 4 hours. Patients are advised to eat judiciously until stools are again formed. Cereals (rice, pasta), boiled foods (potatoes, vegetables), bananas, and crackers are recommended initial foods. Alcohol (cathartic effect), caffeine (increases intestinal motility), and carbonated drinks (gastric distension with reflex colonic contraction) should be avoided. Recommendations vary regarding dairy products, as transient lactose intolerance may occur.

In addition to rehydration, symptomatic therapy includes administering agents to control the diarrhea. These agents include bulking agents, antimotility drugs, and antisecretory medications (Tables 49.6 and 49.7). Antimotility agents should not be used if there is a possibility of a severe inflammatory bacterial diarrhea, particularly a febrile dysentery syndrome. Loperamide (Imodium) is the drug of choice in most situations because of its efficacy and safety. Bismuth subsalicylate (BSS) has antisecretory and antibacterial properties and is considered when vomiting is a significant part of the patient's presentation. It should not be used in the immunosuppressed patient, particularly the HIV population, because bismuth encephalopathy may occur. Diphenoxylate–atropine (Lomotil) has both anti-motility and antisecretory activity, but may cause central nervous system depression, especially in children. Despite their popularity, kaopectate, cholestyramine, lactobacilli, and the anticholinergics have not been shown to be consistently effective. Severe AIDS diarrhea should be treated in stepwise fashion with Imodium (2 to 4 mg PO four times daily), Lomotil (1 to 2 tablets PO four times daily), morphine (MS Contin 30 mg twice daily) or tincture of opium (DTO 0.5 to 1 mL PO four times daily), and octreotide (100 to 500 μg SC three times daily, increasing the dosage 200 μg every 3 days until response is seen).

TABLE 49.6 **SYMPTOMATIC THERAPY FOR DIARRHEA**

General	Intraluminal	Antimotility	Antisecretory
Rehydration	Bulking agents	Opiates	BSS
ORS	Psyllium	Loperamide	Octreotide
IV	Adsorbents	Diphenoxylate	
Diet therapy	Kaolin-pectin	Codeine	
	Attapulgite	Tincture of opium	
	Cholestyramine	Anticholinergics	
	Bacterial agents	Atropine	
	Lactobacillus	Scopolamine	
	Saccaromyces		

Abbreviations: ORS = oral rehydration solution; IV = intravenous; BSS = bismuth subsalicylate.

TABLE 49.7 **ANTIDIARRHEAL THERAPY**

Agent	Dosing	Comments
Loperamide[a] (Imodium)	2 mg PO q3h	Initial dose, 4 mg
		Maximum, 16 mg/day
Diphenoxylate (Lomotil)	2 tablets or 10 mL PO QID	Maximum, 8 tablets/day
BSS[b] (Pepto-Bismol)	2 tablets or 30 mL PO QID	Maximum, 8 tablets/day
Tincture of opium	0.5–1.0 ml PO q4–6h	
Octreotide	100–500 μg SC TID	

Abbreviations: BSS = bismuth subsalicylate; SC = subcutaneous.
[a] Loperamide is the drug of choice. BSS may be used in presentations with significant vomiting.
[b] BSS should not be used in patients with human immunodeficiency virus because of the risk of bismuth encephalopathy.

Antibiotic therapy is usually not indicated for patients with community-acquired acute diarrhea. Antibiotics are appropriate in a limited subset of patients, such as those with dehydration, severe travelers' diarrhea, and immunocompromised hosts, and may be appropriate for those with fever and/ or blood and those considered for hospitalization (Table 49.8). Patients with EHEC (*E. coli* O157) should not receive antibiotics, due to the reported association with HUS. Empiric therapy with a quinolone (norfloxacin, ciprofloxacin, levofloxacin) is generally recommended. Macrolides (e.g., azithromycin) may be used when drug allergies or quinolone resistance are factors, with the caveat that abdominal cramping is a common side effect. Patients with a positive stool culture or parasitic examination should be treated in specific situations: symptomatic infections with certain bacteria (*Shigella*, enteroinvasive *E. coli, C. difficile, V. cholerae*), sexually transmitted pathogens, and parasites. Therapy is reserved for subgroups of patients with *Salmonella, Campylobacter, Yersinia, Aeromonas*, noncholera *Vibrio*, and other strains of *E. coli* (EPEC, EAEC). Treatment of *Salmonella* and *Campylobacter* is indicated for patients with dysentery, systemic illness, bacteremia; or significant comorbidity (immunosuppression, malignancy, sickle cell anemia, prosthetic device, age extremes). In light of the epidemic, therapy for *C. difficile* infection is in evolution (see Chapter 51, Antibiotic-associated diarrhea).

In summary, community-acquired acute gastroenteritis, although common, is usually a self-limited disease. Oral rehydration and symptomatic therapy are appropriate for the majority of patients. Medical evaluation is advised for patients with significant fever, dysentery, abdominal pain, dehydration, or risk factors for severe disease. Laboratory evaluation and antibiotic treatment should be limited to very specific situations.

TABLE 49.8 **ANTIBIOTIC THERAPY BY ETIOLOGIC AGENT**

Etiologic agent	Therapy	Duration	Comments
Bacteria			
Empiric therapy[a]	Quinolone[b]	5–7 days	Indications:
			Fever and positive stool screen[c]
			Dysentery syndrome
			Travelers' diarrhea, severe
Campylobacter	Erythromycin, 500 mg PO bid	5 days	See text for treatment indication
	Quinolone[b]	3 days	
	Azithromycin, 500 mg PO qd	3 days	
Clostridium difficile[a]	Metronidazole, 500 mg PO tid	10–14 days	Metronidazole is the drug of choice given VRE risk.
	Vancomycin, 125 mg PO qid	10–14 days	Bactericidal but very expensive
	Fidaxomicin, 200 mg PO bid	10 days	
EIEC, ETEC[a]	Quinolone[b]	5 days	Treatment is not indicated for EHEC, including O157:H7
	TMP–SMX-DS PO BID	5 days	
EPEC	Quinolone[b]	5 days	
Salmonella	Quinolone[b]	3–7 days	See text for treatment indication
	TMP–SMX-DS PO BID	5–7 days	14 days if immunocompromised or relapsing
Shigella[a]	Quinolone[b]	3–5 days	7–10 days if immunocompromised
	TMP–SMX-DS PO BID	3 days	
	Azithromycin, 250–500 mg PO qd	3 days	
Vibrio cholerae[a]	Doxycycline, 300 mg PO	1 dose	
	Ciprofloxacin, 1 g PO	1 dose	
Yersinia	Ceftriaxone, 2 g IV qd	5 days	For severe infection
	Quinolone[b]	3 days	
Parasites			
Cyclospora	TMP–SMX-DS PO BID	710 days	
Entamoeba[a]	Metronidazole, 750 mg PO TID	10 days	Follow with cyst eradication regimen
	Tinidazole, 2 g PO qd	3 days	
Giardia[a]	Metronidazole, 250 mg PO TID	7–10 days	
	Tinidazole, 2 g PO	1 dose	
Cystoisospora	TMP–SMX-DS PO BID	7–10 days	14 days if immunocompromised
Cryptosporidium	Nitazoxanide 500 mg PO BID	3 days	

Abbreviations: VRE = vancomycin-resistant enterococcus; EIEC, = enteroinvasive *E. coli*; ETEC = enterotoxigenic *E. coli*; TMP–SMX-DS = trimethoprim–sulfamethoxazole, 160–800 mg double-strength tablet; EHEC = enterohemorrhagic *E. coli*; EPEC = enteropathogenic *E. coli*.

[a] Treatment clearly indicated. Treatment for the other listed microbes will depend on the clincal situation.

[b] Quinolone oral therapy options include: ciprofloxacin 500 mg bid, ofloxacin 300 mg bid, levofloxacin 500 mg qd.

[c] Positive stool screen: fecal leukocytes or hemoccult positive.

Food poisoning

Carly R. Davis and Andrew T. Pavia

Foodborne illnesses are caused by ingestion of foods containing microbial and chemical toxins or pathogenic microorganisms. This chapter concentrates on toxin-mediated syndromes, usually called *food poisoning*, rather than on syndromes reflecting enteric infection, such as salmonellosis, shigellosis, vibriosis, and Shiga toxin-producing *Escherichia coli* (STEC) infection. Treatment of these infections is covered in Chapter 49, Gastroenteritis, and in chapters on the specific organisms.

Clinical presentation and diagnosis

Initially, the diagnosis of specific food poisoning syndromes is suggested by the clinical presentation, the incubation period from exposure to onset of symptoms, and the food consumed. The incubation periods, symptoms, and commonly associated foods for specific syndromes are shown in Table 50.1. Incubation periods range from a few hours or less in the case of preformed chemical and bacterial toxins, such as histamine poisoning (scombroid), staphylococcal food poisoning, and *Bacillus cereus*, to several days for bacterial infections (e.g., *Campylobacter jejuni, Salmonella, Yersinia enterocolitica*, and *E. coli* O157:H7 or other STEC) and some types of mushroom poisoning. Therefore, it is essential to obtain a diet history covering 3 to 4 days before the onset of symptoms. A careful history of illness in meal companions may help point to the responsible food. It is clinically useful to consider syndromes grouped by incubation period and symptoms.

Nausea and vomiting within 1 hour

Symptoms developing within 5 to 15 minutes of exposure that resolve over 1 to 2 hours are typical of contamination of food or drink with heavy metals or other nonspecific chemical irritants.

Nausea, vomiting, or diarrhea within 1 to 16 hours

When gastrointestinal symptoms develop 1 to 16 hours after exposure, the likely agents include *Staphylococcus aureus, B. cereus*, and *Clostridium perfringens*. Vomiting is the dominant feature of *S. aureus* and short-incubation, or emetic, *B. cereus* food poisoning. These syndromes result from preformed centrally acting toxins elaborated by the organisms in food when the food is mishandled. In contrast, abdominal cramps and diarrhea are most prominent in long-incubation, or diarrheal, *B. cereus* poisoning and *C. perfringens* food poisoning. In these syndromes, toxins are also elaborated in the small intestine. The duration of illness is usually less than 24 hours. Diagnosis of these syndromes is usually made on epidemiologic and clinical grounds. Laboratory confirmation of *S. aureus* food poisoning is based on isolation of *S. aureus* from food handlers and demonstration of more than 10^5 colonies per gram of the same strain in food or enterotoxin production by enzyme immunoassay. Laboratory confirmation of *B. cereus* and *C. perfringens* can be performed in epidemiologic investigations; it requires collection of food and stool for toxin detection or quantitative cultures.

TABLE 50.1 **INCUBATION PERIOD, SYMPTOMS, AND COMMON VEHICLES FOR MICROBIAL CAUSES OF FOOD POISONING**

Organism	Incubation period (hours) median (range)	Vomiting	Diarrhea	Fever	Common vehicles
Staphylococcus aureus	3 (1–6)	+++	++	0	Ham, poultry, cream-filled pastries, potato and egg salad
Bacillus cereus (emetic syndrome)	2 (1–6)	+++	++	0	Fried rice
Bacillus cereus (diarrheal syndrome)	9 (6–16)	+	+++	0	Beef, pork, chicken, vanilla sauce
Clostridium perfringens	12 (6–24)	+	+++	0	Beef, poultry, gravy
Vibrio parahaemolyticus	15 (4–96)	++	+++	+++	Fish, shellfish
Vibrio cholerae O1 and non-O1	24 (12–120)	++	+++	+	Shellfish
Norovirus	24 (12–48)	+++	++	++	Shellfish, salads, ice
Shigella	24 (7–168)	+	+++	+++	Egg salads, lettuce, sandwiches
Clostridium botulinum	24 (12–168)	++	+	0	Canned vegetables, fruits, sauces and fish; salted fish; bottled garlic, baked potatoes
Salmonella	36 (12–72)	+	+++	++	Beef, poultry, pork, eggs, dairy products, fruit and vegetables, sprouts
Campylobacter jejuni	48 (24–168)	+	+++	+++	Poultry, raw milk
Enterohemorrhagic *Escherichia coli* (e.g., O157:H7)	96 (48–120)	++	+++	+	Beef (especially hamburger), raw milk, salad dressings, lettuce, sprouts, apple cider
Yersinia enterocolitica	96 (48–240)	+	+++	+++	Pork, chitterlings, tofu, milk
Cyclospora cayetanensis	168 (24–336)	+	+++	++	Raspberries, basil, lettuce

Key: 0 = rare (≤10%); + = infrequent (11%–33%); ++ = frequent (33%–66%); +++ = classic (>67%).

Watery diarrhea and cramps within 16 to 48 hours

Diarrhea following a slightly longer incubation period is typical of viral foodborne illness, particularly Norovirus (Norwalk virus), and enterotoxin-producing bacteria, including enterotoxigenic *E. coli* (ETEC), *Vibrio cholerae* O1 and non-O1, and other *Vibrio* species. Most microbiology laboratories can diagnose *Vibrio* infections from stool culture provided the laboratory is aware that *Vibrio* is being considered. Diagnosis of ETEC infection requires detection of enterotoxin production by *E. coli* isolates or detection of the genes for enterotoxin and is limited to reference laboratories. Antigen detection-based enzyme immunoassays using recombinant antigens have been developed for the diagnosis of several gastroenteritis-causing viruses such as rotavirus and adenovirus 40/41; PCR testing can detect norovirus. Multiplex PCR platforms that can detect many of these organisms in one test are in advanced development.

Fever, diarrhea, and abdominal cramps within 16 to 96 hours

Bacterial infections of the gastrointestinal tract and gut-associated lymphatics with *Salmonella, Shigella, C. jejuni, Y. enterocolitica*, and STEC typically follow a longer incubation period and are marked by more prominent signs of colonic inflammation or systemic illness. Diarrhea that becomes bloody within 12 to 36 hours of onset is typical of *E. coli* O157:H7 and other STEC. These organisms are now among the most common causes of bacterial gastroenteritis in North America (see Chapter 49, Gastroenteritis).

Diarrhea, fatigue, and weight loss within 1 to 14 days

Cyclospora infection should be suspected in a patient with diarrhea of several days' duration associated with loss of appetite and weight and prominent fatigue. The incubation period is highly variable, ranging from 1 to 14 days, with a median of 7 days. Recent outbreaks have definitively shown that *Cyclospora* infections in developed countries can result from consumption of contaminated foods, notably fresh raspberries, mesclun lettuce, and basil.

Paresthesias within 6 hours

Chemical food poisoning caused by niacin, histamine fish poisoning, ciguatera poisoning, neurotoxic and paralytic shellfish poisoning, and Chinese restaurant syndrome (monosodium glutamate) present with paresthesias and other symptoms after a brief incubation period. Chinese restaurant syndrome is characterized

TABLE 50.2 **CLINICAL FEATURES OF FISH AND SHELLFISH POISONING**

Syndrome	Incubation period	Symptoms	Vehicles	Duration
Histamine (scombroid)	5 min–1 h	Facial flushing, headache, nausea, cramps, diarrhea, urticaria	Tuna, mackerel, bonito, mahi-mahi, bluefish	Hours
Ciguatera	1–6 h	Diarrhea, nausea, vomiting, myalgia, arthralgia, shooting pains, perioral and extremity paresthesias, hot–cold reversal, fatigue	Barracuda, snapper, grouper, amberjack	Days to months
Neurotoxic shellfish poisoning	5 min–4 h	Paresthesias, nausea, vomiting, ataxia	Shellfish	Hours to days
Paralytic shellfish poisoning	5 min–4 h	Paresthesias, cranial nerve weakness, ataxia, muscle weakness, respiratory paralysis	Shellfish	Hours to days
Domoic acid	15 min–38 h	Vomiting, cramps, diarrhea, confusion, amnesia, cardiac irritability	Mussels	Indefinite
Haff disease		Muscle pain, stiffness, brown urine	Buffalo fish, pomfret, burbot	2–3 days
Pufferfish (tetrodotoxin) poisoning	15 min–20 h	Paresthesias, vomiting, diarrhea, abdominal pain, ascending paralysis, respiratory failure	Pufferfish	Several days

by a burning sensation in the neck, chest, and abdomen with chest tightness and occasionally facial flushing, headache, nausea, and abdominal cramps.

The features of fish and shellfish poisoning are summarized in Table 50.2. Histamine fish poisoning (scombroid) is caused by bacterial decarboxylation of histidine in fish that are inadequately refrigerated, resulting in production of large amounts of histamine. Signs and symptoms are facial flushing, headache, nausea, and, less commonly, urticaria or diarrhea. The fish is often reported to have a peppery or bitter taste. Demonstration of high levels of histamine in the implicated fish confirms the diagnosis.

Ciguatera fish poisoning results from ingestion of fish containing toxins produced by the dinoflagellate *Gambierdiscus toxicus*. Predatory fish such as grouper, amberjack, snapper, and barracuda are usually implicated. The symptoms, which are quite distinctive, usually involve the combination of gastrointestinal and neurologic symptoms, most commonly perioral and distal extremity paresthesias, and reversal of hot and cold sensation. Other symptoms include sensation of loose teeth, arthralgias, headaches, muscle weakness, pruritus, lancinating pains, and hallucinations. Bradycardia, hypotension, and respiratory paralysis may occur. The symptoms may last from a few days to 6 months. The diagnosis is based on the clinical picture; detection of ciguatoxin in the fish by high-performance lipid chromatography (HPLC), radioimmunoassay (RIA) or enzyme-linked immunoassay (EIA), or a new neuro-2a cell-based assay is confirmatory.

Paralytic shellfish poisoning (PSP) and neurotoxic shellfish poisoning (NSP) are closely related syndromes caused by heat-stable neurotoxins produced by dinoflagellates (*Gonyaulax catenella* and *Gonyaulax tamarensis* cause PSP; *Gymnodinium breve* causes NSP). During periodic blooms of the dinoflagellates, which may cause red tides, shellfish concentrate the heat-stable toxins. PSP is more severe and occurs in colder waters. Patients develop symptoms a median of 30 minutes after exposure. Symptoms consist of paresthesias and dysesthesias, beginning with the lips, mouth, and face and progressing to the extremities, and then dysphonia, dysphagia, ataxia, muscle weakness, and, in severe cases, respiratory paralysis occur. NSP occurs primarily near warmer waters and is characterized by similar paresthesias, reversal of hot and cold sensation, nausea, vomiting, and ataxia. Toxin can be detected in samples of the shellfish by bioassay or several investigational assays. Amnesic shellfish poisoning is a recently described syndrome associated with mussels contaminated with domoic acid elaborated by *Nitzchia pungens*. In some patients, gastrointestinal symptoms are followed by memory loss, coma, cardiac arrhythmias, and death. Haff disease is a syndrome of acute rhabdomyolysis thought to be caused by palytoxin in certain bottom-feeding fish, notably buffalo fish, crayfish, pomfret, and burbot. Patients present 6 to 21 hours after ingestion with vomiting, severe myalgia, and stiffness. Elevated creatine phosphokinase (CPK) and other muscle enzyme levels confirm the diagnosis. Tetrodotoxin poisoning results from consumption of improperly prepared pufferfish, manifest as paresthesias, vomiting, diarrhea, abdominal pain, ascending paralysis, and respiratory failure.

Nausea, vomiting, diarrhea, and paralysis within 18 to 36 hours

Foodborne botulism results from exposure to one of three distinct botulinum toxins, A, B, and E, produced when *Clostridium botulinum* spores germinate in food in an anaerobic environment. Gastrointestinal symptoms occur before the onset of neurologic symptoms in about 50% of patients with acute foodborne botulism. Descending paralysis begins with cranial nerve weakness manifested as dysphonia, dysphagia, diplopia, and blurred vision, followed by muscle weakness and respiratory insufficiency. Larger doses of toxin result in shorter incubation periods and more severe symptoms.

Botulism can be differentiated from acute myasthenia gravis and Guillain–Barré syndrome (which may follow *C. jejuni* infection) by botulism's normal cerebrospinal fluid protein, the descending nature of the paralysis, absence of sensory symptoms, normal nerve conduction studies, and typical electromyographic findings of increase in the action potential with rapid repetitive stimulation. Confirmation is based on detection of toxin in food or in serum or stool of patients by mouse toxicity assay or of *C. botulinum* spores in the stool by selective culture.

Mushroom poisoning syndromes

Syndromes of food poisoning from mushrooms fall into at least 10 major categories, outlined in Table 50.3. Parasympathetic syndromes, delirium, disulfiram (Antabuse)-like symptoms, hallucinations, or gastroenteritis may occur after a short incubation period. The more serious syndromes of monomethylhydrazine poisoning, hepatorenal failure from amatoxin-containing mushrooms, delayed myopathy and rhabdomyolysis, and tubulointerstitial nephritis develop after longer incubation periods and may not be suspected initially. If available, specimens of the mushrooms should be examined promptly by a mycologist or poison control expert to confirm the diagnosis. Toxins can be detected in gastric contents, blood, or urine by thin-layer chromatography.

Therapy

Nonspecific therapy

Most food poisoning syndromes are self-limited, and for the majority of episodes, nonspecific supportive therapy is all that is required. Exceptions include botulism, listeriosis, some enteric infections in infants and compromised hosts, and some types of mushroom poisoning.

The mainstay of treatment is fluid and electrolyte replacement to prevent and treat dehydration. The first step is to assess the degree of volume depletion by examining the skin turgor, mucous membranes, vital signs, and mental status. Measuring postural changes in pulse and blood pressure is also helpful in quantifying the volume loss. Slightly dry mucous membranes and thirst indicate mild dehydration (3% to 5% deficit, or 50 to 60 mL/ kg); loss of skin turgor, very dry mucous membranes, postural pulse increases, and sunken eyes indicate moderate dehydration (6% to 9%); and

TABLE 50.3 **CLINICAL SYNDROMES OF MUSHROOM POISONING**

Syndromes (toxins)	Incubation period	Symptoms	Mushrooms
Parasympathetic (muscarine)	30 min–2 h	Sweating, salivation, lacrimation, blurred vision, diarrhea, bradycardia, hypotension	*Inocybe* spp. *Clitocybe* spp.
Delirium (ibotenic acid, muscimol)	30 min–2 h	Dizziness, incoordination, ataxia, hyperactivity, visual disturbance, hallucinations, stupor	*Amanita muscaria, Amanita pantherina*
Disulfiram-like (coprine)	30 min after alcohol	Flushing, metallic taste, nausea, vomiting, sweating, hypotension	*Coprinus atramentarius, Clitocybe clavipes*
Hallucinations (psilocybin)	30–60 min	Mood elevation, anxiety, tachycardia, muscle weakness, hallucination	*Psilocybe cubensis, Panaeolus* spp., *Conocybe cyanopus*
Gastroenteritis	30 min–2 h	Nausea, vomiting, abdominal cramps, diarrhea	Various
Allergic pneumonic syndrome	3–6 h	Nausea, vomiting, rhinitis followed within days by fever, malaise, dyspnea, and reticulonodular infiltrates on chest x-ray	*Lycoperdon* spp. (puffballs)
Methemoglobin poisoning (monomethylhydrazine gyromitrin)	6–12 h	Nausea, vomiting, bloody diarrhea, abdominal pain, vertigo, convulsion, coma, liver failure, hemolysis	*Gyromitra* spp.
Hepatorenal failure (amatoxins, phallotoxins)	6–24 h	Nausea, vomiting, abdominal pain, diarrhea; then jaundice, liver and kidney failure, coma, death	*Amanita phalloides, Amanita verna, Amanita virosa, Galerina autumnalis, Galerina marginata*
Tubulointerstitial nephritis (orellanine)	36 h–14 days	Thirst, nausea, vomiting, flank pain, chills, oliguria	*Cortinarius orellanus, Cortinarius speciosissimus*
Rhabdomyolytic	24–72 h	Fatigue, muscle weakness, myalgia, rhabdomyolysis, renal failure	*Tricholoma equestre, Russula submigricans*

the additional presence of weak pulse, postural hypotension, cold extremities, or depressed consciousness indicates severe volume depletion, above 10%.

Most children and adults with diarrhea can be treated successfully with oral rehydration. This therapy is possible because of the coupled transport of glucose with water and sodium even in severely damaged small bowel. Diarrheal stool contains significant concentrations of sodium, potassium, and bicarbonate, and fluid therapy should replace these losses.

One liter of the World Health Organization's currently recommended replacement solution contains 75 mmol of sodium, 13.5 g of glucose, 20 mmol of potassium, 65 mmol of chloride, and 10 mmol of citrate (as a bicarbonate source). Commercial solutions such as Rehydralyte and Pedialyte have a slightly lower sodium concentration, but they are convenient and readily available, although expensive. A homemade approximation of the oral solution can be made by adding a pinch of salt, a pinch of baking soda, and a spoonful of sugar or honey to an 8-oz glass of fruit juice. For patients with altered consciousness or uncontrolled vomiting, intravenous rehydration with Ringer's lactate should be used initially. The estimated volume deficit should be replaced over 4 hours; after that, ongoing losses should be replaced. Gatorade and commercial soft drinks are poor choices because the low sodium content can lead to hyponatremia and the high osmolarity can exacerbate diarrhea.

Water intake should be allowed ad lib, and solid food can be introduced as soon as it is tolerated. Some patients will develop lactose intolerance after severe or protracted diarrhea, and dairy products should be avoided if they appear to exacerbate symptoms.

Antiemetics may be useful for severe or prolonged vomiting. Ondansetron (Zofran) can be used off-label, 4 to 8 mg orally or intravenously. Alternatively, promethazine (Phenergan), 12.5 to 25 mg PO, IM, IV, or PR, and prochlorperazine (Compazine), 5 to 10 mg orally or intramuscularly (IM), 25 mg rectally, or 2.5 to 10 mg IV could be used. Antidiarrheals should be used cautiously, especially in children. Pepto-Bismol 30 mL (2 tab) orally every 30 to 60 minutes (maximum 8 doses/ 24 hours) may be reasonable if an antidiarrheal is used because it has been shown to bind some enterotoxins. It generally should be avoided in children under 12 because of the salicylate content.

Specific therapy

Specific therapies for food poisoning are outlined in Table 50.4. Gastric emptying and administration of activated charcoal and cathartics (unless diarrhea is already present) are important for virtually all cases of mushroom poisoning. If vomiting has not occurred spontaneously in patients with botulism or ciguatera, the remaining food should be removed from the gut. In botulism, paralytic shellfish poisoning, and ciguatera, death from respiratory failure is the major risk, and monitoring the vital capacity can be lifesaving.

Equine-derived heptavalent antitoxin, which binds botulism toxin types A–G, has been recently approved for the treatment of patients 12 months and older. It is available in the United States through contacting the state health department's emergency line, and they will contact the CDC (770–488–7100) for release of antitoxin. It may prevent further paralysis but does not reverse established symptoms. To be effective, it should be administered early. Dosage and a protocol for administration of a skin test are listed in the package insert. Human-derived botulism immune globulin (BabyBIG) is licensed for treatment of infant botulism caused by toxin types A or B. It can be obtained from the California Department of Public Health (510–231–7600 or www.infantbotulism.org).

In ciguatera poisoning, analgesia and avoidance of unpleasant stimuli such as warm baths are usually adequate. Anecdotal reports in the literature suggest that amitriptyline, 25 to 50 mg/ day orally or gabapentin may be useful for dysesthesias. Intravenous mannitol has been reported to be effective for severe neurologic manifestations, but a single randomized control trial did not show a benefit. For histamine fish poisoning, conventional antihistamines, such as diphenhydramine, 25 to 50 mg PO, IM, or IV, are helpful. Epinephrine or albuterol should be given for bronchospasm. Intravenous cimetidine can be tried for refractory symptoms.

Atropine is a specific antidote for poisoning from muscarine-containing mushrooms, but the dosage (0.01 to 0.02 mg/kg up to a maximum of 1 mg) should be titrated to control excess respiratory secretions and bradycardia rather than other symptoms. Alternatively glycopyrrolate can be used.

Specific treatment is usually not necessary for poisoning caused by ibotenic acid-containing or muscimol-containing mushrooms. Benzodiazepines can be used to control combativeness, agitation, muscular overactivity, and seizures. Cardiac and blood pressure monitoring are necessary because hypotension and bradycardia can result.

For poisoning caused by monomethylhydrazine-containing mushrooms, pyridoxine, 25 mg/kg IV, should be given; the dose can be repeated as needed to control seizures. The methemoglobin level should be measured if possible. If there is symptomatic methemoglobinemia with central cyanosis, methylene blue, 1 to 2 mg/ kg or 0.1 to 0.2 mL/ kg of a 1% solution, should be given over 5 minutes.

The high fatality rate associated with poisoning by *Amanita phalloides* and related amatoxin-containing mushrooms makes it a special concern. Toxin removal should be attempted with activated charcoal and should be continued until 4 days following ingestion because of the extensive enterohepatic cycling. During the initial phase, gastrointestinal symptoms may cause hypotension. This first stage often is followed by a stage of apparent improvement, but hepatic transaminases usually are elevated by 24 to 48 hours. Fulminant hepatic necrosis and acute renal failure begin after 48 to 96 hours. Supportive treatment consists of careful fluid replacement and monitoring of serum glucose and renal and liver function tests. Intravenous silibinin dihemisuccinate (Legalon® SIL) has been shown to decrease mortality in amatoxin mushroom poisonings. High-dose penicillin G can be used if silibinin is not available, but is not as effective, and it does not have additional benefit when used in conjunction with silibinin (and actually has higher mortality than silibinin used alone). *N*-acetylcysteine can be used as an antioxidant to help prevent liver cell death. Liver transplant has been successful in some cases. Assistance from the regional poison control center should always be sought for help with mushroom identification and for the latest treatment information.

TABLE 50.4 **SPECIFIC TREATMENT FOR FOOD POISONING SYNDROMES**

Syndrome	First-line treatment	Comment
Staphylococcus aureus, Bacillus cereus, Clostridium perfringens, Norwalk virus	Fluid replacement, antiemetics (e.g., ondansetron [Zofran], promethazine [Phenergan], prochlorperazine [Compazine])	Oral rehydration is usually adequate if vomiting can be controlled.
Bacterial gastroenteritis	Fluid replacement; antimicrobials helpful for some syndromes	See chapters on specific organisms and Chapter 49, Gastroenteritis, for specific antimicrobial therapy
Clostridium botulinum	Gastric empying, cathartics if food is still in gastrointestinal tract; respiratory support, polyvalent antitoxin[a]	Antitoxin should be given as soon as possible
Cyclospora	Trimethoprim–sulfamethoxazole (160 mg trimethoprim component bid for 7 days)	If not treated, symptoms may be protracted and relapsing
Histamine (scombroid)	Antihistamine (e.g., diphenhydramine 25–50 mg PO, IM, or IV)	H_2 receptor antagonists (cimetidine) have been helpful for refractory symptoms
wCiguatera	Activated charcoal only if there is no vomiting and it has been <1 hour post ingestion; analgesia, antiemetics, supportive measures; atropine for symptomatic bradycardia	Amitriptyline (25–50 mg/d) may help paresthesias; mannitol infusion has been used
Neurotoxic shellfish poisoning	Supportive therapy	
Paralytic shellfish poisoning	Supportive therapy, monitor vital capacity	
Haff disease	IV hydration	Mannitol and bicarbonate have also been used to protect renal tubules
Muscarine-containing mushrooms	Gastric emptying, activated charcoal, cathartics; atropine 0.01–0.02 mg/kg IV up to 1 mg	Titrate atropine to drying of secretions; alternatively glycopyrrolate can be used.
Muscimol- and ibotenic acid-containing mushrooms	Gastric emptying, activated charcoal, cathartics; supportive measures	Benzodiazepines can be used for agitation
Hallucinogen-containing mushrooms	Reassurance, quiet room; benzodiazepines for severe agitation	
Monomethylhydrazine-containing mushrooms (*Gyromitra* spp.)	Gastric emptying, activated charcoal, cathartics; for delirium, pyridoxine, 25 mg/kg IV	For methemoglobinemia, methylene blue 1–2 mg/kg (1% solution 0.1–0.2 mL/kg) over 5 min
Amatoxin-containing mushrooms	Gastric emptying, activated charcoal; correction of fluid and electrolytes; monitoring glucose, liver, and renal function	IV silibinin[b] has been shown to decrease mortality. High-dose penicillin G can be used if silibinin is not available. *N*-acetylcysteine may help prevent liver cell death. Hemodialysis or liver transplantation may be necessary
Orellanine-containing mushrooms	Gastric emptying, activated charcoal, cathartics; cautious correction of fluid and electrolyte problems	Hemodialysis is often necessary

[a] Available through State Health Departments, or the Centers for Disease Control and Prevention (770–488–7100, 24 hours per day).
[b] (Legalon® SIL) is available directly from the principal investigator of an open NIH clinical trial (NCT00915681) by calling 1-866-520-4412.

Reporting

Reporting of suspected foodborne outbreaks to local or state health departments is an important part of management because epidemiologic investigation can clearly establish the responsible food and may prevent many additional cases.

Clostridioides (Clostridium) difficile

Cheston B. Cunha and Burke A. Cunha

Clinical overview of *C. difficile* diarrhea and *C. difficile* colitis

Clostridioides (Clostridium) difficile is a gram-positive anaerobic spore-forming bacillus found in colon flora. The fecal carriage of *C. difficile* is asymptomatic without diarrhea. When *C. difficile* is induced to produce exotoxins (A/B) symptomatic disease (i.e., diarrhea or colitis) follows. The clinical spectrum of infection ranges from watery toxigenic diarrhea to invasive transmural colitis. *C. difficile* diarrhea is primarily an infection of adults. The terms "*C. difficile* infection," "*C. difficile* disease," or "antibiotic-associated diarrhea" should be abandoned as they are nondescriptive and not reflective of the differences in pathophysiology and severity between *C. difficile* diarrhea (CDD) and *C. difficile* colitis (CDC). *C. difficile* diarrhea and *C. difficile* colitis may be acquired in the community or hospital.

The onset of CDD is acute with the sudden onset of profuse watery diarrhea with a distinctive odor. Little or no fever is usual with CDD, as with other secretory diarrheas (e.g., cholera; fecal white blood cells [WBCs] are absent with no red blood cells [RBCs] present). CCD is a toxigenic mucosal infection that in some may progress to an invasive transmural colitis, with fever often >39°C/102°F, abdominal pain, and marked leukocytosis. Patients usually present with either diarrhea or colitis, but some CDC patients have a diarrheal component.

Beyond differences in severity, there are critical pathophysiologic differences between CDD and CDC that have important implications for anti-*C. difficile* therapy. Analogously, CDD is like ulcerative colitis (UC) in that it is a mucosal process without colon wall involvement. In contrast, CDC is like Crohn's disease, a regional enteritis (RE) in that it is a transmural process penetrating into the intestinal wall. These critical differences in pathophysiology have important therapeutic implications. Just as UC is treated differently than RE, similarly, the optimal treatment of CDD differs markedly from that of CDC. In most *C. difficile* studies, treatment is similar for both CDD and CDC, making evaluation of the relative effectiveness of each drug for diarrhea and colitis difficult to evaluate

Community acquired diarrheas (e.g., norovirus diarrhea) must be differentiated from CDD by stool PCR. However, non-CDD due to other infectious agents or medications (laxatives or stool softeners) may test positive for *C. difficile* carriage. Similarly, patients with underlying diarrheal diseases (e.g., irritable bowel syndrome [IBS], inflammatory bowel disease [IBD] due primarily to UC, and to a lesser extent to RE, sprue, Whipple's disease, etc.) occurring in *C. difficile* carriers may be PCR positive for *C. difficile*, thus mimicking CDD. Recurrent *C. difficile* may be due to inadequate therapy or reinfection with *C. difficile*. Mimics of recurrent *C. difficile* include exacerbations of IBS, IBD, or disorders associated with loose stools. Such patients should have stool PCR for *C. difficile,* which should be PCR negative. To differentiate true "recurrent *C. difficile*," from a diarrheal disorder with *C. difficile* colonization clinically, note that PCR-positive mimics have a few loose or soft stools per day versus the 20 to 30 watery movements of bona-fide CDD. If "recurrent *C. difficile*" occurs in a patient suspected of having another infectious cause of diarrhea (e.g., norovirus), then the diagnostic workup should be directed at specific stool test for the other enteropathogen.

C. difficile diarrhea

Community acquired CDD may be diagnosed in adults with otherwise unexplained acute onset of profuse diarrhea (20–30 watery or liquid stools per day), without fever or abdominal pain, and a stool PCR for *C. difficile* toxins (A/B). In terms of differential diagnosis, PCR-positive non-CDD must be differentiated clinically from bona-fide CDD by stool frequency and consistency. PCR-positive non-CDD has only a few soft or semi-formed stools per day. Such cases may be due to drug-related diarrhea (laxatives, stool softeners, macrolides) or alternately to a diarrhea-related disorder (e.g., IBS, IBD, anatomically altered GI tract, malabsorptive disorders, etc.).

Like community-acquired diarrheal disorders, hospital acquired non-CDD may be caused in a variety of ways. Many medications cause increased intestinal motility (e.g., macrolides, laxatives, and stool softeners). Additionally, enteral feeds may result in diarrhea via two mechanisms. First, some enteral feeds cause diarrhea in some patients, not others. Second, enteral feeds, if given rapidly or in high volume, may result in watery diarrhea (e.g., 80–100 mL/h). If high-volume enteral feed is suspected, cut back on the infusion to 20 to 40 mL/h, and diarrhea will decrease markedly or cease in 12 to 24 hours. Importantly, enteral feeds are protective against *C. difficile*. If stools test PCR-positive for *C. difficile* in a patient receiving an enteral feed, suspect *C. difficile* colonization (i.e., not CDD).

It is commonly assumed that "antibiotics" are always the cause of CDD, which is not the case. CDD, if due to antibiotics, may occur up to 8 weeks after antibiotic exposure. Of the many commonly used antibiotic classes, only β-lactams and clindamycin are commonly associated with *C. difficile*. Antibiotics may cause non-CDD by altering the colon flora (e.g., ceftriaxone), by increasing intestinal motility (e.g., erythromycin), or as an irritative diarrhea due to poor oral absorption (e.g., ampicillin, clavulanic acid). Some antibiotics are "protective" against CDD (e.g., doxycycline, tigecycline). In hospital patients with acute onset of CDD, discontinue those medications known to be associated with CDD, which include proton pump inhibitors (PPIs), some psychiatric drugs, and cancer chemotherapy drugs and probiotics. Probiotics may predispose (increased incidence) to CDD and also may make CDD more severe. Cancer chemotherapy is another medication that may induce toxin production in patients with asymptomatic *C. difficile* colonization. The only nosocomial infectious cause of acute onset of watery diarrhea is *C. difficile*. If a stool PCR is negative for *C. difficile*, there is no need for repeat testing. Effective therapy of CDD is manifested by a marked decrease in watery stools per day after 3 days. Repeat testing is not a test of cure, and PCR may remain positive for 8 weeks after infection.

Unless there is a break in hand-washing (from a hospital water problem) or a food-borne outbreak, community-acquired diarrheal pathogens *Salmonella* spp., *Shigella* spp., *Campylobacter* spp., *Yersinia* spp., and *Escherichia coli* should not be considered in the differential diagnosis of nosocomial diarrheas. Stool cultures for community-acquired diarrheal pathogens should not be routinely done for nosocomial diarrhea since *C. difficile* is the only infectious cause of nosocomial diarrhea.

C. difficile colitis

Clinically, CDC differs fundamentally from CDD not just in severity, but also, importantly, in underlying colon pathology. There are two common presentations of CDC. In some cases, the onset of CDC is abrupt with fever (often >39°C/102°C), abdominal pain and tenderness with marked leukocytosis, and no diarrhea. Usually, the entire colon is involved (i.e., *C. difficile* pancolitis). *C. difficile* pancolitis may be mimicked by noninfectious disorders (e.g., UC) or infectious disorders (e.g., cytomegalovirus [CMV] colitis). Early CDC may present as segmental colitis. The differential diagnosis of segmental colitis includes noninfectious etiologies (e.g., ischemic colitis). Alternately, in a patient with CDD, if the profuse watery diarrhea stops abruptly, then progression to CDC is likely. Optimally treated CDD improves over a few days but does not cease suddenly. In this scenario, obtain an abdominal CT scan which confirms the presence of CDC. In contrast, CDD responding to therapy results in a gradual decrease in number of watery stools per day (e.g., 30/day to 27/day to 23/day to 19/day to 15/day to 8/day to 2–3/day, etc.) before stools become soft or semi-formed.

Overview of *C. difficile* diarrhea and *C. difficile* colitis treatment

An anti-*C. difficile* antimicrobial should have a "low resistance potential" and possess a high degree of anti-*C. difficile* activity. Aside from these concerns, the pharmacokinetic PK target of optimal *C. difficile* therapy depends on the site of infection in the colon. Being a secretory diarrhea not unlike cholera, the main PK target for anti-*C. difficile* antimicrobials is the colon mucosa. Accordingly, the aim of PK-based therapy is to provide high intraluminal concentrations of an anti-*C. difficile* antibiotic (e.g., oral vancomycin). Oral vancomycin does not penetrate into the colon wall, which is important since CDD is mucosal. Conversely, vancomycin (intravenous [IV]/oral [PO]) lacks the PK attributes to penetrate the colon wall. Increasing resistance aside, metronidazole for CDD is suboptimal because it is so well absorbed that it results in low intraluminal concentrations. CDC is an invasive process (transmural) primarily involving the colon wall. From a PK perspective, anti-*C. difficile* drugs for CDC must penetrate the colon wall to effectively treat colitis. Vancomycin (IV/PO) doesn't have the proper pKa properties to penetrate the colon wall. Therefore, unless with CDC there is also a diarrheal component, adding oral vancomycin when treating CDC makes little sense. Preferred antibiotics highly effective against *C. difficile* that also penetrate the colon wall include metronidazole, nitazoxanide, and tigecycline.

C. difficile diarrhea therapy

Because in CDD the process is intraluminal and limited to colon mucosa, the aim of therapy is to deliver high intraluminal concentrations of effective anti-*C. difficile* drugs (e.g., oral

vancomycin). Intraluminal concentrations of oral vancomycin are 1,000 to 3,000 μg/mL. Vancomycin resistance is not an issue, nor is systemic absorption. In contrast, intraluminal colon levels with oral or IV metronidazole are very low (subtherapeutic). Furthermore, metronidazole resistance to *C. difficile* is of concern.

With CDD, the effectiveness of oral vancomycin therapy is dose and time dependent: dosing matters. The minimally effective dose of oral vancomycin is 125 mg (PO) every 6 hours, but this dose often fails or results in delayed resolution or prolonged course. Fidaxomicin is considered "non-inferior" but not superior to vancomycin 125 mg (PO) every 6 hours. However, 250 mg (PO) every 6 hours is more dependably effective but also may fail or prolong resolution. The speed of resolution of CDD is "dose dependent" and has important infection control implications: more effective and more rapid resolution has important infection control implications because more rapid resolution means less *C. difficile* exposure to other patients and staff, not to mention patient hospital length of stay.

An effective approach to begin treatment of CDD is to begin with vancomycin 250 mg (PO) every 6 hours and evaluate the response (decrease in stools per day) after 3 days of treatment. If there has been a marked decrease in liquid stools per day (e.g., 16/day or 18/day), then complete 10 to 14 days of therapy with the same dose of oral vancomycin.

If there is little or no decrease in stools per day with vancomycin 250 mg (PO) every 6 hours, increase the dose to 500 mg (PO) every 6 hours and again reevaluate the response (i.e., decrease in stools per day after 3 days). At 500 mg (PO) every 6 hours essentially all patients rapidly respond to this dose.

Since resistance is not an issue, if there is no response (after 3 days) to vancomycin 500 mg (PO) every 6 hours, obtain an abdominal CT scan to rule out colitis. Metronidazole (IV/PO) is highly effective in CDC therapy, but its efficacy is questionable in CDD. Unlike oral vancomycin, oral metronidazole is well-absorbed from the mucosa of the colon, resulting in very low or subtherapeutic intraluminal concentrations. Importantly, while metronidazole is highly effective in CDC (penetrates the colon wall), it is suboptimal for CDD. The only other anti-CDD oral antibiotic comparable to oral vancomycin and superior to metronidazole is nitazoxanide. Therapy for CDD should not be tapered in response to clinical improvement. The patient should receive a full course of oral vancomycin therapy, with the optimal effective dose (500–250 mg orally q6h).

C. difficile colitis therapy

With CDC, the pKa aim of therapy is to achieve therapeutic colon wall levels. High intraluminal levels, key in CDD therapy, are of no benefit in CDC therapy because it is a transmural colon wall process. Also, pancolitis is often accompanied by microscopic translocation of colon flora from the wall into the peritoneum, causing microscopic peritonitis. Pancolitis may also result in colon perforation or toxic megacolon or perforation.

It is prudent to primarily treat the CDC and secondarily to give another antibiotic, with little or no *C. difficile* potential, that is effective against colon flora in potential peritonitis or perforation.

The cornerstone of treatment for *C. difficile* pancolitis has been metronidazole (IV/PO). Alternately, nitazoxanide is highly efficacious in both CDD (superior to metronidazole) and CDC (comparable to metronidazole). Oral or parenteral vancomycin has a limited role in the therapy of CDC and is usually added out of habit or desperation. In cases of CDC *with a diarrheal component*, oral vancomycin may be added to the colitis regimen. Oral vancomycin should not be administered by enema because it may result in colon perforation, since with colitis the colon is inflamed and friable. Early preemptive therapy for potential microbial translocation of bacteria (microscopic peritonitis) or colon perforation is prudent. Therefore, with severe pancolitis, an antibiotic effective against coliforms and *B. fragilis* is reasonable. It doesn't matter which agent is selected, but preferably select one that doesn't predispose to *C. difficile* (e.g., piperacillin/tazobactam). Aside from nitazoxanide, an effective alternate in CDC is tigecycline. Tigecycline has several advantages. First, the use of tigecycline is protective against *C. difficile*. Second, by itself, it is highly effective against *C. difficile*. Third, and importantly, it also provides preemptive therapy of microscopic or gross peritonitis. Optimal therapy for *C. difficile* pancolitis is metronidazole plus tigecycline. In severe cases of pancolitis, nitazoxanide may be given orally via nasogastric or percutaneous endoscopic gastrostomy tube. Treatment of CDC should be continued until clinical resolution on abdominal CT scan. Transition to oral therapy for completion of CDC treatment may be done with nitazoxanide. CDC accompanied by toxic megacolon or colon perforation may require surgical intervention. Should surgery become necessary, tigecycline provides optimal monotherapy for colon surgery necessitated by toxic megacolon and/or colon perforation. Alternately, combination therapy with metronidazole (*C. difficile* and *B. fragilis* coverage) plus a "low *C. difficile* potential" antibiotic (e.g., ceftriaxone for aerobic Gram negative colon flora coverage).

C. difficile diarrhea and *C. difficile* colitis recurrence and relapse

Reinfection or recurrence of CDD is defined as another episode of CDD that has occurred after previous successful treatment. Clinically, cure is manifested by cessation of CDD while stool PCR for CDD may remain positive for 8 weeks following infection. Some

CDD patients will remain colonized (asymptomatic carriage) over time. The diagnosis of reinfection with CDD is a patient who again acutely develops otherwise unexplained, profuse watery diarrhea (20–30 liquid stools per day). Recurrence is easily misdiagnosed in those with *C. difficile* carriage who develop diarrhea due to another infectious or noninfectious diarrheal disorder. Diarrhea in such cases produces few soft or semi-formed stools per day, markedly less in number and volume than with CDD. In such cases, the clinician should try to determine the cause of the non-CDD loose stools and not try to treat *C. difficile* carriage just because the stool PCR is positive. In infectious disease, in general, colonization is more difficult to eliminate than infection, and this applies to CDD as well. Recurrent CDD should be treated the same as an initial episode with oral vancomycin using 500 mg (PO) every 6 hours for a week after clinical resolution. It is prudent to avoid retreatment with oral metronidazole even if successful previously, given its resistance potential and limited effectiveness against oral vancomycin.

A more difficult therapeutic challenge is CDD relapse. Relapse implies interval improvement without cure and is usually due to inadequate treatment due to drug choice, drug dose, or treatment duration. The approach to treating CDD relapse is based on two principles: avoidance of drug "tapering" regimens. High-dose oral vancomycin (500 mg q6h) is highly effective when given for a prolonged treatment course (3 weeks) without tapering the dose. Tapering regimens often fail and are based on the notion that, in the colon, *C. difficile* spores (spores are inert and non-toxin producing) will germinate during the taper and be eliminated by the lower drug dose. In CDD, the organism in the vegetative state is actively growing and producing toxin, but not in the spore stage; this is useful for survival in adverse environmental conditions (desiccation), which clearly is not the case in active infection in the colon. Other drugs that have been used to treat recurrent CDD include rifamaxin and fidaxomicin, which are comparable but not more effective than oral vancomycin 125 mg (PO) every 6 hours.

Fecal microbiota transplants (FMTs) have been used to treat CDD. Caution is advisable since FMTs have rarely transmitted enteric pathogens to recipients. Of the available treatment options, high-dose oral vancomycin (500 mg q6h) is the most reliably effective.

In cases of relapses of CDD, a careful review of the patient's medical history should be done to be sure that any residual *C. difficile* carriage is not induced to produce toxins and result in CDD (e.g., some antibiotics with a "high *C. difficile* potential", PPIs, probiotics, laxatives or stool softeners, some anti-depressants). In the few cases where 3 weeks of high-dose oral vancomycin may fail, it may be necessary to retreat with a second or, very rarely, a third course for cure. Relapse of CDC should be first approached by being sure that the colitis is, in fact, due to *C. difficile* and not a CDC mimic (e.g., ischemic colitis, CMV colitis, ulcerative colitis) in patients with stools PCR-positive for *C. difficile.* From a treatment perspective, nitazoxanide is highly effective, preferred to metronidazole, and may be given orally until the colitis resolves (Table 51.1).

TABLE 51.1 ***CLOSTRIDIUM DIFFICILE*** **DIARRHEA AND *C. DIFFICILE* COLITIS**

Diarrhea †§	**Diarrhea**
Initial episode:	**Initial episode:**
Vancomycin 250 mg (PO) q6h × 7–10 days* If no improvement in 3 days, ↑ dose to 500 mg (PO) q6h × 7 days)	Nitazoxanide 500 mg (PO) q12h × 7–10 days
Relapse:	**Relapse:**
Vancomycin 500 mg (PO) q6h × 14 days	Nitazoxanide 500 mg (PO) q12h × 7–10 days
Recurrence:††	**Recurrence:**
Vancomycin 500 mg (PO) q6h × 1 month (***do not taper vancomycin dose*****).**	Preferred Therapy Nitazoxanide 500 mg (PO) q12h × 7–10 days
If another recurrence,	Alternate Therapy Rifaximin 400 mg (PO) q8h × 10 days
retreat with Vancomycin 500 mg (PO) q6h × 2 months.	**or**
If another recurrence, retreat with Vancomycin 500 mg (PO) q6h *x* 3 months.	Fidaxomicin 200 mg (PO) q12h × 10 days
If dose not tapered and if no colitis, If diarrhea continues, look for alternate diagnosis.	**or**
	Bezlotoxumab 10 mg/ kg × 1 dose (plus an anti-C. difficile antibiotic)
	or
	FMT (potential to transmit enteric pathogens)

* With C. difficile diarrhea (CDD) (not colitis), treatment failure is common with vancomycin 125 mg (PO) q6h and with Metronidazole at any dose.
† When treating CDD or colitis, *discontinue antibiotics with a high C. difficile potential* (e.g., clindamycin, ciprofloxacin, β-lactams *excluding* ceftriaxone).
§ Avoid anti-spasmodics in CDD; use may result in *C. difficile* colitis (CDC).
§§ Colectomy may be life-saving in severe *C. difficile* pancolitis.

Preferred therapy	Alternate therapy
Colitis	**Colitis**
Mild/Moderately severe:	**Mild/Moderately severe:**
Metronidazole 1 g (IV) q24h until cured plus ceftriaxone 1 g (IV) 124h (until associated peritonitis resolves)	Metronidazole 500 mg (PO) q6h until cured **plus either** tigecycline 200 mg (IV) × 1 dose, then 100 mg (IV) q24h until cured or nitazoxanide 500 mg (PO) q12h until cured ± vancomycin 500 mg (PO) q6h if also with diarrhea until cured*
Severe pancolitis:§§ Metronidazole 500 mg (IV/PO) q6–8h until cured **plus** nitazoxanide 500 mg (PO) q12h × until cured **plus** tigecycline 200 mg (IV) × 1 dose, then, 100 mg (IV) q24h until cured	
	Colitis Relapse or Recurrence: Nitazoxanide 500 mg (PO) q12h until cured

* *C. difficile* colitis with no associated diarrhea, oral vancomycin of questionable benefit.

Sexually transmitted enteric infections

Thomas C. Quinn

Introduction

A wide variety of microbial pathogens may be transmitted sexually by the oral–anal or genital–anal routes. Sexually transmitted enteric infections may involve multiple sites of the gastrointestinal tract, resulting in proctitis, proctocolitis, and enteritis. These infections occur primarily in men who have sex with men (MSM) and heterosexual women who engage in anal–rectal intercourse or in sexual practices that allow for fecal–oral transmission. Anorectal infections with syphilis, gonorrhea, condyloma acuminata (human papillomavirus, HPV), lymphogranuloma venereum (LGV), and granuloma inguinale (donovanosis) have been recognized for many years. Over the past two decades, other sexually transmitted pathogens such as herpes simplex virus (HSV) and *Chlamydia trachomatis* have also been recognized as causing anorectal infection. Enteric pathogens traditionally associated with food- or waterborne acquisition but that also may be transmitted sexually include *Giardia lamblia, Entamoeba histolytica, Campylobacter, Shigella*, and *Salmonella*. In patients with AIDS, other opportunistic infections, including *Candida, Microsporida, Cryptosporidium, Isospora, Cyclospora, Mycobacterium avium* complex, and cytomegalovirus (CMV), may also cause intestinal disorders.

Depending on the pathogen and the location of the infection, symptoms and clinical manifestations vary widely. Perianal lesions are usually caused by syphilis, HSV, granuloma inguinale, chancroid, and condyloma acuminata. Rectal infections cause inflammation of the rectal mucosa, commonly referred to as *proctitis*. Symptoms include constipation, tenesmus, rectal discomfort or pain, hematochezia, and a mucopurulent rectal discharge. Proctitis can be caused by gonorrhea, chlamydia, syphilis, and HSV. Proctocolitis involves inflammation extending from the rectum to the colon, and, in addition to the organisms causing proctitis, other enteric pathogens such as *Shigella, Salmonella, Campylobacter, E. histolytica*, and CMV may be involved. Enteritis is an inflammatory illness of the duodenum, jejunum, and/or ileum. Sigmoidoscopy results are often normal, and symptoms consist of diarrhea, abdominal pain, bloating, cramps, and nausea. Additional symptoms may include fever, weight loss, myalgias, flatulence, urgency, and, in severe cases, melena. Sexually transmitted pathogens usually associated with enteritis include *Shigella, Salmonella, Campylobacter, Giardia*, CMV, and, potentially, *Cryptosporidium, Isospora*, and *Microsporida*.

The large number of infectious agents that cause enteric and anorectal infections necessitate a systematic approach to the management of these conditions. While obtaining the medical history, the clinician should attempt to differentiate between proctitis, proctocolitis, and enteritis and should assess the constellation of symptoms that suggest one or another likely infectious cause. The history should be used to investigate types of sexual practices and possible exposure to those pathogens known to cause intestinal infections. Examination should include inspection of the anus, digital rectal examination, and anoscopy to identify general mucosal abnormalities. Initial laboratory tests should include a Gram stain of any rectal exudate obtained with the use of an anoscope. The demonstration of leukocytes provides objective evidence of the presence of an infectious or inflammatory disorder. Cultures for gonorrhea should be obtained from the rectum, urethra, and pharynx, and, if possible, rectal swabs for nucleic acid amplification testing(NAAT) for chlamydia and gonorrhea should be performed. Serologic tests for syphilis should be performed in all cases.

Dark-field examination of any ulcerations and a rapid plasma reagin test should be performed. Cultures for HSV should be performed if ulcerative lesions are present. If proctocolitis is present, additional stool cultures for *Campylobacter, Salmonella*, and *Shigella* should be obtained, and stool examination for *E. histolytica* is indicated. For HIV-positive patients, other pathogens, including *Microsporida*, CMV, atypical *Mycobacteria, Cryptosporidium*, and *Isospora*, should be screened for by stool examination and cultured when possible. Specific information on clinical presentation, diagnosis, and therapy is provided in other chapters on gastroenteritis, intestinal protozoa, and individual enteric pathogens.

Gonococcal proctitis

Rectal infection with *Neisseria gonorrhoeae* occurs predominantly among homosexual men and in women engaging in anal–rectal intercourse. In many cases of women, the patient has no history of rectal intercourse and the infection is thought to have resulted from contiguous spread of infected secretions from the vagina. Symptoms, when present, develop approximately 5 to 7 days after exposure. Symptoms are usually mild and include constipation, anorectal discomfort, tenesmus, and a mucopurulent rectal discharge that may cause secondary skin irritation resulting in rectal itching and perirectal erythema. Although asymptomatic or mild local disease is common, complications such as fistulas, abscesses, strictures, and disseminated gonococcal infection may occur.

Findings of rectal gonorrhea during anoscopy are nonspecific and limited to the distal rectum. The most common finding is the presence of mucopus in the rectum. The rectal mucosa may appear completely normal or demonstrate generalized erythema with local areas of easily induced bleeding, primarily near the anal–rectal junction. Diagnosis is usually made by Gram stain and culture of material obtained by swabbing the mucosa of the rectal area. The sensitivity of Gram stain of rectal exudate for identification of gram-negative intracellular diplococci is approximately 80% when obtained through an anoscope versus 53% for blindly inserted swabs. Cultures inoculated on selective media provide the definitive diagnosis; however, the precise sensitivity of a single rectal culture for gonorrhea may be no greater than 80%. DNA detection assays are now widely available for detection of gonorrhea in urogenital specimens and are equally sensitive to culture.

Due to increasing antibiotic resistance of gonorrhea to cefixime and fluoroquinolones, the Centers for Disease Control and Prevention (CDC) recommends for treatment of uncomplicated urogenital, anorectal, and pharyngeal gonorrhea combination therapy with a single intramuscular dose of ceftriaxone 250 mg plus a single dose of azithromycin 1 g orally. Clinicians who diagnose gonorrhea in a patient with persistent infection after treatment (treatment failure) with the recommended combination therapy regimen should culture relevant clinical specimens and perform antimicrobial susceptibility testing of *N. gonorrhoeae* isolates. When ceftriaxone cannot be used for treatment of urogenital or rectal gonorrhea, several alternative options are available: cefixime 400 mg orally plus azithromycin 1 g orally, or dual treatment with single doses of oral gemifloxacin 320 mg plus oral azithromycin 2 g, or dual treatment with single doses of intramuscular gentamicin 240 mg plus oral azithromycin 2 g orally in a single dose. If a patient with gonorrhea is treated with an alternative regimen, the patient should return 2 weeks after treatment for a test of cure at the infected anatomic site. For all patients with gonorrhea, every effort should be made to ensure that the patients' sex partners from the preceding 60 days are evaluated and treated for *N. gonorrhoeae* with a recommended regimen. If there is continued evidence of proctitis, further evaluation for other agents such as chlamydia, syphilis, enteric bacterial pathogens, and HSV should be considered.

Chlamydia proctitis

Rectal infection with LGV and non-LGV immunotypes of *C. trachomatis* has been well documented. LGV infections are endemic in tropical countries, but they have also been increasing in frequency among MSM in the United States and Europe. LGV infections usually cause a severe proctocolitis characterized by severe anorectal pain, bloody mucopurulent discharge, and tenesmus. Inguinal adenopathy, which is characteristic of genital LGV, is often present. Sigmoidoscopy typically reveals diffuse friability with discrete ulcerations in the rectum that occasionally extend to the descending colon. Strictures and fistulas may become prominent and can be easily misdiagnosed clinically as Crohn's disease or carcinoma. Histologically, rectal LGV may be confused with Crohn's disease because giant cells, crypt abscesses, and granulomas may be present.

The non-LGV immunotypes of *C. trachomatis* are less invasive than LGV and cause a mild proctitis characterized by rectal discharge, tenesmus, and anorectal pain. Many infected individuals may be asymptomatic and can be diagnosed only by routine cultures. However, even in asymptomatic cases, abnormal numbers of fecal leukocytes are usually present. Sigmoidoscopy results may be normal or may reveal mild inflammatory changes with small erosions or follicles in the lower 10 cm of the rectum.

Rectal *C. trachomatis* infection can be diagnosed by nucleic acid amplified tests (NAATs) and nucleic acid hybridization tests. Since chlamydia culture is not widely available for this purpose, NAATs have demonstrated improved sensitivity and specificity compared with culture for the detection of *C. trachomatis* at rectal sites and at oropharyngeal sites. Some laboratories have met Clinical Laboratory Improvement Amendment (CLIA) requirements and have validated NAAT testing on rectal swab specimens for *C. trachomatis*. Serology is useful for the diagnosis of LGV with a complement fixation titer of greater than 1:64. Azithromycin, tetracycline, and doxycycline are the drugs of choice for infection with *C. trachomatis*. Azithromycin, 1 g as a single dose, is effective for urethritis and cervicitis and has been recommended for uncomplicated rectal infections. Doxycycline, 100 mg twice a day for 7 days, is effective except for treating LGV infection, which should be treated for 3 weeks with doxycycline 100 mg orally twice a day. Patients should be followed carefully with repeat sigmoidoscopy, particularly when there is any question about the differential diagnosis of LGV versus inflammatory bowel disease.

Anorectal syphilis

Treponema pallidum can be seen in its early infectious stages with a primary anorectal lesion appearing 2 to 6 weeks after exposure to rectal intercourse. However, clinicians often fail to recognize anorectal chancres and, consequently, syphilis in MSM is diagnosed in a secondary or early latent stage much more often than in the primary stage. Careful perianal examination can reveal unsuspected perianal chancres, but digital rectal examination and anoscopy may be required to detect asymptomatic chancres higher in the anal canal or rectum. When anorectal syphilis causes symptoms, it is often misdiagnosed as a traumatic lesion, fissure, or hemorrhoiditis. When symptoms are present, they include mild anal pain or discomfort, constipation, rectal bleeding, and occasionally a rectal discharge. Primary anorectal syphilis may appear as a single or multiple, mirror-image perianal ulcer ("kissing chancres"). It can also present as an ulcerated mass typically located on the anterior wall of the rectum. Inguinal adenopathy with rubbery, nonsuppurative, painless nodes may be associated with anorectal syphilis; it helps distinguish it from fissures. Secondary syphilis may cause discrete polyps, smooth lobulated masses, mucosal alterations, and nonspecific mucosal erythema or bleeding. In secondary syphilis, condyloma lata may be found near or within the anal canal. These are smooth, warty masses and should be differentiated from the more highly keratinized condyloma acuminata.

