A chest roentgenogram specifically looking for diffuse infiltrates, cavitation, and pleural or pericardial involvement may suggest mycoplasma, mycobacterial, or fungal infection, in that order. Evidence of a mass lesion in this setting suggests carcinoma and possibly meningeal carcinomatosis. With physical findings of focal involvement, an MRI scan should be performed to look for evidence of an intracranial infection or malignancy. In cases of anti-NMDA encephalitis, an abdominal ultrasound should be done because more than half of these patients have an associated tumor, most commonly an ovarian teratoma.

Therapy

The diagnosis and treatment of the aseptic meningitis syndrome is a challenge because differentiating between infectious and noninfectious etiologies can be difficult. For patients with a suspected bacterial etiology or partially treated meningitis, antibiotic therapy should be promptly initiated. In case of aseptic meningitis in an elderly or immunocompromised patient or in case of an unclear picture, antibiotic therapy should be empirically initiated and discontinued if the patient improves symptomatically and cultures are negative. If the patient deteriorates without a clear diagnosis, a repeat lumber puncture may be indicated. Although the management of patients with aseptic meningitis of viral origin includes supportive care in most cases, specific therapy exists for some viral pathogens. Acyclovir may be used to treat meningitis caused by HSV and VZV, and ganciclovir is used for CMV infection. Acyclovir, 10 mg/kg every 8 hours, is used for HSV and VZV; ganciclovir, 5 mg/kg twice a day, is the regimen for CMV. The newer oral antiviral compounds valacyclovir and famciclovir have a fivefold higher bioavailability than acyclovir, allowing less frequent dosing.

No antiviral therapeutic agent for enteroviruses has demonstrated improved outcome in controlled clinical trials. The administration of γ-globulin helps patients with agammaglobulinemia and chronic enteroviral meningitis as well as neonates with enteroviral sepsis and meningitis. Pleconaril is an orally administered antiviral agent that inhibits enteroviral replication by binding the viral capsid. This drug may reach much higher concentrations within the CNS, suggesting its potential use to treat CNS infection. However, pleconaril induces CYP3A enzyme activity and has not been FDA approved because of its potential for drug interactions for only a modest benefit in patients with more severe disease. Pocapavir, another oral capsid inhibitor, is under development to treat chronic enterovirus in immunocompromised persons. There is no specific treatment for WNV infection. At the moment, only supportive care is available in humans, although IVIG and WNV-specific IVIG has been used in severe cases in immunocompromised patients, and interferon and ribavirin have had conflicting data.

Most viral meningitides are benign and require no therapy. For bacterial, fungal, and spirochetal disease, antimicrobial therapy directed against the offending agent is required (see specific chapters) and should not be delayed while awaiting the results of CSF assay. Treatment with doxycycline in association with two other agents may be indicated for patients suspected of having *Brucella*, and doxycycline or chloramphenicol is used for Rocky Mountain spotted fever. Specific therapy with ampicillin plus gentamicin is suggested when *L. monocytogenes* is the suspected agent, especially in elderly and immunocompromised hosts.

Because the differential diagnosis of aseptic meningitis syndrome is so broad, the initial evaluation of the patient in conjunction with the results of CSF studies will determine whether the patient requires antimicrobial therapy pending culture results from blood and CSF PCR. Patients who are toxic appearing, in the extremes of life, or with serious underlying disease should be hospitalized and treated empirically until a clear diagnosis is made. Isolation precautions for contagious diseases should be instituted.

Viral encephalitis

John J. Halperin and David N. Irani

Introduction

Textbook chapters and clinical medicine often work in opposite directions—a mismatch that can be particularly problematic in neurologic and infectious diseases. This chapter focuses on the pathophysiologically defined entity of viral encephalitis. Patients—and the physicians taking care of them—are focused on their fever, headaches, and changes in nervous system function—ranging from mild somnolence to coma, from focal deficits to seizures. Differentiating encephalitis from meningitis from encephalopathy can be challenging at best; determining whether it is due to a specific virus, bacteria, or fungus can be life-saving.

Since different infectious agents have different tropisms, different pathophysiologies, and different clinical manifestations, it is helpful to start by defining the various types of nervous system involvement. Encephalitis is inflammation of the brain parenchyma. As such, it typically directly alters brain function by either impairing functions normally mediated by the damaged area or triggering seizures from it. When the inflammation affects the brainstem or substantial portions of the cerebral hemispheres, level of consciousness is depressed, up to and including coma. In contrast, meningitis, inflammation in the subarachnoid space, by definition does not affect the substance of the brain and therefore should not have a significantly greater impact on brain function than other systemic illnesses. While this is usually true in viral meningitis, bacterial and fungal meningitis often involve the blood vessels traveling through the subarachnoid space to supply the brain, or directly invade the brain, causing a meningoencephalitis with changes in nervous system function. Finally, the word "encephalopathy" is commonly used to denote altered neurobehavioral function secondary to a systemic process that does not involve the nervous system directly. While this categorization is heuristically helpful, clinical medicine is rarely that simple. Patients with sepsis often have altered consciousness, usually on a toxic/metabolic basis but sometimes from central nervous system (CNS) seeding. For example, malaria causes a congestive vasculopathy significantly impairing brain function. Since different etiologies are likely to underlie each of these disease processes, quickly sorting through these overlapping possibilities has important therapeutic and prognostic implications.

Although it is possible to create a long list of microorganisms that can infect the CNS (Tables 76.1 and 76.2), the number responsible for the overwhelming majority of infectious encephalitides is actually remarkably limited. The CNS is extremely well protected—mechanically by the skull, physiologically by the blood–brain barrier. For infection to involve the CNS it must first gain access. Bacteria and fungi typically accomplish this in one of three ways: mechanically, through trauma or neurosurgery; by contiguous spread from infected sinuses or mastoids; or by vascular obstruction causing endothelial damage and extravasation. However, virtually all viruses that cause encephalitis have developed highly specialized mechanisms to penetrate the CNS. Most probably specifically bind to endothelial cells and then penetrate the blood–brain barrier. Polio, rabies, and herpes viruses bind peripheral nerve receptors, then are transported within axons to infect the CNS.

meningoencephalitis	Seizures/postictal state
Acanthamoeba	**Traumatic**
meningoencephalitis	Acute head injury

Diagnosis

Since viral encephalitis is rare and early symptoms are often confusing (déjà vu, olfactory hallucinations, dysphasia) or nonspecific ("confusion"), the single most important step is to think of the diagnosis. While emergency departments are well known for having a low threshold for obtaining brain CTs in any possible neurobehavioral disorder, these are often uninformative in encephalitis, particularly early in the disease process. Blood cultures are often informative in bacterial meningitis, as they can be in sepsis-related encephalopathy, but peripheral blood testing is not usually informative in viral encephalitis—particularly if diagnostic confirmation is needed in a timely fashion. Definitive diagnosis requires cerebrospinal fluid (CSF) examination. Yet this is often delayed, often for fear that a lumbar puncture (LP) might trigger brain herniation in a patient with cerebral edema—problematic since delaying the diagnostic LP for imaging studies can significantly negatively impact outcome,[1,2] Unfortunately, data on LP risk in encephalitis are limited. Infectious Diseases Society of America (IDSA) encephalitis guidelines emphasize the "essential" nature of a CSF exam but state that it should be obtained "unless contra-indicated"—without stating the contra-indications.[3] Bacterial meningitis guidelines[4] suggest risk of herniation is highest—and therefore pre-LP imaging necessary—if there are focal neurologic deficits or altered mental status; although subsequent studies suggest changes in mental status do not inform risk.[5] Unfortunately, in encephalitis, focal deficits and altered mental status are the norm, thus limiting the applicability of this guidance. Since CT scans are often uninformative early in encephalitis, one might conclude that MRI imaging is needed emergently, even further delaying an LP. Fortunately, while MRI is typically more definitive in supporting the actual diagnosis, a CT scan is sufficient to identify the sort of substantial focal cerebral edema that might pose a risk for an LP.

Delays in a diagnosis of encephalitis are particularly problematic with herpes simplex virus (HSV), both because initial symptoms may be confusing and because delayed treatment can

negatively impact outcome. Fortunately, unlike bacterial cultures, diagnostics in viral encephalitis typically rely on nucleic acid testing or antibodies, neither of which is immediately impacted by antiviral therapy; thus rapid institution of anti-HSV treatment before the LP has little effect on diagnostic testing over the next few days—and should be the norm in any case of suspected infectious encephalitis.

CSF in viral encephalitis typically demonstrates a modest pleocytosis, typically dozens to hundreds of leukocytes per milliliter, rarely >1,000. Although ultimately lymphocytic and monocytic, in the first few days neutrophils may predominate. Protein is usually modestly elevated, typically not exceeding several hundred milligrams per deciliter. CSF glucose is usually normal, although in herpes significant hypoglycorrhachia may occur. Historically CSF antibody testing, particularly detection of immunoglobulin M (IgM) antibody, formed the basis for diagnosis but now PCR for herpes viruses has become quite robust. More recently multiplex nucleic acid tests have become available to assist in diagnosis of CNS infections.[6] Although not perfect, they probably provide the best noninvasive tool to identify specific causative pathogens. Recent studies have used next-gen genomic sequencing[7,8] to identify the agents responsible in particularly difficult to diagnose cases. Although still too cumbersome and expensive to be used outside a research setting, as technology advances this testing may well play an increasingly important role.

Despite the limited therapeutic implications of diagnostic testing, timely diagnosis does provide insights that are important therapeutically, prognostically, and epidemiologically. Patients with presumptive encephalitis are usually started on anti-HSV treatment immediately as early treatment of this infection is critical to outcome. However, one would not want to give 3 weeks of nephrotoxic drugs unnecessarily; hence, excluding this diagnosis can decrease risk of iatrogenic complications. Likewise, identification of arthropod-borne infections has important public health implications, indicating the presence of infected arthropods in the ecosystem and indicating that others are at risk.

Neuroimaging, specifically MRI scanning, cannot provide proof of the specific etiologic agent but can be highly informative. Fluid attenuated inversion recovery (FLAIR) sequences can be highly useful in demonstrating the anatomy of the extracellular edema associated with infection and reactive inflammation. Underappreciated is the role of diffusion weighted imaging. While often presumed to be specific for ischemia, this technique actually provides evidence of cellular edema and is frequently abnormal in infectious processes—as it is in Creutzfeldt–Jacob disease, where it presumably provides evidence of the cellular vacuolization occurring in that disorder. Gradient echo sequences can provide evidence of hemorrhage, often seen in HSV-1 encephalitis. Contrast enhancement supports a diagnosis of active inflammation.

Using these techniques, several anatomic patterns can inform the diagnosis. Very early in HSV-1 encephalitis, changes are typically seen in the medial temporal or frontal lobes. Abnormal signal in the thalamus or basal ganglia (T/BG) is quite suggestive of an infectious etiology[9]; this is identified in a third of encephalitis patients with T/BG findings, but only in a fifth of those without. Importantly, this difference is almost entirely due to differences in children, where a specific infectious etiology is identified in about 40% of children with these findings, but only 20% of children—or adults—without them, and the same 20% in adults with T/BG changes. Among children T/BG abnormalities are preferentially associated with respiratory and West Nile viruses (WNV). Although they may occur in HSV-1 and other viral infections, this is not a preferential site of involvement. Curiously, T/BG involvement is disproportionately unlikely in enteroviral infections. In adults, T/BG findings occur but no more frequently than elsewhere. Importantly, a third of adults with these findings have Creutzfeld–Jacob disease; no other etiology disproportionately has findings in T/BG. Although not evident in large systematic studies, T/BG abnormalities do appear to be suggestive of flavivirus encephalitis, occurring in adults and children with WNV, Japanese encephalitis, tick-borne encephalitis (TBE), and Powassan infection, among others. Spinal cord MRI has also proved useful, particularly in flavivirus infections with flaccid paralysis.

Historically, electroencephalography (EEG) played an important role, particularly in HSV-1 encephalitis, where periodic lateralized epileptiform discharges were recognized as an early, fairly characteristic abnormality. While these findings often preceded CT scan changes, with early findings being common on MRI brain imaging and rapidly available results of sensitive and specific nucleic acid-based diagnostics, this has become less important diagnostically. However continuous video EEG has become a very important element in the management of these patients as subclinical status epilepticus is not uncommon in encephalitis, and this is the best tool available both for initial diagnosis and for monitoring treatment response.

Etiology

An etiology can be identified in about 70% of cases of encephalitis—viral in half, autoimmune in 20%.[10] Although numerous viruses can cause encephalitis (Table 76.1), a small number account for the overwhelming majority. From a pragmatic perspective these are most easily conceptualized as *endemic* (herpes, HIV), transmitted human to human, and *epizootic*, transmitted among species by bites of infected arthropods (insects [mosquitoes] and arachnids [ticks]) or animals (rabies). Endemic viruses tend to occur sporadically without seasonal or geographic propensity. Arboviruses follow the pattern of their vectors—in temperate climates, increasing in incidence over the course of the summer and fall, dropping when cold weather kills or immobilizes vectors, and following the geographic distribution of infected host animals (Figure 76.1). Rabies follows the geographical distribution of infected animals, without a temporal pattern.

HSV is the most common cause of endemic encephalitis. With 1,000 to 2,000 cases a year in the United States, it is about as prevalent as WNV encephalitis. Other flaviviruses predominate worldwide, with the TBE complex being widely prevalent throughout Europe and Asia; its cousins, Powassan and deer tick virus are now being recognized as rare causes of encephalitis in the northeast United States.[11] To give perspective, in the United States in 2015,[12] the Centers for Disease Control and Prevention (CDC) confirmed

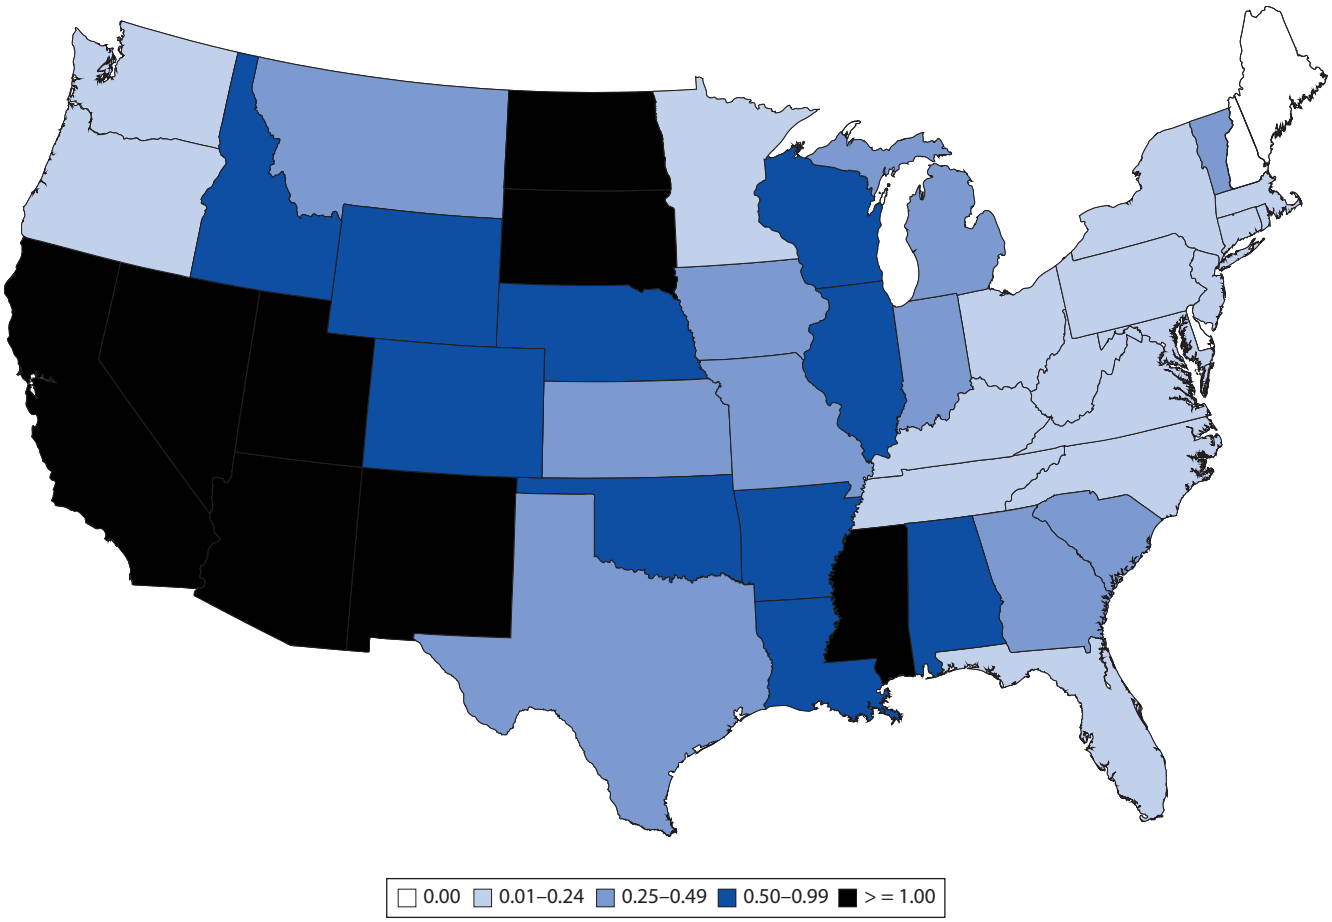

FIGURE 76.1 West Nile virus neuroinvasive disease incidence reported to ArboNET, by state, United States, 2017. West Nile virus neuroinvasive disease incidence maps present data reported by state and local health departments to CDC's ArboNET surveillance system. This map shows the incidence of human neuroinvasive disease (e.g., meningitis, encephalitis, or acute flaccid paralysis) by state for 2017, with shading ranging from 0.01 to 0.24, 0.25 to 0.49, 0.50 to 0.99, and >1.00 per 100,000 population. Neuroinvasive disease cases have been reported to ArboNET from the following states for 2017: Alabama, Arizona, Arkansas, California, Colorado, Connecticut, District of Columbia, Florida, Georgia, Idaho, Illinois, Indiana, Iowa, Kansas, Kentucky, Louisiana, Maryland, Massachusetts, Michigan, Minnesota, Mississippi, Missouri, Montana, Nebraska, Nevada, New Jersey, New Mexico, New York, North Carolina, North Dakota, Ohio, Oklahoma, Oregon, Pennsylvania, Rhode Island, South Carolina, South Dakota, Tennessee, Texas, Utah, Vermont, Virginia, Washington, West Virginia, Wisconsin, and Wyoming.
From ArboNET, Arboviral Diseases Branch, Centers for Disease Control and Prevention

1,455 cases of neuroinvasive WNV, with WNV representing 95% of all arboviral disease. Next most common was Lacrosse virus (55 cases), St. Louis encephalitis (23), and Powassan (6). Human rabies cases are reported once every few years.

Immunosuppression—either iatrogenic in transplant recipients or patients treated for immune-mediated disease such as multiple sclerosis, or from HIV infection or other systemic illnesses—is associated with a number of CNS infections. The most prominent viral brain infection in this context is JC virus, the agent responsible for progressive multifocal leukoencephalitis (PML). It is worth emphasizing that viral presence in the nervous system is not synonymous with encephalitis. Herpes viruses commonly take up long-term residence in neurons—typically sensory neurons of the peripheral nervous system—but do not elicit an inflammatory response unless immunosuppression allows their replication to proceed to the point where a response is triggered. Similarly, CNS infection with the JC polyoma virus appears to be highly prevalent—as is infection with the intracellular protozoan *Toxoplasma gondii*—but these infections only result in encephalitis when the immune system's control of the pathogen fails (i.e., perhaps paradoxically, decreased activity of one arm of the immune system leads to increased inflammation).

Epidemiology

While HSV encephalitis is caused by a viral infection, typically HSV-1 (carried by the overwhelming majority of humans) that on rare occasion happens to invade the CNS, most other encephalitogenic viruses are zoonoses—infections involving multiple species. In rabies, transmission is direct, from one mammal to another; for most others, arthropods serve as vectors among reservoir hosts. Diagnosis typically begins with identifying epidemiologically plausible exposure. For rabies this is a matter of "where": Was the patient in

a place where exposure to rabid animals was possible? For vector-borne infections, "when" becomes equally important. In temperate climates mosquitoes and ticks usually start feeding in spring. If a few infected reservoir hosts are present in the ecosystem, infection can be spread to others, leading to steady amplification of the number of infected vectors in the environment; when enough are present, the likelihood of human exposure becomes significant. For equine encephalitis viruses, this becomes apparent over the course of spring, summer, and fall: first, as presence of virus in pooled mosquitoes, then perhaps in sentinel chickens (chickens maintained solely to monitor seroconversion to these viruses), then in a few horses, and finally in a small number of humans. Public health officials monitor and publish information about this cycle throughout the year; being aware of it can be instrumental in early identification of human arboviral encephalitis cases. An extreme example of this occurred when WNV was first introduced into the United States two decades ago. Human disease first occurred in mid to late summer, but only after a massive and initially mysterious die-off of large numbers of crows and other passerine birds, which served as intermediate hosts and provided massive viral—and therefore infected vector—amplification (Table 76.3).

Clinical manifestations

Most viruses that cause encephalitis cause a wide spectrum of symptoms, well exemplified by WNV, in which about 80% of infected individuals are asymptomatic; 20% develop nonspecific viral symptoms, often including gastrointestinal disturbances; and only 1% develop neuroinvasive disease—half of whom develop meningitis and half parenchymal CNS involvement (i.e., encephalomyelitis). At the other end of the spectrum, rabies appears to cause lethal encephalitis in essentially every infected person. Patients with encephalitis typically develop fever and meningeal symptoms: headache, altered mental status, neck stiffness, photophobia, plus more focal findings. Flaviviruses appear to have a particular predilection for anterior horn cells, causing a polio-like flaccid paralysis in some. The basal ganglia are also commonly involved in WNV, Japanese encephalitis, and Powassan. Brainstem and cerebellar involvement are common in WNV and Powassan.

Powassan, a member of the tick-borne encephalitis virus complex, was first identified several decades ago in Ontario. A recent uptick of cases has allowed more detailed study; a separate clade of virus has been identified and termed "deer tick virus." Most cases of

TABLE 76.3 **CLINICAL AND EPIDEMIOLOGIC CHARACTERISTICS OF MAJOR CAUSES OF VIRAL ENCEPHALITIS IN THE UNITED STATES**

Family/virus	Affected hosts	Peak season/pattern	Geography/incidence	Clinical presentation	Epidemiologic clues
Herpesviridae					
HSV	All ages	Year-round; endemic	Ubiquitous (~2,500 cases/yr)	Focal neurologic deficits; seizures; bizarre behavior	
VZV	Healthy and immunocompromised adults; infants	Year-round; endemic	Ubiquitous	Ataxia; stroke-like episodes; can have an accompanying myelitis	Recent primary varicella rash or herpes zoster dermatomal rash
CMV	Immunocompromised adults; infants	Year-round; endemic	Ubiquitous	Periventricular lesions on brain MRI; accompanying lumbosacral polyradiculitis	Known HIV+ individuals; post-transplant recipients (especially bone marrow recipients)
Retroviridae					
HIV	All ages	Year-round; endemic	Ubiquitous (3,000–4,000 cases/y)	Subacute cognitive deficits; psychomotor slowing	High-risk sexual practices; intravenous drug use
Papovaviridae					
JC virus	Immunocompromised adults	Year-round; endemic	Ubiquitous (400–800 cases/y)	Focal neurologic deficits; multifocal MRI lesions	HIV+ individuals; post-transplantion or immunotherapy
Togaviridae					
Eastern equine encephalitis virus	Young and elderly	Summer and fall; endemic/sporadic	East and Gulf Coasts (5–10 cases/y)	Fulminant deficits; seizures; coma	Outdoor occupation or activities; proximity to marshes or standing water

TABLE 76.3 CONTINUED

Family/virus	Affected hosts	Peak season/pattern	Geography/incidence	Clinical presentation	Epidemiologic clues
Western equine encephalitis virus	Young and elderly	Summer and fall; endemic/sporadic	Midwest and Western States (10–15 cases/y)	Nonfocal deficits; headache	Outdoor occupation or activities; travel or habitation in rural areas
Flaviviridae					
West Nile virus	All ages (but most cases in the young and the elderly)	Summer and fall; epidemic	Nationwide (2,000–4,000 cases/y over the past few years)	Nonfocal deficits; headache; ~20% with a poliomyelitis-like illness	Outdoor exposure (urban or rural); most cases are concentrated in a few states each season
St. Louis encephalitis virus	Young and elderly	Summer and fall; epidemic	Nationwide (~100 cases/y; range 2–1,967 cases/y)	Nonfocal deficits; headache	Outdoor exposure; endemic in rural areas in the West; sporadic urban outbreaks in the Eastern States
Bunyaviridae					
La Crosse virus	Young	Summer and fall; endemic and small case clusters	Midwest and Eastern States (75–100 cases/y)	Often asymptomatic; can cause seizures	Outdoor activities; suburban cases occur near wooded areas
Picornaviridae					
Echoviruses Coxsackieviruses Polioviruses Unclassified viruses (EV-68–EV-71)	Young, especially agammaglobulinemic children	Summer and fall; epidemic	Nationwide (~1,000 cases/y)	Accompanying viral exanthem, conjunctivitis, myopericarditis, herpangina, hand-foot-and-mouth disease	Known community epidemic of picornavirus
Rhabdoviridae					
Rabies	All ages	Year-round; endemic	Nationwide (10–15 cases/y)	Prior animal bite or scratch; autonomic symptoms in ~80%; paralysis in ~20%	Animal contact

Abbreviations: CMV = cytomegalovirus, HIV = human immunodeficiency virus, HSV = herpes simplex virus, MRI = magnetic resonance imaging, VZV = varicella-zoster virus.

human encephalitis previously attributed to Powassan are probably attributable to this agent.

The most clinically characteristic is HSV-1 encephalitis, with its predilection for the medial temporal and frontal lobes (Figure 76.2). In addition to nonspecific symptoms, patients may develop olfactory hallucinations, déjà vu, behavioral changes, and temporal lobe seizures. The disease is highly necrotizing so early recognition and treatment is important. If the patient is unconscious at the time of treatment initiation outcome is much more guarded.

The most recent addition to the list of encephalitogenic flaviviruses is Zika.[11] Although best known for its highly destructive impact on the developing nervous system in the fetus, this mosquito-borne agent can involve the CNS in adults as well. Asymptomatic in about three-quarters of patients, in the remainder it causes a viral syndrome often including a maculopapular rash, polyarthralgias, and conjunctivitis. Guillain–Barré syndrome is almost as likely to follow Zika as it is to follow *Campylobacter jejuni*. Encephalitis has been reported infrequently but has been severe and quite diffuse.

Therapy

General supportive care

Specific therapeutic interventions in encephalitis are limited: specific antivirals are available for several herpesviruses, but few such agents have been found effective in other infections. Overall,[10]

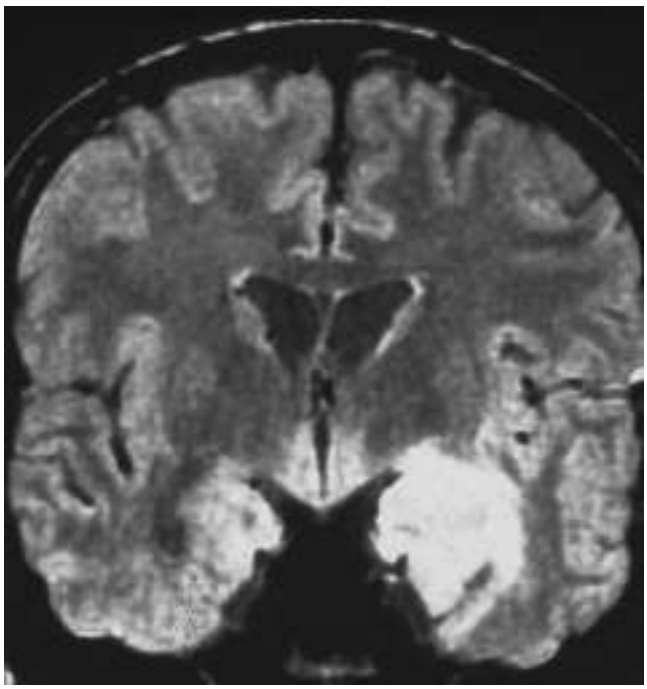

FIGURE 76.2 Coronal fluid-attenuated inversion-recovery MRI from a patient with polymerase chain reaction (PCR)-proven herpes simplex encephalitis (HSE). Hyperintense signal is seen in the medial portion of both temporal lobes as well as in the inferior frontal lobes in a distribution that is highly characteristic of this disease.

about half of all patients with viral encephalitis will have a good outcome, somewhat lower with autoimmune etiologies. Overall mortality in viral encephalitis is >10% with optimal therapy. In HSV-1 in particular, but other etiologies as well, age >65, early coma, immunocompromised state, and delay in treatment for HSV-1 beyond 24 hours are all associated with worse prognosis.

Supportive care is typical of what is needed in neurocritically ill patients: general medical management to prevent complications such as venous thromboembolism, hospital-acquired infections, and nutrition-related complications; and neurospecific issues including early detection and management of seizures—clinical and subclinical—and raised intracranial pressure.

Antiviral therapy

Although there are few effective antiviral regimens for the treatment of patients with acute viral encephalitis, several have demonstrated activity against members of the herpesvirus family (Table 76.4).

Herpesviridae

Acyclovir is the mainstay of treatment for acute HSV encephalitis. In adults, treatment with 10 mg/kg of acyclovir intravenously every 8 hours for 21 days reduces overall mortality from >70% to <20%; importantly, nearly 40% of treated patients recover to the point of returning to normal function. In contrast, clinical trials comparing acyclovir with vidarabine in neonatal HSV-2 encephalitis failed to show significant differences in outcome, and morbidity and mortality remain high. Relapses have occurred after the administration of acyclovir in a few cases outside of large clinical trials; most are associated with persistent fever, perhaps suggesting an inadequate duration of therapy. In some, such treatment failures have been attributed to viral drug resistance or postinfectious encephalomyelitis. Drug-resistant HSV occurs with thymidine kinase alteration or deficiency. Resistant strains have been described in cases of refractory HSE among HIV-infected individuals and should be

TABLE 76.4 **TREATMENT REGIMENS FOR ACUTE VIRAL ENCEPHALITIS CAUSED BY HERPESVIRIDAE**

Virus[a]	Drug of choice	Major toxicities	Alternate regimen[b]	Major toxicities
HSV	Acyclovir, 10 mg/kg IV q8h for 14–21 d	Nephrotoxicity, vomiting, diarrhea, mental status changes	Foscarnet, 60 mg/kg IV q8h or 90 mg/kg IV q12h for 14–21 d	Nephrotoxicity, electrolyte disturbances, nausea, fever
CMV	Induction: ganciclovir, 5 mg/kg IV q12h for 21 d, plus Foscarnet, 60 mg/kg IV q8h or 90 mg/kg IV q12h for 21 d	Bone marrow suppression, rash, fever Nephrotoxicity, electrolyte disturbances, nausea, fever	Cidofovir, 5 mg/kg IV qwk, plus Probenecid, 2 g PO 3 h before cidofovir dose, 1 g 2 h immediately after dose, and 1 g 8 h after dose	Nephrotoxicity, rash, cardiomyopathy
CMV[c]	Maintenance: ganciclovir, 5 mg/kg IV qd, plus Foscarnet, 90 mg/kg IV qd	As above As above	Valganciclovir, 900 mg PO qd	Nephrotoxicity, bone marrow suppression, rash, fever
VZV	Acyclovir, 10 mg/kg IV q8h for 10–14 d	As above	Foscarnet, 60 mg/kg IV q8h for 14–21 d	As above
EBV	Acyclovir, 10 mg/kg IV q8h for 14 d	As above	Ganciclovir, 5 mg/kg IV q12h for 21 d	As above

[a] CMV, cytomegalovirus; EBV, Epstein–Barr virus; HSV, herpes simplex virus; IV, intravenously; PO, orally; VZV, varicella-zoster virus.
[b] Alternate regimens are indicated in the setting of known drug resistance (rare in immunocompetent hosts, but not uncommon in immunocompromised patients who have received extended prior antiviral therapy).
[c] Continue maintenance therapy in HIV-infected patients until CD4 count >100 cells/mm^3 for >6 months.

considered in the setting of a worsening clinical picture and/or CSF persistence of HSV DNA despite appropriate therapy with acyclovir. Intravenous foscarnet is recommended in these cases. In a few, autoimmune antibodies have been identified, leading to successful treatment with immunosuppression.

CMV encephalitis is not uncommon in patients with AIDS, particularly those inadequately controlled by highly active antiretroviral therapy (HAART). It is invariably preceded by viremia and retinitis; many patients have already received some antiviral therapy and may harbor drug-resistant virus by the time the encephalitis develops. Aggressive anti-retroviral therapy is the optimal way to prolong survival in AIDS-related CMV encephalitis. Ganciclovir, one of the mainstays in the treatment of CMV retinitis, has yielded inconsistent results for brain involvement, and its use is limited by significant myelosuppression. Foscarnet crosses the blood–brain barrier more readily, attaining virustatic concentrations in CSF. It, therefore, is an alternative to ganciclovir despite significant renal and electrolyte effects. Unfortunately, although the combination of ganciclovir and foscarnet may transiently stabilize or improve the condition of most HIV-positive patients with acute CMV encephalitis, the regimen does not have an appreciable effect on survival, which averages only 3 months in this setting.

High-dose parenteral acyclovir has been used in the treatment of varicella-zoster virus (VZV) encephalitis, although the efficacy of antiviral drugs has yet to be proved in this disease. Immunocompetent patients with VZV encephalitis often have an associated granulomatous arteritis of the brain, and a brief course of corticosteroids is often empirically added for its anti-inflammatory effects. Encephalitis is a rare complication of Epstein–Barr virus (EBV) infection. The therapeutic benefit of acyclovir in EBV encephalitis remains unproved as well, but it should be strongly considered given the lack of alternative regimens and the relatively low toxicity of acyclovir.

Papovaviridae

Despite occasional anecdotal reports, efforts to treat PML have generally provided inconsistent results. Reversing immunosuppression, when possible, seems to arrest the process. A recent report of successful treatment with externally expanded virus-specific T cells.[13] may provide a novel approach to this infection. Two of three described patients had clinical and imaging improvement, with clearance of JC virus from the CSF. The third, with HIV infection, had reduction in JC viral load and clinical stabilization but no improvement; she opted for hospice care and succumbed 8 months after treatment.

Intracranial suppuration

Brian Wispelwey and Christopher J. Arnold

Brain abscess

A brain abscess begins as a localized area of cerebritis that develops into a collection of pus surrounded by a well-vascularized capsule. Brain abscesses are uncommon, with occurrence rates of 0.18% to 1.3% in large autopsy series. They most commonly result from contiguous septic foci, but hematogenous spread from a distant source and neurosurgical procedures or trauma represent other risk factors. No predisposing factor can be found in approximately 20% of cases (Box 77.1).

The age distribution of patients with brain abscess varies with its cause. A brain abscess from an otogenic focus typically occurs in patients <30 and shows a male predominance. Brain abscess secondary to sinusitis typically occurs in men in their second to third decade of life.

Pathogenesis

The location of a brain abscess is dependent on its predisposing cause. Abscess from a contiguous focus usually occurs in the cortical area of the brain near its causal site. The most common foci of contiguous infections are otitis or sinusitis. Infection from a contiguous site can spread either directly through intervening tissues, bone, and meninges or indirectly through retrograde thrombophlebitis of the diploic or emissary veins. An abscess may also result from an otogenic infection by spread through preexisting channels such as the internal auditory canal or cochlear and vestibular aqueducts. The majority of otogenic brain abscesses are located in the temporal lobe, followed by the cerebellum. Approximately 90% of cerebellar abscesses are secondary to an otogenic infection. Brain abscesses due to sinusitis are almost always found in the frontal lobe.

Brain abscesses secondary to hematogenous dissemination are often multiple and are located in the territory of the middle cerebral artery at the gray–white junction. They have a distant focus of infection, which is most often within the chest. These abscesses are poorly encapsulated and have a high mortality.

Brain abscesses rarely accompany bacteremia if the blood–brain barrier is intact. For example, despite the presence of persistent bacteremia in bacterial endocarditis, brain abscess is rare (9 brain abscesses reported in 218 cases of infective endocarditis).

Causes

Organisms isolated from brain abscesses are outlined in Table 77.1. Although a single organism is detected in the majority of bacterial brain abscesses, nearly 30% are of mixed infection. Streptococci, Enterobacteriaceae, and anaerobes are most commonly found. In contrast, *Staphylococcus aureus* is commonly isolated in pure culture.

Fungal brain abscesses have increased in incidence due to the prevalent use of immunosuppressive agents, corticosteroids, and broad-spectrum antibiotics. *Candida* spp. are the most common fungi in autopsy series. Risk factors for invasive *Candida* infection include the use of corticosteroids, broad-spectrum antimicrobials, and hyperalimentation. Cerebral aspergillosis occurs in 10% to 20% of all cases of invasive

TABLE 77.1 **PATHOGENS IN BRAIN ABSCESS**

Agent	Frequency (%)
Streptococci (*S. intermedius*, including *S. anginosus*)	60–70
Bacteroides and *Prevotella* spp.	20–40
Enterobacteriaceae	23–33
Staphylococcus aureus	10–15
Fungi[a]	10–15
Streptococcus pneumoniae	<1
Haemophilus influenzae	<1
Protozoa, helminths[b] (vary geographically)	<1

[a] Yeasts, fungi, *Aspergillus*, agents of mucor, *Candida*, cryptococci, coccidiodoides, *Cladosporium trichoides*, *Pseudallescheria boydii*.
[b] Protozoa, helminths, *Entamoeba histolytica*, schistosomes, paragonimus, cysticerci.

aspergillosis, although the brain is rarely the only site of infection. Most cases occur in neutropenic patients with underlying hematologic malignancy. Fungi of the *Zygomycetes* most often cause rhinocerebral mucormycosis, particularly in patients with diabetes mellitus and ketoacidosis, hematologic malignancies, or patients on immunosuppressive therapy. Isolated cerebral mucormycosis is most commonly seen in injection drug users. *Scedosporium apiospermum* is a common mold found in soil. Brain abscess with this organism is often associated with near drowning, trauma, or immunosuppression. While numerous other etiologic agents of fungal brain abscess exist, it is also important to highlight the recent rise in *Cryptococcus gatti* brain abscesses in immunocompetent hosts with epidemiologic exposure in the Pacific Northwest. Patients usually have outdoor exposure and may have a delayed time to diagnosis given that cryptococcal infection is not frequently considered among an otherwise immunocompetent population.

There are several protozoa and helminths that produce brain abscess. The most common is *Toxoplasma gondii*, which typically causes an intracerebral mass or encephalitis in immunosuppressed hosts. While clinically better described as an inflammatory lesion rather than suppuration, the larval form of *Taenia solium*, causative of neurocysticercosis, is of considerable burden in Central and South America. Also found among immunocompetent hosts, cysticercosis is the most common cause of acquired seizure in the developing world.

Infections more often found in patients with defects in cell-mediated immunity include *T. gondii*, *Nocardia asteroides*, *Cryptococcus neoformans*, mycobacteria, and *Listeria monocytogenes*. Neutrophil defects are associated with an increased incidence of infections caused by Enterobacteriaceae, *Pseudomonas*, and fungi. Patients with AIDS may develop focal central nervous system (CNS) lesions as a result of a variety of pathogens (Box 77.2).

BOX 77.1

Clinical settings associated with brain abscess

Spread from a contiguous focus
Otitis media, mastoiditis; 40% of all brain abscesses
Sinusitis, frontal
Dental infections (≤10%), typically with molar infections; abscesses usually frontal but may be temporal
Meningitis; rarely complicated by brain abscess (must be considered in neonates with *Citrobacter diversus* meningitis, of whom 70% develop brain abscess)

Hematogenous spread from a distant focus of infection
Empyema, lung abscess, bronchiectasis, cystic fibrosis, wound infections, pelvic infections, intra-abdominal sepsis

Trauma
After penetrating head trauma, brain abscess develops in about 3%, more commonly after gunshot wounds
Neurosurgical procedures; complicated by brain abscess in only 6–17 per 10 000 clean neurosurgical procedures

Cryptogenic
Asymptomatic pulmonary arteriovenous malformation (AVM), a consideration in cases of cryptogenic brain abscess
Cyanotic congenital heart disease is present in 5–10% of brain abscesses and is the most common predisposing factor in some pediatric series

Clinical manifestations

The clinical course of patients with brain abscess varies dramatically. In approximately 75% of patients, symptoms are present for <2 weeks. Importantly, the prominent symptoms are secondary to mass effect, not infection (Table 77.2). Headache, the most common symptom, may be hemicranial or generalized. Varying degrees of altered mental status are present in most patients. Furthermore, fever may be absent in as many as 50% of all cases.

Brain abscesses in certain anatomic locations may cause additional symptoms. For example, cerebellar abscesses are often associated with nystagmus, ataxia, vomiting, and dysmetria. Frontal lobe abscesses induce headaches, drowsiness, inattention, and decline in mental function. Temporal lobe abscesses are associated with early ipsilateral headaches and, if in the dominant hemisphere, aphasia. Intrasellar abscesses simulate pituitary tumors. Brainstem abscesses often cause facial weakness, headache, fever, hemiparesis, dysphagia, and vomiting.

Laboratory findings

Most laboratory tests are not diagnostic for brain abscess (Box 77.3). Lumbar puncture is contraindicated in patients with known or suspected brain abscess. Not only are cerebrospinal fluid (CSF) findings nonspecific, but patients may herniate after the procedure. In one series, 41 of 140 patients deteriorated within 48 hours after lumbar puncture, and 25 died. Similar results have been reported in other studies.

Imaging studies are most useful in making a diagnosis of brain abscess. CT can be used to evaluate all cranial structures, including the paranasal sinuses, mastoids, and middle ear. It can detect edema,

BOX 77.2

Causes of parenchymal central nervous system lesions in patients with AIDS

Toxoplasma gondii

Most common focal lesion

Occurs in about 10% of all AIDS patients

>1 lesion seen on MRI with surrounding edema, mass effect, and ring enhancement

Most common location is the basal ganglia; most *Toxoplasma* IgG positive

Primary lymphoma

Occurs in about 2% of AIDS patients

Lymphoma is B cell in origin

Lesions are hyperdense or isodense on CT with edema, mass effect, and variable enhancement

Caused by Epstein–Barr virus

Progressive multifocal leukoencephalopathy

Occurs in 2–5% of AIDS patients

Lesions occur at gray–white junction and adjacent white matter; usually hypodense without mass effect

Caused by JC virus (Papovavirus)

Less common

Cryptococcus neoformans[a]

Histoplasma capsulatum[a]

Coccidioides immitis[a]

Other fungi; *Aspergillus*, *Candida*, agents of mucormycosis

Mycobacterium tuberculosis[a]

Mycobacterium *avium* complex

Cytomegalovirus[b]

Metastatic malignancy, notably Kaposi's sarcoma

Acanthamoeba

Bacterial brain abscess of *Listeria*, *Nocardia*, *Salmonella*

Syphilis[a]

Abbreviations: CNS = central nervous system; AIDS = acquired immunodeficiency syndrome; MRI = magnetic resonance imaging; CT = computed tomography; IgG = immunoglobulin G.

[a] More commonly meningitis.

[b] More commonly encephalitis.

hydrocephalus, shift, or imminent ventricular rupture. Contrast enhancement is essential. A brain abscess appears as a hypodense center with an outlying uniform ring of enhancement following the injection of contrast. This is surrounded by a variably hypodense region of brain edema.

MRI is the diagnostic procedure of choice for brain abscess. It appears more sensitive than CT for detecting cerebral edema and is more accurate in differentiating the central necrosis of brain abscess from other fluid accumulations. Gadolinium enhancement can provide further structural detail. On T1-weighted images, enhancement of the abscess capsule occurs, while on T2-weighted images, the surrounding zone of edema has high signal intensity, and the capsule appears as hypointense at the abscess margin. Diffusion-weighted

TABLE 77.2 **CLINICAL MANIFESTATIONS OF BRAIN ABSCESS**[a]

Headache	70%	Nuchal rigidity	≈25%
Fever	50%	Papilledema	≈25%
Altered mental status	>50%	Focal neurologic findings	≈50%
Seizures	25–35%		

[a] Fewer than half have classic triad of fever, headache, and neurologic deficits.

MRI can additionally be used to differentiate neoplasm from abscess as pus leads to restricted diffusion, but false positivity can be observed in cystic or necrotic cerebral metastases. Positron emission tomography (PET) or magnetic resonance spectroscopy may further refine sensitivity and specificity and are routinely available in many settings.

Therapy

Most patients with bacterial brain abscess require surgical management. The two available procedures are aspiration and excision. No prospective randomized trial has been performed to compare these procedures. While aspiration causes less tissue damage than excision, and stereotactic aspiration is particularly valuable for deep-seated abscesses, aspiration during early cerebritis stage may risk hemorrhage and all abscesses >2.5 cm require open excision. In one series, no abscess larger than 2.5 cm resolved without surgical therapy. Ventriculostomy is occasionally required if there is evidence of marked increased intracranial pressure due to obstructive hydrocephalus, ventricular rupture, or other uncontrolled mass effect. Medical therapy alone can be considered in the cerebritis stage prior

BOX 77.3

Laboratory tests and imaging studies

Laboratory tests[a]

WBC: moderate leukocytosis present in about 50% (only 10% WBC >20 000) and normal WBC in 40%

Moderate increase in ESR

Chest x-ray film is useful in detecting the origin of hematogenous brain abscess

EEG abnormal in most patients, lateralizes to side of lesion

Imaging studies

CT scan: useful in evaluating the brain, sinuses, mastoids, and middle ear

MRI: appears more sensitive early in illness and in detecting cerebral edema

^{99m}Tc very sensitive; useful where CT or MRI not available

Abbreviations: WBC = white blood cell count; ESR = erythrocyte sedimentation rate; EEG = electroencephalograph; CT = computed tomography; MRI = magnetic resonance imaging.

[a] Lumbar puncture is contraindicated in patients with known or suspected brain abscess.

to development of the abscess capsule or when the abscess is small or inaccessible.

Approach to the patient with suspected brain abscess

Patients who present with altered consciousness, focal CNS signs, or seizures usually are candidates for contrast-enhanced CT or MRI. Lumbar puncture usually is postponed until a space-occupying CNS lesion is excluded. If rapid clinical progression is occurring, blood cultures for bacteria and fungi may be done and empiric antimicrobial therapy begun before neuroimaging. In every case, management should be done in conjunction with a neurosurgeon. A probable focus in the paranasal sinus or middle ear should prompt consultation also with an otolaryngologist. Empiric treatment depends on the presence or absence of immunosuppression, particularly AIDS.

Antibiotics for the treatment of brain abscess should be administered intravenously, be active against the most likely pathogens, reach adequate concentrations in the abscess fluid, and have bactericidal activity. A third-generation cephalosporin, such as cefotaxime, 3 to 4 g every 8 hours, or ceftriaxone, 2 g every 12 hours, is recommended as first-line empirical therapy of community-acquired brain abscess due to its coverage of streptococci as well as its broad gram-negative spectrum of activity. This antibiotic should be used in conjunction with metronidazole, 7.5 mg/kg (often rounded out to 500 mg) every 6 hours, which attains high concentrations in brain abscess pus and has bactericidal activity against strict anaerobes. A high proportion of deep wound infections after neurosurgical procedures are due to methicillin-resistant *S. aureus* (MRSA), *Staphylococcus epidermidis*, and multiresistant Enterobacteriaceae. Therefore, recommended empiric antibiotics for brain abscess after a neurosurgical procedure include meropenem or cefepime plus vancomycin. Empiric antibiotic therapy should be modified or extended based on culture results, clinical status, and radiologic findings (Table 77.3).

Most patients require surgery. An increasing number of publications advocate the use of stereotactic aspiration as the intervention of choice for many cases. If the patient remains stable and the abscess is accessible and encapsulated, aspiration (CT-guided, if possible) is desirable to make a specific bacteriologic diagnosis and narrow the antimicrobial regimen. If, for any reason, excision or aspiration is delayed or not performed, medical therapy with empiric antibiotic therapy should be instituted immediately. Subsequent management depends on clinical and radiographic (CT) parameters. Later neurologic deterioration, enlargement of an abscess after a 2-week interval, or failure of the abscess to decrease in size after 3 to 4 weeks of antibiotics are indications for further surgery. The duration of microbial therapy remains unsettled. Many authorities treat parenterally for approximately 6 to 8 weeks. Duration cannot be determined by resolution of all CT or MRI abnormalities. A cured brain abscess may continue to appear as nodular contrast enhancement on CT scans for 4 weeks to 6 months after completion of successful therapy.

TABLE 77.3 **ANTIMICROBIAL THERAPY FOR BRAIN ABSCESS**

Antimicrobial agent	Total daily dose
Cefotaxime	8–12 g
Ceftazidime	6–12 g
Ceftriaxone	4 g
Chloramphenicol	4–6 g
Metronidazole	30 mg/kg
Nafcillin	9–12 g
Penicillin G	24 million U
Vancomycin	2 g

See text for discussion of relevant combinations.

AIDS patients and other immunocompromised patients

Patients with advanced HIV infection or AIDS and who have CNS lesions on MRI or contrast-enhanced CT consistent with toxoplasmosis are usually begun on empiric therapy with pyrimethamine and sulfadiazine. Pyrimethamine is given to adults as a single loading dose of 75 to 100 mg followed by 25 to 50 mg daily. Folinic acid is given, 10 mg daily, to decrease bone marrow suppression from pyrimethamine. Sulfadiazine is given, 1 g orally every 6 hours. If sulfadiazine is not available, clindamycin is an acceptable substitute at 600 mg intravenously (IV) every 6 hours. Low-grade fever and a gradual onset also prompt this approach. The limitation of empiric therapy is that radiologic distinction between toxoplasmosis and other lesions is not accurate. Progressive deterioration, an atypical CT or MRI, or failure to show clinical and imaging improvement during 2 weeks of therapy generally warrants biopsy or aspiration. Some physicians also use a negative *Toxoplasma* serology to prompt early neurosurgical intervention. Patients taking trimethoprim-sulfamethoxazole (TMP-SMX) prophylaxis for pneumocystosis may be at a lower risk of toxoplasmosis and are therefore more likely to have another diagnosis. Newer diagnostic modalities, such as single-photon emission CT (SPECT), may allow immediate differentiation between *Toxoplasma* and other pathologic processes (see Chapter 101, "Prophylaxis of opportunistic infections in HIV disease").

The range of pathogens for brain abscess is so broad in other immunocompromised patients that empiric therapy has limited value. Early neurosurgical intervention is usually indicated. An exception may be the neutropenic patient in whom fungal abscess is likely, in which case addition of antifungal coverage to antibacterial treatment should be considered. An amphotericin B preparation such as amphotericin B deoxycholate at 0.6 to 1.0 mg/kg/d or liposomal amphotericin B at 5 mg/kg/d will adequately cover brain abscesses from *Candida* species and most endemic fungi. Voriconazole at 4 mg/kg every 12 hours is preferred if an *Aspergillus* species is suspected, and successful combination therapy of voriconazole with an amphotericin B preparation or an echinocandin has been demonstrated.

Corticosteroids

The role of corticosteroids in the treatment of brain abscess remains controversial. They should be restricted to patients who have

progressive neurologic deterioration or impending cerebral herniation and radiologic evidence that the abscess is causing significant cerebral edema and mass effect. The use of corticosteroids may delay the entry of antibiotics into the CNS, impair the clearance of bacteria, inhibit capsule formation, and alter the appearance of follow-up radiologic imaging.

Prognosis

Several factors are associated with a poor prognosis (Box 77.4). In addition, characteristics such as patient's age, abscess diameter, and metastatic lesions also influence outcome. Neurologic sequelae develop in 30% to 55% of patients, and in 17% they are incapacitating. Seizures develop in a variable percentage of patients (12% to >50%).

Subdural empyema

Subdural empyema is the most common sinusitis-associated intracranial infection. The frontal sinus is most frequently implicated, and the most common location of a subdural empyema is the frontal lobe. Other causes of subdural empyema include meningitis, otitis media, prior head trauma, infection of an existing subdural hematoma, or neurosurgical procedure. Subdural empyemas have a male predominance and most often occur in the second decade of life in otherwise healthy individuals. An intracerebral abscess occurs concomitantly in 6% to 22% of cases, and an epidural abscess in 9% to 17%.

Causes

Subdural empyemas are most often monomicrobial; however, polymicrobial infections are common. Organisms found in paranasal sinus cultures often do not correlate with subdural cultures. Aerobic and anaerobic streptococci are the most frequently isolated pathogens. Staphylococci are cultured less often, followed in frequency by aerobic gram-negative bacilli and nonstreptococcal anaerobes (Table 77.4). For example, *Propionibacterium acnes* has been reported following penetrating head trauma and after neurosurgery with the use of dural allograft. Sterile cultures occur in a substantial number of cases, possibly due to the prior administration of antibiotics or difficulties in culturing anaerobic organisms.

TABLE 77.4 **PATHOGENS IN SUBDURAL EMPYEMA**

Aerobic streptococci	32%
Anaerobic streptococci	16%
Staphylococcus aureus	11%
Coagulase-negative staphylococci	5%
Aerobic gram-negative bacilli	8%
Anaerobes	5%
No organism isolated	34%

Clinical presentation

Due to a lack of anatomical constraints to limit the spread of infection in the subdural space, the clinical manifestations can progress rapidly (Table 77.5). Headache and fever are common early symptoms. Altered mental status, focal neurologic deficits, meningismus, papilledema, and vomiting may also result. Seizures are common and occur in 25% to 80% of cases.

Diagnosis

Diagnosis is made by imaging with contrast-enhanced CT or MRI. A subdural empyema appears as a crescent-shaped area of hypodensity adjacent to the falx cerebri or below the cranial vault. With contrast enhancement, an intense line can be seen between the subdural collection and the cerebral cortex. Edema can cause effacement of the basilar cisterns and flattening of the cortical sulci. MRI is more sensitive in detecting subdural empyemas, particularly at the base of the brain, in the posterior fossa, or along the falx cerebri. On MRI, T1-weighted images may reveal mass effect and a hypointense subdural lesion, which in turn is hyperintense on T2-weighted imaging. On diffusion-weighted imaging, subdural empyemas have high signal intensity, in contrast to sterile subdural effusions that have low signal intensity.

Therapy

Surgical intervention using either a burr hole or craniotomy to drain the subdural empyema is an important part of therapy. Drainage is useful to both relieve mass effect and obtain cultures to guide

BOX 77.4

Adverse prognostic factors in brain abscess

Delayed or missed diagnosis
Poor localization, especially in the posterior fossa (before CT)
Multiple, deep, or multiloculated abscesses
Ventricular rupture (80–100% mortality)
Fungal cause
Inappropriate antibiotics

Abbreviation: CT = computed tomography.

TABLE 77.5 **CLINICAL PRESENTATION OF SUBDURAL EMPYEMA**

Headache	
Altered mental status	≈50%
Fever (>39°C [102.2°F])	Majority
Focal neurologic findings Hemiparesis, ocular palsies, dysphagia, cerebellar signs	In all, eventually
Seizures	25–80%
Meningismus	≈80%

antimicrobial therapy. Exploration of a sinus or otologic focus of infection should also be done.

A reasonable empiric antibiotic regimen for a community-acquired subdural empyema would be a third-generation cephalosporin plus metronidazole. Depending on the prevalence of MRSA or the likelihood of coagulase-negative staphylococci, the addition of vancomycin could be considered. Further antimicrobial therapy should be directed against pathogens revealed by Gram stain, culture of aspirated material, and knowledge of the primary site of infection. Parenteral antibiotics are continued for 3 to 6 weeks depending on the clinical response and associated conditions.

Due to the high incidence of seizures, many centers advocate the use of anticonvulsants. Even despite the use of prophylaxis, some small studies have shown a continued high incidence of seizures. Further studies are needed to investigate strategies to decrease this significant complication.

Prognosis

Prognosis is related to the degree of neurologic impairment at presentation. Mortality is approximately 7% in patients who are alert and well-oriented, 21% in patients who are lethargic or comatose but respond purposefully, and 56% in patients who are unresponsive. Neurologic sequelae in the form of hemiparesis and aphasia are common, and up to 40% of patients may have seizures.

Cranial epidural abscess

Cranial epidural abscesses (Figure 77.1) were traditionally the sequelae of sinusitis, mastoiditis, and otitis media. Currently, one of the most common causes of an intracranial epidural abscess is a neurosurgical procedure. The organisms responsible for epidural abscesses are similar to those that cause subdural empyemas.

The dura is essentially adherent to the inner lining of the skull, which constrains the epidural space and limits spread of purulence. Because of this, epidural abscesses are typically slow growing and have an indolent course. Headache may be the only presenting symptom. Over time, complications such as subdural empyema, brain abscess, or meningitis may result. It is the manifestations of these complications that may be the first indication of an intracranial process.

Contrast-enhanced CT or MRI may be used to diagnose an intracranial epidural abscess. Lentiform or crescentic collections overlying a cerebral convexity and/or in the interhemispheric fissure are seen. Treatment is the same as for subdural empyema.

Suppurative intracranial thrombophlebitis

Cavernous sinus thrombosis most commonly results from spread of infection from the sinuses, especially the sphenoid sinus. Infections

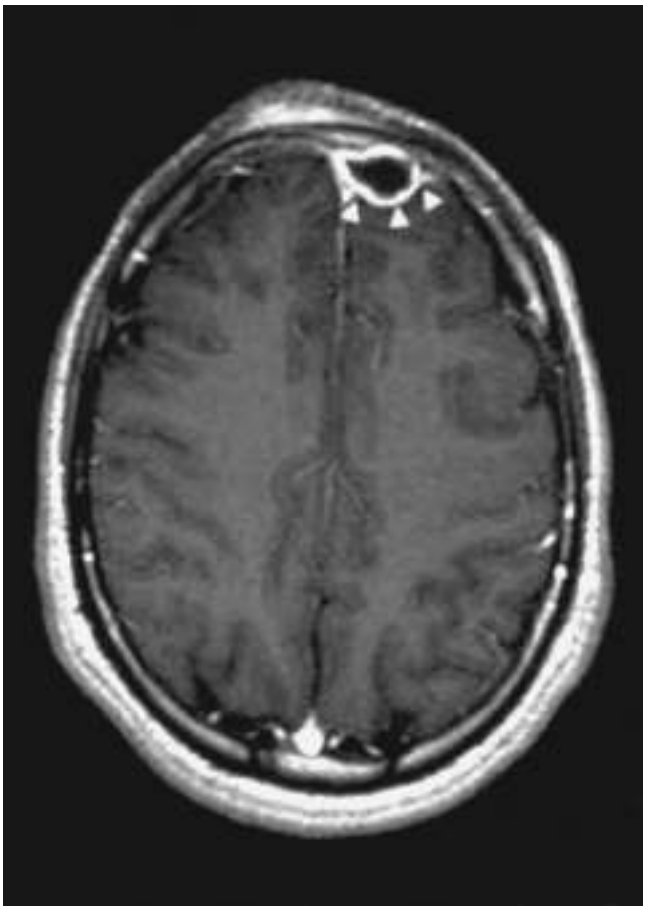

FIGURE 77.1 Epidural abscess associated with frontal sinus disease. Postgadolinium axial T1W MRI showing thick-walled enhancing epidural collection close to the inner table of the frontal bone (*arrowheads*) with adjacent soft tissue swelling.
From Bradley WG. *Neurology in clinical practice*, 4th ed. Oxford: Butterworth-Heinemann, an imprint of Elsevier; 2004.

of the middle third of the face, dental abscesses, otogenic infections, and orbital cellulitis are other sources of cavernous sinus thrombosis (see Chapter 16, "Periocular and retro-orbital infections"). Lateral sinus thrombosis is a serious complication of both acute and chronic otitis media. Infection of the superior and inferior petrosal sinuses may also result from otitis media or mastoiditis. Suppurative thrombophlebitis of the superior sagittal sinus may develop after infection of the face, scalp, or subdural or epidural space or after meningitis.

Pathogenesis

Suppurative thrombophlebitis occurs intracranially because of the close proximity of the dural venous sinuses to other structures in the skull. The transverse sinus receives several important supratentorial veins from the temporal and occipital lobes, as well as many infratentorial veins. The superior petrosal sinus, which receives venous channels from the tympanic structures, also drains into the transverse sinus. The sigmoid sinus, which lies close to mastoid cells, is the inferior continuation of the transverse sinus.

TABLE 77.6 **SUPPURATIVE INTRACRANIAL THROMBOPHLEBITIS: ORGANISM BY SITE OF INFECTION**

Sinusitis	Streptococci
	Staphylococci
	Anaerobes
Soft-tissue infections of the face	*Staphylococcus aureus*
Otitis, mastoiditis	Streptococci
	Haemophilus influenzae
	Gram-negative bacilli
	Staphylococci

The dural venous sinuses and cranial veins are valveless, and blood flow is determined by pressure gradients. Bacteria that enter the facial veins are carried through the cavernous sinuses to the petrosal sinuses and finally the internal jugular vein. Conditions that increase blood viscosity, such as trauma, dehydration, malignancy, and pregnancy, increase the likelihood of developing thrombosis. However, predisposing conditions are not identified in every case.

Causes

The causative pathogen in suppurative intracranial thrombophlebitis depends on the site of the original infection (Table 77.6). *S. aureus* is the most common pathogen in cavernous sinus thrombosis, but other gram-positive cocci such as *Streptococcus* species, gram-negative bacilli, and anaerobes can be seen. The most common bacteria in lateral sinus thrombosis include gram-negative bacilli and anaerobes. Mixed infections are frequent.

Clinical presentation

The clinical presentation depends on the location of disease (Table 77.7). Cavernous sinus thrombosis can present with periorbital edema, chemosis, visual loss, restricted eye movement, and proptosis. Orbital cellulitis and orbital apex syndrome can present similarly. In contrast, preseptal cellulitis is confined to structures anterior to the orbit. Suppurative cavernous sinus thrombosis can spread via intercavernous sinuses to the contralateral cavernous sinus within 24 to 48 hours. The thrombus may also extend to other dural venous sinuses, adjacent vascular structures, or the brain parenchyma. Metastatic spread of septic emboli may occur and most commonly involves the lung.

TABLE 77.7 **SYMPTOMS OF SUPPURATIVE THROMBOPHLEBITIS**

Cavernous sinus thrombosis	Photophobia, ptosis, diplopia, proptosis, chemosis, weak extraocular muscles, papilledema, altered mental status, meningismus, decreased visual acuity, involvement bilaterally; same findings in opposite eye
Septic lateral sinus thrombosis	Headache >80%, earache, vomiting, vertigo associated with otitis, fever and abnormal ear findings, increased facial sensation/pain, sixth-nerve palsy
Superior sagittal sinus	Altered mental status, motor deficits, papilledema, nuchal rigidity, seizures >50%
Inferior petrosal sinus	Gradenigo's syndrome (ipsilateral facial pain and lateral rectus weakness)

Classic symptoms and signs of lateral sinus thrombosis include severe headache, otalgia, spiking fevers, mastoid swelling, and tenderness. However, patient presentations may be highly variable and are influenced by the common occurrence of concurrent intracranial complications and preadmission antibiotics. Symptoms and signs of raised intracranial pressure may result if the thrombosis significantly impairs CSF resorption or cerebral venous outflow. These include headache, nausea, vomiting, sixth nerve palsy, and papilledema. Nuchal rigidity has been reported to occur in 8% to 61% of patients. Unlike meningitis, the nuchal rigidity associated with lateral sinus thrombosis is often unilateral, with negative Kernig and Brudzinski signs.

Diagnosis

On contrast-enhanced CT scan, the most accurate diagnostic finding of sinus thrombosis is the empty delta sign. This consists of a darkened area of thrombus in the vessel lumen, surrounded by the contrast-enhanced sinus wall. The thrombus formed within the lumen of the sinus may present different attenuations according to its developmental stage, and artifacts from adjacent bone structures are factors that may decrease the sensitivity of CT. Contrast-enhanced CT has a sensitivity of approximately 80% for the diagnosis of dural sinus thrombosis. On MRI, an acute thrombus (days 0–3) appears isointense on T1-weighted images and hypointense on T2-weighted images. In the subacute phase (days 3–15), there is increased intensity of the thrombus in both T1- and T2-weighted images. MR venography (MRV) is more sensitive than contrast-enhanced CT or MRI and demonstrates the loss of signal and then absence of flow in the sinus. CT venography may be as accurate as MRV. It is less impaired by motion artifact because of a rapid acquisition time. It more frequently depicts sinuses of smaller cerebral veins with low flow than does MRV. However, its disadvantages include significant exposure to ionizing radiation and the need for intravenous contrast material.

Therapy

Initial IV treatment with antibiotics that have a broad spectrum of activity and good CSF penetration should be used. Surgical removal of the source of infection should also be undertaken. Mortality rates from lateral sinus thrombosis have improved but are still approximately 10%.

Anticoagulation is controversial, and its major risk is intracranial hemorrhage. One study found anticoagulation with antimicrobial therapy may reduce mortality of cavernous sinus thrombosis but only if used early in disease. It has not been proved beneficial in lateral sinus thrombosis.

Spinal epidural abscess

Mark J. DiNubile

Epidural abscess of the spine represents a potentially crippling but treatable cause of back pain. Although relatively infrequent, the incidence appears to be increasing. Early diagnosis and aggressive therapy are essential for optimizing outcomes. Even with an indolent presentation, patients can still suffer seemingly unprovoked catastrophic neurologic deterioration related to delays in recognition and appropriate intervention.

Classification

Epidural abscesses can be separated anatomically into infections involving the spinal or cranial epidural space. Cranial epidural abscesses are discussed in Chapter 77 covering intracranial suppuration.

Spinal epidural infections can have acute and chronic presentations. Categorization by rapidity of onset and progression correlates with certain clinical and laboratory manifestations, bacteriology, anatomic details, pathology, and pathogenesis (Table 78.1). The nontuberculous bacterial spinal epidural abscess constitutes the major focus of this chapter. Tuberculous, fungal, and parasitic abscesses of the spinal epidural space evolve more insidiously than do pyogenic bacterial epidural abscesses. Other than iatrogenic infections, these etiologies are more frequently encountered in tropical and subtropical resource-constrained regions of the world. Metastatic carcinoma and lymphoma represent common alternative diagnoses that can exactly mimic epidural infections.

Another differential feature with therapeutic implications concerns the source of epidural infection. Microbes most commonly access the epidural space by hematogenous dissemination from a distant, sometimes trivial, infectious focus. In contrast, a substantial minority of cases arise from contiguous spread, usually from adjacent vertebral osteomyelitis. Epidural abscesses of hematogenous origin are typically located in the dorsolateral thoracic or lumbar area, where the epidural space is widest. Abscesses that form secondary to adjacent osteomyelitis usually involve the epidural space anteriorly or circumferentially. In some cases, it is hard to determine whether the epidural space represents a primary or secondary site of infection; for example, epidural abscess can be the cause or result of bacteremia or osteomyelitis.

Clinical presentation and course

The classical manifestations of spinal epidural abscess were partitioned by Heusner in 1948 as progressing through four sequential but overlapping stages: (1) spinal ache (or back pain), (2) root (or radicular) pain, (3) weakness, and ultimately (4) paralysis. The actual time between the onset of back pain and development of neurologic deficits can be highly variable. The unpredictable but potentially rapid evolution from backache to neurologic tragedy forces physicians to consider this entity in the differential diagnosis of all patients with new or changing back pain, particularly when fever and localized spinal tenderness coexist. Additional presenting complaints in some patients may include paresthesia

TABLE 78.1 **CHARACTERISTIC FINDINGS IN ACUTE VERSUS CHRONIC SPINAL EPIDURAL ABSCESS**

	Acute	Chronic
Duration of symptoms	<2 wk	>2 wk
Fever	Often present	Low grade or absent
Systemic toxicity	Sometimes	Infrequently
Source	Hematogenous (often from minor skin infection)	Direct extension from vertebral osteomyelitis
Back pain	Always	Always
Localized spinal tenderness	Very common	Nearly universal
Root weakness	Common	Common
Peripheral leukocytosis	Usually present	Often absent
Erythrocyte sedimentation rate/C-reactive protein	Markedly elevated	Markedly elevated
CSF leukocytes[a] (per mm^3)	Usually 50–1,000	Often <50
CSF protein >100 mg/dL	Almost always	Almost always
Anatomic location	Usually posterior to spinal cord	Commonly anterior to spinal cord
Gross pathology	Purulent exudate	Granulation tissue

Abbreviation: CSF = cerebrospinal fluid.
[a] Frank pus may be encountered if a lumbosacral epidural abscess is entered during attempted lumbar puncture. Under such circumstances, the spinal needle must not be further advanced because introducing the needle into the subarachnoid space may precipitate meningitis. The aspirated purulent material should be sent immediately in the airless capped syringe for appropriate studies, including Gram stain and aerobic/anaerobic cultures.

(sometimes described as "electric" in character), paresis, incontinence, constipation, or urinary retention. Atypical presentations include headache or meningismus (with cervical involvement), pleuritic or abdominal pain (with thoracic infection), and hip pain (with lumbar disease).

In patients with epidural abscesses, an inapparent primary source of infection, such as endocarditis, adjacent osteomyelitis, or a distant visceral abscess, may be present. Initially occult infectious foci may ultimately dictate the length of antimicrobial treatment or mandate additional procedures. Not unexpectedly, bacteremia is more often documented in acute hematogenous than chronic locally advancing infections. Especially when *Staphylococcus aureus* is the pathogen, the infection may be multifocal due to seeding of distant sites during a primary or secondary bacteremia.

The dreaded neurologic complications of epidural abscess can arise from either pressure causing compression of the spinal cord or vascular compromise causing ischemic necrosis. Cord compression may be more common, but septic thrombophlebitis is likely responsible for sudden, unforeseen deterioration.

Risk factors

Most, but not all, cases of spinal epidural abscess have recognized local and/or systemic risk factors. Patients with a history of back injury are predisposed to seed the injured area during transient bacteremia and therefore constitute a special risk group for vertebral osteomyelitis and/or epidural abscess. The risk remains long after the initial injury. Penetrating trauma may seed the adjacent bone and epidural space. Suspicion of epidural infection should be raised when a patient with diagnosed osteomyelitis or after recent back surgery, epidural injection, or lumbar puncture reports worsening localized back discomfort.

All patients with bacteremia or candidemia incur some risk of metastatic seeding. Patients with cutaneous infections, infected catheters, dental manipulations, decubitus ulcers, urinary tract infections, or endocarditis can develop a secondary epidural focus through hematogenous spread, even in the absence of previously recognized back injury. The risk appears highest in the aftermath of *S. aureus* bacteremia and is not totally eliminated by the 2 to 4 weeks of antibiotic therapy usually given to such patients. Epidural infection may manifest itself weeks to months later. Under most circumstances, back pain developing or worsening in the year following an episode of *S. aureus* bacteremia should be presumed to represent metastatic infection until proved otherwise. Similar concerns follow candidemia.

Injection drug users may develop infections of the epidural space with or without endovascular seeding. Diabetic patients, patients receiving long-term parenteral nutrition, and patients undergoing hemodialysis also appear to be at increased risk for epidural infection. Infections can arise from epidural injections or catheters due to breach of the anatomic barriers or even contamination of the injected material.

Microbiology

S. aureus remains the predominant pathogen recovered from all types of epidural abscesses, often originating from an unnoticed and otherwise inconsequential primary skin focus. Injection drug use, chronic hemodialysis, and indwelling vascular catheters predispose to *S. aureus* bacteremia associated with metastatic seeding.

A comprehensive clinical history including the epidemiologic circumstances may provide the only clues to otherwise unsuspected pathogens. Gram-negative osteomyelitis, discitis, and epidural infection can complicate injection drug use, where Enterobacteriaceae and *Pseudomonas aeruginosa* need to be considered among the possible pathogens. Gram-negative rods and occasionally enterococci can spread from urinary tract or pelvic infections to the lumbar spine and/or epidural space through vascular anastomoses in Batson's plexus. Less commonly isolated bacterial species include streptococci (especially the *S. milleri* group), coagulase-negative staphylococci (usually postoperatively or after open trauma), and anaerobes (from either the oral or intestinal flora). *Brucella* and *Salmonella* species are considerations under certain circumstances. Rare etiologies like pneumococcus, *Nocardia*, melioidosis, and environmental fungi have been reported.

Tuberculous spondylitis (Pott's disease) is frequently associated with epidural abscess and may be the presenting or sole manifestation of reactivation tuberculosis. Chronic osteomyelitis due to tuberculosis is often clinically and radiologically indistinguishable from disease caused by pyogenic bacteria, although the course is generally more protracted. Histopathology typically reveals fibrous connective tissue studded with caseating granulomata containing multinucleated giant cells. Acid-fast bacilli (AFB) can often be demonstrated by appropriate stains or molecular techniques. Despite paraspinal collections, operative intervention is not routinely required for Pott's disease in the absence of substantial or progressive neurologic involvement.

Nosocomial candidemia can be complicated by osteomyelitis with or without epidural infection and may present as a delayed complication of catheter-related candidemia despite antifungal therapy. Unusual etiologies of epidural abscess have involved *Actinomyces*, *Nocardia*, nontuberculous mycobacteria, *Cryptococcus*, *Blastomyces*, *Aspergillus*, *Exserohilum, Rhizopus*, cysticercosis, and *Echinococcus*.

Diagnosis

Every patient who complains of new or progressive back pain, fever, and local spine tenderness must be quickly assessed for the possibility of spinal epidural abscess. A normal sedimentation rate makes an epidural abscess relatively unlikely.

Not all the symptoms and signs classically attributed to an epidural abscess are present in every patient. With a protracted course, fever and systemic complaints may be diminished. Children especially may exhibit atypical features. In several series, roughly half the reported patients with spinal epidural abscesses were initially given unrelated diagnoses. In oncology and intensive care patients, the symptoms of epidural infection may be obscured by or misattributed to other coexisting problems.

Conventional radiology of the spine is rarely conclusive; early in the process, osseous destruction can be inapparent even in the presence of vertebral osteomyelitis. Although fever is generally unimpressive with chronic epidural abscess, these patients will have abnormal spine radiographs more consistently than patients with acute infection. Findings on bone, gallium, and indium scans and even CT are typically equivocal and thus can delay definitive diagnostic testing and subsequent treatment.

Whether acute or chronic, all patients with suspected epidural space infection require MRI of the spine, CT myelography, or a conventional myelogram on an urgent basis. Gadolinium-enhanced MRI is currently the preferred diagnostic procedure where available. Spinal puncture for myelography when necessary should be performed at a site as far as safely possible from the area of suspected abscess. The needle should be advanced slowly, with frequent aspirations; if pus is encountered, the needle should be withdrawn and the aspirated material sent for appropriate tests. If myelographic contrast material is to be injected into the subarachnoid space, cerebrospinal fluid should be obtained beforehand for stains and cultures, glucose and protein levels, total and differential cell counts, and cytology. Otherwise, lumbar puncture should be avoided unless meningitis is in the differential diagnoses. If nonsurgical management is planned, CT-guided aspiration of the epidural collection may be attempted to obtain specimens for stains and culture (as well as to drain the epidural collection).

Treatment

Traditional management of spinal epidural abscess involves immediate surgical drainage and prolonged antibiotic therapy. Operative evacuation of the abscess allows for decompression as well as procurement of pus and tissue samples for microbiologic processing. Exposure of the entire length of the abscess with adequate drainage, debridement, and irrigation has been standard practice in most situations and can usually be accomplished via a simple laminectomy. Neurologic improvement is often evident soon after decompression. Early surgery improves neurologic outcomes compared with delayed surgical intervention following a failed trial of medical management.

In acute or rapidly progressing cases, antibiotic therapy ought to be initiated promptly and often empirically after blood and other readily accessible sites of infection are sampled for stains and cultures. An antistaphylococcal agent should be routinely included in any empirical antibiotic regimen. With the spread of nosocomial and now community-acquired methicillin-resistant *S. aureus* (MRSA), coverage with antistaphylococcal β-lactam agents has become inadequate for empiric therapy. Antibiotics active against gram-negative and strictly anaerobic bacteria should be added to the regimen when these organisms are suspected based on clinical grounds or epidemiologic context. For example, a patient with a lumbar epidural abscess of suspected urinary tract origin would need broader coverage for gram-negative pathogens. For infections

associated with injection drug use, coverage for *P. aeruginosa* and mouth anaerobes needs to be considered. Many authorities would initiate empiric treatment of all epidural abscesses with broad-spectrum coverage, including vancomycin, metronidazole, and ceftriaxone (or ceftazidime, if *P. aeruginosa* is a suspect). Gram-stained specimens often provide rapid information that can lead to modifications of the planned antibiotic regimen before culture results return.

The initial regimen should be refined once results of stains, cultures, and susceptibility tests from blood, aspirates, or operative samples are available. Aerobic and anaerobic cultures from appropriately processed specimens usually identify the pathogen(s) unless substantial antibiotic treatment has preceded sampling. The dosing guidelines given here are for adults with normal renal and hepatic function. Confirmed methicillin-susceptible *S. aureus* infections have traditionally been treated with nafcillin, 2 g intravenously (IV) every 4 hours (or cefazolin, 1 g IV q8h) in patients not allergic to β-lactam agents. Clindamycin, 600 mg IV every 8 hours, and vancomycin, initially administered as at least 15 mg/kg IV every 12 hours and adjusted to maintain trough levels of 15 to 20 μg/mL, remain the standard alternatives for seriously penicillin-allergic patients. Vancomycin, daptomycin, or linezolid are appropriate when MRSA is recovered or strongly suspected. Community-acquired MRSA may be sensitive to other agents (such as clindamycin, quinolones/rifampin, or trimethoprim–sulfamethoxazole) but susceptibility to these agents should be documented by testing the isolate in the clinical microbiology laboratory before any of these drugs are considered.

Substantial clinical experience supports extended-spectrum quinolones for the treatment of osteomyelitis, discitis, and epidural abscesses. In susceptible staphylococcal infections associated with osteomyelitis, an oral regimen of rifampin 600 mg/d combined with either ciprofloxacin 750 mg twice daily or levofloxacin 750 mg once daily would be a reasonable oral option to complete a prolonged antibiotic course after successful acute management.

For susceptible gram-negative infections, trimethoprim–sulfamethoxazole, an advanced-generation cephalosporin, or a quinolone may be used. Trimethoprim–sulfamethoxazole is not active against *P. aeruginosa*, which mandates treatment with an antipseudomonal β-lactam derivative or ciprofloxacin guided by sensitivity results and sometimes combined with an aminoglycoside antibiotic. Carbapenems or colistin may be necessary for multidrug-resistant gram-negative bacilli. Metronidazole is the drug of choice for most anaerobic infections. Quinolones, trimethoprim–sulfamethoxazole, and metronidazole can be given orally to patients tolerating medication by mouth. The incidence of iatrogenic complications (as well as cost) could be dramatically reduced by discontinuing nonessential intravenous lines and administering antibiotic therapy by mouth when appropriate.

The optimal duration of antibiotic therapy has not been determined in controlled studies. Recommendations range from 4 to 8 weeks. Therapy for at least 6 weeks is typically prescribed, especially when vertebral osteomyelitis coexists or complete surgical drainage was not accomplished.

Selected patients with epidural abscess can be managed conservatively without surgery. Nonsurgical management is more consistently successful in stable patients who present with localized back or radicular pain without objective neurologic signs such as weakness, urinary retention, or incontinence. However, in the majority of cases, a drainage procedure is still considered a critical component of the standard of care under most circumstances, both to establish a microbiologic diagnosis and to decompress the thecal sac.

The optimal procedure requires individualizing the approach for the particular location and extent of the infection. In surgical candidates, decompression and drainage are usually accomplished by posterior laminectomy for dorsal abscesses or by partial or complete anterior or anterolateral corpectomy for ventral abscesses in adults. Complete exposure of the involved segments may be contraindicated in patients with extensive craniocaudal abscesses or spinal instability. Less invasive procedures have been increasingly employed for complicated multilevel infection. Multisegment interlaminar fenestration can replace laminectomy in selected cases with impending anterior instability due to lumbar spondylitis, sometimes accompanied by intraoperative ultrasound to guide decompression in the narrow bony window. Minimally invasive operative procedures or percutaneous CT-guided needle aspiration may be a compromise approach in some patients despite a theoretical concern about inadvertently seeding the subarachnoid space and inducing meningitis during the procedure.

Medical management alone is an appropriate option for neurologically stable patients who exhibit no significant neurologic deficits or have a contraindication to surgery (Box 78.1). Qualifying candidates for medical therapy are not infrequent. Unfortunately, some patients will suffer neurologic progression despite appropriate antibiotics, which can ensue abruptly and unpredictably without warning. The resultant paresis or paralysis may be irreversible, even if surgery is then performed urgently. In addition to mass effect, vascular compromise from septic arterial or venous thrombosis with cord infarction may play a key pathophysiologic role in these tragic cases.

All patients with epidural abscess, whether managed conservatively or not, must be evaluated by careful and repeated physical examinations at least daily for signs of neurologic deterioration. The role for periodic imaging during the course of or after treatment is completed is not well defined.

BOX 78.1

Potential candidates for medical management of spinal epidural abscess without immediate operative intervention

No significant or progressive neurologic dysfunction
Or
Poor surgical candidate
Or
Complete paralysis for >72–96 h
AND
Diagnosis is secure, and causative organism has been identified.

Prognosis

Spinal epidural abscess was often lethal in the pre-antibiotic era. Today, morbidity rates remain disappointingly high. Up to a third of survivors have persistent deficits and unsatisfactory outcomes. In a recent series, 15% of cases had an adverse outcome including paralysis in 8% and a 7% mortality rate.

Presenting symptoms of back pain or radiculopathy are associated with better functional outcomes, regardless of symptom duration, than more severe neurologic findings at presentation. For patients presenting with frank motor deficits, duration of symptoms ("acute" vs. "chronic" presentations) appears to have prognostic implications, with better outcomes when treatment is initiated within 72 hours of onset of weakness. The severity of the neurologic defect at the time of the drainage/decompression procedure is a critical predictor of the ultimate neurologic result. Other prognostic indicators include patient age, the degree of cord impingement on imaging studies, and operative findings of granulation tissue as opposed to purulent fluid.

Conclusion

Epidural abscess is a potentially devastating infection. Early diagnosis and combined aggressive medical–surgical intervention are essential for most patients because neurologic function may deteriorate quickly, leaving irreversible deficits.

Myelitis and peripheral neuropathy

Rohini Samudralwar and Rodrigo Hasbun

Myelitis and peripheral neuropathy complicate many infections. This chapter discusses major infectious etiologies of myelitis (Table 79.1), peripheral neuropathy (Table 79.2), polymorphic syndromes (Table 79.3), and neuropathic syndromes seen in HIV infection (Box 79.1). Furthermore, an algorithm (Figure 79.1) suggests an approach to the clinical and laboratory diagnosis of myelitis and peripheral neuropathy.

Myelitis

Myelitis refers to inflammation of the spinal cord. Myelitis may be infectious or noninfectious and primary—directly attacking cord structures—or secondary—producing adjacent processes altering cord function. Primary myelitis can present as one of three discrete clinical patterns: (1) anterior poliomyelitis, (2) leukomyelitis, or (3) transverse myelitis. Poliomyelitis is inflammation involving gray matter; leukomyelitis is confined to white matter. Transverse myelitis, inflammation of an entire cross-section of the spinal cord, can affect more than one spinal segment. A number of infectious agents are known to cause or to be associated with myelitis. Myelitis can also occur after infection or vaccination, as in the acute disseminated encephalomyelitis (ADEM) syndrome.

There are five cardinal manifestations of spinal cord disease: pain, motor deficits, sensory deficits, abnormalities of reflexes and muscle tone, and bladder dysfunction. The distribution of neurologic deficits depends on the spinal segment(s) affected. Local pain occurs at the site of the lesion and can assume a radicular quality if the nerve roots are involved. Paresthesias have greater localizing value than radicular pain. Weakness is present in virtually all spinal cord disorders and in myelitis may progress over hours, days, or weeks. *Spinal shock* is characterized by absent plantar reflexes and areflexia and atonia below the level of the lesion. More slowly progressive lesions are associated with hyperreflexia and hypertonia. Bladder dysfunction is usually not an early sign of spinal cord disease, although if spinal shock develops, flaccid bladder paralysis ensues with urinary retention and overflow incontinence. Chronic myelopathies cause a spastic bladder and result in urgency, frequency, and incontinence.

Acute primary infectious transverse myelitis must be distinguished from post-infectious secondary myelopathies and other noninfectious causes of myelitis such as multiple sclerosis (MS) or systemic lupus erythematosus. MRI of the spinal cord must be performed early to exclude a compressive lesion.

Tropical spastic paraparesis/HTLV-1–associated myelopathy

Human T-cell lymphotropic virus type 1 (HTLV-1) is a retrovirus associated with adult T-cell leukemia/lymphoma and HTLV-1-associated myelopathy/tropical spastic paraparesis (HAM/TSP). Approximately 15 to 20 million people are infected worldwide, with endemic areas in the Caribbean, southern Japan, Africa, and Italy. Among first-time US blood donors, the prevalence in 2009 was 5 per 10,000, half that seen in 2000. In perhaps 4% of those infected, HTLV-1 causes a chronic meningomyelitis with focal destruction of gray

TABLE 79.1 **MYELITIS**

Syndrome/disease	Organism	Symptoms, signs, and neurologic findings	CNS	PNS	Cord	Other findings	Risk factors
Anterior polio myelitis syndrome	Poliovirus 1, 2, 3	*Onset:* Acute *Clinical patterns:* Spinal and bulbar paralysis *Common features:* Asymmetric flaccid paralysis (AFP)	√		√	"Minor illness" (3–4 d) influenza-like syndrome "Major illness" (5–7 d) aseptic meningitis, myeloencephalitis	Absence of protective immunity and travel in endemic areas
	Nonpolio Coxsackie A, B Echovirus Enterovirus West Nile virus (WNV)	*Onset:* Acute *Clinical patterns:* Similar to polio but milder disease *Asymptomatic infection:* Common except at extremes of age and in immunosuppressed	√		√	CNS phase aseptic meningitis, encephalitis, encephalomyelitis	Seasonal incidence in temperate climates (summer), year-round in tropical climates WNV: Vector borne (*mosquito*) and transmitted by breast milk, blood transfusions, and organ transplants
Ascending myelitis syndrome (leukomyelitis)	HIV-1	*Onset:* Acute/subacute *Clinical patterns*:	√	√	√		See below
	HTLV-1	*Onset:* Subacute/chronic *Clinical patterns*: tropical spastic paraparesis (TSP) or HAM			√	"Rosette cells" in CSF lymphocytes Coinfection with HIV in IVDUs	Injecting drug use Prior residence in endemic areas
	Herpesviruses: CMV, EBV HSV, VZV	*Onset:* Acute *Clinical patterns:* Ascending pattern w/initial plexitis Asymmetric commonly		√	√	Primarily seen in immunosuppressed	Related to epidemiology of primary infection
	Herpes B virus (Monkey B)	*Onset:* Subacute (5–30 d) *Clinical pattern:* Aseptic meningitis Ascending encephalomyelitis	√		√	Prodromal illness: Early (*vesicles*); Intermediate (*numbness, weakness, hiccups*)	Macaque monkey bite or exposure to tissues Laboratory workers exposed to contaminated cell cultures
Transverse myelitis syndrome	*Primary* myelitis VZV Dengue Spirochetes[a] Schistosomiasis Post-meningococcal	*Onset:* Acute (after prodrome) *Clinical patterns:* Sensory motor level Initial spinal shock Hyperreflexia below level of lesion			√		Related to epidemiology of primary infection
	Secondary myelitis: Bacteria, fungi, mycobacteria	*Onset:* Acute/subacute *Clinical patterns:* Radicular-spinal cord syndrome Cauda equina syndrome			√	Related to primary infection and organisms	Injecting drug use Hematogenous osteomyelitis Back surgery: Intraoperative contamination
Acute demyelinating encephalomyelitis (ADEM)	*Mycoplasma*, Lyme, Enteroviruses, EBV, CMV, VZV, dengue, measles, hepatitis A, Semple Rabies vaccine	*Onset:* Acute *Clinical patterns:* Pyramidal and extrapyramidal symptoms, hemiplegia, ataxia, cranial neuropathies, myelitis paresthesias, polyradiculopathy, altered mental status	√		√		Related to epidemiology of primary infection

[a] Spirochetes include: *Borrelia* species (*B. burgdorferi*—Lyme, *B. recurrentis*—relapsing fever), *Leptospira* spp, *Treponema pallidum*.
Abbreviations: CMV = cytomegalovirus; CNS = central nervous system; CSF = cerebrospinal fluid; EBV = Epstein–Barr virus; HAM = HTLV-1-associated myelopathy; HIV = human immunodeficiency virus; HSV = herpes simplex virus; HTLV = human T-cell lymphotropic virus; IDUs = injecting drug users; IVDU = intravenous drug use; PNS = parasympathetic nervous system; VZV = varicella-zoster virus; WNV = West Nile virus.

TABLE 79.2 **PERIPHERAL NEUROPATHY**

Syndrome/disease	Organism/antibiotic	Symptoms, signs, and neurologic findings	CNS	PNS	Cord	Other findings	Risk factors
Polyneuritis: Acute (AIDP) Guillain–Barr é Landry Miller-Fisher Chronic (CIDP)	1. Idiopathic 2. Infection-associated	*Onset*: Acute/subacute and chronic *Common features:* Progressive, symmetric weakness Distal→proximal limbs Truncal→cranial muscles Paresthesias, hypotonia, areflexia *Clinical patterns:* Ascending, descending, bulbar	√	√		Variable autonomic dysfunction (ileus, cardiac)	Preceding viral illness or vaccination, prior episode Infection-associated: Viral (EBV, HIV, dengue, hepatitis) Bacterial (*Campylobacter*) Chlamydia (*C. psittaci*) Mycoplasma (*M. pneumoniae*) Spirochetes (Lyme borreliosis)
Neuropathy due to bacterial toxins	*Corynebacterium diphtheriae*	*Onset:* Acute/subacute *Clinical patterns:* Bulbar symptoms Ascending peripheral neuropathy	√	√		Pharyngitis with pseudomembrane Myocarditis Endocarditis	Absence of protective immunity, epidemic respiratory diphtheria, contaminated wound
	Clostridium botulinum	*Onset:* Acute/subacute (dose-related) *Clinical patterns:* Bulbar symptoms Myasthenia-like weakness	√	√		Autonomic dysfunction (dry tongue, ileus, urinary retention) Decreased vital capacity	Food sources Contaminated wounds (IDUs) Sinusitis in cocaine snorters
	Clostridium tetani	*Onset:* Acute/subacute (dose-related) *Clinical patterns:* Localized, cephalic, generalized	√	√	√	Autonomic Dysfunction Hypertensive crises Decreased vital capacity	Absence or loss of protective immunity Puncture/contaminate wounds Infected neonatal cord stumps
Medication *Acute* Antibacterials	Aminoglycosides Polymyxins	*Onset:* Acute (concentration-related) *Clinical patterns:* Neuromuscular blockade	√	√		Decreased vital capacity Generalized paralysis	Excessive or unadjusted dosage for lean body mass
Subacute Anti-TB Antiretrovirals Antibacterials	Isoniazid ddI, ddC, d4T Chloramphenicol Metronidazole Nitrofurantoin	*Onset:* Subacute (dose and duration) *Clinical patterns:* Symmetric Distal paresthesias and weakness Progressive loss of distal DTRs		√			Isoniazid: Lack of pyridoxine Nucleoside antiretrovirals: Pre-existing neuropathy Excessive or unadjusted dosage Antibiotics: Cumulative dosage
Vasculitis	Polyarteritis nodosa (PAN) Wegener's	*Onset*: Subacute *Clinical patterns:* Mononeuritis multiplex *Common features*: Asymmetric weakness, paresthesias, loss of DTRs in affected areas		√		PAN: Asymptomatic micro-aneurysms Wegener's: sinusitis, pulmonary and renal lesions, +/– eosinophilia	PAN: Chronic active hepatitis B Wegener's: Unknown etiology
Leprosy	*Mycobacterium leprae*	*Onset:* Insidious/acute *Clinical patterns:* Mononeuritis multiplex Polyneuropathy *Common features:* Anesthetic lesions, enlarged nerves		√		Deformity Nerves most commonly affected: Median, ulnar, peroneal	General Genetic susceptibility Prior residence in endemic areas Neuropathy Tuberculoid Reversal reaction

Abbreviations: AIDP = acute inflammatory demyelinating polyneuropathy; CIDP = chronic inflammatory demyelinating polyneuropathy; CNS = central nervous system; DTRs = deep tendon reflexes; EBV = Epstein–Barr virus; HIV = human immunodeficiency virus; IDUs = injecting drug users; PNS = peripheral nervous system.

TABLE 79.3 **POLYMORPHIC NEUROLOGIC SYNDROMES ASSOCIATED WITH INFECTIONS**

Syndrome/disease	Organism	Symptoms, signs, and neurologic findings	CNS	PNS	Cord	Other findings	Risk factors
HIV-associated	HIV-1	*Onset:* Acute, subacute, and chronic *Clinical patterns*: Acute*:* GBS, Bell's palsy, mononeuritis multiplex Subacute/chronic: Vacuolar myelopathy: progressive spasticity; Ascending myelitis (leukomyelitis); Sensory peripheral neuropathy (CIDP)	√	√	√	*Acute* infection: aseptic meningitis, infectious mononucleosis syndrome *Late disease:* concurrent HIV encephalopathy	IVDU, sexual transmission, exposure to contaminated blood or body fluids
Dengue-associated	Dengue virus	*Onset:* acute or postinfectious *Clinical patterns:* Myelitis (transverse), Guillain–Barré syndrome, mono- or polyneuropathy, brachial neuritis, ADEM, encephalitis	√	√	√	Fever, headache, myalgia, arthralgia, rash, headache, leukopenia, thrombocytopenia, elevated liver transaminases	Mosquito exposure in endemic region
Mycoplasma-associated	*Mycoplasma pneumoniae*	*Onset:* acute *Clinical patterns:* Ascending myelitis (leukomyelitis), polyradiculitis	√	√	√	Commonly associated with encephalitis	Recent upper respiratory infection in child or young adult
Neurobrucellosis	*Brucella* spp.	*Onset:* Subacute/chronic *Clinical patterns:* Radiculitis, myelitis, CNS palsies	√	√	√	Encephalitis, meningitis, mycotic aneurysm; Leukoclastic vasculitis, thrombocytopenia and splenomegaly in children	Unpasteurized milk products, occupational exposure to livestock and cattle parturition
Neuroborreliosis	*Borrelia burgdorferi*	*Onset:* Acute and chronic *Clinical patterns:* Acute: Bell's palsy, aseptic meningitis, encephalitis, transverse myelitis Chronic: weakness, paresthesias	√	√	√	*Acute*: Erythema chronicum migrans	Tick-bite Travel or residence in endemic areas
Neurosyphilis	*Treponema pallidum*	*Onset:* Acute and chronic *Clinical patterns:* Acute syphilitic meningitis Chronic asymptomatic Chronic symptomatic (meningovascular, behavioral, tabes dorsalis, myelopathy)	√	√	√	Dementia Gumma (cord/meninges) Uveitis, optic atrophy Deafness	Asymptomatic (abnormal CSF) and symptomatic neurosyphilis occurs after early syphilis. Higher risk with HIV infection with or without standard treatment of primary syphilis
Tuberculosis	*Mycobacterium tuberculosis*	*Clinical patterns:* Meningitis, vasculitis, cord infarction, granulomatous myeloradiculitis, intramedullary tuberculoma, cord compression from vertebral collapse	√		√	Pulmonary disease, meningitis, fever	Travel to or residence in high prevalence region, homelessness, incarceration, institutionalization, contacts with known tuberculosis

TABLE 79.3 **CONTINUED**

Syndrome/disease	Organism	Symptoms, signs, and neurologic findings	CNS	PNS	Cord	Other findings	Risk factors
Schistosomiasis	*Schistosoma* spp.	*Clinical patterns:* Transverse myelitis, subacute myeloradiculopathy, encephalitis	√		√	Fever, abdominal pain, hepatosplenomegaly	Travel to or residence in endemic region
VZV-associated	VZV	*Onset:* Acute *Clinical patterns:* Bell's palsy, Ramsey Hunt syndrome Sensory radiculitis (CNS and PNS) Ascending and transverse myelitis	√	√	√	Dermatomal vesicles Encephalitis Uveitis, corneal ulcer	Immunosuppression (with recrudescent VZV)
Herpes simplex-associated	HSV	*Onset:* Acute and recurrent *Clinical patterns:* HSV-1: Bell's palsy; HSV-2: sacral radiculitis (Elsberg syndrome)	√	√	√	Ascending necrotizing myelitis Mollaret's meningitis	AIDS Primary genital HSV

Abbreviations: ADEM = acute demyelinating encephalomyelitis; CNS = central nervous system; CSF = cerebrospinal fluid; HSV = herpes simplex virus; HIV = human immunodeficiency virus; PNS = peripheral nervous system; VZV = varicella-zoster virus; IVDU = intravenous drug use; GBS = Guillain–Barré syndrome; CIDP = chronic inflammatory demyelinating polyneuropathy.

BOX 79.1

Etiology of neuropathic syndromes in HIV infection

Autoimmune/idiopathic
- Acute inflammatory demyelinating polyneuropathy (*AIDP—Guillain–Barré syndrome*)
- Chronic inflammatory demyelinating polyneuropathy (*CIDP*)

Vasculitis
- Bell's palsy
- Ataxic dorsal radiculopathy
- Mononeuritis multiplex from hepatitis B virus (HBV)-associated cryoglobulinemia

Opportunistic infections
- Cryptococcal meningitis: bulbar palsies
- Herpesviruses polyradiculopathy, sacral radiculitis, Bell's palsy
- Epstein–Barr virus
- Cytomegalovirus (CMV)
- *Varicella-zoster virus* (VZV)
- Herpes simplex type 1 (HSV-1) type 2 (HSV-2)
- Neurosyphilis: Polyradiculopathy
- Tuberculous meningitis: Bulbar palsies

Drug toxicity or nutritional
- Antiretroviral nucleoside analogs
- Dideoxycytosine (ddC)
- Dideoxyinosine (ddI)
- Stavudine (d4T)
- Niacin analog: Isoniazid (INH) without B6
- Neurotoxic antibiotics: Aminoglycosides, chloramphenicol, metronidazole, nitrofurantoin, polymyxins
- Vitamin deficiencies: folate, pyridoxine, B_{12}

matter as well as demyelination of white matter primarily within the posterior columns and corticospinal tracts. Neurologic disease usually begins in the fifth decade; women are more commonly affected than men (~2.5–3:1). Patients typically note bilateral lower extremity weakness and stiffness but may also have difficulty walking and back pain. Neurogenic bladder may develop, and neuropathy may be found. Physical examination shows spastic paraparesis, hyperreflexia, extensor plantar reflexes, and reduced vibratory sensation and proprioception. Typically, the disease is slowly progressive and may ultimately leave patients wheelchair dependent; the upper extremities are usually not affected. HAM/TSP may be preceded, more commonly in children, by infective dermatitis, a dermatologic condition associated with HTLV-1 and characterized by recurrent erythematous, scaly, and crusted rash of the scalp, face, neck, axilla, and groin. In one series, 47% of children and adolescents with infective dermatitis went on to develop HAM/TSP.

In patients with HAM/TSP, the cerebrospinal fluid (CSF) may demonstrate a lymphocytic pleocytosis, elevated CSF immunoglobulin G (IgG), and oligoclonal banding, and demonstrable anti-HTLV-1 antibodies. Diagnosis is established clinically in the presence of HTLV-1 seropositivity and characteristic CSF findings. Distinguishing between incidental HTLV-1 infection and patients with true HAM/TSP may be difficult. Recent studies suggest that anti-Gag, anti-Env, and anti-Tax antibodies may help distinguish patients with true HAM/TSP from persons with asymptomatic HTLV-1 infection. No effective antiretroviral or adjunctive therapies have been established to date.

Herpesviruses

All herpesviruses have been implicated in acute transverse myelitis, especially in the setting of immunosuppression. Herpes simplex virus (HSV) types I and II, varicella-zoster virus (VZV), cytomegalovirus

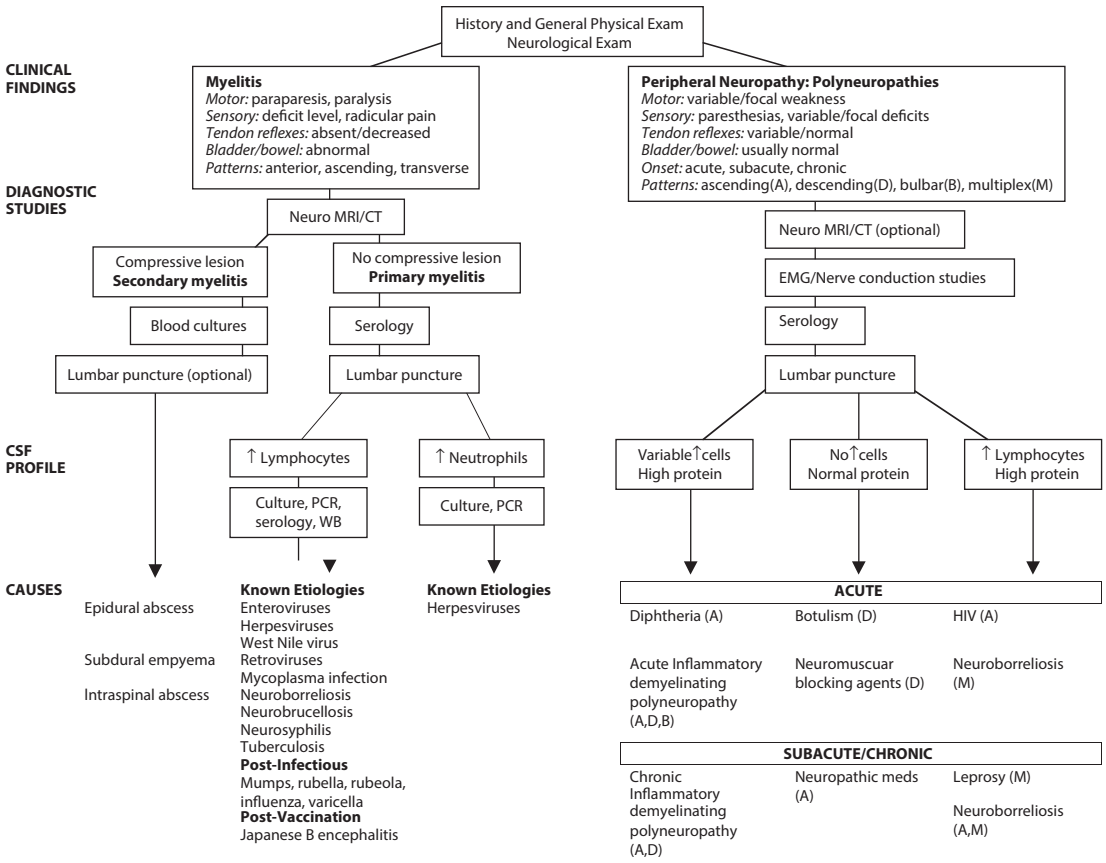

FIGURE 79.1 Algorithm for clinical and laboratory evaluation of acute myelitis and peripheral neuropathy. CSF, cerebrospinal fluid; CT, computed tomography; EMG, electromyogram; MRI, magnetic resonance imaging; PCR, polymerase chain reaction; WB, Western blot.

(CMV), and Epstein–Barr virus (EBV) have all been associated with a nonspecific myelitis, although ascending necrosis of the cord appears to be most typical. Associated clinical findings of concurrent CMV retinitis, peripheral outer retinal necrosis due to VZV, or vesicular skin lesions characteristic of herpes simplex or VZV are helpful in suggesting the diagnosis.

Patients may have fever and characteristically have rapidly progressive neurologic deficits. CSF with lymphocytic pleocytosis, elevated protein, and normal glucose is typical. Early empiric therapy with intravenous (IV) acyclovir, ganciclovir, or foscarnet may preserve cord function pending definitive diagnosis in immunocompromised patients presenting with acute transverse myelitis of unknown origin. Valacyclovir and valganciclovir are attractive agents in suppressing herpes simplex and CMV myelitis, respectively, in immunosuppressed individuals. Oral ganciclovir is ineffective because of limited bioavailability.

Macacine herpesvirus 1, formerly known as *Cercopithecine herpesvirus* and commonly known as herpes B virus or *Herpesvirus simiae*, is a naturally occurring virus among primates of the genus *Macaca*. It can cause fatal encephalitis in humans with associated ascending myelitis following a bite, cage scratch, or other exposure. Patients may develop vesicular lesions at the site of the bite before developing neurologic manifestations. Human B-virus infections are diagnosed by viral culture and serology, which must be performed in certified laboratories. The US Centers for Disease Control and Prevention (CDC) should be consulted in cases of suspected human B-virus infection. In addition to thorough washing, prophylactic oral acyclovir or valacyclovir should be considered after an at-risk exposure. IV acyclovir or ganciclovir should be considered with evidence of any disease (e.g., vesicles), and IV ganciclovir used in cases with central nervous system (CNS) symptoms.

Enteroviruses

The enteroviruses are well-known causes of infectious myelitis, of which poliovirus has been the most historically significant. Poliovirus infection may present with fever, meningismus, and muscle spasms followed by acute flaccid paralysis from infection of anterior horn cells. Largely due to effective vaccination programs, poliovirus is now unusual, but sporadic cases of myelitis due to other enteroviruses—such as Coxsackie A and B, echovirus, and enteroviruses 70 and 71—still occur. Myelitis due to nonpolio enteroviruses, are generally less severe, and causes weakness rather than paralysis. Enterovirus 71—the causative agent of hand-foot-and-mouth disease—is an important exception and may mimic poliovirus in severity. In some cases of viral myelitis, it may be difficult to distinguish between postinfectious, immune-mediated cord injury and direct viral invasion. Detection of virus in CSF is supportive of direct viral invasion. Enteroviruses can be recovered from CSF as well as from blood, pharynx, and stool. The most

reliable diagnostic test is the CSF enteroviral polymerase chain reaction (PCR).

West Nile virus

Since the appearance of West Nile virus (WNV) in the United States in 1999, >30,000 WNV disease cases have been reported to the CDC. Although most WNV infection is asymptomatic or self-limited, neuroinvasive disease (NID) also occurs. Acute flaccid paralysis occurred in 4% of cases reported to the CDC in 2011; it is one of the most serious presentations of NID and mimics poliomyelitis with injury to spinal cord anterior horn cells. Acute flaccid paralysis commonly accompanies WNV encephalitis, appears abruptly, and often results in asymmetric lower extremity weakness.

Areflexia, loss of bladder and bowel function, and signs of denervation may develop. CSF typically demonstrates pleocytosis; diagnosis is aided by serologic and CSF testing for WNV IgM, or serum or CSF PCR. Although no agents are currently licensed to treat WNV disease, emerging case reports and animal studies suggest a potential benefit of IV immunoglobulins (IVIGs) with high WNV antibody titers; this practice warrants further investigation.

Dengue

Neurologic complications of dengue are increasingly recognized, with recent estimates that neurologic disease may complicate 1% to 5% of infections. An array of neurologic manifestations has been encountered, including meningitis, encephalitis, Guillain–Barré syndrome (GBS), mono- and poly-neuropathies, ADEM, and myelitis. Pathogenesis is likely multifactorial and varies for each clinical syndrome encountered. It seems likely that direct neurologic invasion and autoimmune reactions each play a role in myelitis. CSF may demonstrate pleocytosis and elevated protein. Diagnosis is supported by serologic studies and further aided by CSF antibody testing or PCR, though CSF antibody testing is not very sensitive. Care is supportive. Many patients with neurologic complications of dengue infection recover, though perhaps a quarter of patients may have residual deficits.

HIV

Vacuolar myelopathy is a diagnosis of exclusion. Although of distinctive neuropathology, it often coexists with the AIDS-associated dementia complex, also known as *HIV encephalopathy* or *encephalitis*. Vacuolar myelopathy was found in up to 50% of AIDS patients undergoing autopsy before the highly active antiretroviral therapy (HAART) era. In severe cases patients develop spastic paraparesis of the lower extremities with or without involvement of the arms, mimicking HTLV-1 myelopathy. The weakness, which may be asymmetric, evolves over weeks. Coexisting neuropathy is often present. A discrete sensory level is unusual. Sphincter dysfunction occurs late in the course of the disease.

Other viral causes of myelitis

Other viruses associated with myelitis include Japanese encephalitis virus, tick-borne encephalitis virus, and chikungunya virus. Acute flaccid paralysis may occur in rabies infections before proceeding to fatal encephalitis.

Syphilis

Although there are many manifestations of neurosyphilis, four major types of spinal cord disease are associated with *Treponema pallidum* infection: tabes dorsalis, syphilitic meningomyelitis, spinal vascular syphilis with infarction of the (most commonly anterior) spinal arteries, and gummas of the meninges and cord. Because of its varied presentations, syphilis should be considered in the differential diagnosis of nearly all diseases of the spinal cord. The serum rapid plasma reagin (RPR) titer is usually higher than 1:32 in neurosyphilis, and the CSF usually shows a lymphocytic pleocytosis, elevated protein, and normal glucose; HIV infection with or without HAART may impact these parameters. The CSF Venereal Disease Research Laboratory (VDRL) test is specific but generally insensitive. CSF fluorescent treponemal antibody test and *T. pallidum* PCR may also aid diagnosis. Steroids may be added to IV penicillin to prevent cord edema, ischemia, or Jarisch–Herxheimer reaction associated with treatment.

Mycoplasma pneumoniae

CNS complications of *M. pneumoniae* infection are probably the most frequent extrapulmonary manifestation of infection. Although encephalitis is the most common neurologic complication, meningitis, polyradiculitis, ADEM, and transverse myelitis also occur. The exact pathogenesis of CNS disease is unknown, but it may be secondary to direct invasion, elaboration of neurotoxins, autoimmune complexes, molecular mimicry, or vasculitis. A recent respiratory tract infection, especially in a child or young adult, should suggest the diagnosis. Diagnosis can be confirmed with positive CSF *M. pneumoniae* PCR or by retrospectively observing a fourfold rise in antibody titers. If active infection is present, antibiotic therapy may be effective. Tetracycline penetrates the CNS more effectively than macrolides but is contraindicated in young children. Steroids, plasmapheresis, and IVIG have also been advocated but remain controversial.

Brucellosis

Approximately 2% to 5% of patients with brucellosis have neurologic complications, though a recent study of hospitalized patients in an endemic country with brucellosis confirmed neurobrucellosis in 37.5% of patients with neurologic symptoms. Although meningitis with cranial nerve palsies and vasculitis are the most common neurologic manifestations, direct involvement of the brain or cord can result in encephalitis or myelitis, respectively. Myelopathy typically involves the corticospinal tracts and produces a pure upper motor neuron syndrome without sensory findings. Secondary myelitis can occur from granulomatous spondylitis and epidural abscess.

Radiculopathy due to chronic inflammation of intrathecal nerve roots complicates neurobrucellosis in an eighth of patients. CSF usually reveals a lymphocytic pleocytosis, elevated protein, and hypoglycorrhachia. CSF cultures are positive in <50% of

cases. Cultures of blood and tissue fluids may become positive in 2 to 4 days with modern automated liquid culture systems, particularly when specimens are first processed to release intracellular organisms. PCR methods are reportedly more sensitive than culture. Serum tube agglutination (TA) testing can support a diagnosis of brucellosis. CSF TA testing can help confirm a diagnosis of neurobrucellosis; however, there is no commonly agreed upon titer cut-point for CSF TA titers. Treatment of neurobrucellosis requires multidrug therapy, though there is no consensus for an optimal regimen or duration. Surgical exploration and decompression may be warranted for symptomatic epidural abscess. Adjunctive steroids early in meningitis may reduce complications from vasculitis.

Tuberculosis

While meningitis is the most common neurologic manifestation of tuberculosis, myelopathy may be seen as well. Myelopathy may occur secondary to spinal cord or nerve root compression from Pott's disease, to compression from epidural or intramedullary tuberculomas, to vasculitis with cord infarction, or to granulomatous myeloradiculitis from hematogenous seeding of the CNS. Necrotizing tuberculous granulomas may directly affect spinal arteries. Vasculitis can lead to cord infarction. Most patients with tuberculous myelitis have concurrent meningitis, but coincidental pulmonary tuberculosis is less common. Tuberculosis diagnosis and treatment are addressed in detail elsewhere.

Schistosomiasis

Neuroschistosomiasis should be considered in the differential diagnosis of acute myelopathy in regions where *Schistosoma* species are prevalent. A Brazilian study found that 6% of patients with nontraumatic acute myelopathy had spinal schistosomiasis. Half of patients admitted to a Malawian spinal cord rehabilitation center had spinal schistosomiasis.

Myelitis is most common with *S. mansoni* and *S. haematobium* infection. Schistosoma ova spread hematogenously and invade the CNS where the host inflammatory response, including granuloma formation, can lead to acute myelopathy. The lower thoracic and lumbar cords are most commonly affected. Patients may present with lower extremity weakness, cauda equina syndrome, or lumbar or radicular pain. Spinal artery infarction may be found. Diagnosis is challenging; schistosomal ova are found in stool or urine in fewer than half of cases of neuroschistosomiasis. CSF findings may be nonspecific but may show eosinophils and elevated protein levels. Visualization of schistosomal forms in biopsy specimens provides definitive diagnosis. Treatment is with steroids to reduce inflammatory response, followed by praziquantel, though optimal treatment doses and duration are not established.

Toxocara spp.

Toxocara canis and *T. cati* are round worms and the cause of visceral larva migrans; they have occasionally been reported as a cause of myelitis. Patients present with typical symptoms of myelitis; lower extremity weakness is most common. MRI findings often reveal a single inflammatory lesion. Symptoms generally improve after albendazole therapy.

Other parasitic diseases found to cause spinal cord disease include gnathostomiasis, *Taenia solium*, *Toxoplasma gondii*, and *Echinococcus granulosus*.

Fungal diseases

Fungal infections rarely cause spinal cord disease and present most commonly among immunosuppressed persons. Secondary myelopathy from epidural abscess, granuloma, or vertebral compression fracture is most commonly from *Aspergillus*, *Cryptococcus*, or *Candida* species. *Blastomyces* and *Coccidioides* also causes spinal and paraspinal disease. Fungal myelopathy may result from direct iatrogenic inoculation; cauda equina syndrome was noted in 17% of patients in an outbreak of *Exserohilum rostratum* from contaminated glucocorticoid injections. Iatrogenic paraspinal aspergillus infection has also been described.

Acute flaccid myelitis in pediatrics

Acute flaccid myelitis (AFM) refers to the development of decreased tone and weakness secondary to inflammation in the spinal cord. This is also referred to as a polio-like illness and has a broad differential. Many times the etiology remains unknown. AFM can be seen in adults and children, although more commonly in children and young adults. The characteristic features include preceding febrile or respiratory illness, limb weakness and/or cranial nerve involvement, MRI showing gray matter involvement spanning more than one vertebral segment, and CSF analysis with pleocytosis. Limb weakness in AFM is caused by involvement of the anterior horn cells (gray matter in spinal cord), located at the ventral aspect of the spinal cord, controlling strength and hypertonicity. Damage in this area leads to the flaccid, decreased tone and loss of strength distinctive of this entity.

Diagnosis

AFM should be considered in any individual presenting with focal weakness, decreased tone, and preceding illness. Accompanying features include headache, neck pain, or cranial nerve neuropathies. Evaluation should be expedited to prevent eventual paralysis. Initial evaluation includes MRI of brain and spinal cord, lumbar puncture, and serum evaluation of infectious and other inflammatory causes. Spinal MRI should include cervical, thoracic, and lumbar spine with contrast. Imaging typically shows a non-enhancing hyperintensity of the spinal cord on T2/short tau inversion recovery (STIR) sequences spanning one or more spinal segments in the central and/or ventral gray matter. Lumbar puncture shows pleocytosis (usually lymphocytic), elevated protein, normal glucose, and, if possible, should include evaluation of viral or bacterial entities in CSF. To improve diagnostic yields, multiple sites of potential infection can be obtained.

AFM is a CNS disorder but a common mimicker is GBS, a peripheral nervous system disorder that also presents with flaccid weakness. The latter has a gradual onset, usually starts distally and rises to include proximal muscles with loss of reflexes, with electromyography (EMG) showing prolonged distal latencies as opposed to normal sensory nerve conduction studies with AFM. Another CNS disorder that can mimic AFM is ADEM; it is differentiated by the presence of altered mentation, spastic tone, and involvement of white matter on MRI.

Etiology

Since 2012, several cases of AFM have been cited in the United States, particularly between the months of August and October. Etiology of primary myelitis remains broad, most commonly secondary to a virus, but can also include bacteria and tick-borne diseases. Known viral entities include WNV, Coxsackievirus, adenovirus, poliovirus, and enterovirus. Other entities of concern are included in Box 79.2.

Management

Management of AFM first involves airway protection and monitoring of respiratory status in an intensive care unit. Respiratory precautions are of particular concern in AFM involving the cervical cord as some respiratory control centers are located here. In 2014, the CDC convened a panel of experts to review data and create treatment guidelines for AFM. At the time, there was insufficient evidence to advocate for one standard mode of treatment. Immunotherapy is used empirically, specifically steroids, IVIG, and plasma exchange. Caution should be used with steroids if cord swelling is not seen on imaging as this can worsen symptoms, especially if the AFM is caused by an enterovirus. Assuming that AFM is caused by a viral infection, plasma exchange could worsen the underlying disease process as it filters out antibodies. Anecdotally, IVIG has been used with success in reported clinical cases as well as in mice studies. If infectious entities are identified, treatment for these specific organisms should be initiated and seem to provide the most benefit. Early initiation of physical and occupational therapy is critical to regaining muscle function. Patients can make advances in strength months to years following initial presentation. In addition, use of medications such as fluoxetine has also been anecdotally reported to hasten recovery.

BOX 79.2

Known etiologies of acute flaccid myelitis

Viruses
Enteroviruses
Adenoviruses
Herpesviruses (HSV, VZV, EBV)
West Nile Virus
Retroviruses (HIV, HTLV I/II)
Measles
Rubella
Influenza

Bacteria
Mycoplasma
Mycobacterium tuberculosis
Neurobrucellosis

Spirochetes
Neuroborreliosis
Neurosyphilis

Acute disseminated encephalomyelitis

While the focus of this chapter thus far has been myelitis, discussion of infectious causes of spinal cord disease should include ADEM. ADEM may be considered as one among a spectrum of similar diseases including transverse myelitis, MS, and neuromyelitis optica. At least three-quarters of cases are associated with antecedent infection or vaccination. While the pathogenesis is not definitively established, it appears that infectious antigens may stimulate myelin-reactive T-cell populations by molecular mimicry. A number of infectious agents have been implicated as precipitants of ADEM, including viruses—influenza, enteroviruses, EBV, CMV, varicella, measles, mumps, rubella, hepatitis A—and bacteria including *M. pneumoniae*, *Borrelia burgdorferi*, leptospira, and β-hemolytic streptococci. Semple rabies vaccine is the most definitively associated vaccine-related trigger; other vaccines believed to be associated with ADEM include live measles vaccine (though measles virus-induced encephalitis occurs about 10 times more frequently than vaccine-related ADEM); Japanese encephalitis; tetanus, diphtheria, pertussis, and hepatitis B vaccines; and vaccinia.

Children are affected more commonly than adults. Presentations are acute, evolving over hours, usually peaking around 4 to 5 days, and exhibit a variety of neurologic findings, including pyramidal and extrapyramidal symptoms, hemiplegia, ataxia, cranial neuropathies, optic neuritis, paresthesias, and altered mental status. Spinal cord involvement occurs in about a quarter of patients. Peripheral nerve involvement, such as acute polyradiculopathy, is more common among adults, where it is reported in as many as 40% of cases. Fever and systemic symptoms are typically absent as cases tend to be postinfectious rather than concurrent with infection.

Diagnosis is challenging, in part because of differences in definitions found in the literature. The International Pediatric MS Study Group suggests the following criteria to diagnose (pediatric) ADEM: "a first polyclonal, clinical CNS event with presumed inflammatory demyelinating cause," "encephalopathy that cannot be explained by fever," "no new clinical and MRI findings emerge three months or more after the onset," and "brain MRI is abnormal during the acute (three-month) phase." Spinal cord disease has variable enhancement on MRI but large lesions, most often in the thoracic region, are common. Diagnosis is clinical based on history, symptoms, neuroimaging, and exclusion of other diagnoses; no biomarkers of disease have been found. CSF findings are nonspecific, but a mild lymphocytic pleocytosis and elevated protein may be seen. Though

no prospective, randomized trials have been done, most patients are treated with steroids; IVIG and plasmapheresis are generally reserved for refractory or fulminant cases. These treatments should only be considered after effectively excluding acute infections.

Noninfectious myelitis

Several noninfectious causes for myelitis can look similar to infectious transverse myelitis on initial presentation. Most commonly, demyelinating disorders such as MS or neuromyelitis optica spectrum disorder (NMOSD) should be considered. Demyelination describes the damage caused to myelin sheaths, the protective coverings surrounding nerve fibers.

Multiple sclerosis

MS is one of the most common autoimmune, demyelinating entities, affecting nearly 2.3 million people worldwide and typically seen in individuals between the ages of 20 and 40 years. The disease is multifocal and causes temporally distributed CNS damage that eventually leads to axonal damage. Diagnosis is based on McDonald's Criteria, most recently updated in 2017 to coordinate the clinical manifestations with characteristic MRI and CSF markers. Oligoclonal bands are the spinal fluid biomarker that can also be used as confirmation for early diagnosis in the proper clinical setting. Characteristic lesions are found in the periventricular, juxtacortical, and infratentorial locations in the brain, as well as in the cervical and/or thoracic spinal cord.

Many times, an initial presentation for MS is with a transverse myelitis. These lesions tend to be eccentric, extend one to two spinal levels, and enhance in the acute setting. Chronic MS lesions in the spinal cord will remain hyperintense on T2/STIR sequences and in severe cases can be associated with spinal cord atrophy. Differentiating demyelination between infectious myelitis will include several key aspects of history, obtaining brain imaging, and obtaining oligoclonal bands in CSF if necessary. A history of gradual-onset neurological symptoms (weakness, numbness, vision changes, etc.) lasting >24 hours and resolving spontaneously with characteristic lesions can help differentiate MS from other entities.

Treatment involves glucocorticoids in the acute setting, which can be effective in resolving a relapse of the above-mentioned symptoms. Long-term therapy involves disease-modifying agents to prevent further relapses and subclinical progression and aim to limit cognitive dysfunction at later stages. A diverse group of injectable, oral, and infusion immunosuppressive agents and immunomodulators are available, with many newer agents showing greater reduction in relapse rate.

Neuromyelitis optica

NMOSD is mediated by the aquaporin-4 (AQP4) antibody, leading to secondary demyelination. The antibody is in the CNS and is specifically found along perivascular distribution on astrocytic foot processes around blood vessels and glia. NMOSD, originally called *Devic's disease*, was initially characterized as a longitudinally enhancing lesion in the spinal cord with optic nerve dysfunction. The terminology for longitudinal enhancing transverse myelitis refers to lesions traversing more than three vertebral segments. The clinical characteristics defining NMOSD have now expanded to include area postrema syndrome leading to intractable hiccups or nausea/vomiting, symptomatic narcolepsy, or an acute brainstem syndrome. These clinical syndromes, with an MRI that includes characteristic brainstem lesions in the setting of AQP4 seropositivity, can make the diagnosis even when a longitudinal lesion and optic nerve involvement is not seen. This syndrome can be steroid-responsive, but many times requires the use of plasmapheresis in the acute setting. Presence of AQP4 antibody tends to be related to a relapsing course so long-term therapy with immunomodulation should be considered.

Myelin oligodendrocyte glycoprotein antibody disease

Myelin oligodendrocyte glycoprotein (MOG) antibody disease is a demyelinating syndrome associated with the MOG antibody, expressed on the outer membrane of myelin in the CNS. Clinical symptoms are similar to NMOSD with primary characteristics showing optic nerve and spinal cord involvement. Presentations include paraparesis, sensory loss, and bladder sphincter dysfunction. There is a higher predilection for conus involvement than seen in NMOSD. Longitudinally enhancing lesions are predominantly seen rather than shorter segments of spinal cord inflammation. MOG appears to have a higher frequency of focal myelitis and better clinical outcomes. No clinical criteria exist as of yet but patients who are found to be AQP4-negative in prior cohorts have been ultimately found to be MOG antibody-positive. This group also was found to be younger and have a typically monophasic course. There is a significant response to steroid therapy and a similarly rapid relapse on withdrawal of steroids. A majority of patients have a relapsing course and therefore, after steroid, IVIG, or plasmapheresis treatment in the acute setting, immunosuppression should be considered.

Neuropathy

Because there are many patterns of neuropathy of both infectious and noninfectious etiologies, the approach to the patient with peripheral neuropathy begins with identification of the pattern of illness. The history should focus on the duration of symptoms and their relation to antecedent or comorbid illnesses. An acute onset is highly suggestive of an inflammatory, immunologic, vascular, or toxic cause. Because infectious diseases are known to mediate disease via all of these mechanisms, most neuropathies due to infectious diseases will present acutely or subacutely. Chronic neuropathies of infectious origin, although less common, do occur, particularly Hansen's disease (leprosy) and Lyme borreliosis. In

general, an acute onset suggests a more favorable prognosis and should prompt a timely search for the underlying cause to prevent permanent neurologic sequelae. Etiologic clues may be suggested by recent or current systemic illness, such as pharyngitis in diphtheritic neuropathy, *Campylobacter* gastroenteritis in GBS, or epidemiologic exposures such as tick bites or sexual activity. Travel and residence history is also of diagnostic importance in suggesting an entity such as Lyme borreliosis.

The four major anatomic patterns of neuropathy are *mononeuropathy*, *mononeuropathy multiplex*, *polyneuropathy*, and *plexopathy*. Neuropathies are further classified according to the type of functional nerve involvement: *purely motor*, *sensory*, *autonomic*, or *mixed*. In classifying the neuropathy, the physical exam should address the following questions: Does the involvement include more than one functional nerve type? Is involvement symmetric or asymmetric, distal or generalized, ascending or descending? Is there a sensory level? Do motor and sensory deficits overlap, and do they match subjective complaints? Are deep tendon reflexes and other reflexes (e.g., Babinski, genitoanal) normal? Is sphincter function normal? Is there evidence of denervation (e.g., fasciculation, atrophy)? Are there associated skin lesions? Establishing the pattern of illness and rate of onset lets the neuropathic syndrome be identified and points to specific causes. Discussed next are some of the major infectious causes of peripheral neuropathy.

Hansen's disease (leprosy)

Hansen's disease (leprosy) is a chronic mycobacterial infection in which *Mycobacterium leprae* primarily affects the peripheral nervous system and secondarily involves skin and other tissues. *M. leprae* is shed from skin and mucous membranes, and while the mode of transmission is not definitively established, it appears to be transmitted from person to person by respiratory droplets.

Worldwide, Hansen's disease is one of the most common causes of peripheral neuropathy. Although a rare disease in the United States, new cases are still diagnosed, most frequently in immigrants. Of the approximately 228,000 cases reported globally to the World Health Organization (WHO) in 2010, 95% were reported by 17 countries; more than half were from India.

Clinical Hansen's disease ranges a broad spectrum resulting from complex interactions between the organism and the patient's immune system. The cardinal manifestations of Hansen's disease are anesthetic skin lesions, palpably enlarged peripheral nerves, and, in lepromatous patients only, visible acid-fast bacilli on skin biopsy or slit skin smear that do not grow in conventional mycobacterial cultures.

Although skin lesions vary in appearance, anesthesia of the involved skin is the characteristic feature in typical Hansen's disease. Lepromatous disease can result in symmetric anesthesia of the colder areas of the body (e.g., pinnae, dorsa of hands and feet), whereas nerve involvement in indeterminate and tuberculoid disease is typically asymmetric.

The peripheral nerves most commonly involved are the facial, ulnar, median, common peroneal, and posterior tibial nerves. Superficial nerves, such as the ulnar and posterior auricular nerves, are accessible to palpation and are often enlarged and tender. Neuropathic injury to the hands and feet is a significant cause of disability; a complete motor and sensory exam should be performed before beginning therapy. Proprioceptive deficits are uncommon but have been described. Where the disease is rare, such as in the United States, skin biopsy of the most active margin should be performed. Specific details about therapy and prevention of neuropathy can be found in Chapter 140, "Leprosy."

HIV-associated neuropathies

Neuropathy is the most common neurologic disorder associated with HIV. Many causes of neuropathy have been described in HIV-infected persons (Box 79.1). Predominantly sensory neuropathy is the most common neuropathy seen in AIDS and is one of the most debilitating aspects of advanced HIV infection. Its exact cause is unclear, although pathology studies suggest an immune complex vasculitic etiology. Patients often note painful paresthesias of the distal extremities, primarily of the soles of the feet. On exam, patients with progressive HIV neuropathy will exhibit a generalized decrease in sensation in the affected areas and atrophy of the intrinsic muscles of the feet. Deep tendon reflexes of the ankles are eventually lost, but patellar reflexes may be exaggerated by coexisting myelopathy. When reflexes are affected, nerve conduction studies are consistent with distal axonal degeneration. Reversible causes of neuropathy should be excluded. Treatment of HIV predominantly sensory neuropathy is generally unsatisfactory.

Herpesvirus-associated peripheral neuropathies: CMV, HSV, VZV, EBV, and B-virus

CMV infection of the peripheral nerves, essentially unknown prior to AIDS, is often associated with active CMV infection in other systems, particularly retinitis. The capacity of CMV to invade both endothelial and Schwann cells accounts for its varied clinical manifestations. Polyradiculopathy, the most dramatic of these syndromes, is caused by CMV more often than by other herpesviruses. It is characterized by subacute ascending motor weakness, areflexia, incontinence or urinary retention, paresthesias, and variable sensory dysfunction. Patients often report pain in the back and legs. Inflammation of lumbar nerve roots, dorsal root ganglia, and spinal cord result in characteristic CSF findings mimicking bacterial meningitis: pleocytosis with white blood cell counts from 5 to more than 3,000 with a polymorphonuclear predominance, hypoglycorrhachia, and elevated protein. Enhancement of the cauda equina on MRI has been reported. PCR of CMV viral DNA in the CSF is the diagnostic method of choice.

Herpes simplex type 2 can cause sacral radiculitis (Elsberg syndrome) manifested by urinary retention, constipation, erectile dysfunction, sensory loss in a sacral dermatome, and buttock pain. Lumbar spine MRI may show sacral root edema and enhancement, and the CSF HSV-2 PCR is positive. In AIDS patients, the infection can progress to ascending necrotizing myelitis.

Herpes simplex type 1 causes the majority of Bell's palsy episodes. Steroids combined with antivirals such as acyclovir or valacyclovir improve outcomes. Antivirals should not be given without steroids, as meta-analysis revealed worse outcomes with antivirals alone.

VZV can also cause polyradiculopathy in AIDS patients. VZV classically involves the dorsal root ganglia, but spread of inflammation into the cord can reach anterior horn cells, resulting in pain and paralysis. VZV has also been associated with transverse myelitis and myositis. Zoster-associated disease may occur without a vesicular rash (*Zoster sine herpete*). The diagnosis is established with a positive CSF VZV DNA PCR.

Treponema pallidum-associated neuropathy

CNS syphilis may also present as subacute polyradiculopathy in HIV infection. The CSF contains lymphocytes, and the CSF VDRL test is typically positive.

Mononeuropathy multiplex

Mononeuropathy multiplex is a syndrome of simultaneous or sequential neuropathy of noncontiguous nerve trunks evolving over days to years. Characterized by patchy, asymmetric motor and sensory nerve dysfunction, mononeuropathy multiplex is possibly the result of ischemic injury from viral or other infection of the endothelium of the vasa nervorum and immune complex disease. Mononeuritis multiplex may be seen in HIV infection even before immunosuppression has occurred. Some cases are associated with cryoglobulinemia in persons infected with hepatitis B, in which the course is often benign and may not require specific therapy. Recently, parvovirus B19 has been associated with mononeuritis multiplex; case reports have been described with Q fever as well. Lyme is a common cause of radiculopathy and cranial neuropathies in areas endemic for *B. burgdorferi*. In patients with advanced HIV infection and CD4 counts ≤50 mm^3, CMV is the most likely cause.

Inflammatory demyelinating neuropathies

GBS, a heterogeneous syndrome of demyelinating diseases of peripheral nerves with multiple variants, has well-known association with infectious diseases such as EBV, CMV, VZV, HIV, *M. pneumoniae*, psittacosis, Lyme, dengue, and particularly *Campylobacter jejuni*. In more than half of patients, a mild respiratory or gastrointestinal tract illness precedes the onset of GBS by 1 to 3 weeks. Molecular mimicry and cross-reactive antibodies between infectious agents may play a role in the pathogenesis of some variants.

When an inflammatory demyelinating polyneuropathy persists beyond 8 weeks, or recurs, *chronic inflammatory demyelinating polyneuropathy* (CIDP) is considered. CIDP is associated with multiple predisposing factors and is also seen in patients infected with HIV. Like GBS, CIDP has multiple variants but usually presents as weakness with varying degrees of sensory loss. Physical exam reveals proximal muscle weakness. Weakness of the neck flexors is particularly suggestive. As in GBS, CSF albuminocytologic dissociation is common. The presence of leukocytes should raise suspicion of HIV infection. Electrodiagnostic and neuroimaging studies are also helpful. Multiple diagnostic criteria, including the Koski criteria and criteria from the European Federation of Neurological Societies and the Peripheral Nerve Society (EFNS/PNS), have been published.

Plasmapheresis is effective short-term, but deterioration after stopping plasmapheresis is common. Glucocorticosteroids are commonly used, although most supporting evidence is from nonrandomized trials. IVIG is superior to placebo in improving disability and comparable to plasmapheresis and steroids. Immunomodulatory drugs such as azathioprine and methotrexate have been used; additional research is needed to determine whether these may provide significant benefit.

Lyme neuroborreliosis

B. burgdorferi infection can result in acute and chronic peripheral neuropathies. Acute disseminated disease is usually characterized by peripheral and/or cranial neuropathies and meningoencephalitis, usually 4 to 12 weeks after a tick bite. Plexitis, mononeuropathy multiplex, and myelitis also occur with acute infection. Facial palsies occurred in 8% of cases reported to the CDC from 2003 to 2005, and radiculopathy in 3%. In endemic areas, facial palsy with a history of tick bite is sufficient to warrant empiric therapy. Peripheral nerve involvement usually presents asymmetrically as motor, sensory, or mixed radiculoneuropathy. Presentation may vary by Borrelia species; meningoradiculitis and radicular pain (Bannwarth's syndrome) is more common in Europe where multiple Borrelia species are found and associated most frequently with *B. garinii*. Long-standing, untreated Lyme borreliosis can cause intermittent distal paresthesias and radicular pain. Physical examination may be normal, but nerve conduction studies demonstrate axonal neuropathy. Diagnosis and specific antibiotic therapy are discussed in Chapter 162, "Lyme disease."

Neuropathies due to bacterial toxins

Diphtheria

Diphtheria is rare in the United States but is still seen in unimmunized children and in adults with waning immunity. All adults are advised to have a diphtheria booster vaccine every 10 years (in combination with tetanus with or without acellular pertussis); travelers to areas with diphtheria outbreaks or endemic diphtheria are advised to either have completed a primary immunization series or received a booster dose within the past 10 years.

Neurological, cardiac, and renal complications of diphtheria are due to its potent toxin, which acts on elongation factor, a protein critical for mammalian protein synthesis. The toxin causes noninflammatory demyelination of cranial and peripheral nerves through its toxic effect on Schwann cells.

In upper respiratory tract diphtheria, locally produced toxin causes paralysis of the pharyngeal and laryngeal muscles. The patient may speak with a nasal voice and report dysphagia and nasal regurgitation. As disease progresses, within days, the trigeminal, facial, vagal, and hypoglossal nerves are affected ("bulbar phase"), and loss of ocular accommodation is followed in 1 to 2 months by a generalized sensorimotor polyneuropathy ("systemic phase") frequently complicated by myocarditis and injury to other organs.

Botulism

Clostridium botulinum is a ubiquitous, spore-forming, anaerobic gram-positive rod that lives in soil and aquatic habitats. It produces a potent neurotoxin, termed BoNT, capable of binding irreversibly and blocking acetylcholine release at the neuromuscular junction.