Diagnosis of anorectal syphilis is based on serology, perirectal and digital rectal examination, and anoscopy. Detection of motile treponemes by dark-field examination is useful for evaluation of perianal and anal lesions but may be less specific for rectal lesions because pathogenic treponemes can be found in the intestine. Biopsies of rectal lesions or masses should be processed for silver staining if syphilis is suspected. Serologic diagnosis of syphilis is based on the presence of antibodies to non-treponemal and treponemal antigens. A positive Venereal Disease Research Laboratory (VDRL) test or rapid plasma reagin (RPR) test must be confirmed by a positive specific test such as the fluorescent treponemal antibody absorption test (FTA-ABS) or the microhemagglutination assay (MHA). Some clinical laboratories and blood banks now screen samples initially using treponemal tests, typically by enzyme immunoassay. Persons with a positive treponemal screening test should have a standard non-treponemal test with titer performed reflexively by the laboratory to guide patient management decisions. For most HIV-infected persons, serologic tests are accurate and reliable for the diagnosis of syphilis and for following a patient's response to treatment. However, atypical syphilis serologic test results (i.e., unusually high, unusually low, or fluctuating titers) can occur in HIV-infected persons. When serologic tests do not correspond with clinical findings suggestive of early syphilis, use of other tests (e.g., biopsy and dark-field microscopy) should be considered.

Treatment for anorectal syphilis is standard treatment for early syphilis and consists of benzathine penicillin, 2.4 million U IM. Penicillin-allergic patients may be treated with a 14-day course of doxycycline, 100 mg twice daily, or tetracycline, 500 mg four times a day for 14 days.

Shigella, *Salmonella*, and *Campylobacter* infections

Shigellosis presents with an abrupt onset of diarrhea, fever, nausea, and cramps. Diarrhea is usually watery but may contain mucus or blood. Sigmoidoscopy usually reveals an inflamed mucosa with friability not limited to the distal rectum, and histologic examination shows diffuse inflammation with bacteria scattered throughout the submucosa. *Shigella sonnei* and *Shigella flexneri* account for most of the *Shigella* infections in the United States. Diagnosis is made by culturing the organism from the stool on selective media. Treatment is usually supportive with fluid replacement, and antimotility agents should be avoided. Antibiotics are useful in the management of shigellosis because use of appropriate therapy has reportedly shortened the period of fecal excretion and limited the clinical course. However, some authorities believe that antibiotic therapy should be reserved for the severely ill only or the immunocompromised patient because the infection is typically self-limited and resistance has been common. HIV-infected patients who develop *Shigella* infections may require prolonged treatment or suppressive therapy similar to those infected with salmonella. Antibiotic therapy should be chosen according to the sensitivity pattern of the *Shigella* species isolated. Ciprofloxacin, 500 mg twice a day for 7 days, is usually effective unless resistance is evident.

Campylobacter jejuni and *Campylobacter*-like organisms such as *Helicobacter cinaedi* and *Helicobacter fennelliae* have also been associated with proctocolitis in homosexual men. Clinical manifestations of infections resulting from all *Campylobacter* species appear nearly identical. There is often a prodrome with fever, headache, myalgia, and malaise 12 to 24 hours before the onset of intestinal symptoms. The most common symptoms are diarrhea, malaise, fever, and abdominal pain. Abdominal pain is usually cramping and may be associated with 10 or more bowel movements per day. *C. enteritis* is often self-limiting with gradual improvement in symptoms over several days. Illnesses lasting >1 week occur in approximately 10% to 20% of patients seeking medical attention, and relapses are often seen in HIV-infected patients. Fecal leukocytes are uniformly present, and diagnosis is confirmed by isolation of the organisms on selective media in a microaerophilic atmosphere. Therapy consists of fluid and electrolyte replacement and antibiotic treatment. Ciprofloxacin 500 mg twice a day for 7 days or azithromycin 500 mg once daily for 3 days has been used successfully for treatment, but resistance to these antibiotics has also been increasing within recent years and antibiotic susceptibility should be reviewed.

Salmonella infections of the intestinal tract are primarily caused by *S. typhimurium* and *S. enteritidis*. Salmonella has been reported among homosexual male partners, suggesting sexual transmission,

and salmonella bacteremia in an HIV-infected individual is now diagnostic of AIDS. Clinical presentation often depends on the host immune status. In an immunocompetent person, salmonellosis is usually self-limited and causes gastroenteritis. No antibiotic therapy is recommended because symptoms fade within days, and antibiotics have been associated with prolonged salmonella intestinal carriage. In HIV-infected individuals, salmonella infections may cause severe invasive disease and often result in bacteremia with widespread infection. The fluoroquinolones are effective drugs of choice for *Salmonella* infections in immunocompromised individuals. Despite adequate therapy for bacteremia, virtually all HIV-infected patients may suffer recurrent salmonella septicemia. Ciprofloxacin, 500 to 750 mg twice daily, has been effective in suppressing recurrences in such patients.

Parasitic infections

Homosexual men engaging in sexual activities involving fecal contamination such as oral–anal sex are at increased risk for a number of parasitic infections, including *Giardia lamblia, Iodamoeba butschlii, Dientamoeba fragilis, Enterobius vermicularis, Cryptosporidium, Isospora*, and microsporidia. Of these infections, *Giardia* and *E. histolytica* appear to be the most common sexually transmitted parasitic infections. *G. lamblia* is associated with symptoms of enteritis, and *E. histolytica* may cause proctocolitis. Most *E. histolytica* infections are asymptomatic, and <10% of those infected develop invasive disease with amebic dysentery or liver abscess. Most *E. histolytica* strains isolated from homosexual men are the nonpathogenic strains not usually associated with gastrointestinal symptoms. However, when symptoms are present, they may vary from mild diarrhea to fulminant bloody dysentery. These symptoms may wax and wane for weeks to months.

Diagnosis is based on demonstration of *E. histolytica* in the stool in a wet mount of a swab or in biopsy of rectal mucosal lesions. Occasionally, multiple fresh stool examinations are necessary to demonstrate the cysts or trophozoites or *E. histolytica*. For noninvasive disease limited to the lumen only, paromomycin 25 to 30 mg/kg/d in three doses for 7 days is the regimen of choice. Invasive intestinal disease should be treated with metronidazole, 750 mg orally three times daily for 7 to 10 days.

G. lamblia also appears to be sexually transmitted through oral–anal contact. Giardiasis is typically an infection of the small intestine, and symptoms vary from mild abdominal discomfort to diarrhea, abdominal cramps, bloating, and nausea. Multiple stool examinations may be necessary to document infection with *G. lamblia*. When stool examination is negative, sampling of the jejunal mucus by the Enterotest or small-bowel biopsy may be necessary to confirm the diagnosis. Metronidazole 250 mg three times a day for 7 days is recommended. Alternative regimens include tinidazole, 2 g only single dose, or paromomycin, 10 mg/kg orally three times per day for 5 to 10 days.

Although sexual transmission of *Cryptosporidium, Isospora belli*, and *Microsporida* are commonly seen in HIV-infected homosexual men, evidence for sexual transmission is limited. These protozoa primarily infect the small bowel and cause nonspecific watery diarrhea, abdominal cramping, and bloating. Diagnosis is established by a modified acid-fast stain or fluoramine stain of the stool or by concentration and identification of the organism by the sugar-flotation method. A commercially available fluorescein monoclonal antibody assay increases the sensitivity for detection of *Cryptosporidium*. Treatment of *Cryptosporidium* or *Isospora* infections in immunocompetent patients with self-limited diarrhea is rarely required. Among HIV-infected individuals, treatment should be directed toward symptomatic treatment of the diarrhea with rehydration and repletion of electrolyte losses by either oral or intravenous route. Although several antibiotics have been used, including paromomycin and azithromycin, chronic infection and relapses are common. The most effective therapy currently is a reversal of immunosuppression with the use of highly active antiretroviral therapy. It is common for patients with severe diarrhea from *Cryptosporidium* and *Microsporida* to clear their infections by taking combination antiretroviral agents with reduction in the viral load below detectable limits. Successful treatment of the infection presumably results from a subsequent rise in CD4 count and restoration of immune competence sufficient to clear the intestinal infection.

Acute appendicitis

Bian Wu and John Maa

Background and epidemiology

Acute appendicitis is one of the most common surgical emergencies, with a lifetime incidence of approximately 7%. It can occur in males and females of all ages, but is most common in older children and young adults. The diagnosis is often delayed in younger children and the elderly due to atypical presentations.

Pathogenesis

The pathophysiology of acute appendicitis begins with obstruction of the appendicular lumen. The obstruction is commonly caused by a fecalith (impacted stool) in adults and lymphoid hyperplasia in children, but can also result from foreign bodies (undigested seeds), infections (especially parasitic), and tumors (most commonly adenocarcinoma, followed by carcinoid tumors). Luminal obstruction leads to accumulation of distal secretions and increased intraluminal pressure, which results in impairment of venous outflow and, subsequently, arterial inflow. The resulting ischemia yields bacterial translocation, mucosal necrosis, and, eventually, perforation. The natural progression and types of acute appendicitis are described in Table 53.1 (simple acute, suppurative, gangrenous, perforated, associated with abscess). The organisms most typically associated with gangrenous or perforated appendicitis are *Escherichia coli*, *Peptostreptococcus*, *Bacillus fragilis*, and various species of *Pseudomonas*, with most cases being polymicrobial.

Diagnosis

A classic presentation of acute appendicitis includes periumbilical pain that migrates to the right lower quadrant, representing a progression from visceral pain to parietal pain that may occur within a few hours or a few days. Physical examination often reveals point tenderness at McBurney's point, located two-thirds the distance from the umbilicus to the right anterior superior iliac spine. Worsening or diffuse abdominal pain or tenderness are concerning for perforation and peritonitis, as are fevers greater than 38.5°C (101.3°F). Occasionally a palpable mass may be felt in the right lower quadrant, suggestive of a walled-off abscess.

Onset of pain is classically followed by anorexia and nausea, and vomiting may occur. Absence of anorexia and repeated episodes of emesis suggest an alternate diagnosis. Importantly, the classic symptoms of acute appendicitis have limited sensitivity due to variant locations of the appendix and inflammatory irritation of nearby organs. A retrocecal appendicitis may present as flank or back pain, whereas an inflamed appendix in the pelvis may present as dysuria or be confused with testicular or gynecologic diseases. Inflammation of adjacent bowel may cause either an ileus or diarrhea, especially in cases of gross perforation or abscess.

TABLE 53.1 **TYPES OF ACUTE APPENDICITIS**

Type	Characteristics
Simple acute	Mild hyperemia, edema, appendiceal dilation, no serosal exudate
Suppurative	Edematous, congested vessels, fibrinopurulent exudate; peritoneal fluid increased, clear or turbid; may be walled off by omentum, adjacent bowel or mesentery
Gangrenous	Similar to suppurative plus areas of gangrene, microperforations, increased and purulent peritoneal fluid
Perforated	Obvious defect in wall of appendix; thick and purulent peritoneal fluid; may be associated with ileus or bowel obstruction
Abscess	Appendix may be sloughed; abscess at site of perforation: right iliac fossa, retrocecal, or pelvic; may present rectally; thick, malodorous pus

The recent advances in ultrasonography and computed tomography (CT) have markedly improved the accurate diagnosis of appendicitis, especially in "atypical" cases. Ultrasound is noninvasive and an excellent way to evaluate young children for whom avoidance of radiation is desirable. However, the usefulness of ultrasound is technician-dependent and often limited by patient habitus (ultrasound waves penetrate poorly through fat). CT, optimally with IV and PO contrast, yields excellent sensitivity and specificity, but is costly and carries the risk of radiation and contrast exposure. Many diseases may mimic acute appendicitis and it is essential to combine history, physical exam, laboratory values, and imaging studies with clinical experience and judgment to minimize the rate of misdiagnosis.

Treatment

The mainstay of treatment for simple acute appendicitis is prompt surgical removal of the appendix. To prevent progression leading to perforation, it is important to achieve timely and proper source control. While some evidence supports using antibiotics alone to treat simple acute appendicitis, it is our opinion that appendectomy remains the standard of care. Antibiotics alone carry a significant risk of primary failure leading to perforation as well as disease recurrence, and the now widespread use of laparoscopic appendectomy results in lower rates of surgical complications and shorter hospital stays than were achieved with open appendectomy.

Similarly, surgery remains the standard of care for suppurative, gangrenous, and perforated appendicitis. The exception to urgent surgical intervention for acute appendicitis is perforated appendicitis associated with a contained abscess. In such cases, percutaneous drainage together with antibiotics and interval laparoscopic appendectomy in 6 weeks may be the best treatment strategy, to avoid injury to the small bowel and colon. Antibiotic selection should be tailored to the polymicrobial nature of the disease. Typically, an antipseudomonal β-lactamase is used, such as meropenem, cefepime, or piperacillin/ taxobactam. In cases of β-lactamase allergy, combinations such as ciprofloxacin and metronidazole can be used. The most common bacteria that lead to a postoperative infection after appendectomy are: (1) *Bacteroides*, (2) *Klebsiella*, (3) *Enterobacter*, and (4) *E. coli*, although many of these infections are polymicrobial. Gram-positive cocci are less frequently isolated.

Laparoscopic appendectomy is generally recommended over open appendectomy because it results in less postoperative pain, shorter hospital stays, and a faster return to normal activities. The risk of wound infections is lower with laparoscopic surgery than with open surgery (odds ratio 0.43 with 95% confidence interval 0.34–0.54), but the risk of intra-abdominal abscesses is higher (odds ratio 1.87 with 95% confidence interval 1.19–2.93). This higher risk may be due to the more limited ability to perform peritoneal lavage with laparoscopic surgery as compared to open surgery. In fact, studies suggest there is no advantage to irrigation of the peritoneal cavity over suction alone during laparoscopic appendectomy for perforated appendicitis. Thus, open surgery may be preferred for patients with grossly perforated appendicitis. Laparoscopic surgery use is also limited in some parts of the world by the availability of laparoscopic equipment and surgeons trained in minimally invasive techniques.

Perioperative management

During workup for possible acute appendicitis, patients should be kept NPO. Once the diagnosis is made, a general surgeon should be consulted and the operation arranged. Since patients are typically volume depleted (as evidenced by tachycardia, low urine output, elevated creatinine, hemoconcentration), aggressive fluid resuscitation with an isotonic solution should be started, and electrolytes repleted. Should there be signs of perforation or frank peritonitis (as evidenced by worsening diffuse pain, rebound or involuntary guarding on exam, very high fever, findings on CT scan), the patient's operation should be further expedited.

A broad-spectrum antibiotic should be given prior to skin incision and is typically not continued postoperatively, except in cases with gross perforation. Preoperative preparation of the skin is best performed with a chlorhexidine–alcohol scrub. Postoperatively, patients undergoing laparoscopic appendectomy can typically be started on a clear liquid diet immediately and advanced to a regular diet the following morning. Patients with gross perforation and a likely associated ileus are typically kept NPO immediately postoperatively. The diet is then advanced slowly depending on the length of surgery and associated intra-abdominal inflammation or contamination. Patients should begin walking immediately postoperatively to prevent complications such as pneumonia or deep venous thrombosis.

TABLE 53.2 **TYPES OF POSTOPERATIVE INFECTION**

Type	Characteristics	Management
Superficial surgical site infection (SSI)	Cellulitis +/− infected subcutaneous fluid collection	PO or IV antibiotics +/− open skin at bedside to drain fluid followed by packing the wound with gauze
Deep surgical site infection (SSI)	Infection involving the abdominal fascia (may be associated with fascial dehiscence)	IV antibiotics +/− operative debridement
Organ space infection	Intra-abdominal abscess or gross postoperative perforation/peritonitis	IV antibiotics and percutaneous drainage or operative exploration and washout
Pylephlebitis	Infection and thrombophlebitis within the portal venous system	Intravenous antibiotics +/− systemic heparinization

Postoperative complications

Postoperative infections remain the major source of morbidity associated with acute appendicitis. Gross perforation of the acutely inflamed appendix changes the wound classification from clean-contaminated to dirty, with an associated increased risk of postoperative infection from around 10% to 40%. Classification of postoperative infections is dependent on the depth: superficial surgical site infection (SSI), deep SSI, and organ space infection (Table 53.2). While superficial SSIs can typically be managed with a short course of antibiotics with or without bedside opening of the superficial wound, deep SSIs require longer courses of antibiotics and possible return to the operating room for debridement. Organ space infections typically necessitate percutaneous drainage or operative exploration and washout, as well as an extended course of antibiotics.

To minimize the risk of superficial SSIs in cases of perforated appendicitis, the traditional approach after open appendectomy has been to close the fascia, but not the skin edges, to allow for healing by secondary intention or delayed primary closure. This is not typically performed after laparoscopic appendectomy. Laparoscopic appendectomy is associated with a lower risk of superficial and deep SSI, but a higher risk of organ space infection compared to open appendectomy. To minimize the risk of deep SSIs and organ space infections, a Jackson Pratt drain may be left in the abdomen after either open or laparoscopic appendectomy.

For cases of non-perforated appendicitis, postoperative antibiotics do not alter the incidence of superficial SSIs, deep SSIs, or organ space SSIs, but do correlate with higher rates of *Clostridium difficile* infection and urinary tract infection, as well as longer hospital stays. On the other hand, antibiotics play an important role in the postoperative management of perforated appendicitis. Patients with severe sepsis or septic shock in the postoperative period necessitate immediate transfer to the ICU and goal-directed therapy (blood cultures, IV antibiotics, IV fluids, and possible vasopressors). These patients often require return to the operating room for source control.

The presence of a postoperative hematoma significantly increases the risk of both superficial and organ space infections, thus meticulous intraoperative hemostasis is essential. Pyephlebitis (infection and thrombosis within the portal venous system) may occur with any intra-abdominal infection, but is now rare with the use of perioperative antibiotics. Other rare postoperative complications include stump appendicitis (related to incomplete resection of the appendix), cecal fistula (related to loss of seal at the resected appendicular orifice resulting in an organ space infection), and wound dehiscence (associated with deep surgical site infection).

Diverticulitis

Matthew D. Zelhart and Ronald L. Nichols

Diverticulosis coli is an anatomic abnormality of mucosal outpouchings in the colonic wall. Colonic diverticula are often asymptomatic, and the prevalence varies greatly with such factors as geographic location, dietary habits, race, and age. In the United States, the incidence has been noted to increase with age, with up to a third of the population older than 60 being affected and more than two-thirds of the population older than 80 being affected.

The diagnosis of diverticulosis is often made incidentally in otherwise asymptomatic patients at the time of routine surveillance endoscopy or on imaging for other reasons. Most of these patients require only counseling about the need for prophylactic measures such as a fiber-rich diet, adequate fluid consumption, and the prevention of constipation. Discussion of the risk of possible infectious (up to 25% risk) or hemorrhagic complications of the disease should also be undertaken.

Symptomatic diverticulosis presents as two categories. First is bleeding, in the form of lower gastrointestinal hemorrhage. This is very rarely seen in the setting of diverticulitis. The second category of complications is from inflammation in the form of diverticulitis. This can present as perforations, fistulas, or strictures. While rare when compared to the frequency of diverticulosis in the population, clinically significant diverticular disease and its complications continue to tax the diagnostic and therapeutic skills of physicians. Physical findings range from diffuse slight abdominal tenderness to shock secondary to either massive hemorrhage or overwhelming sepsis. Even when clinical manifestations of diverticulosis occur, emergent surgical intervention is necessary in only a minority of patients. During such life-threatening emergencies, the physician must be prepared to resuscitate the patient quickly and proceed to surgical intervention without benefit of a definite diagnosis. These patients may have massive or recurrent gastrointestinal bleeding or could have generalized peritonitis from a perforation of diverticulitis.

Diagnosis of infection

It is often possible to make a presumptive diagnosis of acute diverticulitis on the basis of history, physical examination, and initial laboratory tests. These symptoms include fever, abdominal pain, and tenderness—usually in the left lower quadrant. This presumptive diagnosis allows for the expedited initiation of resuscitative measures, including empiric antibiotic therapy. If the patient is stable, it is best to perform diagnostic radiographic tests as soon as possible to confirm the presumptive diagnosis.

CT is generally thought to be superior and safer than contrast enema studies and ultrasounds for the diagnosis of diverticular disease. For those who still prefer the contrast enema for colonic imaging, water-soluble contrast materials are preferred to barium to avoid barium peritonitis in case of perforation or leakage.

Once diverticulitis has been documented radiographically, further clinical decisions depend on the resolution of signs and symptoms of infection. If they resolve completely and the patient is stable, endoscopic examination of the entire colon is required to evaluate for neoplastic disease or complications such as stricture. Colonoscopy is best performed approximately 6 weeks after symptoms of acute diverticulitis have subsided

to decrease the risk of perforation of the inflamed intestinal wall. Approximately 8% of patients diagnosed with perforated diverticulitis actually have a neoplastic process.

Management of diverticulitis

The greatest number of complications in colonic diverticular disease result from infection. They range from localized short segments of diverticulitis, to abscesses and/or fistulas, to free perforation with generalized peritonitis and overwhelming intra-abdominal sepsis (Figure 54.1). While the cause of the diverticular formation has been established as increased intraluminal pressure, the cause of diverticulitis and its related complications is not clear. Some authorities postulate that a surge in intraluminal pressure is often the cause, and others suggest ulceration, ischemia, and foreign-body perforation. Diverticulitis resulting in bowel perforation is divided into *uncomplicated* and *complicated diverticulitis* (Figure 54.2).

Uncomplicated diverticulitis

Uncomplicated diverticulitis occurs when there is local inflammation or phlegmon associated with diverticulosis but no discrete abscess or perforation (Figure 54.3). This is the most common form of diverticulitis. Penetration of mixed bacterial flora into the wall of the intestine associated with this state initiates peridiverticular infection.

Patients with uncomplicated diverticulitis usually complain of abdominal pain localized to the left lower quadrant. In some cases, however, a redundant sigmoid colon may have sufficient mobility to produce local symptoms in the right lower or right upper abdominal quadrant as well as in the mid epigastrium. These patients are often febrile and have mild leukocytosis. However, they typically respond well to bowel rest, parenteral fluids, and antibiotic therapy. Nasogastric tube insertion is usually unnecessary unless obstructive signs and symptoms are present.

Most patients require a 3- to 5-day course of appropriate parenteral or enteral antimicrobials (Table 54.1), but this has recently been called into question by recent studies that show no difference in recovery between patient treated with or without oral antibiotics;

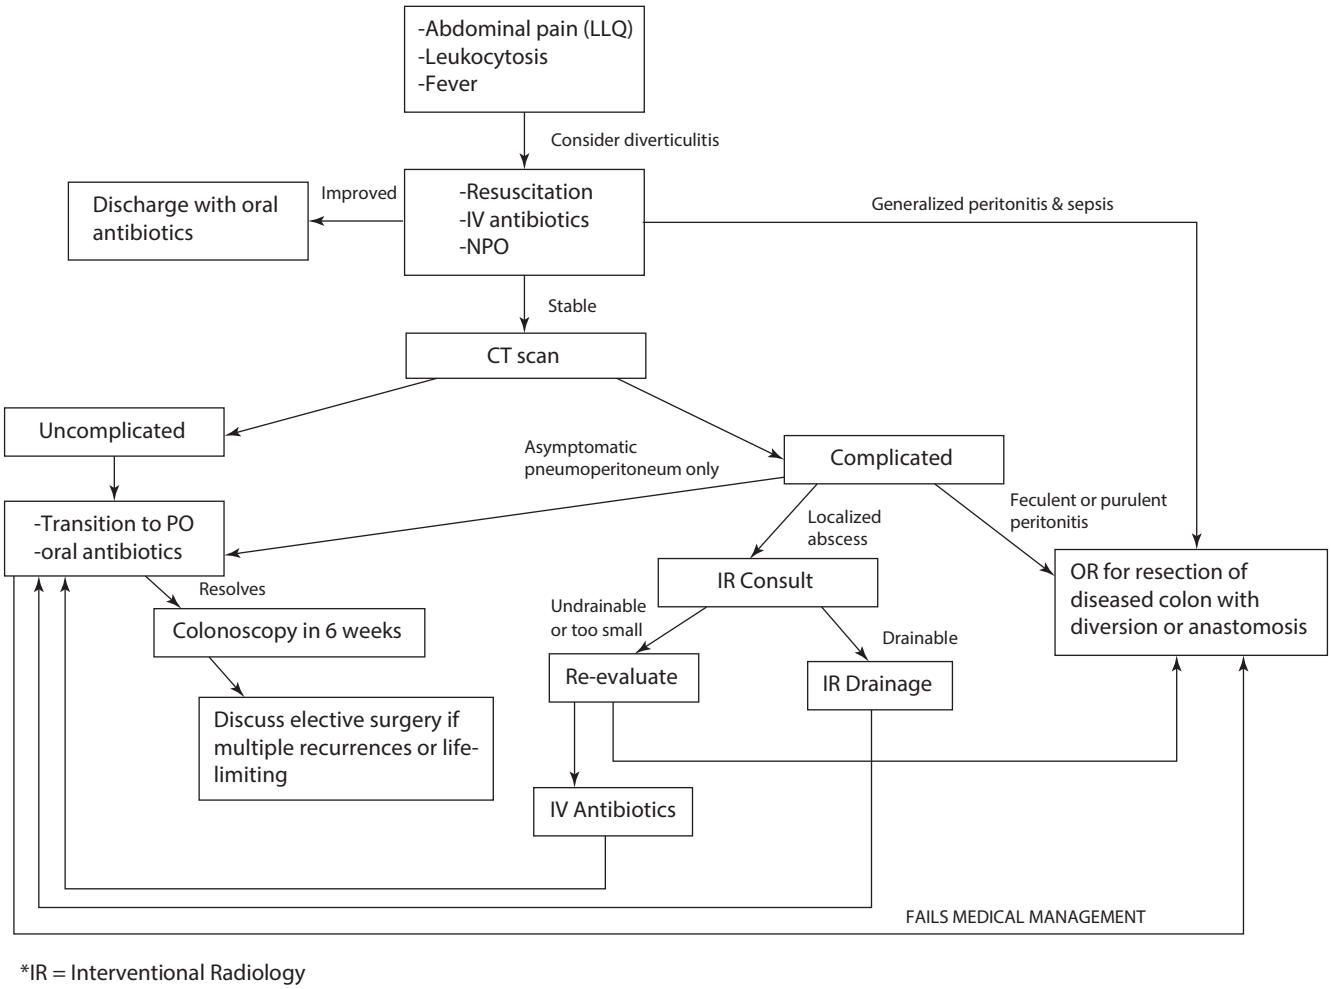

FIGURE 54.1 Algorithm for the workup and treatment of acute diverticulitis.

FIGURE 54.2 Representative images of diverticulosis without inflammation or perforation.

further studies are needed to elucidate this controversy. If patients continue to improve with normalization of the white blood cell (WBC) count, temperature, and abdominal examination, we advance them to a low-residue diet—one that is devoid of poorly digestible foods (e.g., whole corn)—in the acute inflammation stage.

Patients must be followed carefully after resolution of abdominal symptoms. If no disease other than diverticulosis is found on follow-up endoscopy, each patient should follow a fiber-supplemented diet with generous consumption of fluids and a recommended 30 minutes of daily cardiovascular exercise.

Surgery is not generally recommended after uncomplicated diverticulitis in otherwise healthy patients. Rather, we recommend medical therapy, and the decision for elective surgery after resolution should be made on a case-by-case basis. Some factors which may influence the decision to proceed with elective colon resection include frequency of episodes, frequent travel, life-limiting attacks, and immune status of the patient. Such resection can be performed by an open laparotomy technique or by a minimally invasive technique.

Although the medical approach rarely fails to control the signs and symptoms of uncomplicated diverticulitis, surgical resection may become necessary if the infection does not resolve with prolonged parenteral antibiotic therapy. This is normally termed "smoldering diverticulitis." However, patients with very limited symptoms and no signs of systemic sepsis normally respond to oral

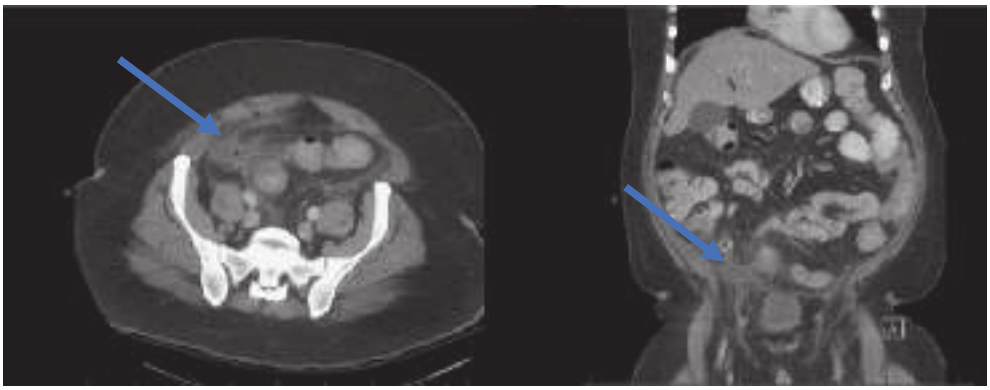

FIGURE 54.3 Diverticulitis with phlegmon and no organized abscess (*arrow*).

TABLE 54.1 **INTRAVENOUS ANTIBIOTICS FOR COVERAGE OF THE AEROBIC AND ANAEROBIC HUMAN COLONIC MICROFLORA**

Drug	Dosage	Frequency
Combination therapy		
Aerobic coverage[a]		
Amikacin	15–20 mg/kg/d	q8–12h
Aztreonam	1–2 g	q6–8h
Ceftriaxone	1–2 g	12–24h
Ciprofloxacin	400 mg	ql2h
Gentamicin	5–7 mg/kg/d	q8h
Tobramycin	5–7 mg/kg/d	q8h
Anaerobic coverage[b]		
Clindamycin	600–900 mg	q8h
Metronidazole	500 mg	q8–12h
Aerobic–anaerobic coverage (single-drug therapy)		
Ampicillin–sulbactam	1.5–3 g	q6h
Cefotetan	1–2 g	q8–12h
Cefoxitin	1–2 g	q6h
Ertapenem	1 g	q24h
Imipenem–cilastatin	500 mg	q6h
Meropenem	1 g	q8h
Piperacillin–tazobactam	3.375–4.5 g	q6h
Ticarcillin–clavulanate	3.1 g	q6h
Tigecycline	100 mg (initial dose) then 50 mg	q12h

[a] To be combined with a drug exhibiting anaerobic activity.
[b] To be combined with a drug exhibiting aerobic activity.

regimens of antibiotics aimed at covering these colonic aerobes and anaerobes (Table 54.2).

Complicated diverticulitis

Complicated diverticulitis occurs when the diverticular inflammation has progressed to a frank perforation. This can manifest itself into an abscess (Figure 54.4) or free perforation of purulent material or feces into the abdomen (Figure 54.5). Complicated diverticulitis is classified into four types by the Hinchey Classification (Table 54.3), although this plays little role in treatment. Most often, complicated diverticulitis presents as a pericolic abscess demonstrated by CT. If these studies reveal a small cavity and the patient is improving, continuation of medical therapy and antibiotics is warranted. However, in patients who are not improving or have a larger abscess cavity, percutaneous drainage may be a useful adjunct.

In patients with a history of an episode of complicated diverticulitis, a long discussion should be had about undergoing elective colon resection. Our approach to preoperative colon preparation is shown in Box 54.1. However, data have not consistently demonstrated that recurrent attacks will occur or that they will become more severe in nature. Decompressing the purulent contents of an abscess via CT-guided percutaneous catheter placement gains time to improve the patient's status with volume replacement and appropriate antibiotic therapy. Once the abscess cavity has been resolved by catheter drainage and symptoms improve, oral intake can be resumed.

TABLE 54.2 **ORAL ANTIBIOTIC REGIMENS FOR TREATMENT OF A MILD EPISODE OF ACUTE DIVERTICULITIS**

Antibiotic	Dosage (mg)	Frequency-duration
Ciprofloxacin	500	BID
Ciprofloxacin and metronidazole	500/500	BID/BID
TMP–SMX DS and metronidazole	800/500	BID/BID
Amoxicillin-clavulanic acid	250–500	TID
Doxycycline	100	q24h

Abbreviations: BID = twice a day, TID = three times a day, TMS–SMX DS = trimethoprim–sulfamethoxazole (Bactrim) double strength.

Patients with free perforations of purulence or feces, or those who do not respond to medical management, are best treated with urgent surgical intervention. There are two essential operative goals. The first is to resect the inflamed colon and control the associated septic complications; surgical resection of the infectious source is superior to simple diversion of colonic contents (colostomy) and drainage or laparoscopic lavage. The second goal is to restore intestinal continuity. Although this may require a second procedure in

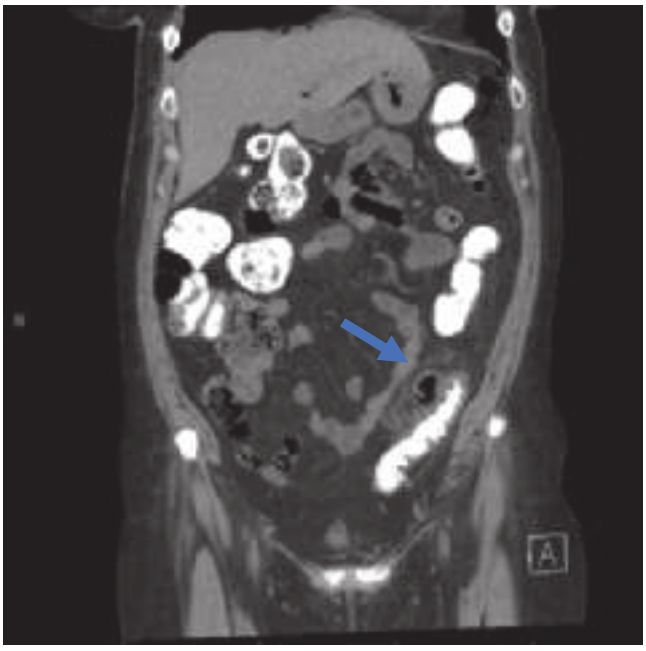

FIGURE 54.4 Perforated diverticulitis with contained abscess (*arrow*).

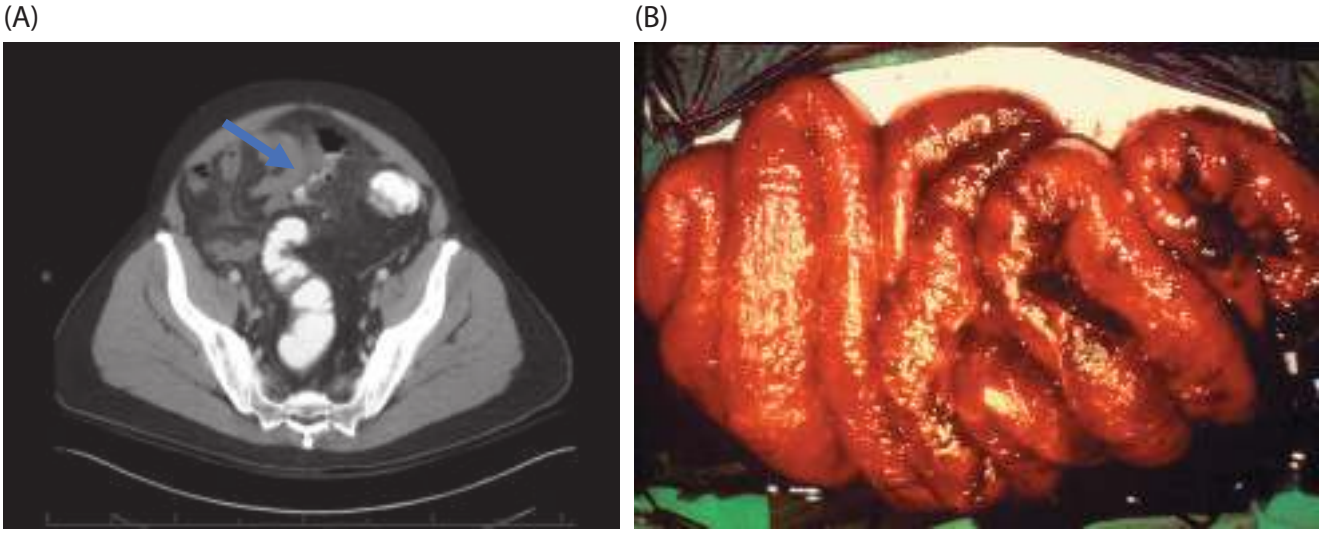

FIGURE 54.5 (A) Perforated diverticulitis with free contrast extravasation (*arrow*). (B) Photo of generalized peritonitis.

some cases, we believe it can often be accomplished safely during the same operation (single-stage procedure) in many patients. This is particularly true in individuals who are not hemodynamically compromised, who have localized diverticulitis, or who have diverticulitis with an associated mesocolonic abscess amenable to en bloc resection and with no intra-abdominal spillage of purulent material.

In summary, if urgent surgery is necessary for localized diverticulitis, we try to remove the inflamed colon, most often performing a primary anastomosis with or without a diverting ileostomy. If this is inadvisable because of hemodynamic instability or gross evidence of peritoneal contamination, we do an end colostomy with a distal pouch provided no distal obstruction is present. Diversion alone is rarely done as it has shown to result in a high mortality rate.

Generalized intra-abdominal sepsis

Patients with free perforation of purulence or feces require prompt fluid resuscitation and empiric antibiotic coverage with an agent or combination of agents that will control both aerobic and anaerobic enteric organisms (Table 54.1). If there is evidence of an unconfined perforation or if the patient is in shock, laparotomy as soon as the patient is stable is often necessary. Laparotomy often reveals fibrinous exudate, free purulence, or fecal material throughout the abdominal cavity (Figure 54.5). If we find diverticulitis, we resect the involved segment and perform a proximal colostomy. Under these conditions, we rarely perform a primary anastomosis. We prefer to leave a closed distal pouch, but only if there is no distal lesion present. Such a lesion could produce a blind-loop syndrome and leakage of the distal pouch, or could require another operation for its removal. If the distal pouch is friable or there is a compromised staple line, a large Malecot drain can be left in the rectal pouch draining exteriorly as a path of least resistance to prevent rectal stump blowout.

After resection, we copiously irrigate the abdominal cavity with normal saline. We strongly believe that if gross peritonitis is present, the skin wound should not be closed tightly. There is some merit to considering negative pressure dressings in these patients as well. Patients who have undergone such surgery usually require careful monitoring in an intensive care unit and appropriate antibiotic coverage.

TABLE 54.3 **HINCHEY CLASSIFICATION FOR COMPLICATED DIVERTICULITIS**

Hinchey stage	
Grade I	Contained pericolic abscess
Grade II	Contained distant abscess
Grade III	Purulent peritonitis
Grade IV	Fecal peritonitis

BOX 54.1

Suggested approach to preoperative preparation for elective colon resection

Two days before surgery (at home)
Low-residue or liquid diet

One day before surgery (at home or in hospital if necessary)
Admit in morning (if necessary and allowed)
1. Continue clear liquid diet, IV fluids as needed
2. Whole-gut lavage with polyethylene glycol, 1 L/h PO starting at 8 AM until diarrhea is clear (no longer than 3–4 h)No enemas

All patients receive 1 g of neomycin PO and 1 g of erythromycin base PO at 1 PM, 2 PM, and 11 PM **Day of surgery**
Operation at 8 AMA single dose of antibiotic with broad-spectrum aerobic/anaerobic activity given IV by anesthesia personnel in the operating room just before incision; repeat dosage if operation lasts >2 h

Many of these patients develop secondary intra-abdominal or pelvic abscesses, which are detectable with CT. If percutaneous drainage is not successful a repeat laparotomy will likely be necessary. Many of these patients will also have prolonged ileus and therefore may require parenteral hyperalimentation to meet the extraordinary metabolic demands of controlling intra-abdominal sepsis. Of course, enteral nutrition should be resumed as soon as possible.

Abdominal abscess

K. Shad Pharaon and Donald D. Trunkey

Intra-abdominal infections generally occur after entry of enteric organisms into the peritoneal cavity. An abscess is the body's way of attempting to contain an infection. Intraperitoneal and retroperitoneal abscesses can develop as a result of appendicitis, diverticulitis, necrotizing enterocolitis, pancreatitis, pelvic inflammatory disease, tubo-ovarian infection, surgery, or trauma. Given the vast number of microbes in our alimentary tract, any penetration of the wall of the gastrointestinal (GI) tract as a result of a vascular, traumatic, or iatrogenic event introduces these microbes into the abdomen. The concentration of microorganisms increases with distal progression down the GI tract. The morbidity of an intra-abdominal infection is 40%. The mortality is 20% in immunocompetent patients, and can be as high as 70% in the immunocompromised. This chapter explains types of peritonitis, locations of abscesses, diagnosis, treatment, common organisms associated with community-acquired and healthcare-associated infections, and suggested use of antimicrobials.

Abdominal abscess often follows or complicates peritonitis (see Chapter 57, Peritonitis). Primary peritonitis is an infection of the peritoneal cavity without an underlying violation of the intestinal wall; the most common cause of primary peritonitis is spontaneous bacterial peritonitis (SBP). The etiology of SBP is thought to be translocation of bacteria through the intestinal wall and into the abdomen. Clinical features of SBP may be subtle or absent, but usually SBP causes abdominal pain from infected ascites. The mainstay of treatment of primary peritonitis is antibiotics. Secondary peritonitis results from perforation of hollow viscera with spillage of intestinal contents, often from appendicitis, diverticulitis, or ulceration. The patient may initially present with severe abdominal pain, tenderness, rigid abdomen, or shock. The peritonitis can be focal or diffuse. If the spillage is small, the patient may not initially seek medical attention. Over the course of a few days the body will attempt to contain it, and an abscess may develop. If the abscess is less than 3 cm, the patient may only need antibiotics. An abscess 3 cm or greater usually needs drainage, and the percutaneous approach is preferred. Some abdominal abscesses progress to severe sepsis and shock, particularly when left untreated. Immunocompromised patients may have perforation with gross contamination of their abdomen, yet be relatively asymptomatic, making diagnosis more challenging. Tertiary peritonitis is a persistent or recurrent infection following treatment of primary or secondary peritonitis and is often found in patients with pre-existing comorbidities or who are immunocompromised.

Abdominal infection is designated uncomplicated or complicated. Uncomplicated infection usually involves one organ, as in acute (non-perforated) appendicitis, cholecystitis, or diverticulitis. Surgical resection is needed for many of these early, uncomplicated infections. Patients usually improve quickly and only need 24 hours or less of antibiotic coverage. Complicated infection extends beyond one organ into the peritoneal space. These infections can be florid fecal peritonitis from a perforated appendix or diverticulum and fecal contamination will often lead to an abscess.

Abscesses can form within the peritoneal lining, usually days after an intraperitoneal infection. Intraperitoneal abscesses commonly follow a perforated appendix or diverticulum, but also occur after tubo-ovarian infection, recent surgery (particularly of the colon), pyogenic liver abscess after biliary tract disease, or splenic abscess from trauma. Patients can also develop retroperitoneal abscesses, such as a pancreatic abscess. This can occur after pancreatitis which progresses through pancreatic necrosis and on to a definable collection. Retroperitoneal abscesses are usually found in one of four spaces: anterior retroperitoneum (lower esophagus, duodenum, pancreas, bile duct, splenic vein, appendix, ascending and descending colon, and

rectosigmoid), posterior retroperitoneum (perinephric, around the ureters, gonadal vessels, aorta, and inferior vena cava), retrofascial (ileopsoas muscle and paraspinous muscles), and retroperitoneal pelvis (prevesical space, retrovesical presacral, and perirectal).

Routine history, physical exam, and laboratory studies are the initial workup of suspected intra-abdominal infection. Some patients may have an unreliable exam, such as those with obtunded mental status, recent analgesia, or immunosuppression. A plain film is useful in establishing "free air" (as a result of perforation of a hollow viscus), pneumatosis (as a result of ischemic bowel), dilated loops (as a result of *Clostridium difficile*), or obstruction as possible signs of abdominal infection. Ultrasound is useful in diagnosing abscess, but it is limited by the skill of the technician and the patient's body habitus. For patients who do not need an emergent operation, computed tomography (CT) is the best imaging modality to detect an abscess.

The cornerstones of treatment of an abscess are source control and antimicrobials. Initially, fluids are given, electrolyte derangements and coagulopathies corrected, and antibiotics started. Source control requires taking measures to eliminate a source of infection, control ongoing contamination, and restore premorbid anatomy and function. In recent years, there has been a shift from open abdominal drainage to percutaneous drainage. Interventional radiologists now approach many abscesses that previously would have been considered best approached by laparotomy. The results of percutaneous drainage are equal clinically and more cost-effective. Percutaneous drainage may result in significantly fewer physiologic alterations in patients and may eliminate or reduce the need for an open operation. An open operation may still be needed for poorly localized, loculated, complex, or diffuse fluid collections, necrotic tissue, or percutaneously inaccessible locations, such as the posterior subphrenic space or among loops of small bowel.

The CT scan findings should be discussed with a surgeon to avoid inappropriate abscess drainage in the presence of free hollow-organ perforation and peritonitis. There are some patients in whom drainage catheter placement is not appropriate, and laparotomy is the procedure of choice. Patients with diffuse peritonitis or a high clinical suspicion of a perforation should undergo surgery as soon as possible, continuing ongoing resuscitation in the operating room. Debridement is indicated in the case of intra-abdominal necrosis, such as infected necrotic pancreas. Open drainage of abdominal abscesses has been associated with enteric fistula formation, adult respiratory distress syndrome, renal failure, and liver failure. Some surgeons leave the abdomen open if source control is uncertain. In some cases, closing the abdomen is not prudent, particularly when the bowel is left in discontinuity or is too dilated to allow closure of the surgical wound, as forcing the abdomen closed can cause abdominal compartment syndrome. Instead, the abdomen can be packed open with a vacuum-assisted device. A second-look operation may be scheduled at the surgeon's discretion.

Antimicrobial treatment is an adjunct to source control. The correct antimicrobial agent started early has been shown to significantly improve outcomes. While cultures from the abscess are necessary, blood cultures are not always needed in the initial workup of patients with suspected intra-abdominal infection. However, in patients who appear toxic or immunocompromised, knowledge of appropriate coverage for potential bacteremia may be helpful in determining antimicrobial therapy. Infections are divided into community-acquired or healthcare-associated (Table 55.1). This distinction is important in determining which bacteria are the likely source and which antimicrobial to choose for initial coverage. All intra-abdominal infections show prevalence of gram positives (*Streptococcus* species, *Enterococcus faecalis*), gram negatives (*Escherichia coli*, *Klebsiella* species, and *Pseudomonas aeruginosa*) and anaerobes (*Bacteroides* and *Clostridium*). Healthcare-associated infections are more likely to have more resistant flora, and those patients that do not respond to the initial empiric antimicrobials may have resistant *P. aeruginosa*, vancomycin-resistant enterococcus (VRE), or *Candida globrata* as their pathogen. The patients most likely to develop severe abdominal infections are those with a high Acute Physiology and Chronic Health Evaluation (APACHE) score, poor nutritional status, inability to achieve adequate source control, or immunosuppression.

TABLE 55.1 **PATHOGENS IN ABDOMINAL ABSCESS**

Community-acquired intra-abdominal infection		
Aerobes	**Anaerobes**	**Healthcare-associated intra-abdominal infection**
Escherichia coli	*Bacteroides*	*Staphylococcus epidermidis/ aureus*
Klebsiella pneumoniae	*Clostridium*	*Pseudomonas aeruginosa*
Proteus mirabilis	*Peptostreptococcus*	*Enterococcus*
Streptococcus	*Fusobacterium*	*Enterobacter*
Enterococcus	*Prevotella*	

The general consensus on antimicrobials is to "hit hard and early," meaning start broad-spectrum antibiotics immediately, and quickly narrow the antibiotics after cultures have returned. The choice of antibiotics depends on whether the infection is community-acquired or healthcare-associated. In some instances, an antifungal is needed. There are several antimicrobial choices available to treat intra-abdominal infections. Many can be treated with a single agent (Table 55.2). Methicillin-resistant *Staphylococcus aureus* (MRSA) is found in some intra-abdominal infections and should be treated with vancomycin. Linezolid, daptomycin, quinupristin–dalfopristin, and tigecycline also provide adequate coverage for MRSA. Empiric treatment of VRE is not recommended unless the patient is at very high risk for an infection due to this organism (such as a liver transplant patient with infection from the biliary tree) or is known to be colonized with VRE; this organism is usually sensitive to linezolid, quinupristin–dalfopristin, daptomycin, and ampicillin. Antifungal therapy is recommended if *Candida* is grown from intra-abdominal cultures. Fluconazole is appropriate for treatment of *Candida albicans*, but an echinocandin (caspofungin, micafungin) should be used for fluconazole-resistant *Candida* species such as *Candida globrata* or *Candida tropicalis* (Table 55.3). If the index of suspicion is high for fungal infection, such as in an

	Cefuroxime + metronidazole	Ceftazidime + metronidazole		Can add linezolid
	Ceftriaxone + metronidazole			Can add daptomycin
	Cefotaxime + metronidazole			Can add quinupristin–dalfopristin
	Ciprofloxacin + metronidazole			Can add tigecycline
	Levofloxacin+ metronidazole		*VRE*	Add linezolid
				Can add quinupristin–dalfopristin
				Can add daptomycin
				Can add ampicillin

Abbreviations: MRSA = Methicillin-resistant *Staphylococcus aureus*; VRE = vancomycin-resistant enterococcus.

immunocompromised patient or in the setting of a healthcare-associated infection, antifungal coverage should be started early, since fungal cultures often require prolonged incubation times. Antimicrobial therapy should be limited to 4 to 7 days, unless source control cannot be obtained. This is a change from previous recommendations which advised broad-spectrum antimicrobials for an empiric 14-day course. Once the patient has no fever for 24 to 48 hours, has a normal white blood cell count, and has clinically improved, the antimicrobial may be discontinued. In most cases, the antimicrobials can be stopped in 7 days or less. Probiotics can be started on patients receiving antimicrobial treatment for intra-abdominal infection.

Patients with inadequate source control, old age, higher level of organ dysfunction, or significant comorbidities are at a higher risk of treatment failure and death. Intra-abdominal infections are frequent and have significant morbidity and mortality. Patients benefit from early diagnosis with early start of antimicrobials and source control.

TABLE 55.3 **TREATMENT OF *CANDIDA***

Fungus	Antifungal
Candida albicans	*Fluconazole*
Resistant Candida, i.e, globrata	*Caspofungin Micafungin*

In most cases, a CT scan will identify the necessary cause of an intra-abdominal infection. There are several choices of antimicrobials, but treatment should start broad and then be tailored to the culture results. When patients improve, stop the antimicrobials to decrease the chance of creating multiresistant organisms. Most patients will do well with close coordination of care among specialists in surgery, radiology, critical care, and infectious disease.

Splenic abscess

Walter Dehority and Thomas R. Howdieshell

The diagnosis of splenic abscess is often overlooked because of its rarity and misleading clinical features as well as the presence of predisposing conditions that obscure its clinical presentation. Hence, it is not surprising that splenic abscess is often diagnosed during postmortem examinations (0.2–0.7% incidence in various autopsy series) even in the era of antibiotics. Contributing factors to an apparent increase in the incidence of splenic abscess include advances in radiologic imaging, comfort with nonoperative management of blunt splenic trauma, and a greater number of patients who have cancer or are otherwise immunocompromised.

Incidence and predisposing factors

Splenic abscesses occur more commonly in males (55–60% in several series), with the average age ranging from 25 to 54 years. Nelken and colleagues describe a bimodal distribution: patients >40 years of age, generally immunosuppressed or intravenous (IV) drug users, who usually present with a multilocular abscess, and patients >70 years of age who are suffering from diabetes and/or a non-endocarditic septic focus and develop a unilocular abscess.

The primary predisposing causes of splenic abscess include metastatic hematogenous infection, contiguous disease processes extending to the spleen, splenic trauma, hematologic disorders (collagen vascular diseases, hemoglobinopathies, malignancy), and immunodeficiency states (acquired, congenital). The incidence of these predisposing causes or risk factors is shown in Table 56.1.

Metastatic hematogenous infections

Infective endocarditis is the most common condition predisposing a patient to splenic abscess (Table 56.1, Figure 56.1). Although the exact incidence is difficult to determine, several studies demonstrated the occurrence of splenic embolization in 31% to 44% of patients with endocarditis. Histologic examination disclosed splenitis in at least 20% of patients. Splenic infarction occurred in 30% to 67% of patients with endocarditis during the pre-antibiotic era, and in 33% to 44% of these patients during the antibiotic era. In 1977, Pelletier and Petersdorf reported the incidence of splenic abscess in patients with bacterial endocarditis to be approximately 2.4%, although a 2012 report described an incidence of 7.3% on autopsy. Mycotic aneurysms are seen angiographically within abscesses, but whether these predispose a patient to or result from splenic abscess remains uncertain.

In addition to endocarditis, a multitude of other infections have been reported as primary causes of splenic abscess (see Table 56.1). Miscellaneous infections include dental abscess, bacteremia after dental extraction, tonsillectomy, peritonsillar abscess, acute parotitis, bronchiectasis, perinephric abscess, decubitus ulcer, complicated infectious mononucleosis, tuberculosis, yellow fever, typhoid fever, diphtheria, cat-scratch disease, and anthrax.

TABLE 56.1 **PRIMARY PREDISPOSING CAUSES OR RISK FACTORS FOR SPLENIC ABSCESS**

Factors	Percentage
Infectious etiology	**68.8**
Endocarditis	15.3
Septic syndrome	11.9
Miscellaneous	11.9
Urinary infection	7.1
Otitis	3.3
Appendicitis	2.8
Pneumonia	2.8
Brucellosis	2.3
Lung abscess	2.3
Malaria	1.9
Diverticulitis	1.9
Amebiasis	0.95
Noninfectious etiology	**31.2**
Contiguous diseases	23.0
Trauma	16.7
Hemoglobinopathies	11.9

Conditions resulting in splenic ischemia and infarct have been implicated in the development of splenic abscess, probably from hematogenous spread of pathogens. Splenic abscess has been reported after splenic artery ligation in the course of liver transplantation surgery, division of the short gastric vessels during laparoscopic Nissen fundoplication, and accidental injection of the splenic artery during endoscopic procedures for gastric bleeding.

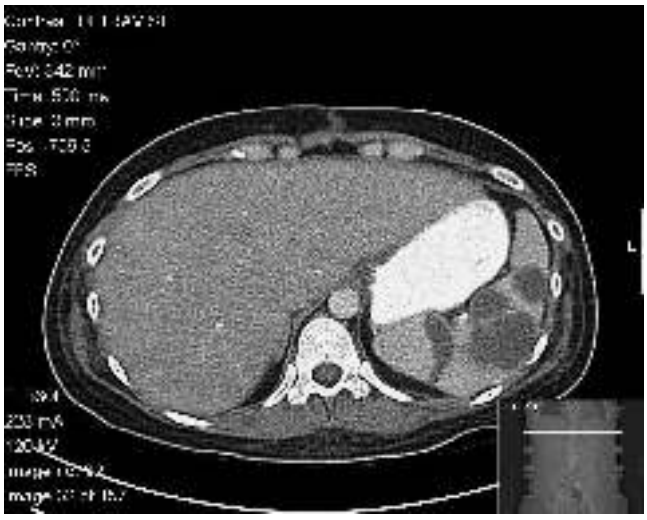

FIGURE 56.1 Multilocular splenic abscess in an intravenous drug abuse patient with bacterial endocarditis.

Contiguous infection

On occasion, splenic abscess can result from the direct extension of disease having its primary focus in adjacent organs. Contiguous extension from diverticulitis, pancreatic pseudocyst or carcinoma, gastric ulcer, carcinoma of the stomach, perihepatic abscess, perinephric and subphrenic abscess, and carcinoma of the descending colon have been reported. Splenic abscess has rarely been reported as an extraintestinal manifestation of inflammatory bowel disease.

Traumatic abscess

Traumatic abscess results from secondary infection and suppuration of contused parenchyma or of a hematoma arising from injury to splenic tissue. In a report by Phillips, the initial traumatic injury was not easily recognized or reported, and most patients developed signs and symptoms of splenic infection after a latent period of 2 weeks to 4 months after sustaining injuries to the left upper quadrant. Splenic abscess has been reported after operative repair of splenic injury (splenorrhaphy) and nonoperative management of blunt splenic injuries diagnosed by CT scan (Figure 56.2). On occasion, radiologic procedures such as splenic artery embolization for hemorrhage control following traumatic injury, splenoportography for portocaval shunt evaluation, and percutaneous transluminal coronary angioplasty have been implicated as causes of splenic abscess, sometimes up to 4 months afterward.

Hematologic disorders

Hemoglobinopathies accounted for approximately 12% of splenic abscesses reported by Alsono-Cohen. Patients with sickle cell disease have an increased risk of acquiring invasive bacterial infections as a result of hyposplenism, including functional defects in opsonization, phagocytic function, and cell-mediated immunity. If a patient with sickle cell disease and prior splenic infarcts develops a transient bacteremia, bacterial seeding of infarcted regions may occur with resultant abscess formation.

The spleen may also be a site of infection in patients with collagen vascular diseases. Splenic abscesses have been reported in patients with rheumatoid arthritis, systemic lupus erythematosus, myelodysplastic syndrome, and polyarteritis nodosa. Pathologic features of the spleen in these illnesses include capsulitis and small infarcts.

Immunodeficiency states

Splenic abscess has been reported complicating AIDS, chemotherapy, cancer (leukemia, lymphoma), bone marrow and solid organ transplantation, long-term steroid use, monoclonal antibody immunosuppressive medications, and conditions such as diabetes mellitus and alcoholism.

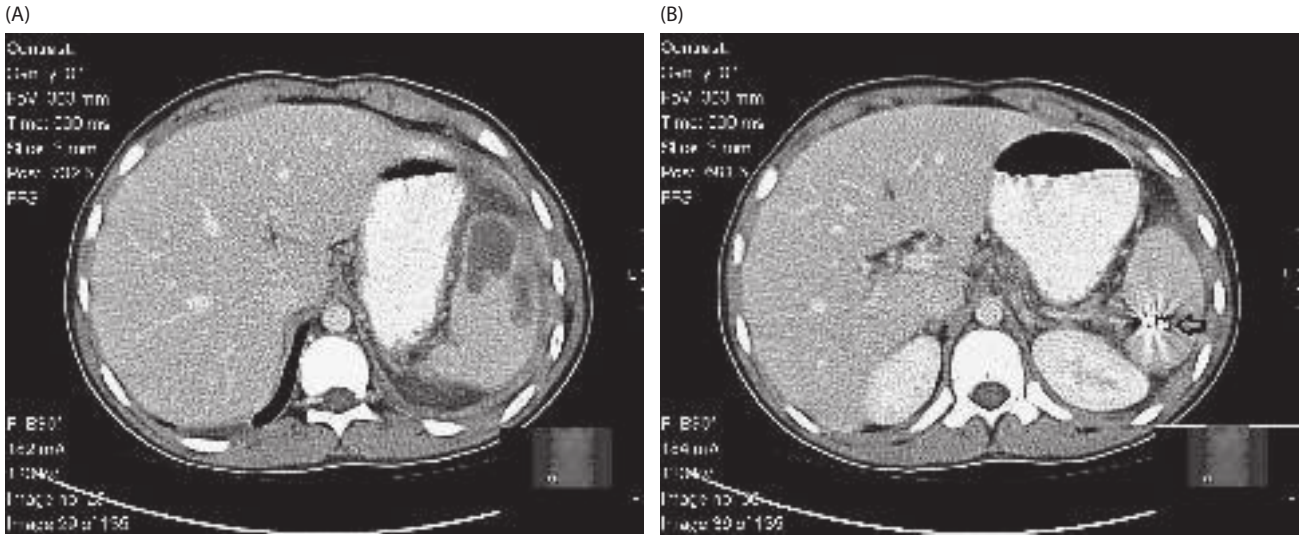

FIGURE 56.2 (A, B) Splenic abscess following nonoperative management of blunt splenic injury including splenic artery embolization. Note embolization coil (B, see *arrow*).

Diagnosis

History and physical examination

The signs and symptoms of a splenic abscess are often insidious, nonspecific, and related to the underlying disease. Table 56.2 characterizes the clinical findings in 227 patients. Fever is the most common symptom, along with pain in the left hypochondrium or vague abdominal pain. Pain is likely caused by splenitis with capsular involvement. Abscesses located in the upper pole of the spleen tend to irritate the diaphragm, causing radiation of pain toward the left shoulder (Kehr's sign) and an elevated, immobile left hemidiaphragm. Splenic rupture also commonly manifests as left shoulder pain. An abscess located in the lower pole of the spleen more often irritates the peritoneal surface, resulting in peritonitis. A deep-seated abscess that does not involve the splenic capsule may be accompanied only by nonspecific symptoms of infection without pain or other localizing signs.

TABLE 56.2 **CLINICAL FINDINGS IN SPLENIC ABSCESS**

Clinical feature	Percentage
Fever	92.5
Abdominal tenderness	60.1
Abdominal pain	57.5
Splenomegaly	56.0
Left upper quadrant pain	39.2
Pleuritic pain	15.8
Toxic syndrome	15.4
Vomiting	14.0

Laboratory findings

Leukocytosis is present in 70% to 80% of patients but is a variable finding. In several series, the white blood cell count varied between 2,400 and 41,000 cells/mm^3. In general, other serum laboratory studies were not helpful. Blood cultures demonstrated growth in 50% to 70% of patients. Of these positive blood cultures, 60% to 75% grew the same organisms as those subsequently isolated from the splenic abscess.

The microbial etiology of splenic abscesses is reported in Table 56.3, representing a compilation of three reports reviewing the microbiology of splenic abscesses from 1900 to 1995. Nearly half of all cases involved aerobic gram-negative bacilli, with *Salmonella* the most common pathogen. *Staphylococcus* spp. were also frequently reported, and at 18.8%, represented the second most common etiology. *Candida* abscesses of the spleen are seen almost exclusively in neutropenic patients with the exception of disseminated candidiasis as a complication of abdominal surgery. Fungal abscesses due to *Candida* are also more likely to complicate the use of broad-spectrum antibiotics, indwelling central venous lines, total parenteral nutrition, systemic steroids, cytotoxic chemotherapy, malignancy, or immunosuppression after organ transplantation. Organisms responsible for AIDS-related splenic abscesses include *Salmonella, Mycobacterium avium-intracellulare, Mycobacterium tuberculosis*, C*andida* spp., *Aspergillus* spp., and *Pneumocystis jirovecii* (*carinii*). A novel *Klebsiella pneumoniae* strain with hypermucoviscous properties has been reported as the cause of hepatic and splenic abscesses in otherwise healthy hosts. In several series, approximately one-fourth of patients with a splenic abscess did not have an organism cultured from the abscess cavity, possibly related to the use of IV antibiotic therapy prior to abscess drainage. In addition, polymicrobial infections may be present, particularly when anaerobic organisms are isolated.

TABLE 56.3 **MICROBIAL ETIOLOGY OF SPLENIC ABSCESSES: 505 CASES FROM 1900 TO 1995**

Organism	Number of cases (%)	
Streptococci	**57**	**(11.3)**

Radiographic findings

The most common findings on chest radiography are an elevated left hemidiaphragm (31%), pleural effusion (28%), and left basilar pulmonary consolidation (18%). Plain abdominal films reveal an abnormal soft-tissue density or gas pattern in only 35% of patients. CT scanning, with a sensitivity of 96% and an associated specificity between 90% and 95% is currently the best diagnostic test for splenic abscess. CT scan may show a homogeneous low-density area, with or without rim enhancement; lucent areas within the spleen containing fluid levels of different densities; and intrasplenic gas formation. CT scan may also be useful for guiding percutaneous abscess drainage.

Ultrasonography has a sensitivity of 60% to 75% in the detection of splenic abscess. The ultrasound appearance of splenic abscess is characterized as a hypoechoic or nearly anechoic, ovoid- or round-shaped area in the spleen, with varying internal echogenicity,

irregular wall, and mild to moderate distal acoustic enhancement. Ultrasonic examinations are not specific, and the findings are highly variable and may be difficult to interpret. However, ultrasonography is low-cost, noninvasive, and readily repeatable to evaluate for interval change or resolution.

Differential diagnosis

The differential diagnosis should include intraparenchymal hematoma, splenic infarction, parasitic and nonparasitic splenic cysts, subphrenic abscess, pulmonary empyema, perinephric abscess, neoplasm, and leukemic infiltration. In a review of 3,372 subphrenic abscesses, Ochsner and Graves found a primary lesion in the spleen in approximately 4% of the cases. Therefore, the possibility of coexistent splenic abscess should be considered in the presence of a subphrenic abscess. Pulmonary empyema as a complication of splenic abscess (4%) may also divert the clinician's attention from the primary lesion.

Treatment

There is no place for long-term medical management of a clinically overt splenic abscess. The mainstay of treatment consists of splenectomy and appropriate antibiotics, with a success rate of 86% to 94%. Mounting evidence has shown that percutaneous drainage plus effective antibiotics is a safe and efficacious therapy. Percutaneous drainage may be used if the patient has a unilocular abscess, is in unstable condition from a recent operation, has had multiple previous operations, or has significant risks for general anesthesia or standard surgical drainage. The catheter can be removed when the drainage is minimal and the cavity has decreased in size, as evidenced by sinogram, ultrasound, or CT scan. If the patient does not improve clinically, splenectomy is recommended. Percutaneous drainage, with a reported success rate of 68% to 75%, is most likely to succeed when the abscess collection is unilocular, has a discrete wall, and has no internal septation. Abscesses containing thick, tenacious, necrotic debris are less likely to be successfully drained percutaneously, as are phlegmons, poorly defined cavities, microabscesses, multiple abscesses, and abscesses originating from a contiguous process. Complications associated with percutaneous drainage include hemorrhage, pleural empyema, pneumothorax (transpleural catheterization), and fistula.

Broad-spectrum antibiotics should be initiated when a splenic abscess is diagnosed. Empiric therapy should include agents effective against staphylococci, streptococci, and gram-negative bacilli, at least until culture results return. A semi-synthetic penicillin in conjunction with an aminoglycoside or a fourth-generation cephalosporin (cefepime) should be considered. If a contiguous abdominal process is suspected, anaerobic agents such as metronidazole should be added, or utilization of a β-lactam with broad-spectrum anaerobic and aerobic coverage, such as piperacillin-tazobactam or a carbapenem, are additional options for single-agent coverage. In immunosuppressed patients, antifungal coverage should be initiated early in the disease process. Some authors recommend continuing antibiotics for 2 to 3 weeks after splenectomy or discontinuation of percutaneous drainage.

The optimal management of fungal splenic abscess remains to be defined. Some authors suggest prolonged courses of amphotericin B, while others recommend splenectomy in conjunction with amphotericin B. The argument in support of splenectomy for fungal abscess is based primarily on reports of bacterial splenic abscess in which nonoperative therapy was associated with high mortality. However, as most cases of splenic candidiasis represent disseminated infection, splenectomy does not address the problem of *Candida* present in other tissues, most notably the liver. There are many reports of confirmed splenic fungal abscesses resolving with antifungal drugs alone. Several case reports and a recent multicenter randomized trial in patients without neutropenia or major immune deficiency indicate that fluconazole may be as efficacious as amphotericin B. Echinocandins are likely to be viable options as well. Patients suspected of having a fungal abscess should have a specific diagnosis made by percutaneous aspiration of the liver or spleen or laparoscopic or open biopsy of the lesions.

Splenic abscess may rupture into the peritoneal cavity, thus causing acute peritonitis. A mortality rate of 50% has been reported in cases of splenic abscess rupture. A splenic abscess may also drain into the stomach, colon, or pleura. However, splenic abscesses most commonly produce repeated bacteremia, which ends in septic shock if not treated. Two-thirds of all splenic abscesses in adults are solitary, and one-third are multiple. In children, however, the opposite is true. Solitary abscesses generally are easier to diagnose and treat and usually are caused by streptococci, staphylococci, or *Salmonella*. Multiple abscesses tend to be caused by gram-negative bacilli or *Candida*. The prognosis is clearly related to patient age, associated diseases, and development of multisystem organ failure.

With early diagnosis and treatment of splenic abscess, the mortality rate can be as low as 7%. Medical therapy appears appropriate for patients with mycobacterial, *P. jirovecii*, and fungal disease. Percutaneous drainage appears reasonable for patients with a singular, unilocular abscess without associated intra-abdominal disease. In patients in whom there is any question about the accessibility, locularity, or singularity of the abscess, or if there is a question of intra-abdominal pathology, splenectomy remains the treatment of choice.

Peritonitis

Linda A. Slavoski and Matthew E. Levison

Peritonitis is inflammation within the peritoneal cavity. This chapter considers infectious causes of peritonitis. Two major types include: (1) primary (spontaneous or idiopathic) and (2) secondary. When signs of peritonitis and sepsis persist or recur after treatment for secondary peritonitis, the clinical entity has been termed tertiary peritonitis. In comparison with patients with other forms of peritonitis, tertiary peritonitis has significantly longer intensive care unit (ICU) and hospital stays, higher organ dysfunction scores, and higher mortality rates (50% to 70%).

Intraperitoneal abscesses can result from (1) localization of the initially diffuse peritoneal inflammatory response to one or more dependent sites (i.e., the pelvis, the right or left subphrenic spaces, which are separated by the falciform ligament, and Morrison's pouch, which is the most posterior superior portion of the subhepatic space and is the lowest part of the paravertebral groove when the patient is recumbent) or (2) at the site of the intra-abdominal source of the infection (e.g., periappendiceal, pericholecystic, or peridiverticular abscess). For management of peritoneal catheter-related peritonitis, see Chapter 96, Dialysis-related infection.

PRIMARY PERITONITIS

Primary peritonitis, also called spontaneous bacterial peritonitis (SBP), is defined as infection within the peritoneal cavity without an evident intra-abdominal source. Primary peritonitis occurs at all ages: in children, in association with postnecrotic cirrhosis and with nephrotic syndrome, and in adults, with ascites from any cause, but most commonly alcoholic cirrhosis. Rarely, primary peritonitis occurs with no apparent underlying disease.

Primary peritonitis has been reported in 10% of all hospitalized patients with alcoholic cirrhosis and ascites. The risk of developing primary peritonitis is greater in patients with more advanced cirrhosis but also increases with coexisting gastrointestinal hemorrhage, previous primary peritonitis, use of proton pump inhibitors, or low protein levels in ascitic fluid (<1 g/dL), presumably because of decreased ascitic fluid opsonic activity.

Primary peritonitis is monomicrobial and only rarely involves anaerobes; if cultures reveal a polymicrobial or anaerobic infection, secondary peritonitis should be suspected. *Escherichia coli* is the most frequently isolated pathogen, followed by *Klebsiella* species and *Streptococcus pneumoniae*.

Cases with positive ascitic fluid culture but low leukocyte counts (<250 neutrophils/mm^3) and no clinical findings of peritonitis are designated as *monomicrobial nonneutrocytic bacterascites* (MMNNB). This may represent early colonization of the peritoneal cavity because some patients progress to SBP; in others it resolves spontaneously. Conversely, some patients have clinical evidence of peritonitis, elevated leukocyte counts (greater than or equal to 250 neutrophils/mm^3) in the ascitic fluid, but negative cultures, called *culture-negative neutrocytic ascites* (CNNA); blood cultures are positive in one-third of cases.

Polymicrobial nonneutrocytic bacterascites (PMNNB) is diagnosed when Gram stain or culture of peritoneal fluid demonstrates multiple organisms and there is less than 250 neutrophilic leukocytes/mm^3. This

variant usually complicates puncture of the intestines during paracentesis, which occurs in less than 1% of paracenteses. Risk factors for this complication include ileus, intestinal adhesions, and inexperience of the operator. If the peritoneal fluid protein concentration is greater than 1 g/dL and the osponic activity of the fluid is adequate, PMNNB is reported to resolve spontaneously.

The route of infection in primary peritonitis may be hematogenous, lymphogenous, via trans-mural migration through the intact bowel wall, or, in women, from the vagina via the fallopian tubes. In addition, clearance of bacteria from blood is delayed in patients with cirrhosis due to decreased phagocytic activity within the reticuloendothelial system, impaired intracellular killing by neutrophils and monocytes, impaired opsonization, and low serum and ascitic complement levels.

The clinical features of primary peritonitis are variable. In children it is often confused with acute appendicitis. The most common sign is fever (often low grade), reported to occur in up to 80% of patients. Fever may be present without abdominal signs or symptoms, or the intraperitoneal infection may be clinically silent. Ascites predating the infection is almost always present. Other signs and symptoms include abdominal pain, nausea, vomiting, diarrhea, diffuse abdominal tenderness, rebound tenderness, and hypoactive to absent bowel sounds. Atypical signs such as hypothermia, hypotension, and unexplained decline in renal function may be present, as well as unexplained encephalopathy, hepatorenal syndrome, and variceal bleeding in cirrhotic patients. Because peritonitis may be clinically inapparent in a patient with ascites and decompensated liver disease, routine paracentesis is necessary in every hospitalized cirrhotic patient with ascites, especially if febrile, to disclose its presence.

The diagnosis of primary peritonitis requires exclusion of intra-abdominal sources of infection, usually by contrast-enhanced computed tomography (CT). Examination of the ascitic fluid is required. The ascitic fluid leukocyte count is generally greater than 250 polymorphonuclear leukocytes/mm^3. Gram stain of the fluid is commonly negative because of the low bacterial density. The diagnostic yield of ascitic fluid culture is enhanced by culturing a large volume (e.g., 10 to 20 mL). Blood cultures should also be obtained because concurrent bacteremia is present in up to 75% of these patients.

Primary peritonitis is managed medically unless secondary peritonitis is suspected, in which case either exploratory laparotomy or laparoscopy is done. Because the Gram stain is often negative in primary peritonitis, the initial choice of antimicrobial agents is empiric and is modified once results of cultures and susceptibility testing are available. Initial therapy should be directed against enteric gram-negative bacilli and gram-positive cocci. Acceptable regimens include the third-generation cephalosporins ceftriaxone and cefotaxime, the fourth-generation cephalosporin cefepime, or one of the newer generation of fluoroquinolones (e.g., levofloxacin or moxifloxacin) that have improved activity against *S. pneumoniae*, including those strains that are relatively penicillin resistant, or β-lactam antibiotic-β-lactamase inhibitor combinations (e.g., ticarcillin–clavulanate or piperacillin–tazobactam).

Fluoroquinolones should not be used for treatment of primary peritonitis if used previously to prevent primary peritonitis, because of the likelihood of a fluoroquinolone-resistant pathogen. If peritonitis develops during hospitalization or in a community where antibiotic-resistant *E. coli* or *Klebsiella pneumoniae* (e.g., extended-spectrum β-lactamase [ESBL]-producing strains) are prevalent, broader-spectrum antimicrobial therapy should be used, such as a carbapenem (e.g., ertapenem, imipenem, meropenem, or doripenem).

Streptococcus pneumoniae and group A streptococci are best treated with high-dose penicillin G, ceftriaxone, or cefotaxime. Methicillin-sensitive *Staphylococcus aureus* is best treated with a penicillinase-resistant penicillin (nafcillin) or with a first-generation cephalosporin (cefazolin). If the strain is methicillin resistant or the patient is allergic to penicillin, vancomycin is used. If *Pseudomonas aeruginosa* is isolated, an aminoglycoside can be given in combination with an antipseudomonal penicillin or cephalosporin, aztreonam, or imipenem or meropenem, or, to avoid the nephrotoxicity and ototoxicity of aminoglycosides, ciprofloxacin combined with another antipseudomonal agent should be used if results of susceptibility testing permit. Intraperitoneal antimicrobial administration is not beneficial.

A clinical response should be evident by 48 to 72 hours with appropriate antimicrobial therapy. Failure to respond should prompt an examination for an alternative or additional diagnosis. Antimicrobial therapy should be continued for 10 to 14 days if improvement is noted; however, shorter-course (5 day) therapy is efficacious if rapid clinical improvement occurs. Treatment of primary peritonitis is ultimately successful in up to 85% of cirrhotic patients, but because of the underlying liver condition, the overall mortality has been reported as high as 95% in some series. Those patients with the poorest prognosis were found to have renal insufficiency, hypothermia, hyperbilirubinemia, and hypoalbuminemia.

Patients with peritoneal fluid neutrophil counts less than 250 cells/mm^3 (MMNNB) and signs or symptoms of infection (temperature greater than 100°F or abdominal pain or tenderness) should receive empiric antibiotic therapy for primary peritonitis, while awaiting results of cultures, because symptomatic patients with MMNNB variant are prone to primary peritonitis even though at time of the paracentesis it is not known whether the cultures will yield bacteria. Because only 15% of asymptomatic patients with MMNNB progress to primary peritonitis, asymptomatic patients with the MMNB variant usually do not need antibiotics and observation is appropriate. In these asymptomatic patients the paracentesis should be repeated as soon as the first culture yields bacteria. Antibiotics are initiated only if signs or symptoms of infection develop or if the second paracentesis demonstrates neutrocytic ascites.

If the peritoneal neutrophil count was at least 250/mm^3, but the peritoneal Gram stain and culture were negative (i.e., CNNA variant of primary peritonitis), antimicrobial therapy should be continued, because CNNA has clinical, prognostic, and therapeutic characteristics similar to that of primary peritonitis, although other possible causes of neutrocytic ascites such as peritoneal carcinomatosis, pancreatitis, and tuberculous peritonitis must be ruled out.

Cirrhotic patients who have had an upper gastrointestinal bleed, ascitic fluid protein <1.5 g/ dL, or recurrent primary peritonitis are at high risk of primary peritonitis and may benefit from antibiotic prophylaxis with norfloxacin (400 mg daily), ciprofloxacin (750

mg once a week), or trimethoprim–sulfamethoxazole (one double-strength tablet once daily for 5 days each week). Prophylaxis may be an option in patients awaiting liver transplantation but may not otherwise prolong survival in patients with end-stage liver disease. Indeed long-term antibiotic use may increase risk of secondary infection with resistant pathogens.

Occasionally, peritonitis may be caused by *Mycobacterium tuberculosis*, usually from hematogenous dissemination from remote foci of tuberculous infection or extension of infection in mesenteric lymph nodes, intestine, or fallopian tubes or ovaries. The diagnosis of tuberculous peritonitis can usually be confirmed by histologic examination and culture of a peritoneal biopsy specimen and fluid. Diagnosis of *Coccidioides immitis* peritonitis can be made by wet mount of ascitic fluid, histology, and culture of the peritoneal biopsy specimen and fluid.

SECONDARY PERITONITIS

Secondary peritonitis is associated with a predisposing intra-abdominal lesion. Numerous intra-abdominal processes may give rise to secondary peritonitis; a partial list includes perforation of a peptic ulcer; traumatic perforation of the uterus, urinary bladder, stomach, or small or large bowel; appendicitis; pancreatitis; diverticulitis; bowel infarction; cholecystitis; biliary sepsis; and female genital tract infection such as septic abortion, postoperative uterine infection, endometritis, or salpingitis.

Secondary peritonitis is usually an endogenously acquired polymicrobial infection. On average, about five bacterial species are isolated, including both obligate and facultative anaerobes. The species of organisms vary with the primary source of the infection. Community-acquired peritonitis secondary to a breach in the integrity of the stomach and duodenum in the absence of obstruction usually involves mouth flora, i.e., mainly β-lactam-susceptible gram-positive cocci and anaerobic gram-negative bacilli, such as *Prevotella melaninogenica* (formerly a member of the *Bacteroides melaninogenicus* group), and *Candida* species. Community-acquired peritonitis from a breach in the integrity of the lower small bowel or colon, or a breach of more proximal portions of the gastrointestinal tract when obstruction is present, involves colonic flora with *E. coli*, *Bacteroides fragilis*, enterococci, other *Bacteroides* species, *Fusobacterium*, *Clostridium perfringens*, other clostridia, *Peptostreptococcus*, and *Eubacterium*. Similar organisms (*E. coli*, enterococci, *Clostridium*, and *B. fragilis*) are also responsible for peritonitis complicating cholecystitis and biliary sepsis. Concomitant bacteremia occurs in 20% to 30% of patients, most frequently from *E. coli* and *B. fragilis*. In patients who acquire their infection in the hospital, antibiotic-resistant organisms such as *Enterobacter*, *Serratia*, *Acinetobacter*, vancomycinresistant enterococci, and *P. aeruginosa* are frequently isolated.

The presenting symptoms are similar to those of primary peritonitis. The rapidity of onset and initial location and extent of peritoneal involvement vary with the inciting event; for example, sudden massive intraperitoneal spillage of gastric contents secondary to traumatic injury produces severe epigastric pain that, within minutes, spreads to involve the entire abdomen. In contrast, the spread of pain from a lesion such as a ruptured appendix or colonic diverticulum is more gradual and limited as the inflammatory process usually has time to wall off.

Pain is the predominant symptom. Pain and abdominal tenderness to palpation are usually maximal over the organ in which the process originated (e.g., epigastrium for a ruptured peptic ulcer, right upper quadrant for cholecystitis, right lower quadrant for appendicitis, and left lower quadrant for diverticulitis). Other findings include fever, nausea, vomiting, and abdominal distension. The patient often lies motionless with the legs drawn up to the chest; any motion is likely to exacerbate the abdominal pain. Blood pressure is usually normal early but may fall with onset of septic shock, and there may be tachypnea and tachycardia. Direct and rebound abdominal tenderness and abdominal wall rigidity are often present. Bowel sounds are absent. Rectal and vaginal examinations, and in women in whom an ectopic pregnancy is suspected, a urinary beta-human chorionic gonadotropin (β-HCG) determination, are necessary.

Often, the diagnostic evaluation must be brief because of the patient's critical condition. Laboratory studies include a complete blood count, serum chemistry profile, liver profile, and amylase and lipase determinations. Appropriate cultures should be done promptly (e.g., blood), although culture of peritoneal fluid is often delayed until the time of laparotomy. Chest radiographs should be obtained to exclude chest conditions that might simulate an intra-abdominal process. Plain radiographs of the abdomen may also be helpful, sometimes revealing free air or fluid, bowel distension, ileus, or bowel wall edema. However, CT of the abdomen and pelvis with contrast is most helpful to localize the infection and indicate its probable source.

Antimicrobial therapy is initiated early to control bacteremia and minimize the local spread of infection. Patients with hemodynamic, respiratory, renal, and other critical organ system dysfunction require immediate appropriate supportive therapy. Surgery is often necessary to drain purulent material that contains bacteria, and excessive levels of proinflammatory cytokines and adjuvants (e.g., fecal matter, food, blood, bile, barium) that would enhance the virulence of peritoneal infection; debride devitalized tissues that foster anaerobic conditions; and control continued peritoneal contamination with bacteria and adjuvants by removing the initiating process (e.g., cholecystitis, appendicitis, and diverticulitis). Optimal management also includes bowel decompression (e.g., by proximal colostomy for perforation, diverticulitis, or colonic carcinoma). Proper timing and adequacy of surgical source control is paramount. To reduce the bacterial load and inflammatory exudate, a lavage of the abdominal cavity is performed, with particular attention to areas prone to abscess formation (e.g., paracolic gutters, subphrenic area).

Some patients, who are too severely ill and unstable from septic shock or coagulopathy to have a definitive procedure at the initial operation, are resuscitated and stabilized in an ICU setting for 24 to 36 hours and returned to the operating room in a series of re-explorations for additional debridement of necrotic tissue and foreign matter, drainage of residual infectious foci, and source control. Swelling of the bowel, retroperitoneum, and abdominal wall may preclude abdominal closure after surgery. Temporary closure of the

abdomen to prevent herniation and contamination of the abdominal contents can be achieved using gauze and large, impermeable, self-adhesive membrane dressings, mesh with or without zipper- or Velcro-like closure devices, or vacuum-assisted closure devices. Advantages of this management strategy include avoidance of abdominal compartment syndrome and easy access for re-exploration. The disadvantages include significant disruption of respiratory mechanics and potential contamination of the abdomen with nosocomial pathogens.

Percutaneous catheter drainage guided by CT scan or ultrasonography may in some cases decrease the need for surgical therapy or delay surgery until the acute process and sepsis are resolved and a definitive procedure can be performed under elective circumstances. Where possible, percutaneous catheter drainage of abscesses and other well-localized fluid collections is preferable to surgical drainage if there is no evidence of uncontrolled perforation.

Antibiotic therapy should begin as soon as blood cultures are obtained but often before peritoneal fluid can be obtained for culture. Initial therapy is often empirical and must have broad-spectrum activity against the suspected pathogens. Peritoneal fluid cultures can be obtained at the time of paracentesis, percutaneous drainage of an intraperitoneal abscess, or laparotomy.

The spectrum of initial empiric antimicrobial coverage for community-acquired acute stomach and proximal jejunum perforations, in the absence of acid-reducing therapy or malignancy, should include aerobic gram-positive cocci and oral anaerobes. The spectrum of empiric antimicrobial coverage for community-acquired (1) distal small bowel-, appendiceal, and colon-derived infection, (2) more proximal gastrointestinal perforations in the presence of obstruction or paralytic ileus, and (3) biliary-derived infection if a biliary-enteric anastamosis is present should include facultative gram-negative bacilli, especially *E. coli*, and enteric streptococci, and obligate anaerobic gram-negative bacilli, especially *B. fragilis* (see Box 57.1).

Inclusion of enterococcal coverage is somewhat controversial. It is prudent to include empiric antienterococcal therapy in an attempt to improve outcome in high-risk patients and in patients with cardiac valvular lesions that place them at high risk for a bad outcome of endocarditis (e.g., prior endocarditis, prosthetic cardiac valves, or complex cyanotic heart disease) (see Box 57.1).

Empiric therapy directed against vancomycinresistant *Enterococcus* (VRE) *faecium* is not recommended unless the patient is at high risk for an infection due to this organism, such as a liver transplant recipient with an intra-abdominal infection from the hepatobiliary tree or a patient known to be colonized with VRE. Antibiotics active against VRE *faecium* include tigecycline, daptomycin, linezolid, and quinupristin–dalfopristin. For the more penicillin-susceptible VRE *faecalis*, ampicillin, linezolid, or daptomycin is appropriate (*E. faecalis* is inherently streptogramin resistant).

Similarly, treatment of *Candida* is controversial. Isolation of *Candida* from blood cultures or as the sole organism within residual or recurrent intra-abdominal infection, or as the predominant organism on Gram staining of peritoneal exudate, requires additional antifungal therapy for patients with severe community-acquired or healthcare-associated infection with either fluconazole

BOX 57.1

Empiric regimens for secondary peritonitis[a]

Single agent

1. β-lactam–β-lactamase inhibitor (piperacillin–tazobactam[b,c])
2. Moxifloxacin[b,c,d,e,f]
3. Carbapenem (imipenem[b,c], meropenem[c], doripenem[c], or ertapenem[g])[d]
4. Tigecycline[b,f,h]

Combinations

5. Cefazolin, cefuroxime, ceftriaxone, or cefotaxime plus metronidazole
6. A third- or fourth-generation cephalosporin (ceftazidime[c] or cefepime[c]) plus metronidazole
7. Levofloxacin[d,e,f] or ciprofloxacin[c,d,e,f] plus metronidazole
8. Aztreonam[c,f,i] plus vancomycin plus metronidazole[b]

[a] These regimens should be adjusted based on the results of culture and susceptibility testing.

[b] Empiric regimens with activity against *Enterococcus faecalis* are preferred for severe or nosocomial infections.

[c] Antipseudomonal

[d] The carbapenems and often fluoroquinolones, but not third-generation cephalosporins or β-lactam–β-lactamase inhibitor combinations, are active against ampC β-lactamase-producing and extended-spectrum β-lactamase (ESBL)-producing aerobic–facultative gram-negative bacilli.

[e] Fluoroquinolones are not recommended for use in patients who have received a fluoroquinolone in the past 3 months or in locales that have high rates (>10%) of fluoroquinolone-resistant *E. coli*.

[f] Tigecycline or fluoroquinolone- or aztreonam-containing regimens can be used in penicillin-allergic patients.

[g] Ertapenem does not cover *P. aeruginosa*.

[h] Tigecycline has shown increased risk of death compared to other drugs when used to treat a variety of serious infections, including complicated intra-abdominal infections.

[i] Aztreonam lacks activity against anaerobes and gram-positive cocci and must be combined with vancomycin and metronidazole.

or an echinocandin (caspofungin, micafungin, or anidulafungin) for fluconazoleresistant *Candida* species such as *Candida glabrata* and *Candida krusei*. Use of fluconazole for non-albicans *Candida* should be based on in vitro susceptibility testing. For the critically ill patient, therefore, initial therapy with an echinocandin instead of a triazole is recommended. Because of toxicity, amphotericin B is not recommended as initial therapy.

Because a significant proportion of *B. fragilis* is now resistant to clindamycin, cefoxitin, and cefotetan, and aminoglycosides have significant nephrotoxicity and ototoxicity, these drugs can no longer be recommended for empiric coverage now that more reliable and less toxic agents are available. For example, although *B. fragilis*, as well as many *Prevotella melaninogenica* are resistant to ampicillin, ticarcillin, and piperacillin, these organisms are sensitive to the β-lactam–β-lactamase inhibitor combinations piperacillin–tazobactam, and ticarcillin–clavulanate, as well as the carbapenems, the fluoroquinolone moxifloxacin, tigecycline, and metronidazole. All these antimicrobial agents, except metronidazole, will also be active against most *E. coli* and therefore can be used as single-drug therapy (see Box 57.1). Ampicillin–sulbactam is no longer recommended for use because of high rates of resistance to this agent among community-acquired *E. coli*.

Because nosocomial intraperitoneal infections are caused by more resistant flora, broader-spectrum empiric regimens are appropriate, as well as for more severe community-acquired infection or infection in immunocompromised patients (Box 57.1). Acute Physiology and Chronic Health Evaluation II (APACHE II) score >15, advanced age, low albumin levels, poor nutritional status, and concurrent malignancy increase risk for a more severe infection.

Local susceptibility profiles should be reviewed and empiric regimens modified accordingly. Empiric regimens should also be modified once results of susceptibility testing are available. However, empiric antimicrobial therapy directed against anaerobes should be maintained, even if anaerobes are not recovered, because of the unreliability of clinical anaerobic methodology.

The duration of antimicrobial therapy after adequate surgery is usually 5 to 10 days but depends on control of the source of the infection, severity of infection, clinical response to therapy, and normalization of the white blood cell count. Only a short course of antimicrobial therapy (about 24 hours) is required for sterile peritonitis that occurs around an infected but resected intra-abdominal organ, such as an appendix or gallbladder. Once the patient can tolerate oral therapy, antimicrobial agents can be given orally rather than intravenously, if oral agents are available that have antimicrobial activity equivalent to that of the intravenous regimen.

The main therapy for any intraperitoneal abscess is early and adequate drainage. Effective management depends on accurate localization of the abscess and discrimination between single and multiple abscesses. In recent years, successful therapy has been accomplished using percutaneous catheter drainage as an alternative to surgery. This method has become possible with the use of refined imaging techniques, especially ultrasonography and CT. The general requirements for CT- or ultrasound-guided percutaneous catheter drainage include (1) an abscess that can be adequately approached; (2) an abscess that is unilocular; (3) an abscess that is not vascular and the patient has no coagulopathy; (4) joint radiologic and surgical evaluation, with surgical backup for any complication or failure; and (5) the possibility of dependent drainage via the percutaneously placed catheter. CT also allows detection of an unsuspected additional intra-abdominal problem that would otherwise require surgical intervention. Percutaneous catheter drainage can be used as an initial approach in a patient too unstable to withstand immediate surgery. Definitive surgery can then be postponed until the patient is in better condition.

Whipple's disease and sprue

Amirkaveh Mojtahed and Payam Afshar

Dr. George H. Whipple, a pathologist at Johns Hopkins Hospital, described the first case of "intestinal lipodystrophy" in 1907. The patient was a 36-year-old male physician with chronic diarrhea, abdominal pain, weight loss, and chronic cough. The patient succumbed 5 years later due to cachexia. Universally fatal prior to the advent of antibiotics, this condition, now recognized as Whipple's disease, has accumulated case reports, case series, and even a prospective study. This rare disease masquerades as a multisystem condition of nonspecific symptoms, rendering the diagnosis inaccessible unless it is included in the differential. Based on the most recent prospective study, the disease is well-managed with appropriate attention to diagnosis and antibiotic therapy.

After the initial case report by Dr. Whipple, progress was made toward establishing a means of diagnosis and treatment. In 1949, periodic acid-Schiff (PAS) staining helped to identify the red appearance of glycoproteins within intestinal macrophages. Shortly afterward, the first microscopic identification of a bacteria-like organism led to the first successful treatment of Whipple's disease with chloramphenicol. Electron microscopy and the advancement of histologic staining helped to further characterize the infectious entity as a gram-positive bacterium. In 1992, polymerase chain reaction (PCR) was used to identify the ribosomal RNA of the organism, classifying it as an actinomycete. Genomic sequencing of the organism in 2003 has brought us to the current classification of this rod-shaped, gram-positive, actinomycete as *Tropheryma whipplei*.

Whipple's disease is a multisystem, exceedingly rare chronic disease. It has an approximated incidence of 1 per 1 million, with a middle-aged Caucasian male predilection. The pathogenesis of *T. whipplei* is important for the explanation of the population at risk and the multisystem nature of the disease. Occupations at risk include farmers, due to soil contact, and sewage plant workers. The mode of transmission of the disease is suspected to be through feces and less often saliva, as viable bacteria have been detected in these samples. Curiously, no reports of human-to-human transmission have been made although humans are the only carriers of *T. whipplei* to manifest clinical disease. Fluorescence in situ hybridization (FISH) has been instrumental in characterizing this as a metabolically active organism of the intestinal mucosa. Ineffectively degraded by macrophages, *T. whipplei* replicate in these mononuclear cells of the lamina propria of the intestinal tract. The persistence of the bacteria in macrophages is related to an impaired T-cell interaction with macrophages. Due to a genetic predisposition, patients with Whipple's disease have an inadequate protective inflammatory immune response compared to the more frequently encountered asymptomatic carriers. Iatrogenic immunosuppression has also been noted to expedite disease progression. Apoptosis of the macrophage initiates the cascade that leads to the multisystem pathology of Whipple's disease via invasion from the intestinal lymphatics and eventual hematogenous spread to distant tissues.

The nonspecific clinical presentation of the condition creates confusion for the clinician and latency in the diagnosis that can span for many years. However, its diagnosis may be expedited with iatrogenic immunosuppression. Whipple's disease is primarily a disease of the gastrointestinal tract with extraintestinal symptoms of arthralgia, fever, and neurologic syndromes. The classic presentation of prodromal migratory destructive peripheral arthralgias (on average 6 years prior to other symptoms), followed by gastrointestinal complaints of diarrhea and abdominal pain, should raise suspicion of Whipple's disease. The gastrointestinal symptoms may result in malabsorption, malnutrition, hypoalbuminemia with abdominal lymphadenopathy,

and eventual anasarca. The seronegative migratory peripheral arthralgia mimics autoimmune rheumatologic conditions leading to needless immunosuppressive treatment, which can result in immune reconstitution inflammatory syndrome (IRIS).

The ominous neurologic manifestations usually occur in conjunction with the gastrointestinal disorder or as disease relapse due to inadequate blood–brain barrier penetration of the antibiotic. These are variable and may include cognitive impairment, psychiatric disorder, sensorimotor impairment, and cranial nerve abnormalities, with the most notable and pathognomonic being oculomasticatory or oculofacial myorhythmias. Central nervous system (CNS) involvement in Whipple's disease, reported at 10% to 40%, is likely underestimated due to underreporting. The rare cardiac manifestations of Whipple's disease include blood culture-negative endocarditis, constrictive pericarditis, myocarditis, coronary arteritis, and congestive heart failure. Mucocutaneous Whipple's pathology includes reports of hyperpigmentation of the skin, vasculitic rash, and hemorrhagic gingivitis. Last, pulmonary complaints of chronic cough with the appearance of pulmonary nodules and endobronchial lesions with noncaseating granulomas that resemble sarcoidosis of the lungs have been reported.

The diagnosis of Whipple's disease must be supported by tissue sampling. A reliable and readily available method of diagnosis is biopsy of the duodenum, an endoscopically accessible replication site of *T. whipplei*. Experts recommend at least five mucosal biopsies including the most distal segment of the duodenum to avoid sampling error. Endoscopic findings span the spectrum from normal to lymphangiectasias, with widening of intestinal villi or more suggestive white plaques denoting lipid deposition. Routine hematoxylin and eosin staining of the intestinal biopsies identifies the foamy cytoplasm of the macrophage while PAS stain enhances the appearance of cytoplasmic granules that represent the glycoprotein component of the *T. whipplei* bacterial cell wall (Figure 58.1). Due to nonspecific PAS-positivity, as can be mimicked by mycobacterial infection, real-time PCR should be used to confirm the diagnosis and monitor response to treatment. FISH can be used in conjunction with PCR for confirmation but is not mandatory. Patients with the diagnosis of Whipple's disease should undergo cerebrospinal fluid (CSF) analysis with PCR to exclude CNS involvement, as neurologic damage may be irreversible and absence of symptoms is not a reliable marker to rule out CNS involvement. If initially positive, repeat lumbar puncture with PCR should be performed to

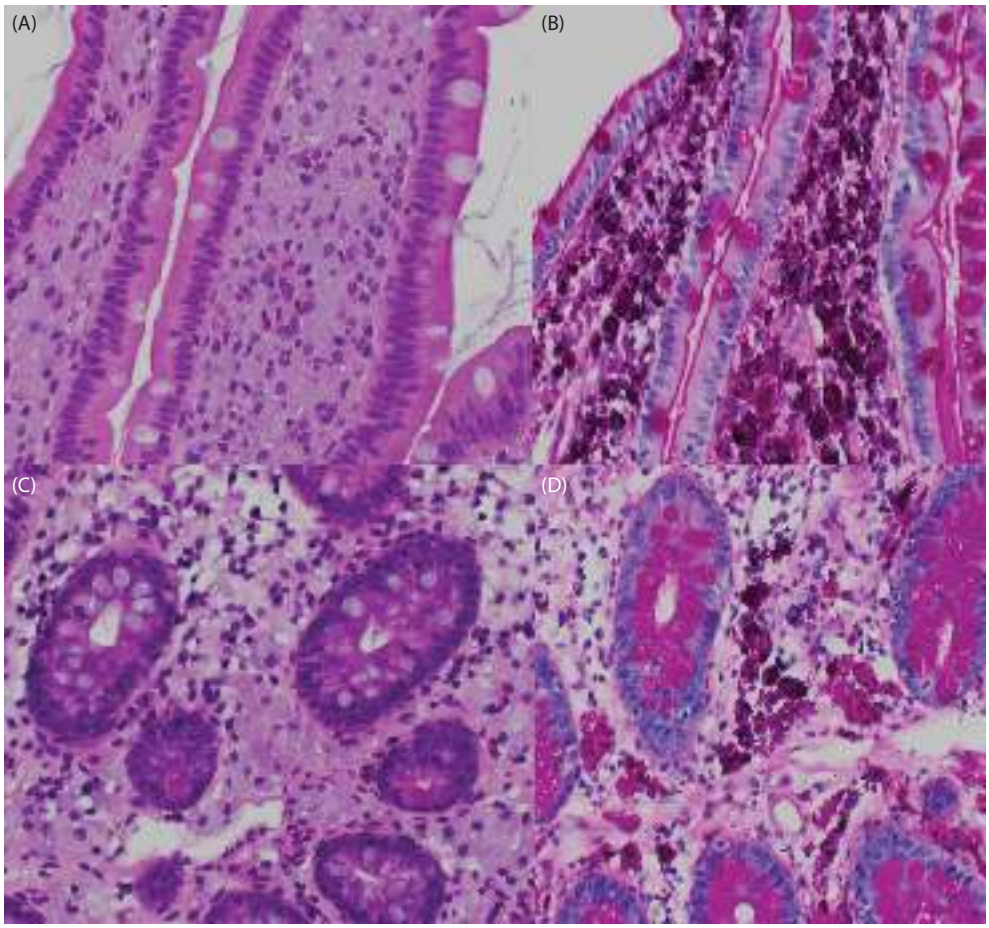

FIGURE 58.1 Histologic sections demonstrate duodenal mucosa with sheets of foamy macrophages in the lamina propria of the duodenum (A) and more uncommon finding in the colon (C) with representative periodic acid-Schiff-diastase (PAS-D) stains (B, D) highlighting the red appearance of *T. whipplei* glycoproteins.

ensure bacterial eradication. Patients with symptoms beyond the gastrointestinal tract should have appropriate tissue sampling (synovial fluid, cardiac valve, lymph nodes, skin, etc.) based on clinical presentation. In a recent small series publication, urine PCR testing has been shown to be an effective, noninvasive means of diagnosis, especially when other diagnostic measures have failed.

Appropriate treatment of Whipple's disease with antibiotics is essential to avoid the inevitable mortality of the condition. In addition, it is imperative that the chosen antibiotic has blood–brain barrier penetration and can obtain high CSF levels. Tetracycline had long been the drug of choice despite a relatively high relapse rate of up to 35%. Poor response in tetracycline retreatment of CNS-involved patients is likely due to poor absorption and lack of blood–brain barrier penetration. Recently, the only prospective, randomized study to examine therapy compared the efficacy of bactericidal ceftriaxone versus meropenem, followed by oral trimethoprim-sulfamethoxazole (TMP-SMZ) for 12 months due to native impaired immune response. Based on long-term follow-up of 89 months, 93% (37/40) patients maintained clinical remission. Penicillin G followed by doxycycline is also a valid therapeutic option (Table 58.1). Clinical response to therapy should occur within 1 to 3 weeks for gastrointestinal symptoms and several weeks for arthropathy. Follow-up studies with duodenal histology and PCR in patients with GI manifestations and CSF analysis with PCR in patients with CNS involvement are recommended.

Life-long prophylaxis should be considered given the known underlying genetic immunologic deficit in patients with Whipple's disease. Issues with resistance, folate deficiency, and Steven-Johnson related to TMP-SMZ have led to increasing use of doxycycline.

IRIS, a recurrence of inflammatory symptoms after an initial objective improvement with antibiotics, is the most frequent and potentially fatal complication occurring during the treatment of Whipple's disease. A protracted history of immunosuppression for a presumed rheumatologic disorder prior to the diagnosis and treatment of Whipple's disease is ubiquitously observed in patients who develop IRIS. Treatment of IRIS includes initiation of steroids and on occasion more potent immunosuppression.

The mortality rate of treated Whipple's disease is unknown, but untreated Whipple's disease is universally fatal. Even with treatment, relapses have been reported months to years after treatment. One factor may be an ongoing genetic impaired immunity to the bacteria, which leads to a relapse, sometimes with a different strain. Close follow up at 6 and 12 months with duodenal biopsies and immunohistochemistry is recommended since PAS-positive macrophages may persist despite successful eradication of the bacteria. Patients with CNS involvement are at higher stakes for relapse and should have a low threshold for retreatment if a relapse is suspected.

TABLE 58.1

Induction therapy	
Penicillin G	2 million units IV q4h for 14 days
Ceftriaxone	2 gr IV daily for 14 days
Meropenem (if penicillin allergy)	1 g IV TID for 14 days
Maintenance therapy	
Trimethoprim-sulfamethoxazole (TMP-SMX)	160/800 mg BID oral for 12 months
Doxycycline (if sulfa allergy), plus Hydroxychloroquine	200 mg once daily oral, *plus* 200 mg TID for 12 months
Lifelong therapy	
Doxycycline	200 mg once daily oral
Trimethoprim-sulfamethoxazole (TMP-SMX)	160/800 mg once daily oral

Tropical sprue

Tropical sprue (TS) is an acquired malabsorptive and likely infectious disease of unknown etiology that may affect locals and travelers in the tropics. Residence in the tropics for longer than a month with chronic diarrhea and nutritional deficiencies are the usual symptomatic hallmarks. Endemic areas include south Asia, Caribbean, Central America, and northern South America while sparing Africa and the Middle East. Most often it is a disease of local inhabitants; however, long-term visitors are also at risk. TS, initially described as a disease of low-socioeconomic populations, can also affect those with access to medical care, adequate hygiene, and nutritional diet. In North America and Europe, TS should be suspected in the long-term traveler after exclusion of common causes of chronic diarrhea and malabsorption.

Several theories for infectious mechanisms exist, but a specific organism has not been implicated. Patients with TS frequently report a preceding acute infectious diarrheal illness. This finding, in addition to a possible mechanism of small bowel injury explained by an overgrowth of aerobic coliform bacteria with resolution of symptoms after antibiotics, justifies an alternative nomenclature of TS: *postinfective tropical malabsorption*.

Patients suffer from chronic diarrhea related to malabsorption of fatty acids and carbohydrates, as well as bile salt–induced diarrhea from terminal ileal (TI) involvement. Loss of brush border enzymes (e.g., lactase), impaired fat absorption leading to steatorrhea, and nutrient deficiencies of primarily folate, vitamin D, and, as the disease progresses, B_{12} are commonly seen in TS. Macrocytic anemia from nutrient deficiency is commonly seen. Steatorrhea also leads to loss of fat-soluble vitamin absorption with subsequent vitamin deficiency clinical sequela.

Diagnosis is by exclusion of close mimics, particularly celiac sprue (CS). The incidence of TS has decreased as the serum testing for CS has improved, suggesting that many of these cases were not TS. Infectious diarrheal illnesses such as *Entamoeba*, AIDS enteropathy, Whipple's disease, *Giardia*, *Isospora*, and *Cryptosporidium* must be excluded. Mucosal scalloping, a common feature of CS, can be present on endoscopy, while biopsies of any region of the small bowel can show partial villous atrophy and intraepithelial lymphocytes. Duodenal biopsies are of highest yield as the ileum is affected in later stages. *Tropical enteropathy*, a subclinical variant of

TS without the usual symptoms, may have similar biopsy changes. A thorough workup is indicated but the diagnosis can also be confirmed by response to treatment.

Three to six months of tetracycline 250 mg four times a day with folate is the first-line treatment regimen. In several case series, initial folate (1–5 mg/d) has been shown to resolve symptoms. B_{12} should also be replaced subcutaneously if deficient. Cholestyramine may reduce diarrheal frequency if TI is involved. Recurrence or relapse can occur in 20% of cases, requiring repeat treatment. If tetracycline is contraindicated in the patient, sulfonamide antibiotics can be used based on a single study.

Small intestinal bacterial overgrowth

Small intestinal bacterial overgrowth (SIBO) is an increased numbers of bacteria residing in the small bowel. Symptoms are linked to malabsorption and excessive bacterial degradation and can include bloating, flatulence, dyspepsia, diarrhea, and anorexia. Deficiency of B_{12} is often recognized. The gold standard is a jejunal aspirate with $>10^5$ CFU/mL bacteria; however, a lower threshold of 10^3 CFU/mL bacteria, especially if coliform, is being considered. A more popular approach is the hydrogen breath test because it is less arduous, is inexpensive, and is more clinically feasible. An abnormal early hydrogen peak is thought to suggest a positive test. Detection of abnormal methane levels is associated with delayed transit and therefore observed in patients with irritable bowel syndrome (IBS) or chronic constipation. Antibiotic reduction of methanogens has been shown to improve symptoms in this subset. Unfortunately, due to varying oro-cecal times and other factors, this form of testing continues to have many critics. Studies are ongoing to identify a more sensitive and specific diagnostic test.

Patients at risk for SIBO generally have altered gut motility or physiology. Risk factors include prior surgeries such as gastrectomy or ileocecal resection, diverticula, fistulas, proton pump inhibitor–induced or unrelated hypochlorhydria, liver disease, chronic pancreatitis, immunodeficiencies, and motility disorders associated with diabetes, scleroderma, and intestinal pseudo-obstruction. IBS patients are more frequently diagnosed with SIBO.

Treatment is primarily antibiotics, management of nutritional deficiencies, and eliminating medications that reduce transit time. Initial diet recommendations should include a lactose-free diet and consideration for a trial of the low FODMAP diet. The current mainstay of therapy is high-dose rifaximin (550 mg TID) for 10 days. Rifaximin is the most effective antibiotic for SIBO with poor absorption; it has a relatively safe side-effect profile, broad antimicrobial coverage, and achieves modulation of the microbiome. Alternatives include metronidazole, oral cephalosporins, amoxicillin-clavulanate, ciprofloxacin, doxycycline, and norfloxacin. Recurrence is common in patients with underlying anatomic or motility disorders. In these cases, repeat treatment courses and improving transit time with pro-motility agents such as low-dose erythromycin can be effective. Unfortunately, probiotics have not proved effective.

Clinical syndromes: Genitourinary tract

59

Urethritis and dysuria

George Pappas, Ioannis A. Bliziotis, and Matthew E. Falagas

The term urethritis refers to inflammation of the urethra, which can be attributed both to infectious and noninfectious processes. The urethral canal essentially represents the first site of the body to be exposed to a variety of sexually transmitted pathogens, and the interaction of these pathogens with the epithelial cells of the urethra gives rise to the syndrome's symptoms.

Dysuria refers to the experience of pain or burning sensation or discomfort in urination, and is a subjective symptom related to varying pathology of the urinary tract. The urethra being the terminal pathway of urine flow, its inflammation most often accounts for experience of dysuria.

Etiology

Traditionally urethritis has been divided into gonococcal urethritis (GU) and nongonococcal urethritis (NGU). *Neisseria gonorrhoeae* as a cause of urethritis has been recognized since ancient years, and in fact its name represents a description, in Greek, of the syndrome's symptoms as defined by Galen: "gono" referring to semen, which was supposed to be the main constituent of the urethral discharge, and "rrhea" a term for flow. Descriptions of urethritis exist in the Old Testament, in the Book of Leviticus, in ancient Chinese documents, and in the Hippocratic Corpus.

NGU has been often considered synonymous to *Chlamydia trachomatis* infection, although a continuously increasing number of pathogens are also implicated (Table 59.1). *Chlamydia trachomatis* is generally thought of as the commonest cause of NGU, especially in younger patients, although some studies suggest that *Ureaplasma urealyticum*, biovar 2, may be a more prevalent cause of infection. Numerous other pathogens have been associated with NGU: *Mycoplasma genitalium* as a cause of urethritis was recognized in the early 1980s; its etiologic role as a sexually transmitted pathogen has been confirmed recently. *Trichomonas vaginalis* is invariably isolated in clinical series of urethritis. *Gardnerella vaginalis* has also been considered a frequent cause of urethritis in certain series. Herpes simplex virus (HSV) is also a potent cause, both as HSV-1 and HSV-2. More rare causes include adenoviruses, lymphogranuloma venereum (*Chlamydia trachomatis* serotypes L1, L2, L3), mycobacteria, and syphilis, as well as gram-negative pathogens (e.g. *Escherichia coli* in cases of strictures or cystitis). Even rarer causes include other viral infections, cytomegalovirus (CMV) in immunocompromised patients, streptococcal species (especially *Streptococcus pyogenes*), *Neisseria meningitidis*, fungi, and anaerobes such as *Bacteroides* species.

Epidemiology

The global annual incidence of urethritis is enormous: An estimated 62 million cases of GU and 89 million cases of NGU occur annually. In the United States alone, approximately five million annual cases are reported, the great majority of which is NGU. The incidence of GU has been declining in the United States since 2000, while inverse trends have been observed for NGU. The latter are accompanied though by a

TABLE 59.1 **ETIOLOGY AND RELATIVE FREQUENCY OF INFECTIOUS URETHRITIS**

Pathogen	Reported frequency in cases of urethritis
Neisseria gonorrhoeae	12%–34%
Chlamydia trachomatis	15%–55% of NGU
Mycoplasma genitalium	3%–38% of NGU
Ureaplasma urealyticum	6%–60% of NGU
Trichomonas vaginalis	<5% of NGU
Gardnerella vaginalis	12% of NGU in a single study
Mycoplasma hominis	Rare, frequency vaguely defined
Herpes simplex virus	Rare
Gram-negative bacteria	Rare
Adenoviruses	Rare
Other: mycobacteria, syphilis, lymphogranuloma venereum, streptococci, *Neisseria meningitidis*, anaerobes, fungi	Very rare/isolated reports

Abbreviation: NGU = nongonococcal urethritis.

declining incidence of chlamydial NGU and may actually reflect the increasing recognition of other etiologies of NGU or the effect of chlamydial control programs. A steady increase of the total urethritis cases reported in males has been observed in France in recent years. The increasing availability of sophisticated diagnostic techniques in developing countries has also helped underline the magnitude of the problem.

There seems to be no racial predilection for the incidence of the syndrome but certain socioeconomic factors may apply, urethritis being more common in low-income populations. Gender predilection seems also not to exist, although the difference in the syndrome's clinical presentation between males and females may account for a larger percentage of female cases that are asymptomatic and thus not reported; on the other hand, while male urethritis is a distinct syndrome, female disease is often misdiagnosed in the context of, or coexists undiagnosed with, inflammation of other sites of the female urogenital tract, most importantly cervicitis. Due to urethritis being a sexually transmitted disease, the age group of 20 to 24 years predominates in reported cases. The use of condoms has been inversely related to the incidence of urethritis. Other risk factors include the use of spermicides (which, however, may predispose to chemical urethritis only), the number of sexual partners, homosexuality in males, unprotected anal sex for heterosexual males, and history of other sexually transmitted diseases.

Clinical manifestations

The disease is often asymptomatic, particularly so in female patients and in cases of chlamydial etiology. Up to 75% of women with chlamydial urethritis experience no symptoms. Gonococcal urethritis exhibits a shorter incubation period than NGU and a more abrupt onset, and is usually symptomatic. Incubation period lies between a few days, for gonococcal disease, and up to 2 weeks for the nongonococcal one. Urethral discharge, dysuria, and urethral pruritus are the cardinal symptoms: Discharge is a product of the polymorphonuclear cell influx in the region as part of the immune response and epithelial cell apoptosis, is usually mucopurulent, most often observed at the morning, may be blood-tinged, and is a result of the inflammatory interplay following entry of the pathogen: this inflammatory response is more pronounced in cases of gonococcal compared to chlamydial urethritis and in males compared to females. Occasionally, in women with gonococcal infection symptoms can result from endocervical infection, such as altered vaginal discharge or intermenstrual bleeding and menorrhagia. Other causes of NGU such as *M. genitalium* tend also to cause symptomatic disease whereas *Trichomonas* infection in males can range from asymptomatic to more severe clinically than GU.

Diagnosis

The diagnosis of urethritis is based on the presence of relevant clinical symptoms accompanied by laboratory findings: Gram stain microscopy of urethral secretions that exhibits five or more white blood cells (WBCs) per oil-immersion field, or a positive WBC esterase test of first-void urine, or a first-void urine sample exhibiting 10 or more WBCs per high-power field. The latter though has been considered inadequate by various studies reporting that 12% of chlamydial infections and 5% of gonococcal ones may be undiagnosed by this criterion.

Gram stain microscopy allows for initial etiologic workup, since the observation of gram-negative intracellular diplococci may allow for a rapid diagnosis of gonococcal urethritis, with a sensitivity and specificity of >95% and >99% respectively in symptomatic men. However, microscopy has poor sensitivity (around 50%) in urethral samples of asymptomatic men and urethral and cervical samples of females. Thus, absence of pathologic findings on a Gram smear does not rule out gonococcal infection, especially in the later situations. Cultures may allow for isolation of the specific pathogen and evaluation of its antimicrobial susceptibility. Due to the increase in worldwide prevalence of cephalosporin-resistant strains of *N. gonorrhoeae*, cultures and susceptibility testing have become useful for new cases of urethritis and essential for cases with recurrence after treatment for GU.

Molecular diagnostic methods have been increasingly applied to urethritis diagnosis, nucleic acid amplification tests (NAAT) being the most popular choices, since they can be performed with urine specimens as well as urethral samples. These assays have shown exquisite sensitivity and specificity both for gonococci and *Chlamydia*, but lack the ability to identify resistant strains of gonococcus. Other NAAT exist for less common pathogens, such as *M. genitalium*, but their standard application in clinical practice has been under dispute. Other diagnostic tests for NGU include a wet preparation for *Trichomonas* diagnosis and a potassium hydroxide (KOH)

TABLE 59.2 **DIAGNOSTIC TOOLS FOR PATHOGENS INVOLVED IN URETHRITIS**

Pathogen	Diagnostic tools	Comments
Neisseria gonorrhoeae	Gram stain Culture NAHT NAAT	Culture and NAHT require urethral swab specimens, whereas NAAT can be performed on urine specimens. Culture allows identification of resistant strains
Chlamydia trachomatis	Culture Direct immunofluorescence Enzyme immunoassays NAHT NAAT	NAHT require urethral swab specimens, whereas NAAT can be performed on urine samples/in females addition of cervical samples increases sensitivity NAAT more sensitive and 100% specific
Mycoplasma genitalium	NAAT	NAAT can be performed on urine samples/in females addition of cervical samples increases sensitivity
Ureaplasma urealyticum, Mycoplasma hominis	Culture	Cultures need specialized media, not performed in everyday practice Urethral swabs preferred to urine samples
Trichomonas vaginalis	Wet preparation Culture NAAT	Wet preparation is 60% sensitive, often negative in males Anaerobic culture of urethral swab or first-void urine, 95% sensitive NAAT is considered superior to cultures (97% sensitivity and 98% specificity), but needs multiple samples in males

Abbreviations: NAAT = nucleic acid amplification tests, NAHT = nucleic acid hybridization tests.

preparation for fungal infections. Table 59.2 summarizes current diagnostic facilities for each pathogen and specific data about each assay's sensitivity and specificity. After confirmation of GU or NGU diagnosis, especially in cases of high-risk populations or GU recurrence, it is advisable to test for other sexually transmitted diseases, including human immunodeficiency virus (HIV) and syphilis, and, in female patients, pregnancy should be ruled out before specific antibiotic recommendations.

Complications

The importance of urethritis as a medical entity lies not in the severity of the syndrome per se, but in its potential complications: these complications may be rare in male patients, but do include formation of strictures or abscesses, prostatitis, epididymitis, infertility, disseminated gonococcal infection, and proctitis. In female patients complications are more common, and may lead to pelvic inflammatory disease, which may be of considerable severity. Females with GU and NGU can become infertile due to symptomatic or asymptomatic infection of the upper genital tract, which may cause direct damage to the uterus or fallopian tubes. Disseminated gonococcal infection can also follow urethritis in females. In pregnant women, chlamydial infection can lead to transmission of the pathogen to neonates leading to ophthalmia neonatum. Another important parameter of urethritis is that local inflammation results in disruption of the integrity of the epithelial barrier, thus urethritis confers an increased risk for HIV transmission. Finally, Reiter syndrome is another complication of GU and NGU. It is characterized by the coexistence of arthritis, urethritis, and conjunctivitis or uveitis due to an autoimmune process after gastrointestinal or genitourinary infections.

Differential diagnosis

Differential diagnosis includes traumatic urethritis, occurring after catheterization, chemical urethritis, noninfectious prostatitis, other infections of the lower urinary tract, and autoimmune urethritis of Reiter syndrome. Dysuria should be differentiated from frequency or urgency, which point to other diagnoses. It is reported that dysuria may be aggravated by alcohol consumption, or during menstruation in females. There are no systemic symptoms such as fever, and presence of such symptoms should orientate the diagnosis elsewhere. Since dysuria may be attributed to infectious processes of the whole genitourinary tract, including prostatitis or even pyelonephritis, but also to noninfectious causes of flow obstruction (including anatomical malformations, neoplasms, or even hormonal causes such as endometriosis, and neurogenic and psychogenic conditions), the significance of this subjective symptom is mainly in localizing the clinician's interest in the genitourinary tract.

A high number of WBCs in urine, termed pyuria, can be observed both in urethritis and other lower urinary tract infections, including cystitis. Pyuria with a negative urinary culture (with $°10^2$ common uropathogenic bacteria/mL of urine) is termed "sterile pyuria". NGU is among the most common causes of sterile pyuria, which include among others tuberculosis of the urinary tract, prostatitis, nephrolithiasis, interstitial cystitis, and urinary tract malignancies.

Treatment

Box 59.1 summarizes the suggested antibiotic regimens used in the treatment of urethritis, in accordance to guidelines from Europe and the USA. Many cases of urethritis resolve spontaneously, or evolve, in cases of NGU, into asymptomatic infection. Nevertheless,

BOX 59.1

Optimal treatment of urethritis and alternative approaches[a]

Gonococcal urethritis
(*all therapies in conjunction with therapy against Chlamydia: azithromycin 1 g orally in a single dose or doxycycline 100 mg orally twice daily for 7 days*)

- First-line regimen:
  Ceftriaxone, 250 mg intramuscularly, single dose
- Second-line, alternative regimens[b]:
  Cefixime, 400 mg orally, single dose
  Azithromycin, 2g orally, single dose (regimen for patients with cephalosporin allergy, no additional treatment for *Chlamydia* needed)
- Alternative regimens of inferior, or unproven efficacy[b]:
  Spectinomycin, 2 g intramuscularly, single dose, or
  Ceftizoxime, 500 mg intramuscularly, single dose, or
  Cefoxitin, 2 g intramuscularly, single dose, plus probenecid, or
  Cefotaxime, 500 mg intramuscularly, single dose,
  Cefpodoxime, 200 mg orally, single dose, or
  Cefuroxime axetil, 1 g orally, single dose

Chlamydial infection

- Azithromycin, 1 g orally, single dose, or
- Doxycycline, 100 mg orally, twice daily for 7 days
- Alternative regimens
  Erythromycin base, 500 mg orally, four times daily, for 7 days, or
  Erythromycin ethylsuccinate, 800 mg orally, four times daily, for 7 days, or
  Ofloxacin, 300 mg orally, twice daily for 7 days, or
  Levofloxacin, 500 mg orally, once daily, for 7 days

Mycoplasma genitalium infection

- Azithromycin, 1 g orally, single dose, or
- Doxycycline, 100 mg orally, twice daily for 7 days (possibility of resistant strains)

Ureaplasma urealyticum infection

- Azithromycin, 1g orally, single dose, or
- Doxycycline, 100 mg orally, twice daily for 7 days (possibility of resistant strain), or
- Quinolones, as used for *Chlamydia trachomatis* infection

Mycoplasma hominis infection

- Doxycycline, 100 mg orally, twice daily for 7 days (possibility of resistant strain), or
- Quinolones, as used for *Chlamydia trachomatis* infection, or
- Clindamycin, dose varying

Trichomonas vaginalis infection

- Metronidazole, 2 g orally, single dose, or
- Tinidazole, 2 g orally, single dose

Pregnancy

- Azithromycin, 1 g orally, single dose, or
- Amoxicillin, 500 mg orally, three times daily, for 7 days
- Alternatively: any erythromycin regimen, apart from erythromycin estolate

[a] Major recommendations from Workowski and Berman, 2006 and Centers for Disease Control and Prevention, 2012.
[b] The patient should return in 1 week for a test-of-cure at the site of infection.

antibiotic treatment of urethritis should always follow the diagnosis to prevent complications and further transmission of the pathogen.

Another important aspect regarding treatment is that gonococcal and chlamydial infection frequently coexist; thus, a diagnosis of gonococcal infection through a Gram smear showing gram-negative intracellular diplococci will warrant treatment of both gonococcal and chlamydial disease. This observation has further raised questions regarding the utility of sophisticated diagnostic assays when Gram smear shows gonococcal disease: it simply is cheaper to treat both for GU and chlamydial urethritis than confirm or exclude chlamydial disease through further testing.