Manifestations of clinical botulism include (1) *infant botulism* in babies between 1 and 6 months of age occurring after ingestion of *C. botulinum* spores and the most commonly encountered form; (2) *adult infectious botulism* or *adult intestinal toxemic botulism*, also caused by ingestion of spores; (3) *food-borne botulism*, involving ingestion of BoNT and often occurring as small food-borne outbreaks; (4) *wound botulism*, from proliferation of *C. botulinum* in a contaminated anaerobic wound or paranasal sinus in cocaine snorters; (5) *inadvertent botulism*, a complication of therapeutic uses of purified botulinus toxin; and (6) *bioterrorism*, where BoNT is dispersed by aerosol or contaminates food and water supplies.

Neuromuscular symptoms of botulism vary with patient age, by whether exposure is from preformed toxin ingestion or from active toxin production in the gut or a wound, and by toxin type. Infants first develop constipation, then hypotonia ("floppy baby syndrome") and ophthalmoplegia. Clinical features include symmetrical cranial neuropathies, autonomic dysfunction, symmetrical "descending weakness"—eye and facial muscles are most sensitive to neuromuscular blockade—in a proximal to distal pattern, and respiratory dysfunction from respiratory muscle paralysis or airway obstruction. Sensory exam is always normal. Wound botulism has the same clinical pattern as food-borne botulism but may be complicated by concurrent bacterial wound infections. In cases of food-borne exposure, the time to onset of disease is usually 12 to 36 hours. Neurologic effects are dose-dependent; people with a common source exposure exhibit differing degrees of neurologic findings depending on the amount of prototoxin ingested. Toxin type also affects the rate and extent of progression of symptoms. Type E has the shortest incubation period, but type A produces more severe illness and requires intubation more frequently (67%).

Tetanus

Tetanus is caused by the toxic action of tetanospasmin, or tetanus neurotoxin (TeNT), produced by the anaerobic spore-forming rod *Clostridium tetani,* which is widely distributed in nature. *C. tetani* is usually introduced into tissues as a spore. Disease only develops under anaerobic conditions that permit growth of the toxin-producing vegetative form. Tetanus toxin is the next most potent toxin after botulinum toxin. TeNT is a protein with three domains endowed with different functions: neurospecific binding, membrane translocation, and proteolysis for specific components of the neuroexocytosis apparatus. While tetanus neurotoxin acts mainly at CNS synapses, the seven BoNT subtypes act peripherally.

Despite availability of effective and inexpensive tetanus toxoid vaccines, cases of tetanus continue to occur in the United States, with fatality rates up to 25%. Primary prevention of tetanus is accomplished by active immunization with vaccines. All adults should complete a three-dose primary vaccination schedule and a tetanus booster every 10 years thereafter. Pregnant women should receive Tdap between weeks 27 and 36 of each pregnancy. *Secondary prevention* refers to post-wound tetanus prophylaxis and varies with vaccine history and type of wound. All wound patients should receive Td if they have received three or fewer tetanus-containing vaccines, if vaccination history is uncertain, or if more than 10 years has elapsed since the last booster in a patient with a minor wound or more than 5 years since the last booster in a patient with a major wound. Patients should also receive tetanus immunoglobulin if wounds are contaminated with feces, soil, or saliva, or if they have wounds from punctures, avulsions, projectiles, crushing, burns, or frostbite.

The "incubation period" is the time from inoculation to symptom onset and reflects the quantity of toxin released and distance traveled to the CNS. The "period of onset"—the time between the first symptom and start of spasms—reflects rate of progression of neurologic disease and is the most important prognostic factor for generalized tetanus. Diagnosis is clinical and confirmed by characteristic neurophysiologic findings and absence of serum antitetanus antibody. CSF is normal. Gram stain and anaerobic cultures of the wound may or may not reveal the organism.

There are three clinical presentations of tetanus: (1) local tetanus with muscular contraction at the site of injury, which may persist or progress to the generalized form; (2) cephalic tetanus affecting cranial nerves, mostly the seventh pair; and (3) generalized tetanus with lockjaw, reflex spasms provoked by external stimuli, opisthotonos, and risus sardonicus. The patient is conscious during spasms and experiences intense pain. Glottal or laryngeal spasm and urinary retention may occur.

The spastic paralysis induced by tetanus toxin is due to the blockade of neurotransmitter release from spinal inhibitory interneurons. When inhibitory signals to motor neurons are blocked, uninhibited motor nerve transmissions continue, resulting in prolonged muscle spasms that can persist for weeks. Autonomic instability also occurs, including labile hypertension, cardiac tachyarrhythmias, peripheral vasoconstriction, and profuse sweating. Neuronal cell death may occur from unopposed excitation.

Acute treatment has four components: (1) local wound debridement and systemic antibiotics; (2) systemic (intramuscular) administration of human antitoxin; (3) control of spasms, with associated intensive care support, sedation with benzodiazepines, and neuromuscular blockade when necessary; and (4) α- and β-adrenergic blockade to prevent secondary autonomic hyperactivity. Details are provided elsewhere. For tetanus survivors, prevention of future risk requires a primary vaccination series for active immunization after the completion of acute therapy.

Reye syndrome

Debra L. Weiner and Amy Kritzer

Background

Reye syndrome is an acute noninflammatory encephalopathy with fatty degenerative liver failure first described by R. D. K. Reye in 1963. Decrease in aspirin use in children, in response to its association with Reye syndrome, and the identification of medications, toxins, and inborn errors of metabolism (IEMs) that present with Reye-like syndrome manifestations have made Reye syndrome exceedingly rare.

While recognizing the rarity of Reye syndrome, the diagnosis should be considered in any child with vomiting, altered mental status, and classic laboratory findings, but it must be a diagnosis of exclusion (Box 80.1). Early recognition and treatment of Reye and Reye-like syndromes, including possible IEMs, is essential to prevent death and optimize the potential for recovery without neurologic impairment.

CDC diagnostic criteria

Pathophysiology

Reye syndrome appears to involve mitochondrial injury resulting in inhibition of oxidative phosphorylation and fatty-acid β-oxidation usually in a virus-infected, sensitized host, most commonly as per 1980–1997 surveillance data from the US Centers of Disease Control and Prevention (CDC) with recent influenza (73%), chickenpox (21%), or diarrheal illness (14%), in association with exposure to mitochondrial toxins, most often salicylates.

Hepatic mitochondrial dysfunction results in hyperammonemia, thought to induce astrocyte edema, which causes cerebral edema and increased intracranial pressure (ICP). Histologic changes include cytoplasmic fatty vacuolization of hepatocytes, astrocyte edema and loss of neurons in the brain, and edema and fatty degeneration of the proximal lobules in the kidneys.

Etiology

Pathogens

Influenza A and B and varicella-zoster are the pathogens most commonly associated with Reye syndrome. Other pathogens include parainfluenza, adenovirus, coxsackie, herpes, rubella, measles, cytomegalovirus, Epstein–Barr, HIV, retrovirus, hepatis A and B, mycoplasma, chlamydia, pertussis, shigella, salmonella, and poliomyelitis. Reye syndrome can occur after vaccination with live viral vaccines.

BOX 80.1

Diagnostic criteria

- Acute noninflammatory encephalopathy with altered level of consciousness
- Hepatic dysfunction, liver biopsy fatty metamorphosis without inflammation or necrosis, or ≥3-fold increase in ALT, AST or ammonia
- No other explanation for cerebral edema or hepatic abnormality
- Cerebrospinal fluid white blood cell count <8/mm3, usually lymphocytes. Opening pressure may be elevated particularly in stages 4, 5 but is usually normal
- Brain biopsy-cerebral edema without inflammation or necrosis

Salicylates

Epidemiologic studies have demonstrated association of Reye syndrome with salicylates, particularly aspirin. While only 0.1% of children who took aspirin developed Reye syndrome, >80% of patients diagnosed with Reye syndrome had taken aspirin in the past 3 weeks. In the United States, a recommendation in 1980 that children not be treated with salicylates led to an immediate and dramatic decrease in the incidence of Reye syndrome. Similar declines were seen in other countries once they issued recommendations against use of aspirin.

Other medications

Nonsteroidal anti-inflammatory drugs, including sodium diclofenac and mephenamic, are thought to produce or worsen Reye syndrome. While data have not substantiated acetaminophen as a single causative agent of Reye syndrome, there is some evidence of possible interaction, synergism, and co-toxicity of aspirin and acetaminophen. Valproate, warfarin, zidovudine, didanosine, tetracycline, some neoplastic drugs, and herbal medications with atractyloside, a diterpenoid glycoside in extracts of the tuber of *Callilepis laureola* (impila poisoning) have been associated with Reye or Reye-like syndrome. Association with antiemetics was postulated but not substantiated.

Toxins

Insecticides, herbicides, aflatoxins, isopropyl alcohol, paint, paint thinner, margosa (neem) oil, hepatotoxic mushrooms, hypoglycin in ackee fruit (Jamaican vomiting sickness), and *Bacillus cereus* cereulide toxin have been reported to cause Reye syndrome.

IEMs

Reye-like syndrome is caused by fatty-acid oxidation defects, particularly medium chain acyl CoA dehydrogenase (MCAD) deficiency and long-chain 3-hydroxyacyl CoA dehydrogenase deficiency (LCHAD); urea-cycle defects; amino and organic acidopathies, such as propionic acidemia and methylmalonic acidemia; primary carnitine deficiency; dihydrolipoamide dehydrogenase deficiency; and disorders of carbohydrate metabolism.

Epidemiology

In the United States, CDC mandatory surveillance reporting began in 1973. From 1979 to 1980, 1,207 cases reported with peak of 555 1979–1980. Between 1987 and 1993, a maximum of 36 cases were reported annually, and since 1994, two cases or fewer annually. Peak age of those diagnosed was 5 to 14 years. Although CDC reporting is no longer mandated, reporting is still required by many local/state health boards

Presentation

Abrupt onset of pernicious vomiting occurs 12 hours to 3 weeks (mean 3 days) after symptoms of viral illness have resolved. Diarrhea and hyperventilation may be the first signs in children <2 years. Neurologic symptoms usually occur 24 to 48 hours after the onset of vomiting, beginning with lethargy and progressing to irritability, agitation, delirium, seizures, and coma.

Exam findings may include dehydration, hepatomegaly, lethargy, encephalopathy, obtundation, coma, seizures, and paralysis. Notably, patients are afebrile with minimal or absent jaundice.

Findings may also include acute respiratory failure, aspiration pneumonia, cardiac arrhythmia, myocardial infarction, cardiovascular collapse, gastrointestinal bleeding, pancreatitis, renal failure, and cerebral herniation.

Clinical staging

Lovejoy described five clinical stages of Reye syndrome 1 to 5. Hurwitz added a nonclinical stage (i.e., stage 0). The CDC added stage 6 for patients who cannot be classified due to treatment. Stage 0 does not meet the CDC case definition because it does not meet the clinical criteria (Box 80.2).

Laboratory abnormalities

Serum bicarbonate is decreased secondary to vomiting. Blood urea nitrogen (BUN) and creatinine are elevated. Venous pH may reveal metabolic acidosis with increased anion gap.

Patients may develop syndrome of inappropriate secretion of antidiuretic hormone, or diabetes insipidus. Glucose, while usually normal, may be low, particularly during stage 5 and in children <1 year.

Ammonia as high as 1.5 times normal (normal ≤80 μmol/L, neonates ≤100 μmol/L) 24 to 48 hours after onset of mental status changes is the most common laboratory abnormality. Ammonia tends to peak 56 to 60 hours after onset of symptoms and may

BOX 80.2

Clinical staging

- Stage 0—Alert, abnormal history and laboratory findings consistent with Reye syndrome, no clinical manifestations
- Stage 1—Vomiting, sleepiness, lethargy
- Stage 2—Restlessness, irritability, combativeness, disorientation, delirium, tachycardia, hyperventilation, dilated pupils with sluggish response, hyperreflexia, +Babinski sign, appropriate response to noxious stimuli
- Stage 3—Obtunded, comatose, decorticate rigidity, inappropriate response to noxious stimuli
- Stage 4—Deep coma, decerebrate rigidity, fixed and dilated pupils, loss of oculovestibular reflexes, and dysconjugate gaze with caloric stimulation
- Stage 5—Seizures, flaccid paralysis, absent deep tendon reflexes, no pupillary response, respiratory arrest
- Stage 6—Patients who cannot be classified due to treatment with medication that alters level of consciousness

return to normal in stages 4 and 5, with clearance from blood more rapid than from brain.

Alanine aminotransferase (ALT) and aspartate aminotransferase (AST) increase to three times normal but may return to normal by stages 4 and 5. Bilirubin is >2 mg/dL, but usually <3 mg/dL, in 10% to 15% of patients. If the direct bilirubin is >15% or total exceeds 3 mg/dL, consider other diagnoses.

Lipase and amylase are elevated.

Lactic dehydrogenase (LDH) may be high or low.

Prothrombin time (PT) and activated partial thromboplastin time (aPTT) are prolonged to greater than 1.5-fold in >50% of patients. Levels of factors I (fibrinogen), II, VII, IX, and X may be low because of the disruption of synthetic activities in the liver. Consumption may contribute to low levels of coagulation factors. Platelet counts are usually normal, but mean platelet volumes may be decreased at early stages of disease.

Free fatty acids and amino acids (e.g., glutamine, alanine, and lysine) may be elevated.

Urine specific gravity is increased. Eighty percent have ketonuria.

Cerebral spinal fluid white blood cell count, by disease definition, does not exceed 8/mm^3. Opening pressure is usually normal but may be elevated, particularly in stages 3 to 5.

Brain CT may reveal cerebral edema, but is usually normal.

Electroencephalography (EEG) may reveal slow-wave activity in early stages and flattened waves in advanced stages.

These derangements are not specific for Reye syndrome and may suggest other etiologies that should be considered.

Differential diagnosis

Differential diagnosis includes meningitis, encephalitis, intracranial bleed, sepsis, gastroenteritis, hepatitis, intussusception with obtundation, adverse drug reactions, toxins, and IEM.

IEM is suggested by age <1 year; recurrence of symptoms; precipitating factors, including prolonged fasting and changes in diet; decompensation out of proportion to intercurrent illnesses; failure to thrive; neurologic abnormalities; and family members with similar symptoms and/or unexplained neonatal/infant deaths.

Treatment

Early recognition, careful monitoring, and aggressive management of possible Reye syndrome, as well as possible IEM, are critical. Support of airway, breathing, circulation; minimizing metabolic demands; avoiding catabolism; promoting anabolic state; correcting metabolic derangements and coagulopathy; ammonia detoxification; and prevention/treatment of increased ICP are the mainstays of treatment (Table 80.1). Reye syndrome has been successfully treated with liver transplant.

TABLE 80.1 **TREATMENT**

Airway, breathing	**Oxygen, endotracheal intubation** as required to maintain airway, control ventilation, and prevent increased ICP Intubation using rapid-sequence agents that minimize increasing ICP Nasogastric tube to decompress the abdomen	Continuous cardiorespiratory monitoring of vital signs, oxygen saturation, end-tidal carbon dioxide wave capnography, blood gas
Circulation	Consider restricting fluids to two-thirds maintenance. **Crystalloids** to restore volume **Blood products** to correct hematologic deficiencies	Overhydration may precipitate cerebral edema. Dehydration may compromise cardiovascular volume and reduce cerebral perfusion. Goal is normal urine output. Albumin is controversial.
Electrolyte derangements	**Sodium, potassium** based on specific abnormalities and/or to prevent abnormalities	If sodium bicarbonate given for acidosis and/or sodium phenylacetate, sodium benzoate for hyperammonemia, adjust fluids to account for high sodium loads.

(*continued*)

TABLE 80.1 CONTINUED

Hypoglycemia	**Dextrose** 25%, 1–2 mL/kg IV followed by D10–15 as needed to maintain glucose 100–125 mg/dL	Check glucose, particularly if age <1 year and/or altered mental status. If concern hypoglycemia producing IEM, maintain glucose 100–150 mg/dL to decrease risk of hypoglycemia.
Acidosis	**Sodium bicarbonate** to correct acidosis is controversial due to potential paradoxical CSF acidosis For pH <7.0–7.2, consider 0.5–2 mEq/kg/h to correct pH to 7.25–7.3	Data regarding pH for which bicarbonate should be administered and appropriate dosage are lacking. Avoid rapid correction/overcorrection
Hyperammonemia	**Sodium phenylacetate, sodium benzoate hemodialysis** should be considered for ammonia >500–600 µg/dL and for patients whose condition fails to respond to initial course of sodium phenylacetate, sodium benzoate	FDA approved for treatment of hyperammonemia due to urea-cycle defects. Contraindicated if underlying liver disease. Consultation with a metabolism expert and/or hepatologist is recommended. Follow package insert instructions. Note dose <20 kg is based on weight, >20k is based on meter-squared.
Nausea, vomiting	**Ondansetron** 1–2 mg IV q8h prn vomiting. Give with sodium phenylacetate, sodium benzoate to prevent vomiting. Consider **antacids** for gastrointestinal protection	Prevent vomiting to avoid increasing ICP. Use with caution if prolonged QTc. Avoid in decompensated patients if known or possible IEM, especially organic academia, fatty acid oxidation defect d/t increased incidence QTc.
Increased intracranial pressure	**Head** midline, head of bed 30 degrees **Ventilation** to maintain **PCO_2 normal** range 35–40 mm Hg Avoid overhydration by restoring fluid deficit with **isotonic fluids** rather than hypotonic fluids, **restrict fluid** to volume necessary to maintain normal urine output, administer **furosemide** 1 mg/kg q4–6h prn fluid overload Prevent increased cerebral metabolic demand, blood flow **Antipyretic** for fever to prevent the increased cerebral metabolism and blood flow from hyperpyrexia **Analgesia/sedation** to alleviate agitation and/or perform for painful interventions **Paralytic** to control shivering **Barbiturate coma, hypothermia** controversial For life-threatening ICP, **mannitol** 20% solution, dose 0.25–0.5 g/kg IV infused over 10–20 minutes up to every 6–8 hours or **hypertonic saline** 3%, dose 3–5 mL/kg over 3–30 minutes	Mannitol preferred to hypertonic saline if giving sodium bicarbonate and/or sodium phenylacetate, sodium benzoate.
Seizures	**Phenytoin** 10–20 mg/kg IV loading dose, followed by 5 mg/kg/d IV divided q6h or fosphenytoin as 10–20 mg/kg phenytoin equivalents	Avoid valproate; causes or worsens hyperammonemia.
Coagulopathy	**Fresh frozen plasma** (FFP) 10–15 mL/kg q12–24h, **cryoprecipitate** 10 mL/kg q6h, **platelets, vitamin K** 1–10 mg IV, **and/or exchange transfusion** **Platelets** should be administered to restore count to >50,000/mm^3 prior to invasive procedures	FFP rapid correction, volume expansion if active bleeding or invasive procedures are required. If fibrinogen <100 mg/dL, consider cryoprecipitate instead of FFP because it has a higher concentration of fibrinogen. Consider vitamin K instead of FFP or cryoprecipitate if correction is not emergent. Exchange transfusion is rarely required.

Abbreviations: FFP = fresh frozen plasma, ICP = intracerebral pressure, IEM = inborn errors of metabolism.

Place central venous and/or arterial lines to monitor hemodynamic status, Foley catheter to monitor urine output, and, as indicated, ICP monitoring device. Use electrocardiogram to monitor cardiac function and EEG to monitor seizure activity.

Prognosis

Mortality has decreased from 50% to less than 20% as a result of early diagnosis, recognition of mild cases, and aggressive therapy, as well as appropriate diagnosis and disease-specific treatment of Reye-like syndromes, including IEMs. Death is usually due to cerebral edema or increased ICP, but may be due to myocardial dysfunction, cardiovascular collapse, respiratory failure, gastrointestinal bleeding, renal failure, and/or sepsis.

Patients who survive may recover completely. US data from peak years 1981–1997 show that 62% of patients with known outcome had full recovery. Poor prognosis was associated with

- Age <5 years (death 42.8% vs. 24.2%; relative risk 1.8, 95% confidence interval [CI] 1.5, 2.1)
- Rapid progression from stage 1 to 3 and/or presentation stage 4 or 5. Meaningful survival beyond stage 3 unlikely. Full recovery possible stages 0–2
- Central venous pressure (CVP) <6 mm Hg
- Elevated ammonia (death 28.6% vs. 8.4%; relative risk 3.4, 95% CI 1.9, 6.2). In survivors, higher levels of ammonia and prolonged hyperammonemia were associated with increased likelihood of neurologic sequelae.
- Serum glucose <60 mg/dL
- Hypoproteinemia
- Muscle involvement
- Antecedent diarrheal illness

Prevention

Salicylates and salicylate-containing medications should be avoided in children. Children with a condition for which salicylates are a mainstay of therapy (e.g., Kawasaki disease) should discontinue salicylate at first signs/symptoms of Reye syndrome and should possibly avoid acetaminophen until salicylates taken have been completely metabolized.

Influenza vaccine is recommended by the CDC for all children >6 months of age.

Progressive multifocal leukoencephalopathy

Christopher M. Perrone and Joseph R. Berger

Introduction

In their seminal report in 1958, Astrom, Mancall, and Richardson described a progressive neurologic syndrome with a characteristic triad of neuropathologic findings: namely, demyelination, giant astrocytes, and oligodendrocytes with abnormal nuclei. They named the disorder *progressive multifocal leukoencephalopathy* (PML). The viral etiology of this neurologic disease was not determined until later. Until the advent of the AIDS pandemic, PML remained a vanishingly rare disorder seen almost exclusively in individuals with underlying immunosuppressive disorders. Prior to the advent of highly active antiretroviral therapy (HAART), PML occurred in approximately 1 in 20 of all HIV-infected persons in developed countries. While the introduction of HAART led to a decline in AIDS-associated PML, AIDS is currently estimated to be the predisposing disorder for about 80% of all PML cases. Hematologic malignancies account for another 10%. However, development of immunosuppressive and immunomodulating therapies has led to a growing incidence of PML in patients with autoimmune disorders. To date, at least 50 drugs have been associated with PML; however, the risk of PML with them varies widely. Three factors can be used to determine whether a drug has a unique risk for PML, namely: (1) whether the underlying disorder being treated is associated with PML in the absence of the drug, (2) whether there is a latency from the initiation of the drug to the onset of PML, and (3) the frequency with which PML is observed with the drug. Used in the treatment of rheumatologic disorders such as rheumatoid arthritis (RA) and lupus, immunosuppressive therapies such as methotrexate, azathioprine, and mycophenolate mofetil have been linked with a number of PML cases. Regarding immunomodulating therapies, the monoclonal antibody natalizumab, an $\alpha 4\,\beta 1$ integrin inhibitor, approved for the treatment of multiple sclerosis (MS) and inflammatory bowel disorders, has been associated with >800 cases of PML since its reintroduction to the market in 2006. Because MS does not predispose to PML, natalizumab seems to be the therapeutic agent with the greatest risk of inducing PML.

JC virus and the pathogenesis of PML

In 1965, Zu Rhein and Chou identified viral particles in glial nuclei resembling papovavirus. Subsequently, Padgett isolated polyomavirus from PML brain in glial cell cultures. The virus has a simple DNA genome of 5.1 kilobases in a double-stranded, supercoiled form, encapsidated in an icosahedral protein structure measuring 40 to 50 nm in diameter. The virus was named the JC virus (JCV) after the initials of the person from whom it was first isolated. JCV DNA encodes for three capsid proteins (VP1, VP2, and VP3) and five regulatory proteins (agnoprotein, t, T, T′135, T′136, and T′165); the latter three are derived by alternative splicing of early viral mRNA. To date, all cases of PML have been associated with JCV, although there are rare reports of other polyomaviruses, in particular BK virus, being associated with a PML-like disorder in immunosuppressed individuals.

JCV uses serotonin receptor 5-HT2A linked to sialic acid for binding to the cell surface. It is likely that other receptors remain to be identified that also permit JCV binding. Following binding, the virus enters the cell through clathrin- and eps15-dependent pathways, following which it is transported to the endoplasmic reticulum through caveosomes. From there, it enters the nucleus. Nuclear DNA binding proteins that selectively interact with the regulatory region of the genome are critical to the tropism of the virus. JCV is most likely carried into the brain by white blood cells. Pathologically, the gray–white junction is the most common location for typical PML. Whether the virus enters the brain by itself or in a cell-associated fashion remains unknown. Some investigators have suggested that the B cell plays a fundamental role in genetically modifying JCV as well as assisting the virus in central nervous system (CNS) entry. T lymphocytes, especially JCV-specific cytotoxic CD8+ T lymphocytes, play an important role in controlling CNS infection with JCV. These cytotoxic T lymphocytes (CTLs) correlate with survival and in the appearance of the immune reconstitution inflammatory syndrome (IRIS). Seroepidemiologic studies demonstrate that the virus is ubiquitous. By the age of 20 years, approximately 50% to 70% of the population or more has been exposed to JCV. The mechanism of spread of JCV remains uncertain. The detection of JCV in tonsillar tissue suggests the possibility of a respiratory or oropharyngeal route, but studies of the expression of reactivated JCV in saliva and oropharyngeal secretions by polymerase chain reaction (PCR) have not demonstrated its presence in immunologically normal individuals. No acute illness has been consistently identified with primary JCV infection. Following infection, latent virus can be demonstrated in many extraneural sites, including kidneys, lymph nodes, tonsils, intestines, and lungs. Urinary excretion of JCV is detected in as many as one-third of all adults. Differences in the virus isolated from the kidney and that from the brain of patients with PML have led to the designation of the former as "archetypal" virus. It has been proposed that the archetype virus is genetically modified in cells of B-cell lineage to a neurotropic form of the virus that subsequently migrates into the brain as cell-associated virus. A number of lines of evidence support the contention that PML is the result of a reactivated latent or persistent non-CNS infection including the demonstration of immunoglobulin G (IgG) directed to JCV in all patients, the demonstration of a neurotropic JCV from blood and tissue months to years before the development of PML in a small group of patients, the presence of JCV-specific antibody within 6 months of the development of PML in a large number of natalizumab-associated PML cases, and the rarity of the illness in children. It is possible that, in rare instances, the disease develops after primary infection. Many controversies surround the pathogenesis of PML. The current proposed hypothesis regarding the development of PML is that it is a stochastic event in which several hurdles must be overcome, including (1) initial infection, (2) establishment of viral latency, (3) mutation of the archetype strain to one that is neurotropic, perhaps within B cells, (4) re-expression of the virus, (5) entry into the brain with establishment of productive infection of oligodendrocytes, and (6) failure of normal immune mechanisms to suppress and/or clear the virus from the brain.

The numbers of AIDS patients developing PML greatly exceed those of patients developing other illnesses having similar degrees of impaired cell-mediated immunity, suggesting that factors related to HIV infection may be amplifying the frequency of the disease. This unique association may be related to the degree and duration of the immunosuppression, alteration of the blood–brain barrier by HIV infection, the upregulation of endothelial adhesion molecules for JCV-infected B lymphocytes due to cytokines elaborated by HIV-infected macrophages and microglial cells in the brain, the B-cell activation associated with HIV, and transactivation of JCV by the HIV tat protein and HIV-induced chemokines.

There appears to be a vastly increased risk of developing PML in patients who receive natalizumab for the treatment of MS or inflammatory bowel disease as well as efalizumab, a lymphocyte function-associated (LFA) antagonist once used in the treatment of psoriasis. It has been proposed that these monoclonal antibodies predispose to PML by preventing the surveillance of the CNS by JCV-specific CTLs and by the release of premature B cells, which hypothetically may increase the likelihood of genetic modification of the archetype JCV to the neurotropic form as well as amplifying JCV replication within these cells. The risk of PML with these pharmacologic agents greatly exceeds that of others reported to date which have been associated with PML.

Pathology

As its name implies, the disease is characterized by multiple sites of demyelination with a distinctive microscopic triad of multifocal myelin and oligodendroglial cell loss with minimal inflammatory infiltrate, hyperchromatic enlarged oligodendroglial nuclei (Figure 81.1), and enlarged and bizarre-appearing astrocytes with irregularly lobulated nuclei. The enlarged oligodendroglia are found

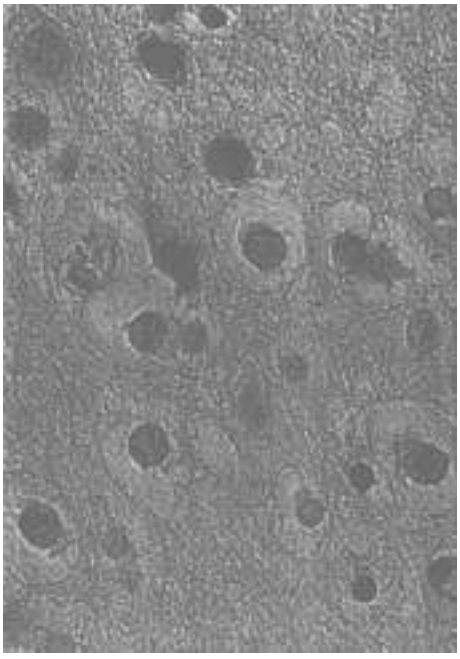

FIGURE 81.1 An abnormal infected oligodendrocyte with enlarged nuclei.

mostly at the periphery of the lesion, whereas the atypical astrocytes are generally more centrally located. Ultrastructurally, the viral particles may be detected by electron microscopy. Alternatively, the virus can be detected by immunohistochemical staining or by PCR. The virus appears in three forms: a filamentous form in nuclei of infected cells and in spherical or paracrystalline forms in either the nucleus or cytoplasm. Virions are visualized mostly in oligodendrocytes and rarely in astrocytes. Infection of oligodendrocyte is productive, whereas the astrocyte is nonpermissive for viral replication. JCV has also been associated with other forms of CNS disease including granular cell degeneration of the cerebellum and encephalitis, and, on occasion, these pathologies may be observed in association with PML.

Epidemiology

The epidemiology of PML may be divided into several epochs characterized by the growth of certain at-risk populations. These include the pre-AIDS era (1958–1981), the AIDS era (1981–1995), the HAART era (1995–2006), and the monoclonal antibody era (2006 to present). Prior to 1982, 200 cases of PML had been recorded by the National Center for Health Statistics and an extensive review of the literature published in 1984 was able to find 230 cases. The overwhelming majority of these cases were the consequence of lymphoid (predominantly B cell) malignancies.

The first reported case of PML as a complication of AIDS came in 1982. Subsequently, the prevalence in the HIV population rose sharply to 5%, accounting for nearly 20% of fatal CNS disease in AIDS patients. Until the mid-1990s, patients with HIV accounted for nearly 90% of PML cases. However, the introduction and refinement of HAART led to a gradual decline in the incidence of PML in HIV patients, as 14.8 cases per 1,000 patient-years in 1996 was lowered to 2.6 in 2005.

The decreased incidence in the HIV population during the HAART era led to increased recognition of PML in patients with rheumatologic conditions. In a review of 35 published cases, there were 22 cases reported between 1995 and 2006. Many of the patients suffered from systemic lupus erythematosus, but other conditions included RA, polymyositis and dermatomyositis, granulomatosis with polyangiitis (GPA), and scleroderma. While underlying autoimmunity may contribute to risk for development of PML, each case was linked to a form of immunosuppressive therapy such as azathioprine, methotrexate, mycophenolate mofetil, chlorambucil, cyclophosphamide, or chronic steroids.

The emergence of monoclonal antibodies has ushered in a new risk of PML in specific patient populations. In 2006, rituximab, an anti-CD20 monoclonal antibody, was approved for the treatment of RA and has subsequently expanded to treatment of GPA and microscopic polyangiitis. As of 2015, PML in the setting of rituximab has been noted in nine patients with RA and two patients with GPA. However, the risk with rituximab pales in comparison to natalizumab, an $\alpha 4\,\beta 1$ integrin inhibitor, which blocks cell adhesion at the blood–brain barrier for treatment of patients with MS and has been linked to >800 cases of PML since 2006.

As newer immunomodulating therapies for MS such as fingolimod and dimethyl fumarate have been linked to PML, patients with MS represent a growing population at-risk for PML. While HIV still represents the greatest risk as a predisposing factor in approximately 80% of PML cases and 10% are attributable to hematologic malignancies, patients with MS and other autoimmune conditions constitute a greater part of the remaining 10%. As reflected over time, the incidence and at-risk populations will continue to evolve with therapeutic advances.

Clinical manifestations

The clinical manifestations of PML are varied and depend on the area of the brain involved as well as the predisposing condition (Table 81.1). In natalizumab-associated PML, the most common abnormalities were behavioral and cognitive abnormalities followed by weakness, whereas, in the HIV-associated PML cases, the most common manifestations have been weakness (generally, hemiparesis), gait disturbance, speech and language disorders, cognitive dysfunction, and visual loss. Ataxia, dysarthria, numbness, headaches, aphasia, seizures, and vertigo are occasionally noted. Rarely, focal cognitive deficits, such as prosopagnosia, apraxia, left-sided neglect, and Gerstmann's syndrome, are observed; however, global deficits such as memory disturbances and personality changes are more common. There may be some differences in clinical presentation of PML based on the predisposing cause. On rare occasion, MRI abnormalities due to PML may be detected in advance of any clinical features; however, symptoms typically intervene within weeks of this observation.

TABLE 81.1 **PRESENTING SYMPTOMS FOR PROGRESSIVE MULTIFOCAL LEUKOENCEPHALOPATHY (PML) IN THE SETTING OF HIV OR NATALIZUMAB**

Symptoms	HIV-associated PML	Natalizumab-associated PML
Weakness	42%	25%
Speech/language impairment	40%	25%
Cognitive abnormalities	36%	50%
Gait abnormalities	29%	14%
Sensory loss	19%	4%
Visual impairment	19%	29%
Seizures	9%	21%
Diplopia	9%	4%
Limb incoordination	6%	14%

Adapted from Clifford et al., 2010; and Berger, 1998.

Radiology

The diagnosis of PML is strongly suggested by the typical appearance on imaging studies. On CT, multiple white matter hypodensities are revealed (Figure 81.2), but MRI is more sensitive. The lesions of PML appear hyperintense on T2 (Figure 81.3) and hypointense on T1. No mass effect is observed in the absence of PML-IRIS, and, with PML-IRIS, brain edema remains rare. The scalloped appearance of these areas is due to subcortical "U" fiber involvement. Although any area can be affected, there is a predilection for the frontal and parieto-occipital regions, perhaps due to the large volume of white matter in these areas. About one-third of patients have posterior fossa involvement, and 5% have only cerebellar and brainstem lesions. Most patients have bilateral abnormal areas, and the basal ganglia may be affected, chiefly due to involvement of myelinated fibers that course through this region. Enhancement had not been considered typical, but in a pre-HAART AIDS PML population, 10% of patients had contrast enhancement on CT scan and 15% had gadolinium enhancement on MRI. In natalizumab-associated PML, 40% to 50% have gadolinium enhancement on MRI. On gradient-recalled echo (GRE) and susceptibility-weighted imaging (SWI) MRI, a thin dark rim may surround PML lesions, which is thought to be the consequence of iron-laden macrophages. Occasionally, the first MRI abnormalities will be multiple punctuate lesions that slowly grow and coalesce. Wallerian degeneration may be observed if survival is long enough.

When PML occurs in association with HIV infection, it must be differentiated from HIV leukoencephalopathy, although this can be difficult on a radiologic basis. The MRI of HIV encephalopathy often shows atrophy, and the white matter lesions do not enhance and are typically isointense on T1-weighted imaging. Clinical distinguishing HIV PML characteristics are its rapid course, subcortical involvement, and focal features. In contrast, HIV encephalopathy or dementia has a more protracted course, is of a cortical nature, and rarely has focal features.

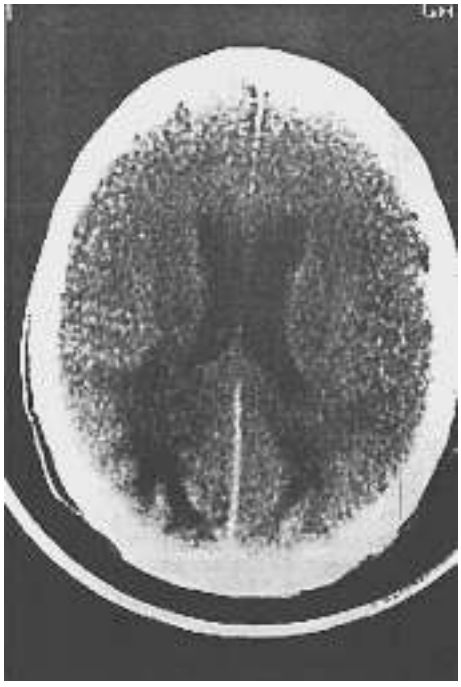

FIGURE 81.2 CT scan shows hypodense abnormalities in bilateral occipital lobes.

FIGURE 81.3 This T2-weighted MRI shows extensive hyperintense signal abnormalities in the right hemisphere white matter and smaller subcortical lesions on the left.

In patients developing PML while under treatment for MS with natalizumab, distinguishing the white matter lesions of MS from those of PML can be difficult. Lesions of MS are often periventricular or have Dawson's finger appearance, and the enhancement typically appears as an incomplete ring or is homogeneous throughout. In contrast, a subcortical location, faint or irregular contrast enhancement, a sharp border toward the gray matter and an ill-defined border toward the white matter on T2-weighted images, as well as T1-hypointensity and diffusion-hyperintense lesions, are suggestive of PML.

Cerebrospinal fluid

Routine studies on cerebrospinal fluid (CSF) are not particularly helpful for diagnosing PML. A mild increase in protein as well as an increase in myelin basic protein may be detected in the CSF. In HIV-infected individuals, the presence of oligoclonal bands and increased IgG synthesis (elevated CSF index) is not infrequently observed but occurs as a consequence of HIV rather than JCV. PCR for JCV is an indispensable test for diagnosing PML in persons with the appropriate clinical and radiographic features. Ultrasensitive quantitative CSF PCR has a specificity that approaches 100% and a sensitivity of 95%. In qualified laboratories, the level of viral detection is on the order of 10 copies/mL.

Diagnosing PML

The 2013 consensus statement for diagnosing PML established two primary approaches. The appropriate clinical presentation and radiologic features combined with the demonstration of JCV in the CSF is sufficient for establishing the diagnosis of PML. The second option, when the clinical picture is more obscure or if the CSF PCR is negative, is confirmation by brain biopsy with immunohistochemistry and classical pathologic features. Tissue diagnosis with brain biopsy is not without error. Brain biopsy for focal lesions in AIDS patients was associated with 93% to 96% sensitivity along with a 12% postoperative morbidity and 2% postoperative mortality. The 2013 American Academy of Neurology guidelines for PML diagnosis segregate PML into definite, probable, and possible categories based on the evidence for diagnosis. A diagnosis can be made comfortably in patients presenting with clinical features and MRI pattern consistent with PML coupled with the detection of JCV DNA by PCR in the CSF. In some patients a definitive diagnosis rests on demonstrating the characteristic histopathologic triad at brain biopsy and detecting the virus.

Prognosis

In the absence of a reversible immunosuppressive disorder, the prognosis of PML is typically grim, with death occurring in most patients between 1 and 18 months (mean 4 months) after disease onset. However, there is a significant difference in prognosis depending on the predisposing factors for disease. For instance, PML associated with AIDS pre-HAART was fatal in about 90% to 95% of cases. After the institution of optimized HAART therapy, 1-year survival increased to close to 50%. Natalizumab-associated PML has a much higher survival rate, approximately 80%, although the vast majority of these patients are debilitated by significant neurologic deficits. Certain features seem to be associated with a greater likelihood of long survival (in excess of 12 months), including PML as the heralding illness of AIDS, lesser degree of immunosuppression (CD4 counts >300 cells/mm^3), enhancement on radiographic imaging, and any evidence of clinical recovery. Low CSF JC viral loads have also correlated with longer survival. The cellular immune response against JCV appears to tightly correlate with a favorable clinical outcome in PML. The presence of JCV-specific CTLs in these patients is likely related to the presence of inflammatory infiltrates in the PML lesions and contrast enhancement seen on imaging studies.

Treatment

To date there are no unequivocally successful therapeutic modalities for preventing or treating PML. The best means to decrease the risk of developing PML for those who are HIV-positive is the institution of HAART therapy. For those who are HIV-negative, there is no form of prophylaxis as their risk for developing PML often stems from a treatment needed for another condition. Once PML is diagnosed, an initial approach to treatment is contingent on the predisposing condition, as reversal will lead to recovered immune function with the aim to contain JCV. In the setting of HIV, HAART should be initiated with a goal of normalizing CD4 counts. The advent of HAART therapy has led to nearly 50% of HIV patients demonstrating long-term survival (>12 months) with PML. Removing an immunosuppressive or immunomodulating medication can have similar benefit. It is recommended that patients who develop PML on natalizumab should undergo plasmapheresis, as nearly 80% will survive.

Following the reversal of the predisposing condition, there is a significant risk that reconstitution of the immune system will lead to an aggressive response to JCV and result in PML-IRIS. In this setting, there may be new or worsening neurologic deficits, new or enlarged lesions, contrast enhancement of lesions, and mass effect that can be fatal, especially in the posterior fossa. If PML-IRIS is evident, administration of corticosteroids is recommended to prevent excessive damage to the infected tissue. However, even if the inflammatory response is contained, the reconstitution of the immune system is not effective long-term strategy for many, such as those with autoimmune disease or organ transplant recipients.

With this understanding, a targeted anti-JCV treatment has been sought. Treatment strategies have focused on antivirals, immune response modulators, and immunization. However, with no reliable animal model of PML and the challenge of timely recruitment for human studies, there have been only five clinical trials of PML treatment to date. In an attempt to inhibit viral replication, cytosine arabinoside, topotecan, cidofovir, enfuvirtide, and mefloquine have been tested. The largest of these trials was the ARA-C trial in AIDS-related PML which compared ARA-C administered intravenously or intrathecally with antiretroviral therapy to antiretroviral therapy alone. It had only 57 patients; all the other trials had smaller numbers of study subjects. None demonstrated any benefit.

The remainder of the literature consists of case reports. There are anecdotal benefits of therapies aimed at preventing JCV cell entry (mirtazapine, risperidone, ziprasidone) and inhibiting JCV DNA replication (leflunomide, ganciclovir). Improvements have occasionally been noted when stimulating the host immune response (interferon-α, interleukin-2, and interleukin-7) and decreasing inflammation (maraviroc, glucocorticoids). With a goal of boosting a JCV-specific T-cell response, immunization with a JCV capsid protein and recombinant IL-7 was beneficial in two cases. However, none of these therapies has been consistently successful.

Identification of an effective treatment strategy for PML remains an active research area. Due to homology of the JC virus and the BK virus, T cells specifically targeting the BK virus have been recently explored in the treatment of PML. Three patients with PML, one with HIV and two with immunosuppression secondary to treatment for myeloproliferative neoplasms, were treated with partially human leukocyte antigen (HLA)-matched, BK virus–specific T cells from healthy donors. In two cases (HIV and non-HIV patients), T-cell infusion was followed by clinical and radiographic improvement in PML as well as clearance of JCV from the CSF. In the third case, there was clinical and radiographic stabilization and reduced JCV in the CSF. As this therapy was well-tolerated, larger studies are needed to adequately measure efficacy.

The development of programmed cell death-1 (PD-1) inhibitors represents another intriguing therapeutic approach. Expression of PD-1, a marker of cellular immune exhaustion, appears to be higher on CD8+ T-lymphocytes in patients with PML compared to healthy controls. With evidence of being able to boost the JCV-specific T-cell immune response, PD-1 inhibition may help to control JCV infection.

Perhaps most alluring in the treatment of PML is the therapeutic potential of antisense oligonucleotides that are designed with a specific complementary base sequence that binds selectively to a targeted region of messenger RNA (mRNA) to prevent the translation of the mRNA into protein. Antisense oligonucleotide directed to JCV T antigen may reduce viral expression by 80%. Antisense oligonucleotides that target other sites of the viral genome, such as transcription sites, may prove to be effective therapeutic strategies. As strong JCV-specific cellular immunity has been associated with a favorable clinical outcome of PML, the enrichment of an autologous population of JCV-specific CTLs using tetrameric MHC class-I/JCV peptide complexes may be demonstrated to be a therapeutic option.

Conclusion

Increasing reports of stabilization or remission of PML and the growing understanding of the pathophysiology of the JC virus provide hope for the future development of curative strategies. The growing number of persons affected with PML permit the organization of carefully designed therapeutic trials to address this issue.

Cerebrospinal fluid shunt infections

Elisabeth E. Adderson and Patricia M. Flynn

Cerebrospinal fluid (CSF) shunts are critical for many patients surviving congenital central nervous system (CNS) anomalies, infection, or intracranial hemorrhage. Infection is a common complication of these devices and a leading cause of morbidity and hospitalization. Clinical studies performed over the past half-decade have more clearly defined the optimal means to prevent and treat these infections.

Pathogenesis

Most CSF shunts are silastic tubes inserted into the cerebral ventricles or subarachnoid space and connected to a pressure-regulating valve on the external skull. The proximal shunt is connected to tubing tunneled under the skin to the peritoneal cavity (ventriculoperitoneal shunt), the right atrium (ventriculoatrial shunt), or pleural cavity (ventriculopleural shunt). Lumboperitoneal shunts drain from the lumbar spinal canal subarachnoid space to the peritoneal cavity.

The reported incidence of CSF shunt infections ranges from 1% to 30%, with an average of approximately 10% in recent studies. Risk factors for infection include previous shunt infection, recent shunt placement or revision, younger age (particularly premature neonates), a less-experienced surgeon, endoscopic surgery, and the presence of a postoperative CSF leak. Prior cardiac surgery and any surgical procedure within 30 days of shunt insertion are risk factors for shunt infection in infants ≤1 year of age. Shunt valve design does not appear to influence infection rates.

The majority (40–75%) of CSF shunt infections are caused by coagulase-negative *Staphylococcus* spp. *Staphylococcus aureus* and gram-negative bacilli are each responsible for between 6% and 35% of infections. *Escherichia coli*, *Klebsiella* spp., and *Pseudomonas aeruginosa* are the most commonly reported gram-negative pathogens. Anaerobic bacteria, especially *Cutibacterium acnes* (formerly *Propionibacterium acnes*), and fungi are occasionally reported.

Most (50–70%) CSF shunt infections occur within 60 days of shunt insertion, and 90% occur in the first 6 months after placement. This timing, and the prominent role of bacteria that normally colonize the skin in causation, suggests that most infections result from the intraoperative contamination of shunt devices. One small prospective study found that contamination of surgeons' gloves by normal skin flora such as coagulase-negative *Staphylococcus* and *C. acnes* was universal and occurred within a short time after surgery was commenced. Less commonly, shunt infections may result from direct extension of surgical wound infections. Infections with delayed onset (after 2–3 months) and those caused by gram-negative bacilli may originate from an intra-abdominal focus (appendicitis, bowel perforation or surgery, trauma) by retrograde spread or bacteremia. Organisms such as coagulase-negative *Staphylococcus* and *S. aureus* adhere to medical devices or to the host proteins that are rapidly deposited on these foreign bodies. Adherent bacteria are enveloped in biofilm, a complex mixture of carbohydrate and proteins that both augments adherence and protects the organism from host immune defenses. Bacteria in biofilm are less susceptible to antimicrobial killing than planktonic organisms. In some cases, biofilm acts as a mechanical barrier to reduce

the penetrance of drugs. Sessile organisms also have reduced growth rates and metabolic changes that may affect the expression and function of drug targets.

Clinical presentation

The clinical presentation of shunt infections may range from almost asymptomatic colonization of the shunt device to fulminant ventriculitis depending on the infecting organism and the patient's underlying medical condition. Illness is frequently nonspecific. It is imperative to exclude CSF shunt infections in patients with unexplained febrile illness or symptoms of shunt malfunction since these infections cannot reliably be distinguished from systemic illnesses or noninfectious causes of shunt malfunction. The most common symptoms include fever, vomiting, lethargy, new or worsening altered consciousness, and irritability. Fever may be absent initially in up to 40% of patients. Some patients have more obvious presentations, with evidence of wound infection, inflammation along the subcutaneous shunt tract, or signs of meningeal irritation or elevated intracranial pressure. Approximately 10% have symptoms and signs of distal infection, including abdominal pain, guarding, gastrointestinal obstruction, or a palpable peritoneal pseudocyst. Patients with infected ventriculoatrial shunts are generally bacteremic and have more prominent fever and other constitutional symptoms. Ventriculoatrial shunt infections are occasionally complicated by an immune complex–mediated glomerulonephritis characterized by hypocomplementemia, hematuria, proteinuria, and renal dysfunction. Symptoms and signs of pleural inflammation are strongly suggestive of shunt infection in patients with ventriculopleural shunts.

Diagnosis

CSF shunt infections are diagnosed by examination and culture of CSF obtained from the shunt reservoir or cerebral ventricles (Table 82.1). Examination of CSF from the lumbar spine is indicated in patients with lumboperitoneal shunts or if ventricular CSF is unremarkable but patients have signs and symptoms consistent with a CNS infection. CSF abnormalities, however, are often subtle, and normal findings do not reliably exclude CSF shunt infections, especially in patients who have received antimicrobial therapy and in immunocompromised patients. CSF abnormalities caused by infection may also be difficult to distinguish from changes related to recent surgery or medical devices. A mild pleocytosis, for example, may accompany mechanical shunt malfunction and hypersensitivity reactions to shunt material. The CSF white blood cell count is usually elevated. A neutrophilic predominance is typical; mild eosinophilia is also relatively common. The CSF protein is generally elevated; low CSF glucose concentrations are less commonly observed. Elevated CSF lactate concentrations may support the diagnosis of CSF shunt infections, and elevated serum C-reactive protein may help distinguish bacterial shunt infections from noninfectious etiologies.

TABLE 82.1 **DIAGNOSTIC TESTS FOR CEREBROSPINAL FLUID (CSF) SHUNT INFECTIONS**

Test	Typical findings
CSF Gram stain	Positive in 70–90%
CSF cultures	Positive in 85%
CSF β-D-glucan and galactomannan detection	May be elevated in fungal infections
CSF cell count	Elevated WBC (usually 100–2,500 cells/mm^3, range 0–18,000 cells/mm^3)
CSF WBC differential	Neutrophil predominance (range 0–93%) Eosinophilia (>5% of WBC) in 15–25%
CSF protein	Elevated (usually 150–400 mg/dL)
CSF glucose	Normal or low (usually 30–60 mg/dL)
CSF lactate	Elevated in 80%
Serum C-reactive protein	Elevated in 80%
Diagnostic imaging	Debris within ventricles, gadolinium enhancement of ventricular ependymal lining, restricted diffusion, periventricular hyperintensities, brain abscess Distal complications of VP shunts: intra-abdominal fluid collections, ascites, fat stranding, bowel wall edema, catheter migration

Abbreviations: CSF, cerebrospinal fluid; VP, ventriculoperitoneal; WBC, white blood cell.

Gram stain examination of CSF permits a rapid diagnosis in 70% to 90% of patients. CSF cultures are positive in about 85% of patients, but less commonly in those who have received antimicrobial therapy prior to CSF sampling and in infections caused by unusual pathogens (e.g., anaerobic bacteria and fungi). Cultures should be obtained prior to administration of antimicrobials if possible. The addition of anaerobic cultures of CSF may increase the yield of *C. acnes*. Bacterial cultures should be held for at least 10 days and fungal cultures for 30 days to detect slowly growing pathogens. Cultures of CSF shunts or drains are recommended if these are removed because of concern for infection. It may be difficult to interpret growth from CSF of bacteria that are commonly considered culture contaminants, such as coagulase negative *Staphylococcus* spp. Growth of such organisms in enrichment broth only, or from only one of multiple cultures obtained from patients who are afebrile and have unremarkable CSF findings, may not reflect a true infection. In contrast, isolation of more virulent organisms, such as *Staphylococcus aureus*, aerobic gram-negative bacilli, and fungi is likely to reflect ventriculitis or meningitis.

Polymerase chain reaction amplification of microbial DNA may be more sensitive than culture, but the specificity of these tests has not been established and they are expensive and may not be readily available. Blood cultures are commonly positive in ventriculoatrial shunt infections but rarely in ventriculoperitoneal and ventriculopleural shunt infections.

Neuroimaging is recommended in patients suspected of having CSF shunt infections to evaluate infection and shunt function. MRI is more sensitive than CT for detecting abnormalities. Abdominal ultrasound or computed tomography are recommended to evaluate suspected complications of distal ventriculoperitoneal shunts.

Therapy

Initial approach to management

In patients with suspected CSF shunt infections, initial management includes obtaining CSF from the shunt reservoir or ventricle for diagnostic studies. Patients with presentations suggestive of ventriculitis or meningitis should begin antimicrobial therapy while awaiting these results. Patients who have mild illness, no evidence of shunt malfunction, a mild pleocytosis, and negative CSF stains may be observed without empirical therapy. Contamination of diagnostic CSF samples is possible. It is prudent, therefore, to obtain a second CSF sample before instituting therapy in cases where antimicrobials have not been administered and the patient's course is not consistent with infection.

Surgical therapy

Management that includes complete removal of the infected shunt, placement of an extraventricular drain (EVD) if required, intravenous (IV) antimicrobials, and shunt replacement once the CSF is sterile has a success rate of >85% and is recommended for most patients with infected CSF shunts. Shunt removal and local debridement is also indicated for wound or shunt tract infections, and other infected hardware, including drains and infusion pumps, should also be removed. A one-stage procedure combining IV and intraventricular antibiotic therapy with immediate replacement of the infected shunt is effective in about 65%. Treatment with antibiotics alone without shunt removal is effective in only a third of patients, likely because of the combination of persistent viable bacteria in biofilms and the limited achievable CSF concentrations of many antimicrobial agents. This treatment may be appropriate, however, for patients with a short life expectancy, an Ommaya reservoir, and those with infections caused by coagulase-negative *Staphylococcus* spp. that respond promptly to aggressive medical therapy. These patients should receive IV and intraventricular antimicrobial agents (administered via an EVD or the shunt) for a minimum of 14 days after CSF sterilization, with meticulous attention to ensuring CSF antimicrobial concentrations are adequate. Patients with isolated infection of an abdominal pseudocyst who do not have positive CSF cultures may be treated by shunt externalization, drainage of the fluid collection, and systemic antimicrobials appropriate for intra-abdominal infections.

Antimicrobial therapy

Empirical antibiotic therapy should be based on the likely pathogen, clinical findings, the severity of illness, and known colonization or infection with antimicrobial-resistant pathogens. Vancomycin plus an anti-pseudomonal β-lactam agent (based on local susceptibility data) is recommended for initial treatment of adults, children with moderate to severe clinical illness, patients with findings suggestive of intra-abdominal infection, and those with gram-negative bacilli seen on CSF stain (Table 82.2). Children with uncomplicated infections may be treated with vancomycin alone, in doses appropriate for intracranial infections. Definitive antimicrobial therapy should be based on culture results and in vitro susceptibility testing and taking the ability of the antimicrobial agent to cross the blood–brain barrier into consideration.

Achieving good CSF penetration is a significant problem with some antimicrobial agents, most notably vancomycin. Serum vancomycin levels should be monitored, aiming for trough concentrations of 15 to 20 μg/mL in those receiving intermittent administration. Patients should be monitored clinically and have CSF cultures monitored every 1 to 3 days to ensure they become sterile. Intraventricular antimicrobial therapy should be considered for patients with suboptimal microbiological or clinical responses to systemic antibiotics, especially those for whom shunt removal is not feasible, although no prospective randomized trials have compared combined parenteral and intraventricular administration with parenteral therapy alone. Other indications include infections cause by microorganisms that are susceptible only to antibiotics with poor CSF penetration and in infections when shunt devices cannot be practicably removed, including infections of Ommaya reservoirs. No antimicrobial agents are currently licensed for intraventricular use, but intraventricular vancomycin and aminoglycosides have few reported adverse affects when used at appropriate concentrations (Table 82.3). Preservative-free formulations of these drugs should be reconstituted in sterile normal saline for administration, and, when an EVD is used for administration, it should be clamped for 15 to 60 minutes to permit diffusion throughout the ventricular system. An alternative "flush" procedure has been described in which a more dilute antimicrobial solution is infused slowly through one EVD and allowed to drain through a second EVD placed in the contralateral ventricle. Antimicrobial CSF concentrations achieved by intraventricular administration are highly variable and should be monitored periodically to both ensure adequate levels and avoid toxicity. A reasonable approach is to obtain CSF for determination of the antimicrobial inhibitory quotient 24 hours after administration of the first dose. Subsequent doses and dosing schedules should be adjusted to maintain a CSF antimicrobial trough concentration that exceeds the pathogen's minimum inhibitory concentration by 10- to 20-fold. Combination therapy with rifampin, which has excellent CSF and biofilm penetration, may be helpful in treating infections caused by susceptible gram-positive bacteria. The possibility that the EVD has become colonized, which occurs in 5% to 10% of cases, should also be considered if CSF cultures are persistently positive. Routine changes of EVDs, however, have not been proved to reduce the risk of colonization or secondary infection.

Continuing management

The optimal duration of therapy for CSF shunt infections has not been systematically studied. Most infections can be treated

TABLE 82.2 **RECOMMENDED DOSES OF INTRAVENOUS ANTIMICROBIAL AGENTS**

Agent	Age[a]	Total daily dose	No. daily doses
Amphotericin B	Neonate <7 days	1 mg/kg	1
	Neonate 8–28 days	1 mg/kg	1
	Children	1 mg/kg	1
	Adults	0.7–1 mg/kg	1
Amphotericin B liposome	Neonate <7 days	–	
	Neonate 8–28 days	–	
	Children	3–5 mg/kg	1
	Adults	5 mg/kg	1
Ampicillin	Neonate <7 days	150–300 mg/kg	3
	Neonate 8–28 days	200–300 mg/kg	4
	Children	300 mg/kg	4
	Adults	12 g	6

Vancomycin	Neonate <7 days	20–30 mg/kg	2–3
	Neonate 8–28 days	30–45 mg/kg	3–4
	Children	60 mg/kg (maximum 4 g/d)	4
	Adults	30–60 mg/kg (maximum 2 g/dose)	2–3

[a] Lower doses and increased intervals are advisable for infants weighing <2,000 g.

for 10 to 14 days after CSF is sterile. Some experts recommend that infections caused by gram-negative pathogens should be treated for 21 days after CSF sterilization. Published studies have described a variety of criteria for the timing of shunt replacement, but most practitioners consider this after the CSF is sterile for 7 to 10 days and CSF protein concentrations fall below 200 mg/dL. Some experts suggest that shunt replacement may be considered as early as 3 days after the CSF is sterile for patients with good clinical responses, infections caused by coagulase-negative *Staphylococcus* spp. or *C. acnes,* and who have no CSF abnormalities.

Outcomes

CSF shunt infections are an uncommon direct cause of death. These infections, however, may be a risk factor for mortality related to underlying medical conditions. Some studies in children have noted an increased incidence of intellectual impairment and learning disabilities in patients with CSF shunt infections compared to those with shunts and no history of infection.

Prevention

Strict attention to disinfection of skin and surgical technique at the time of shunt or EVD placement may prevent many shunt infections. In one study, initial double-gloving with interoperative removal of the outer pair of gloves before handling the shunt catheter reduced infection rates relative to continuous double-gloving and studies evaluating the implementation of a standardized perioperative care bundle have consistently demonstrated reduced shunt infection rates. EVDs should be removed at the earliest feasible time.

TABLE 82.3 **RECOMMENDED INITIAL DOSES AND CEREBROSPINAL FLUID (CSF) CONCENTRATIONS OF INTRAVENTRICULARLY ADMINISTERED ANTIMICROBIALS**

Agent/age	Initial dose	Peak concentration[a] (MG/L)	Trough concentration[b] (MG/L)
Amikacin			
Infants and children	2–50 mg/kg/d	25–30	<5
Adults	5–50 mg/d, usual dose 30 mg/d		
Amphotericin B			
Infants and children	0.01–0.6 mg q1–3 days	NE[c]	NE[c]
Adults	0.01–0.5 mg q2–3d		
Colistimethate			
Infants and children	3.75 mg base activity/d	NE[c]	NE[c]
Adults	3.75–4.2 mg base activity/d		
Gentamicin			
Infants and children	1–4 mg/d	5–20	<2
Adults	4–8 mg/d		
Polymyxin B			
Infants and children	20,000 units/d or 25,000 units q2d	NE[c]	NE[c]
Adults	50,000 units/d		
Tobramycin			
Infants and children	1–20 mg/d	5–20	<2
Adults	4–20 mg/d		
Vancomycin			
Infants and children	2–20 mg/d	50–80	<10
Adults	5–20 mg/d		

[a] Peak concentrations measured 15 to 30 minutes after administration.
[b] Initial trough concentration measured 24 hours after administration of the first dose.
[c] Not established.

Periprocedural prophylactic antimicrobials are recommended for patients undergoing placement of CSF shunts or EVDs. Most studies have used cefazolin, with the first dose of 1 g IV for adults and 20 mg/kg for children within 60 minutes before surgical incision, followed by two additional doses at 8-hour intervals. Vancomycin (adults, 15 mg/kg within 120 minutes before surgical incision and 12 hours later; children, 10–15 mg/kg IV within 120 minutes before surgical incision and q6h for a total of four doses) is an alternative for patients with allergies to β-lactams and in institutions with a high incidence of infections caused by methicillin-resistant *S. aureus*.

The use of shunts and drains impregnated with antimicrobial agents (clindamycin, minocycline, and/or rifampin) significantly reduces infection rates. Antibacterial activity gradually decays over a period of months, in some cases persisting for >90 days after shunt insertion.

Meningitis in patients with CSF shunt infections

Rarely, patients with CSF shunts may develop hematogenous bacterial meningitis caused by common pathogens such as *Streptococcus pneumoniae*, *Neisseria meningitidis*, and *Haemophilus influenzae* type b. These infections can generally be treated by systemic antimicrobial agents alone, without removal of the shunt.

The susceptible host

83

Evaluation of suspected immunodeficiency

Thomas A. Fleisher and Sergio D. Rosenzweig

The need to evaluate immunologic function has become a part of the standard practice of clinical medicine, resulting at least in part from the secondary immunodeficiency produced by HIV infection. In addition, since the early 1990s, the molecular basis of primary immunodeficiency disorders (PIDD) has evolved, with now >350 genetic defects identified impacting host defense with an expanded range of clinical phenotypes associated with the genetic defects. This chapter presents the general methods available to assess immune function, linking these to the clinical infectious history that is suggestive of specific types of PIDDs.

The primary clinical problem that sets the stage for initiating an immunologic evaluation is a history of increased susceptibility to infection. In general, the specific characteristics of the recurrent and/or chronic infections, including organism(s), site(s), frequency, and response to therapy provide critical insights into the most likely type or category of immunodeficiency. Moreover, it has been observed that, in a number genetic defects of immune function, immune dysregulation, autoimmunity, and cancer susceptibility are part of the clinical phenotype in addition to increased susceptibility to infection. These observations clearly expand the spectrum of clinical findings associated with PIDD.

Defects in adaptive immunity involving decreased immunoglobulin levels and abnormal antibody production (humoral immunity) most typically lead to recurrent infections with high-grade encapsulated extracellular bacteria such as *Haemophilus influenzae* (often untypable) and *Streptococcus pneumoniae,* usually affecting the sinopulmonary tract. The protective immune response to these infectious agents depends on the production of antibodies against the capsular carbohydrate antigens present on the surface of the microorganisms. These patients may also have increased susceptibility to selected viruses (i.e., enterovirus). In contrast, the clinical picture of patients with defective T-cell (cellular) immunity typically involves recurrent infections with opportunistic organisms, examples of which include *Pneumocystis jirovecii*, *Candida* spp., cytomegalovirus and others. This demonstrates that functional T cells are required to prevent or clear infection with these opportunistic intracellular microorganisms. A more recent focus of study has been directed at the interface between the adaptive and innate immune systems associated with defects in the interferon (IFN)-γ/interleukin (IL)-12 circuit identified in certain patients with persistent tuberculous or nontuberculous mycobacterial (NTM) infection as well as infections with other intracellular pathogens. The critical role of the lymphoid arm of the innate immune system (natural killer cells) in host defense has been clarified based on defects affecting these cells and resulting in clinical presentations that include increased susceptibility to the herpesvirus family including Epstein–Barr virus (EBV) and herpes simplex virus (HSV) infections, as well as in some cases uncontrolled inflammation. Recently, genetic defects associated with increased susceptibility to cutaneous infections involving both virus and fungi have been defined such that significant, persistent cutaneous infections justify consideration of specific immunologic defects. Abnormalities in the phagocytic arm of innate immunity primarily affecting neutrophils include either decreased cell numbers (infections associated with neutropenia are discussed in Chapter 84, "Infection in the neutropenic patient") or genetically defined neutrophil disorders. These include congenital neutropenias and inherited disorders impacting neutrophil function that result in cutaneous and deep-seated abscesses, pneumonia, periodontitis, and osteomyelitis. This clinical picture of the latter is demonstrated in patients with chronic granulomatous disease (CGD) associated with a set of different genetic disorders that affect the nicotinamide adenine dinucleotide phosphate (NADPH)-oxidase machinery and impair reactive

oxygen species (ROS) generation. Typically, the infections in CGD involve bacteria such as *Staphylococcus aureus*, *Serratia marcescens*, and *Nocardia* spp. as well as fungi such as *Aspergillus* spp. The clinical findings point to the critical role of mobile phagocytic cells in normal host defense. Congenital defects in specific complement components that form another arm of the innate immunity can be associated with recurrent infections. Those impacting the earlier components of the complement cascade also are also linked to the development of autoimmune disease, while those affecting the terminal components of complement result in increased susceptibility to neisserial infections.

Clinical suspicion of a defect in immune function is primarily generated by the medical history, and any patient with a history of increased susceptibility to infection should be evaluated for secondary forms of immunodeficiency due to other comorbidities or HIV infection. The family history has also proved important with the increasing number of immune deficiencies that have been characterized at the molecular level, each with its particular inheritance pattern. The physical examination can provide clues in the case of specific primary immunodeficiencies (e.g., typical facies in the hyperimmunoglobulin E [IgE] [Job] syndrome, scars from abscess drainage sites in CGD, petechiae in Wiskott-Aldrich syndrome, chronic cutaneous viral infections in DOCK8 deficiency, chronic mucocutaneous candidiasis [CMC] in autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy [APECED] syndrome). This may also provide clues to the evaluation of secondary immune disorders (e.g., oral hairy leukoplakia or Kaposi's sarcoma in HIV infection).

BOX 83.1

Evaluation of suspected antibody (B-cell) immunodeficiency

Screening tests

- Quantitative immunoglobulins
- Natural antibody (e.g., isohemagglutinins)
- Circulating specific antibodies
- Post-immunization antibodies
  - Protein antigens
  - Carbohydrate antigens
- IgG subclasses (+/−utility)
- Human immunodeficiency virus testing

Secondary tests

- B-cell immunophenotyping (e.g., CD19+, CD20+, IgM-switched/IgM+ nonswitched, CD27-naïve/CD27+ memory B cells)
- In vitro B-cell function tests (primarily research)

Evaluating B-cell function

Clinical findings that suggest an abnormality in antibody production are recurrent or chronic infections with encapsulated bacteria involving the sinopulmonary tract. Gastrointestinal, hematologic, liver, and autoimmune disorders as well as arthritis (infectious and noninfectious) may also be associated with antibody deficiencies.

The clinical screening of antibody-mediated immune function (Box 83.1) can be accomplished by measuring the levels of the major immunoglobulin classes, IgG, IgA, IgM, and IgE. The results must be compared with age-matched reference intervals (normal ranges) as these levels change significantly during childhood, with the results typically expressed as 95% confidence intervals. The serum immunoglobulin levels are the net of protein production, utilization, catabolism, and loss.

There are no rigid standards regarding the diagnosis of immunoglobulin deficiency, although an IgG value below 4 g/L (400mg/dL) in an adolescent or adult generally suggests an increased risk for infection. Agammaglobulinemia associated with significant recurrent bacterial infection is a definitive indication for intravenous or subcutaneous immunoglobulin replacement therapy after completing the immunologic evaluation to establish a diagnosis.