Various antibiotics have been effective in the treatment of different forms of urethritis. Regimens for gonococcal disease include third-generation cephalosporins administered as a single dose. Ceftriaxone exhibits higher blood microbicidal levels and for a more sustained period than cefixime and should be considered as the optimal regimen (Box 59.1). Oral cephalosporins have proven inferior to ceftriaxone, and gonococcal resistance to cefixime is increasing; thus it is no longer considered a first-line therapy. Other cephalosporins have not proven advantageous compared to the aforementioned regimens. Recent European guidelines recommend an increase in the single dose of ceftriaxone to 500 mg because of resistance.

Azithromycin is efficacious against both gonococci as well as *Chlamydia*; it is thus considered sufficient monotherapy at high doses in cases of established cephalosporin allergy (Box 59.1). Similarly, according to some authors azithromycin should also be the preferred empirical therapy for *Chlamydia* when GU is diagnosed (thus used together with a cephalosporin), since tetracycline resistance is increasing among gonococcal isolates whereas azithromycin is efficacious against both microbes. Spectinomycin, although of exquisite microbiologic efficacy (>98%), is expensive and needs parenteral administration. Quinolones were viewed as potential single-dose monotherapy candidates that could treat both gonococcal and chlamydial infection, but the increasing rates of gonococcal resistance to these agents worldwide made them unsuitable for therapy of GU. On the other hand, ciprofloxacin's efficacy against *Chlamydia* is doubtful.

For chlamydial infection, azithromycin and doxycycline have proven equally successful, with microbial cure rates of 97% and 98%, respectively. Azithromycin is superior in terms of compliance since it can be directly administered upon diagnosis, but doxycycline is of considerably lower cost. Azithromycin may be superior though regarding treatment of *M. genitalium* infections. There is no difference in the percentage or severity of adverse events between the two antibiotic classes. None of the various alternatives has proven superior, although not all of them have been evaluated in randomized trials. Erythromycin is marred by low compliance due to frequent gastrointestinal adverse events.

There is increasing concern regarding emergence of resistance to azithromycin by *M. genitalium*, since recent studies have underlined therapeutic failures in cases of urethritis treated with azithromycin. These studies have shown a potent role for moxifloxacin in such cases. *Ureaplasma urealyticum* follows the susceptibility patterns of *Chlamydia*, although the risk of tetracycline resistance is significant. *Mycoplasma hominis* is resistant to azithromycin and macrolides, but sensitive to tetracyclines, quinolones, and clindamycin.

In pregnancy, gonococcal infection can be treated with the usual cephalosporin regimens, and azithromycin can be considered a safe

regimen for chlamydial infection. In addition, amoxicillin can also be administered safely and efficaciously in these patients.

Patients should be advised to abstain from sexual practices for the following week post treatment initiation, and previous sexual contacts should be traced and tested, extending to a period of 6 weeks prior to diagnosis. If the patient reports no contacts during this period, then the last sexual partner should be notified and tested. Alternatively, sexual partners can be treated on the responsibility of the patients, a practice that has been supported inconsistently as effective. Test of cure is not advisable for patients that become asymptomatic after therapy. However, this follow-up testing for microbiologic eradication is suggested for all pregnant women at 3 weeks after treatment completion and for all patients with gonococcal infection that initially received second-line treatment or alternative regimens.

Of note, there is an increased prevalence of gonococcal infections in patients with a recent previous gonococcal infection, and a similar risk exists for a new chlamydial infection after an initial one in female patients, with reinfection possessing greater potential for complications. Therefore, asymptomatic patients should be retested 3 to 12 months after treatment, although this test is distinct from a test seeking evidence of microbiologic eradication.

Recurrence of urethritis may be attributed to noncompliance with the initial treatment, initial infection by resistant strains (of great importance in GU, which should be excluded by culture upon recurrence), or re-exposure to a non-treated partner. Examples of recurrence in NGU include undiagnosed *Trichomonas* infection, which should be treated with metronidazole or tinidazole, infection by a *U. urealyticum* strain resistant to tetracycline, which should be treated with azithromycin, or *M. genitalium* resistant to tetracycline (or on rare occasions to azithromycin). Another common diagnosis in male patients may be chronic nonbacterial prostatitis, which in a significant percentage is accompanied by sterile urethral inflammation.

Prevention

Prevention through screening has been often advocated: US Preventive Services Task Force supports the annual screening for chlamydial infection in sexually active females aged 24 years or younger, and in older females who belong to certain risk groups (multiple partners, sex workers, etc.). Screening for gonococcal infection should also be advocated to the aforementioned high-risk groups of patients in addition to patients with a history of gonococcal infection or other sexually transmitted disease. On the other hand, some European authorities recommend screening for *Chlamydia* only in high-risk groups. Similarly, routine screening for *Chlamydia* in pregnancy during first visit has not been universally acceptable from a cost-effectiveness point-of-view; however, all women undergoing termination of pregnancy should be tested for chlamydial infection due to the risk of ascending infection. The active research in the field of development of a *Chlamydia* vaccine may offer further prospects in the future for control of urethritis incidence; until then though public health policies should be vigorously implemented.

Vaginitis and cervicitis

Sebastian Faro

INTRODUCTION

Vaginitis and cervicitis are undoubtedly linked in many instances, to some degree. When considering cervicitis as a discrete entity, the most common causes are infections due to *Chlamydia trachomatis* and *Neisseria gonorrheae*. Other causes of cervicitis are human papillomavirus (HPV) and infrequently considered are herpes simplex virus (HSV), *Mycoplasma*, and *Ureaplasma*. The two latter bacteria are commonly found colonizing the lower genital tract in sexually active women and their role in the disease of female pelvic organs is not well understood. However, recent data have implicated the mycoplasmas and ureaplasmas in both obstetric and gynecologic pelvic infections. Other causes of cervicitis have been documented throughout the world, e.g., *Mycobacterium tuberculosis*, *Schistosoma haematobium*, Epstein–Barr virus, amoebiasis, and cytomegalovirus, but are uncommon in the United States. However, when taking a history it is important to determine if there has been recent travel outside the United States, especially to parts of the world where these diseases are prevalent. The patient's past travel experience or her sexual partner's travel experience are important when evaluating the patient with vaginitis and cervicitis. The patient's travel experience can be significant when administering empirical antimicrobial treatment, especially when treating suspected gonococcal cervicitis. *N. gonorrhoeae* acquired from Asia tends to be resistant to the antibiotics commonly administered in the United States to treat gonococcal infection. Therefore, all patients being evaluated for vaginitis should be evaluated for the coexistence of cervicitis.

Vaginitis can be divided into two broad categories: infectious and noninfectious, and either can lead to cervicitis. The most common noninfectious cause of vaginitis is bacterial vaginosis (BV) which has been shown not to be simply an alteration in the indigenous vaginal microbiota. Gram-negative bacteria, especially the obligate anaerobic bacteria, make up a large portion of the vaginal microbiota. The gram-negative bacteria cell wall contains lipopolysaccharide (LPS), which is known to stimulate the cytokine cascade and the proinflammatory response syndrome. Patients with a predominance of gram-negative bacteria, and therefore an increase in the LPS content, in the vagina, have an increased vaginal concentration of tumor necrosis factor-α (TNF-α). This finding suggests that BV is not simply an alteration in the indigenous vaginal microbiota but perhaps should be considered as a subclinical infection. Therefore, in some cases it is difficult to distinguish between vaginitis and vaginosis, e.g., in the patient with BV and trichomoniasis. Patients may have both vaginitis and cervicitis of the same etiology or of different etiologies, e.g., *Trichomonas* can cause both vaginitis and cervicitis, whereas a patient with BV can also have chlamydial cervicitis. It is possible for the patient with BV to have a complex cervicitis involving BV bacteria plus *C. trachomatis* and *N. gonorrhoeae*. These potential situations underscore the need for the physician to consider the possibility of coexisting conditions in order to initiate appropriate treatment.

Many women with vaginitis are asymptomatic and do not seek treatment until they develop symptoms. Women examined for conditions other than vaginitis or even having a well-woman examination can be found to have an abnormal vaginal discharge, which should be evaluated. This is especially important because most chlamydial and gonococcal infections are asymptomatic. Vaginitis can often cause significant health problems and negatively impact the patient's quality of life, such as disruption of personal relationships,

ability to attend work and social activities. Pregnant patients who have vaginitis and cervicitis can experience premature preterm rupture of amniotic membranes, premature delivery, and postpartum endometritis. Patients with vaginitis and cervicitis who undergo pelvic surgery are at risk for post operative pelvic infection. BV has also been associated with complex pelvic inflammatory disease. Therefore, a simple evaluation of the vagina and cervicitis can lead to proper management, resolution of vaginitis and cervicitis, and improve the patient's quality of life.

BOX 60.1

Categories of the indigenous vaginal microflora

1. Healthy vaginal microflora—*Lactobacillus* dominant
2. Aerobic vaginal microflora—dominated by facultative anaerobes
3. Bacterial vaginosis—dominated by obligate anaerobes
4. Lactobacillosis—overgrowth of *Lactobacillus*

INDIGENOUS VAGINAL MICROBIOTA

The indigenous vaginal microbiota is complex and not well understood, especially the possible relationships between the bacteria of the vaginal microbiota, as well as the indigenous bacteria and the host. However, the use of molecular microbiologic techniques, such as polymerase chain reaction (PCR) analysis, has enabled a better understanding and shed new insight in understanding the make-up of the indigenous microbiota (Table 60.1). Molecular techniques have revealed the presence of bacteria that have not been found using classical microbiologic culture techniques. The microflora consists of a vast array of facultative and obligate anaerobic bacteria, and new genera and species are being found as part of the indigenous vaginal microbiota. The indigenous vaginal bacteria can be divided into four categories based on which bacterium or bacteria are dominant (Box 60.1). A "healthy vaginal microbiota" is dominated by *Lactobacillus*; however, not all species of *Lactobacillus* are effective in maintaining a "healthy vaginal microbiota." Species of *Lactobacillus* that are important in maintaining a "healthy vaginal microbiota" are those that produce adequate levels of lactic acid, hydrogen peroxide (H_2O_2), and a bacteriocin termed lactocin. These three factors, and there are likely other factors which are unknown at this time, appear to be significant in maintaining the vaginal environment that is favorable for the growth of *Lactobacillus*. These same factors are hostile to the growth of gram-negative and gram-positive facultative and obligate anaerobic bacteria.

Lactobacillus crispatus, L. jensenii, and *L. gasseri* are the three most common species found in the vagina of women with a "healthy vaginal microflora." Patients with *L. iners*, even in the presence of *L. jensenii* and/or *L. gasseri* appear to have an unstable microflora and are likely to develop "aerobic vaginitis (AVF)" or BV. The direction in which the vaginal microflora will drift and eventually become established appears to be dependent upon whether or not *Gardnerella vaginalis* is present as a member of the indigenous vaginal microbiota.

One mechanism provided by *Lactobacillus crispatus, L. jensenii*, and *L. gasseri* is the production of lactic acid. Lactic acid results in maintaining the vaginal pH < 4.5. This acidic pH favors the growth of *Lactobacillus* and inhibits the growth of facultative and obligate anaerobic bacteria. When lactobacilli are dominant this results in a ratio of lactobacilli to pathogenic bacteria of 1000:1. The concentration of lactobacilli is ≥ 10^6 bacteria/mL of vaginal fluid. This ratio of lactobacilli to pathogenic bacteria is important when considering a surgical procedure on a patient whose vaginal microflora is dominated either by a gram-positive or gram-negative facultative anaerobe or by obligate anaerobes, i.e. when pathogenic bacteria predominate. When the vaginal microflora is disrupted in such a way, especially in the patient undergoing pelvic surgery, transvaginal ovum retrieval, cesarean section, or who has preterm premature rupture of amniotic membranes leading to delivery of a premature fetus, all such patients are at significant risk for the development of a postoperative infection. Therefore, patients undergoing pelvic surgery who have a *Lactobacillus*-dominant indigenous vaginal microflora are likely to derive benefit from surgical antibiotic prophylaxis because of their risk of infection.

A second mechanism is the production of H_2O_2 by many species of *Lactobacillus*, especially *L. crispatus*, *L. jensenii*, and *L. gasseri*; most strains of *L. iners* do not produce H_2O_2. Hydrogen peroxide is toxic to obligate anaerobes because they do not produce catalase. Hydrogen peroxide can be converted to super oxide, which can disrupt DNA. Thus, the production of lactic acid and H_2O_2 appears to work in concert with a third factor, bacteriocin, which is a low-molecular-weight protein that has antibacterial properties. The bacteriocin produced by *Lactobacillus*, known as Lactocin, has been demonstrated to inhibit the growth of *Gardnerella* and *Prevotella* as well as other bacteria.

The cause of an alteration in the indigenous vaginal microflora is unknown. However, one change in the vaginal environment that appears to be instrumental in the disruption of a

TABLE 60.1 **BACTERIA OF THE INDIGENOUS VAGINAL MICROBIOTA**

Lactobacillus crispatus	*Escherichia coli*	*Atopobium vaginae*
L. jensenii	*Enterobacter aerogenes*	*Bacteroides fragilis*
L. gasseri	*E. agglomerans*	*Bifidobacterium*
L. vaginalis	*E. cloacae*	*Prevotella bivia*
L. iners	*Klebsiella oxytoca*	*Fusobacterium*
Staphylococcus aureus	*K. pneumoniae*	*Mobiluncus*
S. epidermidis	*Morganella morganii*	*Megasphaera*
Streptococcus agalactiae	*Gardnerella vaginalis*	*Sneathia*
S. pyogenes	*Peptococcus*	*Peptostreptococcus*

Note: E. agglomerans is now known as Pantoea agglomerans.

Lactobacillus-dominant indigenous vaginal microflora is a change in the vaginal pH. When the pH rises, growth of *Lactobacillus* slows and when pH is between 4.5 and 5, this appears to be a transitional zone. If *G. vaginalis* is present the microflora is destined to develop into BV. If *Gardnerella* is not present then it may well develop into "aerobic vaginitis." This is an important concept to understand because when the gram-negative bacteria are dominant there is an increase in TNF-α in the vagina. Thus, an inflammatory state is created and conditions such as BV are associated with increased risk of an infection in the upper genitalia tract as well as an increased risk of contracting sexually transmitted diseases, e.g., HIV. This inflammatory response involves the endocervical epithelium, making this tissue more receptive to contracting sexually transmitted organisms. In addition, patients with an altered vaginal microflora, e.g., BV, are at increased risk of developing a postoperative pelvic infection when undergoing pelvic surgery.

BACTERIAL VAGINOSIS

BV can be defined as a vaginal microflora that is dominated by obligate anaerobic bacteria. The diagnosis can be established easily with very little cost to the patient and consuming no more than 5 minutes of the physician's time. The clinical criteria are rather easy to determine (Table 60.2) and differentiate the most common types of vaginitis or vaginosis, and can assist in determining proper management. The patient should be reevaluated 1 to 2 weeks after completing treatment to determine if the pH has returned to the acidic range (pH > 3.8 to ≦ 4.5) and if large bacilli are present. If the pH ≥ 5 and microscopic examination of the vaginal discharge does not reveal the presence of large bacilli, the patient's initial vaginitis or vaginosis can reoccur or a different type of vaginitis can evolve. This can occur if the patient is diagnosed with BV and treated with metronidazole or clindamycin. The antibiotic will suppress the anaerobic bacteria and may suppress lactobacilli, allowing the facultative anaerobes to flourish if the pH is not decreased to < 5.

Mycoplasma and *Ureaplasma* are commonly found to be part of the indigenous vaginal microbiota in patients with a *Lactobacillus*-dominant vaginal microflora, aerobic vaginitis, or BV. *Mycoplasma* and *Ureaplasma* are found in approximately 60% of sexually active individuals. It is not understood how or if these bacteria have a role either in maintaining a healthy vaginal microflora or acting in concert with one or more of the pathogenic bacteria to create an environment that favors the growth of the pathogenic bacteria. Thus, there is much speculation regarding the potential role of *Mycoplasma* and *Ureaplasma*; however, other than nongonococcal and non-chlamydial urethritis, and perhaps cervicitis, treatment should not be initiated for these bacteria.

An organism that has gained significant attention is *L. iners*, which seems to be common in patients with an altered vaginal microflora. In addition, *L. iners* appears to rarely be present when *L. crispatus* is dominant. *L. iners* has been reported to be present when *L. jensenii* and *L. gasseri* are dominant. In this latter situation the vaginal microflora appears to be unstable and more easily undergoes shifts in the vaginal microbiota.

BV is made up of a variety of obligate anaerobes which can reach concentrations of $>10^8$ bacteria/ mL of vaginal fluid, mainly pathogenic bacteria. Undoubtedly there are facultative anaerobes present but probably fewer than 10^5 bacteria/mL of vaginal fluid. This concentration of bacteria is important because this is an enormous inoculum and can initiate or contribute to significant infection.

Treatments of BV are not very adequate because of the high recurrence rates (Box 60.2). The typical treatments are all designed to suppress the growth of obligate anaerobic bacteria. Treatments may have a suppressive effect on lactobacilli and not suppress the facultative anaerobic bacteria. However, if the pH does not decrease (<4.5) lactobacilli will not grow and either the obligate anaerobic bacteria or facultative anaerobic bacteria will gain dominance. This is the reason that the patient should be re-evaluated within one to two weeks following treatment. The two key observations that are indicative of whether there was resolution or not are: (1) has the vaginal pH returned <4.5, and (2) are large bacilli present. If the pH ≥ 5 and no large bacilli are present then patient has not responded in a positive manner. Patients who fail to respond should be referred to a gynecologist who has an interest in vulvovaginal disease.

Patients with BV who have greater than 5 WBCs/40× magnifications (wet prep) should be considered to have an infection

TABLE 60.2 **DIAGNOSIS OF AN ALTERED VAGINAL MICROFLORA**

	Healthy	Aerobic vaginitis	Bacterial vaginosis
Bacteria	Lactobacillus	Facultative anaerobes	Obligate anaerobes
Discharge color	White to slate-gray	Dirty-gray to purulent	Dirty-gray
Odor	None	None	Fish-like (Foul)
Microscopic analysis			
Squamous cells	Cytoplasmic membrane easily identified		Clue cells present
	Nucleus easily identified		Nucleus obscured
WBC	<5/hpf	<5/hpf	<5/hpf
Bacteria	Large bacilli	May be one morphotype or multiple morphotypes	Multiple morphotypes

Abbreviations: hpf = high-power field.

BOX 60.2

Treatments for bacterial vaginosis

Metronidazole 500 mg orally twice a day for 7 days, or
Metronidazole gel 0.75%, one full applicator (5 g) intravaginally hs × 7 days, or
Clindamycin cream 2%, one full applicator (5 g) intravaginally hs × 3 days, or
Tinidazole 2 g orally once daily for 2 days, or
Tinidazole 1 g orally once daily for 5 days, or
Clindamycin 300 mg orally twice a day for 7 days, or
Clindamycin ovules 100 mg intravaginally once at hs × 3 days

CDC MMWR, Sexually Transmitted Diseases Treatment Guidelines, December 17, 2010; 59: 1–110.

and should be evaluated for *Trichomonas vaginalis, Chlamydia trachomatis*, and *Neisseria gonorrhoeae*. BV is dominated by gram-negative obligate anaerobes and probably gram-negative facultative anaerobes. The cell wall of gram-negative bacteria contains LPS, the substance that initiates a proinflammatory response. It has been shown that patients with BV have an increased concentration of TNF-α in the vaginal milieu. The increase in TNF-α indicates that BV may not be a condition that initiates a classic inflammatory response, namely a significant increase in WBCs, but is associated with a possible upregulation of the cytokine cascade. This may be significant in patients who develop an infection, e.g., pelvic inflammatory disease, or who are having significant pelvic surgery, placing the patient at significant risk for developing a postoperative pelvic infection.

AEROBIC VAGINITIS

This condition may have a variety of presentations, bacteriologically; that is, dominance can be unimicrobial, e.g., *Streptococcus agalactiae* (group B streptococcus, GBS) or *Escherichia coli* or other unimicrobial vaginitis, or polymicrobial vaginitis. This condition does not resemble BV in that there are no clue cells, often noted as a purulent discharge indicating an inflammatory reaction, and either one bacterial morphotype, e.g., cocci in chains indicating dominance by streptococci or morphologically similar small rods, e.g. *E. coli*, or a variety of morphotypes indicating a polymicrobial condition. Typically the discharge is odorless. Many gynecologists do not advise obtaining a specimen for culture because whatever bacterium or bacteria is recovered is part of the normal vaginal microflora. However, obtaining a culture does assist: (1) in differentiating BV from aerobic vaginitis, (2) in determining which bacterium or bacteria is dominant, and (3) in determining if it is a mixed gram-positive and gram-negative vaginal microbiota. Without determining the microbiology, it would be difficult to administer appropriate treatment. The treatment most frequently administered, without bacteriologic data, is either metronidazole or clindamycin, neither of which is suitable for treating "aerobic vaginitis." Aerobic vaginitis like BV places the patient undergoing pelvic surgery at risk for the development of postoperative pelvic infection. This potential for infection resides in the fact that the inoculum in BV or aerobic vaginitis is extremely high with pathogenic bacteria achieving a concentration ≥ 10^6 bacteria/mL of vaginal fluid.

Treatment for aerobic vaginitis has not been established. Again, a main factor in determining whether or not *Lactobacillus* is dominant is the vaginal pH. The pH of the vagina in patients with aerobic vaginitis is ≥ 5, similar to that seen in patients with BV. This creates an environment that is unfavorable to the growth of *Lactobacillus* and favorable to the growth of pathogenic bacteria. Since there are no studies to guide treatment regimens, the author will give his recommendations based on logic. The evaluation should begin with determining if the patient's vagina contains appropriate species of *Lactobacillus*, i.e., *L. crispatus, L. jensenii*, and/ or *L. gasseri*. If none of these species are present in the patient's vagina restoration of a healthy vaginal microbiota or a *Lactobacillus*-dominant microbiota will not be achieved. If the patient has one or more of these species of *Lactobacillus* present in the vagina, treatment can be instituted either with vaginal boric acid alone or in combination with an antibiotic such as oral first-generation cephalosporin (Box 60.3). Boric acid is administered intravaginally to lower the pH of the vagina and reduce or inhibit the growth of gram-positive and gram-negative pathogenic bacteria. First-generation cephalosporins have a broad spectrum of activity, being active against many gram-positive and gram-negative facultative anaerobic bacteria. Since there is a high concentration of pathogenic bacteria and an extremely low concentration of *Lactobacillus*, the pH of the vagina will be maintained in a range > 3.8 and < 4.5. In order for *Lactobacillus* to grow the pH must be < 4.5 and maintained long enough for *Lactobacillus* to gain a foothold and the growth of pathogenic bacteria to be suppressed. The patient should be re-evaluated within 2 to 3 weeks to determine if the vaginal microbiota has been restored to a *Lactobacillus*-dominant indigenous vaginal microflora.

TRICHOMONAS VAGINALIS VAGINITIS

Trichomonas vaginalis is a sexually transmitted flagellated protozoan that causes significant infection and is transmitted via sexual contact. Trichomoniasis can be symptomatic or asymptomatic and is frequently associated with other sexually transmitted infections

BOX 60.3

Treatment of aerobic vaginitis

Orally administer first-generation cephalosporin + intravaginal administered boric acid vaginal capsules (600 mg) twice a day for 14 days

(STIs). The clinical presentation can, initially, be mistaken as BV. The pelvic exam should be coupled with a microscopic examination of the vaginal discharge; if WBCs are present (>5 WBCs/40× magnification) and no flagellated protozoa are seen a specimen should be obtained either for culture or PCR analysis for the detection of *T. vaginalis*.

Trichomonas vaginitis typically presents with a copious discharge that is dirty gray to purulent, may or may not have a foul odor, and is often found coexisting with BV. If BV is initially the diagnosis and the microscopic examination reveals a typical picture of BV and WBCs are present, STIs such as *T. vaginalis*, *C. trachomatis*, or *N. gonorrhoeae* should be suspected. Approximately 25% of patients infected with *Trichomonas* have petechiae in the vaginal epithelium and or cervix. Microscopic analysis of the vaginal discharge reveals numerous WBCs, clue cells can be present if there is an overabundance of obligate anaerobic bacteria present, and the squamous epithelial cells are well estrogenized. If the clinical presentation is consistent with a possible *Trichomonas* infection but the protozoan is not identified a specimen should be sent for culture or PCR to determine whether or not the patient is infected with *T. vaginalis*. In general, if a patient has a vaginal discharge and complains of vaginal burning or itching or odor but no pathogen has been identified, a specimen should be submitted to the laboratory for the identification of *T. vaginalis* and *Candida*. US Food and Drug Administration (FDA)-approved tests for the identification of *T. vaginalis* are: OSOM Trichomonas Rapid Test (Genzyme Diagnostics, Cambridge Massachusetts), Affirm VP III (Becton Dickenson, San Jose California), Amplicor (Roche Diagnostic Corp.), APTIMA (ASR, Gen-Probe, Inc.).

The treatment of vaginal trichomoniasis is the administration of oral metronidazole (Box 60.4). Approximately 2% to 5% of the patients will be infected with a low-level resistant strain. Metronidazole intravaginal gel is less effective than orally administered metronidazole because it does not achieve adequate levels in the paravaginal and periurethral glands. It is estimated that metronidazole gel administered intravaginally is <50% effective.

BOX 60.4

Treatment for *Trichomonas vaginalis* vaginitis

Initial treatment

Metronidazole 2 g orally in a single dose[a], or
Metronidazole 500 mg orally twice daily × 7 days[b]

Treatment for failures or reinfection

Metronidazole 500 mg orally three times a day[b], or
Metronidazole 2 g orally daily for 7 days[a], or
Tinidazole 2 g orally in a single dose[a], or
Tinidazole 500 mg orally daily for 7 days[b], or
Tinidazole 2 g orally daily for 7 days[a]

[a] CDC MMWR Sexually Transmitted Diseases Treatment Guidelines, 2010

[b] Author's recommendations to tinidazole consultation can be obtained and susceptibility testing of *T. vaginalis* isolates can be performed by the CDC (telephone 404–718–4141; http://www.cdc.gov/std).

There is also a significant rate of reinfection; in one study 17% of treated patients were found to be reinfected. Therefore, the patient's sexual partner should be treated whether or not the partner is symptomatic. The patient should be evaluated within 2 weeks of completing therapy and probably 3 months after the completion of therapy. The patient and her sexual partner should be treated simultaneously and condoms should be used during sexual intercourse and until the first follow-up examination. This will permit evaluation and reduce the chance of reinfection during this initial management of the female patient with vaginal *Trichomonas* infection. A patient suspected of having a resistant strain can be treated by increasing the dose of metronidazole or tinidazole (Box 60.4). Strains of *T. vaginalis* that have low-level resistance tend to respond to tinidazole.

VULVOVAGINAL CANDIDIASIS (VVC)

Vulvovaginal candidiasis (VVC) is a complex condition because approximately 20% of healthy, asymptomatic women have *Candida* as part of their indigenous vaginal microbiota. Therefore, the question that arises when treating women with symptomatic vulvovaginitis is can complete eradication of the yeast be achieved or should complete eradication be a realistic goal? Approximately 75% of women will experience at least one episode of VVC in their lifetime and 40% to 45% will experience two or more episodes in their lifetime. Approximately 10% to 20% will develop complicated VVC and require a detailed evaluation, and 5% will develop chronic or recurrent VVC.

The patient with VVC presents with pruritus of the vulva, external dysuria, pain, swelling of the vulva, and erythema. Signs of VVC are vulva edema, fissures, excoriations, and a vaginal discharge that is white with a consistency that ranges from liquid to pasty; the latter is often described as "cottage cheese-like." Although these signs and symptoms are highly indicative of the presence of VVC other conditions can present with similar signs and symptoms. The diagnosis can be established by performing a microscopic examination (wet prep) of the vaginal discharge and by mixing a second aliquot of the vaginal discharge with a drop or two of 10% potassium hydroxide (KOH). A wet prep must be examined microscopically (best under 40× magnification) to determine that there are no abnormalities of the vaginal discharge. Mixing 10% KOH with vaginal discharge will dissolve all constituents in the discharge except hyphae. Fungal hyphae contain chitin and chitin is resistant to strong alkali. The microscopic appearance of yeast cells are elliptical or pear-shaped cells; some of these yeast cells will have a short hypha projecting from one end of the cell (germ tube), or there will be long branching filaments (hyphae). Determining the vaginal pH can be useful, although a particular pH is not associated with VVC; however, a pH <5 is more commonly associated with VVC than a pH >5. However, candidiasis can also be present in patients with BV, aerobic vaginitis, and trichomoniasis. A patient presenting with clinical symptoms and signs of VVC, a pH <4.5, but for whom the microscopic examination of the vaginal discharge does not reveal candidiasis should have a specimen submitted for culture of yeast,

as should the patient whose wet prep reveals the present of yeast. The yeast should be identified to species because non-albicans species tend to be resistant to the usual antimycotic agents, both prescription and over-the-counter antifungal agents. Patients treated for VVC should be re-evaluated within 2 to 3 weeks following treatment to determine if the patient's signs and symptoms have resolved (clinical cure). If the patient's signs and symptoms have resolved, microscopic examination of the vaginal discharge is not necessary. It is important to remember that 10% to 20% of healthy asymptomatic women harbor *Candida*; because of this it is not possible to eradicate yeast from the vaginal microbiota in all patients. Therefore, isolation and culture of yeast from the vagina is used to determine the species of *Candida* found in the patient's vagina for purposes for enhancing treatment.

Microscopic examination of the vaginal discharge revealing hyphae does not establish the species of *Candida* but can differentiate between the hyphae-producing species of *Candida* and *Candida glabrata*. The latter species does not produce hyphae and presents as budding yeasts. *C. glabrata* is resistant to prescription and over-the-counter antimycotic agents. Treatment of *C. glabrata* can be attempted with standard antimycotic agents but the duration of treatment should be extended to 14 days. Standard treatments for *Candida albicans* range from a single dose to 7-day dosing (Box 60.5). If standard treatment fails to resolve VVC consider that the species is other than *C. albicans*. If the patient was compliant in administering intravaginal medication or taking a complete course of oral medication, the yeast should be isolated, identified to species and if a species other than *C. albicans* is present, alternative treatment should be administered (Box 60.5). If treatment with the typical prescription and over-the-counter antimycotic agents using prolonged dosing (14 days) fails, non-fluconazole azole drugs can be administered, e.g., boric acid gelatin capsules (600 mg) administered intravaginally daily for 2 weeks. The patient's vagina can be painted with gentian violet dye, weekly until the patient's symptoms have resolved. Another approach is to administer amphotericin B (10%) vaginal suppositories twice daily for 10 days. Patients with recurrent VVC should be screened for diabetes and HIV.

BOX 60.5

Treatment regimens for VVC

Prescription agents

Butoconazole 2% cream 5 g in a single dose intravaginal × 1 dose
Nystatin 100 000 unit vaginal tablet intravaginal, daily for 14 days
Terconazole 0.4% cream 5 g intravaginal for 7 days
Terconazole 0.8% cream 5 g intravaginal for 3 days
Terconazole 80 mg vaginal suppository daily for 3 days

Oral agents

Fluconazole 100 mg tablet administered in a single dose

Over-the-counter agents

Butoconazole 2% cream 5 g intravaginal for 3 days
Clotrimazole 1% cream 5 g intravaginal for 7–14 days
Clotrimazole 2% cream 5 g intravaginal for 3 days
Miconazole:
2% cream 5 g intravaginal for 7 days
4% cream 5 g intravaginal for 3 days
100 mg vaginal suppository daily for 7 days
200 mg vaginal suppository daily for 3 days
1200 mg vaginal suppository daily for 1 day
Tioconazole 6.5% ointment 5 g intravaginally in a single application

CDC Sexually Transmitted Diseases Treatment Guidelines 2010.

CERVICITIS

Cervicitis is not a simple condition but can be a rather complex condition that can be difficult to resolve. It is now known that some bacteria are capable of forming a biofilm on tissue, e.g., *N. gonorrhoeae* and *G. vaginalis*. The two most common causes of cervicitis are due to *C. trachomatis* and *N. gonorrhoeae*. One significant problem is treating the patient with cervicitis not due *to C. trachomatis* and *N. gonorrhoeae* because the etiology is often not known. Therefore, when a patient treated for cervicitis not caused by *C. trachomatis* or *N. gonorrhoeae* fails to achieve resolution the condition becomes chronic, and more invasive treatments are undertaken, e.g., cryosurgery or laser ablation. Other bacteria that may cause cervicitis are those bacteria associated with BV, e.g., *G. vaginalis* and *Mycoplasma genitalium*.

A biofilm is a complex matrix produced by bacteria and can contain a variety of bacteria. Biofilms have been associated with several recalcitrant infections involving *E. coli*, *Helicobacter pylori*, and *Pseudomonas aeruginosa*. Recently, *G. vaginalis* and *Atopobium vaginae*, two bacteria commonly associated with BV, have been shown to form a biofilm on the vaginal epithelium of women with BV. This finding could be significant in understanding why some patients with BV fail to respond to treatment and why some patients develop persistent cervicitis, even after cryosurgery or laser ablation. The matrix of biofilms forms a protective covering for the bacteria that dwell within the matrix so that antibiotics, WBCs, immunoglobulin, and antibodies are unable to penetrate the matrix and reach the bacteria.

Diagnosis

The diagnosis of cervicitis is based on the following findings:

1. Purulent or mucopurulent endocervical discharge, bleeding easily induced by gentle palpation of the endocervical epithelium with a cotton-tipped applicator
2. Cervical bleeding associated with sexual intercourse
3. Hypertrophy of the endocervical columnar epithelium associated with detectable or undetectable infection.

The diagnosis of cervicitis is often overlooked because it may be subtle. One indicator of cervicitis is the presence of > 10 WBC/40× magnification in the absence of *T. vaginalis* vaginitis. An endocervical specimen should be obtained and submitted for the

detection of *C. trachomatis* and *N. gonorrhoeae*. Specific tests for *M. genitalium, Ureaplasma urealyticum*, and *Ureaplasma parvum* are not commercially available. Patients found to have chronic cervicitis should also be evaluated for upper genital tract infection, i.e., endometritis and salpingitis. HSV can cause cervicitis but often it is not clinically apparent. In patients with cervicitis and risky sexual practices the workup should include testing for *C. trachomatis, N. gonorrhoeae*, and HSV. The data supporting testing for herpes simplex as a cause for cervicitis are not available but (author's opinion) the workup should include all three microorganisms. Patients known to have contracted genital HSV, even though they do not have an acute outbreak, could be shedding virus asymptomatically and, therefore, an endocervical specimen submitted for HSV detection could be positive and responsible for chronic cervicitis.

Treatment

The treatment of cervicitis due to *C. trachomatis, N. gonorrhoeae*, and *H. simplex* requires two different approaches. *C. trachomatis* and *N. gonorrhoeae* are bacteria and can be treated with antibiotics. If either or both these bacteria are documented as the etiology of the patient's cervicitis, then the patient's sexual partner should be treated at the same time. The patient should be re-evaluated for bacteriologic eradication following treatment. Treatment of HSV does not result in eradication of the virus but can suppress the virus and result in resolution of the cervicitis. The sexual partner of a patient who has been found to be positive for HSV should be evaluated for acute HSV infection. If the sexual partner does not have evidence for present or past HSV infection, antiviral suppressive therapy should be administered to the patient that has a documented HSV infection. If treatment is initiated prior to having laboratory confirmation of the specific etiology, treatment should be instituted against *C. trachomatis* and *N. gonorrhoeae* (Box 60.6). It is preferred to initiate treatment when the tests for *C. trachomatis* and *N. gonorrhoeae* have confirmed the presence of these two sexually transmitted diseases (STDs). Treating the patient based on clinical findings will prevent spread of the infection to the sexual partner or partners. The patient should be advised to refrain from sexual contact until the tests results are known. If either *C. trachomatis* or *N. gonorrhoeae* or both has been detected the patient should be notified and advised that her sexual partner or partners should be informed and treated.

Quinolone resistance among *N. gonorrhoeae* strains is widely disseminated throughout the United States. Therefore in 2007, the Centers for Disease Control and Prevention (CDC) recommended that quinolones not be used to treat *N. gonorrhoeae* infections. Resistance develops rapidly to macrolides and therefore these agents should not be used empirically for the treatment of gonococcal cervicitis. Patients treated with quinolones or doxycycline or azithromycin should have: (1) confirmation of the presence of *C. trachomatis* and/ or *N. gonorrhoeae*, (2) isolates of *N. gonorrhoeae* tested for resistance against cephalosporins, especially ceftriaxone and cefepime, doxycycline, levofloxacin, ofloxacin, and azithromycin. Resistance to cephalosporins has been rare in the United States but has been reported in Asia. The CDC reported that between 1987 and 2008 only four isolates have been resistant to ceftriaxone and 48 isolates have been found to have decreased susceptibility to cefepime. Therefore, patients treated for known gonococcal cervicitis should be asked about travel to the Middle East and Hawaii. They should also be queried about the travel of their sexual contact(s).

BOX 60.6

Treatment for cervicitis

C. trachomatis
- Azithromycin 1 g orally in a single dose, or
- Doxycycline 100 mg twice a day orally for 7 days, or
- Erythromycin base 500 mg orally four times a day for 7 days, or
- Erythromycin ethylsuccinate 800 mg four times a day for 7 days, or
- Levofloxacin 500 mg orally once a day for 7 days, or
- Ofloxacin 300 mg orally twice a day for 7 days

N. gonorrhoeae
- Ceftriaxone 250 mg IM in a single dose, or
- Cefixime 400 mg orally in a single dose, or
- Azithromycin 1 g orally in a single dose, or
- Doxycycline 100 mg orally twice a day for 7 days

CDC Sexually Transmitted Diseases Treatment Guidelines 2010.

Follow-up

The CDC does not recommend follow-up test of cure for those patients treated with the recommended antibiotic regimens, except if the patient is pregnant. However, the author recommends that the patient indeed have follow-up and test-of-cure testing if the patient has one or more of the following:

1. an STD infection in the past,
2. a sexual partner who has had a previous STD,
3. multiple sexual partners, and
4. has not received ceftriaxone as part of the treatment regimen.

Since most recurrent infections occur secondary to reinfection, a detailed sexual history should be obtained to determine the risk of sexual behavior. In addition, patients found to have one or more STDs should be screened for syphilis, HIV, HSV, HPV, and hepatitis B and C.

SUMMARY

Patients with vaginitis should be evaluated for cervicitis. The presence of >5 WBCs/40× magnification in the vaginal discharge and the absence of a pathogen, e.g., *T. vaginalis*, suggests the presence of cervicitis. Cervicitis can be caused by a variety of microorganisms

and some, such as *N. gonorrhoeae* and *G. vaginalis*, can produce a biofilm. The presence of a biofilm creates a problem for the physician treating the patient because the biofilm prevents antibiotics achieving adequate levels within the matrix to eradicate the bacteria. Biofilm typically contains more than one genus and this complicates the treatment of cervicitis. Clinical findings associated with cervicitis are hypertrophy of the endocervical columnar epithelium, which bleeds easily when touched, and the presence of endocervical mucopus. Inflammation of the cervix potentiates acquisition of STDs, especially HIV. Patients who have an STD, such as trichomoniasis, *C. trachomatis*, and *N. gonorrhoeae*, should have a complete evaluation for the possible existence of other STDs. In addition, the patient should be evaluated for HPV. Patients who are positive for the strains associated with cancer need to be educated about the potential for the development of cervical, vaginal, or vulva cancer. A plan of management should be presented to the patient, emphasizing prevention. Thus vaginitis and cervicitis are not minor conditions but can have far reaching effects on the patient's well being.

Epididymo-orchitis

Rebecca Fallis and Daniel Mueller

Introduction

Infectious and inflammatory processes involving the contents of the scrotum can range from those that require acute surgical intervention to findings that are benign in nature. Epididymitis and orchitis are conditions that refer to inflammation of the epididymis and testicles, respectively. Since they are relatively uncommon, clinicians who are not urologists may be unfamiliar with these problems.

Anatomy and definition

The epididymis is a tightly coiled tube on the posterior aspect of each testis that connects the efferent duct to the vas deferens. The epididymis consists of three regions for sperm storage, maturation, and transportation: the head, body, and tail.

Epididymitis involves inflammation or infection of the epididymis and is usually accompanied by pain and swelling. Acute epididymitis is characterized by symptoms that last for <6 weeks. Chronic epididymitis involves symptoms persisting for 6 weeks or longer, and the symptoms may develop more gradually over time. Overall, epididymitis is the most common cause of intrascrotal inflammation.

Orchitis, or inflammation of the testes, is less common than epididymitis. It rarely occurs in isolation except in cases of viral disease. Infection of the epididymis can spread to the adjacent testis, making it difficult to distinguish the clinical entities. Thus, the term *epididymo-orchitis* is used in reference to these combined inflammatory processes of both the epididymis and testes.

Epidemiology

The true prevalence of epididymo-orchitis is unknown, but it is relatively uncommon compared to other urologic conditions. There are approximately 600,000 cases of epididymitis per year in the United States. Epididymitis accounted for 1 in 144 outpatient visits (0.69%) made by males aged 18 to 50 years in 2002 according to the most current published data report. A prospective Canadian study demonstrated that 0.9% of men who presented to outpatient urology clinics in 2004 had epididymitis, which was less common than prostatitis or interstitial cystitis.

In children aged 2 to 13 years, the annual incidence of acute epididymitis is approximately 1.2 per 1,000 with a mean age of 11 years. One-fourth of these boys will have recurrence within 5 years. In adult men, 43% of cases occur between 20 and 30 years of age. Other studies report variable mean ages, but the incidence of epididymitis tends to peak in younger sexually active men, with the majority of cases occurring between 20 and 39 years.

In a case series study, orchitis occurred in 58% of patients diagnosed with epididymitis. Orchitis in the absence of epididymitis is uncommon except in mumps orchitis. US mumps outbreaks in 2006 and 2009–2010 have produced rates of orchitis in postpubertal males ranging from 3.3% to 10%. In the United Kingdom, mumps in postpubertal males is associated with up to 40% incidence of orchitis. Unvaccinated men, as well as those who received a single dose of the vaccine, were at higher risk of developing orchitis as a complication of mumps.

Pathogenesis and risk factors

The exact pathogenesis of epididymo-orchitis has not been clearly elucidated, but it most often occurs as a result of bacterial infection. The infecting organisms may extend to the epididymis in a retrograde fashion when urethrovasal reflux is present. Hematogenous and lymphatic spread may also occur. In children, acute epididymitis is often related to a urinary tract infection or congenital anomaly such as vesicoureteral reflux. In men aged 18 to 35, it is most commonly caused by sexually transmitted infections. The bacteria are introduced during sexual intercourse and then migrate through the genitourinary tract to the epididymis. In older men, epididymitis may be related to urinary stasis from lower urinary tract obstruction in the setting of benign prostatic hyperplasia (BPH), prostate cancer, or urethral stricture.

Risk factors for epididymo-orchitis include a history of urinary tract infections, high-risk sexual activity, genitourinary anatomic abnormalities, urinary tract surgery or instrumentation, strenuous activity, cycling, and prolonged periods of sitting. Invasive urologic procedures have been associated with epididymitis at reported rates of approximately 1% to 2%. These procedures include prostate biopsy, transurethral resection, brachytherapy, laser prostatectomy, and radical prostatectomy. Other mechanical insults such as direct trauma or pressure (e.g., from bicycle riding) have been associated with epididymitis even after vasectomy. Vasectomy itself has been associated with persistent tenderness and a nodular presence in the scrotum—presumably the result of sperm extravasation known as a "sperm granuloma."

Etiology

Infectious

In boys below the age of sexual activity, the microbial flora of epididymitis is a mix of skin and urinary flora. Epididymitis may also be a part of postinfectious syndrome from *Mycoplasma pneumoniae,* enterovirus, or adenovirus in children. Among sexually active adolescents and men <35 years old, acute epididymitis is most commonly associated with a sexually transmitted infection caused by *Chlamydia trachomatis* or *Neisseria gonorrhoeae*. *Mycoplasma* and *Ureaplasma* are isolated more frequently in younger men with chlamydial epididymitis than in other infectious causes of epididymitis, although the role they play in acute epididymitis is unclear. Gram-negative enteric organisms tend to cause epididymitis in older men, although sexually transmitted infections are still common. Additionally, enteric bacteria should be considered in men who practice insertive anal sex.

Many other less common infectious causes of acute epididymitis have been reported (see Table 61.1). *Mycobacterium tuberculosis* (TB) is the most common cause of granulomatous epididymitis. Tuberculosis epididymitis is rare and difficult to diagnose, and it should be suspected in patients with an exposure to TB or who are at high risk for TB, as in HIV. Patients may present with painful or painless swelling, and there is usually bilateral involvement. Seeding of the epididymis may be due to hematogenous spread. Urinalysis usually shows sterile pyuria, but secondary bacterial infection may be present. Diagnosis is made via identification of *M. tuberculosis* from the urine. Since few organisms are present in the urine, direct smears are usually negative and sensitivity of cultures may be only 50%. The sensitivity of TB urinary polymerase chain reaction (PCR) has been reported as 84% to 97%.

BCG-induced tuberculous epididymitis, or *BCGitis*, is caused by therapy with Bacillus Calmette-Guérin used to treat bladder cancer. This attenuated strain of *Mycobacterium bovis* is instilled into the bladder to cause an inflammatory response against the tumor cells. In rare cases, it has been reported to cause granulomatous epididymo-orchitis. Patients develop necrotic areas in the epididymis that may spread to the testes, causing scrotal enlargement with or without pain. Ultrasound reveals a heterogeneous, hypoechoic appearance of the epididymis.

Brucellosis is another less common cause of granulomatous epididymo-orchitis. *Brucella* is endemic to the Mediterranean and Middle Eastern countries, and epididymo-orchitis can occur in 2% to 20% of patients with brucellosis. Patients may have a history of occupational contact with animals or consuming unpasteurized dairy products. Most patients have an acute febrile illness with the most common symptoms being unilateral scrotal pain and swelling. Leukocytosis is often absent, and urinalysis and culture are often normal. Blood cultures for *Brucella* are positive in about 50% of cases, and serologic testing may aid in the diagnosis.

In patients with HIV infection or transplant recipients receiving immunomodulating drugs, various fungal and opportunistic bacterial etiologies of epididymo-orchitis are more likely to occur than in those who are immunocompetent. These include candidiasis, histoplasmosis, blastomycosis, coccidiomycosis, actinomycosis, aspergillosis, nocardiosis, and listeriosis. In males with HIV, cytomegalovirus, salmonellosis, toxoplasmosis, *Ureaplasma urealyticum*, *Corynebacterium* spp., *Mycoplasma* spp., and *Mima polymorpha* have also been implicated. In HIV-infected individuals, syphilitic orchitis caused by the bacterium *Treponema pallidum* is a rare manifestation of gumma in tertiary syphilis. *Haemophilus influenza* type B has been reported as a cause of epididymo-orchitis in adults with HIV, as well as in the pediatric and elderly populations.

Orchitis most often occurs with epididymitis but can occur alone as well. Mumps, a paramyxovirus, is a well-known cause of orchitis. However, epididymitis may develop as a complication. Although the overall incidence of mumps orchitis has fallen dramatically with the widespread use of the MMR vaccine, there have been reported

TABLE 61.1 **CAUSES OF ACUTE EPIDIDYMO-ORCHITIS**

Cause	Organism/disease
Sexually acquired	
Major	*Chlamydia trachomatis*
	Neisseria gonorrhoeae
Other	*Ureaplasma urealyticum?*
	Mycoplasma genitalium
Associated with bacteriuria	
Major	*Escherichia coli*
	Proteus spp.
	Klebsiella pneumoniae
	Pseudomonas aeruginosa
	Enterococcus spp.
Other	*Haemophilus influenzae* type b
	Salmonella spp.
	Staphylococci
	Streptococci
Other infections	
Bacterial	*Mycobacterium tuberculosis*
	Brucella spp.
	Nocardia asteroides
	Actinomyces

Fungal	*Blastomyces dermatitidis*
	Histoplasma capsulatum
	Coccidioides immitis
	Candida albicans
	Candida glabrata
Viral	Mumps
	Mumps vaccine
	Cytomegalovirus (in HIV)
Parasitic	*Toxoplasma gondii*
	Schistosoma haematobium
	Wuchereria bancrofti filariasis
Noninfectious causes	
Drug	Amiodarone therapy
Vasculitis	Behçet's disease
	Polyarteritis nodosa
	IgA Vasculitis
	Granulomatosis with polyangiitis
Other	Sarcoidosis
	Primary autoimmune orchitis
Idiopathic	

outbreaks in the United Kingdom and United States since 2000. They often occurred in postpubertal men in high-density settings, such as college dorms and camps, where the virus can spread through direct contact and respiratory droplets. Postpubertal men with mumps can develop unilateral or bilateral orchitis with some degree of testicular atrophy from inflammation and edema. Vaccination remains the best means to prevent infection, although it is not 100% effective. Mumps orchitis is a self-limited disease and the treatment is supportive with bed rest, scrotal support, and nonsteroidal anti-inflammatory drugs (NSAIDs).

Additional rare infectious causes of epididymo-orchitis and orchitis have been reported. Unusual causes of epididymo-orchitis include congenital syphilis, *Mycobacterium leprae* (Hansen's disease), coxsackievirus, group B arboviruses, varicella, and herpes simplex virus. In South India, epididymo-orchitis can be a rare manifestation of scrub typhus caused by the parasite *Orientia tsutsugamushi*. It was reported as the initial presentation in a 3-year-old boy with painful testicular swelling and fever. Powassan virus was found to be the cause of prodromal epididymo-orchitis in one patient before he presented with encephalitis. The patient was a 63-year-old male from Cape Cod, Massachusetts, who was receiving rituximab for follicular lymphoma.

Noninfectious

Although most cases of epididymo-orchitis are of an infectious etiology, several noninfectious causes have been described. Amiodarone-induced epididymitis is considered a diagnosis of exclusion and is usually reversible once the offending agent is removed. Epididymo-orchitis has been reported in patients with various vasculitides, including polyarteritis nodosa (PAN), Behçet's disease, immunoglobulin A (IgA) vasculitis (formerly Henoch–Schönlein purpura), and granulomatosis with polyangiitis (formerly Wegener's granulomatosis). Sarcoidosis can affect the genitourinary system in 5% of patients. Primary autoimmune orchitis is not associated with a known systemic autoimmune disease. It is characterized by antisperm antibodies directed either to the basement membrane or seminiferous tubules in infertile men. Finally, traumatic causes of epididymo-orchitis may also occur. The etiology of the remaining cases of acute epididymitis is "idiopathic," but advances in microbiology and molecular diagnostic techniques may elucidate specific causes in the future.

Clinical features and differential diagnosis

Acute epididymo-orchitis presents with testicular pain and scrotal edema which is usually unilateral and gradually progressive over several days. Fever, rigors, and leukocytosis may also be present. Urethritis or pyuria, in the absence of bacteriuria, is usually associated with sexually transmitted acute epididymitis. Bacteriuria and voiding symptoms such as dysuria, frequency, and urgency tend to be associated with urinary obstruction and/or structural urogenital disease in

older men. However, dysuria is not always present in these cases. In a retrospective study of 121 patients with acute epididymitis, dysuria was present in 33% of patients, urethral discharge was present in only 5%, and positive urine cultures were found in <25% of patients.

The acutely painful and swollen scrotum has a broad differential diagnosis. The differential diagnosis includes acute epididymo-orchitis, spermatic cord (testicular) torsion, torsion of the appendix testis, incarcerated inguinal hernia, acute hydrocele, thrombosed varicocele, Fournier's gangrene, testicular cancer, and trauma. Pain is not typical of hydroceles or varicoceles, and testicular malignancies can cause pain in about 15% of cases. Importantly, a physician must identify testicular torsion in a timely manner as this necessitates immediate surgical intervention. Testicular torsion cannot be excluded based on physical examination alone, but a high-riding testicle and the absence of a cremasteric reflex are suggestive of the diagnosis. The Prehn sign (i.e., relief of pain with elevation of the testes) suggests acute epididymitis but does not rule out testicular torsion.

Diagnostic workup

Evaluation of suspected epididymo-orchitis is initially based on clinical suspicion of disease from patient complaints of pain and/or swelling within the scrotum. The first challenge is ruling out testicular torsion. The distinction between torsion and inflammation or infection needs to be made quickly, particularly in prepubescent boys, because untreated torsion can jeopardize the testis. Expert urologic consultation may be urgently required. Color Doppler ultrasound showing an enlarged, thickened epididymis with normal to increased testicular blood flow is 70% sensitive and 88% specific for epididymitis. In testicular torsion, the ultrasound reveals a normal-appearing testicle with decreased blood flow and is 82% sensitive and 100% specific. Radionuclide scanning is a sensitive study for torsion, but it is not routinely available. C-reactive protein (CRP) may be helpful in distinguishing torsion versus infection as patients with epididymitis have elevated CRP (96% sensitive and 94% specific). Surgical exploration should not be delayed if the diagnosis remains unclear.

If torsion is not considered likely, the best initial diagnostic study is urine collection for urinalysis and culture. A first-void specimen should be collected if a sexually transmitted infection is thought to be the etiology, whereas a midstream specimen is recommended if the cause is more likely due to an enteric pathogen. If urethral secretions are present, Gram stain is highly sensitive and specific for diagnosing urethritis and can establish gonococcal infection by demonstrating leukocytes containing intracellular gram-negative diplococci. In the era of nucleic acid amplification testing (NAAT), the Gram stain sensitivity has been increased by lowering the diagnostic cutoff for urethritis from ≥5 to ≥2 leukocytes/oil-immersion field. All sexually active men should have NAAT for the detection of gonorrhea and/or chlamydia in a urine specimen. These tests are highly sensitive for *N. gonorrhoeae* and *C. trachomatis* and have largely supplanted urethral cultures to diagnose these infections.

In patients who do not respond to empiric therapy—particularly in those who have unique risk factors based on host immune status, travel history, or geographic location—a more exhaustive workup should be performed in conjunction with urologic consultation. This may include further imaging, additional cultures (e.g., acid-fast bacillus [AFB] and fungal cultures), and direct sampling of the epididymis in some cases.

Treatment

Treatment includes antimicrobial therapy in combination with analgesics, bed rest, and scrotal elevation. Empirical therapy should be initiated before laboratory results are available. Antibiotic choice and duration should be tailored to the specific pathogen if one is identified by culture. See Table 61.2 for empiric antibiotic therapy for acute epididymitis.

TABLE 61.2 **EMPIRIC ANTIBIOTIC THERAPY FOR ACUTE EPIDIDYMITIS**

Population	Most likely causative agent	Most likely causative agent
Children <2 years	Various	Antibiotic treatment for likely underlying enteric organism and referral to a urologist
Children 2–14 years of age	Various, likely anatomic	Treat based on urinalysis or urine culture results
Sexually active adults <35 years	Gonorrhea or chlamydia	Intramuscular ceftriaxone (single 250 mg dose) *and* Oral doxycycline (100 mg BID for 10 days)
Adults who practice insertive anal intercourse	Gonorrhea or chlamydia and an enteric organism	Intramuscular ceftriaxone (single 250 mg dose) *and* Oral levofloxacin (500 mg once daily for 10 days) *or* oral ofloxacin (300 mg BID for 10 days)
Adults >35 years or who have had recent urinary tract surgery or instrumentation	Enteric organism	Oral levofloxacin (500 mg once daily for 10 days) *or* oral ofloxacin (300 mg BID for 10 days)

In the 2015 update to the Sexually Transmitted Diseases (STD) Treatment Guidelines for "epididymitis," the Centers for Disease Control and Prevention (CDC) recommends dual therapy with intramuscular ceftriaxone 250 mg as a single dose plus doxycycline 100 mg orally twice a day for 10 days. In men who practice insertive anal sex, enteric organisms should also be covered. For these individuals, intramuscular ceftriaxone 250 mg single dose plus either oral levofloxacin 500 mg/d or oral ofloxacin 300 mg/d for 10 days should be given. In men >35 years, monotherapy with levofloxacin or ofloxacin alone for 10 days is usually sufficient since sexually transmitted infections are less likely. Fluoroquinolones have good oral bioavailability, spectrum of activity, and penetration of genitourinary tissues. Other agents active against uropathogens (e.g., trimethoprim-sulfamethoxazole, amoxicillin) can be tried in the event of fluoroquinolone failure or intolerance.

Sex partners of patients with epididymitis caused by *N. gonorrhoeae* or *C. trachomatis* who had contact within 60 days of symptoms should be referred for evaluation and treatment. It is also prudent to counsel patients that sexual intercourse should be avoided until they and their sex partners have completed therapy and are without symptoms, although the optimal duration of this period of abstinence has never been studied.

Even though pain may persist for several weeks, patients should respond clinically in the first few days of treatment. Failure to improve may indicate an underlying abscess, tumor, vasculitis, or infarction. It also may indicate a resistant organism or an uncommon fungal or mycobacterial pathogen. In children <14 years being treated for acute epididymitis, a urologist should be consulted to evaluate for potential anatomic abnormalities. Men >50 years should be evaluated for urinary tract obstruction from an enlarged prostate.

Conclusion

Epididymo-orchitis is fairly uncommon compared to other urologic conditions, but it is important for a physician to be able to recognize this clinical entity. The etiology is often infectious, and the likely causative organism may vary based on the patient's age and risk factors. Pure orchitis is usually viral and should be considered in any male with mumps. Once the diagnosis of testicular torsion has been ruled out, the management of epididymo-orchitis can begin with a limited set of diagnostic tests and an empiric trial of antibiotics. For patients with more complex or chronic disease, co-management with a urologist is recommended. In patients who do not respond to initial therapy, this could indicate an unusual infection or noninfectious cause, and further workup should be pursued.

Genital ulcer adenopathy syndrome

Allan Ronald

The control and prevention of genital ulcer disease (GUD) is an important public health priority. Ulcerative lesions may produce local genital pain, some pathogens are transmitted from mothers to their infants, and genital lesions increase the risk of HIV acquisition and transmission following sexual intercourse. Box 62.1 lists the infectious and noninfectious etiologies that may produce genital ulcerations with or without adenopathy. The most commonly transmitted GUD diagnosis and etiologies are syphilis (*Treponema pallidum*), herpes simplex (HSV-1 and-2), chancroid (*Haemophilus ducreyi*), lymphogranuloma venereum (LGV; L1, L2, and L3 serovars of *Chlamydia trachomatis*), and granuloma inguinale or donovanosis (*Calymmatobacterium granulomatis*). Trauma, erosive balanitis, and fixed drug eruptions are common nontransmissible causes of GUD. Fungal and mycobacterial infections, as well as tumors if suspected, should be excluded by biopsy. Because of the limitations of diagnostic tests, a specific etiology is obtained in only 50% to 80% of patients.

Major geographic variation exists in the etiology and prevalence of GUD (Table 62.1). In Europe and North America, about 5% of patients who present to sexually transmitted disease (STD) clinics have a genital ulcer compared with 10% to 30% presenting to similar clinics in Africa and Asia. HSV is the most common cause of genital ulcerations in Europe and North America; syphilis and chancroid have been more common cause elsewhere. However, herpetic ulcers are now more common in most settings, particularly in patients coinfected with HIV, whereas chancroid has largely disappeared. LGV is endemic regionally in the tropics and has reappeared in developed countries as an epidemic among men who have sex with men (MSM), many of whom are HIV-positive. Donovanosis was endemic in New Guinea, India, and Southern Africa but is now rare. Syphilis persists as a global pandemic that has recently reappeared with large outbreaks among MSM. Males who are circumcised have a markedly reduced probability of acquiring chancroid and, to a lesser extent, of acquiring herpes or syphilis following heterosexual intercourse. Circumcision also reduces human papilloma virus infections as well as penile neoplasms.

Clinical presentations

Clinical features of GUD are listed in Table 62.2. The incubation period is usually <1 week for genital herpes and chancroid, 1 to 3 weeks for LGV, and 2 to 6 weeks for syphilis and donovanosis. Depending on the etiology, the initial lesion can be a papule, pustule, or vesicle which erodes to form an ulcer. In men the ulcers are often located on the coronal sulcus but may also be found on the glans, prepuce, and shaft of the penis or, less often, on the scrotum or surrounding skin. Herpes and chancroid have a predilection for involving the frenulum. In women, the ulcers may occur on the labia, in the vagina, on the cervix, on the fourchette, or on the perianal area. Perianal and intrarectal ulcers are common among MSM.

BOX 62.1

Etiologies of genital ulcer disease

Infectious

Bacterial

- *Haemophilus ducreyi* (chancroid)
- *Treponema pallidum* (syphilis)
- *Chlamydia trachomatis* (lymphogranuloma venereum)
- *Calymmatobacterium granulomatis* (donovanosis)
- Balanitis (often polymicrobial but *Candida albicans* is often present)

Viral

- Herpes simplex
- Varicella zoster[a]
- Epstein–Barr virus
- Cytomegalovirus[a]

Parasitic

- *Sarcoptes scabiei*[a]
- *Phthirus pubis*[a]
- *Entamoeba histolytica*[a]
- *Trichomonas vaginalis*[a]

Noninfectious

- Trauma
- Fixed drug eruptions
- Pyoderma gangrenosum[a]
- Behçet's disease[a]
- Reiter's syndrome[a]
- Wegener's granulomatosis[a]
- Neoplasms[a]
- Unknown

[a] Unusual.

Genital herpes

HSV-1 is transmitted primarily by oral contact. In the developing world, the initial infection commonly occurs in infancy, and genital HSV-1 infections are less common. However, in the industrialized world most adolescents have not acquired HSV-1, and this virus is frequently transmitted through oral–genital sex. In all societies, HSV-2 is almost always transmitted by sex. Genital herpes due to both viruses presents as painful multiple, small vesicles that rapidly become superficial ulcers with erythematous margins. Urethral, gynecologic, or cutaneous symptoms may predominate depending on the site of vesicles. Systemic symptoms of fever, myalgias, and headache can occur with an initial infection. A prodrome of paresthesias 12 to 48 hours before the appearance of vesicles is often reported with each recurrence. Painful lymphadenopathy can be present. Following the initial infection, both HSV-1 and HSV-2 remain latent in the sensory ganglion but recur unpredictably. These are usually less severe. However, they tend to be severe and persistent in HIV-infected individuals. Large, painful, often single ulcers occur commonly, particularly in the perianal area.

TABLE 62.1 **GEOGRAPHIC VARIATION IN THE PREVALENCE OF GENITAL ULCER DISEASES IN CLINICS FOR SEXUALLY TRANSMITTED INFECTIONS**

	Southeast Asia/India	Africa	North America/ Europe
Chancroid	+/–	+/–	+/–
Syphilis	+++	+++	+++
Genital herpes	++++	++++	++++
Lymphogranuloma venereum	+	+	+
Donovanosis	+/–	+/–	+/–

Syphilis

The classical ulcer of primary syphilis is solitary, painless, and minimally tender with elevated, well-demarcated margins and an indurated nonpurulent base. Multiple ulcers occur more commonly in women. Lymphadenopathy, if present, is usually bilateral with firm, nontender nodes. All pregnant women should be screened for syphilis as well as HIV at their first prenatal visit. Secondary syphilis can have many cutaneous features, including condyloma and superficial ulcers which often occur in the genital area.

Chancroid

Chancroid typically produces painful, excavated ulcers with irregular, undetermined margins and a purulent base (Figure 62.1). The ulcers can be superficial and may resemble herpetic ulcers. Approximately 50% of the patients will develop painful inguinal lymphadenopathy, which can be unilateral. Lymph nodes may become fluctuant (buboes) and rupture. Untreated ulcers may persist for months and heal with scarring.

An epidemic in children of painful chronic cutaneous lower limb ulcers due to *H. ducreyi* is unfolding in the South Pacific, including Papua New Guinea. It has been described as well in Ghana, West Africa. The *H. ducreyi* isolates appear to be genetically identical to the species that causes chancroid. The epidemiology of its transmission is unknown. Sexual abuse and poor hygiene are possible factors. Clinically it can be confused with yaws and the Buruli ulcer due *Mycobacterium ulcerans*. The *H. ducreyi* ulcers can persist for months unless treated. The macrolides appear to be usually curative. Further information on this emerging "new" illness and strategies for its control and eradication are urgently needed.

Lymphogranuloma venereum

The ulcer of LGV is transient, usually superficial and painless. It precedes the development of inguinal lymphadenopathy by 7 to 30 days, and fewer than a third of the patients recall having had an ulcer. The lymph nodes are tender and may become fluctuant with eventual rupture and formation of draining sinuses. A "groove" sign may be present if nodes above and below Poupart's ligament are involved. Women and homosexual men may have involvement of perianal and perirectal tissues and present with proctitis. Complications

TABLE 62.2 **CLINICAL CHARACTERISTICS OF GENITAL ULCER ADENOPATHY SYNDROMES**

	Syphilis	Herpes simplex virus	Chancroid	Lymphogranuloma venereum	Donovanosis
Incubation period	9–90 d	2–7 d	1–14 d	7–21 d	8–80 d
Primary lesion	Papule	Vesicle	Papule or pustule	Papule, pustule, or vesicle	Papule

of untreated infection include genital elephantiasis, rectal strictures, and perianal fistulas. Other manifestations include meningoencephalitis, hepatitis, erythema nodosum, and erythema multiforme.

Donovanosis

Patients present with a slowly progressive, painless ulceration of the genital area characterized by heaped-up granulomatous tissue. Local extension, healing, and fibrosis may occur simultaneously. Lymphadenopathy is unusual, but "pseudo buboes" caused by subcutaneous extension of the granulomatous process into the inguinal area are common. Systemic spread with involvement of liver, thorax, and bones has been reported but is rare.

Laboratory diagnosis of GUD

Clinical diagnosis of GUD is imprecise because of overlap between the clinical syndromes, the presence of mixed infections, and atypical presentations. Because of these limitations, the diagnosis must be confirmed whenever possible using the relevant laboratory tests (Table 62.3). Specimens should be collected for *H. ducreyi, C. trachomatis*, and herpes simplex cultures and, if available, DNA identification with polymerase chain reaction (PCR). If possible, a dark-field examination should be performed in all patients

TABLE 62.3 **RECOMMENDED TESTS FOR DIAGNOSING GENITAL ULCER DISEASES**

	Recommended tests	Other tests
Chancroid	Culture	Gram stain/PCR
Syphilis	Dark-field examination	PCR
	Direct fluorescent antibody test	
	Serology (e.g., RPR/VDRL, FTA- ABS, MHA-TP)	
Genital herpes	Viral culture	Antigen detection (ELISA), PCR, Serology
Lymphogranuloma venereum	PCR	*Chlamydia* culture
		Serology (complement fixation, microimmunofluorescence)
Donovanosis	Giemsa or Wright stains of tissue smears Histopathology	

Abbreviations: PCR = polymerase chain reaction; RPR = rapid plasma reagin; VDRL = Venereal Disease Research Laboratories; FTA-ABS = fluorescent treponemal antibody absorption; MHA-TP = microhemagglutination test for *Treponema pallidum*; ELISA = enzyme-linked immunosorbent assay.

presenting with GUD unless classical vesical lesions in clusters provide definite evidence of herpes genitalis. The ulcer base is washed with saline, dried with a cotton gauze, and squeezed between the thumb and forefinger until an exudate appears. This can be collected directly onto a coverslip for dark-field microscopy. Vesicles and pustules should be aspirated with a fine-gauge needle or de-roofed and swabbed for viral culture. Fluctuant lymph nodes should be aspirated for *H. ducreyi* and *C. trachomatis* culture. Both *Treponema pallidum* particle agglutination (TPPA) and non-treponemal rapid plasma reagin (RPR), serologic tests should be obtained in all patients with GUD to exclude syphilis. LGV diagnosis is confirmed by PCR or by rising antibody titers or a single titer of 1:64 by complement fixation or 1:512 by microimmunofluorescence.

Approach to the patient with GUD

An algorithm for investigating a patient with genital ulceration is given in Figure 62.2. The history is crucial. Information should be collected about sexual risks, demographics, medication, and travel. Risk factors such as sex work or recent prostitute contact are associated with syphilis and classical chancroid. Travel may suggest the diagnosis of an otherwise uncommon diagnosis such as donovanosis. Self-medication with topical or systemic antibiotics may lead to a false-negative dark-field examination or culture.

Treatment

The drug regimens currently recommended for treating GUD are given in Table 62.4. Treatment traditionally has been initiated only once a laboratory diagnosis has been established; however, the delay inherent in obtaining laboratory results makes it necessary to initiate empiric syndromic therapy at the time of the initial visit. The selected syndromic therapy should be effective for syphilis. Fluctuant buboes should be incised or aspirated. All patients with GUD should be tested for HIV infection.

Patients should be reassessed at 7 days to assess response to therapy. Most patients will show improvement; failure of the lesions to respond should prompt a search for an alternative diagnosis. The RPR as well as a treponemal test should be repeated in all patients. Serology can be negative in 30% of patients at first presentation with primary syphilis.

Syphilis

A single intramuscular (IM) injection of benzathine penicillin G, 2.4 million U, is the treatment of choice for both HIV-infected and -uninfected patients with primary or secondary syphilis. Doxycycline or tetracycline for 14 days can be used in patients with a documented penicillin allergy. Azithromycin resistance is now widespread, and the macrolides are no longer recommended. All patients should be followed with a quantitative RPR or VDRL at 3, 6, 12, and 24 months after treatment. Treatment failure is diagnosed if clinical signs persist or recur, a sustained fourfold rise in titer occurs, or an initially high titer (>1/8) fails to decline by at least fourfold at 6 months. Patients who fail treatment as determined by these criteria should undergo a lumbar puncture. If the cerebrospinal fluid (CSF) is normal, they should be treated with benzathine penicillin G, 2.4 million U IM weekly for 3 weeks. Patients with CSF abnormalities should be treated for neurosyphilis. Because tetracyclines are contraindicated in pregnancy, pregnant patients with a proven penicillin allergy must be desensitized and treated with penicillin. All persons who had sexual contact during the preceding 90 days should be treated and followed with serology.

Chancroid

Trimethoprim-sulfamethoxazole (TMP-SMX) is no longer recommended for the treatment of chancroid because *H. ducreyi* is generally resistant. Erythromycin, 250 mg three times daily for 7

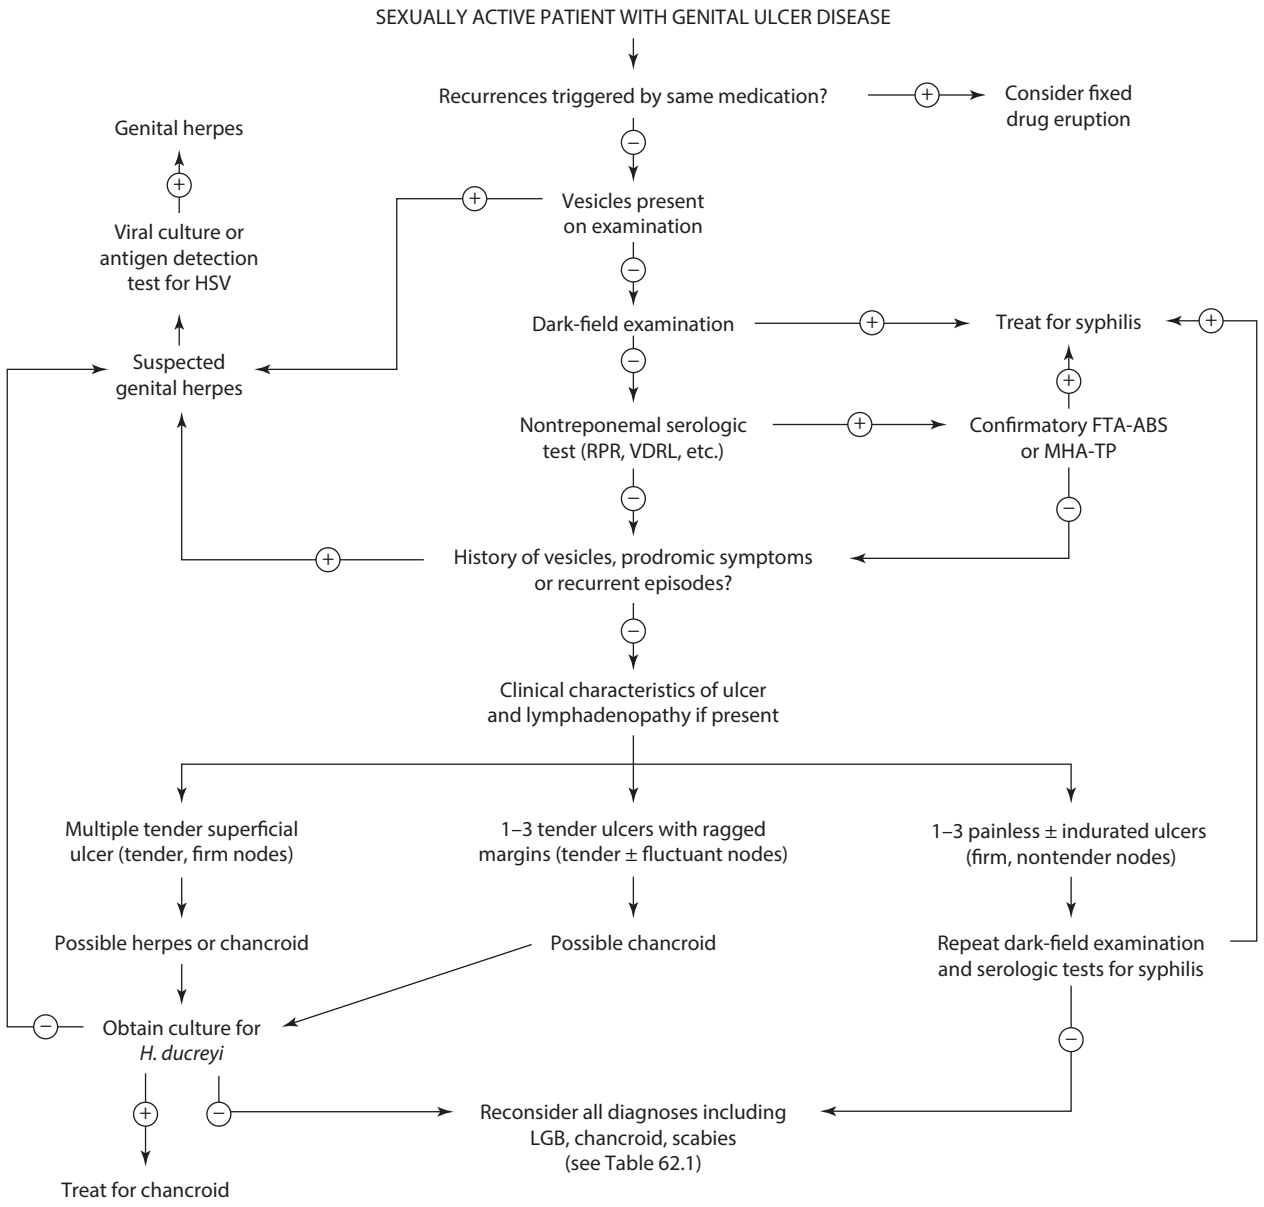

FIGURE 62.2 Diagnostic algorithm for patients with genital ulcer disease.

days, is effective in both HIV-infected and -uninfected patients. A single dose of azithromycin, 2 g or ciprofloxacin, 500 mg, is also effective, with cure rates of >95%. All chancroid patients with initially negative serologies for HIV and syphilis should have these tests repeated at 3 months. All persons who had sexual contact with the patient in the preceding 4 weeks should be treated regardless of evidence of infection.

Lymphogranuloma venereum

Doxycycline for 21 days is the treatment of choice for LGV, but treatment failures may occur, especially in the presence of proctitis, and repeated longer courses of 6 weeks should be prescribed. Pregnant patients should be treated with erythromycin. All sexual contacts within the past 4 weeks should be investigated for rectal, urethral, or cervical chlamydial infection and treated regardless of laboratory confirmation.

Donovanosis

Doxycycline (usually a 2-week course) remains the treatment of choice for donovanosis, although treatment failures occur and require a 4- to 6-week course. When doxycycline therapy fails, patients can be treated with TMP-SMX or ciprofloxacin.

Genital herpes

Acyclovir, valacyclovir, or famciclovir should be used to treat the initial clinical episode of genital herpes, and intravenous acyclovir therapy may be required in severe cases. Prophylaxis is indicated for patients with

TABLE 62.4 **TREATMENT REGIMENS FOR INFECTIOUS CAUSES OF THE GENITAL ULCER ADENOPATHY SYNDROME**

Disease	Recommended regimen	Alternative regimens	Comments
Primary syphilis	Benzathine penicillin G (2.4 million U IM)	Doxycycline (100 mg PO BID × 14 days) or Tetracycline (500 mg PO QID × 14 days)	The Jarisch–Herxheimer (J-H) reaction (acute onset of fever accompanied by headache, myalgia, malaise, nausea, and tachycardia) may occur 2–24 h after initiating therapy for syphilis. Although the J-H reaction may produce fetal distress or premature labor in a pregnant woman, this is not an indication to delay therapy
Chancroid	Erythromycin (250 mg PO QID × 7 days) Erythromycin (500 mg PO QID × 7 days)	Azithromycin (1 g PO × 1 dose) or Ciprofloxacin (500 mg PO × 1 dose) or Amoxicillin-clavulanic acid (500/125 mg PO TID × 7 days)	Single-dose regimens are contraindicated in HIV-seropositive patients because of unexpectedly high failure rates
Lymphogranuloma venereum	Doxycycline (100 mg PO BID × 21 days)	Erythromycin (500 mg PO QID × 21 days) or Sulfisoxazole (500 mg PO QID × 21 days)	Contacts may require treatment
Donovanosis	Doxycycline (100 mg PO BID)	TMP–SMX (160/800 mg PO BID) Ciprofloxacin (500 mg PO BID) Tetracycline (500 mg PO QID)	Treat until all lesions are healed (may take up to 4 wk)
Genital herpes (primary)	Acyclovir (200 mg PO 5 × daily × 10 days) Famciclovir (250 mg PO TID × 5–10 days) Valacyclovir (1 g PO BID × 5–10 days)		Recurrences require treatment only if severe

Abbreviations: HIV = human immunodeficiency virus; IM = intramuscularly; PO = orally; BID = twice a day; QID = four times a day; TID = three times a day; TMP–SMX = trimethoprim–sulfamethoxazole.

concomitant HIV infection or frequent recurrences. Acyclovir, 400 mg twice daily, famciclovir, 250 mg twice daily, or valacyclovir, 1 g once daily, each prevents 90% or more of HSV recurrences. See Chapter 185, "Herpes simplex viruses 1 and 2," for more details of treatment.

Prostatitis

Cheston B. Cunha and Burke A. Cunha

Clinical perspective

The most common types of prostatitis are acute bacterial prostatitis (ABP) and chronic bacterial prostatitis (CBP). ABP must be differentiated from urinary tract infections (UTIs) and CBP must be differentiated from non-bacterial (NBP) prostatitis and recurrent cystitis.

Usual uropathogens that cause ABP include common aerobic Gram negative bacilli (GNB) and group D enterococci (i.e., vancomycin-sensitive or resistant enterococci [VSE/VRE]). Patients with ABP are acutely ill with fever and chills. A history of urinary tract instrumentation (e.g., transrectal prostate biopsy) is not uncommon. Rectal exam reveals a tender prostate. If obtained early, blood cultures are usually positive. Urinalysis (UA) shows intense pyuria and urine culture (UC) is positive in high numbers ($>10^6$/hpf). Without urinary tract stones, microscopic hematuria argues against the diagnosis of ABP. ABP may be complicated by urosepsis or prostatic abscess. In contrast, CBP is an indolent relapsing UTI with or without perineal, genital, or low back pain usually accompanied by frequency, urgency, dysuria, or dysuria. Symptoms may resemble chronic non-bacterial prostatitis (NBP). The differential diagnosis of CBP and NBP is straightforward. In patients with CBP there is persistent (>25 WBCs/hpf) pyuria in the UA and a positive UC with abundant uropathogen (i.e., not *S. aureus* or coagulase negative staphylococci [CoNS]). The prostate exam in CBP is that of an often enlarged, relatively non-tender, prostate.

Differential diagnosis

Classically, a microbiologic diagnosis of CBP is made using the Stamey and Meares protocol to culture expressed prostatic secretions. Most patients with CBP do not have expressed prostatic secretions data, and the diagnosis of CBP is confirmed indirectly as described by UA and UC. Interestingly, pyuria ranges from moderate to heavy and UC shows $>10^6$/hpf uropathogens (not *S. aureus* or CoNS). A practical way to differentiate a positive UA/UC of cystitis from CBP is by the presence or absence of mucus threads in the UA. Unless there is an another explanation for these in the UA, mucus threads are indicative of CBP.

Antimicrobial therapy

CBP patients are usually referred to infectious diseases physicians for antibiotic treatment of persistent/relapsing infection. Repeated treatment failures are most often due to suboptimal (selection and duration) antibiotic therapy for CBP. Antibiotic selection is commonly based entirely on UC susceptibility data without taking into account pharmacokinetic (PK) considerations that determine optimal prostate penetration. Antibiotic susceptibilities are based on peak serum levels (PSL) and a serum pH of 7.4. However, the prostate is highly lipid in nature, and the patient with CBP typically has a prostate pH of 8.4. Ionization

TABLE 63.1 **THE DIFFERENTIAL DIAGNOSIS OF PROSTATITIS**

	Urinalysis				EPS		
	WBCs (pyuria intensity)	Mucus threads	Urine culture	Prostatic pH	WBC (pyuria intensity)	Culture	Uropathogen bacteremia
Acute uncomplicated cystitis (AUC)	+++	-	+++	pH = 6.4	NA	NA	+[a]
Acute bacterial prostatitis (ABP)	+++	-	+++	pH = 8.3	NA	NA	+[b]
Chronic bacterial prostatitis (CBP)	+++	+	+++	pH = 5.1	+++	+++	-
Chronic non-bacterial prostatitis (NBP)	-	-	-	pH = 6.5	-	-	-

EPS, expressed prostatic secretions; NA, not applicable.
[a] Only in compromised hosts with impaired B-cell function (e.g., diabetes mellitus, systemic lupus erythematosus, chronic lymphocytic leukemia, multiple myeloma).
[b] Including cases with prostatic abscess.

potential (pKa) is also a key determinant of prostate penetration in CBP since highly ionized drugs cannot cross lipid-laden epithelial cells to penetrate the prostate parenchyma by passive diffusion. Passive diffusion is determined by the concentration gradient from PSL to prostate and, importantly, by lipid solubility (V_d).

Optimal therapy of CBP is determined by these parameters in addition to appropriate spectrum for the cultured uropathogen. The antibiotic selected for CBP should have the PK properties that, when combined, have a high lipid solubility (high V_d) and an optimal ionization coefficient (pKa). There are relatively few antibiotics that have these characteristics. Since antibiotic therapy for CBP is prolonged (i.e., usually 1–3 months), oral therapy is the preferred approach (Tables 63.1–63.4). Depending on susceptibility, for prolonged oral antibiotic therapy of CBP the most useful clinically effective oral antibiotics include the quinolones (moxifloxacin, levofloxacin), trimethoprim (TMP; preferred to trimethoprim-sulfamethoxazole [TMP-SMX]), doxycycline, minocycline, and fosfomycin. Once therapy is started, if the UA/UC is somewhat improved after 3 days, complete therapy with the antibiotic selected. If there is no improvement in the UA/UC after 3 days, then change to an alternate antibiotic and repeat testing in 3 days until an effective agent is determined.

It is a common misconception that TMP-SMX is preferred for UTIs over TMP alone. Actually, only TMP has the PK properties

TABLE 63.2 **CLINICALLY INEFFECTIVE ORAL ANTIBIOTICS FOR CHRONIC BACTERIAL PROSTATITIS (CBP)**

	Effective uropathogen spectrum	Effective prostate penetration

pKa >8.6 = low ionization → good penetration
pKa <6.8 = high ionization → poor penetration

Abbreviations; GNB = gram-negative bacilli, MDR = multidrug resistant, TMP = trimethoprim, VRE = vancomycin-resistant enterococci, VSE = vancomycin-sensitive enterococci.

to penetrate the minimally inflamed prostate in CBP; SMX is not synergistic with TMP and prostate levels. TMP-SMX may be used, but TMP alone is preferable. Another common misconception concerns quinolone therapy of CBP. First, quinolones have the requisite PK characteristics to concentrate in the noninflamed or subacutely inflamed prostate of CBP. Second, with the exception of moxifloxacin, quinolones penetrate well into urine to effectively treat UTI (e.g., AUC due to susceptible organisms). It is not commonly appreciated that moxifloxacin not only penetrates the noninflamed prostate (e.g., providing prophylaxis for transrectal biopsy well), but also results in higher prostate levels than levofloxacin with the usual doses (e.g., moxifloxacin 400 mg [PO] q24h vs. levofloxacin 500 mg [PO] q24h).

Similarly, minocycline is not usually considered as an antibiotic for UTIs. However, if the uropathogen is susceptible, minocycline penetrates the minimally inflamed prostate even better than doxycycline using equivalent doses (i.e., 200 mg [PO] loading dose, then 100 mg [PO] q12h of either doxycycline or minocycline).

If, after initial improvement, the infection of CBP cannot be eradicated after 1 to 3 months of optimal therapy, the physician should suspect a "protected focus" of infection not usually curable using antibiotic therapy alone. In such cases, transrectal ultrasound should be done to rule out small prostatic abscesses, small prostatic calculi, or prostatic calcifications. In these situations a transurethral resection of the prostate (TURP) is usually necessary for cure in addition to carefully selected prolonged antibiotic therapy.

Pelvic inflammatory disease

William J. Ledger

Introduction

The current emphasis upon evidence-based medicine has poorly served our approach to pelvic inflammatory disease (PID). On paper, the goal of determining the best therapeutic strategy by prospective randomized double-blind studies is laudable, but it makes the assumption that patients with similar risk factors can be grouped into large study groups for such endeavors. It is increasingly apparent that this has not been the case.

PID is a classification that attempts to encompass too wide a range of clinical syndromes. It includes seriously ill women with a tubo-ovarian abscess, who require hospitalization, intravenous antibiotics, and sometimes operative intervention for a cure. In contrast, most women with PID either are asymptomatic or have such mild symptoms that they do not seek medical care. To address these concerns, the International Infectious Disease Society for Obstetrics-Gynecology (I-IDSOG-USA) suggested the term "upper genital tract disease" (UGTI) be used with the designation of the etiologic agent. In addition, the UGTI can be placed in stages, depending upon the clinical severity of the infection.

Epidemiology studies have added to the confusion about risk factors for PID. For the past two decades, study after study has shown bacterial vaginosis (BV) and douching as risk factors for the development of PID, but in separate prospective studies, on BV and douching, no increased risk was seen.

In addition, epidemiologic studies that suffer from inaccurate reporting of condom use and imperfect diagnosis of sexually transmitted disease (STD) infection have been used to bolster the faith-based emphasis upon abstinence over condoms to prevent infection.

Microbiology

The diversity of the clinical picture of PID is matched by the variety of microbiologic findings. There are infections in which a single pathogen dominates, such as *Neisseria gonorrheae*, *Chlamydia trachomatis*, and the group A *Streptococcus*. In contrast, most infections are polymicrobial with aerobes, *Mycoplasma hominis*, *Ureaplasma urealyticum*, or anaerobes involved. Gram-negative anaerobes are particularly important in those women who develop a tubo-ovarian abscess.

Clinical diagnosis

The clinical diagnosis of PID remains a work in progress. More sensitive and more specific invasive techniques to diagnose PID, including laparoscopy, endometrial biopsy, and needle culdocentesis, have been confined to research studies and are not used routinely by clinicians. There is a dependence upon clinical findings, which are variable. In some women, the diagnosis is obvious. This is particularly true in patients requiring care in urban emergency departments. When *N. gonorrheae* is one of the pathogens, the patient usually has severe lower abdominal discomfort, excruciating pain on pelvic examination, and an elevated temperature. This is what a clinician expects with a bacterial infection. Patients seen in the early stages of a gonococcal

infection, however, may present with minimal symptoms, including a new discharge, abnormal bleeding, or urinary urgency and frequency. Another group with an obvious diagnosis are those women with a pelvic abscess. These patients are usually febrile, have tender pelvic masses detected on pelvic examination and confirmed by imaging study such as a pelvic ultrasound. In contrast, women infected with *C. trachomatis* with PID have minimal or no symptoms, and are usually afebrile without an elevated white blood cell count. Many do not seek medical care. Because of this, I share the concerns of the Centers for Disease Control and Prevention (CDC) about the validity of the minimal criteria for physician diagnosis. These criteria—lower abdominal tenderness, adnexal tenderness, and cervical motion tenderness—exclude more women who do not have PID, but they also reduce the number of women with PID who are identified.

There are other signs of early infection that should be called into play by clinicians. Suspect a pelvic infection in a young sexually active woman who has either a new sexual partner or a promiscuous male partner who does not use condoms. Consider this diagnosis whenever these women complain of urgency and frequency of urination, whose urination culture shows no significant growth of bacteria, irregular vaginal bleeding with no obvious cause found on pelvic examination or, most commonly, a new vaginal discharge.

Another problem is that more relaxed physician standards that increase the likelihood of a diagnosis of PID are of no value if the patients do not present for care. The current reality in the United States is that many of these women with few or no symptoms do not consider themselves sick enough to seek medical care. We need a new direction in patient care. Women need to be educated and made aware of the risks of infection if exposed to a new male partner who does not use a condom. They also should be made aware of the subtle signs of pelvic infection and to seek medical care. One possible future strategy will be to have these women test themselves with a vaginal swab that will be polymerase chain reaction (PCR) tested for the presence of *C. trachomatis*. Studies indicate that this would be a feasible strategy.

Treatment

There are no prospective studies available with the statistical power to dictate absolute criteria to determine hospital admission or the best choice of antibiotics to prevent long-term morbidity. One study to compare inpatient versus outpatient therapy had 78.1% of the patients with well-established infections, with symptoms for more than 3 days, before treatment was begun. Well-established infections are not as responsive to antibiotic therapy. In addition, the current clinical reality of care is that treatment regimens have to be initiated before culture or PCR studies identify the pathogens present. Because of this, initial regimens should include antibiotics effective against *N. gonorrheae, C. trachomatis*, and gram-negative anaerobes. Changes in initial choices can be made if bacterial identification suggests that other agents should be used.

In Sexually Transmitted Diseases Treatment Guidelines, 2010, the CDC provide the following options: parenteral treatment (Box 64.1) and oral treatment (Box 64.2). Patients who fail to respond

BOX 64.1

Parenteral treatment

Recommended parenteral regimen A
Cefotetan 2 g IV every 12 hours
OR
Cefoxitin 2 g IV every 6 hours
PLUS
Doxycycline 100 mg orally or IV every 12 hours
Parenteral treatment can be discontinued 24 hours after a patient improves. Clinical oral therapy with doxycycline 100 mg twice a day to complete 14 days of therapy.

Recommended parenteral regimen B
Clindamycin 900 mg IV every 8 hours
PLUS
Gentamicin loading dose IV or IM (2 mg/kg of body weight), followed by a maintenance dose (1.5 mg/kg) every 8 hours. Single daily dosing (3–5 mg/kg) may be substituted.
Parenteral treatment can be discontinued 24 hours after a patient improves. Oral therapy should then be given to complete 14 days of therapy, either clindamycin 450 mg four times a day or doxycycline 100 mg twice a day.
Alternative parenteral regimen
Ampicillin–sulbactam 3 g IV every 6 hours
PLUS
Doxycycline 100 mg orally or IV every 12 hours

BOX 64.2

Oral treatment

Recommended oral regimen
Ceftriaxone 250 mg IM in a single dose
PLUS
Doxycycline 100 mg orally twice a day for 14 days

WITH OR WITHOUT
Metronidazole 500 mg orally twice a day for 14 days
OR
Cefoxitin 2 g IM in a single dose and probenecid, 1 g orally administered concurrently in a single dose
PLUS
Doxycycline 100 mg orally twice a day for 14 days

WITH OR WITHOUT
Metronidazole 500 mg orally twice a day for 14 days
OR
Other parenteral third-generation cephalosporin (e.g., ceftizoxime or cefotaxime)
PLUS
Doxycycline 100 mg orally twice a day for 14 days

WITH OR WITHOUT
Metronidazole 500 mg orally twice a day for 14 days

to systemic antibiotic treatment should be evaluated to see whether pelvic abscess formation has occurred. In women in whom an abscess is discovered aspiration can be done under direct laparoscopic vision or ultrasonographic-guided needle aspiration. The patients who fail to respond to this intervention are few in number, but they may need operative removal of infected tissue to achieve a cure.

Urinary tract infection

Peter Liu, Keith W. Hamilton, and Judith A. O'Donnell

Urinary tract infections (UTIs) account for a significant burden of morbidity, cost, and healthcare resource utilization in both the inpatient and outpatient setting. UTIs occur in patients of all ages, with a predilection for females throughout life and males at each end of the age spectrum. They represent approximately 8.6 million annual visits in the ambulatory setting and are a frequently diagnosed healthcare-associated infection. The term "urinary tract infection" encompasses a group of conditions that includes cystitis, pyelonephritis, and asymptomatic bacteriuria. Appropriate management of a patient with a UTI requires consideration of multiple factors, including age, sex, underlying comorbidities, pregnancy, history of prior UTIs, site of infection, anatomic aberrations, and the pathogen involved.

Determination of the location of the infection as upper versus lower tract is essential to selection of optimal therapy. *Lower urinary tract infection* is infection involving the bladder, or *cystitis*, and is characterized by dysuria, pyuria, urinary frequency, or urinary urgency. *Upper urinary tract infection*, or *pyelonephritis*, is infection involving the bladder and kidney that classically presents with fever and flank pain, with or without the symptoms of lower tract infection.

Differentiating uncomplicated from complicated UTI is also critical to developing an appropriate treatment strategy. An uncomplicated UTI is an infection occurring in an otherwise healthy individual who has no functional or structural abnormalities of the kidneys, ureters, bladder, or urethra. Most adult women with cystitis fall into this category. Complicated UTIs occur in the setting of factors that predispose to persistent or relapsing infection. These factors include functional or anatomic abnormalities of the upper or lower tract (such as urinary retention from anatomic obstruction or neurogenic bladder and nephrolithiasis), the presence of an indwelling bladder catheter, or underlying conditions such as pregnancy, diabetes mellitus, or renal transplantation. Infections with unusual or multidrug-resistant bacteria are often considered complicated. UTIs in adult men are uncommon without complicating factors (such as urinary obstruction or prostatitis), and most cases should be treated as complicated infections. These complicating factors are associated with less favorable treatment responses.

Uncomplicated lower UTIs respond well to therapy of short duration of 3 to 7 days depending on the chosen agent (see Table 65.1). Complicated infections are often associated with factors that may predispose the patient to complications or recurrence and usually require longer courses of therapy (7–14 days or more), but few studies have been performed to determine the optimal treatment courses for complicated UTIs.

Pathogenesis

The pathogenesis of most upper and lower UTIs is related to the ability of microorganisms to establish colonization in the periurethral area and to ascend into the urinary tract and cause infection. These organisms are typically derived from the gastrointestinal tract or vagina. After colonization, the ensuing events that lead to infection are not entirely understood but likely depend on virulence factors of the organism and host anatomy and immune response. Urinary catheters can facilitate both colonization and infection. They are commonly colonized by periurethral flora that migrate along the catheter surface. Interactions between

TABLE 65.1 **ANTIBIOTICS FOR UNCOMPLICATED LOWER URINARY TRACT INFECTIONS**

Drug	Dose and duration	Comments
First-line agents		
TMP-SMX	1 DS (160/800 mg) tablet BID for 3 days	First-line agent unless ≥10–20% rate of Escherichia coli resistance to TMP-SMX locally, history of antibiotic use, within past 3 months, or history of recent hospitalization FDA pregnancy category C; avoid in third trimester
Nitrofurantoin (monohydrate macrocrystals)	100 mg BID for 7 days	Consider for patients with mild to moderate symptoms, and with ≥10–20% rate of *E. coli* resistance to TMP-SMX locally, sulfa allergy, or antibiotic use other than nitrofurantoin within past 3 months FDA pregnancy category B. Alternative agent should be considered if creatinine clearance <40 given inadequate urinary concentration. Pulmonary toxicity including interstitial pneumonitis or pulmonary fibrosis has been described, in particular for patients with documented long-term use.
Fosfomycin	3 g as single dose	Consider for patients with mild to moderate symptoms, and with ≥10–20% rate of *E. coli* resistance to TMP-SMX locally, sulfa allergy, or antibiotic use other than fosfomycin within past 3 months; FDA pregnancy category B. Exhibits activity against multidrug resistant pathogens including vancomycin-resistant enterococci and extended spectrum β-lactamase (ESBL) producing gram-negative rods.
Second-line agents		
β-lactams (e.g., amoxicillin-clavulanate, cephalosporins)	3–7 days (dose depends on individual agent)	There are less efficacy data for these agents compared to data for first-line agents and fluoroquinolones
		Consider β-lactams if ≥10–20% rate of *E. coli* resistance to other agents and rates of resistance to selected β-lactams ≤20%
		Amoxicillin or ampicillin should not be used as monotherapy for empiric treatment; FDA pregnancy category B
Fluoroquinolones Ciprofloxacin Levofloxacin	400 mg BID for 3 days 750 mg/d for 3 days	Consider fluoroquinolones if ≥10–20% rate of *E. coli* resistance to TMP-SMX locally, patient allergy to other agents, and antibiotic use other than fluoroquinolones within past 3 months; FDA pregnancy category C

Antibiotic dose recommendations assume normal renal function.
Abbreviations: TMP–SMX = trimethoprim–sulfamethoxazole; DS = double strength; FDA = Food and Drug Administration.

the catheter and infecting or colonizing organisms facilitate adhesion to the catheter and production of a biofilm, which aids certain microorganisms in evading host defenses. Rarely, UTIs may occur through a hematogenous route of infection.

The majority of upper and lower UTIs are monomicrobial. *Escherichia coli* is the most common pathogen, causing 70% to 90% of all UTIs. Other members of the Enterobacteriaceae family such as *Klebsiella*, *Proteus*, and *Enterobacter* spp. are also common UTI pathogens. Among the gram-positive organisms, *Staphylococcus saprophyticus* and *Enterococcus* spp. are the most frequently identified pathogens. Other bacteria, such as *Pseudomonas* and *Serratia* can be seen more frequently in association with indwelling urinary catheters, and polymicrobial UTIs can also occur in this setting. A polymicrobial infection in the absence of a urinary catheter may suggest an enterovesical fistula or contamination during the specimen collection process. *Candida albicans* is the most common etiologic agent in fungal UTIs, but other *Candida* spp. are becoming increasingly common. Several sexually transmitted infections (STIs), including *Chlamydia trachomatis, Neisseria gonorrhoeae, Trichomonas vaginalis*, and genital herpes simplex virus infection, can cause urethritis, which mimics symptoms of UTI. Therefore, appropriate diagnostic evaluation for STIs should also be performed as part of a UTI workup in sexually active patients, especially if another pathogen is not isolated.

Lower UTI: Cystitis

Typical symptoms of lower UTIs include dysuria, urinary frequency, urgency, and, occasionally, hematuria or suprapubic pain. The presence of fever or flank pain should raise the concern for pyelonephritis. In addition to history and physical examination findings, laboratory tests are often used in the diagnosis of cystitis.

Diagnosis

The diagnosis of cystitis can be made using a combination of clinical and laboratory criteria. Some symptoms, including dysuria, urinary frequency, and hematuria, increase the likelihood of UTI.

The absence of dysuria or back pain and presence of vaginal irritation or discharge decrease the likelihood of UTI. Women with at least one symptom have at least a 35% to 50% likelihood of having cystitis. The presence of dysuria and urinary frequency combined with the absence of vaginal discharge increases the likelihood of UTI to >90%. Patients with a high pretest probability for cystitis and no complicating factors should be treated empirically without additional testing. Patients with a lower pretest probability should have diagnostic testing performed. In these patients, the diagnosis of cystitis can be evaluated using urine dipstick, microscopy, and/or culture.

In ambulatory settings, urine dipstick testing has largely replaced microscopy to diagnose UTI because it is cheaper, faster, and more convenient. Dipstick testing can detect the presence of leukocyte esterase, an enzyme released by white blood cells, and nitrites, byproducts of nitrate metabolism produced by Enterobacteriaceae. A positive test for either leukocyte esterase or nitrite has a sensitivity of 75% and specificity of 82%. Because of the limited sensitivity and specificity of the dipstick test, the dipstick may be most useful for rapid rule-out of UTI among women with a moderate to low pretest likelihood of infection, such as minimally symptomatic patients or those with both bladder and vaginal symptoms. Urine microscopy has a higher sensitivity and specificity compared to the dipstick test. Hemocytometer (counting chamber) measurement of urine leukocytes in an unspun specimen provides the most accurate assessment of pyuria, which is defined as a leukocyte count of ≥10 leukocytes/mm^3. Pyuria is present in almost all women with cystitis in the absence of severe neutropenia (ANC <500). Another method of urinalysis involves the microscopic examination of urine sediment from centrifuged samples. The accuracy of this method depends on the skill of the operator and the level of procedural standardization. The presence of bacteriuria on urine microscopy can also be used to assess the presence of UTI, but it is often difficult to interpret given the ease of specimen contamination with periurethral flora during collection, as well as the overgrowth of bacteria that may result from the improper handling of specimens. Therefore, bacteriuria alone in the absence of pyuria and compatible clinical symptoms should not be used to make the diagnosis of UTI.

Urine culture is not necessary in most otherwise healthy women with cystitis because the causative organisms and their susceptibility patterns are predictable. However, urine cultures should be obtained in patients with refractory symptoms, recurrent UTIs, suspected pyelonephritis, or complicated UTI. Urine cultures should also be obtained in patients with history of or risk factors for antibiotic-resistant pathogens, including in those patients with recent antibiotic use, recent hospitalization, or residence in a long-term care facility. Although suprapubic aspiration or straight catheterization has the best chance of minimizing contamination, midstream or "clean-catch" urine collection remains the most practical method of obtaining urine samples. Quantitative urine cultures are the gold standard for microbiologic diagnosis of UTIs. Growth, identification, and susceptibility testing of the pathogen can offer the most effective means for establishing infection and determining appropriate antimicrobial therapy. Traditionally, bacteriuria with $\geq 10^5$ colony-forming units (CFU) of bacteria per milliliter of urine has been considered diagnostic. This threshold was extrapolated from studies of pyelonephritis and asymptomatic bacteriuria in women. However, based on more recent studies, lower colony counts (10^2 to 10^4 CFU/mL) in association with signs and symptoms of cystitis have also been accepted as diagnostic. The quantitative threshold for UTIs in men remains unclear, but many authorities recommend a lower threshold of 10^3 CFU/mL.

Therapy

Treatment of uncomplicated cystitis can be accomplished with a short course of an effective antimicrobial agent. Because therapy is typically started in the absence of a culture or before culture results become available, understanding common pathogens and local susceptibility patterns is essential. Given that *E. coli* is the predominant UTI pathogen, its susceptibility patterns typically drive empiric antibiotic choices. Table 65.1 outlines general treatment recommendations for uncomplicated cystitis.

In many areas, resistance rates for nitrofurantoin, fosfomycin, and trimethoprim– sulfamethoxazole (TMP-SMX) are <10%. Therefore, these drugs have become the recommended first-line empiric agents for uncomplicated cystitis. However, the rates of resistance vary considerably by geographic region and can exceed 20% in some areas. In particular, the rapidly increasing rate of resistance of *E. coli* to TMP-SMX has raised significant concern about its empiric use for UTI. In vitro and mathematical modeling studies suggest that TMP-SMX should not be used when local resistance rates exceed 20%. Individual risk factors for resistance should also be considered before using TMP-SMX for empiric therapy. Studies have suggested that the highest risk of UTI caused by TMP-SMX-resistant *E. coli* is associated with recent TMP-SMX or other systemic antibiotic use. Other risk factors include recent hospitalization, residence in a long-term care facility, and travel outside the United States within the past 3 to 6 months.

The potential benefits of nitrofurantoin for UTI treatment includes a relatively narrow spectrum of activity, little evidence of in vitro resistance, and bactericidal activity in the urine at therapeutic doses. Nitrofurantoin has been studied primarily for lower UTIs, does not achieve high drug concentration levels in the upper urinary tract, and consequently should not be used to treat upper tract infections. In multiple studies, nitrofurantoin used for 5 days demonstrated similar clinical cure rates as TMP-SMX used for 3 days. It is generally well-tolerated, although hepatotoxicity, peripheral neuropathy, and pulmonary toxicity including interstitial pneumonitis and pulmonary fibrosis have been described, particularly in patients with documented long-term use. The US Food and Drug Administration (FDA) lists a creatinine clearance of <60 mL/min as a contraindication to the use of nitrofurantoin due to concerns for impaired excretion and inadequate urinary concentration. However, recent studies suggest that efficacy is retained for the treatment of lower UTIs with a creatinine clearance of at least 40 mL/min.

Fosfomycin is considered a first-line therapy for lower UTIs and has distinct advantages in certain clinical scenarios. Fosfomycin is administered in a convenient single 3 g dose regimen, achieves high concentration in the urinary bladder, and possesses a favorable side-effect profile with infrequent reports (2–6%) of self-limited nausea and diarrhea. Importantly, it retains in vitro activity against many

multidrug-resistant organisms, including extended-spectrum β-lactamase (ESBL)-producing organisms and vancomycin-resistant enterococci (VRE), and it can sometimes be prescribed for uncomplicated lower UTIs caused by these organisms, thus avoiding intravenous therapy. Several clinical studies have demonstrated high rates of efficacy in lower uncomplicated UTIs, including those due to multidrug-resistant pathogens. One potential disadvantage of fosfomycin is that most microbiology laboratories do not perform routine fosfomycin susceptibility testing and require a special request to do so, and, as such, results may not be available to inform early clinical decision-making. Additionally, robust clinical data describing outcomes in recurrent or complicated infection are lacking. Nevertheless, as multidrug-resistant organisms become more prevalent in the community, fosfomycin will likely have a more prominent role in both empiric and definitive therapy.

The fluoroquinolones have often been used as first-line empiric therapy for cystitis. Currently fluoroquinolone resistance rates in *E. coli* are highly variable depending on geography. In some areas, resistance rates to fluoroquinolones can exceed 20%. Even when resistance rates are <10%, fluoroquinolone use can select for development of multidrug-resistant organisms. Therefore, fluoroquinolones should be reserved as alternative therapy and prescribed for patients who do not tolerate or are not eligible to receive recommended first-line agents. Moxifloxacin and gemifloxacin achieve poor levels in the urine and are not approved for treatment of UTI. Levofloxacin or ciprofloxacin are the fluoroquinolones recommended for treatment of genitourinary tract infections.

Selected β-lactam agents may also be appropriate therapeutic options for uncomplicated cystitis as resistance rates for these agents are <10% in many geographic regions. As compared to TMP-SMX and the fluoroquinolones, there are far fewer clinical outcome data with these agents. Historically, β-lactam agents have been noted to be less effective than TMP-SMX and to potentially cause more disruption of the vaginal flora, leading to vaginal yeast infection. However, in the current climate of increasing resistance to TMP-SMX and fluoroquinolones, the β-lactam agents have once again become a reasonable therapeutic option in some settings. In most regions of the United States, rates of resistance of *E. coli* to amoxicillin exceed 20%, making amoxicillin a poor choice for empiric therapy. The β-lactams that may be considered as UTI treatment based on local susceptibility patterns include amoxicillin-clavulanate, second-generation cephalosporins (cefaclor), third-generation cephalosporins (cefdinir and cefpodoxime), and, in some instances, first-generation cephalosporins (cephalexin and cefadroxil). Broad-spectrum β-lactam agents should be prescribed with caution as their use has also been associated with development of drug resistance.

Patients with cystitis who may not be appropriate candidates for more traditional empiric treatment recommendations include those at higher risk for acquisition of multidrug-resistant pathogens. Patients with recent antibiotic exposure, infection with multidrug-resistant bacteria, hospitalization, or residence in a long-term care facility all carry a higher risk of resistance to first-line agents. Urine should be submitted for culture and susceptibility in such patients, and, if empiric therapy is desired prior to culture results, it should be based on prior culture results and recent antibiotic use.

Complicated UTI

A UTI is considered complicated if any of the criteria discussed in the introduction to this chapter are present. Symptoms of complicated UTI can be similar to those associated with uncomplicated cystitis, including dysuria, hematuria, urinary frequency, and suprapubic pain. However, symptoms can be atypical, especially in those patients with functional or structural abnormalities or with a urinary catheter. The management of candiduria and UTIs occurring in catheterized patients is discussed in detail in Chapter 106, "Infections associated with urinary catheters." Urine culture and sensitivity should be performed for all patients with complicated UTI. Treatment duration for complicated UTIs, including UTIs in men, is usually 7 to 14 days, depending on the choice of antibacterial therapy, due to the potential for higher rates of treatment failure and relapse in complicated infections treated for short courses.

The issues regarding antibiotic choice in light of increasing rates of resistance are similar to those discussed previously for uncomplicated UTIs; however, consideration should be given to the potentially higher risk of resistant pathogens in many populations with complicated UTIs. Therefore, TMP-SMX, nitrofurantoin, and fosfomycin are generally not recommended for the empiric treatment of complicated infections. Nitrofurantoin and fosfomycin, which both poorly penetrate into tissue of the upper urinary tract, should be avoided in situations where there is diagnostic uncertainty of upper versus lower UTI.

Because of the increased rates of resistance, likelihood of upper tract infection, and the limitations of first-line agents in complicated UTI, empiric therapy should be initiated with a broad-spectrum antibiotic such as a fluoroquinolone. Parenteral therapy may be necessary, especially in hospitalized patients or those who cannot tolerate oral medications. In these cases, reasonable choices include third- or fourth-generation cephalosporins or the fluoroquinolones. Choice of empiric therapy should be based on local susceptibility patterns and prior culture data. Therapy should be modified as needed or narrowed where possible once the culture and susceptibility results are available.

Upper UTI: Pyelonephritis

Pyelonephritis is defined as an infection of the urinary tract that ascends to involve the renal pelvis. The organisms that cause pyelonephritis are similar to those that cause cystitis. Characteristic symptoms and signs of pyelonephritis include fever, nausea, vomiting, flank pain, and costovertebral angle tenderness. Symptoms of cystitis may or may not be present. However, pyelonephritis may also mimic appendicitis, cholecystitis, and pelvic inflammatory disease. Therefore, a careful history and physical exam are essential, and a pelvic examination or dedicated imaging studies should be considered in patients who present with atypical symptoms.

As is true with other types of UTI, pyuria is almost always present. Urine dipstick tests for leukocyte esterase and nitrites can be used to screen for the presence or absence of infection, but they cannot differentiate upper from lower tract diseases. Furthermore, they are generally not sensitive enough to rule out pyelonephritis; therefore, urinalysis

should be performed. Urine culture and sensitivity should be performed in all cases of suspected pyelonephritis and therapy adjusted based on susceptibility results. The accepted diagnostic threshold for significant bacteriuria in pyelonephritis is $\geq 10^5$ CFU/mL, although colony counts as low as 10^3 CFU/mL of urine may be seen. Blood cultures should be performed in patients with fever or severe disease. Pregnancy should be ruled out in all women of childbearing age because pregnancy is a predisposing condition for pyelonephritis, and many antibiotics including fluoroquinolones, are contraindicated during pregnancy.

Many patients with uncomplicated pyelonephritis may be treated as outpatients with oral antibiotics. Indications for hospitalization include severe nausea or vomiting, signs of sepsis or severe disease (e.g., high fevers, tachycardia, and hypotension), diagnostic uncertainty, or concerns regarding ability to adhere to treatment plans or follow-up. If the patient is deemed an appropriate candidate for outpatient oral therapy, fluoroquinolones are generally recommended as the first-line agents given the variable and rising rates of resistance to TMP-SMX (Table 65.2). TMP-SMX should be used in

TABLE 65.2 **ANTIBIOTICS FOR UNCOMPLICATED PYELONEPHRITIS**

Drug	Dose and duration	Comments
Outpatient therapy[a]		
Fluoroquinolones		First line agents for treatment of pyelonephritis in the outpatient setting except when contraindicated.
Ciprofloxacin	500 mg BID for 7 days	Must follow up in 48-72 hours to assess response.
Levofloxacin	750 mg/d for 5 days	FDA pregnancy category C
TMP-SMX	1 DS (160/800 mg) tablet BID for 14 days	Use TMP-SMX only if causative organism is shown to be susceptible. If C/S not available, add single dose of parenteral agent (Ceftriaxone or aminoglycoside) pending susceptibility data. FDA pregnancy category C Avoid during third trimester
Other Agents	14 days (dose depends on individual agent)	There are less data for these agents in empiric treatment of pyelonephritis If an agent other than a fluoroquinolone is used for empiric therapy in absence of C/S, add single dose of parenteral agent (ceftriaxone or aminoglycoside) pending susceptibility data Amoxicillin and ampicillin should not be used for empiric treatment of pyelonephritis Nitrofurantoin and fosfomycin should not be used for treatment of pyelonephritis even if isolate is susceptible to these agents
Inpatient therapy[b,c]		
Fluoroquinolones		FDA pregnancy category C
Ciprofloxacin	400 mg IV BID	
Levofloxacin	250–500 mg/d IV daily	
Cephalosporins		FDA pregnancy category B
Ceftriaxone	1 g IV daily	
Cefotaxime	1 g IV q8h	
Cefepime	1 g IV q8h	
Carbapenems		FDA pregnancy category B
Meropenem	1 g IV q8h	FDA pregnancy category C
Doripenem	500 mg IV q8h	
Ertapenem	1 g daily	
Imipenem	500 mg IV q6h	
Aztreonam	1 g q8h	FDA pregnancy category B
Aminoglycosides		FDA pregnancy category D
Gentamicin	5 mg/kg IV daily	
Tobramycin	5 mg/kg IV daily	

[a] If enterococcus suspected, add amoxicillin to regimen.
[b] If enterococcus suspected, add ampicillin to regimen.
[c] Empiric use of broader spectrum agents may be necessary in severe disease or if risk factors for antibiotic-resistant bacteria are present. Streamline therapy based on culture and sensitivity data. Patient can be switched to oral agents once patient responds and if oral option available.
Antibiotic dose recommendations assume normal renal function.
Abbreviations: TMP–SMX = trimethoprim–sulfamethoxazole; DS = double strength; C/S = culture and sensitivity; FDA = Food and Drug Administration.

pyelonephritis only if culture and sensitivity results are available and if the infecting organism is known to be susceptible. There are less data for the use of oral β-lactams for the treatment of pyelonephritis, and these agents may be inferior to fluoroquinolones. If an alternative agent other than a fluoroquinolone is used for outpatient treatment or if fluoroquinolone resistance exceeds 10%, a single dose of a long-acting parenteral agent, such as ceftriaxone or an aminoglycoside, should be administered pending culture and susceptibility. If a urine Gram stain reveals gram-positive cocci (suggesting a possible enterococcal infection), amoxicillin should be added to the regimen.

Antibiotics should be narrowed or adjusted according to culture and susceptibility results. For treatment of mild cases of pyelonephritis in the outpatient setting, the duration of therapy should be 5 to 7 days if a fluoroquinolone is used. If an alternative agent is used, a 10- to 14-day duration of therapy is generally recommended. Patients usually improve within the first 48 to 72 hours of therapy, and it is important for appropriate follow-up within this period to review clinical response and culture results. In the absence of improvement, the patient should be admitted to the hospital for alternative treatment regimens and further diagnostic evaluation.

Patients requiring hospitalization for management of pyelonephritis should be treated initially with parenteral agents (Table 65.2). Local susceptibilities should drive empiric treatment decisions. Reasonable choices include fluoroquinolones, extended-spectrum cephalosporins (third- and fourth-generation), extended-spectrum penicillins (ampicillin-sulbactam or piperacillin-tazobactam), or aminoglycosides. If gram-positive cocci are observed on Gram stain, the addition of ampicillin or use of ampicillin-sulbactam is recommended. Consultation with an infectious diseases expert should be considered in cases of treatment failure or in patients with risk for or history of multidrug-resistant pathogens.

Antibiotic coverage should be narrowed if possible when culture and sensitivity results are available. A 14-day course of therapy is generally recommended for hospitalized patients. If the patient has not improved within the first 72 hours of therapy, dedicated imaging such as renal ultrasound or CT is suggested to evaluate for perinephric abscess, nephrolithiasis, obstruction, or other complication. (See Chapter 67, "Focal renal infections and papillary necrosis.")

Asymptomatic bacteriuria

Asymptomatic bacteriuria is defined as the presence of significant bacteriuria ($\geq 10^5$ CFU/mL) in the absence of signs or symptoms of UTI. The diagnosis of asymptomatic bacteriuria in women is made when *two* separate clean-catch, voided urine specimens demonstrate the same organism. Only *one* sample is required to make the diagnosis in males. In men and women with chronic catheterization, one sample with bacteriuria $\geq 10^2$ CFU/mL is considered diagnostic. Asymptomatic bacteriuria is common in certain populations. Reported prevalence rates range from 1.0% to 5.0% among healthy premenopausal women, 1.9% to 9.5% among pregnant women, and up to 16% of elderly ambulatory women. The prevalence of asymptomatic bacteriuria is even greater among persons in long-term care facilities and in patients with spinal cord injuries. The rate of asymptomatic bacteriuria approaches 100% in patients with chronic urinary catheterization.

Treatment of asymptomatic bacteriuria in most patient populations has no clinical benefit. The only patients who should be screened and treated for asymptomatic bacteriuria are pregnant women and patients undergoing an invasive urologic procedure with a reasonable risk of mucosal bleeding. Pregnant women with asymptomatic bacteriuria have an increased risk of pyelonephritis and are more likely to have premature delivery and low-birth-weight infants. Patients with asymptomatic bacteriuria undergoing urologic procedures with mucosal bleeding, such as transurethral prostate resection, have a higher rate of bacteremia and sepsis. Pregnant women ideally should be screened between weeks 12 and 16 of gestation, but may be screened later if the first prenatal visit occurs after 16 weeks.

Bacteriuria in pregnancy should be treated for 3 to 7 days. Choice of antibiotic should depend on susceptibility results of the urine culture. Fluoroquinolones are contraindicated in pregnancy. Reasonable choices for treatment in this setting include an oral cephalosporin, TMP-SMX, trimethoprim alone, or nitrofurantoin. TMP-SMX should be avoided in the final weeks of the third trimester. Nitrofurantoin should similarly be avoided during the third trimester. Pregnant women should be screened periodically for recurrent bacteriuria following treatment, but the proper screening interval is not known; many obstetricians screen monthly.

Patients undergoing urologic procedures should be screened for asymptomatic bacteriuria prior to the procedure, and treatment should be tailored based on the susceptibility results if the urine culture is positive. Antibiotics should be discontinued at the completion of the procedure unless an indwelling catheter is left in place.

Recurrent cystitis

Recurrent cystitis is defined as two episodes of cystitis over 6 months or three or more infections in a year. Recurrent cystitis can be categorized into two types: relapse and reinfection, although the distinction between the two can be difficult. A recurrent infection is considered a *relapse* if it occurs within 2 weeks of finishing treatment for the previous infection and the pathogen is the same strain. *Reinfection* is defined as recurrent infection with a different strain of bacteria or, if the infection is with the same strain, it occurs >2 weeks after finishing the last treatment course. Relapsing infections can result from inadequate length of therapy, nephrolithiasis, urinary tract obstruction, structural abnormality, perinephric abscess, and chronic bacterial prostatitis. If relapse occurs despite appropriate treatment, further investigation for these syndromes should be undertaken.

Reinfection, which represents a majority of cases of recurrent UTIs, is often multifactorial. Some associated risk factors for women with reinfection include new sex partners, spermicide use, urinary retention, and structural abnormality. Treatment strategies are aimed at modifying these risk factors.

When appropriate, behavioral modification should be the first strategy in managing women with recurrent UTI. Although postcoital voiding in women has not been studied in controlled trials, it is often recommended based on biologic plausibility and anecdotal evidence. Given the minimal costs and side effects, it is reasonable to suggest postcoital voiding to women with postcoital UTIs. Cranberry juice has long been suggested as a preventative measure for UTIs, and a natural compound present in cranberry juice has been shown to inhibit the binding of uropathogens to uroepithelial cells. No strong evidence exists on the clinical efficacy of cranberry juice and cranberry products to prevent recurrent cystitis; however, many patients and healthcare providers have anecdotal success with this preventative treatment. In women who use spermicides, alternative methods of contraception can be considered as a modification strategy to prevent recurrent UTI. Methenamine hippurate, which possesses antibacterial properties and an ability to effectively acidify urine, has also been anecdotally used with varying degrees of success. There is limited clinical data on its efficacy; however, one Cochrane review concluded that methenamine hippurate is safe and effective for short-term prevention of recurrent UTIs in patients without structural or functional urinary tract aberrations.

Loss of estrogen with menopause leads to elevated vaginal pH, loss of lactobacilli in the vagina, and uropathogen-dominant vaginal flora. In postmenopausal women with recurrent UTIs, estrogen replacement therapy has been attempted, and limited clinical data suggest that topical estrogens can help prevent recurrent UTI when compared with placebo. Topical vaginal estrogen therapy offers a reasonable management strategy in postmenopausal women when behavioral interventions fail.

In patients where reinfection affects quality of life despite more conservative interventions, various antibiotic strategies can be highly effective. These strategies include patient-initiated self-treatment, postcoital prophylaxis, and continuous prophylaxis. Patient-initiated self-treatment may be used with short-course regimens in patients with two or fewer episodes per year. Only patients who will reliably contact their physicians if their symptoms do not improve in 48 hours should be considered for this strategy. Alternatively, postcoital prophylaxis can be offered to patients who can temporally associate their UTI recurrences with sexual activity.

In the remainder of women with three or more UTIs per year, continuous low-dose antimicrobial prophylaxis can be considered. Continuous prophylaxis has been shown to be highly effective, although the benefits must be weighed against the expense and the risks of adverse drug reactions and development of antimicrobial resistance. Continuous prophylaxis may be given for 6 to 12 months, and a variety of agents may be used. In general, when prophylaxis is discontinued, women with recurrent UTI usually revert back to their baseline pattern of recurrent infection. If this occurs, prophylaxis can be reinitiated if the uropathogens remain susceptible. Recommended regimens for postcoital prophylaxis and continuous prophylaxis are listed in Table 65.3.

TABLE 65.3 **SUMMARY OF TREATMENT RECOMMENDATIONS FOR RECURRENT URINARY TRACT INFECTIONS**

Prophylaxis	Antimicrobial agent	Dose	Comments
Postcoital (single dose)	TMP-SMX	40 mg/200 mg (1 single-strength tablet)	Eliminates vaginal reservoir without disturbing other flora FDA pregnancy category C; may be used in pregnancy up until end of third trimester
	Nitrofurantoin (macrocrystals)	50–100 mg	FDA pregnancy category B
	Cephalexin	250 mg	Disrupts vaginal flora FDA pregnancy category B
	Ciprofloxacin	125 mg	FDA pregnancy category C; avoid in pregnancy
Continuous[a]	TMP-SMX	40 mg/200 mg (1 single-strength tablet)	Give daily or 3 times a week Eliminates vaginal reservoir without disturbing other flora Safe for years of use FDA pregnancy category C
	TMP	100 mg	See above
	Nitrofurantoin (macrocrystals)	50–100 mg	FDA pregnancy category B
	Cephalexin	125–250 mg	Disrupts vaginal flora FDA pregnancy category B
	Cefaclor	250 mg	Disrupts vaginal flora FDA pregnancy category B
	Ciprofloxacin	125 mg	FDA pregnancy category C

[a] All doses are given daily unless otherwise specified.
Antibiotic dose recommendations assume normal renal function.
Abbreviations: TMP–SMX = trimethoprim–sulfamethoxazole; FDA = Food and Drug Administration.

Candiduria

Jack D. Sobel

Since the early 1980s, the prevalence of candiduria in hospitals has increased by 200% to 300% such that in a community hospital, 5% of urine cultures may yield *Candida*, and in tertiary care centers, *Candida* accounts for almost 10% of urinary isolates, including a quarter of Foley catheter-associated infections. Most positive *Candida* urine cultures are isolated or transient findings of little significance and represent colonization of catheters rather than true infection. Although less than 10% of candidemias are the consequence of candiduria, *Candida* urinary tract infections (UTIs) have emerged as important nosocomial infections.