Measurement of a functional antibody response is often required before immunoglobulin replacement therapy reimbursement is approved and is particularly useful when the total immunoglobulin levels are only modestly depressed (or possibly normal) in the face of a strong history of recurrent infection. The simplest means to accomplish this is evaluation for natural antibodies (e.g., anti–blood group antibodies [isohemagglutinins] and specific antibodies to well-documented prior immunizations). The definitive method is immunizing and assessing preimmunization versus 3- to 4-week post-immunization antibody levels using both protein antigens (e.g., tetanus toxoid) and polysaccharide antigens (e.g., Pneumovax). Guidelines for normal responses, which are usually provided by the testing laboratory, typically consist of at least a fourfold increase in antibody and/or protective antibody levels following immunization. Protective titers to particular antigens or infectious diseases must be individually established and cannot be predicted based on the total levels of immunoglobulins.

An additional and readily available test is quantitation of IgG subclass levels; these are most useful in evaluating the IgA-deficient patient with a history of significant recurrent bacterial infections. However, in many clinical settings the detection of an IgG subclass deficiency still requires the demonstration of an abnormality in specific antibody production before immunoglobulin replacement therapy is indicated. IgG subclass levels acquire a more robust clinical reference range when tested in children >4 years. Moreover, low IgG subclass levels not accompanied by abnormal antibody functional testing are rarely an explanation for underlying recurrent upper respiratory infections.

Despite the preponderance of recurrent opportunistic infections resulting from HIV infection, appropriate testing to rule this out should be considered even in the face of recurrent bacterial infection. This type of clinical presentation may be seen more often in children infected with HIV. Testing focused on viral load may be needed to rule out HIV infection in the face of absent or diminished antibody production because the screening tests depends on an adequate humoral immune response measured by the presence of anti-HIV antibodies (tested by either enzyme-linked immunosorbent assay [ELISA] or Western blot assays).

Additional tests focused on humoral immune function are generally performed in specialized centers and fall into two general categories: evaluation of the number and characteristics of B cells and testing the function of B cells in vitro. The former determines the number of B cells as well as specific surface characteristics of B cells associated with B-cell development and function (e.g., immature B cells, memory B cells, switched B cells, transitional B cells, etc.) and is generally performed by flow cytometry (immunophenotyping). This is evolving as a useful approach to subcategorize certain patients with PIDD involving the humoral arm of adaptive immunity. The latter involves studies that test in vitro B-cell signaling and immunoglobulin biosynthesis but these approaches are generally confined to research centers.

Evaluating T-cell function

A clinical history of recurrent opportunistic infections strongly suggests an abnormality in T-cell function. Immunodeficiency involving T cells has the highest prevalence as a secondary defect associated with HIV infection. Thus, initial screening assays (Box 83.2) should always include testing for HIV infection. In addition, the absolute lymphocyte count (generated from the white blood cell count and differential) and cutaneous delayed-type hypersensitivity (DTH) response to recall antigens have served as standard T-cell function screening tests. The significance of the former relates to the fact that T cells constitute approximately two-third to three-quarters of circulating lymphocytes, with lymphocytes present in higher number than neutrophils in pediatric patients. Therefore, conditions that inhibit T-cell development or increase T-cell destruction will typically result in lymphopenia. The DTH response provides an in vivo window of T-cell function in response to a previously encountered (recall) antigen. However, failure to respond can either reflect T-cell dysfunction (T-cell anergy), lack of prior exposure to the antigen, particular dermatologic problems, or even immaturity of the immune system as seen in very young infants. Consequently, it is prudent to use more than one antigen for testing, and increasing issues with availability of recall antigens have resulted in decreasing availability of DTH testing. Clinical correlates in the medical history linked to a DTH response include the cutaneous response to poison ivy and/or other contact hypersensitivity reactions.

The screening tests for T-cell function are often followed by additional testing to complete the assessment of cellular immunity (Box 83.2). This parallels that of B cells, with quantitation and characterization (immunophenotyping) of T cells and T-cell subsets by flow cytometry (e.g., naïve and memory cells, recent thymic emigrants, etc.) together with in vitro functional testing (e.g., proliferation assays [mitogens, recall antigens, alloantigens], cytokine production, cytotoxicity testing). Both of these approaches are generally available in large medical centers as well as via commercial laboratories.

BOX 83.2

Evaluation of suspected T-cell immunodeficiency

Screening tests

- Human immunodeficiency virus testing
- Lymphocyte count
- Delayed-type hypersensitivity skin tests

Secondary tests

- T-cell enumeration (e.g., CD3+, CD4+, CD8+, naïve/memory T cells)
- T-cell proliferation (mitogen, alloantigen, antigen)
- T-cell cytokine production
- T-cell cytotoxicity

Evaluating defects in the IL-12/23 and interferon-γ pathways

Abnormalities in specific components of a cytokine-linked pathway involving T cells and monocytes/macrophages associated with recurrent infections to a limited range of opportunistic organisms, particularly mycobacteria and *Salmonella* spp., are well-documented. The infections are typically invasive and can fail to respond to long-term multiple-agent antimicrobial therapy. These findings led to a study demonstrating that IFN-γ can be an effective adjunct to antimicrobials in treating certain of these patients. Specific defects involving various components of this pathway have been identified in more than one-half of these patients, with the current research focus being clarification of the molecular basis of the remaining patients. The laboratory evaluation of patients with persistent mycobacterial infection is generally performed in specialized centers and focused on evaluating for defects in the cellular signaling pathways involving IL-12/23 and IFN-γ. More recently, a secondary defect associated with high-titer autoantibodies to IFN-γ has been characterized in association with later onset NTM infection in previously healthy hosts.

Evaluating defects in natural killer cell function

The third arm of the lymphoid system consists of circulating cells distinct from B and T cells, the natural killer (NK) cells. Deficiency in NK cell numbers and/or function has been described in patients with recurrent herpes and human papillomavirus infections, as reported in patients with transcription factor GATA2 haploinsufficiency. The actual GATA2 clinical disorder is far more complex, with infections including organisms other than viruses as well as a significant risk for malignancy together with other findings. This autosomal dominant disorder continues to be characterized as more patients are identified. Additional genetic defects have been characterized associated with increased susceptibility to generalized herpes virus infection (particularly EBV). Another category of NK cell (and cytotoxic T cell) defects is found in disorders with uncontrolled

inflammatory response initiated by specific infections that can lead to multiple organ damage (hemophagocytic lymphohistiocytosis [HLH]). An example of this is the X-linked lymphoproliferative syndrome (XLP) associated with defective NK- and NKT-cell function resulting in increased susceptibility to overwhelming EBV infection, often during childhood, that can initiate HLH. In addition, experimental models point to a role for the NK cell in allograft and tumor rejection. These various disorders point out that discovering the role of NK cells in host defense is an emerging field. Testing of NK-cell function includes immunophenotyping NK cells by flow cytometry using a variety of monoclonal reagents and assessing NK-cell cytotoxicity using standard in vitro assays; these assays are now available via selected commercial labs and medical centers.

Evaluating defects in innate immune signaling

An area of intense current investigation involves the identification of disorders associated with defective signaling by Toll-like receptors (TLR). This is a family of 13 receptors, 10 of which are expressed in humans, and these represent a phylogenetically more primitive arm of the immune system signaling via pattern recognition of unique bacterial, fungal, and viral products. An example of such a process is the activation of monocytes and macrophages by bacterial lipopolysaccharide (LPS) binding to TLR4 (complexed with CD14). This pathway of activating the immune system appears to be one of the first lines in host defense as it does not require prior exposure to the pathogenic microorganism. Two different clinical phenotypes have been identified with genetic defects involving TLR signaling. In one, there is a genetic susceptibility to serious bacterial infections that present in childhood and appear to have decreased lethality starting in adolescence. One of the hallmark features of these patients is the very limited inflammatory response to overwhelming infection (i.e., limited fever and C-reactive protein [CRP] response). The other described defect is associated with the development of herpes simplex encephalitis linked to defects in TLR3 function. Additional alterations in TLR function are likely to be identified, and this represents an evolving field in clinical immunology. Currently, the evaluation of TLR function is confined to a limited number of centers that usually screen by evaluating TLR-induced cytokine production associated with stimulation by a variety of ligands that are specific for one or more of the TLRs.

Evaluating neutrophil function

The clinical features of neutrophil dysfunction usually include recurrent bacterial and fungal infections of the skin, lymph node, lung, liver, bone, and, in some cases, the periodontal tissue. This clinical presentation is most commonly observed with neutropenia as a result of decreased production, altered localization, or increased destruction of neutrophils (see Chapter 84, "Infection in the Neutropenic Patient"). In addition, some primary and secondary abnormalities of neutrophil function also demonstrate patterns of increased susceptibility to infections (Box 83.3).

The clinical pattern of infection often can help to discriminate the underlying problem. Patients with neutropenia and those with the leukocyte adhesion deficiency Type 1 (LAD-1) tend to present with recurrent cellulitis, periodontal disease, otitis media, pneumonia, and rectal or gastrointestinal abscesses. Although LAD-1 is accompanied by a persistent circulating granulocytosis, there is effectively a tissue neutropenia. This is due to the underlying adhesion defect that prevents the directed movement of phagocytic cells, including neutrophils, to sites of infection; other rarer forms of LAD have been subsequently reported (e.g., LAD-2 and LAD-3). In contrast, patients with CGD have significant problems with liver and bone abscesses as well as pneumonias involving certain organisms, including *S. aureus*, *S. marcescens*, *Burkholderia cepacia*, *Nocardia* spp., and *Aspergillus* spp. In addition, CGD patients have exuberant inflammation that may be associated with gastrointestinal and genitourinary complications. More recently CGD patients have been reported infected with the unusual human pathogens *Chromobacterium violaceum* and *Francisella philomiragia*, organisms associated with exposure to brackish water. Finally, these patients tend to have a lower frequency of β-strep and *Escherichia coli* infections than do patients with neutropenia.

Screening studies directed at the evaluation of neutrophil function (Box 83.3) should start with the leukocyte count, differential, and morphologic review. If neutropenia (determining cyclic neutropenia requires a sequential and systematic evaluation over time) and morphologic abnormalities are ruled out, the evaluation then should be directed at assays that provide functional information about neutrophils. Included are the flow cytometric assessment of neutrophil adhesion molecules to assess for the expression of CD11a,b,c and CD18 surface antigens (the β 2-integrins that are absent or depressed in LAD-1 patients) as well as CD15s (absent in LAD-2 patients). The neutrophil oxidative burst pathway can be screened using a flow cytometric assay (dihydrorhodamine [DHR] test) or the simpler but less commonly used nitroblue

BOX 83.3

Evaluation of suspected neutrophil deficiency

Screening tests

- Multiple sequential neutrophil counts
- Review of neutrophil morphology

Secondary tests

- CD11, CD18 assessment
- Respiratory burst assessment
- Nitroblue tetrazolium test
- Flow cytometric test
- Specific enzyme activity testing
- Chemotaxis testing
- In vivo (Rebuck skin window)
- In vitro (Boyden chamber, soft agar assay)

tetrazolium (NBT) test, both of which are abnormal in patients with CGD as well as in X-linked CGD carriers. Finally, evaluation of neutrophil-directed movement (chemotaxis) can be performed in vitro with a Boyden chamber or a soft agar system as well as in vivo using the Rebuck skin window technique. Abnormalities of chemotaxis have been observed secondary to certain pharmacologic agents as well as the leukocyte adhesion deficiency, Chédiak–Higashi syndrome, Pelger–Huet anomaly, and juvenile periodontitis. A hallmark clinical feature of significantly abnormal chemotaxis is diminished neutrophil infiltration and decreased inflammation at sites of infection.

Functional testing of neutrophils has its greatest yield when evaluating patients with recurrent infections associated with a genetic neutrophil abnormality. Many patients with histories of recurrent cutaneous abscesses fail to demonstrate abnormalities in the preceding tests. This likely is related to the relative insensitivity of the available tests in discerning more subtle functional abnormalities.

Evaluating the complement system

The clinical setting in which complement defects should be suspected varies depending on the type of defect. Abnormalities in the early components of the complement pathway may result in recurrent bacterial sinopulmonary infections but typically also have a history of autoimmunity. Defects in the later components of complement affecting the membrane attack complex (MAC, C5–C9) result in increased susceptibility to infections with *Neisseria* organisms, usually presenting with meningitis and/or sepsis. There are rare defects in components of a second complement pathway, the *alternative pathway*, that may also present with recurrent infections.

The best screening test (Box 83.4) for the classical complement pathway is the total hemolytic complement activity (CH50) assay, which is often ordered together with the alternative pathway (AP) 50 test used to screen for defects in the alternative complement pathway. Assuming correct handling of the serum sample (complement components are very labile so any abnormal test result should be repeated to rule out mishandling of the sample), a markedly depressed or absent CH50 result strongly suggests a classical complement component deficiency. If the CH50 and AP50 are both abnormal, it suggests that the common components to both pathways (i.e., late components) are defective. Selected component immunoassays are available in larger laboratories, and component functional testing may be available in very specialized complement laboratories.

BOX 83.4

Evaluation of suspected complement abnormality

Screening tests
- CH50 assay
- AP50 assay

Secondary tests
- Component immunoassays
- Component functional assays

Genetic testing

The availability of nonbiased genetic testing depending on next-generation sequencing (NGS) has revolutionized the capacity to identify patients with inherited defects in immune function. This has resulted in an expanding number of genetic defects linked to PIDD and has also defined a widening spectrum of the clinical phenotypes associated with specific genetic variants. It is now reasonable to introduce genetic testing in the setting of a patient with a laboratory-established defect in immune function. Presently, this involves either targeted NGS using prescribed gene panels linked to PIDD or whole-exome sequencing (WES), with the likelihood that, in the near future, whole-genome sequencing (WGS) will become more readily available. Defining a specific genetic defect can help in better choosing the most appropriate therapy and, with some of the more recently defined immune defects, can lead to a personalized approach to therapy.

Recommendations

The clinical pattern of recurrent infections remains the single most useful clue in determining the likelihood of immune deficiency and identifying the best approach for evaluation. HIV infection remains one of the most likely cause of immune deficiency, and appropriate diagnostic testing for HIV is critical, particularly in the setting of recurrent opportunistic infection. When the history identifies repeated bacterial infections involving the sinopulmonary tract, abnormalities in antibody production, and very rarely complement component deficiency, should be considered. Opportunistic infections suggest T-cell dysfunction, while bacterial and fungal infections of the skin, lungs, and bone strongly suggest defective neutrophil function. The current area of intense investigation is focused on recurrent/chronic infections involving a more limited range of microorganisms or particular organs or organ systems, with much of this focused on the innate immune system or the interface between the innate and adaptive immune systems. It is important to keep in mind that the frequency of infections between affected individuals can vary significantly, and the line distinguishing normal from abnormal is not always clear. However, infections that are recurrent and difficult to treat or those that involve unusual organisms should definitely raise suspicion of an underlying immunodeficiency.

Laboratory studies are essential for evaluating the status of immune function. However, the prudent use of these tests requires that they be applied in an orderly fashion, starting with simpler screening tests selected according to the clinical clues provided from the patient history and examination. The results of these tests are relatively easy to interpret when either clearly normal or absolutely abnormal.

The difficulty arises in determining the actual degree of immune dysfunction when the test results fall in an indeterminant region. To address this, combinations of tests often help to clarify the status of immune function or dysfunction, and involvement of a specialist with extensive knowledge of the clinical presentation and evaluation of PIDD can be crucial.

Infection in the neutropenic patient

Eric Holaday, Aaron Mishkin, and Rafik Samuel

Patients receiving chemotherapy are at high risk for developing neutropenia and severe infections when their neutrophil count is depressed. The American Society of Clinical Oncology (ASCO) and Infectious Diseases Society of America (IDSA) define neutropenia as an absolute neutrophil count (ANC) of ≤1,000 cells/μL. Severe neutropenia is considered <500 cells/μL, and the term "profound neutropenia" is used for an ANC <100 cells/μL. Fever in the neutropenic patient is defined as a single temperature of >38.3°C/101°F or a temperature of >38.0°C/100°F lasting more than an hour. Given the lack of inflammatory cells associated with neutropenia, signs of infection may be subtle. Skin and soft tissue infections may lack the typical induration, erythema, and warmth often seen in patients with an intact immune system. A pulmonary infection may have only a subtle infiltrate on chest radiography, and cerebrospinal fluid pleocytosis may be modest or absent despite ongoing meningitis. Some patients may not mount a fever at all, and the presence of hypotension, tachycardia, or delirium may be the only presenting features of infection.

By its very nature, neutropenic fever occurs in those who are immunologically vulnerable and often carry significant infectious comorbidities, such as central venous access, breakdown of the body's physical barriers to infection, and nutritional deficiencies. Therefore, it is not surprising that febrile neutropenia carries significant morbidity and mortality. Researchers have been investigating modalities to help prevent febrile neutropenia, such as the use of colony-stimulating factors (CSF), dietary changes, and infection control measures. In this chapter, we focus on the main causes of infections in febrile neutropenia and selection of antimicrobial therapies.

Causes of infection in the neutropenic patient

Gram-negative organisms

Gram-negative organisms cause a variety of infectious processes ranging from primary bacteremia to infections of the gastrointestinal, genitourinary, and respiratory tracts. Enteric gram-negative organisms such as *Escherichia coli*, *Klebsiella* spp., and *Enterobacter* spp. play a significant role in the morbidity and mortality due to infection in neutropenic patients. The mechanism of infection is related to chemotherapy-induced mucositis facilitating translocation of these organisms into the bloodstream, which in turn aids their dissemination. Another important organism that can lead to significant disease is *Pseudomonas aeruginosa*, which colonizes patients and may then gain entry through the respiratory tract, disruption of skin and mucosa, and indwelling catheters.

Because infections due to gram-negative organisms, especially *P. aeruginosa*, can be life-threatening, patients with neutropenic fever should be started on an agent with gram-negative and anti-pseudomonal activity. Another concern is increased incidence of plasmid-mediated extended-spectrum β-lactamases in the Enterobacteriaceae family, which inactivate most penicillins and cephalosporins. Carbapenemases can render Enterobacteriaceae and pseudomonas resistant to all β-lactams including carbapenems. Resistance patterns vary significantly among institutions, persons, and over time, and sensitivity testing of bacterial

isolates is important to ensure adequacy of therapy. Appropriate antimicrobial therapy, coupled with source control such as abscess drainage or catheter removal, provides the best chances of treatment success.

One particular infection unique to neutropenic patients is *neutropenic enterocolitis* or "typhlitis," an inflammatory process of the cecum and ascending colon. While the exact etiology of this process is unclear, it is believed to be caused by mucosal injury from cytotoxic agents and impaired host defenses leading to invasion by microorganisms. Patients develop fever and right-sided abdominal pain and are at increased risk for perforation. CT demonstrates right-sided colitis and, in severe cases, can show pneumatosis coli or evidence of bowel perforation. In cases where perforation has not occurred, treatment consists of broad-spectrum antibiotics that cover enteric gram-negative rods, anaerobes, and *Enterococcus* spp. Surgery is technically difficult in these patients and not usually needed as studies have demonstrated that antibiotics are usually able to control the infection until the neutrophils recover.

Gram-positive organisms

Among patients with neutropenia, there has been an increase in severity and numbers of gram-positive infections due to indwelling catheters and damage to mucosal surfaces from cytotoxic chemotherapy. The bloodstream is the most common site of gram-positive infections. The three most common organisms causing bacteremia from indwelling catheters are coagulase-negative staphylococci, *Staphylococcus aureus*, and *Enterococcus* spp. (see Table 84.1). When cellulitis occurs, it is most commonly due to β-hemolytic streptococci and *S. aureus*. Most of these organisms have the potential for antimicrobial resistance, such as methicillin-resistant *S. aureus* (MRSA), and require targeted antimicrobial therapy. Infections due to viridans streptococci resulting in severe sepsis have been noted in patients with severe mucositis, ceftazidime use, or prophylaxis with ciprofloxacin or levofloxacin.

In patients with possible gram-positive infections, vancomycin is an appropriate empiric treatment. It provides adequate coverage for the most common organisms such as staphylococci, streptococci, and most enterococci; however, *Enterococcus faecium* is often resistant to vancomycin. The rates of this resistance are variable among institutions, but may be as high as 90%. *E. faecalis* is less likely to have vancomycin resistance. For patients with vancomycin-resistant organisms or vancomycin allergy, alternative agents include daptomycin or linezolid. Daptomycin is effective in staphylococcal bacteremia and severe skin and soft tissue infection. It is inactivated by pulmonary surfactant and is therefore not recommended for disease affecting the airways. Linezolid is approved for skin and soft tissue infections but should not be used for bloodstream infections.

Duration of treatment for gram-positive organisms varies based on the type of infection. Infections with these organisms do not lead to sepsis syndrome and early mortality as quickly as gram-negative bacteria but may cause significant complications if not treated appropriately. Infections of the skin and soft tissue require at least 7 days of therapy with adequate debridement when indicated. Bacteremia due to *S. aureus* often necessitates 4 weeks of therapy if the source is not located or if the bacteremia does not resolve quickly, whereas enterococcal and coagulase-negative staphylococcal infections can be treated for shorter durations, especially in central line–associated bacteremia with prompt removal of infected catheters.

Anaerobes

Anaerobes are often commensal flora of the gastrointestinal tract but can cause infections in neutropenic patients as a result of mucosal damage. Anaerobic coverage is considered in patients with significant abdominal complaints while awaiting cultures. This includes coverage for *Bacteroides* spp. and *Prevotella* spp. Acceptable antibiotics include ampicillin/sulbactam, piperacillin/tazobactam, carbapenems, or addition of metronidazole to other regimens.

Clostridioides (formerly clostridium) difficile (C. diff) colitis is a concern in those whom develop diarrhea while on antibiotics. Numerous chemotherapies and conditioning regimens cause diarrhea, and chemotherapeutics have antimicrobial activity. When a patient develops significant diarrhea and abdominal pain while receiving antibiotics, consider initiating oral vancomycin while awaiting C. diff testing. An important part of C. diff treatment includes stopping the causative agent; unfortunately, that can be impractical in febrile neutropenia because of the concern for other

TABLE 84.1 **COMMON GRAM-POSITIVE BACTERIA CAUSING INFECTION IN THE NEUTROPENIC PATIENT**

Bacteria	Form of infection	Empiric antibiotic of choice
Staphylococcus aureus	Bacteremia, skin, and skin structure infection	Vancomycin[a]
Coagulase-negative staphylococci	Bacteremia	Vancomycin
Enterococcus spp.	Bacteremia	Daptomycin[b]
β-hemolytic streptococci	Skin and skin structure infection	Penicillin
α-hemolytic streptococci	Bacteremia, endovascular infection	Ceftriaxone[c]
Streptococcus pneumoniae	Respiratory	Ceftriaxone

[a] Variable resistance to β-lactams, and clindamycin.
[b] Incidence of vancomycin resistance is increased in individuals with previous antibiotic exposure.
[c] Penicillin resistance varies; local resistance rates should be reviewed.

infections. Definitive therapy consists of oral vancomycin, however, the presence of ileus may interfere with drug delivery to the site of infection and therefore intravenous (IV) metronidazole or vancomycin enemas are often added as adjuvant therapies. In addition, close monitoring for complications is necessary, as severe or refractory cases may require surgical intervention.

Fungi

Fungal infections are increasingly common among patients with neutropenia, especially those with profound and prolonged neutropenia, such as patients with acute leukemia or lymphoma or those awaiting engraftment post stem cell transplant. Other factors that increase the risk of infection include chronic indwelling catheters, mucosal breakdown, parenteral nutrition, and prolonged antimicrobial therapy.

Candida spp. are the most common cause of fungal infections in these patients and one of the leading causes of catheter-associated bloodstream infections. Therapy for *Candida* bloodstream infection includes initiation of antifungals, preferably an echinocandin, as well as removal of any indwelling catheter to help clear the organism from the bloodstream. In addition, ophthalmologic exam is recommended to rule out endophthalmitis, preferably after white cell counts have recovered. *Candida* may also cause disseminated disease involving organs such as the liver and spleen. In invasive candidiasis, blood cultures are <70% sensitive; therefore, in patients with a high clinical suspicion for candidiasis, imaging of the abdomen with attention to the liver and spleen is necessary. Yeast and mold infections are seldom the initial cause of fever in neutropenic patients but instead present as persistent or recurrent fevers in patients receiving antibiotics. Empiric antifungal therapy and investigation for fungal infection should be considered for patients who remain febrile after 4 to 7 days of appropriate antibacterial therapy or those who received antimicrobial prophylaxis.

With the commonplace usage of yeast-active antifungals, the emergence of molds in a susceptible patient may occur. The most common pathogen in this setting is *Aspergillus*; however, other molds such as the Zygomycetes are increasing in incidence and have a similar presentation. Molds are ubiquitous in the environment and may cause pulmonary or sinus disease in neutropenic patients. Zygomycetes infection should be considered if rhinosinusitis or pulmonary disease occurs while the patient is on voriconazole or an echinocandin.

Pulmonary fungal infections have variable presentations including nodules, infiltrates, infarction, or cavities. A biopsy demonstrating the organism on pathology in addition to a positive culture proves the diagnosis; however, due to procedural risks and patient comorbidities, the diagnosis is often made clinically. Because many filamentous fungi resemble *Aspergillus* on histology, cultures are important to distinguish it from the other molds. Duration of therapy should be prolonged, with radiologic evaluation to demonstrate improvement or cure.

Any patient with neutropenia and fever who complains of sinus congestion, pain, or epistaxis should be evaluated for possible fungal sinusitis. Typical findings include mucosal thickening on radiography and necrosis or eschar on direct visualization. Definitive diagnosis is made by culture and histopathology of biopsy specimens. The treatment course is often protracted but consists of immediate therapy with an appropriate antifungal agent along with rapid surgical debridement.

Pneumocystis jirovecii (*carinii*) is seen in patients with leukemia or lymphoma—especially those who have been on long-term steroids. *Pneumocystis* pneumonia typically presents insidiously with progressive dyspnea, dry cough, and fever, but may also present with a more rapid onset of symptoms resembling a bacterial pneumonia. When this infection is suspected, bronchoscopy with a Gomori-methenamine silver stain (GMS), direct fluorescent antibody staining, or detection of DNA using polymerase chain reaction (PCR) can also aid in diagnosis. The yield of bronchoscopy for the diagnosis of *Pneumocystis* is lower in cancer patients than in HIV-1-infected patients due to lower fungal burden. Therapy including high-dose trimethoprim-sulfamethoxazole (TMP-SMX) and steroids if significant hypoxia is present) should be adequate for a duration of up to 3 weeks.

Because the diagnosis of many fungal infections requires invasive procedures, two serum diagnostic tests can be used to help in the detection of common fungal infections. The β-(1–3)-D glucan test is used to detect a cell wall component of many pathogenic fungi, including *Candida, Aspergillus, Pneumocystis,* and *Fusarium* spp. One significant limitation of the β-(1–3)-D glucan test is that it is not specific for any single fungal species. The galactomannan assay is more specific for *Aspergillus* spp. as it detects the galactomannan in the *Aspergillus* cell wall. False-positive results are seen in both assays with the use of β-lactam antibiotics, while false-negative results are seen in patients who are receiving antifungal therapy. Despite these limitations the β-(1–3)-D glucan and the galactomannan tests can assist in determining the need for empiric treatment.

Other organisms

Respiratory viral infections can cause fever as well as significant morbidity in the neutropenic patient. Expanded availability of quantitative real-time multiplex PCR has assisted in identifying the associated pathogen in patients with respiratory symptoms. Respiratory viral infections are often seasonal, and their identification can help implement infection control practices to halt their spread as well as identify those who would benefit from treatment. While no guidelines exist for the treatment of respiratory viral infections in the neutropenic patient, individuals diagnosed with influenza are generally offered a course of medication even if their symptoms commenced >72 hours prior. The treatment of respiratory syncytial virus with ribavirin and/or intravenous immunoglobulins can be considered. Some centers will additionally offer treatment for parainfluenza or human metapneumovirus although there is great variability in practice. Other common respiratory viruses are treated with supportive care.

Atypical bacteria such as *Legionella*, *Mycoplasma*, or *Chlamydia* can cause pneumonia similarly to those without neutropenia. Mycobacterial infections are not very common in the neutropenic patient but adequate cultures with acid-fast stains can usually establish the diagnosis. Appropriate therapy is determined by the organism and the site of infection but is similar to what is given to

the non-neutropenic patient. Finally, parasites should be considered where the epidemiology is appropriate and the symptoms are consistent with their diseases.

Approaches to the neutropenic patient with fever

Antibiotic therapy in the neutropenic patient with fever

Some patients who present in the outpatient setting do not require admission for neutropenic fever. The cause of the fever should be assumed to be bacterial until proved otherwise. Patients should have pretreatment labs drawn including blood cultures, started immediately on antimicrobial therapy, and observed for several hours before being sent home with close follow-up. The preferred regimen for these patients is a fluoroquinolone plus amoxicillin/clavulanate.

There are numerous sets of criteria for inpatient versus outpatient treatment but ultimately a clinician's judgment is paramount. Characteristics of patients appropriate for outpatient therapy are listed in Box 84.1. If a patient fails to improve on outpatient therapy, there should be a low threshold to admit them for further treatment and workup.

Despite advances in diagnostic imaging and testing, >50% of patients with neutropenia and fever have no identifiable cause. Due to their complexity, comorbidities, and high risk of complications, many patients with neutropenic fever require hospital admission and empiric treatment with IV antibiotics. Antibiotics should include broad gram-negative coverage, including *P. aeruginosa* (Box 84.2).

The role of extended-spectrum gram-positive coverage has been well studied. Despite the preponderance of these organisms as a cause of bacteremia in patients with febrile neutropenia, routine addition of expanded gram-positive coverage does not alter mortality and therefore is not required as empiric therapy. Patients with additional risk for gram-positive infections should, however, receive vancomycin when febrile (Box 84.3).

After patients have been started on empiric agents, reassessment of antibiotics at 2 to 5 days is necessary. By this time, results of initial cultures are available. If an infectious agent is identified, antibiotics can be tailored to that organism. In those who are already on vancomycin, it should be stopped if there is no clinical evidence of an infection secondary to a gram-positive organism. In patients with continued fever at 4 days or in high-risk patients, an antifungal agent can be added to prevent or treat an indolent fungal infection, as discussed later.

BOX 84.1

Characteristics of patients appropriate for outpatient treatment of neutropenic fever

Presents in outpatient setting
Good functional status and low comorbidities
Age <60
Solid tumor or no history of prior fungal infections
Absence of kidney injury, hypotension, or other end organ damage
No severe symptoms

BOX 84.2

Antimicrobial agents for empiric therapy in the hospitalized febrile neutropenic patient

Antibiotic
Cefepime
Imipenem
Meropenem
Piperacillin/tazobactam

Antifungal therapy in the neutropenic patient with fever

There is currently no consensus recommendation on the best agent for empiric antifungal treatment. Candidemia is the most common fungal infection in the neutropenic patient and is rarely considered a contaminant. Multiple agents are available for treatment of *Candida* spp. including the azoles, echinocandins, and polyenes; however, *Candida* spp. have variable resistance to available agents. The triazole fluconazole has activity against many *Candida* spp., including *C. albicans*, *C. tropicalis*, and *C. parapsilosis*, but its activity is limited against *C. glabrata* and *C. krusei*. Therefore, an echinocandin such as micafungin, caspofungin, or anidulafungin is the preferred empiric therapy for candidemia. Echinocandins target the β-1,3-synthase enzyme in the cell wall of *Candida* spp. and are active against nearly all *Candida* spp. Amphotericin, in either its lipid or liposomal form, is an effective alternative but possesses a less desirable toxicity profile including nephrotoxicity and electrolyte wasting. Due to concerns of resistance, azoles are best used in candidemia as step-down therapies in stable patients whose isolates have demonstrated

BOX 84.3

Indications for addition of gram-positive coverage

Hemodynamic instability or severe sepsis
Radiographic evidence of pneumonia
Positive blood culture with gram-positive organism
Clinical suspicion of central line-associated infection
Skin or soft-tissue infection
Colonization with methicillin-resistant *S. aureus* (MRSA), vancomycin-resistant enterococci, or penicillin-resistant *Streptococcus pneumoniae*
Severe mucositis
Prior fluoroquinolone prophylaxis
Use of ceftazidime as empiric gram-negative coverage

susceptibility. Many azoles also have interactions with other agents that are hepatically metabolized.

For the treatment of invasive aspergillosis, the triazoles with mold activity, such as isavuconazole, voriconazole, and posaconazole, are preferred to the various formulations of amphotericin. This is due to their improved side-effect profile and oral availability. Monitoring of steady-state drug levels is recommended for the triazoles as they are metabolized by the liver and can be affected by drug–drug interactions. Isavuconazole is the newest triazole, with high oral bioavailability in its prodrug form, known as isavuconazonium. Echinocandins are not recommended first-line for treatment of *Aspergillus* spp., and their role is limited to salvage therapy or in combination therapy for refractory disease.

For treatment of Zygomycetes, amphotericin and isavuconazole are recommended as first-line therapies. Posaconazole shows acceptable in vitro response and remains an option for step-down or salvage therapy. The oral suspension of posaconazole has variable bioavailability, and therefore the tablet or IV formulation is highly preferred. Combination therapy of amphotericin plus either an appropriate triazole or echinocandin has been utilized, most often in refractory disease, but the data supporting the efficacy of these regimens are limited.

Prophylaxis

Antibacterial prophylaxis is recommended for patients at high risk for febrile neutropenia or a neutropenia lasting >7 days. High-risk patients are those whom have received a stem cell transplant or treatment for acute myeloid leukemia (AML)/myelodysplastic syndrome (MDS). Prophylaxis in these patients is associated with a significant reduction in all-cause mortality. The benefits of prophylaxis in lower risk patient are outweighed by adverse effects (the emergence of resistance, C. diff infection, as well as side effects). Fluoroquinolones remain the antibacterial of choice for prophylaxis due to coverage and tolerability and are recommended over TMP-SMX and cefpodoxime.

Antifungal prophylaxis is recommended for patients at high risk of profound or prolonged neutropenia and severe mucositis for the duration of the neutropenia. These factors increase the risk of *Candida* infections, and therefore the recommended prophylaxis consists of an oral triazole or parenteral echinocandin. For those with elevated risk of invasive mold infection, such as those with AML, MDS, graft-versus-host disease (GVHD), or an allogeneic-stem cell transplant, an azole active against molds, such as voriconazole, posaconazole, or isavuconazole should be utilized instead.

Prophylaxis against herpes simplex virus (HSV) and varicella zoster virus (VZV) are recommended during periods of active treatment or neutropenia. Patients who have received alemtuzumab or an allogeneic stem cell transplant should additionally receive prophylaxis against cytomegalovirus (CMV) with valganciclovir, ganciclovir, foscarnet, or letermovir.

Screening practices for hepatitis B prior to therapy vary widely between international guideline producing bodies. ASCO and IDSA recommend screening those planned to receive an anti-CD20 monoclonal antibody such as rituximab or a stem cell transplant with a hepatitis B surface antigen (HBsAg) test and hepatitis B core antibody (anti-HBc). Those who are HBsAg positive and anti-HBc positive should receive prophylaxis, and those who are HBsAg negative but anti-HBc positive should be closely monitored for hepatitis B reactivation.

Adjunctive agents

Granulocyte and granulocyte/monocyte G-CSFs have been used in patients receiving chemotherapy to shorten the duration and depth of neutropenia. The major complications of G-CSF are bone pain and flu-like symptoms. In controlled trials, human CSFs have been shown to decrease the risk of developing febrile neutropenia and infection associated with intensive chemotherapy.

TABLE 84.2 **COMMON FUNGI CAUSING INFECTION IN THE NEUTROPENIC PATIENT**

Organism	Azole of choice	Echinocandin activity	Amphotericin activity
Candida albicans	Fluconazole	Yes	Yes
Candida tropicalis	Fluconazole	Yes	Yes
Candida parapsilosis	Fluconazole	Yes[a]	Yes
Candida glabrata	Voriconazole[b]	Yes	Yes
Candida krusei	Voriconazole	Yes	Yes
Cryptococcus neoformans	Fluconazole	No	Yes
Aspergillus spp.	Voriconazole	Yes	Yes
Zygomycetes	Isavuconazole	No	Yes
Histoplasma capsulatum	Itraconazole	No	Yes
Coccidioides immitis	Fluconazole	No	Yes
Blastomyces dermatitidis	Itraconazole	No	Yes

[a] *C. parapsilosis* tends to have a higher minimal inhibitory concentration (MIC) to echinocandins, but is usually susceptible.
[b] *C. glabrata* tends to have a higher MIC to voriconazole, but is usually susceptible.

CSFs have also been studied in neutropenic patients who develop fevers. CSFs decrease days of neutropenia, but they have not been shown to decrease duration of fever, use of anti-infective agents, or cost. Importantly, there has been no decrease in mortality. Therefore, the routine use of CSFs is not recommended in neutropenic patients who develop fever.

White blood cell (WBC) transfusions are not currently recommended as an adjunctive therapy for patients with neutropenic fever. Transfusions have significant risk and toxicity including transmission of viral infections such as CMV, graft-versus-host reactions, and fever associated with transfusion reactions. Despite these risks, some centers give WBC transfusions to patients with refractory neutropenia and severe uncontrollable infections. At this point in time, this approach should be considered only experimental.

Infections in patients with neoplastic disease

Amar Safdar and Donald Armstrong

Patients with neoplastic disease and suspected infection require the following main factors to be considered in their evaluation: (1) geographic predisposition for exposure to and to acquire infection including prior colonization with drug-resistant organisms and alteration in hosts' micro-biota; (2) known and unrecognized immune defect or defects due to underlying malignancy or antineoplastic therapy, or both (Table 85.1); (3) breakthrough infections due to drug-resistant pathogens in patients receiving antimicrobial chemoprophylaxis, and (4) familial/genetic predisposition to certain infections in the immunocompromised host. The febrile cancer patient may also have fever from noninfectious conditions such as tumor fever or drug fever. After evaluation, the next question is whether to treat empirically.

Epidemiology

People may be exposed to a variety of organisms through travel, work, habits, or hobbies; in the home; or in other hospitals, outpatient clinics, and infusion centers. A person with children at home is likely to be exposed to a number of infectious agents such as influenza, parainfluenza, respiratory syncytial virus, varicella-zoster virus (VZV), human herpesvirus 6 (HHV-6), and cytomegalovirus (CMV). Hospitals are a rich source of antibiotic-resistant microorganisms, including multidrug-resistant *Staphylococcus aureus* (MRSA), vancomycin-resistant and/or vancomycin-tolerant *Enterococcus* species, multidrug-resistant *Pseudomonas* and *Stenotrophomonas*, and extended-spectrum β-lactamase-producing Enterobacteriaceae such as *Escherichia coli* and *Klebsiella* species. The recent global spread of carbapenem-resistant Enterobacteriaceae (CRE) has underscored the limitations of antibiotic regimens.

A recent review of 27 reports published since 2008 showed gram-negative bacteria continued to be the most prominent cause of bacteremia in cancer patients, especially patients not receiving broad-spectrum antimicrobial prophylaxis. Furthermore, high prevalence of invasive bacterial disease due to multidrug-resistant gram-negative bacteria has had substantial impact on prolonged hospitalization, higher morbidity, and death. It is important to know where an individual has been hospitalized and what resistance patterns are known to inhabit organisms in that hospital. Furthermore, as the spectrum of infection continues to change, it is imperative to follow these trends; just as community-acquired MRSA has recently surpassed hospitalization as a more common source of these resistant bacteria, other traditional risk factors for acquiring an infection may also change. In this regard, potentially life-threatening *Stenotrophomonas maltophilia* lung infections have been observed in cancer patients even in the absence of known risk factors for such infections including (1) severe, prolonged neutropenia, (2) prolonged hospitalization, and (3) stay in critical care units or mechanical ventilation.

Systemic infections due to multiple organisms have been largely underrecognized, probably reflecting underreporting due to the lack of well-established disease definition and guidelines. Polymicrobial infections, including bloodstream, pulmonary, gastrointestinal, and urinary tract, account for 15% to 20% of all infections in cancer patients. It is not uncommon to have gram-positive and gram-negative bacteremia

TABLE 85.1 **INFECTIONS CAUSING PNEUMONIA IN CANCER PATIENTS BASED ON THE UNDERLYING IMMUNE DEFECT**

Immune defect (associated neoplastic diseases)	Bacteria	Fungi	Parasites	Viruses

Abbreviation: HHV-6 = human herpesvirus 6; SARS = severe acute respiratory syndrome; VZV = varicella-zoster virus.
Note: Patients with mixed immune defects include recipients of allogeneic hematopoietic stem cell transplant; acute or chronic graft-versus-host disease; myelodysplastic syndrome; adult T-cell leukemia lymphoma. Antineoplastic agents such as cyclophosphamide, fludarabine, *L. donovani*, and *L. infantum* may lead to serious visceral leishmaniasis. *L. donovani* is seen in Africa and Asia, *L. infantum* is seen in Africa, Europe, Mediterranean, Central and South America. VZV is rarely associated with systemic dissemination in patients with humoral immune defects, or even those with mixed immune dysfunctions. *S. stercoralis* may lead to serious, life-threatening hyperinfection syndrome in patients with marked cellular immune defects.

along with *Candida* spp. bloodstream infection in severely immunosuppressed patients with orointestinal tract ulcers resulting from chemotherapy and/or radiation therapy.

With a thorough knowledge of the epidemiologic background of the patient the physician can direct investigation or start empiric antimicrobial therapy accordingly.

The next step is to consider the patient's underlying immune defect. The immune dysfunction may result from the underlying cancer, or antineoplastic therapy, including monoclonal antibodies. The organisms that must be considered in empiric therapy with reference to the host's immune dysfunction are listed in Table 85.1. In hospitalized patients, the organisms may be specific to the hospital

and, therefore, an empiric regimen appropriate for one hospital may not be appropriate for another. The infectious complication also depends on the nature of the underlying neoplasm. In patients with a hematologic malignancy such as acute myelogenous leukemia, chronic lymphocytic leukemia, multiple myeloma, and lymphoma, the overall frequency of infections may be as high as 75% to 80%, whereas patients with solid tumors such as breast or colon cancer have lower frequency of infection (≤30%) during the course of their disease.

Neutrophil defects

The most common neutrophil defect encountered in patients with malignancy is an absolute neutropenia following cytotoxic chemotherapy. Patients with acute myelogenous leukemia, aplastic anemia, or myelodysplastic syndrome may present with severe neutropenia (≤500 cells/mm^3) due to the underlying disease. It should be remembered that neutropenic patients do not make pus. Physical signs may be absent or altered, as may x-ray findings. After careful evaluation, if there is no obvious site of infection, such as cellulitis or pneumonia, the source of infection is often translocation of bacteria from the gastrointestinal tract, and empiric therapy should be directed against the organisms anticipated to be in that patient's intestinal microbiota at that time. The microbiota may vary according to the hospital the patient is in or has been in, previous courses of antibiotics, and other epidemiologic factors (see Chapter 85, Infections in the neutropenic patient). Recently, despite an overall increase in bloodstream infections due to gram-positive bacteria such as *Staphylococcus* spp., gram-negative bacteria including *E. coli* and *Pseudomonas* spp. have remained an important cause of serious systemic infection in patients with febrile neutropenia. Cather-related bacteremia is often a concern as most patients have indwelling intravascular access devices for chemotherapy and supportive care (see Chapter 107, Intravascular catheter-related infections).

Viridans streptococci can lead to rapidly fulminant sepsis, disseminated intravascular coagulation, multiorgan failure, and shock in neutropenic patients with treatment-induced disruption of orointestinal mucosa.

Patients with prolonged neutropenia (>2 to 3 weeks) are at increased risk of invasive fungal infections (IFI). With the frequent use of fluconazole prophylaxis in high-risk neutropenic patients, a decline in systemic candidiasis has been encouraging, although this has led to a rise in infections due to drug-resistant *Candida* spp. such as *Candida glabrata* and *Candida krusei*. During the past decade, introduction of echinocandin drugs such as caspofungin, micafungin, and anidulafungin has provided a safe and effective alternative for treatment of invasive candidiasis or empiric therapy in patients with persistent febrile neutropenia. In patients with profound neutropenia extending beyond 2 weeks, *Aspergillus* spp. account for most invasive mold disease. During the past two decades, a risk in nonamphotericin B-susceptible mold infections such as *Scedosporium* and *Pseudallescheria* spp. has been noted. Furthermore, increased use of *Aspergillus* active azole-based drugs such as voriconazole has resulted in a higher number of cases of sinopulmonary zygomycosis. Response to invasive mold disease continues to remain a challenge in patients with persistent neutropenia, those receiving high-dose systemic corticosteroids, and patients with graft-versus-host disease (GVHD) following hematopoietic stem cell transplantation (HSCT).

Helper T-lymphocyte defects

CD4$^+$ lymphocyte–mononuclear phagocyte defects are seen regularly in patients with underlying lymphomas, such as Hodgkin's disease, peripheral T-cell lymphoma, cutaneous T-cell lymphoma/mycoses fungoides, and those with leukemia, such as acute lymphoblastic, hairy cell leukemia, human T-lymphotropic virus 1-associated adult T-cell leukemia/lymphoma, recipients of allogeneic HSCT, and patients receiving treatment for post-HSCT GVHD. Antineoplastic therapy that disrupts the adaptive cellular immune response includes high-dose systemic corticosteroids given for extended duration; irradiation therapy; treatment with fludarabine and other purine analogs; and cyclosporine, tacrolimus, and antithymocyte globulins used in the treatment of GVHD. The antineoplastic biologics such as antibodies that inhibit interleukin-2, tumor necrosis factor, and T-cell surface receptors such as CD52 can lead to prolonged and severe defects in the cellular immune function. These patients are prey to an entirely different group of opportunistic pathogens than are patients with neutrophil defects as shown in Table 85.1. Some of these, such as *Mycobacterium tuberculosis*, nontuberculous mycobacteriosis due to *Mycobacterium avium* complex, *Nocardia asteroides* complex, and CMV, produce subacute as well as acute disease, and immediate empiric therapy may not be necessary. In other instances, however, optimal specimens should be collected and empiric therapy instituted for a subacute infection that can become acute and produce rapidly fatal disease in the severely immunosuppressed individual. Examples are tuberculosis, histoplasmosis, and pneumocystosis. If a patient with a severe T-cell defect does have fever and looks toxic without specific signs or symptoms and if there is any question about a B-lymphocyte defect, empiric therapy that covers pneumocystosis (even with negative chest radiographic findings), salmonellosis, and pneumococcus should be initiated. A reasonable regimen for this is ceftriaxone plus trimethoprim–sulfamethoxazole. *Listeria monocytogenes* can lead to serious systemic infection and due to neurotropism, empiric therapy in such patients with suspected bacterial meningitis should include coverage for listeriosis.

In patients with complex cellular immune defects such as those with GVHD receiving corticosteroids, infections due to filamentous fungi such as *Aspergillus* species and nonamphotericin B-susceptible *Pseudallescheria boydii*, *Scedosporium* species, and other black (dematiaceous) fungi may present with asymptomatic pulmonary, sinus, and/or skin lesions. If appropriate therapy with an effective antifungal agent such as voriconazole is delayed, the progressive invasive fungal disease may extend locally and disseminate to the brain. These infections at that stage are often refractory to therapy. However, immune enhancement strategies with recombinant growth factors such as granulocyte–macrophage colony-stimulating

factor and a proinflammatory cytokine such as interferon-γ may be beneficial in select groups of cancer patients with difficult-to-treat invasive fungal infections. Because voriconazole is often preferred to amphotericin B as the drug of choice for the treatment of systemic aspergillosis, a rise in invasive zygomycosis is concerning. Patients who are at a higher risk include patients with refractory leukemia, prolonged neutropenia, corticosteroid therapy, diabetes mellitus, and involvement of paranasal sinuses. In these patients treatment should include lipid formulations of amphotericin B (Am Bisome or Abelcet), although recent experience with posaconazole has led to favorable outcomes in select cancer and HSCT recipients with life-threatening zygomycosis. Because the outcome is so poor in these patients when treated with conventional therapy, other modalities have been tried, including combination antifungals (Abelcet plus caspofungin), hyperbaric oxygen therapy, granulocyte colony-stimulating factor–mobilized donor granulocyte transfusions, recombinant cytokine therapy, and prompt surgical debridement of the devitalized infected tissue.

Splenic and B-cell defects

Patients without a spleen may develop extraordinarily severe infections caused by *Streptococcus pneumoniae* (see Chapter 97, CT overwhelming postsplenectomy infection). They are also at risk for severe infections caused by *Haemophilus influenzae* and *Neisseria meningitidis*. The risk for severe disease due to *Babesia* species in such patients in the Northeastern United States has also been infrequently reported. With the emergence of penicillin-resistant pneumococci, an empiric regimen should contain ceftriaxone and vancomycin. Newer antipneumococcal agents such as linezolid may also be used. Infections with these same organisms are seen in patients with B-cell defects, especially those caused by multiple myeloma and chronic lymphocytic leukemia, in whom hypogammaglobulinemia may be severe and prolonged. In all of these patients, the disease resulting from these encapsulated organisms can be especially severe, with accompanying bacteremia, often with no obvious source. The defect may last for years, and, because of humoral immune dysfunction, these patients may respond poorly to conventional vaccines. Therefore, at present, antibiotic prophylaxis is recommended in cancer patients who are at increased risk of serious pneumococcal disease.

Summary

Evaluation of infections in the patient with neoplastic disease depends on multiple factors, including (1) epidemiologic background, (2) immune defects, (3) resident organisms in a given hospital, and (4) clinical judgment. The first three can be estimated easily. The last requires considerable bedside experience, and, in general, it is prudent to err on the side of treatment rather than observation.

Corticosteroids, cytotoxic agents

Babafemi O. Taiwo and Hannah Nam

Iatrogenic alteration of the immune system occurs with use of corticosteroids or noncorticosteroid immunosuppressants. Although there is overlap, noncorticosteroid immunosuppressants can be broadly divided into cytotoxic antineoplastic drugs and immunosuppressants used in transplantation. Because some of the cells or biologic pathways targeted by therapeutic immunosuppressive agents are essential for the body's defenses against pathogenic microorganisms, the use of immunosuppressants involves walking a fine line between therapy and iatrogenic harm.

The mechanism of action of the immunosuppressant, the dosage used, the length of therapy, and underlying disease(s) all affect the type and severity of subsequent infections. These factors also inform decisions on immunization, prophylaxis, or empirical therapy in high-risk patients.

Corticosteroids

Mechanisms of immune suppression

Corticosteroids exert a broad suppressive effect on the immune system. They achieve this in part by inhibiting transcription factors involved in activating pro-inflammatory genes, and also inhibiting lymphocyte activation, proliferation, and migration. Further, corticosteroids impair cytotoxic T-cell response and delayed-type hypersensitivity reaction. By reducing the production of interleukin-2 (IL-2), interferon-γ, leukotrienes, and tumor necrosis factor (TNF), corticosteroids dysregulate the cytokine response to antigens. Adhesion molecules on endothelial cells are reduced, and the migration of granulocytes to sites of infection is inhibited. Indirectly, corticosteroids impair phagocytosis due to their effect on glucose homeostasis. Antibody formation and turnover are also affected especially at high corticosteroid dosages and with prolonged use, and there may be reversible lymphopenia and monocytopenia. Collectively, these effects blunt cellular immunity and antigen-specific responses. Thus, while corticosteroids can be beneficial to some patients, they increase susceptibility to pathogens, particularly those that are controlled by cellular immune responses. Corticosteroids can also induce anergy and block the normal febrile response to infection. There is essentially no bone marrow suppression.

Corticosteroids as therapeutic agents in infectious diseases

The immunologic and/or inflammatory response to a pathogen may be excessive and deleterious to the host. Because the inflammatory mediators of tissue damage such as TNF, IL-1, and interferon-γ can also cause significant injury at sites distant from the initiating infection, the systemic anti-inflammatory properties of corticosteroids may provide clinical benefit. Glucocorticoids have demonstrated a beneficial role in infections such as severe *Pneumocystis jirovecii* (previously *carinii*) pneumonia (PCP) in HIV-infected individuals, tuberculosis affecting the central nervous system, and some forms of bacterial meningitis. Table 86.1 outlines disease processes for which there is moderate to good evidence that corticosteroids confer clinical benefit.

TABLE 86.1 **INFECTIONS/COMPLICATIONS OF INFECTIONS WITH MODERATE TO GOOD EVIDENCE THAT ADJUVANT CORTICOSTEROID USE HAS BENEFIT**

Infection	Corticosteroid therapy
Acute bacterial meningitis caused by *Haemophilus influenzae* type B in children or *Streptococcus pneumoniae* in adults	Dexamethasone 0.15 mg/kg q6h × 4 d
Pneumocystis jirovecii pneumonia, $P0_2$ ≤70 mm Hg in HIV-infected patients	Prednisone 40 mg BID × 5 d, then 40 mg qd × 5 d, then 20 mg qd for 11 d
Acute severe laryngotracheobronchitis (croup)	Dexamethasone >0.3 mg/kg qd × 3–4 d
Allergic bronchopulmonary aspergillosis	Prednisone 45–60 mg qd until infiltrate clears then taper
Typhoid fever, critically ill with mental status changes or shock	High-dose dexamethasone × 2–3 d
Tuberculous pericarditis, peritonitis and meningitis	Prednisone 60–80 mg qd for several weeks followed by taper
Eosinophilic meningitis caused by helminths (*Angiostrongylus cantonensis, Gnathostoma spinigerum*)	Prednisone 60 mg/d divided into three doses for 2 weeks
Severe histoplasmosis (including cases with obstruction or compression of contiguous structures)	Prednisone 0.5–1.0 mg/kg daily (maximum 80 mg/d) in taper over 1–2 weeks

Abbreviations: HIV = human immunodeficiency virus.

- Epstein–Barr
- Herpes simplex
- Varicella-zoster
- Influenza
- Hepatitis B

Corticosteroids and risk of infection

Myriad pathogens are associated with impaired cellular immunity and corticosteroid use (Box 86.1). Most of the organisms listed rarely cause significant or life-threatening infections in the immunocompetent patient. Some, such as *P. jirovecii*, cause disease only in immunocompromised individuals.

Patients with severe opportunistic infections often have concurrent underlying impairment of cellular immunity separate from the iatrogenic impairment secondary to steroid use. Thus, the risk of infection varies by underlying disease process. For instance, patients with AIDS or childhood acute lymphocytic leukemia have higher rates of PCP than do patients without these diseases but receiving chronic corticosteroid therapy. For patients requiring chronic corticosteroid therapy, the infection rate for many of the pathogens listed in Box 86.1 is actually quite low. Infectious complications are not shown to be increased in those receiving a daily dose of <10 mg or a cumulative dose of <700 mg of prednisone. Overall, the risk increases with the dose and duration of use and may be increased by concomitant administration of other immunosuppressants. Patients who require ≥20 mg of prednisone or an equivalent dose of other corticosteroids for >1 month in combination with a second immunosuppressive drug should receive prophylaxis against PCP and other infections with trimethoprim-sulfamethoxazole (TMP-SMX). Alternative agents include dapsone, atovaquone, and inhaled pentamidine. Of note, aerosolized pentamidine is less effective than the other regimens and does not provide protection against other opportunistic infections covered by TMP-SMX. Skin induration of ≥5 mm after a tuberculin skin test is indicative of latent tuberculosis in the immune-suppressed population.

Cytotoxic antineoplastic agents

Mechanisms of action

Cancer itself is associated with immune suppression, such as neutropenia in acute leukemia or numerical/functional lymphocyte impairment in lymphoma patients. However, clinically significant infections in cancer patients are often related to the effects of cytotoxic antineoplastic agents.

The oldest class of cytotoxic drugs comprises alkylating agents, such as cyclophosphamide, busulfan, melphalan, and chlorambucil.

The purine analogs fludarabine and cytarabine constitute another important class. Although cytotoxic agents are primarily cancer chemotherapeutic drugs, they are also used in hematopoietic stem cell transplantation and severe autoimmune disorders. Antineoplastic agents are a fast-developing area, and data on infectious diseases related to these new agents are still sparse. Immunotherapy approaches are also in early phases of development, including monoclonal antibodies, bispecific antibodies, and chimeric antigen receptor (CAR) T cells, and checkpoint inhibitors such as programmed cell death protein (PD)-1 inhibitors. Recent developments in monoclonal antibodies include cluster of differentiation (CD)33 antibodies such as gemtuzumab ozogamicin or cytotoxic T-lymphocyte associated antigen (CTLA)-4 antibodies such as ipilimumab.

Clinicians must carefully consider the risks when cytotoxic agents are used in patients without cancer, recognizing that these agents, in general, inhibit DNA and/or RNA synthesis and are bone marrow suppressive with a range of effects on B and/or T lymphocytes.

Cytotoxic antineoplastic agents and risk of infection

Inhibition of proliferative cell types by cytotoxic antineoplastic agents is important for their therapeutic effects. However, all replicating cells are affected. Mucositis occurs during cytotoxic chemotherapy due to the effects on proliferative cells of the gastrointestinal and genitourinary systems, as well as on epithelial cells of the skin. Accordingly, cytotoxic chemotherapy predisposes to translocation of normal microflora (e.g., viridans streptococci from the oropharynx and intestinal gram-negative bacteria and *Candida* species) into blood and other sterile spaces, as well as superinfection (e.g., *Herpes simplex virus)* provoking severe illness.

The most common infectious complications of cytotoxic antineoplastic agents arise from therapy-induced neutropenia. Bacterial infections with gram-positive organisms are most common during periods of neutropenia, although gram-negative organisms such as *Pseudomonas aeruginosa* cause the most serious bacterial infections. *Candida* is a common fungal pathogen, likely related to disruption of mucosal integrity by cytotoxic chemotherapy. Because neutrophils are terminally differentiated cells that are continuously replenished through hematopoiesis, the effect of cytotoxic agents is typically reversible within a few weeks of stopping cytotoxic therapy. However, patients with hematologic malignancies and bone marrow transplant recipients are at risk for prolonged neutropenia. When neutropenia is prolonged, patients become at increased risk for fungal pathogens such as *Aspergillus* and *Mucorales.* American Society of Clinical Oncology/Infectious Diseases Society of America (ASCO/IDSA) guidelines (2018) recommend prophylaxis for bacterial and fungal infections when the patient is at risk for prolonged neutropenia.

Cytotoxic agents can also alter T-cell–mediated immune competence. They cause variable numerical reduction in lymphocytes, changes in the ratio of B lymphocytes to T lymphocytes, or changes in ratio of CD4+ T lymphocytes to CD8+ T lymphocytes. In contrast to neutrophils, T-cell populations are heterogeneous, including quiescent long-lived cells and short-lived cells that are sustained by variable levels of antigen-mediated differentiation. Hence, restoration of T-cell populations and immunity after cytotoxic chemotherapy may be incomplete for prolonged periods (even up to 1 year) depending on the affected T-cell populations. These effects predispose patients to viral, fungal, and parasitic infections, some of which are listed in Box 86.1. The immunosuppressive effects of cytotoxic antineoplastic agents on T-cell–mediated immune response are compounded in hematopoietic stem cell transplant recipients by the underlying disease and need for further immunosuppression due to graft-versus-host disease.

Dysfunctional cellular immunity during cytotoxic chemotherapy is associated with reactivation of quiescent infections such as herpesviruses and hepatitis B virus (HBV). Reactivation hepatitis may be fulminant and fatal, and therefore guidelines from the American Society of Clinical Oncology (2015) advise clinicians to consider HBV screening (with hepatitis B surface antigen with or without hepatitis B core antibody) in patients from high epidemiologic risk groups. In addition, screening is recommended if highly immunosuppressive treatment such as hematopoietic transplantation or a regimen containing rituximab is planned. HBV treatment before and during cytotoxic therapy should be considered in those with concerns for chronic HBV (including HBsAg negative/anti-HBc positive), but this should not delay initiation of chemotherapy. Preemptive HBV treatment should continue for at least 12 months after cessation of rituximab-based chemotherapy.

Reactivation of latent tuberculosis can occur during cytotoxic chemotherapy, and the risk varies between patient groups. For example, the risk of reactivation tuberculosis in foreign-born persons with hematologic malignancies was estimated to be 50 to 100 times that of US-born patients, while the risk of tuberculosis in US-born individuals with solid tumors was estimated to be similar to the risk in US-born individuals without cancer. Skin induration of ≥10 mm after a tuberculin skin test is considered indicative of latent tuberculosis in patients with some hematologic malignancies or some solid tumors (e.g., carcinoma of the head and neck).

Importantly, antineoplastic agents differ in their propensity for immunosuppression. Illustratively, vincristine appears less likely to cause infectious complications compared to more toxic agents. The infectious complications of purine analogs deserve special mention because these agents cause profound lymphopenia plus selective suppression (delayed recovery) of CD4+ T lymphocytes that may last several years after administration. Thus, patients have infection risks similar to what occurs in patients with AIDS. Infections caused by cytomegalovirus, *P. jirovecii*, and *Listeria monocytogenes* are particular risks when corticosteroids are used concomitantly.

Recent agents such as immune checkpoint inhibitors targeting CTLA-4, PD-1, and PD-1 ligand (PD-L1) display immune-related adverse events that differ from conventional cytotoxic chemotherapy. While overall risk for infection is relatively low, patients receiving concomitant corticosteroids or TNF- α inhibitors are at risk for developing serious bacterial infections including pneumonia and intra-abdominal infections.

Transplant immunosuppressants

Iatrogenic immune suppression is indispensable to prevent organ rejection posttransplantation. The degree of immune suppression

is the net effect of the underlying condition and treatments that the patient has received over time. This is because the immunesuppressive effects of some drugs can be prolonged and become additive with subsequent treatment. The net immune suppression, hence risk of opportunistic infections, is particularly high in patients who have received multiple treatments for rejection or hematologic malignancies. Overall, due to the growing population of immunosuppressed patients with improved survival and improved diagnostic tools, an increased incidence and spectrum of opportunistic infections has been observed.

Transplant immunosuppressants and risk of infection

For details about immunosuppressant risk in transplanted patients, see Chapter 88. The infectious disease complication is dictated by the synergy between two factors: the epidemiological exposure and the net state of immunosuppression. When the immune defect involves T cells, intracellular pathogens (Box 86.1) can be seen commonly. Thus, calcineurin inhibitors such as cyclosporine or tacrolimus block T-lymphocyte activation and inhibit cell-mediated immunity and are likely to predispose to infection with intracellular pathogens. Treatment antilymphocyte globulin (ALG) and azathioprine are also likely to inhibit cell-mediated immunity and increase the risk of infection with intracellular pathogens. Special vigilance for *Mycobacterium tuberculosis*, endemic fungi, *Cryptococcus*, PCP, and Herpesviridae is warranted in patients receiving these drugs.

In situations where the defect involves B lymphocytes and primary antibody responses, such as is the case with rituximab, infections with extracellular bacteria (Box 86.2) are more likely. Treatment with alemtuzumab can cause profound panlymphocytic effects, leading to overwhelming opportunistic infections from bacterial, viral, fungal, and parasitic causes. Finally, plasmapheresis is associated with increased risk for encapsulated bacterial infections.

Other factors that are predictive of the infectious complication posttransplant include the time elapsed since transplantation, underlying disease, and the presence of active or latent infections in the transplant recipient or donor. In general, infections in the first month posttransplant are caused by bacteria or *Candida* and often are related to the hospitalization and the surgical procedure. With the exception of herpes simplex virus reactivation, opportunistic infections due to transplant immunosuppressants occur after 1-month posttransplant. Epstein–Barr virus is unique in that it can cause posttransplant lymphoproliferative disorder (PTLD), typically after 6 months posttransplant. Belatacept in particular is associated with higher incidence of PTLD when compared to cyclosporine. Appropriate prophylaxis or empiric therapy is necessary to minimize the infectious complications of transplant immunosuppression.

BOX 86.2

Some of the pathogens encountered in patients with deficiencies in humoral immunity and/or granulocytopenia

Gram-negative bacilli
- *Escherichia coli*
- *Klebsiella* spp.
- *Pseudomonas aeruginosa*
- *Enterobacter cloacae*
- *Haemophilus influenzae*
- *Serratia* spp.
- *Proteus* spp.
- *Salmonella* spp.

Gram-positive cocci
- *Staphylococcus aureus*
- *Staphylococcus epidermidis*
- *Streptococcus pneumoniae*
- *Streptococcus pyogenes*
- *Enterococcus* spp.

Anaerobes
- *Bacteroides* spp.
- *Clostridium* spp.
- *Fusobacterium* spp.

Parasites
- *Giardia lamblia*

Fungi
- *Candida* spp.
- *Aspergillus* spp.

Biologics

Rebecca A. Ward, Pritha Sen, and Jatin M. Vyas

Introduction

Biologic therapies have revolutionized nearly every discipline of medicine. As our understanding of the relevant immunologic pathways of cancer, rheumatologic disease, and hematopoietic and solid organ transplantation has evolved, so has the discovery of new monoclonal antibodies for targeted therapy. Currently, >100 monoclonal antibodies have been approved for clinical use. This chapter highlights two major categories of commonly used monoclonal antibodies and their associated infectious complications. We outline the immunologic mechanism of action and indications of use of these important biologic therapies. We also examine the commonly reported infectious complications and summarize the role for pre-implementation diagnostics, post-implementation surveillance, and antimicrobial prophylaxis.

Lymphocyte-depleting therapies

Monoclonal antibodies that target surface proteins found on lymphocytes including alemtuzumab (humanized chimeric monoclonal antibody that recognizes CD52) and rituximab (chimeric murine/human monoclonal antibody directed against the CD20) have been used successfully in the management of lymphoproliferative disorders and autoimmune diseases. We focus on rituximab because of the propensity of available data. Rituximab is constructed with human immunoglobulin G (IgG1) and κ-chain constant regions and heavy and light chain variable regions from a murine antibody to the CD20 antigen, a hydrophobic transmembrane protein which is present on mature B lymphocytes but absent from the surface of normal plasma cells. Rituximab eliminates mature B cells. Although the CD20 antigen is absent from the surface of mature plasma cells, rituximab can be complicated by hypogammaglobulinemia; the precise mechanism is incompletely understood. Rituximab is currently approved for the treatment of non-Hodgkin's lymphoma (NHL), follicular lymphoma (FL), diffuse large B-cell lymphoma (DLBCL), chronic lymphocytic leukemia (CLL), antineutrophil cytoplasmic antibody (ANCA)-associated vasculitides, and pemphigus vulgaris (PV). In addition, rituximab is approved as second-line therapy for rheumatoid arthritis (RA) not responsive to tumor necrosis factor (TNF)-blocking agents. This anti-CD20 monoclonal antibody has also been widely used off-label for lupus, autoimmune hematologic diseases (including primary idiopathic thrombocytopenic purpura and autoimmune hemolytic anemia), multiple sclerosis, bullous dermatologic disorders, immune-mediated glomerular disease, cryoglobulinemia, and desensitization therapy prior to kidney transplantation. The recent ability to administer this drug subcutaneously provides for greater ease in administration at home.

With the expiration of the rituximab patent in the European Union and United States in 2013 and 2016, respectively, an emergence of rituximab biosimilars have surged. In a randomized trial with the biosimilar CT-P10 compared to rituximab plus cyclophosphamide, vincristine, and prednisone (CVP), treatment of advanced FL was efficacious in 97% and 93% of the patients, respectively, with comparable safety parameters.

Similarly, the biosimilar GP2013 resulted in an overall response in 87% of patients (compared to 88% in the rituximab-CVP treatment group). While these results are promising, further studies are warranted to evaluate the robust endpoints previously used to evaluate treatment of follicular lymphoma (i.e., tumor burden, maintenance, long-term effects, etc.) and potential risk of infections.

The B-cell immunomodulatory effects of rituximab can be long-lasting. Rituximab persists in the serum for many months after the drug is initially administered and can cause sustained depletion of B cells for 6 to 9 months after completion of therapy. One year after completion of rituximab, even when the quantitative number of B cells has recovered, these populations of B cells are often functionally nonequivalent to pre-rituximab B cells, with decreased expression of CD27, suggesting a relative deficiency in memory B-cell populations. In a retrospective study, marked differences were noted between different types of vasculitides. Within 9 months, patients with RA or connective tissue disease showed recovered B-cell numbers. On the contrary, patients with microscopic polyangiitis, granulomatosis with polyangiitis, or eosinophilic granulomatosis with polyangiitis showed little to no B-cell repopulation within 9 months. Additionally, late-onset neutropenia can complicate rituximab therapy, with the median time to onset of neutropenia around 102 days, often coinciding with B-lymphocyte depletion.