Candida albicans is the most common species isolated from the urine, whereas non-*albicans Candida* species account for almost half the *Candida* urine isolates. *Candida glabrata* is responsible for 25% to 35% of infections.

Predisposing factors

Candiduria is rare in the absence of predisposing factors. Most infections are associated with use of Foley catheters, internal stents, percutaneous nephrostomy tubes, and age extremes of life. Diabetic patients, especially when their diabetes is poorly controlled, are particularly at risk primarily because of increased instrumentation, urinary stasis, and obstruction secondary to autonomic neuropathy. Concomitant bacteriuria is common and bacterial adherence to bladder epithelium may play a key role in the pathogenesis of *Candida* infection. Antimicrobials similarly play a critical role in that candiduria almost always emerges during or immediately after antibiotic therapy. Antibiotics, especially broad-spectrum agents, act by suppressing protective indigenous bacterial flora in the gastrointestinal (GI) tract and lower genital tract, facilitating *Candida* colonization of these sites with ready access to the urinary tract. Nosocomial candiduria is more common in intensive care unit (ICU)-based catheterized women with concomitant contributory vaginal *Candida* colonization. The pool of critically ill, immunosuppressed medical, and surgical patients has increased, and this increase, together with improved technology, provides an expanded population at risk of developing *Candida* infection.

Most lower UTIs are caused by retrograde infection from an indwelling catheter or genital or perineal colonization. Biofilm formation contributes to *Candida* persistence in the presence of catheters and stents. The upper urinary tract is uncommonly involved during ascending retrograde infection and then only in the presence of urinary obstruction, reflux, or diabetes. Renal candidiasis is usually the consequence of secondary hematogenous seeding of the renal parenchyma; *Candida* species have a unique tropism for the kidney and result in anterograde candiduria.

Clinical aspects

Most adult patients with candiduria are asymptomatic, especially those with indwelling bladder catheters. Only 4% to 14% of patients with candiduria have symptoms of urinary infection. Clinical manifestations depend on the site of infection. *Candida* cystitis may present with frequency, dysuria, urgency, hematuria, and

pyuria. Ascending infection resulting in *Candida* pyelonephritis is characterized by fever, leukocytosis, and rigors and is indistinguishable from bacterial pyelonephritis. Excretory urography may reveal ureteropelvic fungus balls or papillary necrosis. Renal candidiasis is difficult to diagnose when secondary to hematogenous spread and presents with fever and other signs of sepsis. By the time renal candidiasis is considered, blood cultures are usually no longer positive; however, unexplained deteriorating renal function is often evident.

In contrast to adult patients, candiduria in low-birth-weight infants, especially extreme low weight (<1000 g), is synonymous with disseminated *Candida* infection and is associated with high mortality. This patient population is not further considered in this review.

Because isolation of *Candida* from a urine specimen may represent contamination, colonization, or superficial or deep infection of the lower or upper urinary tract, diagnosis is difficult and management depends on the site of infection. Contamination of the sample is particularly common in women with vulvovaginal colonization and may be excluded by repeating urine culture with special attention to proper collection techniques. Differentiating infection from colonization may be extremely difficult if not impossible in some patients, especially if they are catheterized. Accordingly, I often rely on accompanying clinical features to determine the significance of candiduria; unfortunately these are often nonspecific in critically ill patients, and fever and leukocytosis may have several other sources.

Quantitative urine colony counts have some value in separating infection from colonization but only in the absence of a Foley catheter. The latter negates any diagnostic value of quantitative cultures. In noncatheterized patients, counts greater than 10^4 colony-forming units (CFU)/mL are usually associated with infection. It is rare for patients with invasive disease of the kidney, pelvis, or bladder to have 10^3 CFU/mL or less. No definitive cutoffs for defining candiduria have been substantiated. Most patients with urinary tract *Candida* infection have pyuria, but the value of this finding is similarly diminished in the presence of a catheter or concomitant bacteriuria and in neutropenic subjects. Serologic tests of *Candida* tissue invasion are not available. Treatment is preceded by attempts to localize the source or anatomic level of infection. Unfortunately, no reliable tests to differentiate renal candidiasis from the more frequent lower tract infections exist. The extremely rare finding of *Candida* microorganisms and pseudohyphae enmeshed in renal tubular casts is useful when present. Ultrasonography and computed tomography (CT) scans have a useful but limited role in localization. A 5-day bladder irrigation with amphotericin B may be of value in localizing the source of candiduria in catheterized subjects in that post-irrigation persistent candiduria originates from above the bladder, thus identifying patients with need for further studies. Unfortunately, the lengthy nature of this diagnostic test excludes its utility in most febrile, critically ill subjects.

Prognosis

Prognosis depends on the anatomic site of *Candida* infection and the presence of urinary drainage tubes, obstruction, and concomitant renal failure. A high mortality rate of 20% is found in candiduria patients, which is more a reflection of the multiple serious illnesses found in these patients than the consequence of candiduria per se.

Management

More important than the knowledge of antifungal agents for treating candiduria is understanding the indications and rational basis for initiating treatment. Regrettably, despite the availability of a variety of potent antifungal agents, data from controlled studies are scant.

Asymptomatic candiduria

No antifungal therapy is required for asymptomatic candiduria in catheterized adult patients, a common condition, because candiduria often is transient only, and even if persistent rarely results in serious morbidity. Moreover, relapse of candiduria following therapy is common if the patient remains catheterized: In catheterized patients, removal of the catheter and discontinuation of antibiotics often results in cessation of candiduria (40%). Change of catheter results in elimination of candiduria in only approximately 20% of patients.

In contrast, persistent candiduria in noncatheterized patients should be investigated because the likelihood of obstruction and stasis is high. Persistent asymptomatic candiduria in catheterized, low-birth-weight infants, as well as in afebrile neutropenic patients, requires anti-fungal therapy and investigation to exclude the possibility of renal or systemic involvement. Patients with asymptomatic candiduria in whom urologic instrumentation or surgery is planned should have candiduria eliminated or suppressed before and during the procedure to prevent precipitating invasive candidiasis and candidemia. Successful elimination can be achieved by amphotericin B irrigation using a concentration of 50 μg/dL of sterile water for 7 days or with systemic therapy using amphotericin B, flucytosine, or fluconazole. Fluconazole, 200 to 400 mg/day, oral therapy should continue for at least 14 days to maximize cure rates. The management of asymptomatic candiduria in the renal transplant patient is perplexing. Many recipients are diabetic, are receiving perioperative antibiotics and immunosuppressive agents, and have Foley catheters and temporary ureterocystic stents. The risk of ascending infection is high given the above and frequent reflux. Fortunately, occurrence of symptomatic renal infection and candidemia is rare. A large study by Safdar et al. found that treatment and eradication of candiduria did not enhance graft on patient survival.

Candida cystitis

Symptomatic cystitis requires treatment with either amphotericin B bladder irrigation (50 μg/dL) or systemic therapy, once again using intravenous (IV) amphotericin B, flucytosine, or oral fluconazole.

Oral azole agents ketoconazole, itraconazole, and voriconazole are poorly excreted in the urine, and there is limited and suboptimal clinical experience only. In contrast, fluconazole is water soluble, well absorbed orally with more than 80% excreted unchanged in the urine, achieving high urine concentrations, and is highly effective. The optimal dose and duration of fluconazole therapy has yet to be determined, but usually 200 to 400 mg/day is prescribed for 7 to 14 days. Similarly, the duration of therapeutic bladder irrigation with amphotericin B is arbitrary, lasting 5 to 7 days. Amphotericin B bladder irrigation is extremely labor intensive and has largely fallen out of favor, even in symptomatic patients, being replaced by oral fluconazole except in the presence of azole-resistant *Candida* strains. Flucytosine is also excreted unchanged in high concentrations in the urine and is highly active against most *Candida* species, including *C. glabrata*; nevertheless, because resistance develops rapidly to flucytosine when used alone, this agent is rarely used especially because its use is precluded in renal insufficiency.

Single-dose IV amphotericin B, 0.3 mg/kg, has also been shown to be highly efficacious in the treatment of lower urinary tract candidiasis, achieving therapeutic urine concentrations for considerable time after the single administration. More prolonged systemic IV amphotericin B (7 to 10 days) and at conventional dosage of 0.5 to 0.7 mg/kg/day is preferable for resistant fungal species.

Ascending pyelonephritis and candida urosepsis

Invasive upper UTI requires systemic antifungal therapy as well as immediate investigation and visualization of the urinary drainage system to exclude obstruction, papillary necrosis, and fungus ball formation. Previously favored therapy consisted of IV amphotericin B, 0.5 to 0.7 mg/ kg/day, for a variable duration depending on severity of infection, presence of candidemia, and response to therapy, in general 1 to 2 g total dose. However, systemic therapy with fluconazole, 5 to 10 mg/kg/day (IV or oral) for at least 2 weeks offers an effective and less toxic alternative regimen. Moreover, although the echinocandin class of antifungals (caspofungin, micafungin, and anidulafungin) achieves low urinary concentrations, they are effective for kidney parenchymal infections and particularly useful for *Candida* species resistant to azoles. Infection refractory to medical management should be treated surgically with drainage, or in cases of a nonviable kidney, nephrectomy may be indicated. An obstructed kidney with hydronephrosis requires a percutaneous nephrostomy. In some cases, nephrostomy drainage must be combined with local amphotericin B irrigation (50 μg/dL) or fluconazole, particularly with end-stage renal disease and low urinary levels of antifungal agents.

Renal and disseminated candidiasis

Management of renal candidiasis secondary to hematogenous spread is that of systemic candidiasis, including IV amphotericin B, 0.6 to 1.0 mg/kg/day, or IV fluconazole, 5 to 10 mg/ kg/ day. IV voriconazole, 4 mg/ kg twice a day, or any of the echinocandins could be used in preference to amphotericin B. Dosage modifications of fluconazole but not the echinocandins are necessary in the presence of moderate to severe azotemia. Prognosis depends on correction of underlying factors, that is, resolution of neutropenia, removal of responsible intravascular catheters, and susceptibility of the *Candida* species, but most importantly the nature and prognosis of the underlying disease per se. Systemic candidiasis involving metastatic sites of infection requires prolonged therapy for approximately 4 to 6 weeks.

Focal renal infections and papillary necrosis

Ann F. Fisher and Louise M. Dembry

Focal infections of the kidney can be divided into intrarenal and perirenal pathology (Box 67.1). The classification of intrarenal abscess encompasses renal cortical abscess and renal corticomedullary abscess; the latter includes acute focal bacterial nephritis (AFBN), acute multifocal bacterial nephritis, and xanthogranulomatous pyelonephritis (XGP). Perirenal abscesses are found in the perinephric fascia external to the capsule of the kidney, generally occurring from extension of an intrarenal abscess. Papillary necrosis is a clinicopathologic syndrome that develops during the course of a variety of syndromes, including pyelonephritis; it affects the renal medullary vasculature and leads to ischemic necrosis of the renal medulla. The resultant sloughing of papillae may lead to urinary tract obstruction and potentially further renal impairment.

Renal cortical abscess

A renal cortical abscess results from hematogenous spread of bacteria from a primary focus of infection outside the kidney, often the skin. The most common causative agent is *Staphylococcus aureus* (90%). Predisposing conditions include entities associated with an increased risk for staphylococcal bacteremia, such as immunodeficiency, diabetes mellitus, hemodialysis, and injection drug use. The primary focus of infection may not be apparent in up to one-third of cases. Ascending infection is an infrequent cause of renal cortical abscess formation. On rare occasions a renal cortical abscess ruptures through the renal capsule, forming a perinephric abscess.

Patients, predominantly males, present with chills, fever, and back or abdominal pain, with few or no localizing signs (Table 67.1). Most patients do not have urinary symptoms as the process does not generally communicate with the excretory passages. Physical examination may reveal costovertebral angle tenderness and involuntary guarding of the upper lumbar and abdominal musculature. A flank mass or bulge in the lumbar region with loss of lumbar lordosis may be present.

Laboratory data vary, though leukocytosis is common. Radiologic techniques can establish the diagnosis. Ultrasonography is useful diagnostically, may guide percutaneous drainage of the abscess, and may be used to follow response to therapy. CT is the most precise noninvasive diagnostic technique and may guide percutaneous aspiration. MRI with gadolinium may help diagnose a renal abscess and define its extent with accuracy comparable to CT, but without exposure to radiation and ionizing contrast.

Renal cortical abscesses often respond to antibiotics alone without surgical intervention. If the diagnosis is suspected and bacteriologic evaluation of the urine or aspirated abscess fluid reveals large, gram-positive cocci or no bacteria, anti-staphylococcal therapy should be started promptly (Table 67.2). The choice of empiric therapy depends on the susceptibility patterns of *S. aureus* in the community. If methicillin susceptible *S. aureus* (MSSA) is suspected, a semisynthetic penicillin (e.g., oxacillin or nafcillin) or a first-generation cephalosporin, such as cefazolin, is appropriate empiric therapy. Vancomycin should be reserved for patients with a severe immediate β-lactam allergy. If the prevalence of methicillin-resistant *S. aureus* (MRSA) is high,

BOX 67.1

Focal renal infections

Intrarenal abscesses
Renal cortical abscesses (renal carbuncle)
Renal corticomedullary abscesses
- Acute focal bacterial nephritis (acute lobar nephronia)
- Acute multifocal bacterial nephritis
- Xanthogranulomatous pyelonephritis

Perinephric abscesses

empiric therapy with vancomycin should be initiated. In the absence of occult bacteremia, parenteral antibiotics are administered for 10 to 14 days, followed by oral anti-staphylococcal therapy for at least 2 to 4 more weeks. Fever generally resolves after 5 to 6 days of antimicrobial therapy. If there is no response to therapy in 48 hours, percutaneous aspiration should be considered, and, if unsuccessful, open drainage should be undertaken. The prognosis is good if the diagnosis is made promptly and effective therapy is instituted immediately.

Renal corticomedullary abscess

Renal corticomedullary abscesses occur most commonly as a complication of bacteriuria and ascending infection accompanied by an underlying urinary tract abnormality. The most common abnormalities include obstructive processes, genitourinary abnormalities associated with diabetes mellitus or primary hyperparathyroidism, and vesicoureteral reflux. Immunodeficiency conditions, such as HIV/AIDS and renal transplantation, are also risk factors. Enteric aerobic gram-negative bacilli, including *Escherichia coli, Klebsiella*, and *Proteus* species, are common causative organisms. Corticomedullary abscesses can extend and result in perinephric collections. A severe form of acute bacterial interstitial nephritis involving a single renal lobe, AFBN, represents focal inflammation of the kidney without frank abscess formation and may be an early transition phase from acute pyelonephritis to acute multifocal bacterial nephritis or renal abscess. XGP, often clinically indistinguishable from acute pyelonephritis, is an uncommon but severe chronic infection of the renal parenchyma. It is defined by a granulomatous process containing lipid-laden macrophages (i.e., foam cells). It may be related to a combination of obstruction of the renal collecting system due to nephrolithiasis and chronic urinary tract infection. Other

TABLE 67.1 **CLINICAL AND LABORATORY FINDINGS OF RENAL AND PERIRENAL ABSCESSES**

	Renal cortical abscess	Renal corticomedullary abscess	Perinephric abscess
Epidemiology	Males 3× more than females, 2nd–4th decades, hematogenous seeding of kidneys	Frequency is equal in males and females (though 70% of XGP cases are female), incidence increases with age, underlying abnormality of the urinary tract, diabetes mellitus, or immunodeficiency	Males = females, 25% of patients are diabetic, rupture of intrarenal suppurative focus into perinephric space
Clinical presentation	Fever, chills, localized back or abdominal pain	Fever, chills, flank or abdominal pain, nausea and vomiting (65%), weight loss	Insidious onset over 2–3 weeks: fever (early), flank pain (late)
Urinary symptoms	None[a]	Dysuria/other urinary tract symptoms variably present	Dysuria 40%
Physical exam	Flank mass	Unilateral flank mass in 60%, hepatomegaly in 30%	Flank or abdominal mass in ≤50%, 60% have abdominal tenderness
Organisms	*S. aureus*	Enteric aerobic gram-negative rods (*Escherichia coli*, *Klebsiella* spp., *Proteus mirabilis), Pseudomonas, S. aureus.* XGP: 25% are culture negative	Enteric aerobic gram-negative rods with *Proteus* predominance and *S. aureus*; occasionally *Pseudomonas* spp., gram-positive bacteria, obligate anaerobic bacteria, fungi, mycobacteria; 25% polymicrobial
Urinalysis	Normal[a]	Abnormal in 70%	Abnormal in 70%
Urine cultures	Negative[a]	Positive in 60%	Positive in 60%
Blood cultures	Often negative	Often positive	Positive in 40%
Radiologic Findings	Ultrasound: hypoechoic/anechoic mass with internal debris; CT with contrast: enhanced collection	AFBN: Ultrasound demonstrates renal mass with decreased echogenicity. CT scan: hypo perfused wedge/round lesion with no capsule. 1/3 have ascites. XGP: Bear paw sign (CT)	CT scan: rim enhanced collection, central hypoattenuation (rind sign), thickened perinephric fascia and stranding

[a] If there is no communication between the abscess and the collecting system.

TABLE 67.2 **THERAPY OF RENAL AND PERIRENAL ABSCESSES**

	Empiric therapy[a]	Duration[a]	Drainage	Surgery
Renal cortical abscess	Anti-staphylococcal penicillin: oxacillin or nafcillin (1–2 g IV q4–6h) or first-generation cephalosporin: cefazolin (2 g IV q8h) or vancomycin (15 mg/kg IV q12h) if severe immediate β-lactam allergy or if MRSA is suspected	Intravenous antibiotics for 10–14 days followed by 2–4 weeks oral anti-staphylococcal agent depending on antibiotic susceptibility testing	If no response to treatment after 48 h, percutaneous drainage followed by open drainage if no response	
Renal corticomedullary abscess				
Acute focal bacterial nephritis	Extended-spectrum penicillin (piperacillin–tazobactam 3.375 g IV q6h), extended-spectrum cephalosporin (ceftriaxone 1 g IV q24h, fluoroquinolone (ciprofloxacin 200–400 mg IV q12h), ampicillin (1 g IV q4–6h) with gentamicin or cefazolin (1 g q8h) with gentamicin	Intravenous for 24–48 h after resolution of symptoms and fever followed by 2 weeks oral antibiotics based on results of susceptibility testing (cefpodoxime 200 mg q12h or ciprofloxacin 500 mg q12h)	Generally not necessary	
Acute multifocal bacterial nephritis	Same as acute focal bacterial nephritis	Same as acute focal bacterial nephritis	If slow response to antibiotics or large abscess, presence of obstructive uropathy, urosepsis, or advanced age	
Xanthogranulomatous pyelonephritis	Same as acute focal bacterial nephritis	Same as acute focal bacterial nephritis		Surgical excision usually necessary for cure (partial nephrectomy or total nephrectomy)
Perinephric abscess	Initiate broad spectrum gram negative coverage such as piperacillin–tazobactam 4.5 g IV q6h, cefepime 2 g IV q12h, or ceftazidime 2 g IV q8h). Empiric Vancomycin should be included if staphylococcal infection suspected. For β-lactam allergy: ciprofloxacin 200–400 mg IV a12h and. For ESBL-producing organisms, use a carbapenem.	Initial parenteral therapy until clinical improvement, change to appropriate oral therapy until radiographic studies indicate resolution of process	Requires percutaneous drainage followed by open surgical drainage if no resolution	Nephrectomy in cases that do not resolve with antibiotics and drainage

[a] Dosages based on normal renal and hepatic function.
ESBL, extended-spectrum β-lactamase; MRSA, methicillin-resistant *Staphylococcus aureus*.

predisposing factors include urinary obstruction, lymphatic obstruction, renal ischemia, alterations in lipid metabolism, abnormal host immune response, diabetes mellitus, and primary hyperparathyroidism. Due to the insidious nature of XGP, extrarenal fistulas and psoas abscess may also be present at the time of diagnosis. These lesions can mimic renal tumors and often require differentiation through pathologic testing.

Patients typically present with fever, chills, and flank or abdominal pain. Two-thirds of patients have nausea and vomiting, and dysuria may not be present. In some patients, symptoms may be subtle thus delaying the diagnosis. Patients may have a history of recurrent urinary tract infections or prior genitourinary instrumentation. The majority of patients have renal calculi, of which 50% are staghorn calculi. Patients may have a flank mass and/or hepatomegaly on exam. The urinalysis is often abnormal with bacteriuria, pyuria, proteinuria, and hematuria. Patients with acute focal or multifocal bacterial nephritis are frequently bacteremic. Many patients are anemic and have liver function abnormalities.

The nonspecific clinical presentation is associated with a variety of renal processes, including renal cortical abscess, perinephric

abscess, renal cysts, and tumors. Radiographic techniques are necessary to differentiate these various space-occupying lesions. Gray-scale ultrasonography and CT scanning are both used for diagnosing renal corticomedullary abscesses except for XGP, for which gray-scale ultrasound is less specific than CT. For XGP, CT scanning will often demonstrate dilated calyces, a thin parenchyma, and central calculus: the "bear paw sign." More recent validation of contrast-enhanced ultrasound has increased sensitivity in evaluating these lesions as well as allowing the avoidance of nephrotoxic contrast materials and radiation exposure. Alternatively, MRI may be considered for patients with renal insufficiency or allergy to iodinated contrast material.

Determination of empiric antimicrobial treatment should take into consideration the type of renal infection suspected as well as patient factors such as previous urine culture isolates and previous antimicrobial exposure. Fluoroquinolone-resistant and ESBL-producing *E. coli* urinary tract infections are increasing in frequency worldwide. Knowledge of risk, such as healthcare exposure, types of antimicrobial exposure, and travel to endemic areas, can inform the decision to use a carbapenem. It is also recommended to consider the possible risk of carbapenem resistance based on local resistance patterns and patient risk factors. Most patients with acute focal and multifocal bacterial nephritis respond to antibiotic treatment alone within 1 week of starting therapy. Radiologic techniques should be used early for slow response assessment and to ensure resolution of the parenchymal abnormalities after clinical resolution. An intensive trial of appropriate antibiotic therapy can be attempted before considering surgical drainage for lesions localized to the renal parenchyma. A large, well-established abscess may be more difficult to treat successfully with antimicrobial agents alone. Most intrarenal abscesses <3 cm respond to antimicrobial therapy alone, whereas abscesses >3 cm often require percutaneous or surgical drainage. Parenteral antimicrobial agents and intravenous hydration should be administered promptly when the diagnosis is considered. Empiric antimicrobial therapy is directed against the common bacterial organisms in this setting, including *E. coli, Klebsiella*, and *Proteus* spp. (Table 67.2). An extended-spectrum penicillin (e.g., piperacillin–tazobactam) or cephalosporin (e.g., ceftriaxone or cefotaxime) or ciprofloxacin are all appropriate choices. Empiric fluoroquinolones should be avoided as a single agent if local *E. coli* resistance is >10%. Antimicrobial therapy should be modified based on the results of culture and sensitivity testing. Duration of therapy should be individualized. Parenteral antimicrobial therapy should be continued for at least 24 to 48 hours after improvement of symptoms and resolution of fever. Oral antibiotic therapy, based on antimicrobial susceptibility results and oral bioavailability of the agent, is then administered for an additional 2 weeks.

AFBN typically responds to antimicrobial therapy alone, with follow-up radiographic studies showing complete resolution of the intrarenal lesion. Only occasionally is a drainage procedure necessary. Factors associated with failure to respond to antimicrobial therapy alone include large abscesses, obstructive uropathy, advanced age, and urosepsis. Percutaneous abscess aspiration, sometimes with repeated aspirations, combined with parenteral antibiotics has been successful. If obstructive uropathy is present, prompt drainage by percutaneous nephrostomy until the patient is stable and afebrile is appropriate, at which time the lesion should then be corrected. Nephrectomy is reserved for patients with diffusely damaged renal parenchyma or patients requiring urgent intervention for survival in the setting of sepsis.

Patients with XGP generally require surgical excision of the xanthogranulomatous process for cure, although there have been case reports of successful treatment without surgical intervention. Once the tissue is removed, the xanthogranulomatous process ceases and does not recur; however, bacteriuria may recur and require treatment. After excision, the prognosis in those without other urinary pathologic conditions is excellent.

Perinephric abscess

The common etiologic agents of intrarenal abscesses, *E. coli, Proteus* species, and *S. aureus*, are also the common organisms associated with perinephric abscesses. Other gram-negative bacilli associated with this entity are *Klebsiella*, *Enterobacter*, *Pseudomonas*, *Serratia*, and *Citrobacter* species. Occasionally enterococci are implicated, and anaerobic bacteria may account for culture-negative abscesses. Fungi, particularly *Candida* spp., are also important, as is *Mycobacterium tuberculosis*.

A perinephric abscess is a collection of suppurative material in the perinephric space between the renal capsule and Gerota's fascia. Most perirenal abscesses result from the rupture or direct extension of an intrarenal abscess into the perinephric space; chronic or recurrent pyelonephritis, particularly in the presence of obstruction; and XGP. Predisposing conditions for perinephric abscesses are similar to those for intrarenal abscesses. Most patients have underlying urinary tract abnormalities. Patients with polycystic kidney disease, neurogenic bladder, or chronic or recurrent urinary tract infections, with or without calculi, and immunodeficiency may also be at increased risk.

The symptoms of perinephric abscess develop insidiously over a period of 2 to 3 weeks (Table 67.1). Fever is present in 50% of patients. Unilateral flank pain is common (70–80%), whereas chills and dysuria are less common (40%). Costovertebral angle tenderness is often present on exam, and 60% of patients may have abdominal tenderness. Half the patients have a flank or abdominal mass.

The diagnosis should be strongly considered in any patient with a febrile illness and unilateral flank pain that does not respond to therapy for acute pyelonephritis. Contrast-enhanced CT is the radiographic study of choice as it identifies the abscess and defines its extent beyond the renal capsule and the surrounding anatomy, including extension into the psoas muscle. Classic findings are a rim-enhanced collection with central hypoattenuation, "the rind sign," with thickened perinephric fascia and stranding. MRI is an acceptable imaging modality when avoidance of exposure to radiation and iodinated contrast is desired. Ultrasound may identify the abscess structure and extent, although sensitivity is less than with CT imaging.

Early recognition and management contribute to decrease the mortality associated with this entity. Antimicrobial therapy alone is usually inadequate, and percutaneous drainage should be considered. Surgical drainage is considered when an abscess is multilocular, percutaneous drainage fails, or is contraindicated. Most cavities

spontaneously resolve after drainage and antimicrobial therapy. Acute nephrectomy is occasionally indicated. Empiric antimicrobial therapy should be directed against the most common gram-negative pathogens and *S. aureus* (Table 67.2). An aminoglycoside and an anti-staphylococcal β-lactam (e.g., oxacillin, nafcillin), or cephalosporin (i.e., cefazolin) are appropriate initial antibiotics. If MRSA is suspected, vancomycin should be used instead of an anti-staphylococcal β-lactam. A broad spectrum β-lactam may be used in place of an aminoglycoside for gram-negative coverage. When *Pseudomonas aeruginosa* is identified, an anti-pseudomonal β-lactam (e.g., piperacillin–tazobactam, cefepime, or ceftazidime) should be included with or without an aminoglycoside. Alternatively, the aminoglycoside may be discontinued and ciprofloxacin given. If an ESBL-producing gram-negative organism is suspected a carbapenem should replace a β-lactam. If enterococcus is isolated, ampicillin plus gentamicin is the treatment of choice. Therapy should be modified based on culture and antimicrobial susceptibility testing results. Perinephric abscesses caused by mycobacteria and fungi are treated with appropriate antimicrobial agents based on the organism and antimicrobial susceptibility testing.

Perinephric abscesses may cause ureteral compression leading to hydronephrosis. Even after drainage, ureteral stenosis from periureteritis may evolve during the healing process, a late complication of this disease.

Renal papillary necrosis

Renal papillary necrosis is an uncommon severe complication of pyelonephritis (2–5%) that occurs most often with underlying structural renal abnormalities or host immunocompromise (more than half of patients are diabetic) (Box 67.2). Additionally, minimal ischemic insults can result in necrosis due to the limited vasculature of the renal papillae. When papillary necrosis is caused by infection, both kidneys are frequently affected with one or more pyramids involved. As the lesion progresses, a portion of the necrotic papilla may break off, producing a calyceal deformity that results in a recognizable radiologic filling defect. The sloughed portion may be voided and can be recovered from the urine.

Patients present with worsening symptoms of preexisting pyelonephritis. They may have lumbar pain, hematuria, and fever. The diagnosis should be considered in diabetic patients with active pyelonephritis who experience a rapid clinical deterioration and/or worsening renal function. Multiphasic helical CT is helpful in identifying early papillary necrosis. CT may reveal the "ring sign," an area of contrast surrounding a crescent-shaped papilla.

Therapy is directed toward control of infection generally caused by common uropathogens including *E. coli, Proteus*, and *Klebsiella* species (Table 67.2, renal corticomedullary abscess treatment). If the patient does not respond promptly to appropriate antimicrobial therapy, obstruction cannot be alleviated, and infection is subsequently not controlled, nephrectomy may be needed.

BOX 67.2

Conditions associated with development of papillary necrosis

Infection of native and prosthetic joints

Shahbaz Hasan and James W. Smith

Native joint infections

Infections of native joints generally occur in patients with predisposing factors such as trauma, underlying arthritis, immunosuppressive therapy, diabetes mellitus, malignancies, intravenous drug abuse, and other infections (e.g., endocarditis, skin infections, and urinary tract infections). Hematogenous spread of the organism through the highly vascular synovial space leads to an influx of polymorphonuclear leukocytes (PMLs) into the synovium and then to a release of enzymes that destroy the articular surface.

Diagnosis

Patients present with pain and limited motion of the joint. Fever may be mild, with only a few patients having a temperature higher than 39°C (102.2°F). Joint tenderness can be minimal to severe, but most patients have swelling as a result of joint effusions in response to the infection. Involvement of multiple joints is seen in 10% to 20% of cases, especially in viral arthritis and rheumatoid arthritis. Laboratory findings suggestive of septic arthritis include an elevated erythrocyte sedimentation rate and synovial fluid cell counts exceeding 50 000/mL, with more than 75% PMLs. In no individual case do any of these findings distinguish infected from inflammatory arthritis, such as rheumatoid or crystalline arthropathy, so the diagnosis is based on cultures of synovial fluid. On occasion, blood cultures may be positive. In patients with a chronic monoarticular process caused by mycobacterial or fungal organisms, synovial tissue cultures provide a better yield than synovial fluid cultures. Serum antibody tests provide the diagnosis of Lyme or viral arthritis. Polymerase chain reaction (PCR) assay of the joint fluid may yield the diagnosis in partially treated patients or in patients' infections caused by fastidious organisms such as *Mycoplasma, Chlamydia*, or *Borrelia burgdorferi* (Lyme disease). Plain radiographs are seldom of use diagnostically. Computed tomography (CT) and magnetic resonance imaging (MRI) provide more detail of the surrounding soft tissue and may reveal adjacent osteomyelitis. Radionuclear scans may be needed to visualize the sacroiliac joint; however, they are unable to distinguish septic arthritis from other inflammatory arthritis.

Staphylococcus aureus is the most common organism isolated in native bacterial arthritis. However, a variety of other gram-positive and gram-negative organisms have been reported as agents in monoarticular bacterial arthritis. *Neisseria gonorrhoeae* is the main cause of bacterial arthritis in sexually active individuals with no underlying joint disease. It presents with a syndrome of fever, skin lesions, and polyarticular involvement, often with associated tenosynovitis. Any of a number of mycobacterial and fungal organisms can cause a chronic, slowly progressive infection of a single joint with tenosynovitis. Viral agents commonly associated with arthritis include rubella and parvovirus B19 (erythema infectiosum or fifth disease) in women and mumps in men. Hepatitis B infection may manifest as a prodromal syndrome consisting of arthritis and urticaria that disappear with the onset of jaundice.

Therapy

Empiric antimicrobial therapy for suspected bacterial arthritis is started after obtaining appropriate fluid specimens for analysis and culture. The choice of antibiotics depends on the patient's age, risk factors, and results of the synovial fluid Gram stain (Figure 68.1). The antibiotics are modified after obtaining the culture results. The usual course of antibiotics is 2 weeks. Infections from staphylococci and gram-negative bacilli require 3 weeks of treatment. Mycobacterial and fungal infections are treated for up to a year. Initial therapy by causative organism is given in Table 68.1.

Infected joint effusions require repeated needle aspirations of recurrent joint effusions during the first 5 to 7 days of antimicrobial therapy. Most patients respond to needle aspiration. If the volume of fluid and number and percentage of PMLs decrease with each aspiration, no drainage is required. However, if the effusion persists for more than 7 days or the cell count does not decrease, surgical drainage is indicated. Surgical drainage is also indicated when effective decompression with needle aspiration is unlikely (hip joint) or when the joint is not accessible for aspiration (sternoclavicular and sacroiliac joints); if the joint space has become loculated as a result of formation of adhesions; or if thick, purulent material resisting aspiration is encountered. Arthroscopic drainage is an alternative to open drainage for the knee, shoulder, and ankle joints.

Prognosis

Bacterial arthritis is associated with a mortality of 10% to 15%. Up to 25% to 50% of surviving patients are left with residual loss of joint function. Poor outcomes are commonly seen in the elderly and those with severe underlying joint disease, hip infections, or infections caused by mycobacterial or fungal agents.

Prosthetic joint infections

Prosthetic joint surgery has been used with increasing frequency over the past 4 decades. About 1 000 000 arthroplasties are performed in the United States each year. Although most procedures involve the hip and knee joints, arthroplasties of the elbow, shoulder, and wrist are also being performed. Primary indications for surgery generally include rheumatoid arthritis, degenerative joint disease, fractures, and septic arthritis.

Ten-year implant survival rates of 70% to 90% are being achieved at most centers. Most failures result from aseptic loosening of the prosthesis, with infectious complications accounting for fewer than 1% of implant failures. These prosthesis infections necessitate extensive surgical procedures and prolonged use of antibiotics, all of which result in increased cost, morbidity, and rarely, mortality. Risk factors for the development of prosthesis infection include rheumatoid arthritis, previous surgeries at the joint, postoperative wound infection, hematoma, and unhealed or draining wounds at hospital discharge. Other risk factors include sinus tracts to the surgical site, obesity, age, use of immunosuppressive therapies, diabetes mellitus, and distant site infections, especially urinary tract and skin infections. Varying frequency of infection is noted with different joints: Incidence of infections for hip arthroplasties is less than 1%; for knees 1% to 2%; and for elbows 4% to 9%.

Direct inoculation of the joint at the time of surgery and intraoperative airborne contamination probably account for most infections. Evidence of the importance of this is demonstrated by the preponderance of infections caused by skin commensals (Table 68.2) and by reduction in frequency of infection that accompanies the use of prophylactic antibiotics. Hematogenous seeding of the implants is implicated in infections occurring more than 2 years postoperatively.

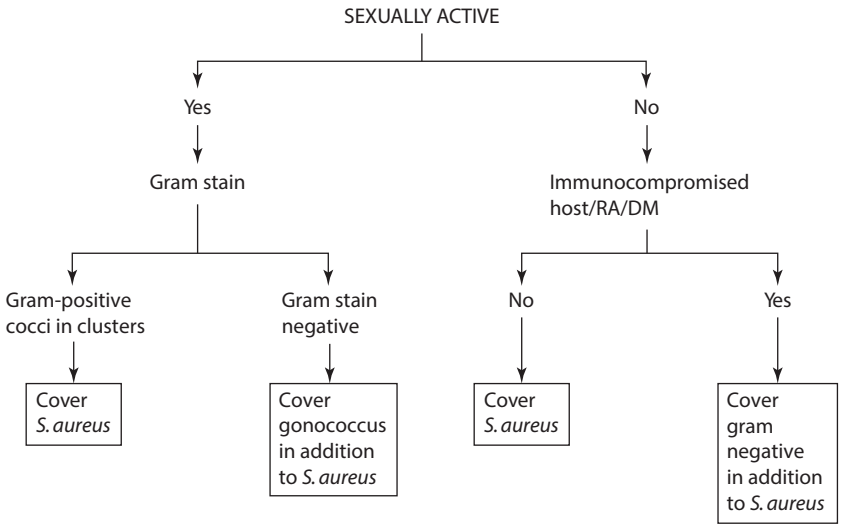

FIGURE 68.1 Empiric antibiotic coverage for nontraumatic, acute monoarticular arthritis. RA = rheumatoid arthritis; DM = diabetes mellitus.

TABLE 68.1 **THERAPY FOR BACTERIAL ARTHRITIS OF NATIVE JOINTS**

Microorganism/infection	Treatment	Duration
Staphylococcus aureus	Penicillinase-resistant penicillins,[a] first-generation cephalosporin,[b] or cefuroxime, 1.5 g q8h	3–4 wk
Methicillin-resistant S. aureus or patient allergic to penicillin	Vancomycin, 1 g q12h daptomycin 4–6 mg/kg/d, or linezolid 600 mg q12h	3–4 wk
Streptococci	Penicillin G, 4 million units q6h, or first-generation cephalosporin[b] or clindamycin, 300 mg q8h	2 wk
Gram-negative bacilli	Antipseudomonal cephalosporins,[c] carbapenem,[d] quinolone[e]	3–4 wk
Disseminated gonococcal infection	Ceftriaxone, 1 g q24h until response, then cefixime, 400 mg PO BID	7–10 d
Septic gonococcal arthritis	Ceftriaxone, 1 g q24h	3 wk
Lyme arthritis	Doxycycline, 100 mg PO BID, or ceftriaxone, 2 g q24h IV	4 wk, 2 wk
Mycobacterium tuberculosis	Isoniazid, 300 mg/d, plus rifampin, 600 mg/d, with ethambutol, 15 mg/kg/d, and pyrazinamide, 1500 mg/day for the first 2 mo	1 y
Fungal arthritis	Amphotericin B, 0.5–0.7 mg/kg/d for a total of 2 g, then itraconazole, 200–400 mg/d PO, or fluconazole, 200–400 mg/d PO	1 y

[a] Nafcillin, 2 g q6h IV.
[b] Cefazolin, 1 g q8h IV, or cephalothin, 1–2 g q6h IV.
[c] Ceftazidime, 2 g q8h IV, or cefepime, 1 g q12h IV.
[d] Imipenem–cilastatin, 500 mg q6h IV, or meropenem, 500 mg q8h IV.
[e] Ciprofloxacin, 400 mg q12h IV, or levofloxacin, 500 mg q24h IV.
Abbreviations: PO = orally; BID = twice a day; IV = intravenously.

Diagnosis

The diagnosis of acute prosthetic joint infection is suspected in those who develop pain and fever within 6 months of the procedure. These findings are similar to those of acute septic arthritis in a native joint. However, most infections tend to be indolent and manifest with local pain and mechanical loosening of the prosthesis. Clinical features, laboratory tests, and imaging techniques may be insufficient to differentiate between aseptic and septic complications (Table 68.3). Hence, the diagnosis of an infection often has to be confirmed on the basis of the intraoperative appearance of the tissues and the presence or absence of acute inflammatory reaction on the intraoperative histopathology specimens. Given the heterogeneity of organisms (see Table 68.2), the joint fluid and tissues must be submitted for aerobic and anaerobic bacterial, fungal, and mycobacterial cultures. Microbiologic culture yield is improved if sampling of tissues is performed with the patient being off antimicrobials for 1 to 2 weeks.

TABLE 68.2 **MICROBIOLOGY OF PROSTHETIC JOINT INFECTIONS**

Organism	Percentage
Staphylococcus aureus	25
Coagulase-negative staphylococci	25
Streptococci	5–10
Enterococci	3–5
Gram-negative bacilli	8–10
Anaerobes	5–10
Mixed	10–15
Others (fungi, mycobacteria, actinomyces, brucella)	1–2

Therapy

The object of successful management of prosthetic joint infections is 2-fold: eradication of infection and maintenance of functional integrity of the joint. Two-stage reimplantations offer the best possible chance for eradication of infection. However, not all patients may be suitable candidates for this extreme surgical undertaking either because of poor bone stock, inability to withstand prolonged immobilization, or inability to eradicate the infectious agent. Such cases may call for other salvage techniques that usually sacrifice joint function for microbiologic cure (Table 68.4). Antibiotic selection is based on the susceptibility pattern of the organisms isolated. The antibiotics of choice for the isolated organisms are similar to those used in native joint infections (see Table 68.1). Unlike native joint infections, the most common organisms isolated in prosthetic joint infections are coagulase-negative staphylococci (see Table 68.2). Therefore this organism should not be considered a contaminant but should be treated. If the prosthesis is removed, parenteral antibiotics are administered for 6 to 8 weeks; however, if management includes retention of the prosthesis, a prolonged course of oral antibiotics (6 months to 1 year) should be given after the completion of the course of parenteral antibiotics. With regard to staphylococci, 2 to 6 weeks of parenteral antibiotics in combination with rifampin is followed by a further 6 weeks of oral agents. Oral agents may include quinolones, if susceptible, such as ciprofloxacin, 750 mg twice daily, or levofloxacin, 500 mg once daily, combined with rifampin, 600 mg once daily. Other alternatives include minocycline or doxycycline, 100 mg twice daily.

TABLE 68.3 **DIAGNOSTIC FEATURES OF PROSTHETIC JOINT INFECTIONS**

	Suggestive findings	Comments
History	Rest pain; lack of postoperative pain-free interval; difficult wound healing; fever	These findings are not specific; they may also be found in aseptic loosening of the prosthesis. Infected prosthesis may be asymptomatic
Physical findings	Swelling; tenderness; limitation of motion; fever; sinus tract	As above
Laboratory tests	Leukocytosis; elevated ESR or CRP	Elevations in these parameters noted in most acute infections but may be normal in chronic, indolent infections
Radiology	Periostitis; endosteal scalloping; focal or diffuse osteolysis	Radiologic findings may be normal. Cannot distinguish mechanical loosening from septic arthritis
Nuclear imaging	Enhanced uptake in the region of the prosthesis	Subjective and reader dependent. Sequential bone and tagged white cell scans provide greater sensitivity and specificity than if done alone. Provides no information about organisms
Joint aspiration	Positive cultures	Sensitivity 60%–80%; specificity 85%–95%; dry taps 10%–15%. More useful in symptomatic cases; provides specific information about organisms and sensitivities; detection of previously undetected infections. Yield improved if patient is off antibiotics for 2 weeks

Abbreviations: ESR = erythrocyte sedimentation rate; CRP = C-reactive protein.

Prevention

Perioperative antibiotic coverage includes agents directed against the most common causative agents, that is, gram-positive cocci. A first-generation cephalosporin will achieve this. The antimicrobial agents are administered within 30 to 60 minutes of surgery and are continued for up to 24 hours postoperatively. For patients known to be colonized with methicillin-resistant *S. aureus* (MRSA), an additional dose of vancomycin should be administered. Antibiotic-impregnated beads and cement have also been used extensively because they have the advantage of delivering high local levels of antibiotics with minimal systemic toxicity. Laminar air-flow devices and body exhaust suits have been recommended to prevent intraoperative contamination; however, it is unclear whether these considerably expensive techniques are cost-effective.

There is no convincing evidence of benefit of routine prophylaxis with antibiotics for patients with prosthetic joints undergoing uncomplicated dental, urinary, or gastrointestinal procedures. The risk of infection is similar to that of endocarditis developing in the general population. In a joint advisory statement, however, the American Dental Association and the American Academy of Orthopedic Surgeons have suggested prophylaxis regimens similar to those set out by the American Heart Association for endocarditis in certain high-risk patients undergoing high-risk dental procedures.

TABLE 68.4 **TREATMENT OPTIONS FOR PROSTHETIC JOINT INFECTIONS**

Technique	Method	Comments
Reimplantation (exchange arthroplasty)	Removal of prosthesis and cement, immediate reimplantation (one stage) or delayed reimplantation (two stages)	Technique of choice. Excellent functional results and good microbiologic cure. Patient must be physically able to undergo major surgery and prolonged immobilization. Adequate bone stock necessary for reimplantation
Resection arthroplasty	Removal of prosthesis and cement, extensive debridement of adjacent bone	Used if reimplantation not possible because of major bone loss, recurrent infections, poorly responsive organisms (e.g., fungi) and patient mobility not essential/necessary for reimplantation Provides good microbiologic cure at the expense of joint function
Arthrodesis	Removal of prosthesis and cement and fusion of joint	If mobility is needed but patient cannot undergo reimplantation May require prolonged immobilization
Amputation		Radical treatment may be necessary following multiple revision attempts, intractable pain, or life-threatening infection
Implant salvage	Chronic antibiotic suppression, alone or with local debridement and retention of prosthesis	Indicated if patient is unable or refuses to undergo major surgery. May be successful provided duration of symptoms ≤ 3 wk, no sinus drainage, no radiologic evidence of loosening, and the microorganism is highly susceptible to antibiotics

Bursitis

Richard H. Parker

Inflammation of bursal sacs, or bursitis, is a common condition. Bursa are fluid-filled sacs that act as cushions between tendons and either bone or skin. There are more than 150 bursae in the human body. Most cases of bursitis involve either the olecranon or the prepatellar bursa, and the majority are related to trauma. At most 20% to 30% are infected either primarily or secondary. A much smaller percent are the result of inflammation associated with rheumatologic disorders. Possibly the most common scenario for septic arthritis is a needlestick for corticosteroid injection into a bursa as therapy for nonseptic bursitis. Septic bursitis can also occur as a complication of bacteremia without a history of trauma to the involved area. Septic bursitis is less common in the pediatrics patient but does occur and is usually associated with acute trauma such as sports-related injuries.

Septic and nonseptic bursitis of superficial bursae such as at the olecranon and prepatellar sites may present as both red and tender areas (Figure 69.1). Clinical features, including fever or infection at another site, may help differentiate infected from noninfected. Bursitis of deeper bursae, such as trochanteric bursitis is usually not infectious but tuberculous bursitis of the greater trochanter and other deeper sites has occurred. Microorganisms from the skin cause most infectious bursitis. *Staphylococcus aureus* may cause about 90% of infected bursa. However, any microorganism (hemolytic streptococci, gram-negative bacilli, or fungi) if introduced can infect these spaces. As with other infectious diseases, the immunocompromised host may be infected with unusual opportunistic microorganisms.

Diagnosis of septic bursitis requires aspiration of fluid for microscopy, culture, cell counts, and glucose (Table 69.1).

Therapy

Therapy is started following a decision as to whether the inflammation is infectious or noninfectious (Figure 69.2). Noninfectious bursitis is treated with immobilization, heat, and anti-inflammatory agents and referred to orthopedics depending on the severity or response to therapy. Septic bursitis might require hospitalization for surgical drainage and intravenous antimicrobial therapy. However, most patients are not septic, toxic, or immunocompromised and may be considered compliant and therapy can be initiated with oral antimicrobial agents and the patient is followed closely as an outpatient. Home intravenous infusion therapy is an option but should be restricted to therapy of methicillin-resistant *S. aureus* (MRSA) or other pathogens that require use of drugs that can be given only intravenously or when patients cannot tolerate oral medications.

FIGURE 69.1 Red, swollen olecranon bursa. (From *Resident and Staff Physician*, March 2006.)

Initial therapy must use a good antistaphylococcal agent and may be oral therapy for nonseptic patients. In one report of 82 cases, a cloxacillin-based regimen resulted in cure of all but one patient. All patients received intravenous therapy until afebrile, including gentamicin in 35 patients. In areas where MRSA is common, intravenous vancomycin, daptomycin, or linezolid should be initiated. Linezolid has excellent bioavailability with equal efficacy for MRSA either IV or orally. Clindamycin may be useful in community-acquired MRSA provided inducible clindamycin resistance has been ruled out by appropriate studies. Therapy to cover an infection caused by gram-negative bacilli and/or anaerobes should be started if the septic bursitis occurs in the lower extremity or in an immunocompromised patient. Oral antimicrobial agents, if not started initially, can be used within 48 to 72 hours. Well-tolerated, once-a-day therapy is considered preferable for compliance. Total duration of therapy is usually 3 to 4 weeks. The recurrence of fluid after initial aspiration requires reaspiration and consideration for surgical drainage or bursectomy.

TABLE 69.1 **FINDINGS IN BURSAL FLUID RELATED TO CAUSES OF BURSITIS**

Finding	Normal	Trauma	Sepsis	Rheumatoid inflammation	Microcrystalline inflammation
Color	Clear yellow	Bloody xanthochromic	Yellow, cloudy	Yellow, cloudy	Yellow, cloudy
WBC	0–200	≤ 5000	1000–200 000	1000–20 000	1000–20 000

Acute and chronic osteomyelitis

Ilona Kronig, Pierre Vaudaux, Domizio Suvà, Daniel Lew, and Ilker Uçkay

Introduction, epidemiology, and clinical manifestations

Osteomyelitis is a common term for bone infection, although noninfectious inflammation of bones and adherent structures exist. Strictly speaking, osteomyelitis implicates affection of bone and marrow. The term osteitis would be often more appropriate because no one knows how much infection is inside the marrow in a given episode. As for any infection, physicians like to create big groups of disease headed as acute (AO) and chronic osteomyelitis (CO), although this distinction does not much determine daily clinical practice. For physicians, a commonly accepted definition of AO is a recent bone infection with systemic inflammatory response, while CO requires minimal symptom duration of 6 weeks to 3 months. Another classification system is the presence of a sinus tract, sequestra, or involucra, which are anatomicopathologic hallmarks of chronic infection. Finally, surgeons have their classification schemes, based on practical aspects of the surgical approach, of which the Cierny-Mader classification is one of the most frequent. The terms acute or chronic are not used in this classification. Generally, surgeons understand a CO as infection requiring surgery, with already established sequestra and bone deformities.

AO is a hematogenous infection that occurs mostly in prepubertal children and in the elderly and is usually located in the metaphyseal area of long bones (children) or in the spine (elderly). It is the result of a local proliferation of bacteria within bone after a septicemic storm. Alternatively, AO can originate locally following trauma or orthopedic surgery (surgical site infection). In contrast, CO has two origins. It may result from either a neglected sequel of AO, or from the continuous spreading of chronic ulcers in paraplegics, bedridden patients, or diabetic patients with foot problems. Epidemiology of osteomyelitis is heterogeneous with variability among involved bones, pathogens, and settings. For example, resource-poor countries may reveal a higher proportion of tuberculous osteomyelitis or CO due to post-traumatic origin compared to resource-rich countries, as well as a higher prevalence of foot osteomyelitis among elderly patients.

Pathogenesis in detail

Every chronic infection begins with an acute phase. Bacteria adhere to bone matrix and orthopedic implants via receptors to fibronectin and other structural proteins, then hide intracellularly by developing a biofilm. Patchy ischemic bone necrosis occurs when the inflammation occludes the vascular tunnels. Segments of bone devoid of blood supply can become separated and are called sequestrate. This creates an ideal culture medium for bacteria and at 48 hours, abscesses are formed. Meanwhile, osteoblastic activity occurs, in some cases exuberantly, causing periosteal apposition and new bone formation, named involucrae. When sequestrate or involucrae become fibrotic, sclerosis may result. Bone sclerosis usually indicates infection present for more than 1 month.

Microbiologic and pathologic criteria

Infection is almost exclusively of bacterial origin, much less due to fungi (in intravenous drug abusers or in skull osteomyelitis in immunesuppressed individuals) or parasites (e.g., echinococcosis). For all categories of osteomyelitis except for the jaw, *Staphylococcus aureus* is the prominent pathogen, contributing up to two-thirds or three-quarters of the study population, followed by streptococci and gram-negative pathogens such as *Pseudomonas aeruginosa*. As for any infection, virtually any bacteria can cause osteomyelitis. Skin commensals such as coagulase-negative staphylococci, propionibacteria, corynebacteria, or *Bacillus* spp. are mostly encountered in implant-related infections, but almost never alone in AO or CO without implants. Polymicrobial infection is frequent in trauma and long-lasting ulcerations, but not in hematogenous infections.

Diagnosis

Clinical signs (sinus tract with or without discharge) and radiographs (sequestra, involucra, fistulas) are suggestive for diagnosis of CO, but no noninvasive test can definitively establish or exclude infectious osteomyelitis. That is why it is extremely important to get adequate sampling of infected bone for bacteriologic or molecular identification by polymerase chain reactions (PCR). Swabs, even if taken from a deep area, should be avoided. The ultimate proof of infection requires growth of the same pathogen in several, at least two, (intraoperative) bone samples. In case of pretreatment with antimicrobial agents or suspicion of slow-growing pathogens such as in tuberculosis, brucellosis, or nocardiosis, the incubation time might be prolonged beyond the usual 5-day period and other, nonstandard laboratory tests, performed. Histology may help to confirm the clinical suspicion.

Treatment

The mainstays of management include adequate debridement, obliteration of dead space, wound protection, and targeted antimicrobial therapy.

Surgical therapy

Debridement *sensu latu* summarizes different surgical approaches: sequestrestomy, necrosectomy, intramedullary reaming, and removal of orthopedic material (when possible or indicated), except those essential for stability. Debridement must often be repeated for the removal of all nonviable tissue (second look). Surgeons know how extensively they were able to perform this debridement. There are no exact possibilities to estimate the completeness of such a debridement. A variety of techniques has been used such as cancellous bone grafting and implantation of acrylic beads impregnated with antibacterial agents. In case of vascular insufficiency, restoration of a good blood flow is performed by vascular bypass or endovascular stenting. If the stability of the bone is compromised, a two-stage procedure might be required. The first stage consists in extensive debridement, dead space management (eventually with antibiotic-containing beads or cement), bone stabilization with external fixation, and coverage with dressings. After 3 weeks of antibiotic treatment comes the second stage: new debridement, removal of the beads or cement, filling in of the dead space with bone graft, bone stabilization with internal fixation (plate and/ or intramedullary nail), and soft-tissue coverage. Local administration of antibiotics, e.g., by gentamicin beads, has long been advocated because of the benefit of a local diffusion limited in time and space. However, at present, the use of local antibiotic delivery in combination with systemic antibiotic prescription has not yet shown any supplementary beneficial effect in terms of remission rates. The major disadvantage of local beads is the presumed need for a subsequent surgical removal. Small dead space is left unchanged if the soft-tissue coverage is good. Large dead spaces are filled to reduce the likelihood of continued infection and stability loss. If a cavity cannot be filled by surrounding soft tissue, a local muscle flap or free tissue transfer obliterates the space. Autologous bone grafts usually enhance stability after 6 to 8 weeks. As a last resort, the Ilizarov fixation device is used in patients with chronic extensive and difficult to treat CO. The Ilizarov technique may bridge bone defects as long as 15 cm by continuous traction that can be started 10 days after implantation of the device.

Antimicrobial therapy

In contrast to surgical science with many related publications, the optimal antibiotic treatment post-debridement for implant-free, nondiabetic long bone osteomyelitis among adults is not well defined. Most studies primarily focused on the choice of antibiotic agents, rather than their duration, dosing, or route of administration. Usually, single-agent chemotherapy is adequate for the treatment of osteomyelitis (Table 70.1). In the past decades, according to experimental models, antibiotics were parenterally administrated on a mostly empirical basis for 4 to 6 weeks, followed by an oral course of antimicrobials for several weeks or months. Without doubt, bone penetration of antibiotic agents is optimized by parenteral administration, with a serum bioavailability per definition of 100%. On the other hand, parenteral medication should be limited to save unnecessary costs, prevent catheter-related complications, and to increase patient and nursing comfort. The estimated proportion of complications attributed to a prolonged IV course ranges around 15%. Recent studies allowed new approaches to antimicrobial therapy based on experimental models and clinical validations. Thus, there is a growing consensus for a switch to the oral route after 2 weeks of IV treatment. Several antimicrobial agents have already proven clinical efficacy upon oral intake: quinolones, linezolid, clindamycin, trimethoprim–sulfamethoxazole (TMP–SMX), and fusidic acid combined with rifampin. These drugs have oral bioavailabilities of 90%.

TABLE 70.1 **ANTIBIOTIC TREATMENT OF OSTEOMYELITIS[A]. LOCAL RECOMMENDATIONS AT GENEVA UNIVERSITY HOSPITALS**

Parenteral treatment	(Duration 0–2 weeks) Antibiotics	Alternatives
Staphylococcus aureus		
Methicillin resistant	Vancomycin 2 × 15 mg/kg	Teicoplanin (400 mg q24h, first day q12h)
		Daptomycin 6–10 mg/kg/d
		Linezolid 2 × 600 mg/d
Methicillin susceptible	Flucloxacillin 2 g q6h	Cephalosporins of I or II generation
Streptococci	Penicillin G (3 Mio U q4–6h)	Cephalosporins of I or II generation
Gram-negatives	Ceftriaxone	Ceftazidime, cefepime
Anaerobes	Amoxicillin-clavulanate	Metronidazole, carbapenems, clindamycin
Oral treatment	**(Duration 6–12 weeks)**	
Gram-positives	Clindamycin 3 × 600 mg	Levofloxacin 2 × 500 mg
		Trimethoprim–sulfamethoxazole 2 cp forte (2 × 960 mg)
		Linezolid 2 × 600 mg
		Fusidic acid 3 × 500 mg (not as monotherapy)
Gram-negatives	Ciprofloxacin 2 × 750 mg	Trimethoprim–sulfamethoxazole 2 × 960 mg
		Levofloxacin 2 × 500 mg
Anaerobes	Metronidazole 3 × 500mg	Clindamycin 3 × 600 mg

[a] Adapted from: Uçkay I, Buchs NC, Seghrouchni K, et al. Bacterial osteomyelitis: etiopathogenesis and management. In: Signore A, ed. *Management of Osteomyelitis*, 1st edn. Chapter 2. Rome, Italy: University of Rome; 2013:15–26.

Total duration of antibiotic therapy

In general practice, the duration of antibiotic administration is standard for most pathogens with few exceptions: pathogens for which the literature provides long-lasting antibiotic treatments (tuberculosis, other mycobacteria such as in buruli ulcer, fungi, Q fever, nocardiosis, or brucellosis). There are no clinical studies or documented records indicating the superiority of the 4- to 6-week course over shorter durations. In the retrospective study of Rod-Fleury et al., the duration of total post-debridement antibiotic treatment or its initial parenteral part only played no role on the remission incidences. One week of IV therapy had the same success as 2 to 3 weeks or more. Four weeks of total antibiotic treatment led to the same outcome as 4 to 6 weeks or more than 12 weeks. Less than 6 weeks was equal to more than 6 weeks. Haidar et al. listed small individual reports in animals and humans that obtained remission of osteomyelitis with antibiotic durations ranging from 1 to 4 weeks.

Intravenous agents

The most frequently used antibiotic agents, the β-lactam antibiotics, ubiquitously show low oral bioavailability and a low intra-osseous penetration. Since the bone penetration of vancomycin is only about 15% to 30% of the serum concentration, minimal trough serum levels of 20 to 25 mg/ L are believed to treat bone infections best. In continuous perfusion, the changes in serum concentrations are much lower than in intermittent application. However, continuous perfusion does not guarantee a better outcome in terms of remission. Daptomycin depolarizes bacterial membranes and yields a rapid, dose-dependent bactericidal effect. It is only available in parenteral form and administered once a day at a dose of 6 to 8 mg/kg. This makes it suitable for an outpatient treatment. Aminoglycosides are less active in synovial fluid or in bone.

Oral agents

Linezolid can be administered orally at a dose of 600 mg BID, due to its high bioavailability of 100%. Besides an expensive price, it is associated with reversible bone marrow suppression, e.g., thrombopenia. Optic neuropathy and non-reversible peripheral neuropathy have been reported in 2% to 4% of patients with prolonged administration. A severe serotonin syndrome in co-medication with certain antidepressive drugs, such as monoamine oxidase inhibitors, has been described. TMP–SMX is an inexpensive folate antagonist. However, one reason for failure in severe osteoarticular infections might be the amount of thymidine released from damaged host tissues and bacteria. Thymidine may antagonize the antistaphylococcal effects of TMP–SMX. Hence, TMP–SMX failure may well depend on the amount of tissue damage and bacteria burden. Oral fusidic acid 500 mg tid has demonstrated efficacy in CO. Most experts do not recommend fusidic acid in monotherapy because of development of resistance. The antibiotic can be combined with rifampin. For anaerobic, streptococcal, and staphylococcal clindamycin-sensitive osteomyelitis, bacterial protein synthesis inhibition by clindamycin 600 to 900 mg TID is an option, as is metronidazole for anaerobic

disease and quinolones for gram-negative infection. *Pseudomonas aeruginosa* and other nonfermenting gram-negative rods may rapidly develop resistance during quinolone monotherapy. Therefore, a combination with another parenteral drug for prolonged IV treatment in pseudomonal osteomyelitis would be wise, but antibiotic treatment adjusted to this situation has not been studied so far.

In acute flare-ups of CO that cannot be operated on due to various reasons (polymorbid patient, extended lesions compromising mechanical stability or gait), antibiotic therapy can aim for palliation. In these circumstances, a targeted antimicrobial therapy can be prescribed for 10 to 20 days, in order to calm down the situation, and not to cure. Hyperbaric oxygen therapy consumes very substantial resources. It provides oxygen to promote collagen production, angiogenesis, osteogenesis, and healing in the ischemic or infected wound. Several authors have suggested that adjunctive hyperbaric oxygen therapy might be useful in the treatment of human CO, even if the results are not consistent. The adjunctive role of hyperbaric oxygen in osteomyelitis is difficult to assess because of the multiple confounding variables of patient, surgery, organism, bone, and antibiotic therapy. Today, although recognized for reimbursement by some healthcare systems, the evidence base for hyperbaric oxygen therapy for diabetic foot care still remains weak.