It is important to note the potential impact on newborns of rituximab treatment in pregnant women. Rituximab can freely pass through the placenta during the third trimester, and reductions in the B-cell populations have been noted during the first weeks of life in these newborns. Additionally, low expression of κ-deleting recombination excision circles may result in B-cell immunodeficiencies testing to be erroneously positive in these infants.

The nature and duration of these immunomodulatory effects of rituximab have implications for infectious complications. The risk of infection is elevated with increased number of rituximab courses, low serum IgG lasting as least 6 months, comorbid conditions (e.g., chronic lung disease, cardiac disease, extra-articular condition in RA patients), and the use of granulocyte colony-stimulating factor. In a study evaluating the preemptive use of rituximab in treating Epstein–Barr virus (EBV)-related posttransplantation lymphoproliferative disorder (PTLD), individuals receiving rituximab had a significantly higher incidence of bacterial infections, predominantly from gram-negative bacilli (including *Pseudomonas* and *Haemophilus*), gram-positive cocci, and atypical mycobacteria, as compared to controls. Increased rates of post-rituximab viral infections have also been reported, with hepatitis B virus (HBV) reactivation, cytomegalovirus (CMV) infection, and varicella-zoster virus (VZV) all well documented and with the median time from initiation of rituximab treatment to diagnosis of viral infection approximately 5 months. HBV reactivation occurring in the context of rituximab therapy has been specifically associated with significant morbidity and mortality. The median duration of time from rituximab administration to HBV reactivation is approximately 3 months, with 29% of cases occurring >6 months after the last dose of rituximab. While the control of HBV infection is mediated by HBV-specific cytotoxic T lymphocytes, the profound and durable depletion of circulating B lymphocytes prevents adequate antigen presentation and is thought to be a major contributing factor involved in HBV viral replication and reactivation complicating rituximab therapy. Although the risk of HBV reactivation is greatest in hepatitis B surface antigen positive (HBsAg (+)) individuals, HBV core antibody positive patients (HBcAb (+)) are also at risk for serious complications. Moreover, in a meta-analysis of patients with NHL treated with rituximab therapy where 387 individuals were found to have HBV reactivation, 304 were HBcAb (+)/HBsAg (−) individuals while only 83 individuals were HBsAg (+). Thus, early identification of patients at risk for HBV reactivation—before they receive rituximab therapy—is critical for avoiding morbidity and mortality from HBV-related disease. In patients who will receive rituximab therapy, screening for chronic HBV infection with HBsAg, HBcAb, HBsAb, and serum HBV DNA testing is indicated. HBsAg (+) individuals—regardless of whether HBV DNA is detectable in the serum—should be initiated on antiviral therapy immediately to block viral replication and disease progression prior to administration of rituximab. While there have been differing opinions as to whether HBcAb (+)/HBsAg (−) individuals should be monitored by serial HBV DNA and liver function tests (LFTs) versus immediately placed on preemptive antiviral therapy, more recent recommendations are to use prophylactic antiviral therapy in these individuals as well. While the nucleoside analog lamivudine has been most extensively studied for antiviral prophylaxis of chronic HBV, high rates of lamivudine resistance have been reported. Therefore, newer nucleoside analogs including entecavir and tenofovir—either alone or in combination—are the preferred prophylactic therapy for chronic HBV infection in the setting of rituximab administration. Current guidelines suggest initiation of anti-HBV viral therapy 1 to 2 weeks prior to rituximab therapy with continuation of antiviral therapy for a minimum of 6 months after this biologic therapy is discontinued and recommend concomitant close monitoring of HBV DNA and LFTs during the course of rituximab therapy.

Progressive multifocal leukoencephalopathy (PML), a severe and fatal central nervous system (CNS) demyelinating disease caused by reactivation of the polyomavirus John Cunningham (JC) virus, has also been reported in individuals with lymphoproliferative disorders treated with rituximab. For example, HIV-negative individuals with CLL treated with fludarabine and rituximab have been described to have clinical syndromes compatible with PML, with JC virus detectable by PCR in the cerebrospinal fluid; these patients survived only months after the diagnosis of PML was made. It is not clear if PML from reactivated JC virus was a direct result of mature B-lymphocyte depletion caused by rituximab or a consequence of concurrent T-cell–depleting therapies. Many patients with lymphoproliferative disorders who developed PML received multiple other chemotherapeutic agents, including purine analogs, corticosteroids, and alkylating agents in addition to rituximab, thus making it difficult to ascribe the presentation of PML to rituximab-related immunomodulatory effects alone. Nevertheless, given that PML has been described in individuals receiving rituximab therapy, it remains important for clinicians to remain vigilant about any neuropsychiatric decline that may be attributable to JC virus-related disease.

While no firm guidelines exist regarding prophylaxis against *Pneumocystis jirovecii* (*carinii*) pneumonia (PCP) in non–HIV infected patients who are immunosuppressed, there is evolving

evidence that PCP prophylaxis is warranted in individuals who receive rituximab as either mono- or combination therapy, particularly in the setting of use in individuals for hematologic malignancies or underlying renal disease.

It is important to ensure that vaccinations against polio (inactivated), influenza (inactivated), *Haemophilus influenzae*, pneumococcus, tetanus, diphtheria, pertussis, hepatitis A and B, and meningococcus (when indicated) are up to date in individuals who may receive lymphocyte-depleting biologic therapies. Administration of live viral vaccines during the course of or in the peri-administration period of rituximab is contraindicated. The UK Department of Health does provide some guidance on the timing of live vaccine administration in patients who receive biologic agents, suggesting that live vaccines should not be given 4 weeks before first administration of any biologic agent or 12 months after rituximab.

Tumor necrosis factor-α inhibiting therapies

TNF-α–blocking therapy has revolutionized the care of individuals with rheumatologic disorders and inflammatory bowel disease (IBD). Four monoclonal antibodies to TNF-α—infliximab, adalimumab, golimumab, and certolizumab—are clinically used routinely. Infliximab is a chimeric monoclonal antibody comprising human immunoglobulin constant regions with murine variable regions, while adalimumab and golimumab have both human constant and variable immunoglobulin regions. These monoclonal antibodies against TNF-α are approved for the treatment of RA, psoriasis, psoriatic arthritis, and ankylosing spondylitis. Infliximab, adalimumab, and certolizumab (a pegylated humanized Fab fragment) are all approved for use in Crohn's disease. Infliximab, adalimumab, and golimumab are additionally approved for use in ulcerative colitis. Adalimumab is further indicated for juvenile idiopathic arthritis, hidradenitis suppurative, and uveitis. Furthermore, certolizumab is indicated for non-radiographical axial spondylarthrosis. Etanercept has a different mechanism of action from the anti–TNF-α monoclonal antibodies and is a soluble TNF-α receptor that binds both TNF-α and lymphotoxin. Etanercept is used to treat RA, psoriatic arthritis, plaque psoriasis, juvenile idiopathic arthritis, and ankylosing spondylitis. A systematic review revealed greater patient retention over 2 years from the initiation of treatment with golimumab when compared to other TNF-α inhibitors, specifically in the treatment of axial spondyloarthritis. Furthermore, this persistence may be lower in biologics-experienced compared to the naïve patients.

Similar to the lymphocyte-depleting therapies, there is an emergence of novel biosimilars to TNF-α inhibitors. Results from the 52-week NOR-SWITCH study demonstrated that changing from the originator (infliximab) to the biosimilar CT-P13 does not impact disease severity of all indicated diseases, safety, or immunogenicity. On the contrary, another study reported 24% of patients discontinued CT-P13 due to adverse events during a 6-month period. In a randomized, double-blind, phase 3 transition study, patients with RA had similar efficacy, immunogenicity, and safety when transitioned to the biosimilar SB2 compared to infliximab or ABP501 compared to adalimumab. Switching between the biosimilar, GP2015, and the originator etanercept product in patients with psoriasis has comparable efficacy, safety, and immunogenicity in the EGALITY phase III confirmatory efficacy and safety study. Little is known regarding the risk for infection in these biosimilars and whether the risk is comparable to TNF-α inhibitors.

TNF-α is released by activated macrophages and is essential in the control and containment of intracellular pathogens. TNF-α production recruits inflammatory cells to an area of infection and stimulates the formation and maintenance of granulomas that physically contain infection. In addition, TNF-α directly activates macrophages, which phagocytose and kill mycobacteria and other pathogens. Thus, inhibition of TNF-α significantly increases the risk of infection. Indeed, adverse effects of TNF-α inhibition includes infections, malignancies, reaction at injection site, heart failure, and demyelinating disease. In a meta-analysis of nine randomized control trials to assess the harmful effects of infliximab and adalimumab versus methotrexate or other disease-modifying antirheumatic drugs (DMARDs), the odds ratio of risk of serious infection associated with anti–TNF-α therapy was 2.0. The rate of risk of serious infection in patients with rheumatologic diseases treated with anti–TNF-α agents ranged from 3 to 6 infections per 100 patient-years, with approximately a 2.2 increase in relative risk of infection with use of these biologic agents. Anti–TNF-α therapy has also been shown to double the risk of opportunistic infections (OIs) in individuals with IBD. Similar risks were reported in a 2018 study comparing all of the TNF-α inhibitors, which may be higher with the interleukin-6 receptor inhibitor tocilizumab.

Anti–TNF-α therapies are not equivalent in their risk of infectious complications; in fact, the infectious risks associated with infliximab and adalimumab therapies are higher than that associated with etanercept. This observation is particularly relevant for mycobacterial and fungal OIs, where, compared to etanercept, infliximab has been associated with a two- to sevenfold increased risk of coccidioidomycosis, histoplasmosis, and tuberculosis (TB), with a shorter time to TB onset (17 vs. 48 weeks) and a higher proportion of TB cases with disseminated or extrapulmonary disease (25% vs. 10%). Other studies demonstrate a 12-fold greater risk of latent TB infection (LTBI) reactivation with infliximab compared to etanercept. Interestingly, the risk of acquiring nontuberculous mycobacterial infections (including *M. avium*, *M. chelonae*, *M. abscessus*, *M. marinum*) appears to be equal whether TNF-α antibodies or soluble receptors are used for therapy. Although the exact immunologic differences portending the infectious risks associated with anti–TNF-α monoclonal antibodies and the soluble TNF-α receptor inhibitor are not known, multiple mechanisms have been postulated. Unlike etanercept, monoclonal antibodies to TNF-α may have the ability to cross-link transmembrane TNF-α and induce apoptosis of TNF-producing cells. The anti–TNF-α monoclonal antibodies also bind TNF-α with greater avidity and for longer duration than etanercept; the half-life of infliximab is approximately 11 days and its biologic effect can persist up to 2 months, whereas etanercept has a half-life of 3 days and its effect on TNF-α is much more short-lived. Etanercept binds strongly to soluble TNF-α alone, whereas infliximab binds TNF-α irreversibly and has high avidity for both

soluble and transmembrane TNF-α, thus prolonging inhibition of TNF-α more than etanercept.

The most common types of infection in RA patients treated with anti–TNF-α therapy are upper and lower respiratory tract infections, urinary tract infections, and skin infections. In the Research Axed on Tolerance of bIOtherapies (RATIO) registry, where all cases of OI in patients receiving anti–TNF-α therapy for rheumatologic indications over a 3-year period were documented, multiple OIs were found in individuals receiving infliximab, adalimumab, or etanercept. The median time to occurrence of an OI from the initiation of anti–TNF-α therapy was found to be approximately 16 months. Twenty-six percent of infected individuals required hospitalization in an ICU and 10% ultimately died from OI-related complications. In almost all cases, infections were due to intracellular organisms. One-third of infections were bacterial (including *Listeria*, *Nocardia*, nontyphoidal *Salmonella, Legionella*, atypical mycobacterial spp.), 40% viral (primary and reactivation varicella, herpes simplex virus [HSV], CMV), 22% fungal (*Pneumocystis*, *Aspergillus* spp., *Cryptococcus*), 4% *Mycobacterium tuberculosis*, and 4% parasitic (*Leishmania*). Listeriosis and legionella infections ultimately became black box warnings for anti–TNF-α therapies on US packing inserts. Interestingly, the anatomic sites of infection in anti–TNF-α therapies were often unusual (i.e., TB cases were predominantly extrapulmonary, and there were several cases of *Listeria* and *Salmonella* causing septic arthritis). At OI diagnosis, anti–TNF-α therapy was discontinued in all but one patient; anti–TNF-α therapy was resumed in 40% of patients after a median duration of 1.7 months of therapy for the OI. Postoperative *Staphylococcus aureus* infection has also been observed in individuals on anti–TNF-α therapy, with increased wound dehiscence and postoperative bleeding noted in individuals who had continued anti–TNF-α therapy close to the perioperative time period.

In a meta-analysis of 22 randomized controlled trials of adults with either Crohn's disease or ulcerative colitis receiving biologic therapy, anti–TNF-α therapy was found to double the risk of OI. In IBD patients receiving anti–TNF-α therapy, infection with *Streptococcus pneumoniae*, *Legionella pneumophila*, *Salmonella* spp., *Listeria monocytogenes*, *Nocardia*, and *Clostridium difficile* species have all been observed. Infection with *M. tuberculosis*, herpes simplex, primary varicella, herpes zoster, CMV, EBV, and oral/esophageal candidiasis was also reported.

M. tuberculosis infection is a well-documented risk in the early phase of anti–TNF-α treatment and often manifests as extrapulmonary and disseminated *M. tuberculosis* infection rather than isolated pulmonary infection. The majority of TB infection observed in the context of anti–TNF-α therapy is due to reactivation of LTBI rather than newly acquired TB infection. For these reasons, screening for LTBI is recommended prior to initiation of anti–TNF-α therapy, and repeated screening is recommended for individuals who may have acquired TB since their first screening. Diagnostics options for evaluating LTBI prior to or during anti–TNF-α therapy include regular tuberculin skin test (TST), boosted TST, and interferon-γ release assay (IGRA) using *M. tuberculosis*-specific antigens. For individuals found to have LTBI, there are limited data on the time interval during which patients should be on LTBI therapy before initiation of anti–TNF-α therapy, although there is some evidence that suggests concurrent LTBI and anti–TNF-α therapy is acceptable. If an active TB infection is diagnosed while an individual is on anti–TNF-α therapy, guidelines suggest discontinuation of anti–TNF-α therapy. Patients with Crohn's disease treated with a TNF-α inhibitor and an existing *M. paratuberculosis* infection induces survival of the bacteria, which may contribute to elevated risk of infections. However, there are reported cases of clinical worsening with discontinuation of anti–TNF-α therapy in the setting of disseminated or extrapulmonary TB. The hallmark of this clinical scenario—termed *paradoxical reaction*—is the presence of worsening inflammation despite evidence for microbiologic response and improvement. In this specific clinical situation, the optimal timing of reinitiation of anti–TNF-α therapy is not clear.

Endemic fungal infection is also a well-described complication in patients on anti–TNF-α therapy. Histoplasmosis, which can present as asymptomatic infection, severe pneumonitis, mediastinal lymphadenopathy, chronic pulmonary cavitary disease, pericarditis, and arthritis, is the most commonly reported invasive fungal infection in patients treated with TNF-α inhibitors and is actually reported more frequently in these immunocompromised hosts than TB. Even in the United States, individuals on anti–TNF-α therapy had significantly increased risk of histoplasmosis infection with mortality as high as 20%. Similar to *M. tuberculosis*, there is an increased risk of histoplasmosis with the anti–TNF-α monoclonal antibody therapies as compared to etanercept; the incidence of histoplasmosis is estimated at 18.8/100,000 persons treated with infliximab, compared to 2.7/100,000 persons treated with etanercept. Like histoplasmosis, blastomycosis infection (presenting as CNS involvement or severe pulmonary infection in the immunocompromised host) and coccidioidomycosis infection (presenting as acute or subacute pneumonia) are typically acquired as a new infection rather than reactivation in individuals on anti–TNF-α therapy. Since coccidioidomycosis often is asymptomatic, in individuals who reside in endemic areas (southwestern United States, Central America, South America) without prior history of fungal infection, a chest radiograph and *Coccidioides immitis* serology are recommended prior to initiation of anti–TNF-α therapy. Interestingly, a retrospective study suggested screening preceding anti–TNF-α therapy may reduce risk of symptomatic coccidioidomycosis. Other fungal infections such as invasive pulmonary aspergillosis, cryptococcal cavitating pneumonia, reactivation of pulmonary paracoccidioidomycosis, meningitis and disseminated disease, oral/genital candidal infection, and PCP have been less commonly described in the setting of anti–TNF-α therapies.

The impact of anti–TNF-α therapy on the incidence of viral infections is less clear. CMV infection is known to complicate therapy with TNF-α antagonists; while CMV reactivation is common, disseminated life-threatening end-organ disease is less common. Primary varicella and reactivation HSV and herpes zoster have been identified in individuals with IBD treated with anti–TNF-α therapy. While there is limited literature on hepatitis B (HBV) reactivation in the setting of TNF-α blockade, animal models do suggest that TNF-α promotes clearance of HBV and that TNF-α is secreted by HBV-specific cytotoxic T lymphocytes (CTL) and synergizes with interferons to suppress HBV viral activity. There have been case reports of individuals with chronic HBV who

developed fulminant hepatitis after being treated with infliximab. For this reason, prophylactic anti-HBV therapy is recommended during the duration of anti–TNF-α therapy and for 3 to 6 months post completion of anti–TNF-α therapy in HBsAg(+) individuals and can be considered in HBcAb(+) individuals. Hepatitis C infection does not appear to progress in the setting of TNF-α blockade. The limited data on HIV infection in the setting of anti–TNF-α therapy suggest that HIV infection does not progress in individuals where anti–TNF-α therapy is used. However, there are limited data on HIV outcomes and risk for OI in the setting of anti–TNF-α therapy, and, consequently, HIV infection is still considered a relative contraindication to initiation of anti–TNF-α therapy. Human papillomavirus (HPV) infection is not a contraindication for use of anti–TNF-α therapy, though individuals with extensive cutaneous and/or anogenital HPV-related disease are at high risk for progressive skin disease. Individual case reports of EBV-related PTLD in the setting of anti–TNF-α therapy have also been reported. PML from JC virus reactivation is not a common complication of anti–TNF-α therapy.

In addition to identifying epidemiologic risk factors that place an individual on anti–TNF-α therapy at risk for reactivation of LTBI, endemic fungal infection, and/or reactivation of latent herpesvirus or chronic HBV infection, ensuring that vaccinations are up to date prior to initiation of anti–TNF-α therapy is critical in preventative care. All patients receiving anti–TNF-α therapy should be vaccinated against pneumococcus and should receive inactivated influenza vaccination annually. Hepatitis B vaccination is also prudent. Other non-live vaccines can be given according to established US Centers for Disease Control and Prevention (CDC) guidelines/schedules. Live attenuated vaccines including intranasal influenza, oral polio, measles/mumps/rubella, yellow fever, and zoster should not be administered in individuals who have been recently treated with anti–TNF-α therapy, and guidelines suggest waiting a minimum of 6 months after infliximab and 4 weeks after etanercept is completed before any live vaccine is considered for administration.

Infection in transplant patients

Raymund R. Razonable

Introduction

Infections are common complications of organ, tissue, and stem cell transplantation. Whether it is due to a bacterium, virus, fungus or parasite, the clinical disease caused by any of these pathogens is often severe, leading to increased morbidity and potential mortality. Several factors inherent to the transplant recipient or related to the donor, the environment, and circumstances surrounding the transplant procedure (such as surgical techniques and immunosuppressive drugs) increase the risk of infectious complications. Depending on risk profiles of transplant recipients, some infections are predictable and preventable, while others remain unexpected. Generally, the overall risk of infection after transplantation is determined by (1) epidemiologic exposures of the donor and recipient and (2) the overall net state of immunosuppression.

Risk factors of infection after transplantation

Epidemiologic exposures

The major sources of pathogens are (1) the transplant recipient who may harbor latent, active, or subclinical infection prior to transplantation; (2) the donor who may harbor latent, active, or subclinical infection that could be transmitted through the allograft (donor-transmitted infections); and (3) the environment (including the healthcare setting and the community). Table 88.1 lists some of the common risk factors for acquiring infection after transplantation.

The transplant candidate and recipient

The epidemiologic exposures of transplant candidates should be assessed to determine the risk of infection after transplantation and guide preventive measures. A detailed medical and exposure history should be elicited during their evaluation for transplantation. Box 88.1 lists the tests that are recommended in the evaluation of transplant candidates (and their donors) prior to organ transplantation. During the process of their evaluation, some transplant candidates will be found to have active infection (such as subacute bacterial peritonitis in liver candidates with ascites; or pneumonia in lung transplant candidates; or line-associated bloodstream infection among stem cell, heart, and kidney transplant candidates with indwelling vascular catheters); in general, these infections do not absolutely preclude organ and tissue transplantation, but these infections should be adequately controlled and treated prior to and after the transplant procedure. Often, serologic evidence of past infection would suggest the presence of latent viruses, such as cytomegalovirus (CMV), varicella-zoster virus (VZV), and Epstein–Barr virus (EBV), or parasites, such as *Toxoplasma gondii* (especially for heart recipients) and *Strongyloides stercoralis*.

TABLE 88.1 **RISK FACTORS FOR ACQUIRING INFECTION FOLLOWING SOLID ORGAN TRANSPLANTATION**

Preoperative period	Intraoperative period	Postoperative period
Lack of pathogen-specific immunity (e.g., CMV-seronegativity)	Presence of pathogens in the transplant allograft (donor-transmitted infections)	Prolonged hospitalization
Severity of underlying clinical illnesses and comorbidity (e.g., high MELD score)	Prolonged operative time Complicated surgical procedure (e.g., break in intestinal compartment)	Prolonged stay in intensive care unit (and need for indwelling vascular and urinary catheters, endotracheal tubes)
Fulminant hepatic failure	Profound blood loss and infusion of large volume of blood products	Prolonged antibiotic use (invasive fungal infections and *Clostridium difficile*)
Renal failure (especially need for renal replacement therapy)	Choledochojejunostomy (for liver recipients)	Renal insufficiency (especially need for renal replacement therapy)
Active infection (e.g., peritonitis, bacteremia, viral hepatitis)	Indwelling vascular and urinary catheters Endotracheal intubation	Gastrointestinal and biliary complications (e.g., biliary leaks)
Prior fungal infection (i.e., coccidioidomycosis and aspergillosis)		Vascular complications (e.g., thrombosis and surgical site hematoma)
		Anastomotic leaks (e.g., biliary leak, ureteral leak, bronchial dehiscence) Wound dehiscence
		Allograft rejection Lymphocyte-depleting drugs (e.g., anti-thymocyte globulins, alemtuzumab) Immunosuppressive drugs
		CMV and HHV-6 reactivation
		Reoperation within 1 month after transplantation
		Retransplantation

Abbreviations: HHV = human herpesvirus; CMV = cytomegalovirus.

Knowledge of the presence of latent and subclinical infections will guide implementation of prevention efforts prior to, or after, organ and tissue transplantation. For example, seronegativity to VZV suggests the need to vaccinate the transplant candidate at least 28 days prior to organ transplantation and immunosuppression. Likewise, latent tuberculous infection, as detected either by tuberculin skin testing or interferon-γ release assay, should be treated preferably prior to organ and tissue transplantation.

The transplant donor

The epidemiologic exposures of transplant donors should be determined so that the potential for donor-transmitted infections is reduced. Screening for CMV, EBV, VZV, *T. gondii* (especially for heart transplant donors), hepatitis B and C viruses, and HIV are routinely performed in transplant donors (Box 88.1). Risk for tuberculosis in the donor should also be elicited based on history, while living donors should undergo tuberculin skin testing or interferon-γ release assay. Transplant donors often have prolonged stay in the hospital prior to organ harvest, and they may have acquired nosocomial infections which could be transmitted to the transplant recipient through transplantation (Table 88.2). Clinical suspicion or documentation of potential donor-transmitted infection should be reported to the national database so that recipients of all organs from the infected donor can be screened and managed accordingly.

The environment

The healthcare environment is a major source of pathogens that may cause infectious disease in transplant recipients. Moreover, surgical and other invasive procedures, such as the insertion of indwelling urinary catheters, intravascular catheters, and endotracheal tubes, could serve as portals of entry for infectious pathogens.

Many infections are acquired by the transplant recipients in the community setting where natural transmission of pathogens continually occurs. Classic examples are respiratory viral and bacterial pathogens which can cause potentially severe pneumonia or other respiratory illness in transplant recipients. Table 88.2 lists the epidemiologic exposures and the pathogens associated with specific exposures.

BOX 88.1

Selected infectious disease screening tools in the evaluation of donors and recipients prior to transplantation

Human immunodeficiency virus (HIV) antibody (HIV RNA in selected cases)
Herpes simplex virus (HSV) 1 and 2 IgG antibody
Cytomegalovirus (CMV-IgG) antibody
Epstein–Barr virus (EBV) antibody panel
Varicella-zoster virus (VZV) antibody
Toxoplasma antibody (in heart recipients)
Rapid plasma reagin test and treponemal tests for syphilis
Human T-cell lymphotropic virus (HTLV) I and II antibody (selected cases only, based on epidemiologic risk)
Hepatitis C virus (anti-HCV) antibody (HCV RNA in selected cases)
Hepatitis B virus (HBV) surface antigen, surface antibody, and core antibody
PPD skin testing or interferon-gamma release assay (e.g., QuantiFERON TB test) (for living donors and all recipients)
Strongyloides stercoralis serology (with stool ova and parasites for candidates from endemic areas)
Coccidioides immitis serology (for candidates and donors from endemic areas)
Trypanosoma cruzi serology (for donors and recipients from endemic areas)

TABLE 88.2 **EPIDEMIOLOGIC EXPOSURES AND SELECTED PATHOGENS THAT CAUSE INFECTIOUS DISEASES IN TRANSPLANT PATIENTS**

Community-acquired infections	
Residence or travel to endemic areas	*Mycobacterium tuberculosis, Strongyloides stercoralis, Blastomyces dermatitidis, Histoplasma capsulatum, Coccidioides immitis, Trypanosoma cruzi*, human herpesvirus 8, *Plasmodium* species, dengue virus, Zika virus
Exposure to index cases	*Mycobacterium tuberculosis*, respiratory viruses (influenza, parainfluenza, respiratory syncytial virus, adenoviruses)
Contaminated food and water	*Salmonella* spp., *Campylobacter jejuni, Listeria monocytogenes, Giardia lamblia, Cryptosporidium parvum*
Environmental source	*Aspergillus fumigatus, Nocardia* sp., *Sporothrix schenckii*, norovirus, *Legionella pneumophila*
Vector-borne	West Nile virus, tick-borne diseases, *Plasmodium* species, Zika virus
Nosocomial infections	
Contaminated air	*Aspergillus fumigatus*
Contaminated water	*Legionella pneumophila*
Hand contact	Methicillin-resistant *Staphylococcus aureus,* vancomycin-resistant enterococci, drug-resistant gram-negative bacilli, influenza virus
Hospital environment	*Clostridium difficile,* multidrug-resistant bacteria including methicillin-resistant *Staphylococcus aureus,* vancomycin-resistant enterococci, drug-resistant *Pseudomonas aeruginosa*

Net state of immunosuppression

The major factors that influence the overall net state of immunosuppression are (1) the intensity of drug-induced immunosuppression (dose, frequency, duration, and magnitude of effect on the T-cell compartment), (2) the presence of inherent immunodeficiency, and (3) other factors such as the reactivation of immunomodulating viruses, increasing age, and presence of other comorbidity (e.g., diabetes mellitus).

Immunosuppressive drugs are essential to maintain allograft survival (by preventing and treating acute and chronic graft cellular rejection and humoral rejection among the solid organ transplant [SOT] recipients) and to prevent and treat acute or chronic graft-versus-host disease (in allogeneic hematopoietic stem cell transplant [HSCT] recipients). The use of induction immunosuppression, often with T-lymphocyte–depleting drugs such as anti-thymocyte globulins and alemtuzumab, markedly impair cell-mediated immune function. The degree of drug-induced immunosuppression is especially intense during the first 3 months after organ and stem cell transplantation and is characterized by severe impairment of cellular and humoral immunity. Although defect in cell-mediated immunity is a well-recognized effect of the immunosuppressive drugs, impairment in humoral immunity, as indicated by severe hypogammaglobulinemia, may also occur. The individual and collective suppressive effects of these drugs on the immune system places the patients at high risk of opportunistic infections. In particular, lymphocyte-depleting agents increase the risk of CMV disease, human herpesvirus 6 (HHV-6), *Aspergillus* spp., and *Pneumocystis jirovecii*. Severe hypogammaglobulinemia may also increase the risk of infections with encapsulated organisms such as *Streptococcus pneumonia*.

There is increasing evidence that inherent defects in innate and adaptive immunity may augment the net state of immune deficiency, further increasing the risk of infections after transplantation. Increasing age, diabetes, and other comorbidity (such as

renal failure) augment the risk. Reactivation of latent viruses with immunomodulating properties, such as CMV and HHV-6, during periods of intense drug-induced immunosuppression may paradoxically further enhance the overall state of immunosuppression, leading to increased risk of bacterial and fungal opportunistic infections.

Time course of infections after transplantation

Infections after SOT and HSCT follow a temporal pattern that is predicted by risk factors related to time since transplantation. Figures 88.1 and 88.2 depict the timing of infections after SOT (Figure 88.1) and allogeneic HSCT (Figure 88.2). However, this traditional timeline is evolving, influenced by various factors, most notably the use of antimicrobial prophylaxis. For example, CMV infection and disease traditionally occurs during the first 3 months after SOT, but this has been delayed among high-risk CMV donor-positive/recipient-negative SOT patients to the first 3 months after completion of antiviral prophylaxis. In addition, widespread use of antimicrobial prophylaxis has modified the drug susceptibilities of various pathogens, as exemplified by the emergence of fluconazole-resistant *Candida* spp. infections in centers utilizing fluconazole prophylaxis. There is also increasing incidence of drug resistance among bacterial pathogens, which complicates empiric antimicrobial prophylaxis and treatment approaches.

Timetable of infections after solid organ transplantation

Infections after SOT follow a characteristic time frame that reflects epidemiologic and clinical factors and the net state of immunosuppression. These time frames are important to remember during the clinical evaluation of SOT patients presenting with various clinical syndromes after transplantation. In this regard, clinical syndromes such as pneumonia and cellulitis may occur at any time, but the offending pathogen may vary depending on its onset after transplantation.

The first month after solid organ transplantation

The three major sources of infections during this period are (1) infection that is present in the recipient prior to transplantation (i.e., bacterial peritonitis in liver recipients, catheter-related bloodstream infection in kidney recipients, bacterial pneumonia in lung recipients, and infected cardiac device in heart transplant recipients), (2) infection transmitted in the allograft (e.g., unrecognized or undiagnosed bacterial, viral, parasitic, and fungal infection prior to organ harvest), and (3) infections related to surgery and hospitalization.

The majority of infections that occur during the first month after SOT are related to surgical procedures and hospitalization (Figure 88.1): surgical site infections due to *Staphylococcus* spp. and *Streptococcus* spp. or other nosocomially acquired pathogens; catheter-associated urinary tract infections with gram-negative bacteria such as *Escherichia coli*, gram-positive bacteria such as

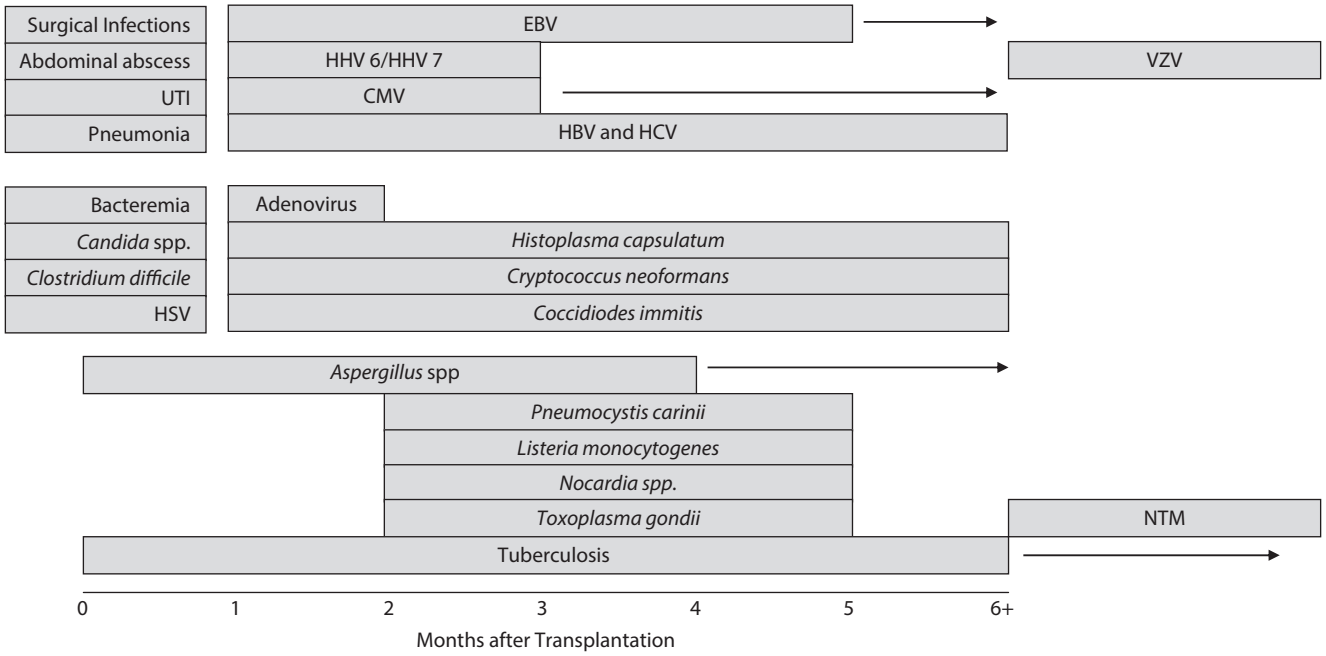

FIGURE 88.1 Natural history timeline of infections following solid organ transplantation in the absence of antimicrobial prophylaxis.

CMV, cytomegalovirus; EBV, Epstein–Barr virus; HBV, hepatitis B virus; HCV, hepatitis C virus; HHV, human herpesvirus; HSV, herpes simplex virus; NTM, nontuberculous mycobacteria; UTI, urinary tract infection; VZV, varicella-zoster virus.

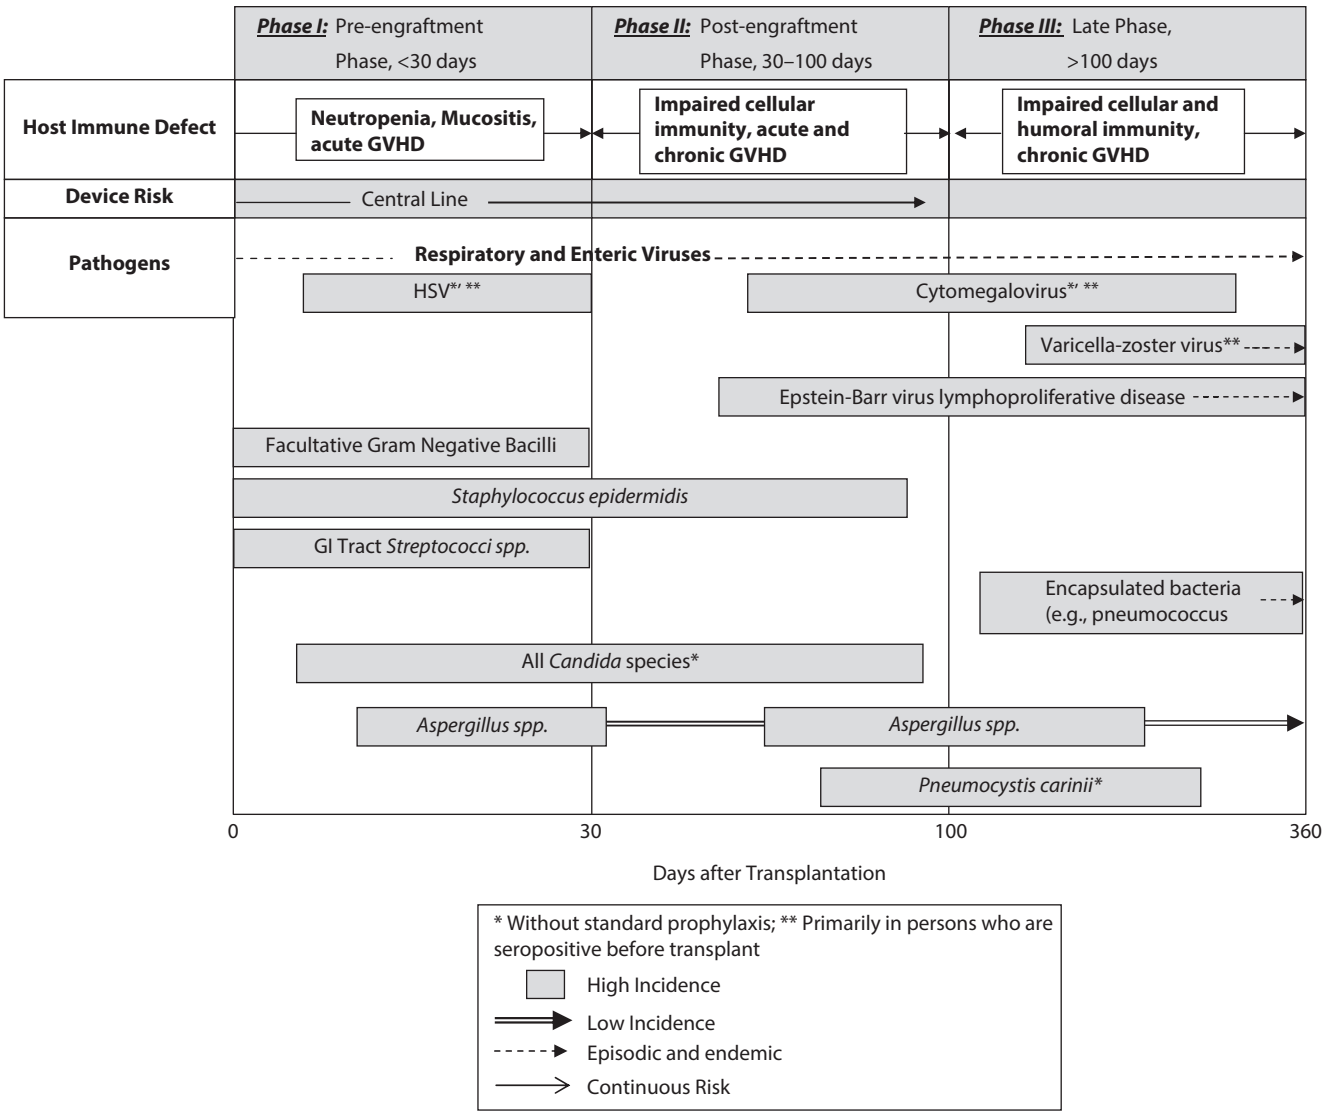

FIGURE 88.2 Natural history timeline of infections following allogeneic hematopoietic stem cell transplantation in the absence of antimicrobial prophylaxis. GI, gastrointestinal; GVHD, graft-versus-host disease; HSV, herpes simplex virus.

enterococcus, and fungi such as *Candida albicans*; nosocomial and ventilator-associated pneumonia due to drug-resistant *Pseudomonas aeruginosa, Acinetobacter* spp., *Staphylococcus aureus*, and others; and catheter-associated bloodstream infection with gram-positive bacteria such as *S. aureus*, enterococcus, and coagulase-negative staphylococcus are seen. Polymicrobial intra-abdominal infections are especially common among liver recipients who require abdominal re-exploration (for hepatic artery thrombosis, bleeding, biliary leakage, or retransplantation). Prolonged hospitalization increases the risk of nosocomial pneumonia, urinary infections, and antibiotic-related *Clostridium difficile* diarrhea. The widespread use of antibacterial agents for prophylaxis and treatment of defined infections has led to the rising incidence of *C. difficile* infection during this early posttransplant period.

During this time period, herpes simplex virus (HSV) types 1 and 2 commonly reactivate and may cause localized ulcerative or disseminated disease in the HSV-seropositive SOT recipients; antiviral prophylaxis has significantly decreased its incidence. Donor-transmitted infections such as an unrecognized fungal infection (due to *Histoplasma capsulatum* or *Cryptococcus neoformans*) and other unusual infections such as West Nile virus (WNV), rabies virus, or lymphocytic choriomeningitis virus may be manifested clinically during this period, often with poor outcomes. One clue to the possible donor-transmitted infection is the occurrence of similar clinical syndromes among multiple recipients of organs from the same organ donor.

Second to the sixth month after solid organ transplantation

The impact of intense immunosuppression resulting from the use of lymphocyte-depleting induction therapy and the immune-paralyzing effect of a combination of immunosuppressive drugs becomes evident during this second period after SOT. Accordingly, this is the period when most opportunistic infections classically

occur. During this period, infections due to CMV, EBV, HHV-6, *Aspergillus fumigatus*, and *Pneumocystis jirovecii* occur. In the absence of antiviral prophylaxis, CMV reactivates and cause fever and end-organ disease during this period. Invasive aspergillosis, most commonly due to *A. fumigatus*, may occur during this time, especially among patients transplanted for fulminant hepatic failure, those on renal replacement therapy, and those with epidemiologic exposure (i.e., exposure to areas of construction or previous colonization among lung transplant recipients) and profound immunosuppression. Pneumonia is the most common clinical presentation of aspergillosis, but the clinical illness may disseminate to any body organ system, possibly due to the vasculotropic nature of *Aspergillus* spp. and cause abscesses in many organs, including the liver and the brain. Infections with endemic fungi (e.g., *H. capsulatum* and *Coccidioides immitis*) may occur during this period to cause pneumonia or disseminated disease. *P. jirovecii* pneumonia traditionally occurs during this opportunistic period but prophylaxis with trimethoprim-sulfamethoxazole (TMP-SMX) has made this infection and those due to *Nocardia* spp. uncommon during this early period.

Beyond the sixth month after solid organ transplantation

There are generally two types of SOT patients with varying risk of infection during this period: (1) those with good allograft function and minimal immunosuppression and (2) those with poor allograft function as a result of recurrent rejection or chronic allograft dysfunction. In addition, liver transplant recipients with underlying chronic viral hepatitis (due to hepatitis B or C) may develop an accelerated clinical course characterized by graft failure if not prevented or treated and, subsequently, the need for retransplantation. These patients may benefit from prophylaxis with hepatitis B immunoglobulin and nucleoside or nucleotide analogs (for hepatitis B patients), or targeted therapy with direct-acting antivirals (for hepatitis C patients).

The vast majority of transplant patients will have good allograft function, and their level of immunosuppression has already been reduced to minimal levels. These patients are primarily at risk of infections similar to those observed in nonimmunocompromised populations. However, a small group of SOT patients will have poor graft function as a result of recurrent rejection or chronic dysfunction; these patients are generally considered to be over-immunosuppressed and remain at high risk of opportunistic infections, including *P. jirovecii, L. monocytogenes, C. neoformans, Nocardia asteroides*, CMV, and *Aspergillus* spp. infections. Patients with a persistent hypogammaglobulinemia are particularly at risk of pneumonia and bacteremia due to encapsulated organisms.

Infection with endemic mycoses, such as *C. immitis* in patients living in the Southwest United States, may occur in patients with epidemiologic exposures such as residence in certain geographic regions. One of the most common opportunistic infections during this time is the reactivation of VZV causing dermatomal zoster, with potential for dissemination. In endemic areas, HHV-8 may reactivate to cause Kaposi's sarcoma (KS) and, less commonly, Castleman's disease and primary effusion lymphoma; in these endemic regions, KS is one of the most common malignancies in transplant recipients. CMV disease is increasingly observed during the late period (i.e., beyond the sixth month after SOT, especially among high-risk CMV D+/R− SOT recipients who receive 6 months of antiviral prophylaxis; termed *post-prophylaxis delayed onset CMV disease*). Late-onset CMV disease may also sporadically occur years after transplantation, and these patients may present with atypical clinical presentations that could lead to severe morbidity and potential mortality if diagnosis and treatment is delayed.

EBV may occur at any time after SOT and cause posttransplant lymphoproliferative disorder. Infections due to respiratory pathogens such as *S. pneumoniae*, and seasonal viruses such as influenza virus and respiratory syncytial virus may occur with increased severity at any time after transplantation.

Timetable of infections after hematopoietic stem cell transplantation

Infections after HSCT follow a traditional pattern (Figure 88.2) that reflects the severity of immune dysfunction and the different phases of immune recovery after transplantation.

The pre-engraftment period (0 to 30 days after HSCT)

The two major factors that influence the risk of infection during this period are (1) severity and duration of neutropenia and (2) disruption of mucocutaneous barrier, such as mucositis and use of vascular access catheters. *Candida* spp. is traditionally a prevalent fungal infection during this period, and, hence, antifungal prophylaxis with an azole (choice of azole depends on the risk) is commonly used. As the duration of neutropenia is prolonged, the risk for *Aspergillus* spp. is increased, and, in these high-risk patients, prophylaxis with voriconazole or voriconazole is preferred. HSV reactivation commonly occurs to cause mucosal ulcerations that complicate chemotherapy-induced mucositis. Breaks in mucocutaneous barrier, such as severe mucositis, may cause translocation of oral and gastrointestinal flora. For example, this predisposes to severe systemic infection and septic shock due to viridans group streptococcus. Gram-positive bacteria such as *S. aureus* and coagulase-negative staphylococci and vancomycin-resistant enterococcus, gram-negative bacteria such as *E. coli* and *P. aeruginosa*, and fungi such as *C. albicans* may gain entry into the bloodstream through indwelling vascular catheters. HSCT patients are commonly febrile during this period, especially during periods of severe neutropenia, and receive empiric broad-spectrum antimicrobial therapy. However, this may predispose them to develop *C. difficile* diarrhea.

Post-engraftment period (days 30–100 after HSCT)

This period is highlighted by an impaired cell-mediated immunity and is characterized by the occurrence of classic opportunistic infections. Following engraftment, the risk of acute and chronic graft-versus-host disease is increased and immunosuppressive drugs are given to prevent this complication, thereby increasing the risk of opportunistic infections. This period is classically associated with the occurrence of CMV infection, which could manifest as severe and potentially fatal pneumonia if not detected and treated early.

Allogeneic HSCT recipients undergo serial (at least once weekly) CMV surveillance using CMV nucleic acid testing (or alternatively, pp65 antigenemia) so that CMV reactivation is detected early and treated promptly. Alternatively, patients may receive anti-CMV prophylaxis, preferably with letermovir (since valganciclovir is associated with leukopenia and may delay or impair engraftment), but this may only delay the onset of CMV disease to beyond 100 days after HSCT (post-prophylaxis delayed onset CMV infection), particularly among those with severe immunosuppression. HHV-6 and adenovirus infections may occur during this period and cause febrile illness, rash, and hepatitis. Posttransplant acute limbic encephalitis is a classic clinical presentation of HHV-6 disease after allogeneic HSCT. *Aspergillus* spp., *Fusarium* spp., *Mucor* and *Rhizopus* spp. may cause invasive disease. Risk of *P. jirovecii* pneumonia is reduced by prophylaxis with TMP-SMX or inhaled pentamidine.

Late phase (beyond 100 days after HSCT)

In some HSCT patients, such as those with chronic graft-versus-host disease, the period beyond 100 days after transplantation is characterized by persistent impairment in cell-mediated and humoral immunity as a result of the administration of augmented immunosuppression. In these patients, infections with CMV, VZV, EBV, *Aspergillus* spp., and *P. jirovecii* may continue to occur, and they may benefit from prolonged administration of antimicrobial prophylaxis.

The majority of HSCT patients will have adequate immune reconstitution during this period, and the risk of infections will be lower although still at a relatively higher rate compared to healthy hosts. Once fully engrafted and immune reconstitution is achieved, allogeneic HSCT recipients may benefit from vaccination program to reestablish immunity against vaccine-preventable diseases. Infections with community-acquired respiratory viruses such as influenza, parainfluenza, and respiratory syncytial viruses may occur and so do infections with encapsulated bacteria such as *S. pneumoniae* and *Haemophilus influenzae*. These infections with encapsulated bacteria are particularly more common among patients with persistent low levels of immunoglobulins.

Selected pathogens and syndromes

Bacterial infections

Any bacterial pathogen can cause clinical disease, often with increased severity and morbidity, in transplant patients. Surgical site infection is often due to *S. aureus* and other gram-positive bacteria. Bloodstream infection due to gram-positive and gram-negative bacteria may occur among HSCT recipients, especially during the period of mucositis and neutropenia. In many of these cases, bloodstream infection is related to indwelling vascular catheters. One of the causes of septic shock in HSCT recipients with severe mucositis is bloodstream infection due to viridans group streptococci. Kidney transplant recipients are particularly at high risk of developing urinary tract infection, most often due to *E. coli,* other members of the *Enterobacteriaceae*, and enterococcus, especially during the first 6 to 12 months after transplantation. Bacterial pneumonia and tracheobronchitis may occur among lung recipients, potentially due to impaired mucociliary clearance. Intra-abdominal bacterial infections, such as cholangitis, peritonitis, and abscesses, may occur during the early period after liver transplantation; many of these intra-abdominal abscesses are polymicrobial in etiology and include members of the *Enterobacteriaceae*, enterococcus, anaerobes, and *Candida* spp. Table 88.3 lists the most common strategies for the prevention of bacterial and other infections after transplantation.

In HSCT patients, it is standard practice to provide antibacterial prophylaxis during the high-risk period of neutropenia, primarily to prevent sepsis due to *P. aeruginosa*. Antibacterial prophylaxis with fluoroquinolones is a standard practice, but this is associated with a risk of sepsis due to viridans group streptococci, especially during the period of mucositis. The addition of penicillin to quinolones, to reduce the risk of viridans group streptococcal sepsis, has been associated with emergence of resistance in enterococcus. Empiric treatment of HSCT patients with fever during the period of neutropenia should include broad-spectrum anti-Pseudomonal cephalosporins (cefepime or ceftazidime), piperacillin-tazobactam, or carbapenems; vancomycin may be added empirically for severe sepsis and if there is concern for pneumonia and line-related sepsis. Some experts have advocated the use of intravenous immunoglobulins (IVIG) to prevent bacterial infections, such as sinopulmonary infections with *S. pneumoniae*, in patients with hypogammaglobulinemia.

Mycobacterium species

Transplant candidates should be screened for latent tuberculosis (TB) infection (LTBI) by history, tuberculin skin test (TST), or interferon-γ release assays (IGRA) and treated preferably prior to transplantation. Some cases of donor-transmitted TB have been reported, and hence all living donors are also screened for the infection by history, TST, or IGRA. Deceased donors should be screened for possible TB through detailed history.

Pulmonary TB is the most common clinical presentation, although dissemination and extra-pulmonary disease may occur. Involvement of the transplanted organ allograft raises concern for donor-transmitted TB, and should alert for screening of all organ recipients from the same organ donor. The diagnosis of TB is confirmed by mycobacterial culture, acid-fast smear, and molecular testing such as polymerase chain reaction (PCR) assays. Treatment of *M. tuberculosis* in transplant recipients is similar to that in the non-transplant population, initially with use of isoniazid, rifamycin, ethambutol, and pyrazinamide. However, it is important to remember that rifampin has strong interaction with tacrolimus and cyclosporine, and their systemic drug levels should be monitored closely.

In the transplant patient, atypical mycobacteria, such as *Mycobacterium avium* complex may be a cause of pulmonary infection after lung transplantation. *Mycobacterium abscessus*, *M. chelonae*, *M. fortuitum*, and *M. marinum*, among others, should be considered potential causes of skin lesions, tenosynovitis, or joint infection. Non-tuberculous mycobacteria may colonize and

TABLE 88.3 **SUGGESTED PROPHYLACTIC STRATEGIES IN TRANSPLANTATION**

Indication	Prophylaxis	Dose and duration	Comments
Perioperative prophylaxis (SOT)	Cefotaxime	1–2 g q8h IV for 24 h	Should be adjusted based on resistance patterns; alternative agents (vancomycin plus quinolone) may be used if resistance risk is high
Perioperative prophylaxis (SOT)	Cefazolin	1–2 g q8h IV for 24 h	Should be adjusted based on resistance patterns; alternative agents (vancomycin plus quinolone) may be used if resistance risk is high
Neutropenia prophylaxis (HSCT)	Quinolone (e.g., levofloxacin)	500 mg PO once daily (for the duration of neutropenia)	Reduce risk of gram-negative sepsis, particularly *Pseudomonas aeruginosa*; risk of viridans streptococcal sepsis is not completely prevented
Pneumocystis jirovecii	Trimethoprim-sulfamethoxazole	80 or 160 mg of trimethoprim component PO once daily	Trimethoprim-sulfamethoxazole may protect against *Nocardia* spp., *Listeria* spp., and other bacteria Alternatives: pentamidine, atovaquone, dapsone
Herpes simplex virus	Acyclovir	200–400 mg PO BID–TID for 28 d	Should be withheld when ganciclovir or valganciclovir is used; valacyclovir may be used if available
Cytomegalovirus	Valganciclovir	900 mg once daily; duration variable (3–12 months depending on the organ and risk profile)	Used as prophylaxis; dose should be increased to 900 mg BID for preemptive therapy; may protect against HHV-6, HSV, VZV
Cytomegalovirus (HSCT only)	Letermovir	480 mg PO once daily (240 mg PO once daily if with cyclosporine)	Used as prophylaxis; does not have activity against HHV-6, HSV, VZV
Hepatitis B virus	Hepatitis B immunoglobulin with nucleotide/nucleoside analogs	10,000 IU daily for first week then q4wk (the dose of nucleotide and nucleoside analog varies depending on the drug)	Maintain serum HBIg level >100 IU; may be used in combination with nucleotide analogs such as lamivudine and entecavir
Candida spp.	Fluconazole	200–400 mg PO daily (duration varies depending on the transplant type)	Targeted to patients with risk factors for Candida infections, such as complicated and prolonged surgery or profound blood loss
Coccidioides spp.	Fluconazole	200–400 mg PO once daily (duration varies depending on risk profile)	At-risk transplant recipients in endemic regions
Aspergillus spp. and other invasive mycelial infection	Itraconazole Voriconazole Posaconazole Echinocandin Amphotericin B	Variable drug dose and duration depending on the fungi of interest	Administered to patients with risk factors such as prolonged neutropenia, and fulminant hepatic failure

Abbreviations: HBIg = hepatitis B immunoglobulin; PO = orally; IV = intravenous; tid = 3 times daily; HHV = human herpesvirus; HSV = herpes simplex virus; VZV = varicella-zoster virus
Role of oral bowel decontamination solution is highly debated, and not routinely recommended.

contaminate central venous catheters, especially among allogeneic HSCT recipients, and lead to bloodstream infection. Antimicrobial treatment will depend on the mycobacterial species and surgical debridement (if abscesses, arthritis, and tenosynovitis) or catheter removal (for line-related bloodstream infections).

Nocardia species

Nocardia spp. typically cause pneumonia but can disseminate to involve the joints, skin, and especially the brain. Imaging of the brain is recommended to rule out central nervous system involvement in patients with *Nocardia* infection. Risk factors for nocardiosis include the severity of immunosuppression as influenced by immunosuppressive drugs, graft rejection, and neutropenia. The routine use of TMP-SMX prophylaxis during the first 3 to 6 months after transplantation, while intended to prevent *P. jirovecii* pneumonia, may also prevent some cases of nocardiosis and has lowered its incidence. However, breakthrough nocardia infections may still occur even in patients receiving TMP-SMX prophylaxis. The diagnosis is established using a modified acid-fast stain and culture. Antimicrobial resistance has been reported; antimicrobial susceptibility testing of the isolate is recommended. Depending on the severity of the disease, empiric therapy may include 2 or 3 agents active against *Nocardia* species.

Viral infections

Cytomegalovirus

CMV is the most common infection that causes significant morbidity and preventable mortality after transplantation. CMV infection occurs traditionally (in patients not receiving antiviral prophylaxis) during the first 3 months after SOT and HSCT. In CMV D+/R− SOT recipients who receive antiviral prophylaxis, the onset of CMV infection and disease has been delayed to the first 3 to 6 months after completion of antiviral prophylaxis, a condition termed post-prophylaxis delayed onset CMV infection.

CMV causes direct and indirect effects that negatively affect the outcome of organ and tissue transplantation. The direct effects, otherwise known as *CMV disease*, can be manifested as CMV syndrome (febrile illness, flu-like illness, myalgias, and bone marrow suppression) or end-organ disease (CMV pneumonitis, gastrointestinal disease, hepatitis, retinitis, encephalitis, allograft infection, and others). The indirect effects of CMV infection include its association with increased risk of acute and chronic allograft rejection, higher risk of other opportunistic infections such as invasive fungal disease and EBV posttransplant lymphoproliferative disorder, and higher rate of chronic allograft dysfunction, such as accelerated vasculopathy in heart recipients, bronchiolitis obliterans in lung recipients, and tubulointerstitial fibrosis in kidney transplant recipients. Increase risks of graft versus host disease and mortality have been reported in allogenic HSCT recipients with CMV reactivation. Risk factors for CMV disease include a CMV mismatch status; a CMV-seronegative SOT patient who receives solid organ allograft from a CMV-seropositive donor (CMV D+/R− mismatch) is at highest risk of CMV infection and disease after SOT. In contrast, a CMV-seropositive HSCT patient who receives hematopoietic stem cells from a CMV-seronegative donor (reverse CMV D−/R+ mismatch) represents a high risk after allogeneic HSCT. Immunosuppressive regimens such as antithymocyte globulins, antilymphocyte globulins, alemtuzumab, and mycophenolate mofetil increase the risk of CMV. The diagnostic tests for CMV after transplantation include molecular tests such as quantitative PCR to detect and quantify CMV nucleic acid (currently considered the most sensitive assay for CMV detection), while pp65 antigenemia (which detects pp65 expressed in neutrophils during active CMV infection) is considered the alternative test. Viral culture is highly specific but with poor to modest sensitivity, and it is no longer widely available. Histopathology remains as the gold standard for the diagnosis of end-organ CMV disease. Serology is not useful for diagnosis of acute CMV disease because transplant patients have delayed and impaired ability to develop antibodies during infection.

Prevention of CMV disease is an integral component in the management of transplant recipients. There are two major methods of prevention: (1) antiviral prophylaxis through the administration of antiviral drugs, most commonly with valganciclovir (or letermovir for CMV-seropositive allogeneic HSCT recipients) to all patients at risk of CMV disease and (2) preemptive therapy through the administration of antiviral drugs, most commonly with IV ganciclovir or oral valganciclovir, to transplant patients with asymptomatic CMV infection as indicated by a positive pp65 antigenemia or CMV PCR test. Treatment of CMV disease is with IV ganciclovir or oral valganciclovir. Oral valganciclovir has been used for treatment of mild to moderate CMV disease, while IV ganciclovir is preferred for severe disease. Because of adverse effects such as nephrotoxicity and electrolyte imbalances, cidofovir and foscarnet are reserved only for the treatment of ganciclovir-resistant CMV disease. Letermovir is not clinically approved for treatment of clinical disease. CMV viral load monitoring to detect the response to antiviral treatment is recommended once weekly; antiviral treatment is continued until clearance of the virus is demonstrated and clinical symptoms have resolved.

Herpes simplex virus

The vast majority of HSV infections after transplantation represent reactivation of endogenous latent virus. Most commonly, the clinical presentation is orolabial and genital ulcers, although disseminated disease may occur in the form of hepatitis, pneumonitis, and esophageal disease. Most of the HSV infections occur during the first month after SOT and HSCT but antiviral prophylaxis with acyclovir (or valganciclovir, which is intended primarily against CMV) has reduced its incidence. The diagnosis of mucocutaneous HSV disease is based mainly on clinical findings of typical herpetic lesions. PCR testing to demonstrate the viral DNA may confirm the diagnosis. Treatment is with oral acyclovir, valacyclovir, and famciclovir for a duration guided by clinical response.

Varicella-zoster virus

Because >90% of the adult population has antibodies against VZV, almost all cases of VZV disease after SOT and HSCT represent reactivation disease. Most commonly, this is manifested clinically in the form of mono- or multidermatomal zoster. Disseminated VZV disease, with possible visceral involvement, may occur in severely immunocompromised transplant recipients. The incidence of VZV disease is approximately 10% of all transplant patients. The median onset of disease is 9 to 14 months after transplantation. The diagnosis is based on clinical grounds, with typical vesicular lesions in a dermatomal distribution (for typical localized disease) or in a widespread distribution (for disseminated disease). Treatment is with IV acyclovir for serious disease and with oral valacyclovir for limited or localized disease. Duration of treatment should be guided by clinical response. Vaccination with adjuvant herpes zoster subunit vaccine for VZV-immune transplant candidates >50 years is strongly recommended. In allogeneic HSCT recipients, acyclovir prophylaxis for up to 1 year is given to prevent zoster. The use of live attenuated zoster vaccine is contraindicated after transplantation since there is potential for activation and dissemination of the attenuated vaccine strain. The role of adjuvant herpes zoster subunit vaccine for transplant recipients is currently under investigation.

Epstein–Barr virus and posttransplant lymphoproliferative disorder

EBV posttransplant lymphoproliferative disorder (PTLD) consists of all clinical syndromes associated with EBV-driven

lymphoproliferation, whether this is nodal or extranodal, symptomatic or subclinical, localized or disseminated, monoclonal or polyclonal, benign hyperplasia or true malignancies containing chromosomal aberrations. Primary EBV infection is the most significant risk factor for EBV PTLD especially among severely immune compromised transplant recipients, particularly those who have received lymphocyte-depleting antibodies. CMV disease also further increases the risk of PTLD potentially due to its immunesuppressive effects. The incidence of PTLD varies among organ transplant types; it is highest in small bowel and lowest in kidney transplant recipients. The diagnosis of EBV PTLD is confirmed by histopathology of specimens obtained by excisional biopsy. Surveillance measures such as PCR assays to quantitate EBV viral load are commonly utilized to assess the risk of PTLD in high-risk EBV D+/R− patients. Detection of EBV by PCR in high-risk patients should trigger evaluation for PTLD and reduction in the degree of immunosuppression. The clinical utility of EBV PCR for diagnosis of PTLD is debatable. Although low or absent EBV viral load has a very good negative predictive value, the specificity of higher EBV load is only modest. The first-line treatment of EBV PTLD is reduction in immunosuppression. Since EBV PTLD is predominantly through B-cell proliferation, rituximab alone or in combination with chemotherapeutic agents is the treatment of choice. Prophylaxis with acyclovir and valganciclovir is of theoretical value but has not been proved to be effective for prevention. Antiviral therapy has no role in the treatment of established PTLD.

Human herpesviruses 6 and 7

HHV-6 (A and B) and HHV-7 infect >95% of humans. Primary infection with HHV-6 and HHV-7 is uncommon in adult transplant recipients. However, secondary reactivation from latency is very common in adult transplant recipients, but the vast majority is subclinical and transient. In the minority of cases, HHV-6 can cause a febrile illness, bone marrow suppression, hepatitis, pneumonitis, and encephalitis. In allogeneic HSCT recipients, a condition known as *posttransplant acute limbic encephalitis* is attributed to HHV-6 infection. The most common diagnostic test for HHV-6 and HHV-7 is nucleic acid amplification by PCR using blood and other body fluid such as cerebrospinal fluid. Serology is rarely helpful and not widely available. Viral culture is also not readily available and it has slow turnaround time. Histopathology and immunohistochemistry may be used to confirm the diagnosis of tissue-invasive disease. There are no solid clinical trial data to guide antiviral treatment of HHV-6 and HHV-7, although HHV-6 appears to be susceptible to ganciclovir, cidofovir, and foscarnet, whereas HHV-7 may be resistant to ganciclovir.

Human herpesvirus 8

Infections with HHV-8 cause KS and, less commonly, Castleman's disease; primary effusion lymphoma; and other nonmalignant myelosuppressive disease. HHV-8 may occur as primary infection or reactivation of latent virus. The incidence of posttransplant HHV-8 infection and disease parallels the geographic seroprevalence of HHV-8, so that it occurs at a rate of <1% in the United States to as high as 5% in HHV-8 endemic regions of the world such as Saudi Arabia, South Africa, and the Mediterranean region. KS is considered the most common malignancy in kidney recipients in some parts of the Middle East. The median time to the onset of KS is 22 months after transplantation. Skin involvement is the most common manifestation, and visceral lesions such as gastrointestinal and pulmonary KS may also be observed. Reduction (or withdrawal) of immunosuppression is the mainstay of treatment. Surgery and chemotherapy with doxorubicin, vincristine, and bleomycin has been used for treatment.

Polyomaviruses BK and JC

Infection with the BK polyomavirus is mainly reported in kidney transplant recipients, where it causes tubulointerstitial nephritis; this is often manifested clinically as an unexplained rise in serum creatinine and impairment in renal function. Ureteral stenosis and strictures may also be observed. In HSCT recipients, BK virus may manifest as hemorrhagic cystitis. The definitive diagnosis of BK virus–associated nephropathy is made by histopathologic examination of kidney biopsy specimens. Routine screening for BK virus infection in blood or urine is recommended after kidney transplantation, and the detection of BK viremia above the threshold 10,000 copies is treated with reduction in immunosuppressive therapy. High BK viral load in the plasma has been directly correlated with BK virus–associated nephropathy. In HSCT recipients, the role of BK virus in hemorrhagic cystitis is indicated by very high BK viral load in the urine. Infection with the JC virus causes a highly fatal syndrome of progressive multifocal leukoencephalopathy (PML). Diagnosis of PML is suggested by typical MRI findings and the demonstration of JC virus in the cerebrospinal fluid by PCR. Reduction in immunosuppression is the mainstay of treatment for both BK virus infection and PML. Cidofovir (and investigational brincidofovir) and leflunomide are used as experimental therapies but are of no proven benefit. Surveillance testing, with the use of blood or urine PCR or urinary decoy cell testing, is used to identify BK infection early, which is treated preemptively with reduction in immunosuppression in efforts to prevent its progression into allograft failure.

Parvovirus B19

Parvovirus B19 primarily infects and lyses erythroid cells and clinically manifests mainly as recurrent and refractory anemia. Almost all transplant patients with parvovirus B19 infection have anemia, and some also have low platelet count and leukocyte counts. It should be considered a potential cause of failure of engraftment in HSCT recipients. Organ-invasive manifestations may occur in the form of pneumonitis, hepatitis, and myocarditis, although these are not common. The definitive diagnosis is bone marrow examination to demonstrate pure red cell aplasia and giant pronormoblasts. Serology may be used as a noninvasive test, but this may be falsely negative in some patients due to delayed and impaired ability of transplant patients to mount an antibody response. Nucleic acid testing by PCR to demonstrate the presence of parvovirus B19 DNA in clinical specimens is preferred. PCR is considered the most sensitive method

for diagnosis, while bone marrow examination is highly specific for the disease. The treatment is with IVIG, although the dose and duration are not defined. Reduction in the degree of immunosuppression should be considered, and red cell blood transfusion should be given for symptomatic patients and those with severe anemia.

Hepatitis C virus

Chronic hepatitis C is a common indication for liver transplantation. Persistence of infection is the hallmark, and, with immunosuppression, the clinical course of HCV may be accelerated after transplantation. In the past, this was treated with interferon and ribavirin, with modest response. More recently, there has been rapid expansion of direct-acting antiviral drugs for the cure of hepatitis C. With cure rates exceeding 95%, the outcome of liver transplantation for chronic hepatitis C has remarkably improved. Moreover, the directly acting antivirals have allowed for HCV-infected organs to be transplanted to HCV-negative candidates. This has increased the availability of organs, as some HCV-uninfected transplant candidates are accepting offers of HCV-infected organs as long as they can be treated with highly effective direct-acting antivirals in the posttransplant period.

Fungal infections

Fungi may cause opportunistic infection in transplant recipients. However, it is essential to differentiate whether the isolation of fungi in clinical samples represents colonization or true infection. Factors that could indicate true fungal infection include (1) the presence of compatible clinical symptoms, (2) radiographic signs, and (3) isolation of the fungus in more than one clinical sample. Confirmation of true invasive fungal infection is made by the demonstration of the fungal pathogen on biopsy specimens. The diagnosis may be considered probable or definitive based on the strength of evidence. The use of PCR assays to demonstrate fungal nucleic acid (such as *P. jirovecii*) and detection of antigens such as galactomannan and β-D-glucan in clinical samples offer non- or less-invasive methods for diagnosis.

The most common fungal infections in transplant patients are caused by *Candida* spp., *Aspergillus* spp., and *C. neoformans*. The majority of invasive fungal infections during the early posttransplant period are due to *Candida* spp., and these are often related to surgical procedures, indwelling urinary and intravascular catheters, and prolonged antibiotic use. *Aspergillus* spp. may also occur during the early period after transplantation, especially among patients with prior colonization, fulminant hepatitis (for liver recipients), prolonged neutropenia (for HSCT recipients), and severe immunocompromise. *Mucorales* spp. and *Fusarium* spp. infections may be seen in hematopoietic stem cell recipients with prolonged neutropenia. Zygomycosis due to *Mucor* spp., *Rhizopus* spp., and others is a highly fatal invasive fungal disease. *C. neoformans*, endemic mycoses such as *Histoplasma capsulatum*, dermatophytes, hyalohyphomycoses, and phaeohyphomycosis may also occur, often during the later period after transplantation. *Coccidioides* spp. infections are especially common in endemic regions, causing potentially fatal disseminated disease.

Liver transplant patients are at especially high risk of fungal infection with *Candida* spp. and *Aspergillus* spp. Antifungal prophylaxis, usually with low-dose amphotericin B, azoles, or an echinocandin, is given to liver transplant patients with certain risk factors such as fulminant hepatitis, those who require renal replacement therapy, those who undergo abdominal re-exploration, those who have high blood transfusion requirement, and those who require retransplantation. Lung transplant recipients with certain risk factors (hyperacute rejection, ischemic bronchial segments, *Aspergillus* spp. colonization, CMV disease, anastomotic dehiscence, and retransplantation) are at higher risk of developing invasive fungal disease, especially with *Aspergillus* spp. Heart transplant patients may infrequently develop invasive fungal infection, most often with *Candida* spp. causing mediastinitis. Kidney transplant patients are at risk of fungal infection, most commonly presenting as catheter-associated candida urinary tract infection. Pancreas and intestinal patients are also at high risk of invasive *Candida* spp. infections, often as part of a polymicrobial intra-abdominal abscess. Allogeneic HSCT recipients are at high risk of *Candida* spp. infection related to indwelling vascular and urinary catheters and mucositis, while prolonged neutropenia increases their risk for mycelial fungal infection, especially *Aspergillus* spp. and zygomyces.

Treatment of opportunistic invasive fungal diseases entails reduction in immunosuppression, surgery (debridement, debulking, or resection in some cases), and antifungal drug therapy. Depending on the fungal pathogen and the severity of disease, three classes of antifungal drugs are available—amphotericin B (deoxycholate and lipid formulations), echinocandins (caspofungin, micafungin, and anidulafungin), or azoles (fluconazole, itraconazole, voriconazole, posaconazole, and isavuconazole). There are three different antifungal strategies: (1) therapeutic, which is the treatment of established fungal infection; (2) preemptive, which is the administration of antifungal drug to transplant patients at high risk of invasive fungal disease as suggested by clinical and laboratory features; and (3) prophylactic, which is the administration of antifungal drug to all at-risk patients to prevent infection.

Pneumocystis jirovecii

P. jirovecii is one of the most important opportunistic fungal pathogen that causes pneumonia in SOT and HSCT patients. The clinical presentation is often subacute with low-grade fever, progressive dyspnea, hypoxemia, and nonproductive cough. This is accompanied by typical radiographic finding of diffuse pulmonary infiltrates. Extrapulmonary disease may occur rarely. Coinfection with CMV and *Aspergillus* spp. is not uncommon. The overall incidence has decreased with the use of prophylaxis, most commonly TMP-SMX, and alternatively with dapsone or aerosolized pentamidine. The current guidelines recommend the use of *P. jirovecii* prophylaxis during the periods of immunocompromise in all allogeneic HSCT and SOT recipients. The duration of prophylaxis is at least 6 months after transplantation; the duration should be prolonged in patients who remain highly immune compromised from augmented use of drugs to treat recurrent rejection or graft-versus-host disease. The diagnosis of *P. jirovecii* pneumonia requires the demonstration of the organism in lung tissue and respiratory secretions with the use of calcofluor staining or methenamine silver stain or by molecular tests such as PCR. The treatment of choice is TMP-SMX with or without

corticosteroids in patients with significant hypoxemia. Alternative therapies include pentamidine, atovaquone-dapsone-trimethoprim, primaquine-clindamycin, and pyrimethamine-sulfadiazine.

Parasitic infections

Parasitic infections are increasing becoming more common after transplantation as a result of international travel, immigration, and transplant tourism. An increasing number of transplant procedures are performed in parasite-endemic regions. In the transplant recipient, parasitic infections may occur as a result of primary infection, reactivation of latent endogenous infection, or "activation" of an active but subclinical infection. Allograft-transmitted parasitic disease may also occur, as illustrated by the occurrence of donor-derived primary toxoplasma infection after heart and liver transplantation. A detailed exposure and travel history is essential in defining parasitic infections that may cause an opportunistic infectious disease syndrome in transplant recipients.

Toxoplasma gondii

T. gondii infection after transplantation may manifest with fever and lymphadenopathy and could progress to cause tissue-invasive infection, including myocarditis and cardiomyopathy, pneumonia, and neurologic manifestations. Parasitism is often extensive in the brain, heart, lungs, and lymphoid organs. Infection is especially more common in heart transplant recipients since the parasite may be harbored in cardiac muscles and thus could be transmitted through the heart allograft. The diagnosis is suspected based on exposures and may be confirmed by serology and the demonstration of the organism in biopsy specimens. Molecular testing using PCR may also be utilized. The prevention of toxoplasmosis is recommended mainly in heart transplant recipients, especially when there is a *Toxoplasma* D+/R− serologic mismatch. The suggested prophylaxis is pyrimethamine and sulfadiazine or TMP-SMX. Many centers provide lifelong TMP-SMX prophylaxis for heart transplant recipients at high risk of toxoplasmosis. Alternative regimens include dapsone with pyrimethamine and atovaquone. The treatment of toxoplasmosis after transplantation includes the synergistic combination of pyrimethamine and sulfonamide or clindamycin.

Trypanosoma cruzi

Trypanosoma cruzi is a vector-borne parasite that causes Chagas disease (or American trypanosomiasis) and may be manifested as fever, myocarditis, and heart failure in transplant recipients. Skin nodules, panniculitis, and brain abscesses may also occur in transplant recipients. Infection should be suspected in patients residing in endemic regions, such as Latin America, where the triatome vector may transmit the parasite through bites. Reactivation of latent infection may occur. Donor-derived infection has also been observed in transplant recipients of organs from donors from endemic regions. Diagnosis and monitoring is through the PCR or the detection of trypomastigote in the buffy coat layer. Skin lesions may be biopsied to demonstrate the presence of the parasite. Treatment of Chagas disease is with benznidazole and nifurtimox in addition to reduction of immunosuppression.

Strongyloides stercoralis

Strongyloides stercoralis is a nematode whose larval stage has the tendency to disseminate in the setting of immune compromise, with larval accumulation in the lungs causing Loeffler's syndrome or eosinophilic pneumonia. Peripheral eosinophilia is often present. Gut penetration by the larva may also cause the translocation of bacteria and fungi and leads to systemic bacterial and fungal hyperinfections. This hyperinfection syndrome may be associated with pneumonitis, abdominal crisis, eosinophilic meningitis, and septic shock. Polymicrobial bloodstream infection, including *Candida* spp., gram-negative organisms such as *E. coli*, and other gut-derived bacteria, may occur and clue in for the diagnosis. Death is often due to gram-negative bacterial septic shock. The treatment options for *S. stercoralis* infection are thiabendazole, ivermectin, and albendazole. Treatment of other superimposed infections should complement parasite-directed therapy.

Conclusion

Infections cause significant morbidity and preventable mortality after transplantation. Infections in transplant recipients are generally more severe, and, at times, the classic clinical manifestations of these infections may be atypical. Hence, a high degree of suspicion is necessary for prompt and proper diagnosis of these infections.

Infections portend a worse allograft and patient survival outcome after transplantation. Hence, the major goal is prevention, prompt diagnosis, and aggressive treatment. To the extent possible, reduction of the degree of pharmacologic immunosuppression should complement antimicrobial therapy.

Diabetes and infection

Sylvia J. Shaw and Raza Iqbal

Diabetes mellitus (DM) affects >30.3 million people in United States; 84.1 million are known to have prediabetes. Worldwide, the prevalence of diabetes will increase 366 million by 2030. More than 90% of diabetic patients have type 2 diabetes. Diabetes is a metabolic and vascular disease; both microvascular and macrovascular complications are related to blood glucose control and disease duration and are more commonly seen in the elderly. The annual cost of diabetes is tremendously expensive; according to American Diabetes Association, it was $245 billion in 2012. While nearly $70 billion of this figure was associated with reduced workforce productivity, the remaining $176 billion occurred as healthcare expenditures. Annual increments of healthcare costs ranged from $11,710 to $16,883 per patient with diabetic foot ulcer, or as high as $13 billion nationally, in addition to the cost associated with diabetes itself.

Diabetic patients have increased risk for infections (Table 89.1) and are accountable for 50% of hospital admission or outpatient visits. Respiratory and foot infections are overrepresented and have increased risk of infection-related mortality.

Predisposing factors to infection

Uncontrolled diabetes alters host immune response and has been implicated in disorders of immune function by alteration of polymorphonuclear leukocyte (PML) chemotaxis, phagocytosis, and decreased intracellular bactericidal activities. The effect of hyperglycemia on phagocytic activity is associated with an increase in cytosolic calcium and is reversible with the improvement of blood glucose level. There are other metabolic imbalances that impair the immune system, such as presence of acidemia. In addition, presence of chronic inflammatory changes may contribute to the metabolic imbalances. Tumor necrosis factor (TNF-α), interleukin (IL)-1β, IL-6, and IL-18 are known to activate the stress hormones, creating hyperglycemia and insulin resistance.

Hyperglycemia was reported to impair complement receptor-3 and Fcy receptor–mediated phagocytosis. Defective cellular immunity includes decreased opsonization and response to phytohemagglutinins and poor skin test reactivity. Diabetics also have poor granuloma formation. All these changes are aggravated by microcirculatory failure, which alters the diffusion of both cellular and humoral factors to the affected site. The risk of infection also is enhanced by the presence of peripheral and autonomic neuropathy and peripheral arterial disease (PAD). Obesity is also a risk factor for moderate or severe infection-related morbidity.

Respiratory infections

Respiratory infections in the diabetic population are associated with increased mortality. Diabetic patients are four times more likely to die from pneumonia or influenza compared to nondiabetics. The risk of

TABLE 89.1 **COMMON INFECTIONS ASSOCIATED WITH DIABETES MELLITUS**

Organ system	Type of infections
Respiratory	Pneumonia
	Aspiration pneumonia
	Pulmonary tuberculosis
Head and neck	Mucormycosis
	Invasive otitis externa
Gastrointestinal	Periodontal infections
	Candida esophagitis
	Emphysematous cholecystitis
Genitourinary	Upper and lower urinary tract infections
	Emphysematous cystitis
	Emphysematous pyelonephritis
	Papillary necrosis
	Perinephric abscess
	Fungal urinary tract infection (UTI)
Skin and soft tissue	Superficial infections
	Superficial necrotizing infections
	Deep necrotizing infections
	Diabetic foot infections (mild/moderate/severe)
Nosocomial	Soft tissue
	UTI
	Respiratory tract infections

developing staphylococcal pneumonia is increased since 30% of diabetics are nasal carriers of *Staphylococcus aureus.* Patients with DM have a higher risk of developing pneumonia (*Streptococci*, *Klebsiella, Legionella*) following influenza, so immunization against pneumococcus and influenza is recommended. Patients not vaccinated for pneumococci should be vaccinated with both polysaccharide and conjugated vaccine according to Advisory Committee on Immunization Practices (ACIP) guidelines. The incidence of acute bronchitis, pneumonia, or exacerbation of chronic obstructive pulmonary disease (COPD) is similar in type 1 and type 2 diabetics. Diabetic patients are also prone to aspiration pneumonia, especially in the presence of gastroparesis (occurs in 40–60% of patients with DM). The risk of aspiration also increases with impairment of consciousness (i.e., hypoglycemia, hyperosmolar state).

The incidence of tuberculosis is 16 times higher in the diabetic population than in the nondiabetic population, and atypical locations are common. For this reason, a positive purified protein derivative (PPD) skin test with 10 mm induration is considered positive even with a normal chest radiograph and requires isoniazid (INH) or rifapentine and INH according to current guidelines. Diabetes also predisposes to cavitary lung disease with coccidioidomycosis, and disseminated and extrapulmonary coccidioidomycosis is more common in diabetics. Pulmonary mucormycosis is complicated by fungal vascular invasion and high mortality. These infections require cultures, serology, imaging study, and biopsy for confirmatory diagnosis. Antifungal agents (voriconazole, posaconazole, or amphotericin B) should be initiated early pending the laboratory results.

Mucormycosis

More than three-fourths of cases of rhinocerebral mucormycosis occur in diabetics, particularly in the presence of diabetic ketoacidosis. It is a medical emergency with high mortality if early diagnosis is not made. Mucormycosis is caused by a group of fungi known as *Mucorales*, the most common genera being *Rhizopus, Absidia*, and *Rhizomucor*. These fungi invade nasal and paranasal membranes as well as blood vessels, resulting in thrombosis and tissue infarction. Local spread of infection results in ophthalmoplegia, blindness, cavernous sinus thrombosis, meningoencephalitis, and brain abscesses, leading to rapid death in untreated cases. Patients with mucormycosis may present with facial or ocular pain, nasal stuffiness, generalized malaise, and fever. Periorbital edema, chemosis, and nasal black eschars or necrotic turbinates are common presentation. Diagnosis is made by biopsy of the necrotic eschars and demonstration of nonseptate thick-walled hyphae with special staining. CT scan or MRI can be helpful in assessing the extent of disease and can aid the surgeon in debridement. Treatment with intravenous (IV) amphotericin B, 1 mg/kg/d, or liposomal amphotericin B, 5 mg/kg/d, should be started as soon as possible with surgical consultation for debridement. Posaconazole (800 mg in divided doses) is the oral agent that can be effective in 60% to 70% of patients with zygomycosis. Hyperbaric oxygen therapy also is reported to be beneficial. Those who survive may require reconstructive surgery and long-term psychological counseling due to facial disfiguration. Even with early diagnosis and treatment, mortality with mucormycosis can be as high 50%, but 100% if untreated.

Invasive otitis externa

Invasive otitis externa is an aggressive infection usually caused by *Pseudomonas aeruginosa*. Rarely, the etiologic agent is *Aspergillus, Klebsiella pneumoniae*, or other organisms. More than 90% of patients have diabetes, often with poor metabolic control. Patient usually presents with severe ear pain. Clinically, the disease begins with periauricular cellulitis and granulation tissue at the junction of the cartilaginous and osseous portions of the external auditory canal. When infection spreads, it results in parotitis, mastoiditis, septic thrombophlebitis, cranial nerve palsy, and meningitis. Osteomyelitis of the temporomandibular joint, skull base, and cervical vertebrae can also occur. Facial nerve VII palsy occurs in 30% to 40% of cases and does not necessarily carry a poor prognosis. However, development of palsies of cranial nerves IX and XII implies deep infection. This can be complicated by sinus thrombosis and central nervous system (CNS) infection, which results in death in 30% of patients. The use of MRI or CT scan can help to assess the extent of infection and needed debridement. CT scan is ideal for assessment of bone erosion; MRI was slightly better at demonstrating medial skull base disease due to its ability to delineate changes in the fat content of the marrow. Since bone erosion distinguishes malignant external otitis from external otitis, CT scan is better test for

initial diagnosis, while MRI is better for establishing the extent of disease and monitoring response to therapy.

Parenteral antipseudomonal antibiotic therapy is generally recommended. Combination therapy of β-lactam agents (piperacillin, ceftazidime, cefepime, imipenem, or aztreonam) with or without an aminoglycoside can be used. Oral quinolones can be used if susceptibilities are available. If *Aspergillus* is the causative organism, liposomal amphotericin B needs to be used. Hyperbaric oxygen therapy may have an adjuvant effect.

Widespread use of topical and oral fluoroquinolones for treatment of otitis externa may make the isolation of *Pseudomonas* difficult and has contributed to emergence of *P. aeruginosa* resistant to ciprofloxacin.

Gastrointestinal infections

Periodontal infections are considered the sixth complication of diabetes since 1993 and affect 17.3% of the diabetic population and 9% of the general public. The risk factors for periodontal disease are increase salivary glucose, decrease salivary pH, small-vessel disease, changes in collagen metabolism, and immune changes (i.e., inflammatory cytokines). *Porphyromonas gingivalis* is the most common pathogen. Professional cleaning and local treatment of periodontal infections may be adequate. However, antibiotic treatment is needed if patients develop dental symptoms. *Candida* esophagitis has been reported to occur with increased frequency in diabetic patients and more often in those who receive broad-spectrum antibiotics. The most common presentation is retrosternal pain or dysphagia after the ingestion of cold or hot drinks. Oral thrush can be absent. Endoscopic examination and biopsy are the preferred diagnostic procedures. Treatment with oral fluconazole if no dysphagia (400 mg initial dose, followed by 200 mg/d) is necessary for a minimum of 3 weeks or at least for 2 weeks after resolution of symptoms. An alternative therapy is itraconazole, 100 mg swished in mouth daily for 3 weeks. Oropharyngeal infection can be treated with itraconazole, 200 mg swished in mouth daily for 1 to 2 weeks. Infections with resistant *Candida* spp. also respond to voriconazole intravenously or orally or caspofungin intravenously. Success of treatment may depend on strict diabetic control.

Emphysematous cholecystitis is a surgical emergency, characterized by gas production in or around the gallbladder. The infection is highly virulent and often induced by multiple pathogens; among the most common are *Clostridia* (50–70%) and gram-negative bacilli such as *Escherichia coli* and *Klebsiella*. Other common organisms reported are *Salmonella enteritidis, Campylobacter*, and *Bacteroides fragilis.* This infection is predominantly seen in diabetic male patients (70%) and is associated with gallbladder gangrene (74%) and perforation (21%). Gallstones are present in half of these patients. Diagnosis requires serial x-ray examinations or CT scan. Treatment requires high-dose parenteral broad-spectrum antibiotics aimed at both anaerobic and gram-negative bacteria (imipenem or piperacillin-tazobactam), together with prompt surgical intervention. There is high mortality even with early diagnosis (15–25%).

Urinary tract infections

Diabetic female patients have a two- to fourfold higher incidence of bacteriuria. Diabetic women are at risk to develop recurrent asymptomatic bacteriuria, which in general is benign and seldom permanently eradicable. Treatment of asymptomatic bacteriuria is not recommended since the outcome does not change and chances of a patient colonized with resistant organism is increased. Diabetic patients have a higher prevalence of developing nosocomial urinary tract infection (UTI) and a higher risk of developing pyelonephritis. Predisposing factors are the presence of neurogenic bladder, uncontrolled diabetes and glycosuria, recurrent vaginitis, renal disease, and urologic instrumentation.

Emphysematous cystitis is often the result of infection with *E. coli* or other Enterobacteriaceae. More than 80% of DM patients present with pneumaturia. Gas in the urinary bladder wall and the collection system may be seen on either plain x-ray or CT scan studies. The disease usually responds to antibiotics targeting the Enterobacteriaceae.

Emphysematous pyelonephritis is a life-threatening suppurative infection of the renal and perirenal tissue. It occurs predominantly in diabetic patients (70–90%), more often in women. The disease is usually unilateral, more often affecting the left kidney. More than 40% of cases have underlying urinary tract obstruction; *E. coli* is the predominant isolated organism (70%). Patients present with fever, chills, flank pain, confusion, and often sepsis. Thrombocytopenia, cognitive changes, and proteinuria are independent risk factors for poor outcome. Patients present with fever of unknown origin, and the diagnosis is made by demonstration of gas on plain x-ray film or CT scan of the abdomen. Treatment usually requires a combination of surgical intervention, removal of urologic obstruction when present, and frequently unilateral nephrectomy and antibiotic therapy. Rarely the emphysematous cystitis can coexist with emphysematous pyelonephritis, and this condition has a mortality rate as high as 50%. Survival rate is >90% in patients who have both surgical and antibiotic treatment versus 25% in cases treated with antibiotics alone.

Papillary necrosis can occur as a complication of emphysematous pyelonephritis or as an isolated entity. More than 50% of cases are described in diabetic patients. Other cases are analgesic abuse, sickle cell disease, and urinary tract obstruction. Many patients present acutely with fever, ureteral colic, microscopic or macroscopic hematuria, and pyuria, with renal failure developing in 50% of cases. Some patients have an indolent presentation and may pass sloughed papillary tissue in the urine. Diagnosis can be made by renal ultrasound. However, the test of choice is retrograde pyelography. For patients who present with obstruction and do not pass the detached papilla spontaneously, surgical removal is indicated through cystoscopy with ureteral instrumentation.

Perinephric abscess should be suspected in patients who present with "pyelonephritis" but who have a poor response to 4 or 5 days of IV antibiotic therapy. One-third of cases are described in diabetic patients who present with pyuria, moderate fever, and a mass over the affected kidney (50% of cases). Among the gram-negative organisms, *E. coli* is the most common isolate, and ascending

infection is the usual route of spread. The diagnosis requires use of renal ultrasound, CT, or MRI studies, which also can help exclude ureteral obstruction. Surgical drainage is mandatory (open surgery or percutaneous catheter placement) in combination with IV antibiotics.

Fungal UTIs occur with increased frequency in the diabetic population, especially after long-term broad-spectrum antibiotics or Foley catheter placement. Most of the patients have asymptomatic candiduria and are afebrile. Elderly females with candiduria and UTI symptoms should be evaluated for yeast or atrophic vaginitis. However, severe infections complicated with fungus ball formation, obstruction, and sepsis have been reported. For this reason, all asymptomatic (presumably colonized) patients should be carefully observed for any signs of deterioration. Development of fever or azotemia must be investigated for possible ureteral obstruction, renal involvement, or disseminated fungal disease. Quantitative colony counts of only 10,000/mL of yeast in the urine may be sufficient to cause disease. Among the most common isolates are *Candida albicans, C. tropicalis*, and *C. glabrata*. Antifungal agents according to susceptibilities should be used. Patients who have evidence of obstruction will require urological intervention.

Skin and soft tissue infections

Superficial infections are often caused by *S. aureus*, which commonly colonizes the nasal mucosa and skin of diabetic patients. The most common soft tissue infections reported in the diabetic population are impetigo, carbuncles, cellulitis, folliculitis furuncles, necrotizing fasciitis, septic bursitis, and subcutaneous abscesses. Elimination of *S. aureus* carrier state require use of bacitracin ointment to the nares and oral administration of rifampin, Bactrim, or minocycline (two drugs in combination). Recurrent abscesses require drainage and antibiotic therapy.

Superficial necrotizing infections

Crepitant (anaerobic) cellulitis is a superficial process produced by multiple organisms, most often anaerobes. Infection is seen more frequently in diabetic patients with chronic, nonhealing, lower extremity ulcers. Crepitus is present on palpation because of subdermal and subcutaneous gas dissection. Treatment of this infection requires appropriate parenteral antibiotics and surgical debridement. Necrotizing fasciitis occurs when infection spreads along the superficial fascial planes without muscle involvement. This is a mixed infection (type I variant) that is present in 90% of cases caused by aerobes and anaerobes (e.g., *Streptococcus pyogenes*, *Bacteroides species*, *Enterococcus* species, *Peptostreptococcus, E. coli, Proteus*). Group A streptococci either alone or in combination with *S. aureus* (type II variant) is present in 10% of cases. Group B streptococci–induced necrotizing fasciitis has also been reported. This potentially lethal infection frequently presents with cutaneous necrosis, suppurative fasciitis, vascular thrombosis, and extreme systemic toxicity. In the later stages of the infection, destruction of the small nerve fibers results in patchy area of skin anesthesia. Necrotizing fasciitis early in its evolution is clinically indistinguishable from other soft tissue infections. The most affected sites are upper and lower extremities, perineum, groin, and thorax. Mortality rate is 30% to 70% if diagnosis is delayed. Management requires thorough debridement and drainage, using the "filleting procedure," and broad-spectrum antibiotics (i.e., Zosyn, imipenem). The subcutaneous tissue is left open, and irrigation with normal saline or Ringer's lactate solution is performed. Many patients require repeated debridement followed later by reconstructive surgery. Infection produced by *S. pyogenes* is often complicated by toxic shock syndrome. It should be treated with penicillin and clindamycin in combination with debridement. IV immunoglobulin (IVIG) is used in severe cases.

Deep necrotizing infections

Necrotizing cellulitis (nonclostridial myonecrosis) is produced by the same bacteria responsible for necrotizing fasciitis. This form of infection occurs most commonly in diabetic patients (75%) and involves the muscle, skin, fat, and fascia. Necrotizing fasciitis of the male genitalia (Fournier's gangrene) is associated with diabetes in 40% to 60% of cases. Infection can also affect the abdominal wall or perineum, especially after surgery, penetrating trauma, or instrumentation. Treatment requires coverage of both aerobic and anaerobic pathogens and should cover *S. aureus*, gram-negative enteric organisms, *E. coli, Proteus, Bacteroides fragilis*, and *Enterococcus* species. All patients need to have aggressive debridement, resection of the necrotic muscle, hyperbaric oxygen, and supportive therapy.

Clostridial myonecrosis, if present, requires aggressive surgical debridement and appropriate antimicrobial therapy.

Diabetic foot infection is responsible for 20% of hospital admissions and a frequent precursor of amputations. Predisposing factors are peripheral neuropathy, PAD, immunopathy, and history of a previous ulcer. The severity of diabetic foot infection can vary from mild and superficial (often monobacterial, caused by *S. aureus* or *Staphylococcus epidermidis*) to severe deep infection. Tissue gangrene is usually induced by polymicrobial (mixed aerobic and anaerobic) infections. The MRI study is used to make the diagnosis of bone involvement and also to delineate the extent of bone resection necessary to treat osteomyelitis. Clinically, a probe to bone can be suggestive of osteomyelitis. If any patient has diminished or absent peripheral pulses, arterial Doppler (with both pressure and wave form studies) and/or transcutaneous oxygen tension (TcPo2) are needed. An ankle brachial index of <0.80 mm Hg or a $TcPO_2$ of <40 mm requires vascular consultation.

Mild infections without systemic symptoms can be treated with oral antibiotics (Augmentin, quinolones, or first-generation cephalosporins) and require close follow-up at 48 to 72 hours. If parenteral therapy is considered, cefazolin or vancomycin (methicillin-resistant *S. aureus* [MRSA] suspected or colonized) may be used for presumed monobacterial infection. Moderate nonlimb–threatening infections require local debridement and parenteral antibiotic therapy with a broader coverage. The empiric therapy

can be altered based on culture results of biopsy, ulcer curettage, or aspiration (Table 89.2). No systemic treatment should be done unless a wound is infected. For soft tissue infection, duration of therapy should be based on the clinical outcome. Limb-threatening infections (extensive cellulitis, deep ulcer, plus lymphangitis and/or osteomyelitis) may require broad coverage (piperacillin-tazobactam, imipenem, or meropenem). Surgical debridement should be done promptly. Bone infection may require extirpation of the affected bone or amputation. Preservation of the ambulatory capacity should be considered. The intraoperative culture should be used to guide the choice of antibiotic therapy. Following surgery, duration of treatment should be guided by an estimate of residual infection. Long-term (6 weeks) of treatment is recommended for residual osteomyelitis. Therapeutic goals are achievable by IV followed by oral antibiotics. Oral antibiotics are available that achieve therapeutic levels in bone. Studies support the use of oral antibiotics to achieve similar therapeutic results when compared to parenteral therapy for chronic osteomyelitis. Therefore, the risks and cost of parenteral antibiotics can be avoided. There is no evidence that antibiotic therapy of longer than 4 to 6 weeks improves the outcomes compared to shorter regimens.

Nosocomial infections affecting skin/soft tissue, the urinary tract, and the respiratory system are common in diabetic population, and 50% of organisms isolated from diabetic foot ulcers are MRSA. Vancomycin-resistant enterococci (VRE), diphtheroids (group JK), and *Pseudomonas* are also common pathogens. Culture-guided antibiotics selection is recommended. Management of these infections may require use of newer antibiotics such as linezolid

TABLE 89.2 **SUGGESTED EMPIRICAL ANTIBIOTIC REGIMENS, BASED ON CLINICAL SEVERITY, FOR DIABETIC FOOT INFECTIONS**

Route and agent(s)	Mild	Moderate	Severe
Advised route	Oral for most	Oral or parenteral, based on clinical situation and agent(s) selected	Intravenous, at least initially
Dicloxacillin	Yes	–	–
Clindamycin	Yes	–	–
Cephalexin	Yes	–	–
Trimethoprim–sulfamethoxazole	Yes	Yes	–
Amoxicillin/clavulanate	Yes	Yes	–
Levofloxacin	Yes	Yes	–
Cefoxitin	–	Yes	–
Ceftriaxone	–	Yes	–
Ampicillin/sulbactam	–	Yes	–
Linezolid[a] (with or without aztreonam)	–	Yes	–
Daptomycin[a] (with or without aztreonam)	–	Yes	–
Ertapenem	–,	Yes	–
Cefuroxime with or without metronidazole	–	Yes	–
Ticarcillin/clavulanate	–	Yes	–
Piperacillin/tazobactam	–	Yes	Yes
Levofloxacin or ciprofloxacin with clindamycin	–	Yes	Yes
Imipenem–cilastatin	–	–	Yes
Vancomycin[a] and ceftazidime (with or without metronidazole)	–	–	Yes

Definitive regimens should consider results of culture and susceptibility tests as well as the clinical response to the empirical regimen. Similar agents of the same drug class may be substituted. Some of these regimens may not have US Food and Drug Administration approval for complicated skin and skin-structure infections, and only linezolid is currently specifically approved for diabetic foot infections.

[a] For patients in whom methicillin-resistant *Staphylococcus aureus* infection is proved or likely.

(MRSA, VRE), daptomycin (MRSA, VRE), oritavancin, telavancin, and others.

Overall, because patients with DM have a high incidence of chronic kidney disease, adjustment of the antibiotic dose based on renal function is imperative. Drug interaction and toxicity should be always considered prior to therapy since these patients are frequently on multiple medications.

Infectious complications in the injection and non-injection drug user

Carlo Contoreggi

Drug abuse is a widespread public health problem and many of its medical complications are infectious due to the transmission of blood-borne, environmental, and respiratory infectious agents. The ongoing opioid epidemic has changed the face of addiction in the United States and Canada; this has resulted in more published data characterizing the medical complications associated with substance abuse in both non-injection and injecting drug users (DUs/IDUs). According to the US Centers for Disease Control and Prevention (CDC) *Morbidity and Mortality Weekly* (2016), there has been a five-fold increase in opiate-related deaths (from both prescription and street opiates, such as heroin and fentanyl) from 1999 to 2014. This reflects the catastrophic nature of the epidemic and its expanding effects on society as a whole.
As before, DUs/IDUs are less likely to access care and maintain adherence for optimal benefit of treatments. Recent studies find that social and access factors related to criminalization and economic status are major barriers to care, including highly active retroviral therapy (HAART) for HIV-positive individuals. Increasing treatment options and societal acceptance of harm reduction efforts have been demonstrated to improve outcomes in countries that have undertaken them.

Endocarditis

The most serious infectious complication in the injection user is endocarditis. This is a life-threatening infection of the heart valves and/or endocardium associated with septic parenteral injections. Right-sided valvular infections are very frequent in IDUs due to septic inoculations. Intravenous (IV) injections increase the susceptibility of right-sided valvular and other structures to infection. Concurrent pulmonary hypertension from drug adulterants, such as talc, may also predispose to right-sided disease.

Despite the high prevalence of endocarditis, the offending pathogens are not specific to injectors. *Staphylococcus aureus*, often methicillin-resistant (MRSA), is the most commonly identified organism, but other pathogens are seen. These include *Pseudomonas*, *Serratia*, *Enterococci*, *Streptococcus* groups A and B, and *Streptococcus viridans*. Increasingly, fungal pathogens are seen with and without immunodeficiency.

Clinical diagnosis of endocarditis in the drug abuser can be difficult. The hallmark symptom is fever. Other constitutional symptoms such as chills, sweats, and arthralgia are less specific as they are commonly observed in opiate withdrawal. The physical signs associated with left-sided endocarditis are seldom present. Coexistent HIV-1 immunodeficiency (non- or poor adherence with HAART) appears to predispose to more severe systemic infections.

Because clinical diagnosis alone presents challenges, echocardiography is the primary method by which to diagnose and monitor endocarditis treatment. Blood cultures and other routine tests are used to identify pathogens and antimicrobial sensitivities. Transthoracic and transesophageal echocardiography are used to evaluate suspected endocarditis (e.g., high clinical suspicion but negative blood cultures). Detection of

valvular vegetations, valve disease with hemodynamic compromise, associated intraventricular shunts, or abscesses, or the presentation of patients with persistent fever, continued bacteremia, or clinical deterioration may mandate serial testing.

Therapy should be multidisciplinary as patients may be unwilling to comply with adequate treatment regimens especially if inpatient hospital stays and serial testing are required. Combination short-course IV followed by oral therapy may be considered. Left-sided disease, large vegetations, or presence of cardiovascular compromise mandates more intensive therapy. Medication selection is an evolving science, and isolation of pathogen and discovering drug sensitivities are critical in this respect. Mortality with right-sided disease is low; the presence of left-sided valvular and/or chordae tendineae involvement, fungal pathogens, congestive heart failure, other cardiovascular compromise, vegetations of >20 mm, and HIV-1 (ineffective treatment w/HAART) with immune compromise all greatly increase morbidity and mortality. Inflammatory myocarditis can be seen independently of and with endocarditis. Causation is multifactorial; cocaine, HIV-1 infection, and inflammatory responses from adulterants in drugs are common causes.

Pulmonary infections

Complications due to IV drug use include pneumonia, aspiration pneumonitis, lung abscess, and septic pulmonary emboli. Talc contamination of the injected drugs enters the bloodstream and lodges in the pulmonary capillary bed, causing foreign-body granulomatosis that results in pulmonary fibrosis, acute inflammatory pneumonitis, and pulmonary hypertension. Septic pulmonary emboli may result in clinically evident ventilatory and perfusion mismatch on scintigraphic imaging.

Chronic inhalation of drugs and their adulterants will accelerate alveolar destruction and result in early-onset chronic obstructive pulmonary disease (COPD) and emphysema. Chronic immunosuppression from HIV increases likelihood of pneumonitis, community and immunocompromised pneumonia, and other respiratory disorders. Chronic smoking of opiates and cocaine is often associated with COPD. Smoking (nicotine/marijuana) may result in decreased vital capacity, a decrease in diffusion capacity, and small airway disease. IDUs also have a 10-fold increased risk of community-acquired pneumonia compared to the general population due to failure to vaccinate, the destructive action of marijuana/tobacco abuse, and increased susceptibility to viral and bacterial exposures.

Neurologic complications

Multiple serious neurologic complications are associated with drug abuse, most commonly with injection use. Neurologic disease often compounds underlying drug use–related pathology. Endocarditis is associated with ischemic stroke, encephalitis, cerebral hemorrhage, and brain abscess. A non-IDU/DU population with endocarditis was found to have about a 15% chance of a neurologic complication of stroke, encephalitis, and hemorrhage often with long-lasting residual deficits, and one would expect frequency and severity of complications to be higher in more medically compromised groups.

Bone and joint infections

According to Jicha et al., osteomyelitis and associated septic arthritis from disseminated cutaneous infection are the second most common drug use infections. Direct injection at or near the affected area as well as systemic bacterial seeding is common. Gram-positive organisms and *Pseudomonas aeruginosa* are the most commonly implicated organisms. Osteomyelitis most commonly affects the fibrocartilaginous joints such as the vertebral, sternoarticular, and sacroiliac joints. In addition to bacterial infections, fungal infections are increasingly described in both immunocompetent and immunodeficient hosts (i.e., diabetics, end-stage renal disease, HIV, and cancer). Treatment protocols do not differ from other immunosuppressed hosts; bone or joint cultures are necessary for accurate diagnosis. Compliance with long-term therapies poses additional problems with adherence in the DUs/IDUs.

Skin and soft tissue infections

Septic parenteral injections frequently lead to skin and soft tissue infections. Infectious and chemical thrombophlebitis, abscesses, and cellulitis are common venous insults. Life-threatening cutaneous infections include fasciitis, myonecrosis, and gangrene. Tissue crepitans, extensive cellulitis, evidence of systemic toxicity, severe pain, and sepsis suggest serious and life-threatening infections. Plain radiographs may be helpful, although MRI is optimal to determine the extent of soft tissue, bone, and marrow involvement.

Injected drugs and their adulterants often damage veins. Progressive venous sclerosis is common. With loss of peripheral access, deeper and more dangerous sites (i.e., femoral, axillary, jugular, penile, and mammary veins) may be used. More serious infections, thrombosis, and gangrene can result from injections at these sites.

Once IV access is less accessible, many substance abusers will administer drugs subcutaneously. Staphylococci and streptococci are frequent pathogens. However, with immunosuppression, other bacterial pathogens are encountered. *Escherichia coli, Klebsiella, Bacteroides*, *Clostridia*, and mixed flora consisting of both aerobic and anaerobic organisms as well as fungal organisms such as *Candida* are seen.

Small localized infections can be treated locally with or without systemic antibiotics. Severe infections should be managed with surgical debridement and inpatient antibiotic therapy.

Viral hepatitis

The opiate crisis of the past decade has markedly changed the epidemiology of hepatitis infections. Hepatitis A, B, C, and D (HBV, HCV, and HDV), respectively are associated with fecal–oral (HAV), parenteral, and sexual transmission (HBV, HCV, and HDV). The incidence of HBV and HCV in IDU populations is very high worldwide, with a significant proportion showing coinfection with both HBV and HCV.

Chronic HBV infection is associated with persistent hepatitis B surface antigen (HBsAg) and hepatitis Be antigen (HBeAg), although presence of hepatic inflammation varies widely. Positive HBeAg is associated with increased infectivity, more severe disease, and eventual cirrhosis. The HBV virion itself is not cytotoxic but mediates a host cytotoxic T-cell response that causes hepatocellular inflammation and necrosis. Coinfection with HIV-1, with its associated cellular immune deficiency, reduces the severity of the host immune response. Progressive HIV-1–associated cellular immunodeficiency can reduce hepatic inflammation and lowers serum transaminase concentrations. Other serologic measures of HBV infection in HIV-1 are not diminished.

HDV, or delta particle infection, is also common. This infection, which requires coinfection with HBV, imparts a more severe course than HBV alone. Coinfection with HBV and HDV is associated with increased incidence of fulminant hepatic failure. Vaccination with HBV vaccine also prevents HDV infection.

Therapeutic interventions for HCV have markedly improved over the past 5 years with the advent of multimodal antiviral therapies. Greater than 95% of patients w/HCV can be cured with a single course of therapy. Failure to treat DUs and IDUs increases morbidity and lethality in mid to later adulthood. In addition there is increasing evidence that IDU patients who have been successfully treated with antiviral medications may become reinfected with continued injection behaviors. Statistics are now emerging that, although reinfection appears infrequent, this may increase.

Interventional dynamic modeling of HCV infections in Switzerland found that aggressive treatment with antiviral therapy of ≥10% of the IDU HCV-infected pool per year would result in a >99% reduction in total cases by 2030. Discontinuation of injection use removes these individuals from the HCV dissemination pool. As with most other medical conditions that affect the DUs/IDUs, integration of medical treatment with effective substance abuse and psychiatric care improves efficacy while improving the overall quality of life. Individuals stabilized with opiate substitution therapy (i.e., methadone or buprenorphine) can show sustained clinical responses/disease eradication comparable to non–drug-abusing populations. This presents a rational public health direction to alleviate HCV in drug users in North America.

Despite improvements in therapy of patients with hepatitis C, substance abuse, alcohol abuse, and comorbid psychiatric disorders are major barriers to achieving improvement and disease remission. There remains considerable debate on the ethics of performing liver transplants in patients with alcohol and drug abuse. When organ recipients significantly outnumber available cadaver organs, many transplant groups routinely disqualify patients with substance abuse from consideration. However, the increasing the number of living donor transplants has increased availability and reduced the morbidity and mortality of chronic liver disease and liver failure; it is unclear how these procedures will impact drug users.

Immunologic abnormalities

Opiate receptors (μ-, κ-, δ-, and ζ-opioid receptors) are found in the central nervous system (CNS), spinal cord, and immune elements. Widely distributed in CNS glial/immune cells, they are also widely found in peripheral immune tissues and the digestive tract. A main function of ζ-receptors, also called *opioid growth factor receptors*, is modulating immune cellular growth, development, and immune regulation. Opiate ligands (endogenous or pharmacologic) have affinity to the ζ-receptor and the μ-receptor, as well as affinity to other immune regulatory receptors (Toll-like receptor 4 [TLR-4], nitric oxide [iNOS], and glutamate receptors). All of these regulate inflammation, apoptosis, and neoplastic proliferation. Exogenous opiate concentrations can activate or deactivate these receptors as full agonists, antagonists, or inverse agonists. Immune modulation on a molecular level by opiates has been studied for decades. In vitro, in vivo, and, increasingly, limited clinical studies have shown that low doses of the μ-, and ζ-opioid receptor antagonist naltrexone may have important albeit limited beneficial effects in immune disorders (inflammatory bowel disease, multiple sclerosis, and fibromyalgia). The molecular actions of opioids in these immune regulatory pathways in opiate abusers are largely unknown and will require further investigation.

Opiate abusers show subtle abnormalities in serum immune marker activation/immune responsivity independent of HIV and other retroviral/systemic infections. In vitro measures of cellular immunity can show diminished cellular cytotoxic/killer cell action and decreased cytokine and immune cell signaling. Natural killer (NK) cell and cytotoxic T-cell (CTL) functions are impaired. Drug users can also show abnormalities in circulating immune factors including elevated plasma immunoglobulins, especially the immunoglobulins M (IgM) and G (IgG); false-positive rheumatoid factor and syphilis serology; febrile agglutinins; acute phase reactants; and complement fixation tests. Cellular immunity abnormalities are evident in both the DU/IDU, with the IDU often more severely affected. HIV-1 antibody-negative parenteral opiate abusers may have elevated total T-lymphocyte counts as well as increases in both T-helper and T-suppressor cells. Injection behaviors increase HIV susceptibility. Measures of cellular immunity show diminished function. Cellular immune functions are essential for host recognition of pathogens and for immune stimulants such as those in vaccines. Without intact cellular immunity, future HIV-1 vaccine efficacy may be decreased in active DUs/IDUs.

Effective substance abuse treatment with discontinuation of septic injections may restore immunocompetence. Immune studies of patients maintained on methadone show some reversal of immune dysfunction after discontinuation of IV injections. The durability of these improvements especially with aging is unknown.

Tuberculosis

Tuberculosis remains a significant global health problem. Mycobacterium tuberculosis (TB) remains endemic in vulnerable, chronically ill, and marginalized populations (i.e., IDUs, the HIV-1 infected, prisoners, the homeless, and alcoholics). Other important risk factors for TB infection include diabetes, malnutrition, and smoking; these risk factors are supra-additive. TB is a highly virulent pathogen that infects both immunocompetent and immunodeficient individuals. Coinfection of TB and HIV-1 is present in a significant number of new TB cases. In those infected with HIV-1, TB primarily shows pulmonary involvement early, whereas with progressive immunosuppression, disseminated extrapulmonary TB is not uncommon.

Immune deficiency is due to both impaired humoral and cellular immunity. Antigen presentation from monocytes, NK, CTL, macrophages, and Th-1 to Th-2 cells is impaired, resulting in defective antibody production. Critically, suppression of immune competence due to heightened anti-inflammatory cytokine production (IL-10) can suppress the immunity in the infectious microenvironment. Other cytokines (interferon [IFN]-γ, interleukin [IL]-12, tumor necrosis factor [TNF-α]) can either enhance or partially negate localized immunosuppression action(s). Susceptibility to TB can also be increased by direct pharmacologic actions of drugs of abuse; opiates, as noted previously, can have immune-suppressive effects as can nicotine. Persistent localized (bronchoalveolar) and systemic inflammation can also render a host more susceptible to infection. It is likely that more frequent parenteral injections and exposure to immunosuppressive opiates/other drugs of abuse and adulterants increases an injector's risk to active TB.

All HIV-1–infected IDU patients should be tested for TB as early in the course of their disease as possible because the first several years post seroconversion show peak infection rates. Patients should be tested for TB every 6 months or if clinical symptoms dictate. Previously untreated individuals with past exposure to TB as evidenced by positive tuberculin skin test (TST) with positive purified protein derivative are at high risk for recurrence of latent infection with progressive immunodeficiency. Positive results for the TST in immunocompetent individuals is induration of at least 15 mm, 10 mm for the IDU, and 5 mm for HIV-positive patients. Anergic responses are common in these populations, though there is no clear consensus for additional testing. Immunocompromised hosts who are TST positive and recently exposed to TB should receive prophylaxis, as should anergic individuals with known environmental exposure or patients who are at high risk. If compliance with TST is poor, chest radiography of high-risk individuals has been demonstrated to increase disease detection.

Fungal infections

Fungal pathogens infect in the setting of moderate to severe immunosuppression, with CD4 counts in the 250/mm^3 to 100/mm^3 range. Invasive *Candida* infections are commonly seen as vaginitis in mild to moderate immunosuppression; oropharyngeal and invasive esophageal candidiasis is seen in moderate disease. Systemic colonization and CNS infection is seen with profound immunodeficiency. Fungal endocarditis requires more intensive pharmacotherapy and carries higher morbidity and mortality in the general population and in the DU/IDU.

Opportunistic viral infections

Herpes simplex virus, varicella-zoster virus, cytomegalovirus, and Epstein–Barr virus are common viral pathogens seen with immunosuppression. Varicella-zoster vaccination should be considered especially in patients in their sixth decade, although an incomplete/anergic response should be considered.

Conclusion

The integration of substance abuse treatment with primary and specialized care for infectious diseases, immunodeficiency, psychiatric, and other medical conditions is most effective for clinical outcome and cost of care. Addiction is a brain disease with neurochemical underpinnings disrupting decision-making, cognition, emotional control, motivation, drug abuse, sexual drive, and impulsivity. Impaired executive functioning limits adherence with therapy. A provider's acceptance of these patients is critical for successful management; many providers have difficulty with these patients, thus a team approach may be most effective for care delivery.

Buprenorphine is a μ, κ mixed agonist/antagonist opiate and a more acceptable alternative to methadone. It is widely available and can be administered in more convenient settings (i.e., doctors' offices). Buprenorphine has achieved increased financial coverage through private insurance, Medicaid, and other social services, which improves treatment availability and adherence. Therapeutic constraints can influence treatment options for comorbid medical conditions, such as prescribing oral instead of IV antibiotics, diagnostic testing, and duration of therapy. The incidence of comorbid psychiatric conditions such as affective disorders, thought disorders such as schizophrenia, schizo-affective disorders, and posttraumatic stress disorder is high and can limit treatment efficacy. Access to social workers, mental health professionals, and specialized providers who can coordinate complex services improves outcomes.

Societal realization and acceptance of harm reduction strategies have made additional treatment options more accessible to more substance users. These programs have been effective in Europe and Canada. However proposed changes in US federal government policies are inconsistent; there are potential reversals on treatment availability and harm reduction which seriously endanger efforts to reduce drug use and its associated morbidity and mortality. That said, prison and sentencing reforms for nonviolent drug offenders have been enacted. Political policies can undermine public health concerns; the experience in Indiana in 2015 exemplifies this. Over the course of months, the incidence of HIV infection spiked in IDUs. Attempts to introduce and expand harm reduction efforts,

especially needle exchange, were politically blocked by the governor and the legislature. The failure to implement a timely response resulted in hundreds of unnecessary HIV infections with the consequence being increased morbidity and eventually medical costs.

The demographics of opiate epidemic have changed; previously DUs/IDUs were older, often people of color, from the inner city, and of lower socioeconomic status (SES). Now a broader spectrum of individuals is affected. Rural outstrips urban areas in some geographic regions. The majority of injection users are no longer from minority groups. Younger individuals from higher SES backgrounds are nearly as likely as more disadvantaged groups to begin to abuse opiates and inject drugs. Injection heroin use is increasing along with prescription opiate abuse in younger addicts. Adulterated drugs are common, with exceptionally high-potency opiates such as fentanyl contributing to climbing numbers of overdose deaths.

There is a serious deficiency of gender-specific data, which are critical in delivering effective therapies and treatment interventions. Male IDUs outnumber females by approximately 4 to 1 but research relevant to harm reduction, transmitted blood-borne viral and sexually transmitted infections, endocrine dysfunction, injection-related complications, mental health, and physical and sexual violence has rarely been addressed in women. Gender equity and basic human rights are in question, with the need to refine approaches to address the high morbidity associated with gender disparities. Recognition of the special vulnerabilities of women is critical to effectively address harm reduction and disease complications and progression.

The Affordable Care Act of 2010 ("Obamacare") along with Medicaid expansion made access to treatment greater, but with increasing opiate abuse in both urban and rural areas, the availability of care is often limited. These changes are now in political danger with reversals to the policies of the 1980s and 1990s becoming more likely. Healthcare is a basic human right, and it is critical for successful drug abuse treatment and associated acute and chronic comorbid medical conditions. The challenges in treating this population are changing but are no less important for overall public health. Integrating treatment and care with a more diverse population offers new challenges. Clinicians must better tailor care and treatment to alleviate this ongoing crisis.

Infections in the alcoholic

Laurel C. Preheim and Manasa Velagapudi

Approximately 18 million adults in the United States meet criteria for alcohol use disorders (AUD). The National Institute on Alcoholism and Alcohol Abuse (NIAAA) has provided a definition of low-risk drinking. Alcohol use above these limits is associated with increased risk for AUD or its associated health complications. For women, low-risk drinking is defined as no more than 3 drinks on any single day and no more than 7 drinks per week. For men, it is defined as no more than 4 drinks on any single day and no more than 14 drinks per week. NIAAA research shows that only about 2 in 100 people who drink within these limits have AUD.

Patients with AUD have an increased susceptibility to bacterial infections such as pneumonia, tuberculosis (TB), peritonitis, and bacteremia. They are also more likely to develop viral hepatitis and HIV disease. Acute and chronic alcohol ingestion exerts direct and indirect effects on host defenses against infection (Box 91.1). Alcohol consumption has been shown to alter the microbial communities of the gastrointestinal tract and the respiratory tree, including the oropharynx, mainstem bronchus, and lower bronchoalveolar spaces. The role of these changes in the microbiome and their influence on the immune response is under intensive investigation. Some studies suggest that the immunotoxic effects of ethanol are due to direct cytotoxicity and to a shift in the balance of cytokines produced from the pro-inflammatory to more immunoinhibitory products. However, the adverse effects of ethanol itself may be indistinguishable from those due to concomitant alcoholic liver disease and other conditions related to AUD, including malnutrition, poor hygiene, adverse living conditions, and abuse of tobacco and other drugs. This discussion includes infections associated with increased frequency or severity in these patients (Box 91.2). Antibiotic suggestions are made according to current treatment guidelines, but therapeutic decisions should always be made with the knowledge that alcoholic liver disease can interfere with the metabolism and excretion of certain agents and that some antimicrobials can cause or exacerbate hepatic dysfunction.

Pneumonia

Bacterial pneumonia usually follows aspiration of oropharyngeal flora into the lungs. Severe intoxication is associated with altered consciousness and a diminished cough reflex. Elevated ethanol levels can interfere with cilial function on the surface of respiratory epithelial cells. Most patients with AUD also smoke cigarettes, which further impairs mucociliary defenses against infection of the respiratory tract. The most frequent bacterial causes of pneumonia in alcoholics include *Streptococcus pneumoniae*, anaerobes, aerobic gram-negative bacilli, and *Haemophilus influenzae*.

Standard diagnostic approaches are used to evaluate alcoholic patients who exhibit signs or symptoms of pneumonia. Organisms seen on sputum Gram stain often can help guide empiric antibiotic therapy. In addition to obtaining sputum and blood cultures, any significant pleural fluid visible on chest radiographs should be sampled for appropriate stains and cultured for aerobic and anaerobic organisms. Serum procalcitonin may be elevated, and urinary antigen testing for *Legionella* and pneumococcus should be considered.

BOX 91.1

Immunodefects and alcohol use disorders

Microbiome alterations (dysbiosis and/or overgrowth)
- Gut (small and large intestine)
- Respiratory tract (oropharynx, mainstem bronchus, alveoli)

Mechanical defects (lung)
- Diminished cough reflex
- Impaired glottal closure
- Lung atelectasis due to ascites
- Decreased ciliary function

Mechanical defects (gut)
- Increased intestinal permeability

Humoral immunity
- Increased serum immunoglobulins
- Decreased alveolar IgG subclasses
- Decreased complement activity
- Decreased serum bactericidal activity

Cell-mediated immunity
- Decreased skin test reactions
- Decreased numbers of T lymphocytes
- Alterations in T-lymphocyte subsets
- Altered cytokine production
- Decreased suppressor cell activity
- Decreased lymphocyte mitogenic response
- Decreased natural killer cell function
- Altered antigen presentation by macrophages and dendritic cells

Phagocytes
- Granulocytopenia (rare)
- Decreased granulocyte chemotaxis
- Decreased granulocyte bactericidal activity
- Decreased macrophage phagocytosis
- Decreased macrophage bactericidal activity

Abbreviation: IgG = immunoglobulin G.

BOX 91.2

Infections in alcoholics

Bacterial pneumonia
- *Streptococcus pneumoniae*
- Anaerobes
- *Klebsiella pneumoniae*
- *Haemophilus influenzae*

Tuberculosis

Spontaneous bacterial peritonitis
- *Escherichia coli*
- *K. pneumoniae*
- *S. pneumoniae*

Bacteremia
- *E. coli*
- *S. pneumoniae*
- *Streptococcus pyogenes*
- *Clostridium perfringens*
- Non-01 *Vibrio cholerae*
- *Vibrio vulnificus*
- *Salmonella*
- *Bartonella quintana*

Endocarditis
- Gram-negative bacteria
- *S. pneumoniae*
- **Meningitis**

Pancreatic abscess

Hepatitis B and C

HIV infection and AIDS

Abbreviations: HIV = human immunodeficiency virus; AIDS = acquired immunodeficiency syndrome.

Because the severity of bacterial pneumonia is increased in patients with AUD, hospitalization for parenteral antibiotic therapy is usually indicated. The length of hospital stay and the need for intensive care units are likely to be higher, and the expected mortality rate is greater than twice that for nonalcoholics.

Pneumococcal pneumonia

Streptococcus pneumoniae, or pneumococcus, remains the most common cause of both community-acquired bacterial pneumonia and bacterial meningitis in adults. Outbreaks of pneumococcal pneumonia have occurred among residents of shelters and prisons, where close proximity enhances the risk of transmission. Patients with AUD have the usual signs and symptoms of pneumococcal pneumonia, including a sudden onset, often with a single shaking chill, fever, and subsequent productive cough. Secondary complications, including acute respiratory distress syndrome (ARDS), empyema, and bacteremia, are common in alcoholics, particularly those with liver disease. Despite appropriate therapy, the reported overall mortality for adult bacteremic pneumococcal pneumonia increases from approximately 20% to >50% in patients with cirrhosis. The Advisory Committee on Immunization Practices recommends pneumococcal polysaccharide vaccine for all alcoholics. However, the antibody responses may be blunted, and the efficacy of the vaccine has been questioned in this high-risk population.

Current guidelines on the management of community-acquired pneumonia in adults with AUD recommend either the empiric use of a respiratory fluoroquinolone such as moxifloxacin or levofloxacin, or the combination of a β-lactam agent such as ceftriaxone or ampicillin-sulbactam with a macrolide such as azithromycin. For less severe cases not requiring inpatient treatment, combination therapy is recommended using an oral β-lactam agent (e.g., high-dose amoxicillin, amoxicillin-clavulanate, or cefuroxime) *plus* either a macrolide (azithromycin or clarithromycin) or doxycycline. Alternatively, an oral respiratory fluoroquinolone could be used.

Anaerobic pneumonia

Anaerobic oropharyngeal bacteria, including peptostreptococci, *Fusobacterium* spp., and *Prevotella melaninogenica*, are commonly involved in aspiration pneumonia and can cause lung abscess and empyema. Intoxication interferes with several host defenses against aspiration of oropharyngeal contents. Elevated circulating ethanol levels can disrupt the coordinated beating of cilia on respiratory epithelium and thus impair mucociliary clearance of inhaled or aspirated organisms. Inebriation also can be associated with diminished gag and cough reflexes. Alcoholics frequently have severe periodontal disease, which can increase the number of anaerobic organisms in the aspirated inoculum. Clinical signs and symptoms of anaerobic pneumonia commonly progress slowly over weeks or months before patients present with malaise, low-grade fever, cough producing foul-smelling sputum, and/or weight loss. Recommended therapy includes a β-lactam/β-lactamase inhibitor such as piperacillin-tazobactam, ampicillin-sulbactam, or amoxicillin-clavulanate. Alternatively, a carbapenem may be used such as ertapenem or meropenem. Clindamycin is indicated for anaerobic pleuropulmonary infections in patients who are allergic to penicillin.

Gram-negative pneumonia

Gram-negative bacilli such as *Klebsiella pneumoniae* and *Enterobacter* spp. are more likely to colonize the oropharynx and cause pneumonia in alcoholics than in nonalcoholics. The combination of bloody sputum and an upper lobe infiltrate with a bulging fissure that has been classically associated with *Klebsiella* pneumonia is rarely seen today. Mortality with gram-negative bacillary pneumonia exceeds that of pneumococcal pneumonia and increases further if neutropenia is also present. For pneumonia due to Enterobacteriaceae, recommendations include either a third-generation cephalosporin such as ceftriaxone, a fourth-generation cephalosporin such as cefepime, or a carbapenem such as ertapenem or meropenem. If the pathogen is an extended-spectrum β-lactamase producer, a carbapenem should be used. Alternative antimicrobials include β-lactam/β-lactamase inhibitor combinations or a fluoroquinolone.

For patients with pneumonia due to *Pseudomonas* who are not in septic shock or at high risk for death and for whom the results of antimicrobial sensitivity testing are known, monotherapy with an effective antipseudomonal β-lactam such as piperacillin, cefepime, ceftazidime, aztreonam, or imi-, mero-, or doripenem is recommended. For patients who remain in septic shock or at risk of death when results of susceptibility testing are known, combination therapy using one of the preceding antibiotics with either an antipseudomonal fluoroquinolone (ciprofloxacin or levofloxacin) or an aminoglycoside such as gentamicin is recommended. An alternative regimen would be an aminoglycoside plus the antipseudomonal fluoroquinolone. For a patient whose septic shock resolves when antimicrobial sensitivities are known, continued combination therapy is not recommended. The coccobacillus *H. influenzae* frequently causes pneumonia in alcoholics. Resistance to antibiotics other than penicillin and ampicillin is rare. Recommendations include either a third-generation cephalosporin such as ceftriaxone, a β-lactam/β-lactamase inhibitor, a carbapenem, or a fluoroquinolone.

Acute respiratory distress syndrome

The incidence of ARDS in patients with AUDs has been reported to be 70% compared with 31% in patients without AUDs. AUD patients are approximately four-fold more likely than nonalcoholic patients to develop ARDS. In addition, alcohol-related ARDS is associated with poorer outcomes, including combined outcomes of death or persistent hospitalization. Gut-associated bacteria are enriched in the lung microbiome of both an experimental sepsis model as well as in humans with ARDS. This suggests that gut–lung translocation and dysbiosis of the lung microbial communities may contribute to the development of ARDS.

Tuberculosis

TB has historically been associated with ethanol abuse, and alcoholics have 15 to 200 times the TB incidence rates of nonalcoholics. A 2017 meta-analysis found that there were about 10.4 million TB cases around the world in 2015, and it was associated with about 1.4 million deaths. In all studies, on average, abusing alcohol increased the risk of contracting TB by 35%. The Biomed central public health study reported that people who drank >40 g of alcohol per day dramatically increased their risk of contracting TB. Alcohol abuse is associated with malnutrition, which increases the risk of TB.

Homelessness and immunocompromising conditions such as HIV disease have also been linked to an increased incidence of TB. Most cases occur in urban areas, where outbreaks of TB have occurred among indigent alcoholics housed in shelters.

After decades of steady decline, the number of new cases of TB in the United States started to rise in the late 1980s and continued to climb into the early 1990s. Due to renewed control efforts, the number of new cases has again declined annually since 1992.

Most individuals remain asymptomatic early in the disease. They may note a gradual onset of malaise, fatigue, anorexia, weight loss, afternoon fevers, or night sweats. Cough is frequent, generally producing mucopurulent sputum that may be blood tinged. The most common abnormality on chest radiographs is multinodular cavitary infiltrates in the apical or subapical posterior areas of the upper lobes or in the superior segment of a lower lobe. Pleural effusions may be present. Findings of TB are confined to the lower lung fields in up to 18% of patients.

Hospitalized patients suspected of having active pulmonary TB should be placed under airborne infection precautions. The diagnosis of TB depends on isolation of *Mycobacterium tuberculosis* from clinical specimens. For evaluation of active pulmonary TB, sputum samples are helpful, but yield is increased by more direct collection methods such as via bronchoalveolar lavage. Susceptibility testing should be performed on *M. tuberculosis* isolates from any clinical specimen.

Several tests are available for the evaluation of clinical specimens in the diagnosis of active TB. Culture, the gold standard for isolating *M. tuberculosis*, provides organisms for speciation, strain identification, and susceptibility testing but may require up to 2 months. Acid-fast stains should be performed on clinical samples the day of collection. They are helpful in ruling out mycobacterial disease but are less sensitive than culture. Positive acid-fast stains do not distinguish between *M. tuberculosis* and other mycobacteria.

Newer assays employ nucleic acid amplification directly on clinical samples. They offer same-day results, more sensitivity than acid-fast stains, and the ability to detect members of the *M. tuberculosis* complex. Nucleic acid probes on culture isolates are even more sensitive. These nucleic acid probes complement other tests and are helpful in initiating therapy. However, cultures are still needed for species identification within the *M. tuberculosis* complex and for susceptibility testing.

Although there is no convincing evidence that alcohol abuse is associated with increased risks of extrapulmonary TB infection, miliary TB should remain in the differential diagnosis of fever of unknown origin in an alcoholic patient.

Alcoholic patients are less likely than nonalcoholics to be compliant with therapy for TB and thus are more likely to relapse. Current treatment guidelines with special emphasis on directly observed therapy should be followed to reduce risks of both therapeutic failure and emergence of drug-resistant strains (see Chapter 155, "Tuberculosis"). Recent medical literature supports the effectiveness of integration of AUD treatment into routine TB care.

Peritonitis

Up to 30% of patients with alcoholic liver disease and ascites develop spontaneous bacterial peritonitis (SBP). In this condition bacterial cultures of ascitic fluid are positive, the fluid contains >250 neutrophils/mm^3, and there is no evident intra-abdominal source of infection. Aerobic gram-negative bacilli, especially *Escherichia coli*, cause approximately 75% of SBP infections. Aerobic gram-positive cocci, including *S. pneumoniae, Enterococcus faecalis*, other streptococci, and *Staphylococcus aureus*, are responsible for most other SBP cases. Anaerobes cause only 6% of SBP cases, presumably because of the relatively high pO_2 of ascitic fluid.

Because enteric bacteria predominate in SBP, it is thought that the gut is the major source of organisms for this infection. Several mechanisms have been proposed to explain the movement of organisms from the intestinal lumen to the systemic circulation. Cirrhosis-induced depression of the hepatic reticuloendothelial system impairs the liver's filtering function, allowing bacteria to pass from the bowel lumen to the bloodstream via the portal vein. Cirrhosis also is associated with a relative increase in aerobic gram-negative bacilli in the jejunum. A decrease in mucosal blood flow due to acute hypovolemia or drug-induced splanchnic vasoconstriction may compromise the intestinal barrier to enteric flora, thereby increasing the risk of bacteremia. Finally, bacterial translocation may occur with movement of enteric organisms from the gut lumen through the mucosa to the intestinal lymphatics. From there, bacteria can travel through the lymphatic system and enter the bloodstream via the thoracic duct. It is assumed that SBP caused by nonenteric organisms is also due to bacteremia secondary to another site of infection, with subsequent seeding of the peritoneum and ascitic fluid.

Patients with severe acute or chronic liver disease have decreased serum complement levels, diminished serum bactericidal activity, and reduced bacterial clearance by macrophages of the reticuloendothelial system. Because the ability of ascitic fluid to opsonize bacteria and thus facilitate phagocytosis correlates closely with total protein concentration, patients with low ascitic fluid protein levels are at particular risk for SBP. Other risk factors have been associated with SBP, including gastrointestinal bleeding, fulminant hepatic failure, and invasive procedures such as the placement of peritoneovenous shunts for the treatment of ascites. An elevated bilirubin level is also correlated with a high risk of peritonitis in patients with cirrhosis.

Many patients exhibit other findings of end-stage liver disease such as hepatorenal syndrome, encephalopathy, and variceal bleeding. Other clinical features include fever, vomiting, abdominal pain, and physical signs of peritonitis. However, signs or symptoms of infection are absent in approximately one-third of patients with SBP, so diagnostic paracentesis is indicated for all alcoholic patients with ascites. Fluid should be submitted to the laboratory for chemistry tests, cell count and differential, and microbiologic stains and cultures. Centrifugation of ascitic fluid and Gram stain of the sediment will reveal organisms in 25% to 68% of patients with SBP. Some authorities recommend that a portion of ascitic fluid be inoculated directly into blood culture bottles at the bedside. Peripheral blood cultures should be performed if SBP is suspected.

Empiric therapy should be directed against the most likely gram-negative and gram-positive pathogens discussed earlier. Recommended choices include either a third-generation cephalosporin, β-lactam/β-lactamase inhibitor combination, or a carbapenem (see Chapter 57, "Peritonitis").

Tuberculous peritonitis can occur in patients with alcoholic liver disease. Clinical findings resemble those of bacterial peritonitis, and acid-fast stains of ascitic fluid are usually negative. The diagnosis is best made with stains and cultures of peritoneal tissue, especially when obtained by peritoneoscope-directed biopsy. The treatment regimen is the same as for pulmonary TB.

Bacteremia and sepsis

The liver plays a major role in clearing bacteria from the bloodstream. Alcoholic cirrhosis adversely affects hepatic reticuloendothelial system function. Both intrahepatic and extrahepatic arteriovenous shunts divert blood from macrophages that line liver capillary beds. In addition, both acute intoxication and cirrhosis interfere with bactericidal activity of these tissue phagocytes. Complications of liver cirrhosis including hypocomplementemia, neutropenia, and reduced serum bactericidal activity may also contribute to bacteremia in these patients.

E. coli is the most common cause of spontaneous bacteremia in alcoholic and cirrhotic patients. Additional organisms

causing bacteremia or sepsis include other gram-negative bacilli, *S. pneumoniae*, group A streptococci, and *Clostridium perfringens*.

Alcoholics with cirrhosis are particularly susceptible to sepsis caused by non-01 *Vibrio cholerae* and *Vibrio vulnificus*, an opportunistic pathogen found in marine waters. Bacteremia can follow ingestion of contaminated shellfish, or exposure to seawater can result in a cutaneous infection. The latter may progress from erythematous or ecchymotic patches to bullae formation, subcutaneous necrosis, and bacteremia. *V. vulnificus* infections are associated with high mortality rates. The recommended antibiotic therapy includes doxycycline with ceftazidime. Alternative regimens include cefotaxime or ciprofloxacin.

Nontyphoidal salmonella septicemia, especially due to *Salmonella typhimurium* and *S. choleraesuis*, has been associated with alcoholic liver disease. Homeless people and alcoholics are also at increased risk for bacteremia due to *Bartonella quintana*, and the seroprevalence for this organism is high among homeless people in both the United States and Europe.

Bacteremia with or without sepsis syndrome is associated with increased mortality among alcoholics. A multicenter study conducted in four US urban university hospitals confirmed that a history of chronic alcohol abuse substantially increases the risk of ARDS for critically ill patients with septic shock. These patients also experienced greater frequency and severity of nonpulmonary organ dysfunction and, for survivors, an increased length of hospital stay.