Special features

Vertebral osteomyelitis (in conjunction with spondylodiscitis)

Apart from nosocomial infection after spine surgery, hematogenous spread is generally the most common origin of vertebral osteomyelitis and/or spondylodiscitis. The incidence is estimated at 0.2–to 2 annual cases per 100 000 patients involving mostly patients in the mid-ages with a male to female ratio of 2:1 for which the reason remains unclear. Usually, the management of a vertebral osteomyelitis is essentially conservative, but may require early drainage surgery and stabilization of the spine. The indications of surgery are failure of medical treatment, abscess formation, impending instability, or neurologic signs of spinal cord compression. The needle biopsy through CT guidance is currently the process of choice to obtain micro-biologic and histologic samples. In the absence of clinical sepsis, a second biopsy should be repeated when the first one is negative (by withholding antibiotic therapy). If the culture is still negative, most physicians propose an empirical therapy or request a surgical biopsy for diagnosis. No randomized controlled studies have evaluated antibiotic regimens for vertebral osteomyelitis. Practically, the choice of antibiotic agents is not different from any other osseous infections, except that an initial parenteral treatment of at least 3 to 4 weeks is usually suggested by experts. Prolonged antibiotic treatment beyond 4 or 6 weeks is only recommended for patients with abscesses that have not been drained.

Diabetic foot osteomyelitis

A diabetic foot problem is practically always a good example for multidisciplinary diagnosis and therapy. Suspicion of osteomyelitis is confirmed by microbiology or radiologic destruction in the case of toe osteomyelitis. Bone biopsy (with histology if sufficient material) is valuable for establishing the diagnosis and for defining the pathogenic organism(s). Concomitant treatment includes proper wound cleansing, debridement of callus and necrotic tissue, and offloading of pathologic pressure. There are no data to support the superiority of any particular route of delivery of systemic antibiotics or the optimal therapy duration. Therapy aimed solely at aerobic gram-positive cocci may be sufficient for mild to moderate infections in patients who have not recently received antibiotic therapy. Broad-spectrum empirical therapy is required in severe infections. Bioavailable oral antibiotics are sufficient in most mild and moderate osteomyelitis. In severe diabetic foot infections, antibiotics are given initially IV to achieve maximal tissue concentrations in an area already compromised by arteriopathy, although no evidence for a superiority of IV medication exists. The results of conservative therapy with prolonged courses of oral antibiotics challenge conventional advice that excision of infected bone is essential. Conservative success rates are cited as 75% and as 77% over a median period of follow-up of 2 years. However, conservative treatment might not reverse the high incidence of a second episode of osteomyelitis in a long-term follow-up, since the cause has not been removed by conservative treatment in most cases. A corrective surgery or an amputation for toe and mid-foot osteomyelitis is often indicated, providing the level of amputation does not compromise walking and does not require prostheses.

Sacral osteomyelitis

This disease is chronic and related to decubitus in patients with multiple comorbidities and/or neurologic disorders. It is particularly difficult to treat, since there is no remission if the reason for CO cannot be reversed. In these chronic decubitus patients, the infected sacral bone often cannot be excised and the patient cannot be improved neurologically. Prevention is of outmost importance. A thorough daily nursing care and debridement is the key to success. In ameliorated cases, plastic surgeons may graft on the naked bone. The ideal duration of antibiotic administration is unknown. The aim is not to eradicate bone infection, but to control it. More data are needed in this field of osteomyelitis.

Jaw osteomyelitis

Chronic mandibular osteomyelitis occurs after dental procedures, trauma, or in very poor settings of noma disease. There has not been much research in the past. The causative pathogens are often polymicrobial and stem from the oral flora. *Actinomyces* spp. are particular pathogens that may mimic neoplasm. Treatment consists of maxilla-facial surgery, often repeated, and of long-lasting oral antibiotic therapy for which the choice of amoxicillin–clavulanate covers the majority of the oral flora.

Clinical follow-up during therapy

Osteomyelitis patients must be regularly followed up throughout the treatment, for early detection of complications, adverse events, and control of wounds. A substantial quality improvement of care would be the use of diagnostic imaging to judge how long therapy

remains necessary; for example by repeated positron emission tomography (PET) scans (which has to be investigated yet). Indeed, the duration of antibiotic administration for CO is usually decided from the start and kept thereafter; independently of the individual case and markers. C-reactive protein (CRP) is widely used in the follow-up of patients with localized bone and implant infections, but trauma or surgery may result in its transient elevation. Indeed, many CO cases have a normal CRP level even before treatment.

Particularities of pediatric osteomyelitis

As a general principle, pediatric AO and CO cases are similar to those of adults. However, epidemiologically speaking, there are more primary AO than among adults, affecting 8 per 100 000 children, predominantly boys. The long bones are most frequently infected. CO of the adult may originate several years after bone contamination from an infant AO source, e.g. after bone trauma in childhood. Primary AO is mainly due to *S. aureus* (70% to 90% of cases), and rarely due to other pathogens, with one exception: *Kingella kingae* is a pathogen mostly encountered in osteoarticular infections among infants around 3 to 6 years of age. Specific PCR for *K. kingae* detection is available. *Haemophilus influenzae*, another infant pathogen, is much rarer, and declined considerably after the implementation of vaccination programs all around the world.

In terms of therapy, most infant AO cases are hematogenous without sequestrae. These cases can usually be treated without surgical debridements purely conservatively, while the duration is shorter than for adult disease. Indeed, review suggests that early transition from intravenous to oral therapy, after 3 to 4 days in patients responding well, followed by oral therapy to a total of 3 weeks may be as effective as longer courses for uncomplicated AO. This recommendation does not apply to neonates. The choice of the antibiotic agents is similar to that for adults, with a few exceptions that should be avoided (according to the manufacturer) among infants: quinolones and tetracyclines.

Outcome of treatment

Many experts advocate that if the bone is infected, it may remain infected throughout the life and even beyond, unless amputation is performed. Recurrences of osteomyelitis after several years, if not decades, have been reported and there is no internationally accepted minimal follow-up duration. Some authors suggest that "arrest" or "remission" is a more appropriate term than "cure" for defining outcome in CO. According to current literature, remission is "defined" as the resolution of all signs and symptoms of active infection after a minimal follow-up period of 1 to 2 years. Generally, remission rates for CO among adults oscillate between 40% and 90% with a peak of success around 80%, almost independently of the surgical technique, the duration of intravenous or total antibiotic therapy, or the causative pathogen.

Future

The future will probably provide a firm place in the antibiotic armamentarium for some of today's investigational agents such as dalbavancin, telavancin, and other compounds under development. It should not be forgotten that most, if not all, new molecules might be equivalent to established antibiotics in terms of remission rates in vivo. Additional prospective trials need to be performed before innovative approaches are proposed. As an example, bacteriophage therapy is a challenging approach and may prove to be superior to established combined antibiotic therapies. Finally, it is very difficult to evaluate osteomyelitis in small clinical studies or single centers. Sample size and international definitions need to be improved. Hopefully, future data will be collected from prospective and multicenter human cohort studies.

Polyarthritis

Kathryn H. Dao and John J. Cush

The co-occurrence of fever and arthritis educes a broad set of diagnostic considerations, especially infection. Yet most forms of infectious arthritis typically involves one to three joints (monarthritis to oligoarthritis). The presence of a greater number of joints involved (polyarthritis) with fever evokes a more unusual and challenging range of diagnostic possibilities. Knowledge of prevalent forms of polyarthritis capable of fever can facilitate an early, accurate diagnosis and appropriate therapy.

Polyarthritis is defined as inflammatory pain with swelling affecting four or more joints. The distribution, chronology of joint inflammation, and host factors (e.g., demographics, comorbidities, geography) help refine the diagnostic possibilities. The presence of fever is unique as most polyarticular conditions do not manifest substantial or sustained fever. Nevertheless, fever or pyrexia is further evidence of an inflammatory, infectious, or autoimmune disorder. This chapter examines the diagnostic approach to polyarthritis and pyrexia.

History and physical exam

The diagnosis of any disease relies heavily on the history and physical examination. Eliciting an accurate history will identify those who are at risk for significant morbidity and mortality. The goals of the encounter are to (1) relieve symptoms, (2) identify and treat the underlying disease, and (3) avoid irreversible organ damage. Characteristics distinguishing arthritis from arthralgia include warmth, erythema, swelling, or joint effusion localized to the joint capsule. Inflamed joints often will have restricted range of motion (or contracture), muscle strength weakness, and limited function. The key diagnostic elements from the history and physical exam are algorithmically portrayed in Figure 71.1.

Demographics

Age, sex, and geography are important clues. Gout and reactive arthritis (ReA) are more common in men. Rheumatoid arthritis (RA) and systemic lupus erythematosus (SLE) are more prevalent in women. Septic arthritis is more likely in the young, elderly, and immunosuppressed. Giant cell arteritis (GCA) is unlikely in patients <50 years. Opportunistic infections, parasites, and chikungunya fever should be considered in travelers with fever and polyarthritis.

Symptom onset

It is important to acknowledge how and under what circumstances symptoms first manifest. Provocations, such as antecedent infection, drugs, trauma, or travel should be identified. Abrupt onset of symptoms, occurring in hours/days, may indicate infection or gout/pseudogout. ReA or parvovirus infection should be considered in a patient who initially presents with a viral illness then develops acute oligo- or polyarthritis.

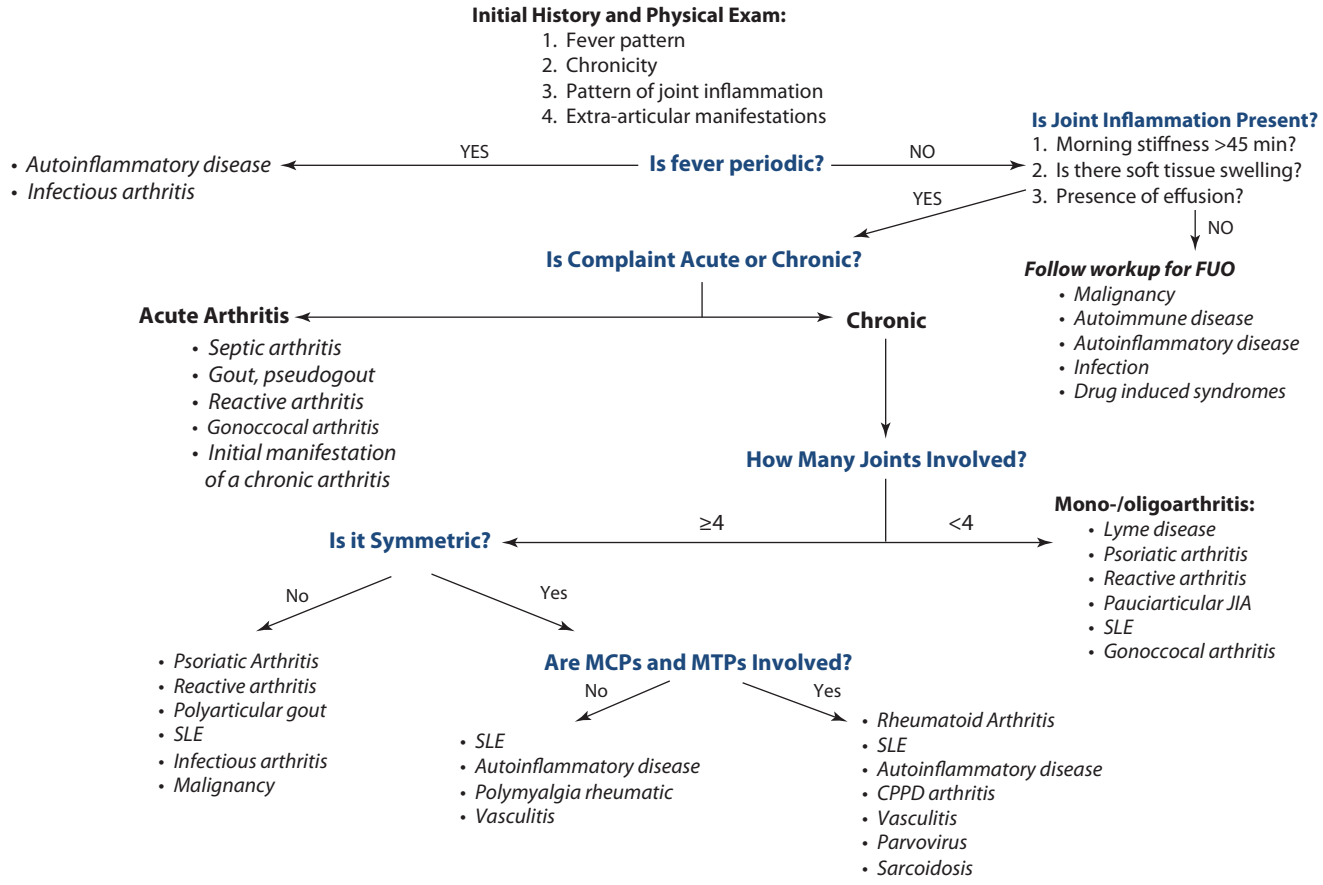

FIGURE 71.1 Algorithm for assessing fever and polyarthritis.

CPPD, calcium pyrophosphate dihydrate; FUO, fever of unknown origin; JIA, juvenile idiopathic arthritis; SLE, systemic lupus erythematosus.

Arthritis lasting ≥12 weeks indicates a chronic disorder, such as autoimmune disease, chronic infection, or malignancy.

Pattern of joint involvement

Observe the number, location, and symmetry of joint involvement. Acute monarthritis is common in patients with ReA, septic arthritis, and gout, whereas a chronic monarthritis should be considered to be tuberculous, fungal, or neoplastic in origin. In contrast, patients who have diffuse symmetrical polyarticular involvement (e.g., hands, wrists, shoulders, knees, ankles) are likely to have a chronic systemic disease such as SLE, chronic viral infections, or RA. Spinal involvement may be a manifestation of tuberculous infections or a spondyloarthritis. Shoulder and hip girdle pain with high inflammatory markers should alert the consideration of polymyalgia rheumatica (PMR) or septic arthritis.

The timing of joint involvement is also useful. Varying patterns of presentation have been described, including *intermittent/episodic pattern* with flares punctuated by periods of complete remission (e.g., gout, pseudogout, autoinflammatory diseases), *additive pattern* where symptoms begin with a few joints and progress to involve more joints with time (e.g., RA, SLE, hepatitis B, parvovirus), or *migratory pattern* where certain joints are affected for a time then remit, only to reappear elsewhere in other joints (e.g., gonococcal arthritis, acute rheumatic fever).

Fever pattern

Fever is a nonspecific significant feature of inflammation driven by a specific immune, infectious, or noxious stimuli. Fever can manifest in patterns that may suggest certain diagnoses and can be described as continuous or sustained, intermittent, relapsing, periodic (e.g., quotidian, tertian, quartan), spiking, or low-grade. Studies have examined the significance of fever pattern and found that few fever curves convey any significance.

Most drug reactions, vasculitides, and viral infections present with continuous fevers; the double quotidian fever curve with spikes twice a day has been associated with visceral leishmaniasis (kala-azar) and malarial infections. Patients with systemic-onset juvenile idiopathic arthritis (soJIA) or adult-onset Still's disease (AOSD) display quotidian (or double-quotidian) fever that is truly circadian, occurring at the same hour each day (usually late afternoon or evening). The magnitude of fever has not been shown to correlate with the degree of disease severity; however, infectious etiologies should

be strongly considered in patients with temperatures of >38.9°C/102°F. Despite extensive research on the topic of fever and fever patterns, their predictive value is often less than stated in textbooks.

Differential diagnoses for polyarthritis and fever

Most causes of polyarthritis and fever can be classified into one of the following categories: infection, rheumatologic diseases (e.g., autoimmune, autoinflammatory, and crystalline diseases), or neoplastic illness (Box 71.1). While literature reviews indicate infections account for the majority of fevers of unknown origin (FUO), rheumatologic diseases and malignancies each account for a minority (~20% to 25%) of cases.

Pyrexia and polyarthritis may become an issue in patients with an *existing* rheumatic disorder who are hospitalized for (1) fever, (2) musculoskeletal trauma, (3) a new medical comorbidity (e.g., infection, neoplasm), or (4) disease flare. Importantly, rheumatic patients are less likely to be admitted for their rheumatic disease, but they are much more likely to be hospitalized for a new medical problem, comorbid condition, or complication of drug therapy.

Infections

Bacteria, viruses, and atypical microorganisms can cause polyarthritis directly as a pathogen (e.g., tuberculous arthritis) or indirectly through an immune-mediated response (e.g., reactive arthritis with *Chlamydia*, *Yersinia*, *Salmonella*, *Shigella*, *Campylobacter*, *Ureaplasma urealyticum*, and *Clostridium difficile*). Septic arthritis can result from hematogenous seeding of the synovial membrane due to bacteremia, direct introduction from a penetrating trauma (e.g., animal bite or joint injection), or extension from a contiguous focus of infection. Chapter 68, "Infection of native and prosthetic joints," details further information on evaluating the septic joint. It is estimated that 20% of septic arthritis will have a polyarticular presentation that may be severe and more likely in the immunosuppressed.[1] Other risk factors for developing polyarticular septic arthritis include corticosteroid use, age, prior septic arthritis, diabetes, chronic renal or hepatic disease, gout, and RA.

Microbes commonly cultured directly from infected joints have included staphylococci, streptococci, enterococci, *Neisseria* spp., *Borrelia* spp., and gram-negative bacilli. While conventional cultures from joint tissue or fluid are considered the gold standard in detecting septic arthritis, the16S rRNA gene PCR combined with sequencing (16SPCR) method is finding a place in clinical practice, particularly in detecting prosthetic joint infections.[2] The rationale of using 16SPCR is that the16S ribosomal subunit is conserved in all bacterial ribosomal genes (rDNA); real-time polymerase chain reaction (rt-PCR) followed by DNA sequencing will allow the detection, amplification, and identification of any bacterial DNA in the sample. Conventional cultures may be difficult to interpret, and they have poor specificity in distinguishing contaminants in tissue specimens; rates of false positives and false negatives are high especially with a single sample obtained during a surgery or if patients have been treated with empiric antibiotics.[3]

BOX 71.1

Differential diagnoses of polyarthritis and fever

Infections
- Bacterial endocarditis
- Staphylococcal infections
- Streptococcal infections
- *Escherichia coli* infections
- *Pasteurella* spp.
- Gonococcal and meningococcal infections
- Brucellosis
- *Streptobacillus moniliformis*
- Parvovirus B19
- Viral hepatitis
- Cytomegalovirus
- Epstein–Barr virus
- Human immunodeficiency virus
- Enteroviruses
- Chikungunya and other alphaviruses
- Rickettsial infections
- Secondary syphilis
- Tuberculosis
- Atypical mycobacterial infections
- Fungal infections

Autoimmune diseases
- Systemic lupus erythematosus
- Rheumatoid arthritis
- Vasculitis (e.g., MPA, GCA, GPA)
- Reactive arthritis (from prior exposure to: *Chlamydia, Yersinia, Salmonella, Shigella, Campylobacter, Ureaplasma urealyticum*, and *Clostridium difficile*)
- Sarcoidosis

Autoinflammatory diseases
- Adult onset Still's disease (AOSD)
- Systemic-onset juvenile idiopathic arthritis (SoJIA)
- Muckle–Wells syndrome (MWS)
- Familial Mediterranean fever (FMF)
- Tumor necrosis factor receptor-associated periodic syndrome (TRAPS)
- Behçet's
- Crystalline diseases (gout, CPPD, calcium hydroxyapatite)

Malignancies
- Lymphoma
- Leukemia
- Paraneoplastic syndromes
- Multiple myeloma
- Solid tumors ± metastases

Miscellaneous
- Serum sickness
- Thyrotoxicosis
- Rheumatic fever
- Cryoglobulinemia
- Drug-induced syndromes
- Poststreptococcal arthritis
- Cryoglobulinemia

Abbreviations: MPA = microscopic polyangiitis; GCA = giant cell arteritis; GPA = granulomatous polyangiitis; CPPD = calcium pyrophosphate dihydrate.

Multiple tissue sampling may improve the predictive value of the cultures,[4] but the advantages of 16SPCR are many, including (1) rapid results, usually within 24 hours; (2) greater specificity than conventional cultures; (3) the ability to detect infection in a single sample rather than having to have multiple samples; and (4) the capacity to identify infection even in patients who have been on empiric antimicrobial therapy. 16SPCR should be consider a tool to complement routine cultures. When cultures of microorganisms are unsuccessful, rt-16SPCR has proved helpful. Rt-PCR has improved sensitivity in detecting *Borrelia burgdorferi* in synovial fluid of patients with Lyme arthritis where serologic bands for Lyme disease have been nondiagnostic; in addition, it also has been used to diagnose *Tropheryma whipplei* (Whipple's disease) in elderly white males who present with weight loss, fever, arthritis, and gastrointestinal symptoms.

Viruses also have been linked to polyarthritis, including parvovirus B19, mumps, rubella, hepatitis B and C viruses, cytomegaloviruses, Epstein–Barr virus, HIV, enteroviruses, and insect-transmitted arboviruses. In some patients, a detailed travel history will guide the diagnostic considerations and specific testing needed to detect these infections. Severe cases of debilitating polyarthritis have been associated with the alphaviruses: Chikungunya, Zika, O'nyong-nyong virus, Sindbis virus, Ross River virus, and Mayaro virus.[5] Due to global expansion and urbanization, these viruses have been able to travel with their vectors to new geographic locations and are now considered a growing threat to developed countries. Patients infected by these viruses can develop chronic rheumatic manifestations that persist for months to years.

For example, Chikungunya and Zika viruses share the common mosquito vector, *Aedes aegypti*; both may cause fever, rash, and polyarthritis and tend to be reported among those dwelling in or visiting the Caribbean and tropics. Chikungunya characteristically causes fever >39°C/102°F, headache, myalgia, rash, and severe joint pain that may become a chronic polyarthritis resembling seronegative RA. Similarly, the onset of a Zika infection may herald symptoms of fever, rash, arthritis, myalgias, and conjunctivitis, yet prolonged fevers and polyarthritis are less likely.

Autoimmune and autoinflammatory diseases

Endogenous pyrogens released by an aberrant immune system drive the pathology in autoimmune and autoinflammatory diseases. SLE, sarcoidosis, and vasculitis are examples of autoimmune diseases manifesting with polyarthritis and fever, but rarely does RA present with fever. Typically, other clues are present suggesting an autoimmune diagnosis. Patients with SLE may have a history of a photosensitive rash, alopecia, or serositis. In sarcoidosis, fever may accompany the triad of arthritis, erythema nodosum, and hilar adenopathy (Löfgren syndrome) or have features of uveitis or parotitis. Granulomatosis with polyangiitis (GPA), polyarteritis nodosa (PAN), and other vasculitides often present with malaise, weight loss, or upper or lower respiratory or renal manifestations, at times with multiorgan involvement.

In most autoimmune diseases, fever is low grade (e.g., <38°C/100°F) and indolent, in contrast to the *autoinflammatory* diseases where fever is impressive (e.g., ≥39°C/102°F) and recurrent. High-titer autoantibodies and antigen-specific T cells that are typically absent in autoinflammatory diseases are prominent features with autoimmunity.

Familial Mediterranean fever (FMF), tumor necrosis factor (TNF) receptor-associated periodic syndrome (TRAPS), and Still's disease (including both soJIA, and AOSD) are but a few examples of the autoinflammatory diseases. Among these, Still's disease is the most common autoinflammatory and autoimmune cause of FUO). Most autoinflammatory disorders have unprovoked, recurrent episodes of fever, serositis, arthritis, and cutaneous inflammation resulting from specific genetic mutations affecting the innate immune system. In cryopyrin-associated periodic syndromes (CAPS), which include familial cold autoinflammatory syndrome (FCAS) and Muckle–Wells syndrome (MWS), mutations in the NLRP3 gene affect components of inflammasomes (e.g., cryopyrin) which are important in recognizing microbial products and endogenous danger signals. Interestingly, recent evidence suggests genes in the same NLR family may be implicated in gout.

Gout and crystalline diseases

Polyarticular gout and pseudogout may manifest high fevers during acute attacks of monarticular or polyarticular gout. The frequency of fever during gout attacks is unknown but is unlikely to affect the majority of patients. Distinguishing between septic arthritis and acute gout is difficult in some: both may present as acute monarthritis with fever and have a similar laboratory profile (extreme neutrophilia, high acute phase reactants), and both may coexist in the same patient simultaneously. An accurate diagnosis may be confounded because up to 50% of gout patients can have a normal serum uric acid level during the acute attack. Synovial fluid analysis can identify crystals, but empiric antibiotics may still be necessary until Gram stain/cultures are reported. While gout tends to manifest as podagra or as a lower extremity monarticular or oligoarticular arthritis, those with arthropathy from calcium pyrophosphate dihydrate (CPPD) may present with acute oligoarticular or polyarticular upper extremity and lower extremity disease. Sometimes, pseudogout may declare as a chronic seronegative inflammatory polyarthritis with chondrocalcinosis confirmed by positively birefringent rhomboid crystals. Patients presenting with crowned dens syndrome (CDS) related to calcium hydroxyapatite crystal deposition (CPPD) in the periodontoid ligaments of the atlas can exhibit high fever, severe occipital headache, and neck stiffness that mimic aseptic meningitis.

Malignancy

Paraneoplastic syndromes with rheumatologic features have been described in most cancers. Lupus-like syndromes with fever, arthritis, and rash have been associated with ovarian cancer, breast cancer, and hairy cell leukemia. PMR symptoms have been described with multiple myeloma and solid tumors. Carcinomatous polyarthritis is often confused with RA but generally has an explosive onset and asymmetric disease pattern. Rheumatic symptoms may coincide or antedate the diagnosis of malignancy. Typically, paraneoplastic manifestations do not respond to standard rheumatologic doses of

steroids or disease-modifying agents but will resolve as the underlying cancer is treated.

The urgency to distinguish a rheumatic condition from malignancy is paramount in children. Seventy-five percent of childhood acute lymphoblastic leukemia (ALL) will present with fever and musculoskeletal pain before blasts appear in the peripheral smear. Several studies examined the predictive factors for malignancies versus JIA based on clinical and laboratory data in children with musculoskeletal pain. Highly predictive factors for malignancy were elevated lactate dehydrogenase (LDH), anemia, and neutropenia. An increased LDH greater than twofold was found exclusively in children with malignancies. Musculoskeletal pain was observed at similar frequencies in children with JIA and neoplasia, though fever tended to be recurrent in those with malignancy.

Drug-induced syndromes

Certain medication adverse effects manifest as a musculoskeletal complaint with fever. Best characterized are medications that can cause drug-induced lupus, such as hydralazine, procainamide, isoniazid, propylthiouracil, sulfonamides, quinidine, TNF inhibitors, and minocycline. Symptoms may include joint/muscle pain, fever, skin rash, pleural disease, and cytopenias which can appear weeks to months after exposure to the offending drug; remission will occur upon withdrawal of the agent.

The advent of a novel class of chemotherapy, the immune checkpoint inhibitors (i.e., ipilimumab, nivolumab, pembrolizumab, etc.), has resulted in a new syndrome and wide array of immune-related adverse events (irAEs). Drug-related irAEs may manifest as musculoskeletal symptoms (arthralgias, myalgias, arthritis), rheumatic conditions (seronegative RA, psoriatic arthritis, PMR, myositis, Sjögren's syndrome, GPA, lupus), or other organ disease (colitis, thyroiditis, pneumonitis, hypophysitis, neuropathy), but are uncommonly febrile.[6]

Laboratory tests and radiologic investigations

Routine labs

While the erythrocyte sedimentation rate (ESR) and C-reactive protein (CRP) provide surrogate measures of inflammation, they do not discriminate well between infection, rheumatologic diseases, or malignancy. Other laboratory measures often are used to suggest the diagnosis. Patients with soJIA or AOSD often have high ferritin and abnormal liver function tests. SLE may manifest with hypocomplementemia, lymphopenia, and thrombocytopenia. A low haptoglobin with elevated LDH may suggest hemolysis, but high elevations in LDH should be investigated further and malignancy excluded, particularly in children or patients with concomitant weight loss, fever, and lymphadenopathy. Blood cultures are important in endocarditis and systemic infection due to bacteria and fungi.

Serologies

Autoantibodies are found in various autoimmune diseases. The presence of the rheumatoid factor (RF) and antinuclear antibody (ANA) are nonspecific and can be seen in patients with infection, malignancy, and rheumatologic disorders. Other serologic markers offer better specificity and diagnostic utility. The anti-citrullinated peptide antibodies (anti-CCP) carry the same sensitivity as RF for RA, but with better specificity (>90%). When present with the RF, the anti-CCP has a positive predictive value for RA of >99%. The cytoplasmic antineutrophil cytoplasmic antibody (c-ANCA) is also highly specific; its presence indicates GPA; similarly, double-stranded DNA and anti-Smith antibodies are specific for SLE. Antibodies against microbial antigens should be obtained when suspicion is high for infection based on contact or travel history. Relevant assays available to evaluate for infections causing fever and polyarthritis include serologies to parvovirus B19, cytomegalovirus, hepatitis B and C, streptolysin O, *Borrelia* spp., and *Brucella* spp. Further information about testing for these infections is covered in other chapters.

Synovial fluid analysis

Arthrocentesis with synovial fluid analysis is a useful adjunct to diagnosing patients and relieving symptoms. Evaluation of synovial fluid should include cell count, crystal analysis, and Gram stain/cultures for routine and atypical (e.g., acid-fast bacilli, fungi, spirochetes, gonococci) microorganisms. Inflammatory fluid is usually yellow and turbulent; white blood cell counts (WBC) range from 5,000 to 50,000 cells/mm^3, with predominance in neutrophils. In the presence of infection or gout, WBC may exceed 50,000 cells/mm^3. Synovial fluid from septic arthritis and gout generally has a higher percentage of neutrophils (>85%) compared to other inflammatory arthritides. Prompt evaluation under polarized microscopy will maximize the yield for crystal identification. Consider obtaining a 16SPCR on tissue or synovial fluid specimens in patients with suspected joint infections but in whom routine cultures are negative.

Radiography

Radiographic changes early in disease often are absent, but sometimes characteristic x-ray findings of inflammatory arthritis are found: soft-tissue swelling, joint effusion, juxtaarticular osteopenia, joint space narrowing, chondrocalcinosis, and bony erosions. Identification of these abnormalities is important as studies have shown that radiographic damage correlates with loss of productivity and increased disability.

Other imaging modalities such as MRI and ultrasound (US) have proved sensitive for detecting synovitis, abscesses, and vasculitis where clinical exam and conventional x-rays have failed. Their advantages include the ability to detect subtle inflammatory abnormalities as well as permitting more accurate placement of the needle in diagnostic arthrocentesis or tissue biopsy. Before ordering any tests, the potential benefits should be weighed against limitations of long examination times, availability of equipment, costs, and skills of the observer to interpret pathology.

Overreliance on laboratory testing to establish a diagnosis is ill-advised; the strength of laboratory testing and imaging is greatly enhanced when they are used to confirm a reasonably strong clinical suspicion garnered from the history and examination.

Conclusion

Fever and joint inflammation pose a diagnostic challenge as infection, rheumatologic disease, and malignancy can present similarly. Assess the demographics, chronology, and pattern of fever and joint involvement when formulating a differential diagnosis. Prompt evaluation, early referral, and expedient initiation of therapy are paramount to reducing morbidity and mortality associated with polyarthritis and pyrexia.

Infectious polymyositis

Shanthi Kappagoda and Upinder Singh

Infectious polymyositis is a rare entity in which there is generalized muscle damage (rhabdomyolysis) caused by an infectious agent. The syndrome of rhabdomyolysis results from muscle necrosis and is characterized by muscle pain, elevated serum creatinine phosphokinase (CPK) concentrations, and myoglobinuria, which may lead to renal dysfunction. The muscle injury in rhabdomyolysis occurs in a generalized pattern and lacks the specific focus of infection as seen in pyomyositis. The entity of pyomyositis is discussed in "Chapter 22, Deep soft-tissue infections: Fasciitis and myositis."

A variety of factors can lead to rhabdomyolysis. These include crush and compression injuries, drug and alcohol ingestion, metabolic and electrolyte disturbances, hypothermia and hyperthermia, envenomation, and a variety of infections. This review focuses on infectious causes of rhabdomyolysis. It is important to distinguish rhabdomyolysis caused by a pathogen from that caused by sepsis, hypotension, or electrolyte imbalances that accompany a severe systemic infection.

Viral infections

The wide spectrum of viral infections that have been reported to cause rhabdomyolysis are listed in Box 72.1. Influenza is the most common viral cause of rhabdomyolysis, followed by HIV and enteroviral infection. Whether the higher incidence with influenza results from a predilection of the virus for muscle tissue or from the more frequent reporting due to physician awareness and ease of diagnosis is unclear. Pandemic H1N1-induced rhabdomyolysis was not clearly associated with an increased incidence or severity when compared to seasonal influenza A; however, patients with higher CPK levels fared worse and had longer ICU stays.

Renal dysfunction in rhabdomyolysis secondary to influenza infection is common and not related solely to the level of CPK elevation. The precise mechanism predisposing to renal damage from influenza-induced rhabdomyolysis is unclear; however, aggressive measures should be taken to preserve renal function in these individuals.

Rhabdomyolysis adds to the spectrum of clinical presentations of HIV infection. Many musculoskeletal syndromes associated with HIV infection have been documented, ranging from myopathy to rhabdomyolysis. Muscle damage can occur in a variety of clinical scenarios in association with HIV infection, including acute seroconversion and antigenemia, end-stage disease with myopathy, and myositis resulting from medication side effects. Muscle biopsies of patients with HIV-induced rhabdomyolysis reveal a nonspecific inflammatory myopathy with focal necrotic areas and regenerating fibers.

The precise pathophysiology underlying virus-induced rhabdomyolysis is unknown; however, three mechanisms have been postulated: direct viral invasion, toxin generation, or an autoimmune response to the virus. Some authors have suggested that direct viral invasion of muscle fibers causes muscle necrosis. Data to support this hypothesis include the identification of viral inclusions, viral DNA, and the isolation of viruses in tissue culture from the muscles of infected patients. In addition, electron microscopy has identified viral particles, and biopsies reveal a lymphocytic infiltrate in the infected muscles. This evidence strongly suggests

BOX 72.1

Viral causes of rhabdomyolysis

Seasonal influenza virus A and B
Influenza A H5N1 (avian) and HINI (swine)
Human immunodeficiency virus
Coxsackievirus
Herpesviruses (HSV, VZV, CMV, EBV, HHV-6)
Echovirus
HTLV-1
Adenovirus
Parvovirus B19
Parainfluenza virus
RSV
Mumps
Measles virus
Hepatitis B and C
Severe acute respiratory syndrome (SARS)-associated coronavirus
Flavivirus (dengue virus; West Nile virus)
Chikungunya virus
Rotavirus
Ebola virus

Abbreviations: HSV = herpes simplex virus; VZV = varicella-zoster virus; CMV = cytomegalovirus; EBV = Epstein–Barr virus; HHV-6 = human herpesvirus 6; HTLV-1 = human T-lymphotropic virus 1; RSV = respiratory syncytial virus.

that direct viral invasion may have a causative role in precipitating rhabdomyolysis. However, various reports documenting normal muscle biopsies or hyaline degeneration and myonecrosis but no viral particles by immunofluorescence and electron microscopy are used to refute this theory. Biopsies of clinically affected musculature that are essentially normal raise the possibility of a circulating "toxin" or cytokine causing rhabdomyolysis. However, to date, no putative toxins have been isolated.

Bacterial infections

Many bacterial agents have been reported to cause rhabdomyolysis (Tables 72.1 and 72.2). The most common associations are with *Legionella* spp., followed by *Streptococcus* spp., *Francisella tularensis*, and *Salmonella* infections. An increasing number of bacterial agents are being associated with this entity due to better diagnostic techniques, an increasing population of immunocompromised individuals, and increasing physician awareness. Individuals with bacterial infections resulting in rhabdomyolysis have significant morbidity (57% with renal failure in one study) and mortality (38% in one series).

Two proposed mechanisms of muscle injury by bacteria include toxin generation and direct bacterial invasion. *Legionella* is believed to release an endotoxin or exotoxin that causes rhabdomyolysis.

TABLE 72.1 **BACTERIAL CAUSES OF RHABDOMYOLYSIS**

Gram-positive bacteria	Gram-negative bacteria
Streptococcus pneumoniae	*Legionella* spp.
Staphylococcus aureus	*Francisella tularensis*
Group B streptococcus	*Salmonella* spp.
Streptococcus pyogenes	*Vibrio* spp.
Listeria spp.	*Brucella* spp.
Staphylococcus epidermidis	*Escherichia coli*
Bacillus spp.	*Pantoea agglomerans*
Clostridium spp.	*Klebsiella* spp.
Viridans streptococci	*Aeromonas* spp.
Streptococcus suis	*Haemophilus influenzae*
β-hemolytic streptococci	*Neisseria* spp.
Streptococcus gallolyticus	*Coxiella burnetii*

Biopsies that are negative for the organism by immunofluorescence support this hypothesis. Organisms such as *Streptococcus* and *Salmonella* cause muscle damage by direct bacterial invasion as well as by decreasing the oxidative and glycolytic enzyme activity of skeletal muscle and activating lysosomal enzymes. A number of bacterial pathogens, including *Staphylococcus aureus, Streptococcus pyogenes, Vibrio* spp., and *Bacillus* spp., have been demonstrated in muscle biopsy specimens, lending credence to the hypothesis of direct bacterial invasion. Rickettsial illnesses such as Rocky Mountain spotted fever can cause muscle injury through vasculitis as well as direct muscle invasion. A variety of cytokines, such as tumor necrosis factor-α and interleukin-1, released during systemic infections from a broad range of infections, can result in skeletal muscle proteolysis.

Fungal, parasitic, and mycobacterial infections

While fungal myositis with the rare progression to rhabdomyolysis is uncommon and occurs primarily in the immunocompromised host, there are a variety of parasitic infections known to cause myositis that may progress to rhabdomyolysis even in the normal host. In particular, organisms such as *Trichinella* that encyst in muscle following initial infection may result in severe myositis depending on the initial organism burden. This classically occurs in the extraocular muscles but can progress to other striated muscles and result in severe muscle weakness. *Plasmodium falciparum* has been linked to myositis with severe rhabdomyolysis resulting in renal failure with higher frequency than in the non-falciparum strains. Muscular complications of *Mycobacterium tuberculosis* and nontuberculosis mycobacterial infections are uncommon and most often are the result of contiguous spread of *M. tuberculosis* to the psoas muscles from vertebral osteomyelitis (Tables 72.2 Boxes 72.2, 72.3).

Russell's viper	Hornets
Pit vipers including *Protobothrops flavorviridis*	Wasps
Taipan	Desert centipede

Envenomations and drug toxicity

Envenomations reported to cause rhabdomyolysis are listed in Box 72.3. Snake bites are commonly reported to cause muscle injury and include bites inflicted by, among others, the Mojave rattlesnake, Russell's viper, *Crotalus durissus terrificus* (South American rattlesnake), Australian snake, tiger snake, and seasnake. These patients present with swollen, tender muscles and high CPK levels. In contrast to viral and bacterial causes of rhabdomyolysis, envenomations generally cause a larger myotoxic insult. A large proportion of these patients also subsequently develop acute renal failure, presumably directly related to the increased renal toxicity from myoglobin. Spider bites of the brown recluse spider (loxoscelism) and the widow spiders (latrodectism) are also associated with rhabdomyolysis. The mechanism of muscle damage in these cases appears to be a direct myotoxic activity of the various venoms.

It is also important to remember the role of drugs, including antimicrobials, when evaluating the cause of rhabdomyolysis. Daptomycin is the most widely known drug with this side-effect profile; however, a multitude of other antimicrobials have been linked to rhabdomyolysis. Box 72.4 lists some of these agents.

Renal failure in rhabdomyolysis

The renal dysfunction associated with rhabdomyolysis arises from a variety of interrelated factors. In muscle injury, both myoglobin and heme proteins are released, although neither is directly toxic to the glomerulus. Heme protein can result in renal tubular injury through a variety of mechanisms: (1) renal vasoconstriction, (2) direct renal tubular cell cytotoxicity, or (3) intraluminal cast formation and tubular obstruction. Therapeutic measures that increase renal blood flow and decrease tubular obstruction are useful in preventing renal injury in these patients.

BOX 72.4

Antimicrobials and rhabdomyolysis

Daptomycin
Raltegravir
Bactrim
Colistin
Fluoroquinolones
Linezolid
Fusidic acid
Clarithromycin
Voriconazole

Therapy and management

The general management of rhabdomyolysis includes supportive care and treatment of the underlying predisposing condition or infection. The general approach is as follows: (1) maintenance of a high degree of suspicion for rhabdomyolysis in the appropriate clinical setting; (2) appropriate diagnostic workup, including CPK levels, urinalysis, and urine myoglobin levels; (3) rapid institution of organism-specific drug therapy; and (4) supportive renal care. Renal function can be protected by maneuvers such as volume expansion and possibly urine alkalinization. Other metabolic disturbances resulting from muscle injury, such as hyperkalemia and metabolic acidosis, also may need specific therapy.

Iliopsoas abscess

Larson Erb and Pamela A. Lipsett

Overview

Iliopsoas abscess (IPA) is a rare condition defined by a collection of purulence in the iliopsoas muscle compartment. IPA is classified in two distinct varieties based on the etiology of the disease. IPA can be either *primary* wherein the infection spreads via a hematogenous or lymphatic route, or *secondary* when it is a contiguous extension of another infection, most often musculoskeletal, intra-abdominal, or genitourinary.

Symptoms can consist of a classic triad of back/flank pain, fever, and a limp on ambulation (flexion deformity); however, all three are rarely present and more generalized symptoms of malaise and weight loss may be present. The common presentation with more vague and general symptoms often leads to a delay in diagnosis and treatment that significantly worsens associated morbidity and mortality. Early and effective management is key to a successful recovery.

While IPA classically is associated with *Mycobacterium tuberculosis* infection, in actual practice it is much more frequently related to *Staphylococcus aureus* in primary IPA, often with methicillin-resistant strains (MRSA). Secondary IPAs are more frequently associated with enteric organisms that have extended outside the gastrointestinal or genitourinary tract.

Anatomy

The iliopsoas muscle group is comprised of two distinct muscles, the iliacus and the psoas major. Their function is as primary hip flexors. An additional accessory psoas muscle may be present in anywhere from 10% to 65% of the population. The iliacus muscle inserts along the superior portion of the iliac fossa, passes under the inguinal ligament, and inserts onto the lesser trochanter of the femur. The psoas major arises from the spinal processes between T12 and the five lumbar vertebrae and passes along the retroperitoneum and under the inguinal ligament where it ultimately inserts onto the lesser trochanter as well. Due to their common tendinous insertion on the lesser trochanter they are frequently grouped together as a single iliopsoas muscle; however, when considering IPA pathology it is likely best to consider them as two distinct structures with different pathologies and outcomes depending on location of infection. The psoas fascia invests the muscle group and runs from the lumbar vertebrae to the iliopubic eminence.

The blood supply of the two groups differs, with the supply for the psoas major derived from four lumbar arteries with outflow via lumbar veins. The iliacus is supplied by the medial circumflex femoral artery and the iliac branch of the iliolumbar artery. Both have a rich blood supply and are adjacent to the retroperitoneal lymphatics which may contribute to *primary* IPAs. The nerve supply of the psoas major is via the lumbar neural plexus from L1 to L3, and the iliacus is innervated by L2, L3, and branches of the femoral nerve.

As a group, the iliopsoas is in close proximity to the colon, appendix, kidneys, ureters, quadratus lumborum, and the transverse spinous processes of the lumbar vertebrae. All of these may be sources of contiguous infection leading to *secondary* IPA (Figure 73.1).

FIGURE 73.1 Coronal views of a CT scan with oral and intravenous contrast agents demonstrating a left-sided iliopsoas abscess. The patient suffered multiple gunshot wounds to the abdomen. Contrast is seen within the psoas, and the distal ureter is visualized. A collection in the left upper quadrant with air bubbles but no contrast is seen beneath the gastric bubble.

Etiology

Primary IPA occurs when a distant infection seeds to the iliopsoas via hematogenous or lymphatic spread. This typically results from intravenous drug use (IVDU), neoplasms, immunodeficient states, and chronic immunosuppressive disease states such as renal failure or diabetes mellitus. Primary IPA is more frequently the source in bilateral infections. Other sources of primary IPA include endocarditis, infected aortic aneurysms, infected vascular grafts, and femoral artery catheterization. In short, in populations at risk of circulating microbes, IPA is a potential infection.

Secondary IPA represents a contiguous extension of another infection into the iliopsoas muscle group. Previously these were primarily thought to occur from gastrointestinal disease such as fistulizing Crohn's disease, diverticulitis, or a perforated cancer. Newer case series, however, demonstrate a greater incidence of disease resulting from adjacent musculoskeletal structures, with psoas muscle abscesses typically in the form of spondylodiscitis of the lumbar spine and iliacus abscesses from sacroiliac (SI) joint or hip infections. Urologic sources of secondary IPA include urinary tract infections, nephrolithiasis, urinary tract cancers, and genitourinary tract instrumentation. Gynecologic causes include tubo-ovarian abscess, perforated uterus from septic abortion, or intrauterine contraceptive device complications. Rarer etiologies include trauma, infected vascular grafts in the retroperitoneum, mycotic femoral aneurysm/pseudoaneurysm, and septic hip arthritis.

Causative organisms vary significantly between primary and secondary IPA. Typically, the abscesses are not polymicrobial, and in primary IPA the most common organism identified is *S. aureus*. Secondary IPAs with a gastrointestinal or urinary source typically will have enteric bacteria, most commonly *Escherichia coli*; however, frequently implicated organisms include *Bacteroides, M. tuberculosis, Streptococcus viridans, Enterococcus faecalis,* and *Peptostreptococcus*. There are also case reports of a number of other atypical bacterial infections resulting in IPA as well.

Patients with HIV/AIDS most typically will present with a primary IPA from *M. tuberculosis* or less commonly *S. aureus*. Primary IPA from *M. tuberculosis* may be the result of hematogenous spreading from a primary respiratory infection. HIV patients presenting with a secondary IPA will most often have a lumbar spondylodiscitis or genitourinary source, again often from *M. tuberculosis*.

Epidemiology

IPA remains a rarely encountered condition, and to date there is no definitive worldwide series estimating the incidence of the disease. Based on published case series, large tertiary care hospitals in the developed world can expect to see on the order of 3 or 4 cases per year. As an example, Alonso et al. evaluated 15 years of admissions at the Johns Hopkins Hospital in Baltimore, Maryland, in the United States and identified a total of 61 cases of IPA, equating out to roughly 4 cases per year. In resource-poor and tropical countries younger patients may present with undetected staphylococcal bacteremia, while in developed countries secondary presentation with gastrointestinal disease has been more common. However, in countries where HIV disease and drug use is more common, primary IPA may dominate.

The rate of diagnosis of IPA is increasing, with the earliest published literature suggesting a dramatically lower incidence (Ricci et al. estimated global incidence at 3 cases globally per year, though this is likely secondary to underreporting). Increasing use of CT scan and MRI has likely increased the detection of cases. Increasing numbers of immunosuppressed patients secondary to posttransplantation status and HIV/AIDS and increasing rates of IVDU has increased the at-risk population for IPA. This increase may have increased the actual incidence of the disease.

The incidence of primary versus secondary IPA was initially thought to vary widely based on geography, with IPA cases in Africa and Asia largely being primary. Secondary IPA cases likely represent around 80% of cases in the developed world. The previously mentioned case series by Alonso et al. demonstrated a sharp increase in incidence from 0.5 cases per 10,000 admissions between 1993 and 2004 and 6.5 cases per 10,000 admissions from 2005 to 2007. Of those admissions, 80% were noted to be secondary, with the contiguous source most often skeletal (48%) or intra-abdominal (23%). The causative organism was identified as MRSA in 25% of all cases

and in 37% of the cases that had definitive microbiologic diagnosis. Within this study, risk factors for IPA included IVDU (21%), neoplasm (18%), diabetes mellitus (15%), and HIV (15%). Only 11% had an inflammatory bowel disease, and 10% had suffered trauma within the preceding 30 days.

A larger, multicenter (11 hospital) review of 124 IPA cases in Spain was published by Navarro et al. in 2009. Of those patients, only 21.8% of patients had a primary IPA while 78.2% were secondary. The main sources of secondary IPA were 50.5% musculoskeletal, 24.7% intra-abdominal gastrointestinal tract, and 17.5% urinary tract. Definitive microbiologic diagnosis was achieved in 75% of cases, most typically yielding *S. aureus, E. coli,* and *Bacteroides*. In patients with a musculoskeletal origin, 42.9% were ultimately the result of *S. aureus* infection, while in patients with urinary or gastrointestinal sources *E. coli* represented 61.5% and 42.1% of the infections, respectively. Only 21.5% of cases were polymicrobial. Risk factors included diabetes mellitus in 18.5% of patients, chronic liver disease in 16.1% of patients, neoplasm in 11.3% of patients, and HIV in 6.3% of patients. Regarding outcomes, 5% died due to complications from IPA, and 15.8% had some form of recurrent infection. Risk factors of mortality included advanced age and *E. coli* infection.

There also appears to be clinical significance in whether the offending organisms are gas-forming or not. Hseih et al. performed a retrospective review of 88 cases in Taiwan between July 2007 and February 2013. In this study, 31% of cases had gas-forming organisms, and that group of patients experienced a much higher mortality rate than those with non–gas-forming organisms (44% vs 16.4%). Moreover, they identified that in patients with gas-forming organisms both percutaneous drainage and antibiotic therapy alone were associated with very high mortality, whereas open drainage had very good outcomes. Specifically, only 2 out of 13 gas-forming IPA patients who had percutaneous drainage had a good outcome, and only 1 of 6 gas-forming IPA patients who were treated with antibiotics alone survived. Conversely, 7 of 8 patients who underwent surgical drainage had a good outcome.

Diagnosis

A focused history and physical is essential for the diagnosis of IPA. History should focus on immunosuppression, inflammatory bowel disease, IVDU, recent surgery or hardware (such as a hip prosthesis or lumbar fusion), and recent infections. There is a classic triad of IPA symptoms consisting of back/flank pain, fever, and a limp (flexion deformity): however, this triad is only seen in 10% to 30% of cases. Active contraction and passive extension of the iliopsoas muscle group may be painful, so patients tend to flex and externally rotate the thigh to minimize discomfort. A classic psoas sign may be present on examination. Additional symptoms may be vague, such as night sweats, malaise, and weight loss. Abdominal pain or a mass in the back, flank, or groin may all suggest IPA as well. Immunocompromised patients may be particularly difficult to diagnose based on history and symptoms as they may have few or no symptoms. In one recent report Takada et al. in 2015 reviewed 15 patients and noted that the time from presentation to diagnosis was an average of >20 days.

Laboratory testing should include a CBC, a comprehensive metabolic panel, C-reactive proteins, and erythrocyte sedimentation rate. Frequently patients with IPA will manifest a leukocytosis and potentially elevated blood urea nitrogen, creatinine, or electrolyte disturbance. Blood cultures, and if identified, abscess aspirate, can be critical in identifying the causative organism and tailoring antibiotic therapy to the patient. Direct aspirate is superior to blood cultures due to higher yield and greater specificity.

The preferred imaging modality for IPA is with CT scan with intravenous contrast and oral contrast if a gastrointestinal source may be contributing. CT scan approaches 100% sensitivity for IPA, but it can struggle to differentiate from hematoma. In patients with a very short interval of time between initial symptoms and non-enhanced CT scan, an abscess may not yet be identified but instead diffuse swelling of the muscle is seen. In the paper by Takada et al. sensitivity from days 1 to 5 ranged from 33% to 50% on CT and MRI, but was 100% for all patients after day 6. Delayed washout of intravenous contrast with a rim-enhancing lesion increases the specificity for abscess. Additional findings may suggest an etiology aside from IPA, for instance irregular lesion margins may suggest neoplasm (67% sensitivity), and diffuse involvement of the muscle may suggest hematoma (88% sensitive). The CT scan is particularly strong at diagnosing the associated pathology in secondary IPA and can also be used to help plan for and guide needle aspiration and drainage of the abscess collection.

MRI can also be effective at detecting IPA with rim-enhancing fluid collections on post-contrast images suggesting IPA. Alterations of T1 signal within the lesion may help differentiate the age of the lesion. MRI, however, can also struggle to delineate abscess from hematoma. Furthermore, MRI struggles at identifying and defining gastrointestinal disease that may be the source of a secondary IPA and can lead to delay in surgical treatment that may otherwise be appropriate.

Ultrasound may be a reasonable screening tool in the emergency department, but it is operator dependent and lacks sensitivity and specificity compared to other examinations. It is, however, noninvasive and cost-effective. A positive ultrasound finding should be followed up with a definitive CT study.

Treatment

Initial treatment of a patient presenting with IPA should consist of standard sepsis bundle care. This should include adequate fluid resuscitation, collection of blood cultures, and early implementation of broad-spectrum antibiotics. Antibiotic therapy should cover *S. aureus* as well as enteric organisms. Given rising rates of MRSA, the authors suggest appropriate coverage with vancomycin depending on local resistance patterns as well as for critically ill patients and high-risk patients. Culture sensitivities should ultimately be used to guide antibiotic therapy in a targeted fashion as soon as available.

In cases where the etiology of secondary IPA is readily apparent, antibiotic therapy can be targeted early on to cover the most likely

offending organisms. Table 73.1 shows pathogens implicated in IPA by etiology.

Primary IPA empiric coverage should include antibiotics for *S. aureus,* coagulase-negative *Staphylococcus, M. tuberculosis,* and *Mycobacterium avium.* Vancomycin should be the initial choice for any critically ill patient with risk factors for MRSA. Other options would include oxacillin or clindamycin with an aminoglycoside.

In cases of secondary IPA, enteric organisms should be covered including *E. coli, Klebsiella, Bacteroides, Peptostreptococcus, Proteus, Clostridium,* and *Salmonella.* Treatment options include monotherapy with ertapenem or cefotetan; however, in critically ill patients the authors would advise piperacillin-tazobactam, imipenem, or meropenem. In penicillin-allergic patients, clindamycin combined with an aminoglycoside, a third-generation cephalosporin, aztreonam, or a fluoroquinolone may be adequate initial therapy.

Initial treatment of either form of IPA should be with intravenous antibiotics and can be de-escalated to oral regimens once culture and sensitivity data are available. Table 73.2 shows treatment options for IPA by classification. Table 73.3 shows the clinical signs and symptoms of patients with an iliopsoas abscess.

Antibiotic therapy alone may be sufficient for smaller abscesses; however, many cases will require either percutaneous drainage or operative incision and debridement. Percutaneous aspiration is significantly less invasive than open drainage and may be a safer option for critically ill patients. As such, CT-guided aspiration by interventional radiology has become the mainstay of interventional management for most cases of IPA. During CT-guided drainage abscess fluid should be sent for Gram stain and culture. A pig-tail catheter drain should be retained, and a sinogram (or drain study) should be performed to confirm cavity obliteration prior to removal of the drain. Yacoub et al. describe an algorithm for CT-guided drainage and antibiotic therapy and report on 41 patients with a 90% success rate for resolution of IPA without surgery. The described algorithm involves CT scan for initial diagnosis. If the abscess is <3 cm, antibiotics alone were employed. If >3 cm, percutaneous image-guided drainage was utilized in addition to antibiotics. A study of 7 patients who were not surgical candidates demonstrated percutaneous drainage was effective in 71%, drained an average of 62 cc (10–130 cc), and retained their drainage catheters for a mean of 8 days. Two of the 7 patients required a second drainage procedure (Table 73.4).

Despite recent advances in interventional radiology-guided drain placement, some cases remain appropriate for surgical intervention. Hseih et al. published a report from Taiwan that suggested that patients who have gas-forming pathogens should be treated with a surgery-first approach, while patients with non–gas-producing pathogens appear to do equally well with either percutaneous or laparoscopic or open approaches. Cases that have either failed to resolve with image-guided drainage procedures or have an intra-abdominal pathology driving a secondary IPA that requires correction of the offending source organ to resolve should be considered for operative therapy. Additional factors that may drive open drainage include

TABLE 73.1 **PATHOGENS FOUND IN ILIOPSOAS ABSCESSES**

Iliopsoas etiology	Pathogen
Primary	
Intravenous drug abuse Immunocompromised	*Staphylococcus aureus*, coagulase-negative Staphylococcus, especially methicillin-resistant *S. aureus, Mycobacterium tuberculosis, Mycobacterium avium* Occasional gram-negatives
Secondary	
Gastrointestinal, e.g., Crohn's disease, fistula, cancer, pancreatic, recent operation	*Escherichia coli, Klebsiella, Enterococcus* sp., *Proteus* sp., *Bacteroides* sp., *Peptostreptococcus, Clostridium*, *Salmonella enteritidis*
Genitourinary	*E. coli, M. tuberculosis, Enterococcus* sp.
Lumbar/Back	*M. tuberculosis, S. aureus*, coagulase negative staphylococcus
Trauma	Enteric and *Staph* organisms *Edwardsiella tarda*

TABLE 73.2 **ANTIMICROBIAL TREATMENT OPTIONS FOR ILIOPSOAS ABSCESSES**

Iliopsoas etiology	Treatment option
Primary	
Intravenous drug abuse Immunocompromised	Initial coverage should include specific coverage for *S. aureus* but should also include gram-negative coverage until the final organism(s) are known. *Options*: Oxacillin (or nafcillin) and aminoglycoside, cephalosporins, especially cefepime, fluoroquinolones, clindamycin, and aminoglycoside. Vancomycin should be considered for critically ill patients and those with high risk of methicillin resistance.
Secondary	
Gastrointestinal, e.g., Crohn's, fistula, cancer, pancreatic, recent operation Genitourinary Lumbar/Back Trauma	Initial empiric coverage for all secondary abscesses should be broad spectrum and should include gram-negative aerobes and anaerobes. *Options: Monotherapy: Moderate Illness*: Cefotetan (cefoxitin), ertapenem, piperacillin–tazobactam; *Severe illness*: Piperacillin–tazobactam, imipenem, meropenem, *Combination Therapy*: Clindamycin + aminoglycoside, clindamycin and third-generation cephalosporin (cefotaxime, ceftriaxone), clindamycin and aztreonam, clindamycin and fluoroquinolone

TABLE 73.3 CLINICAL SIGNS AND SYMPTOMS OF PATIENTS WITH AN ILIOPSOAS ABSCESS

Clinical sign or symptom	Percentage of patients with sign or symptom

Positive blood cultures	70

multiple loculations within the abscess or need for debridement of extensive areas of necrotic muscle or tissue. The typical surgical approach is a lower abdominal, muscle-splitting, extraperitoneal incision to access the retroperitoneum. Surgical planning should be guided by CT imaging. If there is an intraperitoneal process driving a secondary IPA a midline laparotomy may be required for source control. Incision and drainage via the groin, thigh, or back is not recommended.

TABLE 73.4 COMPARISON OF DIFFERENT CT FEATURES IN DISTINGUISHING ABSCESSES FROM NEOPLASMS AND HEMATOMAS OF THE ILIOPSOAS COMPARTMENT

CT feature	Sensitivity (%)	Specificity (%)	Accuracy (%)
Enlargement of both psoas and iliacus muscle	29	52	41
Low attenuation of the lesion	100	43	70

Irregular lesion margins	52	43	48
Fat infiltration	62	48	55
Fascial disruption	57	57	57

Abbreviation: CT = computed tomography
Modified from Lenchik L, Dogvan DJ, Kier R. CT of the iliopsoas compartment: Value in differentiating tumor, abscess, and hematoma. *AJR Am J Roentgenol*. 1994;162:83–86.

Outcome

Current mortality rates for IPA appear to range between 3% and 5%, though the relative rarity of this disease process combined with its frequently occult nature may lead to underestimations for mortality. Ricci et al. initially published an overall mortality rate of 2.5% for primary IPA, but an 18.9% mortality rate for secondary IPA. The primary cause of death was sepsis, with delayed or inadequate treatment of sepsis being the largest risk factor. More recent studies by Alonso et al. noted only 2 patient deaths out of 61 cases identified, and the 2009 case series from Spain by Navarro et al. had an overall mortality rate of 6.6%, with 5% being due to complications of IPA. Risk factors of mortality included advanced age (>65), bacteremia, and *E. coli* growth on cultures. A 2013 study by Hsieh et al. identified 88 patients with IPA and reported a mortality rate of 25%.

Outcome is largely determined by early diagnosis, appropriate management of sepsis with adequate fluid resuscitation, collection of blood cultures, initiation of broad-spectrum antibiotics, and prompt source control (Table 73.5).

Conclusion

- Primary IPA occurs when the iliopsoas muscle abscess forms as the result of hematogenous or lymphatic seeding. Secondary IPA occurs as the direct extension of a nearby infection, most often musculoskeletal, intra-abdominal, or genitourinary in nature.
- *S. aureus* is the most commonly isolated organism in primary IPA. Enteric organisms, including *E. coli*., are the most commonly isolated organisms in secondary IPA.

TABLE 73.5 PATHOGENS FOUND IN ILIOPSOAS ABSCESSES

Iliopsoas etiology	Pathogen
Primary	
Intravenous drug abuse	*Staphylococcus aureus*, coagulase-negative Staphylococcus, especially methicillin-resistant
Immunocompromised	*S. aureus, Mycobacterium tuberculosis, Mycobacterium avium* Occasional gram-negatives
Secondary	
Gastrointestinal, i.e., Crohn's disease, fistula, cancer, pancreatic, recent operation	*Escherichia coli, Klebsiella, Enterococcus* sp., *Proteus* sp., *Bacteroides* sp., *Peptostreptococcus, Clostridium*, *Salmonella enteritidis*
Genitourinary	*E. coli, M. tuberculosis, Enterococcus* sp.
Lumbar/Back	*M. tuberculosis, S. aureus*, coagulase-negative staphylococcus
Trauma	Enteric and *Staph* organisms

- The classic triad of back/flank pain, fever, and flexion deformity or limp is only present in 10% to 30% of cases. Additional symptoms of malaise and weight loss may be present.
- Risk factors for primary IPA include immunosuppression/HIV, IVDU, and chronic disease. Secondary IPA risk factors include lumbar spondylodiscitis, inflammatory bowel disease, and neoplasm.
- CT scan is the preferred imaging modality for diagnosis.
- Treatment of small collections may consist of antibiotics alone; larger collections may require image-guided percutaneous drainage. In rare cases operative intervention may be required. Secondary IPA may require an operative intervention for source control of the inciting infection.
- Early diagnosis and effective treatment with antibiotics and percutaneous drainage (if indicated) is critical to reducing morbidity and mortality related to IPA.