Chronic alcoholic patients also have a three-fold or greater increased risk for developing a severe infection or septic shock after surgery. A German study evaluated patients with and without a history of chronic ethanol abuse who developed severe sepsis. At the onset of infection and during early septic shock, chronic alcoholic patients had lower plasma levels of pro-inflammatory cytokines, including interleukin (IL)-1β, IL-6, and IL-8. The authors concluded that ethanol abuse altered proinflammatory cytokine production and thus the host's immune defenses to infection.

Endocarditis

Alcoholism is one of the strongest risk factors for pneumococcal endocarditis, and reports link cirrhosis with increased frequency and severity of endocarditis due to other bacteria. It is a less common but significant complication of cirrhosis, seen in up to 14% of cirrhotic patients. The aortic valve is most likely to be involved, and many patients have no demonstrable underlying cardiac valvular abnormalities. Compared with that in nonalcoholics, endocarditis in cirrhotic patients is also more likely to involve gram-negative bacilli such as *E. coli* and less likely to be caused by α-hemolytic streptococci.

Other infections

Meningitis

Numerous studies have identified ethanol abuse as a risk factor for bacterial meningitis. In one series, seizures were a presenting symptom in 18% of 88 alcoholic patients, 23% had coexisting infection (pneumonia, 23%; endocarditis 9%), 40% developed respiratory failure, 58% had unfavorable outcome, and 25% died. The most common causative organisms were *S. pneumoniae* (76%). *Listeria monocytogenes* (8%), and *Neisseria meningitidis* (6%). Other less common causes of bacterial meningitis that have been linked to AUDs include *Capnocytophaga canimorsus,* group B streptococcus, aerobic gram-negative bacilli, and anaerobes. In addition, ethanol abuse has been linked to increased risk of severe infection by West Nile Virus, including meningitis and encephalitis.

Pancreatitis and pancreatic abscess

Alcohol abuse is a common cause of acute and chronic pancreatitis, and infectious complications including development of a pancreatic abscess are potentially catastrophic. Primary abscesses characteristically evolve rapidly and culminate in severe sepsis. Secondary abscesses, which may present weeks after the acute inflammation, commonly involve infection of a pancreatic pseudocyst.

The cardinal signs of a pancreatic abscess are high fever, septicemia, a rapidly enlarging abdominal mass, and multisystem organ failure in severe cases. Early surgical drainage is important. Initial empiric antibiotic therapy should be aimed at the most common pathogens, including *E. coli*, other enteric aerobes, and anaerobic gram-negative bacilli. Recommended choices include a β-lactam/β-lactamase inhibitor combination or a carbapenem.

Viral hepatitis

Hepatitis viruses and alcohol abuse are the two main causes of liver cirrhosis. In patients with chronic infection due to hepatitis B virus (HBV), the prevalence of e antigen tends to be higher, and levels decrease more slowly in alcoholics versus nonalcoholics. Current evidence suggests that alcohol use may adversely affect cellular immune responses to the virus and is associated with increased risks of cirrhosis and hepatocellular carcinoma in chronic HBV infection. In addition, alcoholics have a lower rate of responsiveness to the hepatitis B vaccine.

Hepatitis C virus (HCV) is found at a high incidence in alcoholic patients, and 20% to 30% of patients infected with hepatitis C will progress to cirrhosis. The interaction between HCV and alcohol use that affects immune responses, cytotoxicity, and oxidative stress results in more persistent HCV infection and more extensive liver damage. Some studies suggest that even moderate alcohol consumption may accelerate liver damage and hasten the clinical progression of hepatitis C infection. In a meta-analysis, the relative risk of progression to cirrhosis or decompensated liver disease was 2.3 times higher among patient with HCV and AUD compared to abstainers. Abstinence from alcohol also has been shown to result in a reduction of viremia. HCV infection in patients with AUD is associated with poorer outcomes such as longer hospital stays and elevated overall and liver-related mortality.

Alcohol abuse is considered a relative contraindication to interferon-based therapy of hepatitis C due to concerns regarding patient compliance. Response rates to interferon therapy are diminished by alcohol use, and the effectiveness is further reduced

if alcohol consumption is increased. Response to direct antiviral agents is not affected by alcohol use. Alcohol consumption not a contraindication to start treatment with a direct antiviral agent, although it is very important to emphasize the importance of abstinence. Adults with hepatitis C infection tend to consume greater amounts of alcohol than do nonalcoholics.

Human immunodeficiency virus infection

Individuals with HIV infection have significantly higher rates of alcohol use than the general population. Studies have reported the prevalence of alcohol abuse or dependence to range from 20% to 40% among HIV-infected patients.

Use of alcohol and recreational drugs can lead to risky behaviors including unprotected sex that increase the chances of exposure to and transmission of HIV infection. It is not certain whether alcohol consumption increases the rate of HIV replication within the host, although ethanol intake has been shown in some studies to increase HIV replication in isolated human blood mononuclear cells. It is likely that the well-described adverse effects of ethanol on cell-mediated immune function may reduce host defenses against HIV infection.

Aside from the direct effects of acute alcohol ingestion, the concomitant malnutrition and liver disease seen with chronic alcoholism may amplify the immunosuppressive effects of ethanol and hasten the progression from asymptomatic HIV infection to manifestations of AIDS.

The effect of ethanol ingestion on progression from asymptomatic HIV infection to AIDS-defining opportunistic infections has not been clearly established, but there are recent studies showing associations between heavy alcohol consumption with declines of CD4 cell counts and decreased ability to suppress HIV viral load. Heavy alcohol users receiving antiretroviral therapy are twice as likely to have CD4 counts of <500 than are light or nondrinkers, and antiretroviral-treated heavy alcohol users are four times less likely to achieve a positive virologic response. Furthermore, there is evidence that any alcohol use among HIV-infected patients is associated with diminished compliance with antiretroviral therapy.

Infection in the elderly

Kent Crossley

Although virtually all significant infections are discussed throughout this book, certain aspects of infectious diseases in older individuals need to be emphasized. This chapter stresses the unique aspects of infection in the elderly (defined here as >65 years of age). Infections that occur in long-term care institutions are briefly discussed.

Infections in the aged are an important area of concern for medicine. The number of individuals who are older than 65 is increasing dramatically and is disproportionate because of lower birth rates. Although representing only 13% of the US population at present, the elderly consume 25% of all prescription medications and a similarly excess amount of other healthcare services. With few exceptions (some viral infections and venereal diseases), most common infections occur more often in older individuals.

Although mortality associated with many infections is increased in the elderly, age alone is now seen as a relatively unimportant risk factor for infection-related death or serious morbidity. Rather, it is the variety of comorbid conditions that are increasingly common with advancing age that appears to be closely associated with greater morbidity and mortality from infection.

Since the early 1990s, it has become clear that there is a general hyporesponsiveness of the immune system in elderly individuals. This is the most likely explanation for the muted symptoms and signs that are a common denominator of infections in the aged. In a number infectious illnesses, maximum temperatures, white blood cell count elevations, and the overtness of clinical signs and symptoms are all less pronounced in older individuals. In clinical terms, this means that an elderly patient may have a serious bacteremic infection without chills, fever, or leukocytosis.

Principles of antibiotic use

Table 92.1 summarizes recommendations for treatment of common infections in the elderly. Important points include the following:

1. Aminoglycoside antibiotics are best avoided in older individuals because of their toxicity. Although probably appropriate in neutropenic, immunocompromised elderly or in the presence of documented *Pseudomonas* infection, try to use other agents when possible. With careful monitoring, once-daily administration of these drugs for at least 10 days does not appear to be associated with more side effects in the elderly.
2. Because most antibiotics (quinolones, aminoglycosides, and most penicillins are examples) are excreted by renal routes and because of the decline in renal function with increasing age, higher dosages may be potentially more toxic in the elderly.
3. Broad-spectrum therapy is appropriate initially in the treatment of serious infection if the cause is unclear. Older individuals lack the physiologic reserve of younger adults and usually have one or more comorbid diseases. In the presence of a serious infection, the elderly can rapidly deteriorate. Using drugs that are active against most of the likely causes of the infection (with the least possible toxicity) is the best approach.

TABLE 92.1 **ANTIBIOTICS RECOMMENDED FOR INITIAL (EMPIRIC) THERAPY FOR THE ELDERLY**

Infection	Antibiotics	Comments
Acute fever, unidentified source	Ertapenem, 1 g q24h IV, or imipenem, 0.5 g q6h IV, or meropenem, 1.0 g q8h IV plus vancomycin 15 mg/kg q12h IV	Broad spectrum, limited toxicity. For critically ill patients needing empiric therapy.
Urinary tract infection	*Gram-negative organisms*: Third-generation cephalosporin (e.g., ceftazidime, 2.0 g q8–12h), or broad-spectrum penicillin with β-lactamase inhibitor (e.g., piperacillin–tazobactam, 3.375 g IV q6h), or imipenem, or meropenem, or quinolone (e.g., ciprofloxacin, 400 mg IV q12h) *Gram-positive organisms*: Vancomycin, 10–15 mg/kg q12h IV	Consider imipenem or meropenem if in LTCF or a recurrent infection; use in combination with low-dose aminoglycoside (e.g., gentamicin, 40–60 mg/d) if resistant organisms are probable Oral quinolone (e.g., ciprofloxacin, 250 mg BID) appropriate if not seriously ill Vancomycin is active against enterococci, staphylococci, and streptococci
Pneumonia	Third-generation cephalosporin (ceftriaxone, 1 g IV q12h) or ertapenem, 1 g IV q24h plus a macrolide (e.g., azithromycin, 0.5 g/24h IV)	Consider using ceftazidime or imipenem for nosocomial pneumonia Macrolide (preferably azithromycin, 500 mg on day 1, then 250 mg on days 2–4), or quinolone with antipneumococcal activity (e.g., levofloxacin, 500 mg/d) for oral therapy in less seriously ill patients
Pressure sores	Broad-spectrum β-lactam agent with β-lactamase inhibitor (e.g., piperacillin–tazobactam), ertapenem or imipenem (doses as above)	Other treatment regimens active against Bacteroides, and enteric gram-negative organisms, may be used. Add vancomycin if gram-positives present in wound
If a patient is not acutely ill, treatment can wait until specimens for culture have been obtained. All sores will be colonized. A decision to treat as infected is based on presence of signs of infection (such as purulence, local inflammation, and systemic response such as fever or leucocytosis).		
Infective endocarditis	Vancomycin, 15 mg/kg IV q12h with gentamicin 1 mg/kg IV or IM q8h	Modify as appropriate after results of cultures and antibiotic susceptibility testing are available
Infectious (bacterial) diarrhea	Ciprofloxacin (500 mg PO BID) or other quinolone for 1–3 days. Azithromycin if recent travel to Southeast Asia	Consider *Clostridium difficile* if recent antibiotic use.
Meningitis	Third-generation cephalosporin (e.g., ceftriaxone, 2 g IV q12h) plus ampicillin, 2 g IV q4h plus vancomycin 10–15 mg/kg IV q6h	*Listeria monocytogenes* is not susceptible to cephalosporins
Septic arthritis	Vancomycin 10–15 mg/kg IV q6h plus ceftazidime 1–2 g IV q8–12h	Gram stain may be used to narrow therapy.

Abbreviation: LTCF = long-term care facility.
Therapy should be modified as appropriate after results of Gram stain, culture, and antibiotic susceptibility testing are available. Renal function in patients receiving vancomycin and gentamicin therapy must be carefully monitored.

Urinary tract infection

Urinary tract infection (UTI) is increasingly common with increasing age. This reflects obstruction from prostatic enlargement in men and a variety of changes in the defense mechanisms of the female urinary system. The risk of instrumentation and catheterization, procedures often associated with development of infection also increases in the elderly population.

Asymptomatic bacteriuria is more common in both elderly men and women than in younger subjects. Multiple studies have demonstrated that treatment of bacteriuria is without value, primarily because it usually recurs after therapy.

Escherichia coli accounts for the bulk of UTIs in young women. In older individuals, the bacteriology is more complex. Infecting organisms include *E. coli* but also bacteria from other genera (e.g., *Serratia* and *Pseudomonas*) that are often resistant to multiple antibiotics. For this reason, urine culture and sensitivity should always be done before initiating therapy in an elderly individual.

Recent studies indicate that treatment of lower UTI in elderly women may be safely done with 3-day therapy. In men, a 2013 study examining 40,000 episodes of UTI showed that shorter course therapy (<7 days) was as effective as longer periods of treatment. While trimethoprim-sulfamethoxazole (TMP-SMX) or a quinolone are good initial choices for treatment of a lower UTI, resistance to these drugs is increasing in frequency and a drug such as fosfomycin may be required.

For patients with upper tract infection and for those who are seriously ill, therapy should be initially parenterally. Selection should

be guided by Gram stain of the urine. If gram-negative organisms are present, a broad-spectrum β-lactam agent with activity against *Pseudomonas aeruginosa* (e.g., piperacillin-tazobactam) or a quinolone would be an appropriate initial choice. If a gram-positive organism is present in the Gram stain (nearly always representing staphylococci or enterococci), vancomycin would be the most appropriate antibiotic to start, pending culture and susceptibility results. Multiply resistant gram-negative organisms may cause infection in patients with previous UTIs, those who have recently taken antibiotics, nursing home residents, and immunosuppressed patients. In these situations (and in documented *Pseudomonas* infections), imipenem, meropenem, or another broad-spectrum β-lactam should be given with an aminoglycoside. Often a transition to oral therapy can be made after 48 to 72 hours.

Infections in individuals with chronic indwelling urinary catheters should be treated only when symptomatic. Virtually all catheterized patients will have asymptomatic bacteriuria. Treatment of catheterized patients with symptomatic infection should be based on culture and sensitivity. Catheter replacement is often done before initial therapy for these infections and is associated with better outcomes.

Pneumonia

Pneumonia is an increasingly common problem with increasing age. *Streptococcus pneumoniae* is the single most common cause in the elderly. Patients who are 65 or older should receive both the newer pneumococcal vaccine (PCV13) as well as the older 23 valent. Recommendations by the US Centers for Disease Control and Prevention (CDC) on timing of dosing should be consulted. Gram-negative organisms (e.g., *Haemophilus influenzae, Moraxella*, and, less often, enteric organisms such as *E. coli*) are also causal. Nonbacterial organisms such as *Mycoplasma pneumoniae* and *Chlamydia pneumoniae* are also recognized as important causes of pneumonia in older adults. *M. pneumoniae* and *C. pneumoniae* may each account for up to 10% of episodes of acute pneumonia in the elderly. Respiratory syncytial virus (RSV) was recently recognized as a significant cause of pneumonia in the aged. Although RSV-associated illness is similar to clinical influenza, bronchospasm is more common. Rhinoviruses also occasionally cause pneumonia in older individuals.

Because of the variety of agents that may cause pneumonia in the elderly, attempts to document the etiology of the infection by sputum cultures (and blood cultures if the patient is seriously ill) are important. Sputum cultures after initiation of treatment are usually of no value; appropriate cultures need to be obtained before starting therapy.

In an otherwise healthy elderly adult living in the community, initial therapy for pneumonia could be with either a macrolide or a quinolone. The newer quinolones (e.g., levofloxacin) have activity against *S. pneumoniae*, many gram-negative organisms and atypical agents such as *Mycoplasma*. Because of their broad spectrum and once-daily dosing, these agents have become increasingly popular in the outpatient therapy of pneumonia in elderly individuals. The quinolones are preferred over macrolide in elderly patients with significant comorbidities or in those who live in an institution.

For patients with community-acquired pneumonia who are hospitalized, empiric treatment should be broad-spectrum and effective against gram-positive and gram-negative bacteria as well as atypical agents. Broad-spectrum parenteral β-lactams, such as a third-generation cephalosporin (e.g., ceftriaxone) or a penicillin/β-lactamase inhibitor combination (e.g., piperacillin–tazobactam) in conjunction with a parenteral macrolide (e.g., azithromycin), represent optimal therapy. Although limited data are available, in a patient with a functioning gastrointestinal tract, oral therapy with a newer quinolone (such as levofloxacin) may be a possible option. While parenteral therapy is most often appropriate in patients who are ill enough to be hospitalized, the nearly complete absorption of the quinolones after oral dosing and their broad spectrum suggest this may become a convenient and cost-effective approach.

Tuberculosis

About one-quarter of tuberculosis (TB) cases in the United States occur in individuals >65. This is a special problem for nursing homes because the incidence in long-term care is about four times that in the community. Older individuals with a positive tuberculin skin test or a positive TB blood test who have one of a number of additional risk factors (e.g., recent steroid therapy, living in a high risk setting [e.g., shelters or prisons], or immigrants from countries with a high prevalence of TB) or who have recently converted their test need to be treated with isoniazid, 300 mg/d for 9 months, or rifampin for 4 months. Managing clinical tuberculosis in an elderly individual is similar to that in a younger patient. Monitoring for hepatic toxicity is advisable.

Pressure ulcers

Efforts to attempt to prevent pressure-associated ischemia are extremely important. Once an ulcer develops, infection often follows. Topical antimicrobials are ineffective in the management of these lesions. Systemic antimicrobials should be used if clinical cellulitis is evident at the margin of a pressure ulcer or if there is evidence of deep infection or osteomyelitis. Therapy needs to be effective against anaerobic bacteria and both gram-negative and gram-positive organisms. Oral therapy might include a combination of an oral cephalosporin and metronidazole or amoxicillin-clavulanate. Appropriate parenteral therapies include imipenem, piperacillin-tazobactam, or one of the broader spectrum cephalosporins (e.g., ceftriaxone and cefotaxime) or a quinolone combined with metronidazole or clindamycin for anaerobic coverage. If material can be obtained for culture (usually best done by needle aspiration), therapy can be modified when results are available.

Most other skin and soft tissue infections in the aged, as in younger individuals, are caused by group A β-hemolytic streptococci or *Staphylococcus aureus*. Treatment of these infections is not

significantly different in older individuals. Community-acquired methicillin-resistant *S. aureus* (MRSA) is of concern in all patients with skin and soft tissue infection. For seriously ill patients, vancomycin is appropriate. In outpatient treatment, TMP-SMX should be used.

Bacteremia

In one recent study, nearly 15% of the cases of community-acquired bacteremia were in individuals >84 years. Usual primary sites of infection include the urinary tract, intra-abdominal sites, the lower respiratory tract, and skin and soft tissue. Evaluation should rule out abscess or obstruction of an airway or hollow viscus.

Meningitis

Streptococcus pneumoniae remains the most common cause of meningitis in older adults. The second most common cause is *Listeria monocytogenes*. This is important to know when selecting therapy because *Listeria* is not killed by cephalosporins, and initial therapy of meningitis of unknown cause in an elderly individual must include ampicillin, which is active against *L. monocytogenes*.

Infections in residents of long-term care facilities

All the infections that occur in older individuals may develop in residents of long-term care facilities (LTCFs). MRSA and, in some areas of the United States, vancomycin-resistant enterococci (VRE) have a strong association with LTCF residency. Residents are also especially prone to epidemic respiratory or gastrointestinal diseases, particularly in winter months. Selecting antibiotic therapy for patients who reside in LTCFs requires an awareness that resistant gram-negative organisms, MRSA, and VRE are all potential pathogens. Overuse of antibiotics and antimicrobial stewardship in LTCFs are recognized as increasingly important.

Neonatal infection

Patrick G. Gallagher and Robert S. Baltimore

Bacterial infections

Epidemiology

Neonatal infections are usually classified according to time and mode of onset in three categories: (1) prenatal, (2) perinatal (early onset), and (3) nursery-acquired (late onset). The division in time between early and late onset is usually 2 to 7 days of age (Table 93.1). Different investigators have divided early-onset from late-onset infections at different days of life but most early-onset infections are evident during the first day of life. Infections that begin within the first month of life are considered neonatal, but many intensive care units for neonates provide continuing care for infants several months of age with complex problems that are the result of prematurity and complications of neonatal disorders. Therefore, neonatal nursery-associated infections may occur in infants up to a year or more of age. Bacterial infections due to rapidly dividing high-grade pathogens that set in substantially before birth usually result in a stillbirth. Often it is difficult to distinguish infections acquired shortly prior to birth from those acquired as a result of contact with maternal vaginal, fecal, or skin flora during delivery.

Neonatal sepsis occurs in approximately 2 to 4 per 1000 live births in the United States. Worldwide reports vary from <2 to 50 per 1000 live births. The rates of early-onset sepsis have fallen to <1.0/1000 in the United States and Western Europe. Risk factors noted in Table 93.1 have a very strong predictive influence on infection rates. Full-term infants born without incident have a very low incidence of infection, lower than any other population of hospitalized patients. Infants susceptible to early-onset postnatal infections are primarily those born prematurely. Those premature infants born to mothers with an infection or whose membranes rupture more than 18 hours before delivery may have an infection rate of 20% or more. In extremely premature infants extra vigilance is required for early recognition and treatment of infection. Premature infants are much more likely to develop sepsis as a consequence of the amnionitis caused by ascending infection than are full-term infants. Similarly, premature infants are at a greater risk for developing an invasive infection if born to a mother with peripartum infection than are full-term infants. The practice of treating parturient women suspected of having amnionitis with antibiotics is probably an important factor in the decrease in early-onset sepsis observed in the United States.

Hospital-acquired infection in the nursery is an important and growing problem, and now represents most of the infections seen in neonatal units. As the technology for treating very premature and very sick infants has increased, so too has the population of surviving immunocompromised infants who require therapy with ventilators, intravascular catheters, total parenteral nutrition, and various surgical interventions, each of which carries a substantial risk of infection (see Table 93.1). The liberal use of broad-spectrum antibiotics in neonatal care units increases the risk of acquisition of pathogens by interfering with the development of normal flora in these infants. Recent data suggest that antibiotic treatment early in life increases the risk of developing neonatal necrotizing enterocolitis. In contrast, the risk of acquiring hospital-acquired viral infections appears to depend mostly on the chances of contact with the virus and not pre-existing disease

TABLE 93.1 **CHARACTERISTICS OF PRENATAL, EARLY-ONSET, AND LATE-ONSET NEONATAL INFECTIONS**

	Prenatal onset	Early-onset infections	Late-onset infections
Age at onset	Prior to birth	Birth to 2–7 days	2–7 to 30 days
Primary route of transmission	Transplacental or ascending	Maternal flora transmitted peripartum	Hospital-acquired
Risk factors	Maternal infection Prolonged premature rupture of membranes	Prolonged premature rupture of membranes Septic or traumatic delivery Maternal infection, especially urogenital Fetal anoxia Male sex Maternal factors (poverty, pre-eclampsia, cardiac disease, diabetes)	Extreme prematurity Mechanical ventilation Contact with hands of colonized personnel Contact with aerosols of bacteria Contaminated equipment (e.g., isolettes, ventilators, IV lines) Debilitating illness, including bronchopulmonary dysplasia and short gut syndrome Congenital anomalies Surgery (including necrotizing enterocolitis) Prior exposure to broad-spectrum antibiotics
Most common pathogens	Cytomegalovirus Syphilis *Toxoplasma* Maternal vaginal flora Human immunodeficiency virus	*Escherichia coli* Group B streptococci, *Klebsiella* spp. *Enterococcus* spp., *Listeria monocytogenes* Other Enterobacteriacae (*Proteus, Citrobacter, Enterobacter*)	Those causing early-onset infections *Staphylococcus aureus* Coagulase-negative staphylococci *Pseudomonas aeruginosa* and other gram-negative rod species resistant to first-line antibiotics *Candida* spp.

Abbreviation: IV intravenous.

in the infant. Infants with chronic lung disease or congenital cardiac conditions are particularly susceptible to severe infection with respiratory syncytial virus and human metapneumovirus. Therefore, community activity of respiratory and gastrointestinal viruses and defects in the barriers to prevent spread, especially poor adherence to handwashing, within the unit appear to be the most important risk factors for viral infection.

Microbiology

Table 93.1 lists the major bacterial organisms responsible for early and late postnatal sepsis. The organisms that cause meningitis in the neonate are the same. *Escherichia coli* and group B streptococci have accounted for about 80% of early-onset sepsis and meningitis in the past. The rate of group B streptococcal infection has declined about 80% since the widespread adoption of intrapartum antibiotic prophylaxis to prevent early-onset group B streptococcal disease.

Since the early 1990s the microbiology of late-onset sepsis has shifted, with an increase in commensal organisms, particularly staphylococci and *Candida* spp. This shift appears to be due to the increased survival of extremely premature infants with increased utilization of mechanical ventilation, central venous catheters, parenteral alimentation, and broad-spectrum antibiotics. Empiric therapy is guided by published information on the microbiology of neonatal infections as well as information about local bacterial and fungal isolates which should be kept by hospitals with neonatal units.

Antimicrobial therapy

Empiric therapy for early-onset sepsis

Antibiotics for early-onset infections are generally commenced prior to the identification of the infecting organism. Neonates, especially premature ones, typically fail to manifest classic signs and symptoms of infection. Thus, many schemata have been developed for empiric antibiotic treatment of infants with multiple epidemiologic risks alone or nonspecific signs and laboratory test abnormalities plus epidemiologic risk factors. The common features of these schemata are recognition of the risk factors listed in Table 93.1; the possibility that severe infection may present as temperature instability or other vital sign changes, unexplained hyperbilirubinemia, vomiting, or changes in feeding; and the recognition that a very short delay in treatment may result in overwhelming sepsis and death. Such schemata vary from hospital to hospital according to the population served, the type of hospital, and resources for screening. Screening tests may also include hematologic findings such as white blood cell count, the ratio of immature to mature cells of the granulocyte series, acute phase reactants such as erythrocyte sedimentation rate, C-reactive protein, procalcitonin, mannose-binding lectin, and serum amyloid A, upregulation of neutrophil cell surface adhesion molecules such as CD64 and CD11b, and concentrations of certain lymphokines such as interleukin-6 (IL-6), IL-8, and tumor necrosis factor-α, and each has been reported to have moderate positive and negative predictive values.

TABLE 93.2 **EMPIRIC ANTIBIOTIC TREATMENT FOR PRESUMED NEONATAL SEPSIS (WITH OR WITHOUT MENINGITIS)**

Age and location of infant at onset	Antibiotic regimen	Alternative regimens
Early-onset sepsis	Ampicillin *plus* gentamicin[a]	Ampicillin *plus* cefotaxime
Late-onset sepsis (up to 1 month)		
Readmission from the community	Ampicillin *plus* cefotaxime (or ceftriaxone[b])	Ampicillin *plus* gentamicin[a] *with* or *without* cefotaxime (or ceftriaxone[b])
In the hospital, with no intravenous catheter(s)	Ampicillin *plus* gentamicin[a]	Ampicillin *plus cefotaxime* (or ceftriaxone[b])
In the hospital, with intravenous catheter(s)	Oxacillin or vancomycina *plus* gentamicin[a]	Vancomycin[a] *plus* cefotaxime (or ceftriaxone[b])

[a] Adjust dose according to concentration of the antibiotic in the blood once a steady state has been achieved.
[b] Ceftriaxone can displace bilibrubin from albumin thus intensifying hyperbilirubinemia and may also cause deposition of sludge in the gallbladder so it should be used with caution in newborns.

Treatment is designed to provide adequate antimicrobial activity against the organisms listed in Table 93.1. Often the focus of infection is unknown initially but in the absence of a detectable extravascular source, therapy is directed against bacteremia and meningitis because experience demonstrates that these are the most likely foci. If pneumonia or a urinary tract infection is present, physical exam or screening tests, chest radiograph, and urinalysis will demonstrate these foci. Tables 93.2 and 93.3 list the antibiotics found to be effective and commonly used for neonatal infections. The recommended dosing (Table 93.3) takes into consideration the absorption, metabolism, distribution, and excretion, which differ from those of older children and change rapidly during early life.

Empiric treatment is generally an extended-spectrum penicillin with an aminoglycoside or extended-spectrum (third-generation) cephalosporin (Table 93.2). A majority of pediatric infectious disease practitioners continue to use an extended-spectrum penicillin, usually ampicillin, with an aminoglycoside, usually gentamicin. The advantages of this combination are low cost, considerable experience, and low toxicity. The advantages of the extended-spectrum cephalosporins are greater activity against many of the pathogens and excellent central nervous system penetration in the presence of inflammation. There is concern, however, about the development of resistant flora if these agents are used routinely. Prior treatment with third-generation cephalosporins increases the risk for invasive infections due to *Candida* species. Also *Listeria* and *Enterococcus* species which occur in ill neonates are resistant to the cephalosporins. If gram-negative bacillary meningitis is diagnosed, it is reasonable to use ampicillin plus an extended-spectrum cephalosporin as a first choice until the pathogen is identified.

When transmission of *Staphylococcus* from mother to infant is suspected, an anti-staphylococcal agent should be included.

Empiric therapy for late-onset sepsis

The neonates most likely to have late-onset infections are ill residents of an intensive care nursery. Ideal empiric antibiotic therapy takes into consideration the resident flora of the nursery, especially isolates from previously infected neonates, and the particular risk factors of the patient. If intra-vascular cannulas have not been used, if the infant has not been treated for a previous infection, and if there have not been isolates of gentamicin-resistant gram-negative aerobic bacilli, it is appropriate to use the same empiric treatment as for early-onset sepsis (see Table 93.2). In fact, this is usually not the case, and another regimen is often more appropriate. Ill infants frequently have one or more intravascular catheters in place, and these may be the focus of infection. The most common bacterial species causing catheter-associated infections are coagulase-negative staphylococci and *Staphylococcus aureus*. Although penicillinase-resistant semisynthetic penicillins (oxacillin, nafcillin) are usually the agents of choice against staphylococci, resistance to this class, commonly called methicillin-resistant *S. aureus* (MRSA), is rising in many institutions. Some institutions report high endemic rates of MRSA in neonatal intensive care units (NICUs). In addition, coagulase-negative staphylococci appear to have a higher incidence in very-low-birth-weight infants, and these pathogens are more likely to show methicillin resistance. Therefore, in institutions with substantial methicillin resistance of staphylococci it is reasonable to use vancomycin for empiric treatment of late-onset catheter-associated infections until susceptibility is known. Generally an aminoglycoside is added. If an infant develops new symptoms of infection while receiving gentamicin, either amikacin or third-generation cephalosporin is substituted.

Penicillin is used for group B streptococci; ampicillin or ampicillin plus gentamicin is used for *Enterococcus* species or *Listeria*. For gram-negative bacillary infections ampicillin or ampicillin plus an aminoglycoside or third-generation cephalosporin (depending on susceptibility) is continued for 7 to 10 days unless there is a focal infection in addition that requires a longer duration of treatment. For peritonitis due to necrotizing enterocolitis, the addition of clindamycin to the regimens recommended for sepsis may be of value for treatment of staphylococci and gram-negative rod anaerobes. The duration is determined based upon response to treatment.

If *Pseudomonas aeruginosa* is a likely pathogen, tobramycin is preferred to gentamicin because of higher activity. Extended-spectrum β-lactam agents such as ceftazidime and piperacillin–tazobactam are also used for *Pseudomonas* species. If infections

TABLE 93.3 **DOSE SCHEDULES OF FREQUENTLY USED PARENTERAL ANTIBIOTICS FOR NEONATAL INFECTIONSA**

	<7 days of age		>7 days of age	
ANTIBIOTIC AGENT	**DAILY DOSE (per kg)**	**DOSES/DAY**	**DAILY DOSE (per kg)**	**DOSES/DAY**
Penicillins				
Penicillin G	50 000–100 000 units[b]	2–3[c]	100 000–200 000 units	3–4
Ticarcillin, ticarcillin–clavulanate	150–225 mg	2–3	225–300 mg	3–4
Piperacillin, piperacillin–tazobactam	150–225 mg	2–3	225–300 mg	3–4
Penicillinase-resistant penicillins (oxacillin, nafcillin)	50–100 mg	2	100–200 mg	3–4
Ampicillin	50–150 mg	2–3	100–200 mg	3–4
Aminoglycosides				
Amikacin[d]	7.5–20 mg	1–2	22.5–30 mg	3
Gentamicin[d]	5 mg	2	7.5 mg	3
Tobramycin[d]	5 mg	2	7.5 mg	3
Cephalosporins				
Cefotaxime	100 mg	2	100–200 mg	3
Ceftazidime	100–150 mg	2–3	100–150 mg	3
Ceftriaxone	50 mg	1	50–75 mg	1
Miscellaneous antibiotics				
Clindamycin	10–15 mg	2–3	15–20 mg	3–4
Vancomycin[d]	20–30 mg	2	30–45 mg	3
Chloramphenicol[d]	25 mg	1	25–50 mg	1–2
Aztreonam	60–90 mg	2–3	90–120 mg	3–4
Metronidazole	7.5–15 mg	1–2	15–30 mg	2
Antifungal agents				
Amphotericin B	0.5–1.0 mg	1	0.5–1.0 mg	1
Amphotericin B lipid complex or liposomal	3–5 mg	1	3–5 mg	1
Flucytosine (oral)[e]	100–150 mg	4	100–150 mg	4
Fluconazole[f]	3–12 mg	1	3–12 mg	1
Antiviral agents				
Acyclovir	45–60 mg	2–3	45–60 mg	2–3

[a] Dosing of very small premature infants (1200 g birth weight) may require longer dose intervals, and specialized literature or a pharmacy specialist should be consulted.
[b] Where there is a dose range the higher figure is used for treatment when meningitis is present. For sepsis without meningitis the higher end of the dose range is recommended for more severe infections or when the measured serum antibiotic concentration is lower than the therapeutic range.
[c] Where there is a range of number of doses/day the greater number and higher dose is used for neonates with a birth weight over 2 kg and the lower number doses with lower daily dose are for neonates with a birth weight under 2 kg.
[d] Dosing should be guided by laboratory determination of serum antibiotic concentrations once a steady state has been reached.
[e] Limited data on dosing neonates. Dose indicated is from cases in the literature.
[f] Limited data in neonates. Child dose is listed.

due to gentamicin-resistant gram-negative bacilli have recently been encountered in the unit, amikacin or netilmicin are the aminoglycosides of choice. Ideally, each neonatal treatment unit would monitor pathogens isolated and adjust empiric treatment accordingly.

Isolation of *Candida* from blood or a closed space requires prompt institution of antifungal treatment. For candidemia, first remove intravascular catheters and treat with amphotericin B or one of the lipid-associated forms of amphotericin. Once there has been speciation, one may consider treatment with fluconazole or other azoles if it is a susceptible species. Although it is controversial, there is evidence that fluconazole prophylaxis is effective at reducing neonatal candidiasis and candidemia in NICUs. At this time, prophylaxis with fluconazole (3 or 6 mg/kg/day, twice weekly) is

recommended primarily for neonates with a birth weight of <1000 g in units having a high rate of candidal infections.

Adjunctive therapy of sepsis

In addition to antibiotic therapy, infants with sepsis require intensive medical management. Care should be provided to address fluid and electrolyte, metabolic, nutritional, respiratory, cardiovascular, renal, and hematologic needs. Extracorporeal therapies, including continuous renal replacement therapy (CRRT), plasma-based removal techniques, and extracorporeal membrane oxygenation (ECMO), have been explored in the treatment of neonatal sepsis. The most experience is with ECMO, which has been used successfully for the treatment of refractory septic shock in neonates. The use of agents to support or enhance the neonate's immune response is controversial. Exchange transfusion, transfusion of concentrated white blood cells when there is severe neutropenia and bone marrow failure, commercial intravenous immunoglobulin preparations, and organism-specific immunoglobulin preparations are either ineffective or only slightly better than placebo. Hematopoietic growth factors, such as granulocyte colony-stimulating factor (G-CSF) and granulocyte–macrophage colony-stimulating factor (GM-CSF), have been studied in septic neonates with neutropenia, but results are inconclusive, and their use is not currently recommended. Steroids have not been proven to be of benefit in neonatal sepsis or meningitis.

Therapy and management of other focal infections

Meningitis

The doses of some antibiotics are increased when treating meningitis to allow for lower antibiotic concentrations in central nervous system tissue and cerebrospinal fluid (CSF) due to the blood–brain barrier. Bactericidal antibiotics are preferred to bacteriostatic agents. Routine intrathecal or intraventricular administration of antibiotics does not improve outcome. Intraventricular instillation may occasionally be warranted when resistant organisms are not eradicated using conventional antibiotics.

Ampicillin plus gentamicin or cefotaxime are recommended for empiric treatment of neonatal meningitis. Cefotaxime is preferred over ceftriaxone because the latter antibiotic has high protein binding which can increase free bilirubin in the blood. Complications and delayed sterilization are more common with gram-negative bacillary meningitis in the newborn than with meningitis in children beyond the neonatal period caused by the usual organisms for that age group. In evaluating the infant being treated for bacillary meningitis, it is recommended to repeat the lumbar puncture every 48 hours until the CSF is sterile to monitor antibiotic efficacy. Continued positive cultures may signal the need to change antibiotics or look for a focus such as a brain abscess with cranial imaging. Assuming no complications, antibiotics are usually continued for 3 weeks. For group B streptococcal meningitis repeat lumbar puncture has little value when there is a good clinical response and no late complications. Resistance of group B streptococci to penicillin and ampicillin has not been reported. Length of treatment is 2 to 3 weeks. Hydrocephalus is an unfortunately common complication of neonatal meningitis, usually associated with severe ventriculitis, and it is important to monitor the head circumference and serial head ultrasound examinations, if indicated, throughout therapy. Infants who develop an increase in ventricular size should be evaluated by a neurosurgeon. At this time there are no data to suggest that adjunctive steroid treatment is either safe or beneficial for neonatal meningitis.

Pneumonia

Neonatal pneumonia can occur prenatally, in association with early-onset sepsis, as a complication of a noninfectious respiratory condition such as respiratory distress syndrome or meconium aspiration, or as a nosocomial pneumonia associated with mechanical ventilation. Prematurely born infants > 1 month of age may develop chronic lung disease of prematurity, which has not been determined to be an infectious disease. Rarely is diagnostic lower-lung tissue or sputum of good quality available for microbiologic diagnosis. Thus there is little information on optimal therapy for pneumonia as an isolated infection. In general, the bacterial pathogens are the same as those for early- and late-onset sepsis, and empiric antimicrobial treatment is the same. Antibiotic therapy is usually for 10 to 14 days and extended to 21 days for the rare cases of staphylococcal pneumonia. In addition, organisms of maternal origin such as *Chlamydia trachomatis*, which can be treated with erythromycin or sulfisoxazole, and genital mycoplasmas such as *Mycoplasma hominis* and *Ureaplasma urealyticum*, for which there is no proven treatment, may be encountered. There are reports of treatment of *U. urealyticum* with macrolide antibiotics but so far little convincing evidence of efficacy.

Urinary tract infection

Percutaneous bladder puncture is the best method of culture to avoid contamination. Bladder catheterization is acceptable but is more likely to result in contamination of the urinary tract. If the same organism is recovered from the urine and the blood, it may not be clear whether the urinary tract was the initial focus of infection or was seeded from blood unless there is an obvious urinary tract anatomic abnormality. Late-onset urinary tract infections may be associated either with a congenital malformation or urinary tract instrumentation or be spontaneous, with no discoverable underlying cause. Initial antibiotic treatment should be similar to the approach to the neonate with sepsis according to Table 93.2 and, following identification of the pathogen continued with one of the agents listed in Table 93.3, according to the susceptibility of the isolate. Due to unpredictable absorption of oral antibiotics the treatment is generally with parenterally administered drug. Although treatment for 10 to 14 days with an agent that has renal concentration and excretion is conventional, the neonate, like older individuals, may have a poor response or relapse in the presence of obstruction, a foreign body, or incomplete voiding. Due to the high rate of congenital malformations in neonates with urinary tract infections or vesicoureteral reflux, imaging studies should be part of the evaluation and management.

Skeletal infections

Septic arthritis and osteomyelitis in the neonate are generally secondary to bacteremia. *S. aureus* is the most frequently isolated organism, and group B streptococci and gram-negative aerobes, especially *E. coli*, are also encountered. *S. aureus* skeletal infections in the neonate are often severely destructive and associated with later disabilities, and may be associated with multiple foci and rupture through the incompletely formed epiphyseal plate. Magnetic resonance imaging helps evaluate arthritis and osteomyelitis because metabolic bone disease of prematurity may make interpretation of radiographs difficult. Empiric therapy is similar to sepsis, but an agent active against *S. aureus* such as oxacillin or nafcillin (or vancomycin if MRSA is suspected) should be added. Management includes aspiration of infected bone or septic joint, and open drainage should be considered if aspiration is insufficient to drain the focus. Length of treatment is generally at least 3 weeks for septic arthritis and at least 4 weeks for osteomyelitis. A longer course may be necessary if there is delayed sterilization, late appearance of a second focus, unusual organism, or other complications. There is too little experience with oral agents for skeletal infections in the neonate to recommend this route.

Viral infections

Herpes simplex infections

Herpes infections of the newborn are transmitted from the mother's genital tract to the infant, usually at delivery but, rarely, ascending infection may occur in utero. The incidence is approximately 1 in 3000 to 5000 deliveries although published rates vary considerably. Infants of mothers with primary genital herpes lesions at the time of delivery rather than recurrent herpes are at highest risk, but mothers of infants with herpes infection are often unaware of ever having had genital herpes. The incubation period is generally from 3 or 4 days to a month after birth. Most neonatal herpes infections are due to herpes simplex virus type 2. The presentation of neonatal herpes may include (1) only cutaneous, eye, and mucous membrane manifestations (vesicles); (2) only central nervous system infection; or (3) disseminated visceral infection. Combinations of the three may also occur. Severity and prognosis are worst for disseminated visceral disease and best for cutaneous disease.

Acyclovir is the antiviral agent of choice. Moderately ill infants who are treated early in the course of infection benefit most. The recommended dose is now higher than that previously recommended. The usual dose in a term infant is 60 mg/kg/day divided every 8 hours. The optimal duration of treatment is unknown, but although early studies used a duration of 10 days, most practitioners extend the course to 14 to 21 days (the latter when the infection is disseminated or the central nervous system is involved) because of reports of recurrences with the shorter regimen. Some recommend repeat lumbar puncture to follow the polymerase chain reaction (PCR) and to extend treatment until the CSF PCR is negative.

Cytomegalovirus infection

Cytomegalovirus (CMV) infection of the neonate usually derives from mother to infant during gestation, but CMV may also be acquired by the infant at the time of delivery or postnatally. The diagnosis of congenital CMV infection is established by detecting virus by culture or other techniques in urine, blood, or other tissues during the first 3 weeks of life. Many laboratories utilize rapid culture techniques combined with direct immunofluorescence detection using antibodies against intermediate-early or early CMV antigens but PCR tests have taken over for diagnosis in some laboratories. The use of PCR and quantitative antigenemia in the blood, which have been useful in following older immunocompromised individuals, may be useful in confirming neonatal infection as well as in following the course of infection.

Numerous antiviral agents treat CMV infection, including ganciclovir, valganciclovir, foscarnet, cidofovir, and CMV immunoglobulin. However, there is limited experience in treating congenital infection with these agents. One study showed that infants with symptomatic congenital CMV infection and evidence of central nervous system involvement treated for 6 weeks with ganciclovir (6 mg/kg intravenously every 12 hours) have less hearing loss at 6 months and fewer developmental delays at 12 months compared to untreated controls. Concerns of marrow suppression and other potential long-term effects, such as germ cell toxicity and carcinogenicity, have led many to restrict the use of ganciclovir to treatment of congenital CMV with central nervous system involvement. A recent study demonstrated superiority of oral valganciclovir for 6 months compared to 6 weeks of treatment for congenital CMV disease.

Varicella-zoster virus

Infants born of mothers who have active varicella are in danger of developing overwhelming infection due to varicella-zoster virus (VZV) if the mother's lesions appear in the period between 5 days before delivery and 2 days after delivery. The rationale is that infants exposed during this period may have received a large dose of VZV intravenously by transplacental exposure. Infants exposed earlier in utero receive antibody transplacentally from the mother and generally develop a mild infection. Infants exposed after birth also develop mild varicella. If an infant is exposed to VZV during the critical perinatal period described above, treatment with varicella-zoster immunoglobulin (VariZIG) 125 units (one vial) or immune globulin, intravenous given as soon as possible after delivery or exposure is recommended. Neonates who develop severe perinatal VZV infections can be treated with acyclovir at a dose of 45 mg/kg/day in three divided doses for 5 to 7 days.

Viral pneumonia

Respiratory syncytial virus, influenza viruses, parainfluenza viruses, and adenoviruses can cause severe respiratory disease in neonates, and the diagnosis is made by viral culture or rapid antigen tests. In general, antimicrobial treatment is not available. Ribavirin by aerosol, which in earlier studies appeared to shorten the course of

respiratory syncytial virus-associated bronchiolitis in infants, is no longer recommended for routine use because subsequent studies cast doubt on the efficacy of ribavirin even for older infants.

Pregnancy and the puerperium

Infectious risks

Raùl E. Istùriz and Jorge Murillo

Infectious diseases that occur during pregnancy and the puerperium pose special risks to the mother, fetus, and infant. Any intervention must be weighed against possible side effects.

Urinary tract infections

For pregnant women it is recommended to culture urine at the first prenatal visit. Treatment should be provided if the urine culture is positive.

Short courses (3 days) of antimicrobial therapy are usually effective in eradicating asymptomatic bacteriuria. Penicillins, cephalosporins, aztreonam, ertapenem, imipenem, and meropenem are considered safe. Sulfonamides, including TMP–SMX, are avoided in the first trimester and near term (because of kernicterus).

Recommended regimens include amoxicillin, 500 mg orally three times a day; amoxicillin–clavulanate, 875 mg twice a day; nitrofurantoin, 100mg every 12 hours; sulfisoxazole, 500 mg three times a day; cephalosporins, such as cefuroxime–axetil, 250 to 500 mg every 12 hours, or cefpodoxime, 100 mg every 12 hours, can also be used. Fosfomycin, 3 g PO as a single dose, was shown to be effective when compared with other drugs administered for a longer time.

Urine culture should be performed 1 week after therapy and monthly until the end of pregnancy. Suppressive therapy until delivery is recommended for women who have persistent bacteriuria after two or more courses of therapy.

In acute cystitis, pyuria is found in most patients, and urine culture should be performed. Patients should be treated for 3 to 7 days if symptoms suggesting pyelonephritis are absent. The same antibiotic regimens suggested for asymptomatic bacteriuria can be utilized. Quinolones are contraindicated in pregnancy. Follow-up urine culture should be obtained 1 week after therapy. For recurrent infections, antimicrobial prophylaxis should be considered for the duration of pregnancy.

When acute pyelonephritis is the presumptive diagnosis, we admit pregnant patients to the hospital, culture urine and blood, and treat with intravenous antibiotics until the patient is afebrile for 24 hours. Then, oral therapy can be used to complete 10 to 14 days of therapy. If fever and symptoms persist >48 hours after treatment imaging studies of the urinary tract and repeat urine culture should be obtained. Antibiotic prophylaxis should be considered in patients with recurrent pyelonephritis, with periodic urine cultures for the remainder of the gestation.

Empiric treatment of acute pyelonephritis includes the following: ceftriaxone, 1 g IV every 24 hours, ceftazidime, 2 g IV every 8 hours, cefepime, 2 g IV every 12 hours, piperacillin–tazobactam, 4.5 g IV

every 8 hours, ertapenem, 1 g IM every 24 hours, meropenemand aztreonam, 1 to 2 g IV every 8 hours. We avoid aminoglycosides whenever possible.

Premature rupture of fetal membranes and intra-amniotic infection

Premature rupture of fetal membranes (PROM) can occur at any time before uterine contractions and labor start. Subclinical infection or inflammation of the chorioamniotic membranes causes an important proportion of cases. Intra-amniotic infection (IAI), present in 40% to 75% of women with PROM, is the infection of the membranes, the amniotic fluid, the placenta, and/or the uterus. It is associated with a 50% rate of preterm deliveries before gestation week 30.

Maternal fever and tachycardia and fetal tachycardia are common manifestations of IAI. Maternal leukocytosis is common. Maternal bacteremia occurs in up to 10% of cases but is more common when virulent organisms (*Escherichia coli* 15%, group B streptococcus 18%) are causing the infection. Abnormal labor, necessity for C-section, hemorrhage, wound infection, and endometritis are maternal complications. Fetal and neonatal complications include sepsis, pneumonia, respiratory distress, intraventricular hemorrhage, and low apgar score.

When IAI is suspected amniocentesis is performed. Amniotic fluid is obtained for aerobic (group B streptococcus, *E. coli*, enterococci) and anaerobic (*Peptostreptococcus, Bacteroides*, and *Fusobacterium* species, *Gardnerella vaginalis*, and *Mobiluncus* species) cultures. Samples for Gram stain (48% sensitivity, 99% specificity), glucose level (sensitive when below 15 mg/dL), white blood cell count (above 30/mm^3), and leukocyte esterase activity (trace or greater) and measurement of amniotic fluid cytokines (interleukin [IL]-1a, IL-6, IL-8, and tumor necrosis factor [TNF]) can be obtained at the same time. Antibiotics are used immediately. Ampicillin, 2 g IV every 6 hours, plus gentamicin, 5.1 mg/kg once daily, continued for 1 dose after delivery; clindamicin, 900mg IV every 8 hours, can be added after cord clamping in cesarean deliveries to reduce endometritis. Alternatives include ampicillin–sulbactam, 1.5 to 3 g every 6 hours; or piperacillin–tazobactam, 3.375 to 4.5 g every 6 hours. For serious infections due to resistant bacteria, such as extended-spectrum β-lactamase-producing gram negatives, carbapenems (meropenem, doripenem, ertapenem) can be substituted.

Mycobacterial infection in pregnancy

The diagnosis and treatment of pregnant women with active tuberculosis (TB) follows the same steps as in the nonpregnant individual. A human immunodeficiency virus (HIV) serology is mandatory. PPD is safe and accurate during pregnancy. Provided no multidrug resistance is suspected, the initial regimen consists of isoniazid (with pyridoxine 50 mg/day), rifampin, and ethambutol, for 2 months, followed by rifampin and isoniazid for 7 months. Isoniazid may exhibit increased maternal liver toxicity during pregnancy. Pyrazinamide is not currently recommended in the United States for routine use. Expert consultation is advised.

Therapy for latent TB infection (LTBI) may be started even during the first trimester, with isoniazid (5 mg/kg/day, maximum 300 mg) for 9 months (supplemented with pyridoxine) or rifampin (600 mg/day) for 4 months. Breastfeeding is not discouraged.

In pregnant AIDS patients, the treatment of disseminated disease due to *Mycobacterium avium* complex (MAC) is difficult. Azithromycin (Food and Drug Administration [FDA] category B) is the preferred macrolide for MAC prophylaxis and treatment (see Chapters 157, Tuberculosis, and 158, Nontuberculous mycobacteria). Again, expert consultation is advised.

Malaria and pregnancy

Pregnant women are more vulnerable to high parasitemia, severe infection, and mortality; fetuses are more vulnerable to low birth weight (LBW), prematurity, stillbirth, congenital disease, and death. Hence, exposure to malaria should be avoided, and diagnosis and treatment of identified cases should be prompt. The geographic distribution of drug-resistant malaria parasites, the clinical features in obstetric patients, and the laboratory diagnosis are the same as described in Chapter 200, Malaria. We recommend hospitalization for all pregnant women with malaria. All antimalarial drugs have potential fetal toxicity. Chloroquine phosphate, the blood schizonticide of choice for oral prophylaxis (500mg [300mg base] once a week beginning a week prior to potential exposure and continued for 4 weeks afterwards) and therapy (1 g [600mg base] stat, and then 500 mg in 6 hours and 500mg daily for two doses) is generally considered safe and is effective for treatment of plasmodial species other than chloroquine-resistant *Plasmodium falciparum*. Pregnant women should receive chloroquine once a week until the end of pregancy when primaquine can be administered to eradicate dormant hypnozoites that may be in the liver. Mefloquine appears safer than other antimalarial drugs, but concerns remain about stillbirth, LBW, and neuropsychiatric and cardiac side effects. Tetracyclines are contraindicated during pregnancy, but IV clindamycin (10mg/kg followed by 5mg/kg every 8 hours) is an alternative. Artesunate plus clindamycin is indicated during any trimester of pregnancy; for treatment in the second or third trimester, an artemisinin-based combination regimen known to be effective in the region of acquisition of malaria may be preferable. Atovaquone (250mg) combined with proguanil (100mg) is highly effective against chloroquine- and mefloquine-resistant *P. falciparum* malaria, but data in pregnancy are scarce. Rescue has been successful with atovaquone–proguanil combined with artesunate in multidrug-resistant *P. falciparum* infections without recorded toxicity. Small studies suggest that artemisinin-derived antimalarials are well tolerated. Quinine sulfate or quinidine gluconate with or without clindamycin are alternative regimens that require continuous monitoring of vital signs, blood glucose, and electrocardiogram (ECG). For severe malaria

in the second and third trimester, parenteral artesunate is preferred over quinine/quinidine. Treatment should be started immediately with the most readily available drugs. Exchange transfusions might be added in severe malaria during pregnancy, but their benefit is controversial.

During pregnancy, chloroquine alone or with proguanil remains preferred for chemoprophylaxis where still effective; where not, mefloquine may be used. Doxycycline and primaquine must be avoided. Pregnant women should not visit malarial zones; when unavoidable, dedicated chemoprophylaxis, intermittent preventive treatment, and antivector strategies that include insecticide-treated nets are paramount.

Toxoplasmosis

The rationale for early treatment of toxoplasmosis acquired during gestation is to decrease fetal infection. When the maternal diagnosis is established during pregnancy, spiramycin, a macrolide antibiotic with an antibacterial spectrum similar to erythromycin (1 g orally three times a day) reduces the rate of transmission of infection to the fetus by approximately 60%. The drug, available in the United States through the FDA (1–301827–2335), is continued until delivery, assuming fetal infection has been excluded. If fetal infection is confirmed (the diagnostic method of choice is amniotic fluid polymerase chain reaction [PCR] examination for *Toxoplasma gondii* DNA after 18 weeks of gestation), oral pyrimethamine, 25 mg/day, plus sulfadiazine, 4 g/day, is superior and therefore should be started together with folinic acid, 10 mg/day, as soon as the diagnosis is established.

Serologic screening is to be performed before pregnancy or at the first prenatal visit, before gestational week 22, and finally near term in previously seronegative women. If the tests are or become positive, acute immunoglobulin M (IgM) (requires confirmation in a reference laboratory), IgA, or IgE can prove recent infection and mandate therapy. Maintenance trimethoprim–sulfamethoxazole (TMP–SMX) for *Pneumocystis jirovecii* (*carinii*) pneumonia (PCP) prophylaxis may prevent toxoplasmosis.

Herpes simplex virus infection of the genital tract

Maternal fetal transmission occurs by direct contact during vaginal delivery. Ascending or transplacental infection rarely occurs. Acyclovir, an antiviral drug with an excellent safety profile, has been used in pregnancy including the first trimester. The same experience is accumulating with the use of valacyclovir and famciclovir.

For primary genital infection, acyclovir is recommended at a dose of 400 mg PO, three times a day for 10 to 14 days. For one or more symptomatic recurrences of genital herpes simplex virus during pregnancy, acyclovir, 400 mg PO three times a day, given at 36 weeks through delivery is beneficial. In preterm premature rupture of membranes at less than or equal to 31 weeks in women with active genital herpetic lesions, expectant management is warranted, and acyclovir therapy may shorten the duration of the lesions, but no further data are available.

The greatest risk for neonatal herpes is in women who shed virus during delivery, which is most common in those who acquired herpes in the third trimester. Additional risk factors include mothers younger than 21 and the use of fetal scalp electrodes. Although cesarean section does not prevent all neonatal lesions, for women with a history of genital herpes and either active genital lesions, vulvar pain, or burning at the time of delivery, cesarean section should be offered.

Prophylactic cesarean delivery is not indicated for women with a history of recurrent herpetic lesions and no evidence of active lesions at the time of delivery. In such women, acyclovir prophylaxis from week 36 is preferred to cesarean delivery.

The use of antiviral therapy during delivery is controversial; antiviral therapy can reduce the rates of viral shedding (and thereby reduce newborn exposure) but data are incomplete and the approach should be individualized. The benefit of treating asymptomatic mothers at delivery is unknown. After delivery, a high index of suspicion and immediate isolation and treatment of infants with early infections are warranted.

Vaccination during pregnancy

Yearly inactivated influenza vaccine (IIV) is indicated during pregnancy; Tdap vaccination is recommended during each pregnancy regardless of the interval since prior dose. Antipneumococcal vaccination may be given if other risk factors are present; meningococcal and hepatitis vaccines may be indicated on the basis of medical or epidemiologic indications. Live-virus vaccines such as varicella, zoster, and MMR are contraindicated. Always consult the current vaccine recommendations and updates.

Influenza

The risk of complications is increased in pregnant women with influenza. Vaccination is the best protection for the mother and protects the infant for 6 months. The Centers for Disease Control and Prevention (CDC) recommends influenza vaccination to all women who are pregnant or will be pregnant during influenza season regardless of trimester. Live attenuated influenza vaccine (nasal route) should not be utilized during pregnancy. A trivalent or tetravalent vaccine should be utilized.

The diagnosis during pregnancy is clinical and treatment should be initiated within 2 days of symptoms, although data suggest a benefit of treatment if started later. Treatment of influenza outweighs the potential risk to the fetus. Women within 2 weeks postpartum should also be treated promptly. Pregnant women with presumptive influenza should be treated with antivirals, despite an updated vaccination history, since vaccine is not 100% effective.

Oseltamivir and zanamivir are antiviral drugs to which the majority of influenza viruses are susceptible since 2009. Although they are Pregnancy Category C drugs, prenatal exposure to these drugs has not shown increased fetal risk.

Oseltamivir is preferred to inhaled zanamivir because of greater experience using the drug during pregnancy. The dosing for oseltamivir is 75 mg orally every 12 hours and for zanamivir 10 mg (2 inhalations) every 12 hours administered for 5 days. Longer treatments have been used in patients who persist very ill after 5 days of therapy. Antiviral prophylaxis should be considered for pregnant women and for women up to 2 weeks postpartum. Zanamivir is considered the drug of choice for prophylaxis in pregnancy due to its low systemic absorption. Secondary respiratory complications may be seen especially in asthmatic patients. The dose recommended for prophylaxis is zanamivir 10mg (2 inhalations) once a day for 10 days or oseltamivir 75mg orally daily for 10 days. When fever develops during the first trimester, acetaminophen should be added to the antiviral therapy.

Human immunodeficiency virus (HIV) infection

Antiretroviral therapy during gestation includes two separate issues: treatment of maternal HIV infection and prevention of prenatal transmission. Treatment with antiretrovirals during pregnancy reduces the HIV viral load to undetectable levels and lowers the risk of perinatal infection from 25% to 30% without therapy to less than 2%. Therefore, combination antiretroviral therapy is indicated to all pregnant women with HIV regardless of the baseline CD4 count and HIV viral load. The goal of therapy is to achieve an undetectable HIV viral load using the most sensitive assay. Certain antiretroviral drugs should be avoided in pregnancy, e.g., efavirenz, because of teratogenic effects; didanosine and stavudine are more toxic than the available preferred nucleoside reverse transcriptase inhibitors (NRTI). Nevirapine, a non-nucleoside reverse transcriptase inhibitor (NNRTI), has caused hepatotoxicity in women with CD4 counts >250 cells/mm^3. The recommendations for the use of antiretroviral drugs to prevent or reduce perinatal transmission of HIV are updated periodically, and the reader is encouraged to consult the web site http://AIDSinfo.nih.gov for current guidelines.

For HIV-infected pregnant women on antiretroviral therapy and failure of virologic suppression, there is no clear recommendation. Raltegravir has been used later in pregnancy; however, the reports on safety and efficacy are anecdotal. Intrapartum care using IV zidovudine as therapy or prophylaxis depends on the maternal viral load. If the patient receiving antiretroviral combination has a viral load < 400 copies/mL, IV zidovudine is no longer necessary. However, if the viral load is > 400 copies/mL or unknown at the time of delivery, IV zidovudine is indicated during labor, regardless of the mode of delivery or antiretroviral regimen. IV zidovudine during labor and delivery or before a cesarean section (started 3 hours prior to surgery) should be initiated at the following doses: 2 mg/kg IV as a loading dose followed by continuous IV infusion of 1 mg/kg/hour until delivery. Continue other antiretrovirals on schedule and minimize the duration between rupture of membranes and delivery through stimulating labor. Additionally, cesarean section at 38 weeks of gestation is recommended to all patients if the viral load is above 1000 copies/mL near the time of delivery.

Parvovirus B19 infection

Infection with parvovirus B19 during pregnancy can lead to vertical transmission complicated by fetal heart failure, anemia, hydrops fetalis, and death.

All pregnant women exposed to or with symptoms suggestive of parvovirus infection should have IgM and IgG antibody testing. Those found to have a positive IgM who are beyond 20 weeks of gestation should have weekly ultrasounds for at least 8 weeks after the acute infection to look for signs of fetal hydrops. When hydrops fetalis develops, usually maternal IgM antibodies are absent. If pregnant women with recent parvovirus B19 exposure have negative IgM and IgG serologies, then testing maternal plasma for parvovirus B19 DNA should be performed, since it is a more sensitive test. There is no effective drug treatment for parvovirus B19 infections and it is difficult to avoid contact with infected individuals since they are contagious before symptoms develop; hand washing and avoiding sharing drinks, food, or utensils, may reduce transmission.

Postpartum endometritis

Infection of the uterine cavity remains a significant cause of postpartum fever. Fever, tachycardia, suprapubic pain reflecting uterine tenderness, and purulent cervical drainage are characteristic findings. Purulent foul-smelling lochia and uterine subinvolution are also found in some women. A fever of greater than or equal to 38° C after 24 hours of delivery and within 10 days postpartum is significant. Endometrial cultures are not routinely done since it is difficult to obtain uncontaminated samples through the cervix. Cervical cultures for gonorrhea and samples for chlamydia nucleic acid amplification should be obtained if not done previously, as well as blood and urine cultures.

Early onset of suspected infection suggests group A streptococci; onset between day 3 and 7 postpartum suggests enteric bacteria and anaerobes and late onset after 7 and even 14 days suggest *Chlamydia* infection. Cesarean delivery, especially after the onset of labor, is more frequently associated with endometritis.

Ultrasound and/or computed tomography can establish the presence and characteristics of a mass, especially if palpated, and guide decisions for aspiration or further procedures. Therapy includes draining pelvic collections and the uterus if indicated. Initial antibiotic therapy is empiric and should be broad spectrum covering aerobes and anaerobes.

Clindamycin and gentamicin are commonly used; alternative drugs with similar efficacy include piperacillin–tazobactam and carbapenems (imipenem, meropenem, doripenem, or ertapenem). Doxycycline should be added to the previous antibiotics if *Chlamydia* is suspected or diagnosed. Therapy is continued until the patient is clinically improved and afebrile for at least 24 hours; oral antibiotics are rarely prescribed after successful parenteral therapy. If bacteremia is present, at least 7 days of antibiotic therapy is recommended, switching to PO therapy if appropriate oral alternatives are available. Defervescence is expected after 48 to 72 hours of therapy; persistent fever may suggest resistance, abscess, absence of therapeutic drug blood levels, or septic pelvic thrombophlebitis.

Cesarean section

The risk of infection after cesarean delivery is higher than after vaginal delivery. Surgical site infections usually develop between 4 and 7 days after the surgical procedure and wound infections are diagnosed in 2.5% to 16% of these patients. It has been reported that a subcutaneous hematoma is a major risk factor for infection in a high percentage of patients after discharge. Group A or B β-hemolytic streptococci usually cause an early infection manifested by fever and cellulitis. Infections caused by *Staphylococcus aureus*, enteric bacteria, or vaginal flora usually appear later. A wound containing pus may require drainage, debridement, irrigation, and vacuum wound therapy may also be useful once local infection is controlled. Cellulitis at the wound site can be treated with broad-spectrum antibiotics alone if there are no signs of fluid collections.

For severe infections, especially if deeper tissue extension is suspected, broad-spectrum antibiotics covering *S. aureus* (including methicillin-resistant *S. aureus* [MRSA]) and microbial flora at the site of surgery should be started immediately. This can be accomplished with vancomycin or daptomycin. The antibiotic therapy for deeper pelvic infections is described in the section on postpartum endometritis.

Lactational mastitis

Acute breast infections during breastfeeding cause fever and breast discomfort, and occur in 2% to 10% of lactating women. Risk factors include nipple excoriations or cracking, prolonged unilateral engorgement with inadequate milk drainage, and previous mastitis. *S. aureus*, and more frequently MRSA have become the most important pathogens. Group A or B streptococcus, *E. coli*, anaerobes (*Bacterioides* species), coagulase-negative staphylococci and *Corynebacterium* species are frequently isolated. These microorganisms penetrate the nipple, colonize the stagnant milk, and then produce mastitis. Ultrasound is an effective method to diagnose abscesses and is useful to guide abscess drainage.

In patients with mild to moderate infection and with risk factors for MRSA, trimethoprim–sulfamethoxazole DS (1 tablet PO every 12 hours) or clindamycin (300 to 450 mg PO every 6 hours) can be used. Linezolid (600mg PO every 12 hours) is also an acceptable effective alternative. In patients with mild to moderate infections and with no risk factors for MRSA, dicloxacillin (500mg PO every 6 hours), or clindamycin (300 to 450 mg PO every 6 hours) can be used if the patient is allergic to β-lactam drugs.

In patients with severe infections (systemic toxicity, hemodynamic instability) vancomycin at 15 mg/kg IV every 12 hours should be immediately started, and if Gram stain of the abscess or drainage shows the presence of gram-negative bacilli, broad-spectrum empiric antibiotic therapy including a third-generation cephalosporin or a β-lactam/β-lactamase inhibitor combination should be promptly added. Patients should be treated for at least 10 days. Continuation of lactation is encouraged during therapy. Breast pumps are useful until the mother can resume nursing.

Hepatitis

Acute hepatitis A during pregnancy is similar to the nonpregnant population. So far, there has not been perinatal transmission reported. Premature labor is a risk if severe disease develops during the third trimester. Other complications include PROM, premature contractions, vaginal bleeding, and placental detachment. Overall, children have a favorable outcome. When acute hepatitis B is diagnosed during gestation, it is usually not linked to high mortality or fetal malformations. The infection is not severe and termination of pregnancy is not considered. If hepatitis B occurs earlier in pregnancy, there is a 10% transmission rate during the perinatal period; however, transmission increases significantly if the acute infection is diagnosed near or at the time of delivery. Perinatal transmission occurs most efficiently when the infant mucosal membrane comes in contact with infected maternal secretions during birth, especially if the mother is HBeAg positive. Transmission can also happen in utero or after birth.

Universal maternal screening for hepatitis B virus infection is strongly recommended, and any women in labor with known hepatitis B status should be considered potentially infectious. The use of prophylactic hepatitis B immunoglobulin immediately after birth followed by hepatitis B recombinant vaccine within 12 hours, and completion of three doses within the first 6 months of life, reduces hepatitis B virus transmission to rates of 10% or less. Hepatitis B maternal vaccination is not contraindicated during pregnancy or lactation.

Hepatitis D coinfection during pregnancy is managed as described for hepatitis B. The risk of transmission of hepatitis C from mother to infant is approximately 2%. Cesarean section delivery and avoidance of breastfeeding are not recommended for hepatitis C-infected women.

Hepatitis E virus infection and fulminant hepatic failure have a mortality rate of 10% to 25% in women during the third trimester. Vaccines are presently in development. Also, there is no evidence that immunoglobulin protects against hepatitis E, including lots produced where infection is endemic.

Varicella

Varicella-zoster virus infection is more severe during pregnancy. The risk of congenital varicella syndrome appears to be low, between 0.4% and 2%.

Varicella pneumonia during gestation is a severe disease, usually developing within 1 week of the rash, may rapidly progress to respiratory failure, and it is a medical emergency. Patients are febrile, hypoxemic, with chest x-rays showing diffuse nodular infiltrates. Intravenous acyclovir is indicated at a dose of 10 mg/kg every 8 hours.

Uncomplicated varicella infections in a pregnant female can be treated with acyclovir (20mg/kg PO every 6 hours) for 5 days. Although the use of this drug has not been studied in pregnancy, a prospective registry of acyclovir use during gestation has not revealed an increased rate of birth defects.

Pregnant women who have been exposed to varicella-zoster virus are eligible for prophylaxis with varicella immune globulin, if they have no history of disease or negative serologic evidence of prior exposure. VariZig, which is a purified immune globulin made from plasma containing a high level of antivaricella antibodies, should be administered within 10 days of exposure. The dose recommended is 125 units/10 kg of body weight given intramuscularly, the maximum dose is 625 units. There are no data to support the use of acyclovir for reducing the risk of varicella in exposed pregnant women.