Bacterial meningitis

Jennie E. Johnson and Allan R. Tunkel

Introduction

Meningitis is an inflammation of the meninges, mainly the inner meninges comprised of the arachnoid and pia mater, which surround the brain and spinal cord and through which cerebrospinal fluid (CSF) flows. Meningitis can be caused by viral, bacterial, fungal, or parasitic infections or by noninfectious etiologies such as medications, inflammatory diseases, and malignancies, as well as by autoimmune disorders. Bacterial meningitis occurs most commonly by hematogenous spread but can also occur by direct invasion from the sinuses, ear, or postoperatively.

Rates of bacterial meningitis in the Unites States have declined significantly in the past decades, with the overall incidence of bacterial meningitis being 1.38 cases per 100,000 across all age groups. This trend is largely due to availability of effective vaccines against the most common pathogens and education of high-risk populations. Despite this decline, the case fatality rate of bacterial meningitis in the United States has remained fairly stable at around 14.3% but varies depending on pathogen and host factors.

Clinical presentation

The classic clinical presentation in patients with bacterial meningitis is that of fever, headache, meningismus, and signs of cerebral dysfunction (confusion, delirium, or a declining level of consciousness) (Table 74.1). In a review of 493 cases of acute bacterial meningitis in adults, the classic triad (i.e., fever, nuchal rigidity, and change in mental status) was found in only two-thirds of patients, but all had at least one of these findings. In another review of 696 episodes of community-acquired bacterial meningitis, the triad of fever, neck stiffness, and altered mental status was present in only 44% of episodes, although almost all patients (95%) presented with at least two of the four symptoms of headache, fever, stiff neck, and altered mental status. A recent prospective study from the Netherlands of 1,412 episodes of bacterial community-acquired meningitis in adults demonstrated the classic triad in 41% of patients, with the most common presenting symptoms being headache (83%), fever (74%), neck stiffness (74%), and altered mental status (71%). The meningismus may be subtle, marked, or accompanied by Kernig and/or Brudzinski signs. However, in a prospective study that examined the diagnostic accuracy of meningeal signs in adults with suspected meningitis, the sensitivity of these findings was only 5% for Kernig sign, 5% for Brudzinski sign, and 30% for nuchal rigidity, indicating that they did not accurately distinguish patients with meningitis from those without meningitis, and the absence of these findings did not rule out the diagnosis of bacterial meningitis. Cranial nerve palsies and focal cerebral signs are seen in 10% to 20% of cases. In an observational study of 696 patients with community-acquired bacterial meningitis, cerebral infarction occurred in 25% of episodes, and, in 36% of those, specifically with pneumococcal meningitis. Seizures occur in about 30% of patients. Papilledema is observed >5% of cases early in infection, and its presence should suggest an alternative diagnosis. As meningitis progresses,

TABLE 74.1 **PRESENTING SIGNS AND SYMPTOMS IN ADULTS WITH BACTERIAL MENINGITIS**

Signs or symptoms	Relative frequency (%)
Headache	≥85
Fever	≥80
Meningismus	≥80
Altered sensorium	≥75
Classic Triad (headache, meningismus and altered sensorium)	≥40
Vomiting	~35
Seizures	~30
Focal neurologic findings	10–35

patients may develop signs of increased intracranial pressure such as coma, hypertension, bradycardia, or palsy of cranial nerve III.

To further characterize the accuracy and precision of the clinical examination in adult patients with acute meningitis, patient data on 845 episodes of acute meningitis (confirmed by lumbar puncture or autopsy) in patients aged 16 to 95 years were reviewed. The results demonstrated that individual items of the clinical history (i.e., headache, nausea, and vomiting) had a low accuracy for the diagnosis of meningitis in adults. However, on review of the accuracy of physical examination findings, the absence of fever, neck stiffness, and altered mental status effectively eliminated the likelihood of acute meningitis; the sensitivity was 99% to 100% for the presence of one of these findings in the diagnosis of acute meningitis. Despite these findings, physicians should have a low threshold for performance of lumbar puncture in patients at high risk for bacterial meningitis.

Certain symptoms or signs may suggest an etiologic diagnosis in patients with bacterial meningitis. About half of the patients with meningococcemia, with or without meningitis, present with a prominent rash that is localized principally to the extremities. The rash typically is macular and erythematous early in the course of illness, but it quickly evolves into a petechial phase with further coalescence into a purpuric form; the rash may evolve rapidly, with new petechiae appearing during the physical examination. Patients with *Listeria monocytogenes* meningitis have an increased tendency toward focal deficits and seizures early in the course of infection; some patients may present with ataxia, cranial nerve palsies, or nystagmus as a result of rhombencephalitis. A prodrome of fever, headache, myalgias, chills, gastroenteritis, and other systemic symptoms may occur on average 3 to 4 days prior to presentation. Fever is the most common presenting symptom (>90%), followed by altered mental status (66%) and headache (46%); one-half to two-thirds of patients have nuchal rigidity. In addition, many patients with bacterial meningitis have predisposing illnesses; up to 40% of patients with pneumococcal meningitis have preceding ear, sinus, or lung infections.

Furthermore, certain patient populations may not present with many of the classic symptoms or signs of bacterial meningitis. Neonates often do not have meningismus and may present with a number of nonspecific signs such as temperature instability, change in affect or level of alertness, lethargy, irritability, vomiting, diarrhea or respiratory distress. Young children, aged 1 to 4 years, most commonly present with fever, vomiting, and nuchal rigidity. Elderly patients, particularly those with underlying medical conditions (e.g., diabetes mellitus, cardiopulmonary disease), may present insidiously with lethargy or obtundation, no fever, and variable signs of meningeal inflammation. In one 30-year study of 185 patients 65 years and older, the diagnosis of community-acquired bacterial meningitis was more difficult because of the absence of characteristic meningeal signs. Immunocompromised patients, such as those with prolonged neutropenia, AIDS, certain malignancies, or receiving immunomodulating therapies, may also present in a subtle manner because of the impaired ability of the patient to mount a subarachnoid space inflammatory response. In patients with head trauma, the symptoms and signs consistent with meningitis may be present as a result of the underlying injury and not meningitis. In all of these subgroups of patients, altered or changed mental status should not be ascribed to other conditions unless bacterial meningitis has been excluded by CSF examination.

Diagnosis

Bacterial meningitis is diagnosed by examination of CSF obtained via lumbar puncture. In virtually all patients with bacterial meningitis, the opening pressure is elevated (>180 mm H_2O), with values >600 mm H_2O suggesting the presence of cerebral edema, intracranial suppurative foci, or communicating hydrocephalus. The CSF white blood cell count is elevated (usually 1,000–5,000 cells/mm^3, with a range of ≤100 to >10 000/mm^3); patients with low CSF white blood cell counts (from 0 to 20/mm^3), despite high CSF bacterial concentrations, tend to have a poor prognosis. There is usually a neutrophilic predominance (≥80%), although approximately 10% of patients with acute bacterial meningitis will present with a lymphocytic predominance in CSF (more common in neonates with gram-negative bacillary meningitis and patients with *L. monocytogenes* meningitis). A decreased CSF glucose concentration (≤40 mg/dL) is found in about 60% of patients; a CSF-to-serum glucose ratio of <0.23 is observed in about 70% of patients. The CSF protein is elevated in virtually all cases (usually 100–500 mg/dL). Gram stain examination of CSF permits a rapid, accurate identification of the causative microorganism in about 60% to 90% of patients with bacterial meningitis; the specificity is nearly 100%, and the likelihood of detecting the organism is greater with higher CSF bacterial densities. CSF cultures are positive in 80% to 90% of patients with community-acquired bacterial meningitis; the yield of culture is decreased in patients who have received prior antimicrobial therapy. Elevated CSF lactate concentrations may help differentiate between bacterial and aseptic meningitis with a sensitivity and specificity reported as high as 97% and 96%, respectively. However, the accuracy is lowered in patients pretreated with antimicrobial therapy prior to lumbar puncture or in those with other CNS diseases such as head trauma or stroke.

In patients without a positive CSF Gram stain or culture, the diagnosis of bacterial meningitis can be difficult to establish or

reject. A number of studies have examined a combination of clinical features, with or without test results, to develop models to predict the likelihood of bacterial meningitis compared to other potential agents, usually viruses. Despite positive results in a number of studies utilizing prediction models, clinical judgment should continue to be used in decisions for administration of empiric antimicrobial therapy in patients with suspected bacterial meningitis.

In patients with bacterial meningitis and a negative CSF Gram stain, several rapid diagnostic tests that can be considered for detection of specific bacterial antigens in CSF have been developed to aid in the etiologic diagnosis. Polymerase chain reaction (PCR) has been used to amplify DNA from patients with meningitis caused by several meningeal pathogens. The clinical utility of PCR for the diagnosis of bacterial meningitis was assessed in one study with a broad range of bacterial primers, yielding a sensitivity of 100%, specificity of 98.2%, positive predictive value of 98.2%, and negative predictive value of 100%. Another study demonstrated the sensitivity of broad-based PCR to be 59% (standard culture was 43%) with a specificity of 97% (standard culture was also 97%). Consequently, broad-based PCR can be used to detect the most common microorganisms with only one test, can be done within 2 hours in most industrialized countries, and has adequate sensitivity and excellent specificity. Further refinements are needed, however, before this technique can be used in patients with presumed bacterial meningitis when CSF Gram stain and cultures are negative. Currently available latex agglutination techniques have a sensitivity ranging from 50% to 100% (although these tests are highly specific) and detect the antigens of *Haemophilus influenzae* type b, *Streptococcus pneumoniae, Neisseria meningitidis, Escherichia coli* K1, and *Streptococcus agalactiae*. However, the routine use of latex agglutination for the etiologic diagnosis of bacterial meningitis has recently been questioned and is no longer routinely recommended because bacterial antigen testing does not appear to modify the decision to administer antimicrobial therapy, and false-positive tests have been reported. An immunochromatographic test is also available for detection of *S. pneumoniae* in CSF; the overall sensitivity was 95% to 100%.

TABLE 74.2 **RECOMMENDED ANTIMICROBIAL THERAPY FOR ACUTE BACTERIAL MENINGITIS BASED ON PRESUMPTIVE IDENTIFICATION BY POSITIVE GRAM STAIN**

Microorganism	Therapy
Streptococcus pneumoniae	Vancomycin plus a third-generation cephalosporin[a,b]
Neisseria meningitidis	Third-generation cephalosporin[a]
Listeria monocytogenes	Ampicillin or penicillin G[c]
Haemophilus influenzae type b	Third-generation cephalosporin[a]

[a]Ceftriaxone or cefotaxime.
[b]Addition of rifampin may be considered; some experts would add rifampin if dexamethasone is also given.
[c] Addition of an aminoglycoside should be considered.

Therapy

Initial approach to management

In patients with the clinical presentation of acute bacterial meningitis, the initial management includes obtaining blood cultures and performing a lumbar puncture. If the CSF formula is consistent with the diagnosis of bacterial meningitis, targeted antimicrobial therapy and adjunctive dexamethasone (see later discussion) should be initiated based on results of Gram stain (Table 74.2). However, if no etiologic agent can be identified on initial CSF analysis, empiric antimicrobial therapy and adjunctive therapy should be initiated rapidly based on the patient's age (Table 74.3). In patients with a clinical presentation of bacterial meningitis in whom there is a delay in performance of lumbar puncture or if there is suspicion of an intracranial mass lesion that is causing their neurologic presentation (i.e., those with focal neurologic deficits, abnormal level of consciousness, new-onset seizure, or papilledema on funduscopic examination or those who are immunocompromised or have a history of CNS disease), a noncontrast CT scan of the head should be performed before lumbar puncture. In these patients, blood cultures must be obtained and appropriate antimicrobial and adjunctive therapy given prior to lumbar puncture or before the patient is sent to the CT scanner to potentially reduce the increased morbidity and mortality associated with bacterial meningitis when initiation of appropriate antimicrobial and adjunctive therapy is delayed. Although there are no prospective data on the timing of administration of antimicrobial therapy in patients with bacterial meningitis, a retrospective cohort study in patients with community-acquired bacterial meningitis demonstrated that a delay in initiation of antimicrobial therapy after patient arrival in the emergency room was associated with an adverse clinical outcome when the patient's condition advanced to a high stage of prognostic severity, thus supporting the assumption that treatment of bacterial meningitis before it advances to a high level of clinical severity improves clinical outcome. While the yield of positive CSF cultures may decrease with initiation of antimicrobial therapy prior to obtaining CSF for analysis, the pretreatment blood cultures, CSF formula, and/or Gram stain will likely provide evidence for or against a diagnosis of bacterial meningitis.

Adjunctive therapy

Dexamethasone is the only adjunctive therapy recommended for certain bacterial causes of meningitis. By reducing the subarachnoid space inflammatory response, which leads to cerebral edema and elevated intracranial pressure, adjunctive dexamethasone administered prior to the initiation of antimicrobial therapy has been demonstrated to improve outcome in patients with meningitis caused by *S. pneumoniae* and *H. influenzae* in developed countries. A meta-analysis confirmed the benefit of adjunctive dexamethasone (0.15 mg/kg q6h for 2–4 days) for *H. influenzae* type b meningitis and, if commenced with or before parenteral antimicrobial therapy,

TABLE 74.3 **COMMON BACTERIAL PATHOGENS AND EMPIRIC THERAPEUTIC RECOMMENDATIONS BASED ON AGE IN PATIENTS WITH MENINGITIS**

Age or predisposing condition	Common bacterial pathogens	Empiric antimicrobial therapy
<1 month	*Streptococcus agalactiae* *Escherichia coli* *Listeria monocytogenes*	Ampicillin plus cefotaxime, ampicillin plus cefepime, or ampicillin plus an aminoglycoside
1-23 months	*S. agalactiae* *E. coli* *Haemophilus influenzae* *Streptococcus pneumoniae* *Neisseria meningitidis*	Vancomycin plus a third-generation cephalosporin[a,b,c]
2-50 years	*S. pneumoniae* *N. meningitidis*	Vancomycin plus a third-generation cephalosporin[a,b,c]
>50 years	*S. pneumoniae* *N. meningitidis* *L. monocytogenes* aerobic gram-negative bacilli	Vancomycin plus ampicillin plus a third-generation cephalosporin[a,c]
Immunocompromised state	*S. pneumoniae* *N. meningitidis* *L. monocytogenes* aerobic gram-negative bacilli	Vancomycin plus ampicillin plus either cefepime or meropenem
Head trauma or after neurosurgery	*Staphylococci* Diphtheroids *Pseudomonas aeruginosa* *S. pneumoniae* *Acinetobacter baumannii*[d] ESBL gram-negative bacilli[d]	Vancomycin plus either ceftazidime, cefepime, or meropenem

[a]Ceftriaxone or cefotaxime.
[b] Add ampicillin if meningitis caused by *L. monocytogenes* is suspected.
[c] Some experts would add rifampin if dexamethasone is also given.
[d]If considered, would use meropenem as part of the empiric regimen.

suggested benefit for pneumococcal meningitis in childhood. Evidence of clinical benefit was strongest for hearing outcomes. In adults with acute bacterial meningitis, a prospective, randomized, placebo-controlled, double-blind multicenter trial in 301 patients demonstrated that patients randomized to receive adjunctive dexamethasone were less likely to have unfavorable outcome and death; benefit was most evident among the subgroup of patients with pneumococcal meningitis. Based on the available evidence, adjunctive dexamethasone (0.15 mg/kg q6h for 4 days with the first dose administered 10–20 minutes before, or at least concomitant with, the first dose of an antimicrobial agent) should be utilized in adults with suspected or proven pneumococcal meningitis. Adjunctive dexamethasone should not be given to adults who have already received antimicrobial therapy because administration in this setting is unlikely to improve patient outcome. The data are inadequate to recommend adjunctive dexamethasone in adults with meningitis caused by other meningeal pathogens; continuing dexamethasone in patients with culture-proven meningococcal meningitis did not lead to improvement in rates of unfavorable outcome, although its use was not associated with harm. Additionally, a recent prospective study of patients with invasive *L. monocytogenes* infection in France demonstrated that 31 (13%) of 252 patients with *L. monocytogenes* meningitis who received adjunctive dexamethasone had a statistically significant lower survival than those who did not (17 [53%] of 32 vs. 157 [73%] of 216), although this outcome has not been observed in other studies of patients with *Listeria* meningitis. Some authorities would initiate dexamethasone in all adults because the etiology of meningitis is not always ascertained at initial evaluation, given that *S. pneumoniae* accounted for 58% of all cases of meningitis in the United States between 1998 and 2007.

Despite the positive benefits of adjunctive dexamethasone in patients with *S. pneumoniae* or *H. influenzae* meningitis, its routine use in patients in the developing world has been controversial. In one randomized, double-blind, placebo-controlled trial from Malawi in adults, there were no significant differences in mortality, although almost 90% of the patients in this trial were infected with HIV and likely had advanced disease. In a Cochrane meta-analysis of 24 studies involving 4,041 participants, adjunctive dexamethasone did

not reduce overall mortality, but there was a trend to lower mortality rates in adults; corticosteroids were associated with lower rates of severe hearing loss, any hearing loss, and neurologic sequelae, but these benefits were only seen in studies from high-income countries.

In addition, the use of adjunctive dexamethasone is of concern in those with pneumococcal meningitis caused by highly penicillin- and cephalosporin-resistant strains, in which patients may require antimicrobial therapy with vancomycin. In this instance, a diminished CSF inflammatory response after dexamethasone administration might significantly reduce vancomycin penetration into CSF and delay CSF sterilization. The published trials have not examined outcome in patients with these resistant isolates who have received adjunctive dexamethasone, and it is unlikely that this question will be definitively answered in the near future given the difficulty in enrolling adequate numbers of patients with these resistant strains into clinical trials. However, CSF vancomycin penetration was not reduced by dexamethasone in a study in which a continuous infusion of vancomycin (at a dose of 60 mg/kg/d) was utilized. For any patient receiving adjunctive dexamethasone who is not improving as expected, a repeat lumbar puncture 36 to 48 hours after initiation of antimicrobial therapy is recommended to document sterility of CSF.

Antimicrobial therapy

Once the infecting meningeal pathogen is isolated and susceptibility testing known, antimicrobial therapy can be modified for optimal treatment (Table 74.4). Recommended antimicrobial dosages for meningitis in adults with normal renal and hepatic function are shown in Table 74.5. The following sections review recommendations for use of antimicrobial therapy in patients with bacterial meningitis based on the isolated meningeal pathogen.

TABLE 74.4 **SPECIFIC ANTIMICROBIAL THERAPY FOR ACUTE BACTERIAL MENINGITIS**

Microorganism	Standard therapy	Duration of therapy
Streptococcus pneumoniae		10–14 d
Penicillin MIC ≤0.06 μg/mL	Penicillin G or ampicillin	
Penicillin MIC ≥0.12 μg/mL		
Ceftriaxone or cefotaxime MIC <1.0 μg/mL	Third-generation cephalosporin[a]	
Ceftriaxone or cefotaxime MIC ≥1.0 μg/mL	Vancomycin plus a third-generation cephalosporin[a,b]	
Neisseria meningitidis		7 d
Penicillin MIC <0.1 μg/mL	Penicillin G or ampicillin	
Penicillin MIC 0.1–1.0 μg/mL	Third-generation cephalosporin[a]	
Listeria monocytogenes	Ampicillin or penicillin G[c]	≥21 d
Streptococcus agalactiae	Ampicillin or penicillin G[c]	14–21 d
Haemophilus influenzae		7 d
β-lactamase – negative	Ampicillin	
β-lactamase – positive	Third-generation cephalosporin[a]	
Escherichia coli and other Enterobacteriaceae	Third-generation cephalosporin[a,d]	21 d
Pseudomonas aeruginosa	Cefepime or ceftazidime	21 d
Staphylococcus aureus		10–14 d
Methicillin-sensitive	Nafcillin or oxacillin	
Methicillin-resistant	Vancomycin	
Staphylococcus epidermidis	Vancomycin[e]	10–14 d

[a] Ceftriaxone or cefotaxime
[b] Consider addition of rifampin if the ceftriaxone MIC is >4 μg/mL.
[c] Addition of an aminoglycoside should be considered.
[d] Choice of a specific antimicrobial agent must be guided by in vitro susceptibility test results.
[e] Addition of rifampin should be considered.
Abbreviation: MIC = minimal inhibitory concentration.

TABLE 74.5 **RECOMMENDED DOSAGES OF ANTIMICROBIAL AGENTS FOR MENINGITIS IN ADULTS WITH NORMAL RENAL AND HEPATIC FUNCTION**

Antimicrobial agent	Total daily dose (IV)	Dosing interval (h)
Amikacin[a]	15 mg/kg	8
Ampicillin	12 g	4
Aztreonam	6–8 g	6–8
Cefepime	6 g	8
Cefotaxime	8–12 g	4–6
Ceftazidime	6 g	8
Ceftriaxone	4 g	12–24
Chloramphenicol[b]	4–6 g	6
Ciprofloxacin	800–1,200 mg	8–12
Gentamicin[a,c]	5 mg/kg	8
Meropenem	6 g	8
Moxifloxacin[d]	400 mg	24
Nafcillin	12 g	4
Oxacillin	12 g	4
Penicillin G	24 million U	4
Rifampin	600 mg	24
Tobramycin[a]	5 mg/kg	8
Trimethoprim-sulfamethoxazole[e]	10–20 mg/kg	6–12
Vancomycin[f,g]	30–60 mg/kg	8–12

[a] Need to monitor peak and trough serum concentrations.
[b] Higher dosage recommended for pneumococcal meningitis.
[c] Intrathecal dosage is 1–8 mg; usual daily dose is 1–2 mg for infants and children, and 4–8 mg for adults. Intrathecal dosing should always be used in combination with a parenteral agent.
[d] No data on optimal dose needed in patients with bacterial meningitis.
[e] Dosage based on trimethoprim component; many authorities utilize a dose of 5 mg/kg every 8 hours.
[f] Maintain serum trough concentrations of 15–20 μg/mL.
[g] Intrathecal dosage is 5–20 mg; most studies have used a 10-mg or 20-mg dose.

Streptococcus pneumoniae

The recommended therapy of pneumococcal meningitis has been changed based on pneumococcal susceptibility patterns. Pneumococcal strains with minimal inhibitory concentrations (MICs) of ≤0.06 μg/mL are considered susceptible to penicillin and those with MICs of ≥0.12 μg/mL are considered resistant. Resistant strains have been reported from many countries throughout the world, including the United States, where the prevalence of penicillin-nonsusceptible *S. pneumoniae* ranges from 25% to >50%. Because initial CSF concentrations of penicillin are only approximately 1 μg/mL after parenteral administration of standard high dosages, penicillin cannot be recommended as empiric antimicrobial therapy when *S. pneumoniae* is considered a likely infecting pathogen in patients with purulent meningitis. Of additional concern is that pneumococcal strains resistant to the third-generation cephalosporins have been described in patients with meningitis. Several alternative agents have been examined for the treatment of meningitis caused by penicillin-resistant pneumococci. Chloramphenicol is one agent that has been studied, although clinical failures with chloramphenicol have been reported in patients with penicillin-resistant isolates. Vancomycin has also been evaluated, but as a single agent is likely to be suboptimal for therapy of pneumococcal meningitis.

Based on these data, it is recommended that, for empiric therapy of suspected pneumococcal meningitis, the combination of vancomycin and a third-generation cephalosporin (either ceftriaxone or cefotaxime) should be used pending in vitro susceptibility results. This combination was synergistic in a rabbit model of penicillin-resistant pneumococcal meningitis and was synergistic, or at least additive, in the CSF of children with meningitis. If the organism is sensitive to penicillin (MIC ≤0.06 μg/mL), penicillin is the drug of choice. For penicillin-resistant strains (MIC ≥0.12 μg/mL), in vitro susceptibility to the third-generation cephalosporins should be determined. If the MIC to ceftriaxone or cefotaxime is <1.0 μg/mL, a third-generation cephalosporin is used. However, if the MIC to ceftriaxone or cefotaxime is ≥1.0 μg/mL, vancomycin plus the third-generation cephalosporin are continued for the entire treatment period. Some investigators have also recommended the addition of rifampin, although no clinical data support this recommendation; rifampin should be added only if the organism is susceptible and there is a delay in the expected clinical or bacteriologic response. In patients not responding, intrathecal or intraventricular vancomycin remains a reasonable option.

Several other antimicrobial agents appear promising for the therapy of penicillin-resistant pneumococcal meningitis. Meropenem, a carbapenem with less proconvulsant activity than imipenem, has been utilized in children and adults with bacterial meningitis, including cases caused by *S. pneumoniae*, with microbiologic and clinical outcomes similar to those following treatment with cefotaxime or ceftriaxone. However, in one study of 20 cefotaxime-resistant pneumococcal isolates, 4 were intermediate and 13 were resistant to meropenem, suggesting that meropenem may not be a useful alternative agent for treatment of pneumococcal isolates that are highly resistant to penicillin and cephalosporins. Newer fluoroquinolones (e.g., moxifloxacin) that have excellent in vitro activity against *S. pneumoniae* have also been shown to have efficacy in experimental animal models of penicillin-resistant pneumococcal meningitis, although only trovafloxacin has been shown in a clinical trial to be as efficacious as ceftriaxone, with or without vancomycin, in children with bacterial meningitis. Although trovafloxacin is no longer used because of concerns of liver toxicity, these data suggest the potential usefulness of the newer fluoroquinolones in the treatment of bacterial meningitis. Although further clinical trials are needed before these agents can be recommended as first-line therapy for patients with bacterial meningitis, a combination of a third-generation cephalosporin plus a newer generation fluoroquinolone may emerge as the treatment of choice for pneumococcal meningitis in the future.

Neisseria meningitidis

The antimicrobial agent of choice for therapy of *N. meningitidis* meningitis is penicillin G or ampicillin. These recommendations may change in the future as a result of the emergence of meningococcal strains that are resistant to penicillin G, with a MIC range of 0.1 to 1.0 μg/mL. In a population-based surveillance study for invasive meningococcal disease in selected areas of the United States, 3 of 100 isolates had penicillin MICs of 0.125 μg/mL. However, the clinical significance of these isolates is unclear because patients with meningitis caused by these organisms have recovered with standard penicillin therapy. Some authorities would treat patients with meningococcal meningitis with a third-generation cephalosporin (either ceftriaxone or cefotaxime) pending susceptibility testing of the isolate. Single-dose ceftriaxone was also found to be noninferior compared with chloramphenicol when used against epidemic meningococcal meningitis in one study, suggesting that this agent should be utilized during meningococcal epidemics in the developing world.

Listeria monocytogenes

Despite their broad range of in vitro activity, the third-generation cephalosporins are inactive against *L. monocytogenes*. Therapy for *Listeria* meningitis should consist of ampicillin or penicillin G, with addition of an aminoglycoside considered in proven infection because of documented in vitro synergy. In in vitro studies, β-lactams are bacteriostatic for *L. monocytogenes*, and the addition of an aminoglycoside has been shown to synergistically enhance killing. However, there are mixed data with regards to benefit of aminoglycosides in both animal and clinical studies. A number of retrospective studies did not show improved outcomes with aminoglycoside synergy, and one showed higher mortality with aminoglycoside use. Other large studies, including a recent prospective study, showed statistically significant increased survival. Subsequently, both US and European guidelines for the treatment of *L. monocytogenes* meningitis recommend the consideration of adding an aminoglycoside rather than a formal recommendation for combination therapy.

In the penicillin-allergic patient, trimethoprim-sulfamethoxazole, which is bactericidal against *Listeria* in vitro, should be used. Meropenem may also be used as an alternative agent, although rare treatment failures have been reported. Despite favorable in vitro susceptibility results, chloramphenicol and vancomycin are associated with unacceptably high failure rates.

Haemophilus influenzae

The therapy of bacterial meningitis caused by *H. influenzae* type b depends on whether the strain produces β-lactamase. For β-lactamase–negative strains, ampicillin is recommended, and for strains that produce β-lactamase, a third-generation cephalosporin (i.e., ceftriaxone or cefotaxime) should be used. In addition, a third-generation cephalosporin should be used as empiric therapy in all patients in whom *H. influenzae* type b is a possible pathogen. Chloramphenicol is not recommended because chloramphenicol-resistant isolates have been reported throughout the world, and, even in patients with chloramphenicol-sensitive isolates, a prospective study found chloramphenicol to be bacteriologically and clinically inferior to ampicillin, ceftriaxone, or cefotaxime in the therapy of childhood bacterial meningitis caused predominantly by *H. influenzae* type b. Although cefuroxime, a second-generation cephalosporin, initially appeared to be efficacious in the therapy of *H. influenzae* type b meningitis, a study comparing cefuroxime with ceftriaxone for childhood bacterial meningitis documented delayed CSF sterilization and a higher incidence of hearing impairment in the patients receiving cefuroxime. Cefepime has been compared with cefotaxime in a prospective randomized trial for treatment of meningitis in infants and children; cefepime was found to be safe and therapeutically equivalent to cefotaxime and can be considered a suitable therapeutic alternative for treatment of patients with this disease.

Aerobic gram-negative bacilli

Outcome from meningitis caused by aerobic gram-negative bacilli has been greatly improved with the availability of the third-generation cephalosporins (cure rates of 78% to 94%). Ceftazidime, a third-generation cephalosporin with enhanced in vitro activity against *Pseudomonas aeruginosa*, led to a cure in 19 of 24 patients with *P. aeruginosa* meningitis in one study when used alone or in combination with an aminoglycoside. Similar results were observed in a study of pediatric patients in which seven patients were cured clinically and nine were cured bacteriologically when receiving ceftazidime-containing regimens. In patients with aerobic gram-negative bacillary meningitis not responding to conventional parenteral antimicrobial therapy, concomitant intraventricular or intrathecal aminoglycoside therapy should be considered, although this mode of therapy was associated with a higher mortality rate than systemic therapy alone in infants with gram-negative meningitis and ventriculitis.

Several other antimicrobial agents (e.g., imipenem, meropenem, cefepime, aztreonam, colistin) have been successfully used in isolated case reports and in small series of patients with meningitis caused by aerobic gram-negative bacilli. Imipenem has been efficacious, although a high rate of seizure activity (33% in one study) limits its usefulness in patients with bacterial meningitis. The fluoroquinolones (e.g., ciprofloxacin) have also been used in some patients with bacterial meningitis, although their primary usefulness is for therapy of meningitis caused by multidrug-resistant gram-negative organisms or when the response to conventional therapy is inadequate; these agents should not be used as first-line empiric therapy in patients with meningitis of unknown etiology because of their poor in vitro activity against *S. pneumoniae* and *L. monocytogenes*. For empirical treatment of *Acinetobacter* meningitis, intravenous meropenem, with or without an aminoglycoside administered by the intrathecal or intraventricular route, has been recommended; if the organism is found to be resistant to carbapenems, colistin (usually formulated as colistimethate sodium) or polymyxin B should be substituted for meropenem and may also need to be administered by the intrathecal or intraventricular route.

Staphylococci and streptococci

Meningitis caused by *Staphylococcus aureus* should be treated with nafcillin or oxacillin; vancomycin is used for patients who are allergic to penicillin or when the organism is methicillin resistant. For meningitis caused by coagulase-negative staphylococci (e.g., *S. epidermidis*), vancomycin is recommended; rifampin should be added if the patient fails to improve. Daptomycin, linezolid, or trimethoprim-sulfamethoxazole is considered an alternative agent in patients with staphylococcal meningitis. Ceftaroline has been used to successfully treat two patients with methicillin-resistant *S. aureus* (MRSA) meningitis and one with a ventriculoperitoneal shunt infection. In patients with meningitis caused by *S. agalactiae*, ampicillin plus an aminoglycoside is recommended based on documented in vitro synergy and because of the emergence of penicillin-tolerant strains; alternatives include ceftriaxone and vancomycin.

Prevention

Immunoprophylaxis

Streptococcus pneumoniae

The 13-valent pneumococcal conjugate vaccine (PCV13) four-dose primary series is recommended in children at 2, 4, and 6 months of age, with a fourth dose given between age 12 and 15 months. The routine use of the prior 7-valent pneumococcal conjugate vaccine (PCV7) beginning in 2000 demonstrated a 79% reduction overall in invasive pneumococcal disease in children <5 years and a 99% reduction in disease caused by the seven serotypes in PCV7. There was a 30.1% percentage decrease in the rate of pneumococcal meningitis in all ages. An indirect effect of the PCV7 vaccine program was a decline in rates of invasive pneumococcal disease in unvaccinated adult populations. Currently, PCV13 is recommended to be given in conjunction with PPSV23 as a one-time dose in those at higher risk for invasive pneumococcal disease and persons over age 65 years.

The 23-valent pneumococcal polysaccharide vaccine (PPSV23) is recommended for all adults over the age of 65 and those at higher risk for pneumococcal disease. Due to its poor immunogenicity in young children, it is only approved for those over the age of 2 years.

Neisseria meningitidis

Quadrivalent conjugate vaccines against meningococcal disease caused by serogroups A, C, W, and Y have been in use in the United States since 2005. The two available in the United States are Menactra and Menveo. Current recommendations are for vaccination of children between 11 and 18 years of age with a booster at age 16 in those who receive the first dose prior to age 12 years. Special populations such as college students aged 19 to 21 years residing in dormitories; those living in hyperendemic regions; those with prolonged risk of exposure; those with asplenia, sickle cell disease, HIV, or complement deficiencies; and those residing in a region with an ongoing meningococcal outbreak should also be vaccinated. Long-term immunogenicity is unknown.

There are two vaccines, Bexsero and Trumenba, licensed in 2015 and 2014, respectively, in the United States, against meningococcal disease caused by serogroup B. These are both approved for use in persons aged 10 to 25 years at increased risk for meningococcal serogroup B disease.

Haemophilus influenzae

In the United States, there are currently three monovalent vaccines approved by the Food and Drug Administration (FDA)—ActHIB (PRP-T), Hiberix (PRP-T), and PedvaxHIB (PRP-OMB)—and one combination vaccine (Pentacel). The monovalent vaccines can be administered as early as 6 weeks of age but are usually given in a primary series starting at 2 months of age with a booster dose at 12 to 15 months of age. More than 95% of infants who receive the full primary series of vaccine develop protective antibodies, and immunity is thought to be long-term. Routine vaccination of infants against *H. influenzae* type b has been largely effective in reducing the overall incidence of *H. influenzae* type b meningitis by 90%.

Chemoprophylaxis

It has become clear in recent years that the spread of several types of bacterial meningitis can be prevented by chemoprophylaxis of contacts of patients with meningitis. The rationale is for eradication of nasopharyngeal colonization, thereby preventing transmission to susceptible contacts and the development of invasive disease in those already colonized. Chemoprophylaxis is recommended for contacts of a case of meningococcal meningitis. The definition of a "close contact" has not been clearly elucidated, but usually refers to persons who have had prolonged exposure of 8 hours or longer while in proximity of 3 feet or less of the index case and include household contacts, daycare center members, and anyone directly exposed to the patient's oral secretions (e.g., through kissing, mouth-to-mouth resuscitation, endotracheal intubation, or endotracheal tube management); the index case may also need to receive prophylaxis if he or she is treated with an antimicrobial agent (e.g., penicillin or chloramphenicol) that does not reliably eradicate meningococci from the nasopharynx of colonized patients. Chemoprophylaxis should also be administered to close contacts who have received the quadrivalent meningococcal conjugate vaccine because the vaccine does not confer protection against serogroup B meningococcus. The optimal regimen to prevent invasive meningococcal disease is controversial. At present, the US Centers for Disease Control and Prevention (CDC) recommend rifampin, ciprofloxacin, or ceftriaxone, which are all 90% to 95% effective at eradicating nasopharyngeal carriage. Rifampin (600 mg in adults, 10 mg/kg in children beyond the neonatal period, and 5 mg/kg in infants <1 month of age) is given at 12-hour intervals for 2 days, whereas ciprofloxacin (500 mg in adults) or ceftriaxone (250 mg IM in adults) only requires one dose. However, three cases of ciprofloxacin-resistant *N. meningitidis* were reported in North Dakota and Minnesota, leading the CDC to no longer recommend ciprofloxacin for meningococcal prophylaxis in

selected counties of those states; decreased susceptibility of meningococci to the fluoroquinolones has also been reported in South Africa, indicating the need for continued surveillance. Ceftriaxone is probably the safest alternative in the pregnant patient. Azithromycin (500 mg orally once) was also shown to be as efficacious as the four-dose regimen of rifampin in the eradication of meningococci from the nasopharynx. Widespread chemoprophylaxis to low-risk contacts should be discouraged because of the concern over emergence of resistant organisms and possible future limitations on this approach.

Aseptic meningitis

Burt R. Meyers and Dalilah Restrepo

Aseptic meningitis syndrome is associated with symptoms, signs, and laboratory evidence of meningeal inflammation with spinal fluid findings that suggest a viral or noninfectious origin. Clinically, patients present with headache, nausea, meningismus, and photophobia, symptoms that are also common in patients with bacterial meningitis. A stiff neck, with or without a Brudzinski or Kernig sign, may be observed. Patients usually appear nontoxic but may have changes in mental status, including irritability. Other signs of possible viral infection may include pharyngitis, adenopathy, morbilliform rash, and evidence of systemic viral infection, including myalgia, fatigue, and anorexia. There are usually no signs of vascular instability, and the course is often self-limiting.

Aseptic meningitis is a syndrome of multiple etiologies, both infectious and noninfectious (Table 75.1). Infections are usually of viral origin but also may be due to mycobacteria, fungi, rickettsiae, and parasites. Group B Coxsackieviruses (mostly serotypes 2 through 5) and echoviruses (mostly serotypes 4, 6, 9, 11, 16, and 30) are responsible for >90% of cases of viral meningitis. Herpesvirus, arboviruses, lymphocytic choriomeningitis virus (LCM), Lyme disease, leptospirosis, and acute HIV are the etiologic agents that make up most of the remaining infectious cases. Noninfectious causes include drug reactions, collagen vascular diseases (i.e., lupus erythematosus, granulomatous arteritis), sarcoidosis, cerebral vascular lesions, epidermal cysts, meningeal carcinomatosis, serum sickness, and nonfocal lesions of the central nervous system (CNS). Specific syndromes (i.e., Mollaret's meningitis, Still's disease) may produce a similar clinical picture. The etiologic diagnosis of aseptic meningitis is often complicated by the numerous possible causes and the lack of specific diagnostic tests.

Etiology

Infectious agents

The most common causes of viral meningitis are the enteroviruses, herpesviruses, and HIV. Some viruses passively enter through the skin or respiratory, gastrointestinal, or urogenital tract and may cause initial infection at the entrance site. Some viruses spread through nerve endings by retrograde transmission via neuronal axons (i.e., poliovirus, rabies virus, herpesvirus). Enteroviruses, LCM, mumps, and arthropod-borne viruses replicate initially in muscle cells or mesodermal cells. Other viruses enter via the nose, cause infection of the submucosa, and then enter the subarachnoid space. Most viruses probably enter the CNS following viremia with primary replication at the site of entry and dissemination into the systemic circulation to either anchor and grow in the choroid plexus or pass directly through it into the CNS. Enteroviruses and HIV are carried by this route.

Enteroviruses are the most common cause of viral meningitis, occurring mostly during summer and fall but may continue to cause CNS infection throughout the winter. The presentation is not distinctive, and the disease presents with abrupt onset and fever, nausea, vomiting, and photophobia. Rash and upper respiratory symptoms may be present. Another increasingly common cause of viral meningitis is represented

TABLE 75.1 CAUSES OF ASEPTIC MENINGITIS

Infectious	
Enterovirus	Echovirus Coxsackievirus A and B Poliovirus Enterovirus 68–71
Herpesvirus	Herpes simplex virus (HSV) 1 and 2 Varicella-zoster virus Epstein–Barr virus Cytomegalovirus HSV-6
Paramyxovirus	Mumps virus Measles virus
Togavirus	Rubella virus
Arbovirus	Eastern equine encephalitis virus Western equine encephalitis virus Venezuelan encephalitis virus
Flavivirus	Japanese encephalitis virus Murray Valley encephalitis virus St. Louis encephalitis virus West Nile virus Powassan Dengue virus Zika virus
Bunyavirus	California encephalitis virus LaCrosse encephalitis virus Jamestown Canyon virus Oropouche virus
Reovirus	Colorado tick fever virus: Coltivirus
Arenavirus	Lymphocytic choriomeningitis virus
Rhabdovirus	Rabies virus
Retrovirus	Human immunodeficiency virus Human T-cell lymphotropic virus (HTLV)-I
Adenovirus	
Mycoplasma	*Mycoplasma pneumoniae*
Fungi	*Cryptococcus neoformans* *Coccidioides immitis* *Histoplasma capsulatum* *Candida* spp. *Aspergillus* *Blastocystis* *Sporothrix schenckii*
Mycobacteria	*Mycobacterium tuberculosis*
Rickettsia	*Rickettsia rickettsii* *Anaplasma*
Spirochetes	*Treponema pallidum* (syphilis) *Borrelia burgdorferi* (Lyme) *Borrelia recurrentis* (relapsing fever) *Leptospira* spp. (leptospirosis)
Parasites	*Angiostrongylus cantonensis* (eosinophilic meningitis) *Toxoplasma gondii* *Gnathostoma spinigerum* *Taenia solium* (cysticercosis) *Trichinella spiralis* *Taenia canis* (visceral larva migrants) *Negiceria fowleri* *Acanthamoeba* spp.
Bacteria	Partially treated bacterial meningitis *Listeria monocytogenes* *Brucella* *Nocardia* Acute or subacute bacterial endocarditis Parameningeal focus (brain or epidural abscess) *Chlamydia* spp. *Actinomyces* spp.
Noninfectious	
Drug reactions	Nonsteroidal anti-inflammatory agents Antineoplastic agents (Daratumumab) Antibiotics (trimethoprim-sulfamethoxazole, amoxicillin, isoniazid) Immunosuppressants (orthoclone, azathioprine) Immunoglobulin IV Vitamin B
Malignancy	Primary medulloblastoma Metastatic leukemia Hodgkin's disease
Collagen vascular disease	Lupus erythematosus Behçet's/adult-onset Still's disease
Trauma	Subarachnoid bleed Traumatic lumbar puncture neurosurgery
Chemicals	Lead, mercury Contrast agents Disinfectants, glove powder
Neurologic disorders	Cerebral vascular lesions Epidermal cysts Brain tumors
Systemic disorders	Sarcoidosis Vasculitis Autoimmune disorders, anti-NMDA encephalitis
Miscellaneous	Serum sickness Mollaret's meningitis Meningeal carcinomatosis Vaccination Postinfectious viral syndromes Posttransplantation lymphoproliferative disorder Kikuchi syndrome

by herpes simplex virus (HSV). Although HSV encephalitis is mostly caused by HSV-1, meningitis is generally caused by HSV-2. In patients presenting with HSV meningitis genital lesions may be present, and one-quarter of the cases presenting with primary genital herpes have meningeal involvement. However, in the case of recurrent Mollaret's meningitis, which is due to HSV-2 in 80% of cases, genital lesions are usually absent. Primary HIV can present as aseptic meningitis with headache, nausea, vomiting, fever, and stiff neck. This disease is self-limiting and can be the only manifestation of HIV for many years. Unfortunately, if patients are not diagnosed at the time of their acute illness, they may infect a number of sexual partners before the diagnosis is established. Interestingly, early onset of aseptic meningitis has not been associated with late neurologic manifestations in HIV-1 infection, and treatment is symptomatic. Other than during the acute phase, aseptic meningitis may also be present during different stages of the disease. The diagnosis may be later complicated by the fact that cerebrospinal fluid (CSF) pleocytosis is less common with advanced immunosuppression. Exposure to excretions of rodents can cause exposure to the LCM, a human zoonosis caused by a rodent-borne arenavirus. The infection, more common during the winter, presents often as an influenza-like syndrome.

Nonviral causes of meningitis often have a more complicated course than viral meningitis and must be recognized because they may have specific therapy. Agents such as bacteria, mycobacteria, and fungi enter the body through the respiratory tract, including the pharynx, sinuses, skin, or lung, and travel to the CNS via the bloodstream. Pneumonitis may be followed by fungemia or bacteremia. Coccidioides meningitis has to be considered in patients with indolent symptoms such as persistent fever and headache who live or traveled from the Southwestern United States and Central or South America. Meningitis is frequently not recognized in this population and may be lethal. *Treponema pallidum* and *Borrelia burgdorferi* enter the CNS after bloodstream invasion.

Infections with flaviviruses can manifest with encephalitis. In the case of Dengue, this is part of the systemic disorder associated with hemorrhagic fever, but it can also be directly neuroinvasive or appear as a neuromuscular complication (e.g., Guillain-Barré syndrome or transient muscle dysfunctions) or with neuro-ophthalmic involvement.

West Nile virus (WNV) is a bird virus and is spread within the avian reservoir by mosquitoes. The main vectors, *Culex pipiens*, *C. restuans*, and *C. tarsalis*, are abundant and ubiquitous in water in puddles and containers, sewers, storm drains, and catch basins. It usually causes mild flu-like symptoms 3 to 14 days after infection. However, 1 in 150 cases will develop serious manifestations, mainly meningoencephalitis, meningitis, or encephalitis. CSF invariably shows a pleocytosis, with a predominance of neutrophils in up to half of these patients. Laboratory diagnosis involves testing serum or CSF for viral-specific neutralizing antibodies. Several WNV immunoglobulin M (IgM) enzyme-linked immunosorbent assay (ELISA) kits are available in the United States.

Because the ELISA can cross-react between flaviviruses (e.g., systemic lupus erythematosus, dengue, yellow fever, WNV, Zika, Chikungunya), it should be viewed as a screening test only. Initial serologically positive samples should be confirmed by neutralization test.

Noninfectious agents

Anti-N-methyl-D-aspartate (NMDA) receptor encephalitis is a severe autoimmune disorder characterized by severe psychiatric symptoms, seizures, decreased consciousness, autonomic dysregulation, and dyskinesias.

Anti-NMDA receptor encephalitis has been regarded as the second most common immune-mediated cause of aseptic meningitis after acute disseminated encephalomyelitis and is more prevalent than all antibody-associated encephalitides. It is most common in young women and children.

Diagnostic workup

In establishing a diagnosis, clues in the history, physical examination, and CSF examination (Box 75.1) are important.

History

Many viral infections are seasonal, occurring during late summer and early fall (e.g., the enteroviruses), whereas mumps and LCM peak during winter and spring. Other viruses such as HSV-2 and HIV occur in any season. WNV and equine-associated meningoencephalitis outbreaks occur from late summer to early fall. Avian (for WNV) or equine sources (for equine encephalopathy) with spread via mosquitoes is the presumed route of infection to humans. Furthermore, a history of exposure to patients with known viral illness often suggests enteroviral infection. Similar presentation in association with genital lesions should suggest HSV-2 meningitis, although genital lesions are absent in about 15% of the cases.

Exposure to mice and rodents suggests LCM, less commonly *Leptospira* species, or hantavirus, which may cause a severe pulmonary syndrome. History of sexual contacts should be elicited because HSV, syphilis, and HIV may present with aseptic meningitis. All patients, including the elderly, should be questioned about risk factors for HIV infection, including sexual promiscuity, intravenous (IV) drug use, sexual preference, and history of transfusions with blood or blood products. Human T-cell lymphotropic virus (HTLV)-I infection may also present with the diagnosis of spastic paraparesis.

Syphilitic meningitis is an important cause of aseptic meningitis, especially prevalent given the soaring incidence of this infection in recent years, as per surveillance by the US Centers for Disease Control and Prevention (CDC). Syphilitic meningitis may coexist with the primary or secondary infection or may follow it by as much as 2 years.

Geographic location, both domicile and travel history, should be evaluated. Exposure to insects such as the tsetse fly in Africa could suggest trypanosomiasis, and mosquito bites in a traveler to India, the Caribbean, or South America associated with fever and rash may suggest chikungunya (CHK) or Zika virus. *Histoplasma*

BOX 75.1

Diagnostic workup for aseptic meningitis syndrome

Clinical evaluation

History
Season (summer, enteroviruses, Rocky Mountain spotted fever)
Geographic area (Colorado tick fever, Babesia, *Anaplasma*, Lyme disease)
Exposure to other patients (mumps, varicella)
Tick, mosquito bites (malaria, Lyme disease), tsetse fly (trypanosomiasis)
Exposure to animals (rabies, hantavirus, LCM)
Sexual history (HIV, HSV, syphilis)
IVDU (endocarditis)
Drug reactions (immunoglobulin, OKT-3, NSAIDs, antibiotics)

Physical examination

Spinal fluid
Opening pressure
Leukocyte count predominance
a. Neutrophils (initial echo, polio, HSV, Mollaret's, TB)
b. Lymphocytes (Coxsackie, enterovirus)
c. Eosinophils (*Angiostrongylus*, *Gnathostoma*)
d. Abnormal cells (Mollaret's, lymphoma, WNV)
Protein ≤40 mg/dL
Glucose ≤40 mg/dL or ≤50% serum
Gram stain, AFB smear, Papanicolaou stain (Mollaret's meningitis)
Cryptococcal antigen, India ink
Immunoelectrophoresis ± Autoimmune antibodies; anti-NMDA
Wet mount (toxoplasmosis, amebae)
Bacterial, mycobacterial, fungal cultures
PCR for enterovirus, HSV, VZV (in immunocompromised patients), CMV, EBV, Zika virus (epidemiologic exposure)
Antibodies to *Borrelia burgdorferi*, *Brucella*, *Histoplasma capsulatum* antigen and anti-histoplasma antibody testing by complement fixation, beginning with undiluted CSF, complement-fixing IgG antibodies, or immunodiffusion tests for IgM and IgG for *Coccidioides immitis* (chronic or recurrent presentation)

Serologic testing

Cryptococcal antigen
Histoplasma urinary and serum antigen (MiraVista Diagnostics)
Lyme disease ELISA, Western blot
Rocky Mountain spotted fever indirect fluorescent antibody test (state health departments)
ANA
HIV-I/HIV-2 antibody
HTLV-1
Serum and CSF VDRL
Autoimmune antibodies (Anti-NMDA)

Other

PPD
Quantiferon Gold
Chest x-ray film
CT, MRI
Echocardiogram

Abbreviations: LCM = lymphocytic choriomeningitis virus; HIV = human immunodeficiency virus; HSV = herpes simplex virus; IVDU = intravenous drug use; OKT-3 = orthoclone; NSAIDs = nonsteroidal anti-inflammatory drugs; TB = tuberculosis; WNV = West Nile virus; AFB = acid-fast bacilli; PCR = polymerase chain reaction; VZV = varicella-zoster virus; CMV = cytomegalovirus; EBV = Epstein–Barr virus; CSF = cerebrospinal fluid; ELISA = enzyme-linked immunosorbent assay; ANA = antinuclear antibody; HTLV-1 = human T-lymphotropic virus type 1; VDRL = Venereal Drug Research Laboratory.

capsulatum, *Coccidioides immitis*, and *B. burgdorferi* occur mainly in certain sections of the United States. Recent contact with a pet or camping suggests *Rickettsia*, *Anaplasma*, or *Borrelia* related to a tick bite. Mosquito bites may result in WNV infection or equine meningoencephalitis virus infection. Rabies, although rare, should be considered if the patient had contact with the secretions of an infected skunk, raccoon, dog, fox, or bat. Drinking untreated water on backpacking trips may result in *Leptospira* infection, ingestion of unpasteurized milk and cheeses may cause brucellosis, and contaminated processed meats (i.e., frankfurters) may cause *Listeria monocytogenes* infection in pregnant women, elderly, and immunocompromised hosts.

Meningitis due to fungi is a consideration primarily in patients affected by HIV and in those who have organ transplantation, immunosuppressive chemotherapy, or chronic corticosteroid therapy. However, the most common pathogen, *Cryptococcus neoformans*, can occur in immunocompetent hosts, including a rare case reported in a daily cannabis smoker without evidence of immunodeficiency.

Vasculitides found in patients of Mediterranean origin include Behçet's disease and familial Mediterranean fever. Certain drugs, including IV immunoglobulin (IVIG), trimethoprim-sulfamethoxazole, nonsteroidal anti-inflammatory drugs (NSAIDs), and immunosuppressants, have been associated with aseptic meningitis syndrome. Intracranial infections often present with headache and fever. Brain, epidural, or subdural abscesses may be present in patients with a history of upper respiratory tract infection (i.e., otitis media, sinusitis) or infection of the teeth or gums. CT scan or MRI may aid in this diagnosis. Aseptic meningitis syndrome has been associated with subacute bacterial endocarditis; physical stigmata, including conjunctival petechiae, cardiac murmurs, retinal lesions, and evidence of embolic phenomenon, may be found. Infection with either mycobacteria or fungi or a history of malignancy must be considered.

It is important to investigate recent antibiotic use. Partially treated bacterial meningitis should be suspected if the patient has received prior oral antimicrobial therapy and has persistently low CSF glucose or pleocytosis with a negative Gram stain. Consideration of any medication including supplements and vitamins, in particular excess vitamin B, has been associated with neurologic signs. Recurrent bouts of meningitis with a benign clinical picture and unknown etiology suggest Mollaret's meningitis.

Physical examination

A physical examination may elicit findings that may suggest a specific agent. Generally the patient is febrile and nontoxic, pulse and respiration normal, with or without evidence of meningismus. Examination of the skin may reveal a morbilliform or vesicular rash consistent with enteroviral infection, primary HIV or syphilis, or evidence of a tick bite. However, a rash can be observed also in some cases of meningococcemia. The scalp should be examined carefully, especially the area behind the ears. Petechiae on the hands and feet usually suggest rickettsial infection. Examination of the eyes for conjunctival petechiae and funduscopic examination may reveal lesions typical of infectious endocarditis. In the right epidemiologic exposure, diffuse petechiae should raise suspicion for severe Dengue. Other lesions usually found by funduscopic examination are associated with cytomegalovirus (CMV) or *Toxoplasma*, especially if there is suspicion of HIV. The oral cavity may show thrush with or without cervical adenopathy. Presence of parotid or testicular swelling enlargement is consistent with mumps meningitis. The chest examination is usually normal, but a murmur in this setting suggests endocarditis; a pericardial rub suggests coxsackievirus infection or a collagen vascular syndrome. Hepatomegaly, splenomegaly, or adenopathy may suggest a systemic disease, including disseminated viral or fungal infection. Genital ulcerative lesions may be present in vascular syndromes such as lupus erythematosus and may also be consistent with HSV-2 infection. Examination of the neck may reveal evidence of stiffness on flexion and a positive Brudzinski and/or Kernig sign. Focal or multiple cranial nerve involvement suggests lesions such as a brain, subdural, or epidural abscess; embolic phenomena may also produce these lesions. Asymmetric flaccid paralysis suggests WNV infection, as well as a macular papular rash which can occur in up to 50% of patients with WNV infection and meningitis. Physical examination may also reveal a typical malar rash or other signs of collagen vascular disease.

Laboratory data

The CSF should be examined and opening pressure recorded; in aseptic meningitis the CSF is clear with a normal or mildly increased opening pressure. The white blood cell (WBC) count is usually <500/mL, but it can reach 1,000/mL with a predominance of lymphocytes. However, CSF differential cell counts may reveal a predominance of polymorphonuclear leukocytes mostly with echovirus, poliovirus, mumps, HSV, *Mycobacterium tuberculosis*, and Mollaret's meningitis. A shift toward a lymphocyte predominance during the first week of the disease occurs. Pleocytosis has been reported in 25% of patients with enteroviral infection. Eosinophils in the CSF suggest parasitic disease secondary to *Angiostrongylus*, *Taenia* spp., or *Schistosoma japonicum* or *Paragonimus westermani*. Meningeal carcinomatosis is suggested when abnormal cells are seen, and large granular cells with indistinct cytoplasm suggest Mollaret's meningitis. Fat droplets have been seen following epidermoid cyst rupture. Spinal fluid glucose should be compared with simultaneously drawn blood glucose. Normal levels of CSF glucose (40 mg/dL or >50–66% of the blood levels) suggest viral meningitis. However, the glucose content may be lower than normal in 18% to 33% of cases, and viruses such as herpes, mumps, LCM, and polio can cause hypoglycorrhachia (Table 75.2). A study of CSF from 334 cases of WNV infection showed that it usually presents with CSF pleocytosis, increased protein, and normal glucose. The protein levels in aseptic meningitis are usually normal or slightly elevated; levels >800 mg suggest CSF block with infection or tumor although this has also been associated with chemical meningitis. A wet prep of CSF should be examined to look for *Toxoplasma gondii* or amebae (e.g., histolytica). Gram stain and bacterial culture should be performed because a partially treated bacterial infection or infection with *L. monocytogenes* may occasionally present with a predominance of lymphocytes. Acid-fast smears, culture, and polymerase

TABLE 75.2 **DIFFERENTIAL DIAGNOSIS OF CEREBROSPINAL FLUID (CSF) GLUCOSE CONCENTRATIONS**

Normal CSF glucose concentration	Decreased CSF glucose concentration
Enteroviruses	Partially treated bacterial meningitis
Mumps virus	*Listeria monocytogenes*
Arthropod-borne viruses	*Mycobacterium tuberculosis*
Herpes simplex virus-1 and -2	*Candida*
Human immunodeficiency virus	*Cryptococcus neoformans*
Influenza virus types A and B	*Coccidioides immitis*
Measles, subacute sclerosing panencephalitis	*Histoplasma capsulatum*
Varicella-zoster virus	*Blastomyces dermatitidis*
Cytomegalovirus	Herpes simplex virus-1
Treponema pallidum	Mumps virus
Borrelia burgdorferi	Lymphocytic choriomeningitis virus
Leptospirosis	Poliovirus
Rickettsia rickettsii	Sarcoidosis
Human monocytic ehrlichiosis	Leptomeningeal carcinomatosis
Anaplasma phagocytophilum	
Behçet's disease	
Migraine	
Vasculitis	
Postinfectious encephalomyelitis	
Nonsteroidal anti-inflammatory agents	
Orthoclone	
Azathioprine	
Trimethoprim-sulfamethoxazole	
Isoniazid	
Intravenous immunoglobulin	

chain reaction (PCR) (non-US Food and Drug Administration [FDA]-approved) should be done to rule out mycobacterial infections, and India ink stain or determination of cryptococcal antigen in the CSF should be performed.

The CSF should also be sent for routine fungal and mycobacterial cultures. With the increasing use of the nucleic acid detection tests, viral cultures from CSF are not useful and should not be performed routinely. Viral cultures are laborious and time-consuming, and they need to be performed in four different cell lines that are then evaluated daily for cytopathic effect. The findings are then confirmed by a neutralizing or an immunofluorescence antibody test. The overall sensitivity of virus isolation from the CSF of patients with aseptic meningitis is between 3% and 40%. In a recent review of more than 20,000 CSF viral cultures, 0.1% or fewer recovered species were non–enteroviruses and non-herpesvirus, suggesting that when nucleic acid amplification testing is performed, viral cultures have no additional benefit. If indicated, simultaneous viral cultures are obtained from throat washings and stool specimens.

CSF should be sent for PCR, which is available for the detection of a range of pathogens, particularly viruses. This technique is highly sensitive and specific, with results available within 24 hours and requiring only small volumes of CSF. PCR is the best assay for the detection of HSV-1, HSV-2, varicella-zoster virus (VZV), human herpesvirus 6 and 7, CMV, Epstein–Barr virus (EBV), enteroviruses, respiratory viruses, and HIV in CSF samples. CSF IgM antibody tests for WNV are positive usually by the seventh to eighth day of infection. Zika virus RT-PCR assay and IgM is available for serum and CSF. PCR for *Chlamydia pneumoniae* can also be performed from a CSF sample. Respiratory viruses, *C. pneumoniae*, and *Mycoplasma pneumoniae* can also be detected from throat samples and enterovirus nucleic acid from stool samples; however, these cannot confirm the etiology of the meningitis. The use of PCR for the diagnosis of infectious origins of aseptic meningitis has resulted in increased identification of the enterovirus, which allows the discontinuation of antimicrobial therapy, decreases hospital length of stay and costs, and enables patients to return to their usual environments.

The use of multiplex PCR facilitates assay of multiple viruses on the same sample. The sensitivity and specificities of this technique are similar to those of the single PCR. Examination of the peripheral blood reveals a WBC count that is usually normal or may be $<5{,}000/mm^3$. The differential is also normal, although occasionally a left shift of polymorphonuclear leukocytes has been observed. Eosinophilia has been described in parasitic infections and in drug and serum sickness reactions. Leukopenia associated with thrombocytopenia may suggest *Anaplasma* and *Rickettsia* infection, and nonspecific changes in hepatic enzymes may be found in viral infections. Sedimentation rate may be normal or elevated. Blood cultures should always be performed, because *L. monocytogenes*, *Brucella*, and rarely some typical pathogens, such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae*, may present with a predominance of lymphocytes in the CSF. Infectious endocarditis from either bacteria or fungi can be considered in the appropriate clinical setting when a patient has positive blood cultures.

If fungal disease is suspected, serologic studies should be performed for cryptococcal antigen and *C. immitis*. *Histoplasma capsulatum* urinary antigen should be tested. PCR for *M. pneumoniae* is also warranted. A Venereal Disease Research Laboratory (VDRL) test should be performed on CSF. PCR tests have been developed using a variety of syphilitic antigens. They are quite specific but do not distinguish live from dead organisms. When rickettsial diseases are suspected (i.e., Rocky Mountain spotted fever or Lyme disease), appropriate serologic tests should be performed, but therapy should not be delayed while tests are pending. If rabies is suspected, an immunofluorescence test on conjunctival scrapings or subcutaneous neck fascial biopsy is the best method for establishing the diagnosis. Other serologic tests include antinuclear antibody (ANA) to rule out systemic lupus erythematosus. Given the appropriate clinical setting, HIV testing may be warranted. The virus in CSF may be detected through PCR. Low CSF lactate levels may distinguish

aseptic meningitis from bacterial meningitis, though pretreatment with antibiotics may reduce the clinical accuracy.

If vesicular lesions are present, immunofluorescent staining for HSV-1, HSV-2, and VZV and viral culture from the lesion should be performed. If lesions other than vesicular lesions are found, careful examination by dark field may reveal evidence of *T. pallidum*. Petechial lesions should be stained and cultured for bacteria and stained with immunofluorescence antibody for *Rickettsia rickettsii*. Throat and stool cultures should be obtained for confirmation of enteroviral infection.