Neonatal varicella-zoster virus infection is a serious disease that results from the transmission of the virus from the mother to the fetus within 5 days before to 2 days after delivery. The management of newborns exposed to varicella-zoster virus is discussed in Chapter 94, Neonatal infection.

Dialysis-related infection

Peter Mariuz

Data from the US Renal Data System (USRDS) 2018 Annual Report show that the crude incidence rate for end-stage renal disease (ESRD) was 378 per million persons. On December 31, 2015, there were 703,243 prevalent cases of ESRD. In 2015, 87.3% of incident individuals began hemodialysis (HD), 9.6% started peritoneal dialysis (PD), and 2.5% received a preemptive kidney transplant. In 2015, 80% of patients who initiated HD used a catheter for vascular access. Infections remain a common cause of death among patients receiving long-term dialysis and a leading cause of hospitalization. Sepsis is responsible for >75% of these deaths. Abnormalities of cellular immunity, neutrophil function, and complement activation are associated with chronic renal failure and cited as risk factors for the increased susceptibility to infection. Additional predispositions for bacteremia include comorbid conditions (diabetes mellitus, hepatitis C infection), receipt of immunosuppressive therapy, and anemia. Most dialysis-related infections are caused by common microorganisms rather than by opportunistic pathogens and are primarily related to access site for both HD and PD. This chapter focuses on the treatment of infections related to dialysis access devices.

Types of access devices for dialysis

The catheters available for hemodialysis (Table 95.1) differ according to the duration of use (acute versus chronic), tunneled versus non-tunneled, cuffed versus non-cuffed, and, with regards to PD catheters, intraperitoneal versus extraperitoneal designs. An arteriovenous (A-V) fistula is an anastomosis most frequently of the radial artery to the cephalic vein. Other vessels in the arm can also be used. An A-V graft uses a tube made of polytetrafluoroethylene (PTFE, Teflon) to make the A-V connection. There are two types of HD catheters: non-cuffed, non-tunneled, for acute use (<2 weeks) and cuffed, tunneled catheters for chronic use. Catheters are made of either silicone or polyurethane; the specific material does not affect infection rates. Peritoneal catheters for acute use (≤3 days) have the same basic design: a relatively stiff length of straight or slightly curved nylon or polyethylene tubing with side holes at the distal portion. They are placed at the bedside, inserted over a guidewire. These catheters lack cuffs which may protect against bacterial migration from the skin to the outer surface of the catheter and consequently have a high rate of infection when used for longer than 3 days. There are multiple PD catheter designs for chronic use. The subcutaneous segments can be straight or curved (swan-neck) and may have one or two cuffs. The intraperitoneal configuration may be straight or coiled. They are made of silicone rubber or polyurethane with side holes at the distal end. PD catheters can be placed by use of guidewire and dilators, peritoneoscopy, or, less frequently, laparoscopy. Infection rates are not affected by specific mode of placement. The silicone rubber or polyurethane surface elicits growth of squamous epithelium in the subcutaneous tunnel and at the catheter's entry and exit sites. The Dacron cuffs provoke a local inflammatory response resulting in the formation of fibrous and granulation tissues within 4 weeks. Both epithelial and fibrous tissues inhibit bacterial migration along the tunnel. Additionally, the fibrous tissue anchors the catheter, which may decrease infection rates. Examples of peritoneal catheters for chronic use include the straight or curled Tenckoff catheter, which is widely used in the United States, the swan-neck Missouri, and the Toronto Western Hospital catheters. It

TABLE 95.1 **VASCULAR ACCESS DEVICES FOR HEMODIALYSIS**

Temporary venous access (usually <2–3 weeks) for ESRD	Permanent access for ESRD
Single- or double-lumen venous catheter inserted over guidewire into the internal jugular vein, femoral vein[a], or less frequently subclavian vein	Arteriovenous fistula using autogenous saphenous vein or graft using PTFE
Silastin-Teflon shunt for CAVH or CAVHD	Dacron-cuffed double-lumen silicon catheter (Permcath) surgically inserted into the subclavian or internal jugular vein through a subcutaneous tunnel.
Twin wide-bore femoral catheter for CAVH or CAVHD	Scribner arteriovenous shunt (historical interest).

Abbreviations: ESRD = end-stage renal disease, PTFE = polytetrafluoroethylene; CAVH = continuous arteriovenous hemofiltration; CAVHD = continuous arteriovenous hemodialysis.
[a] Femoral vein placement is associated with high rate of infection, so it is usually removed by 72 hours.

has not been shown that any of these newer catheters provide any advantage over the Tenckoff design.

Infectious complications of vascular access devices

Chronic venous catheter use may be complicated by exit site infection, tunnel infection, and catheter-related blood stream infections (CRBSIs). Each dialysis session requires four tubing connections and thus presents a high risk for introduction of microbes through the hub and lumen of catheters. CRBSIs infection rate ranges from 3.8 to 6.6 episodes per 1,000 days for nontunneled catheters versus 1.1 to 5.5 episodes per 1,000 days for tunneled catheters, both of which are markedly higher than for A-V fistulas and grafts. The relative risk for infection-related hospitalization and death is increased two- to three-fold for catheter-dependent HD patients compared to those with A-V fistulas, and the relative risk for CRBIs is estimated to be 10 times higher. Local infections occur at the exit site or along the tunnel of percutaneously inserted catheters. The clinical presentations of exit site infection include pain, erythema, tenderness, induration, and purulent discharge within 2 cm of the site. Tunnel infections are associated with pain, erythema, tenderness, or induration involving the subcutaneous tract of the catheter. Infection of autologous A-V fistulas and prosthetic PTFE A-V grafts manifests as cellulitis, perifistular abscess, false aneurysm, draining sinus, and, in PTFE fistulas, bleeding when the graft's suture lines are involved. Fever, leukocytosis, or left shift in the differential leukocyte count may be present. Other clinical manifestations of CRBSIs may include hemodynamic instability, hypothermia, altered mental status, nausea and vomiting, malaise, and catheter dysfunction.

Both exit site and tunnel infections may be complicated by concomitant bacteremia, sepsis, and suppurative thrombophlebitis. Bacteremia may lead to metastatic foci of infection, including septic arthritis, septic pulmonary emboli, endocarditis, osteomyelitis, brain abscess, and splenic abscess. Bacteremia and sepsis often present without signs or symptoms of infection at the vascular access site. Catheter-related colonization without clinical manifestations of infection has been reported in up to 55% of HD catheters. Most CRBSIs arise from the lumen following bacterial colonization and biofilm formation. Eradication of bacteria in endoluminal biofilm requires very high concentrations of antibiotics (up to 1,000 times the concentrations needed to kill bacteria in solution). Systemic antibiotic therapy alone without catheter removal yields cure in only one-third of these CRBSIs.

Microbiology

A specific microbiologic diagnosis of access-related infection can frequently be made by Gram stain and culture of purulent material from the cannula exit site or with A-V fistulas from needle exit sites or abscess fluid. Blood cultures drawn from the vascular access device along with other peripheral sites (e.g., from vessels not intended to create future HD fistula, for example hand veins) should be obtained to aid in identification of the access site as the origin of infection if possible. If peripheral blood cultures cannot be obtained a blood culture drawn during dialysis from the HD circuit should be obtained. Access site origin of bacteremia is suggested if catheter blood cultures have an earlier time to positivity (at least 2 hours) compared to the time to positivity of blood cultures from another site. Other sources of bacteremia should be excluded. The organisms responsible for access device infection are shown in Table 95.2.

TABLE 95.2 **MICROBIOLOGY OF ACCESS DEVICE INFECTIONS**

Hemodialysis	Peritoneal dialysis
Staphylococcus aureus (40–80%)	*Staphylococcus epidermidis* and *S. aureus* (50%)
Other gram-positive bacteria (*S. epidermidis*, streptococci, including enterococci, diphtheroids), Gram-negative organisms (*Escherichia coli, Pseudomonas aeruginosa, Acinetobacter* spp., and other enteric gram-negative bacteria) (20–40%), polymicrobial (10-20%), fungi (<5%).	Other gram-positive bacteria (streptococci, including enterococci, diphtheroids) Gram-negative organisms (*E. coli, P. aeruginosa, Acinetobacter* spp., and other enteric gram-negative bacteria) occasionally fungi.

Percentages in parentheses are approximate proportional incidence from numerous references.

Therapy

Therapy is based on the results of cultures obtained from infected sites and blood. Initial management plans are shown in Table 95.3. Additionally, relative indications for removal of either catheter or A-V fistula or graft include suppurative thrombophlebitis; septicemia; bacteremia with metastatic foci of infection; infections caused by *Staphylococcus aureus, Pseudomonas aeruginosa*, mycobacteria, and fungi; lack of response to medical therapy within 48 to 72 hours; and recurrent infection in a catheter with the same pathogen. Tunnel infection requires removal of the catheter. Any associated fluid collections associated with an A-V fistula or graft should be drained. In the absence of exit site and tunnel infection, sepsis, or metastatic foci of infection, exchange of the catheter over a guidewire may be attempted. If there is no resolution of fever, bacteremia, or fungemia in 48 to 72 hours, the catheter should be removed. CRBSIs caused by coagulase-negative staphylococci (not *S. aureus* or fungi) seem very amenable to guidewire exchange. Intravenous (IV) vancomycin is often used in initial therapy for access device infections as methicillin-resistant *S. aureus* (MRSA) is the most common pathogen. The type of dialyzer, dialysis flow rate, patient size, and level of residual renal function can make vancomycin serum levels difficult to predict. Therapy should be initiated with a loading dose of 15 to 25 mg/kg of vancomycin given preferably after dialysis. The second dose, 5 to 10 mg/kg, is given after the next dialysis session. Before the third dialysis session, a predialysis serum vancomycin level should be done to determine the vancomycin dose to be given after the third dialysis session. A standard postdialysis dose can be started once target serum concentrations have been achieved. Other antimicrobials with good activity against staphylococci are alternatives to vancomycin. Linezolid or daptomycin can be used in patients with allergy to vancomycin or for organisms with reduced sensitivity to vancomycin. Daptomycin dosing is 6 mg/kg, every 48 hours (preferably after dialysis), and for linezolid, 600 mg by mouth or IV every 12 hours. Methicillin-sensitive staphylococci (MSSA) should be treated with cefazolin 20 mg/kg after each HD session rather than nafcillin, which requires administration every 6 hours and placement of a separate IV line. Duration of therapy is 3 to 4 weeks if there is no evidence of endocarditis or other metastatic focus of infection.

Fifteen to thirty percent of infections are caused by gram-negative bacilli. If gram-negative organisms are suspected, an aminoglycoside, cefepime, or aztreonam should be used in combination with the antibiotics noted earlier for suspected infection caused by gram-positive organisms; treatment duration is 2 weeks. Vancomycin-resistant enterococci (VRE) resistant to ampicillin should be treated with IV daptomycin 6 mg/kg every 48 hours (preferably after dialysis) or linezolid 600 mg by mouth or IV every 12 hours. The initial choice of antimicrobials should be influenced by the sensitivity of organisms prevalent in the patient's geographic region. Surveillance blood cultures should be obtained 1 week after completion of antimicrobial therapy if catheter is not removed.

When catheter salvage is attempted, antibiotic lock therapy (ALT) has been recommended in addition to parenteral antibiotics for uncomplicated catheter infections. The rationale for this is the known difficulty to eradicate bacteria in endoluminal biofilm with parenteral therapy. With ALT the catheter lumen is filled with several milliliters of antimicrobial solution at concentrations several fold higher than the minimum inhibitory concentration (MIC) of the antibiotic for the infecting organism in combination with 50 to 100 U of heparin. Vancomycin (1–5 mg/mL), gentamicin, or amikacin (1–2 mg/mL); ciprofloxacin (0.2 mg/mL); and cefazolin (5 mg/mL) have been used most often. The solution is allowed to remain (lock) in the catheter for as long as possible and changed every 48 hours. The same volume of solution is removed before the next dose of antibiotic or other medications or solutions are administered. The optimal duration of ALT is not known, but it has been used most frequently for 10 to 14 days after each dialysis session. ALT is also used to prevent CRBSIs. Well-designed, appropriately powered, randomized, controlled trials that show efficacy of ALT to treat CRBSIs are lacking.

Lock therapy rather than catheter removal should not be used when the patient has sepsis, septic thrombophlebitis, endocarditis, osteomyelitis, neutropenia, *S. aureus*, mycobacterial or fungal infection, or exit site or tunnel infections.

TABLE 95.3 **TREATMENT OF HEMODIALYSIS ACCESS-SITE INFECTIONS**

Type of infection	Therapy
Exit-site infection in a temporary access device with or without bacteremia[b]	Catheter removal and vancomycin,[a] 1 g IV; subsequent doses based on serum levels; aminoglycosides or broad-spectrum β-lactam antibiotics if gram-negative organisms suspected
Tunnel infection[b]	Catheter removal and antibiotics as above
Catheter-related sepsis	Catheter removal; empiric broad-spectrum antimicrobial therapy with vancomycin and gentamicin, 1.5 mg/kg IV in a single dose; subsequent antimicrobial therapy based on pathogen and sensitivity pattern
Suppurative thrombophlebitis	Catheter removal, antimicrobial therapy based on pathogen and sensitivity pattern; surgical consultation for possible exploratory venotomy
Arteriovenous fistula infection	Vancomycin and gentamicin as above; incision and drainage of abscess; ligation or removal of prosthetic arteriovenous fistulas if response to treatment is not prompt; surgical repair of a malfunctioning infected shunt may be possible

[a] Alternatives to vancomycin include daptomycin and linezolid (see text).
[b] 10–14 days is often used for exit and tunnel infections with catheter removal; if the catheter remains in place, 2–3 weeks of antimicrobials and repeat blood culture 1 week after antimicrobial therapy completed.

Infections associated with peritoneal dialysis catheters

There are two main types of chronic PD: continuous ambulatory PD (CAPD) and automated PD (APD). Whether PD catheter infections are less frequent with CAPD or APD remains unproved. Thirty percent of patient transfers from PD to HD are a consequence of catheter complications and peritonitis. PD catheter exit site and particularly tunnel infections may result in peritonitis and catheter loss. Peritonitis accounts for 15% to 35% of hospital admissions for patients on PD. Quality standards set an infection rate of <0.67 episodes per patient per year on dialysis, while reported rates from different centers vary from 0.24 to 1.66 episodes per patient per year. About 18% of episodes result in catheter removal; 3.5% result in death.

Exit site infections present with purulent discharge from the exit site, and erythema may or may not be present. Pericatheter erythema without purulent drainage may be an early sign of infection particularly if >14 mm in diameter around the exit site. A tunnel infection, which usually occurs in the presence of an exit site infection, can present with erythema, induration, tenderness, and abscess in the area between the catheter cuffs but is often occult, as demonstrated by ultrasonography. Ultrasonography will reveal an area of hypoechogenicity (fluid collection) between the tube or the cuff of the catheter and surrounding tissues. Indications for tunnel sonography include presence of exit site infection, recurrent peritonitis, and for assessment of the efficacy of therapy and prognosis of tunnel infections. A sonolucent area around the exit site >1 mm thick following therapy and the involvement of the proximal cuff are associated with poor outcome. A specific microbiologic diagnosis can be made by performing a Gram stain and culture of purulent exudate. The organisms responsible for PD catheter infections are shown in Table 95.2. *S. aureus* and *P. aeruginosa* exit site infections are frequently associated with concomitant tunnel infections and often result in catheter-associated peritonitis.

Therapy

Therapy is ultimately based on the results of microbiologic culture data. Initial management plans are shown in Table 95.4. Therapy should be continued until the exit site appears normal. Indications for catheter removal include peritonitis, bacteremia, sepsis, recurrent peritonitis with same pathogen, and infection caused by fungi. Relative indications for catheter removal are tunnel infections (particularly if there is no response to therapy noted on serial ultrasound examinations), involvement of the deep cuff (which often leads to peritonitis), chronic exit site infections (no cure after 2–4 weeks of therapy), and exit site infections associated with involvement of the superficial cuff as noted on ultrasound. Ultrasonographic evidence of tunnel involvement is associated with frequent catheter loss (50%) because of refractory or recurrent peritonitis. A ≥30% decrease in the size of the fluid collection after 2 weeks of therapy is often associated with catheter salvage. Prolonged courses of antimicrobial therapy, although sometimes necessary, should be avoided to decrease the chance of development of antimicrobial resistance. Infections with VRE and, more ominously, vancomycin-insensitive strains of *S. aureus* and *S. epidermidis* reported in dialysis patients receiving prolonged (months of) treatment make the judicious use of this drug imperative. In chronic exit site infections, adjunctive surgical therapy may help control infection and result in catheter salvage. Surgical procedures that have been used include cuff shaving (removal of the external cuff), debridement and curettage of the exit site and sinus tract, incision, and debridement along the subcutaneous tunnel with exteriorization of the superficial cuff and relocation of the exit site. It is not known which of these is most effective. Among gram-positive organisms, *S. aureus* is more

TABLE 95.4 **TREATMENT OF PERITONEAL DIALYSIS ACCESS DEVICE INFECTIONS**

Type of infection	Therapy
Exit site erythema without purulent discharge	Topical mupirocin, chlorhexidine, hydrogen peroxide, or povidone iodine BID; avoid mupirocin with polyurethane catheter
Gram-positive exit site infection	For MSSA dicloxacillin, 250–500 mg PO q6h, or cephalexin, 500 mg PO BID, or trimethoprim-sulfamethoxazole, 160/800 mg PO BID. Clindamycin may also be used. IV or IP route can be used. For methicillin-resistant staphylococci: vancomycin, IV 1 g every 3–5 days depending on blood levels. Rifampin, 600 mg PO qd, can be added for possible synergistic effect. Ultrasound to rule out tunnel or cuff involvement; 2–3 weeks of therapy generally recommended; shave external cuff and explore tunnel if infection persists; if this fails, catheter removal
Gram-negative exit site infection	*Pseudomonas aeruginosa* should be suspected pending culture results. Ciprofloxacin, 250 mg PO BID; not to be taken within 2 hours of phosphate binders or antacids; alteration of therapy based on culture and sensitivity results. If infection is slow to resolve or recurrent *Pseudomonas* infection add a second drug such as IP aminoglycoside, cefepime, piperacillin–tazobactam, or a carbapenem. Therapy should be continued for 2–3 weeks. Catheter removal if infection persists beyond 2–3 weeks; early catheter removal should be considered if *Pseudomonas* or *Stenotrophomonas* isolated.
Tunnel infection	Antimicrobials as for exit site infections with removal of catheter.

Abbreviations: BID = twice a day; MSSA = methicillin-sensitive *Staphylococcus aureus*; PO = orally; IV = intravenously; IP = intraperitoneally.

commonly associated with poor response to medical therapy, tunnel infections, and catheter loss.

Peritonitis

Peritonitis is a common complication of PD. Although the incidence varies from center to center, the average incidence is 1.3 episodes per patient per year. A modest reduction in the incidence of peritonitis has been achieved with use of Y-set transfer kit and twin-bag disconnect systems (particularly infections from skin flora). Bacteria gain entry to the peritoneum from the catheter, often after improper technique in connecting the transfer set to the dialysate bag or the catheter to the transfer set from the outside surface of the catheter; as a consequence of exit site or tunnel infection; or by hematogenous spread or from the bowel or pelvis. Clinical manifestations include abdominal pain, fever, chills, malaise, nausea, vomiting, constipation, or diarrhea with abdominal tenderness, rebound tenderness, and leukocytosis. The peritoneal fluid may appear cloudy and will almost always contain >100 white blood cells per cubic millimeter of fluid after a dwell time of at least 2 hours, with 50% or more polymorphonuclear leukocytes. In any suspected PD infection, including those that appear to be localized to the exit site, a Gram stain and culture and a cell count and differential of the peritoneal fluid should be done.

Microbiology

A single pathogen is usually involved. Polymicrobial infection suggests a perforated viscus or other intra-abdominal or pelvic pathologic process. Most cases of peritonitis (70%) are caused by gram-positive bacteria. Collectively, *S. aureus* and *S. epidermidis* account for almost 50% of infections. *P. aeruginosa* and enteric gram-negative bacilli constitute 20% to 30%, and fungi, mostly *Candida albicans*, <1% to 10%. Some 5% to 20% of cases are culture negative. Though infrequent, fungal peritonitis is associated with significant morbidity and mortality, with death rates as high as 25%. Up to 40% of patients cannot resume PD because of damage to the peritoneal membrane that prevents effective dialysis. Mycobacterial peritonitis may be caused by *Mycobacterium tuberculosis* or non-tuberculous mycobacteria.

Therapy

Antibiotics may be given by the IV, oral, or intraperitoneal (IP) route if compatible with PD fluid. The IP route is preferred because of its convenience. Fourteen days of therapy is usually adequate. Three weeks of therapy is recommended for *S. aureus*, *Enterococcus*, *Pseudomonas/Stenotrophomonas* species, or polymicrobial peritonitis. There is no therapeutic advantage to IV therapy for peritonitis. Helpful information for the initial choice of antimicrobials includes peritoneal fluid Gram stain results, history of microbe-specific peritonitis, coexistent exit site infection, and intra-abdominal pathology. If the Gram stain does not show gram-positive bacteria or gram-negative bacteria or is unavailable, empiric therapy should be initiated with vancomycin and gentamicin.

After 24 to 48 hours, 70% to 90% of dialysate fluid cultures will yield a specific pathogen, and therapy should be modified accordingly. For *S. aureus* or *S. epidermidis* sensitive to nafcillin, this may be given at 125 mg/L in each exchange or a first-generation cephalosporin or clindamycin may be used. Addition of rifampin, 600 mg/d orally, can be considered for patients responding slowly to the initial regimen but should not be used for more than a week as resistance to this drug often develops with prolonged use. In areas where tuberculosis is endemic, the use of rifampin to treat *S. aureus* peritonitis should be avoided. If the patient does not improve within 5 days (refractory peritonitis), the catheter should be removed. Other indications for catheter removal include relapsing peritonitis (recurrence of peritonitis with same pathogen within 4 weeks), fungal peritonitis, and refractory exit site and tunnel infection. For MRSA, vancomycin, 15 to 30 mg/kg IP every 5 to 7 days for CAPD, and for PD a 30 mg/kg loading dose followed by 15 mg/kg every 3 to 5 days. In both, achieving a trough level of >15 μg/mL is recommended. If the patient is not responding to vancomycin, consider substituting linezolid 600 mg IV or orally every 12 hours; IP dosing is not recommended as linezolid is not stable in PD fluid, or daptomycin can be used, 6 to 8 mg/kg every 48 hours especially if the vancomycin MIC is >1 μg/mL. If the organism is sensitive, clindamycin, 300 mg/L loading dose and then 150 mg/L maintenance can be used. For enterococci sensitive to ampicillin, give 125 mg/L IP in each exchange and consider continuing the aminoglycoside although is difficult to do so as these antibiotics cannot be given by IP concomitantly. Oral amoxicillin may also be considered. Recent International Society for Peritoneal Dialysis (ISPD) guidelines recommend using vancomycin, 2 g IP (per week) because of concerns regarding the stability and activity of ampicillin in PD fluid. Vancomycin is recommended for patients with penicillin allergy. Treatment of VRE depends on the antimicrobial sensitivities of the specific organism. If VRE is not ampicillin-susceptible, give linezolid, 600 mg IV or orally every 12 hours, or daptomycin, 4 mg/kg (6–8 mg/kg if bacteremia present) every 48 hours, preferably after dialysis. Because enterococci are part of the intestinal flora, intra-abdominal pathology should be considered. For other gram-positive organisms, therapy should be based on antibiotic sensitivity results. For gram-negative organisms other than *P. aeruginosa* and *Stenotrophomonas maltophilia*, a first-generation cephalosporin may suffice. If the microbe is resistant to cefazolin, the choice of another cephalosporin should be based on sensitivity testing. For *P. aeruginosa* or *S. maltophilia*, consider use of two agents (one being an aminoglycoside) chosen based on sensitivity testing results and continue for at least 3 weeks. However, eighth-nerve toxicity may complicate aminoglycoside use, particularly after 2 to 3 weeks of therapy. If the infection is catheter-related, the catheter should be removed with continued administration of antibiotics for 1 week.

Polymicrobial or anaerobic infections suggest a perforated viscus, and therefore surgical consultation is required. Vancomycin and an aminoglycoside should be continued or changed to a cephalosporin based on sensitivity testing, with addition of metronidazole, 500 mg IV or orally every 8 hours.

If yeast are identified on Gram stain, fluconazole, 200 mg orally or IP daily should be used. The catheter should be promptly removed

and treatment continued for at least 10 more days. Voriconazole, caspofungin, and amphotericin B are alternatives to fluconazole for patients who do not respond or who have organisms insensitive or less sensitive to fluconazole such as *Candida krusei* and *C. glabrata*. After catheter removal, infections with filamentous fungi should be treated with amphotericin B or voriconazole.

Most patients with peritonitis demonstrate significant clinical improvement within 2 to 4 days. Patients who do not respond to therapy should be re-evaluated. Peritoneal fluid should be obtained for cell count and differential, Gram stain, and culture. In addition, intra-abdominal or gynecologic pathology requiring surgical intervention, unusual pathogens (fungi, mycobacteria), and sclerosing peritonitis must be considered. The catheter should be removed and cultures obtained for patients whose original cultures are negative but who remain symptomatic after 2 to 4 days.

Less common pathogens

There are conflicting data regarding the intrinsic risk of dialysis patients for developing tuberculosis. It is likely that any predisposition of patients to pulmonary tuberculosis is related more to the prevalence of tuberculosis in the community than to host factors. However, there is a higher incidence of extrapulmonary tuberculosis in patients receiving PD. Treatment is the same as for patients without ESRD, except that the dosing of some agents must be adjusted for renal failure and others should be avoided. Isoniazid is given at 150 mg/d orally with a supplemental dose after dialysis. Rifampin requires no dosage adjustment. The dosage of ethambutol is 5 mg/kg/d orally with a supplemental dose after dialysis. Some believe that pyrazinamide use should be avoided if possible; ethionamide is given at 250 to 500 mg/d orally.

Listeria monocytogenes septicemia, meningitis, and endocarditis have been rarely described in patients with ESRD, usually as a complication of iron overload or during immunosuppressive therapy. Yersiniosis complicating iron overload has also been reported. Disseminated or rhinocerebral phycomycosis in nondiabetic patients receiving hemodialysis may be related to deferoxamine use. Treatment includes amphotericin B, posaconazole, and surgical debridement of infected sites.

Asplenia-associated Infections

Larry I. Lutwick

What more thou didst deserve than in thy name,
And free thee from the scandal of such senses
As in the rancor of unhappy spleen
Measure thy course of life, with false pretenses
Comparing by thy death what thou hast been.

– "A Funeral Elegy," W. Shakespeare, 1612

Introduction

The human spleen (Figure 96.1) (in German: *milz*; also, *ohnemilz*: "without a spleen, asplenic") is an organ that at one point had been deemed as nonessential as the appendix and traditionally had been deemed the source of anger and melancholy thoughts. Thus, the expression "venting one's spleen" is to rid oneself of anger caused by someone or something by attacking someone or something other than the source of that anger. A similar therapeutic process, laughter ("If you desire the spleen, and will laugh yourself into stitches, follow me," Shakespeare [Figure 96.2], *Twelfth Night*, Act III, Scene 2), is also linked to the spleen.

It seems ironic, therefore, that these concepts reflect that this collection of immune cells in the left upper quadrant of the abdomen actually do appear to function as a way of cleansing the body. Indeed, Shakespeare's "unhappy spleen," one that has been removed from residence (by splenectomy) or whose function is embarrassed by one or another disease (hyposplenism), predisposes (by not appropriately performing its cleansing function) its former owner to an infectious disease process with substantial morbidity and mortality by becoming *ohnemilz*.

This disease, overwhelming postsplenectomy infection (OPSI), also referred to as postsplenectomy sepsis (PSS), is one of a group of infectious disease processes, such as bacterial meningitis and meningococcemia, for which diagnosis and therapeutic intervention are required immediately to minimize disease impact. Using Ben Franklin's (Figure 96.3) "ounce of prevention is worth a pound of cure" concept, prevention as well as therapeutic intervention is an important part of any discussion of OPSI.

Risks and timing of OPSI

The individual risk of OPSI depends on the cause of splenectomy as well as the time after the procedure. Overall, the lifetime risk of 1% to 2% is estimated related to trauma or idiopathic thrombocytopenic purpura (ITP), 3% for spherocytosis, 6% for Hodgkin's disease and portal hypertension, and as high as 11% for thalassemia. Although some asplenic conditions clearly have a lower risk of OPSI, if OPSI, develops the

FIGURE 96.1 The spleen.

morbidity and mortality are not lower in these cohorts. About 5% to 6% of total OPSI cases occur in individuals with poorly functioning spleens. A partial list of diseases associated with hyposplenism can be found in Box 96.1.

No ideal assay is available to measure adequate splenic function. The presence of Howell–Jolly bodies (nuclear remnants in

BOX 96.1

Common causes of hyposplenism

Blood diseases
- Primary thrombocytosis
- Sickle cell hemoglobinopathies

Gastrointestinal diseases
- Celiac disease
- Ulcerative colitis

Splenic infiltration
- Amyloidosis
- Sarcoidosis
- Malignant infiltration

Vasculitic diseases
- Autoimmune thyroiditis
- Lupus erythematosus
- Rheumatoid disease

Others
- Ethanolism
- Long-term parenteral nutrition
- Spleen irradiation
- Splenic vein thrombosis

circulating red blood cells [RBCs]) is too insensitive. Quantification of red cells containing "pocks" (actually vacuoles containing hemoglobin found in older RBCs) as seen by interference microscopy, however, appears to be a valuable tool.

About 50% of cases of OPSI following a splenectomy occur within 2 years of the event and about 75% within 5 years. It is important to know, however, that 2% to 3% of cases occur 20 years or longer after the event, and there have been reports of OPSI four decades after the onset of *ohnemilz*.

Presentation and diagnosis

The classical presentation of OPSI is one that often begins with an alert, relatively nontoxic patient who might walk into an emergency department complaining of fever and chills associated with myalgias and diarrhea. The individual deteriorates quickly, developing lactic acidosis due to organ hypoperfusion, disseminated intravascular coagulation (DIC), and multiorgan failure. This gastroenteritis-like presentation can, but should not, divert attention away from OPSI in the at-risk individual.

The progression to septic shock and death in these individuals can happen within hours of initial presentation. Overall mortality rates are 50% to 60%, with a majority of the deaths within 24 hours. Encouragingly, relatively recent pediatric data suggest that increased survival rates can result from prompt recognition, and overall incidence can decrease with preventative measures. Purpura fulminans (Figure 96.4) has been associated with OPSI as well as with meningococcemia. It causes considerable endothelial injury, resulting in arterial thrombosis and gangrene of one or multiple extremities. If the affected individual survives, multiple extremity amputations can result.

Prompt diagnosis requires knowledge of the issue with spleen function or absence in an appropriately ill patient. Confirmation requires positive blood cultures for the bacterial etiology. Blood cultures are often positive within 6 to 8 hours due to the high initial bacteremia, which is as much as 10,000 times the organism load of a more routine bacteremia. Because of this massive bacteremia, organisms can be found in the buffy coat of the peripheral blood and sometimes on a standard peripheral smear. It should be noted that Wright stain, routinely used on peripheral blood smears, will stain all bacteria blue, even the usual "red" organisms on Gram stain of gram-negative bacteria.

Pathogens

Streptococcus pneumoniae

Pneumococci are without question the most canonical cause of OPSI. This α-hemolytic, polysaccharide-encapsulated, gram-positive diplococcal bacterium has a distinctive morphology on staining, a so-called lancet shape (Figure 96.5). Its capsule is a well-recognized virulence factor, interfering with phagocytosis by preventing effective C3b opsonization of the bacterial cells. Overall, *S. pneumoniae* is involved in 50% to 90% of OPSI cases, with the percentage of pneumococcal OPSI cases tending to increase with age. In series that include single case reports, pneumococci are often underrepresented because many case reports relate to less common causes of infection in asplenic hosts.

No single type or group of the 90 different capsular types appears to be more associated with OPSI than other forms of invasive pneumococcal disease. With the use of pneumococcal polysaccharide vaccination, however, especially in places with universal immunization using the newer 13-valent conjugated product, a shift of serotypes can occur.

It is important to note that antimicrobial drug resistance has become increasingly prevalent. Some isolates are only less sensitive to penicillin (particularly relevant in bacterial meningitis), some are fully resistant to penicillin, and some may be resistant to penicillin as well as the extended-spectrum cephalosporins such as ceftriaxone. The local epidemiology of pneumococcal resistance must be considered in the empiric treatment of OPSI. High levels of penicillin resistance are reported in Spain, parts of eastern Europe, and South Africa (Figure 96.6). In the United States, resistance is more prevalent in

FIGURE 96.4 Purpura fulminans.

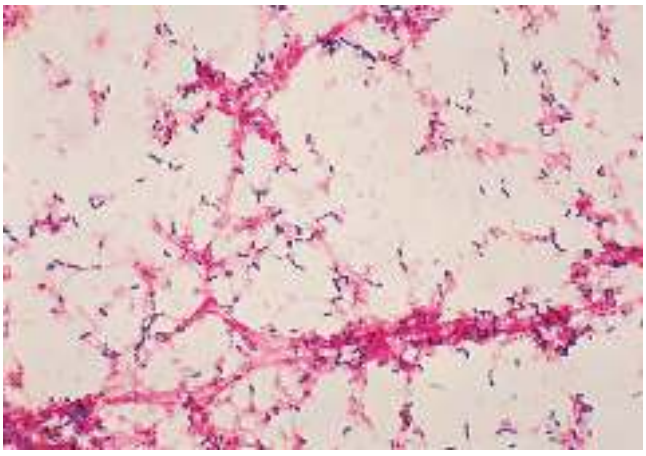

FIGURE 96.5 Pneumococcus.

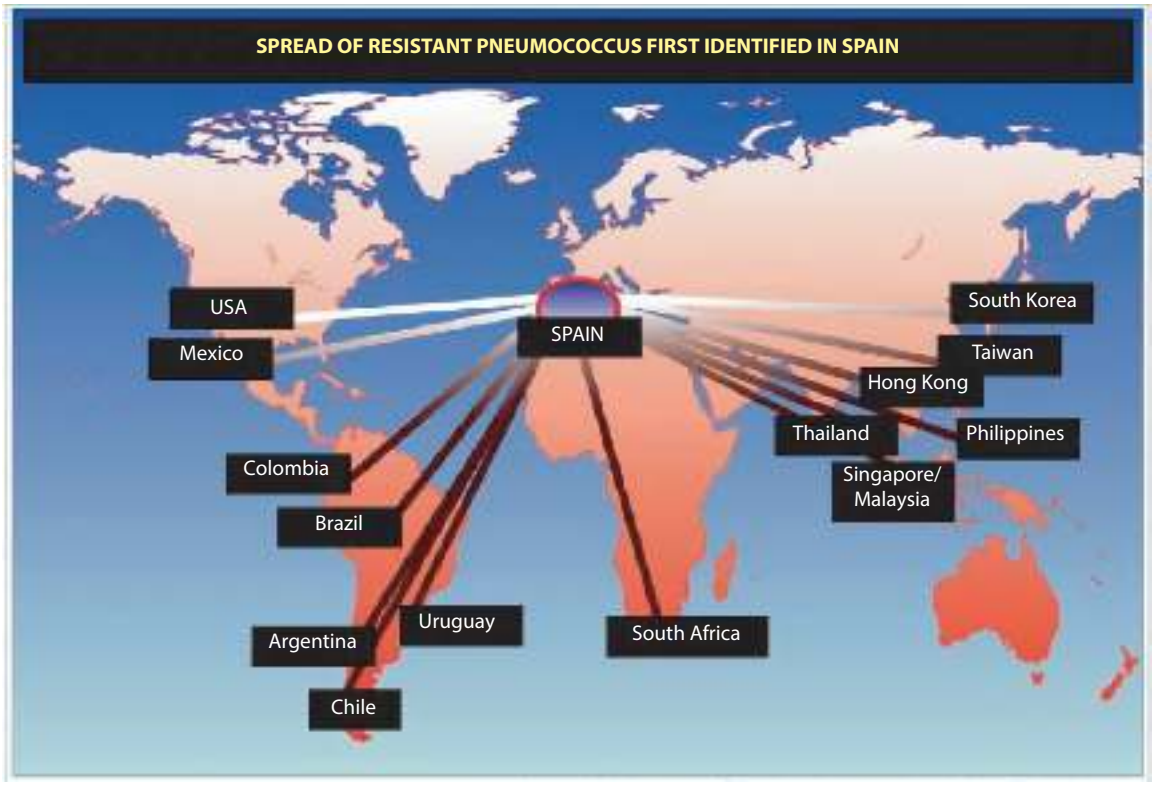

FIGURE 96.6 Spread of resistant pneumococcus.

Alaska and the South but can be found anywhere. It is yet to be determined whether changes in serotypes in the post-conjugate vaccine era will in the long run increase or decrease antimicrobial resistance.

Haemophilus influenzae type b

Although studies report the frequency of *Haemophilus influenzae* type b (Hib)-associated OPSI to be about 10 times lower than that of pneumococcus, Hib is classically the second most common cause of OPSI. It has primarily affected children <15 years. *H. influenzae* is a small polysaccharide-encapsulated pleomorphic gram-negative coccobacillus (Figure 96.7) that can be confused with pneumococcus if the Gram stain technique is poor (over- or underdecolorized). Like pneumococcus, the type b capsule is a major virulence factor for invasive disease.

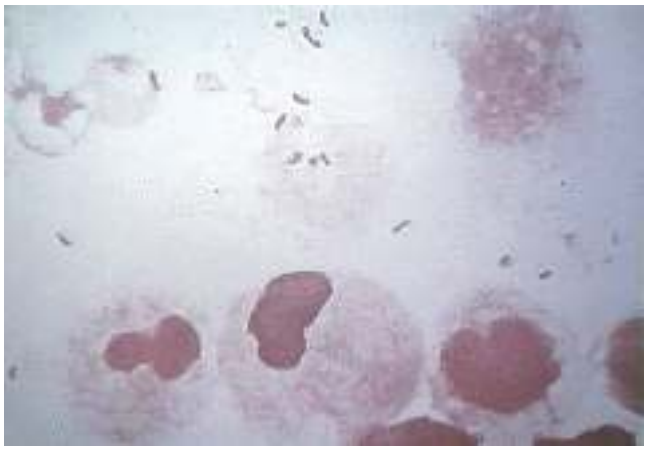

FIGURE 96.7 *Haemophilus influenzae*.

The incidence of invasive Hib disease (and correspondingly of Hib-related OPSI) has dramatically decreased because of the use of the conjugated Hib vaccine. Neither nontypeable strains nor non-b capsular organisms have been found to be significant causes of OPSI, although nontypeable organisms may cause usually non-invasive infection in the human respiratory tract. When choosing antimicrobial therapy, it is important to know that many *H. influenzae* strains produce β-lactamases.

Other bacterial organisms

Capnocytophaga canimorsus, a fastidious gram-negative rod formerly referred to as CDC group DF-2, is usually transmitted to humans from dog bites. Human infection with this part of canine and feline oral normal flora is relatively mild when occurring in the eusplenic host. Of reported severe cases, however, predisposing conditions can be identified in 80%, primarily asplenia or a hyposplenic condition. The presence of an eschar at the bite site 1 to 7 days after the bite or observation of gram-negative bacilli in the blood buffy coat or peripheral smear is highly suggestive of *C. canimorsus* infection.

The organism does not have a capsule as the pneumococcus and Hib do but appears to escape from immune surveillance by blocking the typical proinflammatory response of human macrophages, perhaps related to the inability of Toll-like receptor 4 to respond to the organism. β-lactamase activity can be seen in 30% of strains.

Although *Neisseria meningitidis* (the meningococcus) is often cited as the third most common cause of OPSI and does occur in the asplenic host, it does not appear that meningococcemia is either more severe or more frequent than in eusplenic individuals. Because meningococci are encapsulated and can cause quite severe invasive infection, most authorities include preventative strategies for it in dealing with the noneusplenic person.

Salmonellosis has been associated with, but does not play a large role in, OPSI. Most reports are associated with illnesses where cell-mediated immunity defects from either the illness or its treatment predispose to salmonellosis, as in children with sickle cell anemia. Sickle cell disease, however, does cause hyposplenism, as previously noted.

Intraerythrocytic parasitemias

The human spleen plays a key role in malarial parasite clearance by removal of intraerythrocytic parasites from the RBC without red cell destruction (pitting). Because pitting is absent or much diminished in the splenectomized or hyposplenic person, removal of malarial parasites (either killed by medication or viable) is delayed and disease may falsely appear to be more severe. During antimalarial therapy, delayed clearance in the noneusplenic does not, therefore, necessarily reflect antimalarial resistance. In partially malaria-immune individuals, the course of *Plasmodium falciparum* infection is not much changed by asplenia, but more fever and higher levels of parasitemia occur and there seems to be a risk for more symptomatic malaria episodes. How this relates to the nonimmune splenectomized person traveling into a malarious area is not clear, but appropriate prophylaxis is indicated regardless of splenic function.

In babesiosis, however, splenectomized patients are clearly at higher risk for illness with much higher levels of parasitemia (Figure 96.8) due to the lack of a spleen. This high parasitemia is associated with significant hemolysis. In the United States, infections have been reported from many states, but the most endemic areas are the islands off the coast of Massachusetts (including Nantucket and Martha's Vineyard) and New York (including eastern and south-central Long Island, Shelter Island, and Fire Island) and in Connecticut. Many of the initial individuals diagnosed with babesiosis were asplenic prior to the recognition that mild and even asymptomatic infections with babesiosis may occur in areas of endemicity for this tick-borne organism. These noneusplenic individuals are responsible for most cases of morbidity and mortality related to babesiosis. These individuals may also acquire the infection by blood transfusion without travel into a highly endemic area because their underlying diseases associated with noneusplenism may cause the need for transfusion.

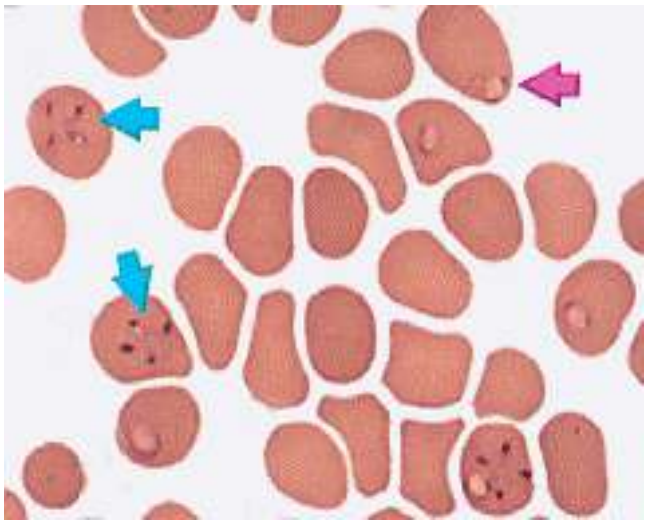

FIGURE 96.8 Babesiosis.

Therapeutic interventions

Active intervention early on in the form of antimicrobial therapy administration is crucial to patient survival. For this reason, two modalities should be utilized in the prehospital stage of this process, both aimed at shortening the time to first dose of antimicrobial treatment. For these to be relevant, the asplenic or hyposplenic person has to be aware of the condition and communicate this knowledge to the physician involved. One modality often mentioned in reviews of this infection is having the asplenic person fill, keep current, and carry with him or her a prescription for an appropriate orally administered antimicrobial agent (Box 96.2). The drug should be taken, ideally after talking with a physician by telephone, if a febrile

BOX 96.2

Suggested regimens for initial extramural oral therapy[a]

Ampicillin or amoxicillin
- Dose: 2 g
- Contraindicated in β-lactam hypersensitivity
- Not active against β-lactamase-producing organisms
- Not active against penicillin-resistant pneumococci

Amoxicillin-clavulanate
- Dose: Two 875 mg amoxicillin/125 mg clavunate tablets
- Contraindicated in β-lactam hypersensitivity

Trimethoprim-sulfamethoxazole
- Dose: Two 800 mg sulfamethoxazole/160 mg trimethoprim tablets
- Contraindicated in sulfonamide hypersensitivity
- Inconsistent activity for pencilling-resistant pneumococci

Clarithromycin or azithromycin
- Dose: 2 g
- Inconsistent activity for pencilling-resistant pneumococci

Moxifloxacin
- Dose: 800 mg

[a] Minimal to no data on any of these regimens in overwhelming postsplenectomy infection.

BOX 96.3

Treatment options for suspected bacterial overwhelming postsplenectomy infection (OPSI)

Rationale: Adequate coverage for *S. pneumoniae* and *H. influenzae*
Ceftriaxone 2 g IV q12h
Alternative in severe β-lactam allergy
Moxifloxacin 400 mg IV q24h
Plus
Vancomycin 1 g IV q12h
Alternatives in vancomycin-intolerant patients
Moxifloxacin 400 mg intravenously q24h

illness develops, especially with prostration while the person is coming to seek healthcare. It is not a substitute for medical care. The second prehospital modality comes into play when a potential OPSI case presents at a physician's office. Similar to suggestions for a patient with suspected bacterial meningitis, if available, a dose of an antimicrobial such as ceftriaxone should be given intravenously or intramuscularly. This should be done even if blood cultures cannot be performed. For obvious reasons, no controlled trials of these methods of early treatment have been or will be done.

Upon emergency department arrival, it is imperative for the patient to impart the appropriate information regarding the spleen and the new symptoms at once to facilitate immediate triage. Specific therapy (Box 96.3) could consist of an extended cephalosporin such as ceftriaxone, a β-lactam/β-lactamase inhibitor, a newer fluoroquinolone, and/or vancomycin. The therapy must afford adequate activity against the encapsulated pathogens commonly implicated in OPSI. Choice of initial antimicrobial therapy should be guided by the community antimicrobial resistance profile.

In addition to antimicrobial therapy, aggressive cardiovascular and hemodynamic support is given as needed. Whether adjuvant immunologic interventions decrease morbidity and/or mortality is not known, but, in animal models, granulocyte-stimulating factor and intravenous immunoglobulin have been studied.

If an intraerythrocytic protozoan is involved, therapy should be directed in that direction. Box 96.4 lists some of the current therapies for falciparum malaria and babesiosis. Response to therapy for babesiosis in the noneusplenic person, however, clinically appears to be much slower, independent of the delayed clearance of parasitized erythrocytes.

BOX 96.4

Treatment options for intraerythrocytic protozoa in overwhelming postsplenectomy infection (OPSI)

Babesiosis
(The usual adult dose treatment is for 1 week, but consider longer lengths of treatment in asplenic patients with significant hemolysis. Exchange transfusions have been used as an adjunct in severe cases.)
Atovaquone 750 mg PO q12h
Plus
Azithromycin 500 mg PO on day 1 then 250 mg PO per day
Or
Clindamycin 600 mg PO q8h
Plus
Quinine 650 mg PO q8h

Falciparum malaria
(Most strains except from parts of Central America, the Caribbean, and the Middle East should be considered to be chloroquine-resistant and that antimalarial should not be used except with cases from known "sensitive" areas.)
Usual adult dose oral therapies (for parenteral treatment of severe falciparum malaria, consult WHO reference)
Atovaquone-proguanil fixed combination
4 tablets daily for 3 d
Or
Artemether-lumefantrine fixed combination[a]
4 tablets BID for 3 d
Or
Quinine 650 mg q8h for 7 d
Plus
Doxycycline 200 mg daily for 7 d
Or
Clindamycin 600 mg 2× daily for 7 d

[a] Not US Food and Drug Administration (FDA) approved.

Abbreviations: OPSI = overwhelming postsplenectomy infection; PO = orally; WHO = World Health Organization.

Prevention

Education

The importance of patient (and the respective family) education cannot be overemphasized. A philosopher once reflected that the half-life of truth is 8 months, underscoring the importance of physicians to continue to remind asplenic or hyposplenic patients and/or their families to tell any physician involved in their medical care of the splenic defect. A medical alert bracelet or necklace could also assist in this task. Early knowledge of asplenia can prompt earlier treatment of presumptive OPSI.

The widespread knowledge of OPSI has also changed the landscape of surgical splenectomy. Whenever possible, the organ or part of it is retained in an effort to provide adequate organ function. In trauma situations, repair instead of removal is preferred. Splenectomy, however, can still be required in the management of a variety of disease states.

Vaccination

The current Centers for Disease Control and Prevention (CDC) guidelines recommend administering the 23-valent unconjugated pneumococcal polysaccharide vaccine (PPV23) to all children >2

years with anatomic or functional asplenia at least 8 weeks after the last 13-valent conjugated pneumococcal vaccine (PCV13). A second dose 5 years later is then suggested. In asplenic adults who have been previously immunized with PPV23, a dose of PCV13 should be given 1 or more years after the last PPV23. If no PPV23 had been given, a single dose of PCV13 should be given followed by a PPV23 at least 8 weeks later. Another PPV23 can be given 5 years later and again at age 65. It is not unreasonable to consider more frequent revaccination with these vaccines. Additional repeated immunizations with this vaccine are not recommended by the CDC, probably due to the lack of adequate safety studies (Box 96.5). A number of case reports have surfaced documenting occurrence of OPSI with vaccine-related strains of pneumococci sepsis despite administration of the pneumococcal polysaccharide vaccine. This may be related to lack of an adequate response to the polysaccharide of the infecting type.

The quadrivalent meningococcal A, C, Y and W-135 polysaccharide vaccine, the monovalent type B outer membrane vaccine and the Hib conjugated vaccines are also part of CDC recommendations for asplenic adults. The reader is referred to the most recent CDC guidelines for the most up-to-date immunization advice.

Hyposplenia or functional asplenia is not a contraindication to receiving any otherwise indicated live, attenuated vaccines such as measles, mumps, and rubella (MMR), varicella-zoster virus (either for varicella or zoster), or yellow fever. Influenza vaccine should be administered yearly.

Antimicrobial prophylaxis

Prophylactic antimicrobial therapy after splenectomy has been advised by some experts, but this has primarily been advocated in the pediatric population. Children are usually started on penicillin prophylaxis for the first 2 years, and studies conducted in sickle cell disease patients have demonstrated significant reduction in the incidence of pneumococcal sepsis. Sustained lifelong prophylaxis has been advocated by some authorities, but the issues of noncompliance and selection of resistant strains along with adverse drug reactions have prevented this from becoming the rule. There are no controlled trials to recommend lifelong antimicrobial prophylaxis in asplenic adults; however, the practice should be strongly considered if a patient has had an episode of OPSI.

BOX 96.5

Bacterial vaccines to consider in patients with asplenia/hyposplenia

23-valent unconjugated pneumococcal vaccine
Contains types 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19A, 19F, 20, 22F, 23F, and 33F
13-valent conjugated pneumococcal vaccinea
Contains types 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F
Conjugated H. influenzae vaccine
Contains type b
Quadrivalent meningococcal vaccine
Contains types A, C, Y, and W-135a
Monovalent outer membrane protein meningococcal vaccine
ContainsType B

[a] Not formally approved by the US Food and Drug Administration (FDA) for adults <65 years of age.

HIV infection

Initial evaluation and monitoring

Aaron E. Glatt, Andréa Sciberras, and Steven M. Weiss

Infection with human immunodeficiency virus (HIV) can be devastating news to newly diagnosed patients. However, with earlier recognition of the infection and the advent of simple one-pill combination antiretroviral regimens, HIV is now considered a chronic disease process, and those infected and treated can expect a relatively normal life and life expectancy.

More than 36 million people worldwide, and more than 1 million in the United States are living with HIV infection. Primary care physicians need to be familiar with the history, clinical presentation, complications, early detection, and treatment of HIV infection, especially during the early stages of the infection. Both the US Centers for Disease Control and Prevention (CDC) and the US Preventive Services Task Force (USPSTF) made a Grade A recommendation to screen all patients (18–65 years) for HIV in 2006. As a result, primary care physicians will care for a growing population of newly identified, relatively asymptomatic HIV patients, and they will need to be familiar with and adhere to the latest recommendations for early treatment and prevention of transmission.

HIV clinical presentation

Patients can present with different complaints depending on the length of time they have been infected with HIV. Approximately 2 to 6 weeks after acquisition of HIV infection, patients may present with vague complaints consisting of upper respiratory–like illness, fatigue, low-grade fevers, rash, nausea, and/or diarrhea. This "seroconversion illness" may resemble mononucleosis or influenza. However, many patients with newly acquired infection are completely asymptomatic. During the initial presentation, it is important for clinicians to establish the route and risks for acquisition of HIV with open, nonjudgmental questions. This is essential for reducing further transmission of the virus, as well as recognizing any complications. Once the seroconversion illness, when present, resolves, patients enter a mostly asymptomatic latent stage which can last for 10 years or more without treatment and, with proper treatment, can last their entire lifetime. However, if their disease status worsens, the astute physician will first begin to see class B symptoms (see Box 97.1), which will then be followed by opportunistic infections which then signify progression to clinical AIDS (see Box 97.2).

BOX 97.1

Category B conditions in HIV-infected individuals

Candidiasis, oropharyngeal
Candidiasis, vulvovaginal; persistent, frequent or poorly responsive to therapy
Cervical dysplasia (moderate or severe)
Cervical carcinoma *in situ*
Constitutional symptoms, such as fever (38.5°C/101°F) or diarrhea lasting >1 month
Hairy leukoplakia, oral
Herpes zoster (shingles), involving at least 2 distinct episodes or >1 dermatome
Idiopathic thrombocytopenia purpura
Listeriosis
Pelvic inflammatory disease, particularly if complicated by tubo-ovarian abscess
Peripheral neuropathy
Bacillary angiomatosis

BOX 97.2

Category C/AIDS-defining illnesses[a]

Candidiasis of the trachea, bronchi, or lungs
Candidiasis of the esophagus
Cervical carcinoma, invasive
Coccidioidomycosis, disseminated or extra pulmonary
Cryptococcosis, extra pulmonary
Cryptosporidiosis, chronic intestinal (>1 month duration)
Cytomegalovirus (CMV) disease (other than liver, spleen, nodes), CMV retinitis (with loss of vision)
Encephalopathy; HIV related
Herpes simplex: Chronic ulcer(s) (>1 month duration) or bronchitis, pneumonitis, or esophagitis
Histoplasmosis, disseminated or extra pulmonary
Isosporiasis, chronic intestinal (>1 month duration)
Kaposi's sarcoma
Lymphoma, primary brain
Lymphoma (immunoblastic or equivalent term)
Mycobacterium avium complex or *Mycobacterium kansasii*, disseminated or extra pulmonary
Mycobacterium tuberculosis, any site (pulmonary or extrapulmonary)
Mycobacterium, other species or unidentified species disseminated or extrapulmonary
Pneumocystis jiroveci (*carinii*) pneumonia
Progressive multifocal leukoencephalopathy
Pneumonia, recurrent (not PJP, 3 or more times in 1 year)
Salmonella septicemia, recurrent
Toxoplasmosis of brain
Wasting syndrome due to HIV
CD4 count <200

[a] A patient with any one of these conditions is defined as an AIDS patient regardless of CD4 T-cell count.

History and physical examination

HIV infection causes and predisposes to multiple organ diseases. Evaluation should be systematic and comprehensive. After a detailed chief complaint and history of present illness are obtained, a thorough review of past medical, surgical, and social histories; medications; allergies; and systems on all patients is necessary. Obtaining a history of all past antiretroviral therapy (ART) regiments is particularly useful and important. Detailed physical examination, with careful documentation of baseline observations, is essential for early recognition of new problems. It is important to recognize that ART may significantly alter the natural history of HIV infection. In addition, ART may be associated with significant side effects such as lipodystrophy, lipoatrophy, gastrointestinal issues, and other signs and symptoms. However, the majority of these side effects are from older medication regimens that are now used less frequently.

General

Fever, weight loss, malaise, fatigue, shaking chills, night sweats, and loss of appetite can be initial findings of significant illness. They are less common in early HIV infection. They may signify worsening immunosuppression or an acute secondary infection. Weight and nutritional assessment should be recorded at each visit.

Skin

The skin of many HIV-infected persons may be affected secondary to infectious and noninfectious dermatologic disorders. Skin or nail pigmentation and rashes of all varieties can occur in disseminated or localized fashion. Many skin diseases don't follow common "textbook" presentations. They may be clues to underlying serious illness, coinfection, or worsening immunosuppression. Needle tracks or skin popping indicate intravenous drug abuse and are indications to discuss rehab and/or prevention of transmission by not sharing needles (Table 97.1).

Lymph nodes

Nonspecific small, symmetric, mobile nodes are commonly seen in patients with HIV infection; these often reflect nonspecific reactive hyperplasia. Acute generalized lymphadenopathy can be seen during seroconversion. Non-Hodgkin's lymphoma (NHL) and infectious pathogens can present as single or multiple nodes. At each visit, lymph node groups should be assessed for size, quantity, texture, and tenderness. Biopsy is usually not indicated and is not helpful unless the etiology is unclear, the nodes are rapidly enlarging or asymmetric, and/or they are associated with fever and weight loss.

Head, eyes, ear, nose, and throat

Candida and herpes simplex virus often cause painful cheilitis, stomatitis, or pharyngitis and can manifest at any stage of HIV infection. Candida (oral thrush), cytomegalovirus (CMV) (oral ulcers), Epstein–Barr virus (EBV) (oral hairy leukoplakia), varicella-zoster virus, mycobacterial infection, *Cryptococcus neoformans, Histoplasma*

TABLE 97.1 **COMMONLY SEEN CUTANEOUS MANIFESTATIONS IN HIV PATIENTS**

Etiology	Clinical features
Bacterial infection	
Bacillary angiomatosis	Fleshy, friable, protuberant papules-to-nodules that tend to bleed very easily
Staphylococcus aureus	Folliculitis, ecthyma, impetigo, bullous impetigo, furuncles, and carbuncles
Syphilis	May occur in different forms (primary, secondary, or tertiary); chancre may become painful due to secondary infection
Fungal infection	
Candidiasis	Mucous membranes (oral, vulvovaginal), less commonly *Candida intertrigo* or *paronychia*
Cryptococcosis	Most common on the head and neck; typically present as pearly 2–5 mm translucent papules that resemble molluscum contagiosum papules; other forms include pustules, purpuric papules, and vegetating plaques
Seborrheic dermatitis	Poorly defined, faint pink patches, with mild to profuse fine, loose, waxy scales in the nasolabial folds and hair-bearing areas such as the eyebrows, scalp, chest, and pubic area
Arthropod infestations	
Scabies	Pruritus with or without rash; generalized but can be limited to a single digit, more severe in Norwegian type
Viral infection	
Herpes simplex	Painful vesicular lesion in clusters; perianal, genital, orofacial, or digital; can be disseminated
Herpes zoster	Painful dermatomal vesicles that may ulcerate or disseminate (polydermatomal)
HIV	Discrete erythematous macules and papules on the upper trunk, palms, and soles are the most characteristic cutaneous finding of acute HIV infection
Human papilloma virus	Genital warts (may become unusually extensive)
Kaposi's sarcoma (herpesvirus 8)	Erythematous macule or papule, enlarge at varying rates, violaceous nodules or plaques, occasionally painful. Can be seen anywhere on/in body including skin, mucosa, and all major organ systems
Molluscum contagiosum	Discrete umbilicated papules commonly on the face, neck, and intertriginous site (axilla, groin, or buttocks)
Noninfectious	
Drug reactions	Mild rash to Stevens–Johnson syndrome
Nutritional deficiencies	Mainly seen in children and patients with chronic diarrhea; diffuse skin manifestations, depending on the deficiency
Psoriasis	Scaly lesions; diffuse or localized; can be associated with arthritis
Vasculitis	Palpable purpuric eruption (can resemble septic emboli)

Abbreviation: HIV = human immunodeficiency virus.

capsulatum, Kaposi's sarcoma, squamous cell carcinoma, and NHL may be visible on oral examination. Idiopathic aphthous ulcers are a significant cause of troublesome oral pain. Toothache and dental tenderness may indicate periodontal disease or abscess and may cause both fever and headache. Gingival and periodontal infection are particularly aggressive in patients with HIV infection.

Facial pain, nasal obstruction, postnasal drip, and headache can be caused by sinusitis, which occurs frequently in HIV infection. Atopy may coexist.

Blurred vision, scotoma, floaters, and/or decreased visual acuity may suggest CMV retinitis or other opportunistic infectious retinochoroiditis. Complete eye examinations at baseline and when retinitis is a consideration are essential, especially in hosts with CD4 cell count of $<50/mm^3$. This is especially important if ART is not successful and/or patients are noncompliant with ART. CMV retinitis may appear as a "ketchup and cheese," "pizza," or brushfire appearance on ophthalmologic exam.

Headache of new onset or changing character may be an early manifestation of a central nervous system opportunistic process, and a CT or MRI scan of the head is usually warranted.

Cardiopulmonary

Precise baseline pulmonary and cardiovascular examinations are important because of increasing pulmonary and cardiac complications in advancing HIV disease. Shortness of breath at rest or with exertion, its duration and progression, whether a cough is dry or productive, sputum color, amount, and odor may help with the differential

diagnosis. Hemoptysis can be caused by tuberculosis, thrombocytopenia, bacterial pneumonia, or other lung pathology. Chest pain can be caused by pneumonia, spontaneous pneumothorax (often *Pneumocystis*-related), pericarditis, herpes zoster, or HIV-related cardiomyopathy. Palpitations and postural hypotension may suggest symptomatic anemia.

Gastrointestinal

Gastrointestinal diseases are increasingly frequent as HIV disease progresses. Odynophagia, dysphagia, retrosternal chest pain, nausea, anorexia, and weight loss are commonly associated with esophagitis due to *Candida*, herpes simplex, CMV, or, more rarely, lymphoma. Hepatic or splenic enlargement may be an early manifestation of HIV-related complications, and baseline size should be accurately quantified and documented.

Right upper quadrant pain associated with fever and elevated liver enzymes may indicate viral or drug-induced hepatitis, cholelithiasis, or acalculous cholecystitis related to *Mycobacterium avium* complex (MAC), cryptosporidiosis, microsporidia, or CMV.

Epigastric or left upper quadrant pain may indicate drug-induced pancreatitis. Abdominal distension, tenderness, masses, constipation, or fecal incontinence may be caused by Kaposi's sarcoma, lymphoma, carcinoma, gastrointestinal opportunistic infections (CMV, histoplasmosis, tuberculosis), or parasitic infestation. Diarrhea occurs in 30% to 66% of adults with HIV. *Salmonella, Cryptosporidium, Isospora*, CMV, microsporidia, and other enteric pathogens commonly occur. Constipation is commonly seen in patients taking methadone, heroin, or opioids, as well as other medicines. Antibiotic use predisposes patients to *Clostridium difficile* infection. There is also a higher incidence of irritable bowel syndrome among HIV patients, but it is a diagnosis of exclusion.

Painful defecation or rectal pain can be caused by trauma, perirectal abscess, herpes, squamous cell carcinoma, or other sexually transmitted diseases (STD; e.g., lymphogranuloma venereum, LGV), all of which are increased in persons having anal intercourse. Careful, nonjudgmental sexual and social histories may help identify pathogens. Perirectal areas should be carefully examined for lesions, abscess, fissures, proctitis, and ulcerations. Stools should be tested for occult blood.

Genitourinary, obstetric, and gynecologic manifestations

Painful, frequent urination may indicate urinary tract infection, STD, or vulvovaginitis. The latter are more common and possibly more difficult to treat in HIV infection. Recurrent or severe vaginitis, vaginal discharge, and pruritus are common and may not be related solely to sexual practices. Prompt evaluation of all genital discharges, ulcers, and lesions will allow correct identification of any STD.

Women should be queried regarding menstrual history, fertility, method of birth control, and numbers and dates of pregnancies and abortions. Menstruation may become irregular in worsening HIV infection, and fertility declines as well. Prior tubal scarring from salpingitis or pelvic inflammatory disease predisposes to ectopic pregnancy and infertility. An external genital, rectal, and complete pelvic examination (speculum and bimanual), including Pap tests and appropriate cultures and stains, should be performed initially and then annually if exams are normal. Direct HPV testing is replacing Pap smears in many situations because they are more sensitive and specific.

Neurologic

Neuropsychiatric complications occur in many HIV-infected patients, yet symptoms may go unrecognized because of coping strategies and the large reserve available until significant deterioration is noted. Subtle neurologic deterioration, memory loss, and poor concentration may be the only early signs of HIV dementia, which often starts at an earlier age. Central and peripheral neurologic complications may be caused by HIV infection, opportunistic infections, medications, or malignancy. Illness can occur at any stage of HIV infection, albeit with different manifestations. Symptoms depend greatly on the location of the abnormality and the pathophysiology involved. Peripheral neuropathy is still quite common regardless of disease status and can occur years or even decades after seroconversion. With the advent of new and better antiretroviral therapies, progressive multifocal encephalopathy is rarely seen now; however, it also occurs usually years or even decades after seroconversion. Intracranial mass lesions are usually a late complication of HIV disease.

Distal predominantly sensory polyneuropathy, chronic inflammatory demyelinating polyneuropathy, mononeuropathy, herpesvirus and CMV radiculitis, and neuropathies of vitamin deficiency are commonly seen. Neurologic evaluation and appropriate diagnostic testing may differentiate treatable from less responsive pathology. A carefully documented baseline neurologic examination, including mental status assessment; cranial nerve testing; and evaluation of sensation, strength, coordination, and reflexes, should be part of an initial and yearly comprehensive evaluation. Mini-mental status test results should be clearly documented.

Musculoskeletal

Myalgia and proximal muscle weakness, tenderness, and wasting may be manifestations of primary HIV or drug-related myositis. Forms of arthritis that are not uncommon include severe, persistent oligoarthritis, primarily affecting the large lower limb joints with exquisite pain; psoriatic arthritis with erosive changes and crippling deformities; and septic arthritis caused by *Staphylococcus aureus*, especially in substance abusers. Changes in fat distribution secondary to ART may also be present.

Medical history

A clear history of prior HIV-related events, CD4 cell counts, viral load, resistance patterns, ART, complications, opportunistic infections, and malignancies will help stage HIV infection, provide prognostic information, and clarify therapeutic options. Opportunistic infections signify marked immunocompromise and

are discussed at length in Chapter 100, "Opportunistic infections in HIV."

Untreated HIV infection significantly increases the risk of tuberculosis and increases the yearly rate of conversion from latent to active tuberculosis to 7% to 8%, compared with an approximate 10% *lifetime* conversion rate in non-HIV patients. Tuberculosis also makes HIV infection worse, with a more rapid progression to AIDS. Purified protein derivative (PPD) or QuantiFERON-TB status, previous exposure to tuberculosis, and previous prophylaxis or treatment (date, duration, outcome, and medications) are critical. Noncompliance, prior hospitalizations, and geographic and social factors play major roles in the development of drug resistance and the choice of agents for empiric management. Syphilis may increase the rate of HIV acquisition as well as other STDs, and initial presentation can be varied in coinfected patients. Any STD presenting with an ulcer/ulcerations also increases the risk of acquiring HIV.

Medications

Polypharmacy, with prescription agents and vitamin, mineral, and herbal supplements, and alternative medications are very common. They can cause or change disease manifestations and be associated with adverse effects and toxicity, which can be confused with symptoms of HIV-related disease. For example, vitamin overdosing may cause diarrhea, abdominal cramps, peripheral neuropathy, increased intracranial pressure, headache, anorexia, nausea, and vomiting. Drug interactions, sometimes leading to ART failure, are also common and must be diligently sought for both prescription and nonprescription medicines. Patients should be encouraged to bring *all* their pills, both prescribed and over-the-counter, to each office visit.

Allergy

The astute physician should differentiate between *allergic reaction* and *intolerance*, which is commonly misinterpreted as allergy. The specific reaction, duration, and resolution of toxicity for each medication should be noted, as well as a clear temporal relationship with all factors potentially involved. Rash and fevers are the most common type of adverse drug manifestations and must be differentiated from infectious etiologies common in HIV.

Social history

Particular attention must be given to all aspects of the psychosocial history, especially residence status, occupational history, substance abuse, and sexual history. A complete sexual history should be obtained, including orientation, practices, lifetime number of partners, prostitution, and any previous STDs. Care should be taken to take the sexual history in a nonjudgmental fashion and in private. If at all possible, one should never take a sexual history in the presence of the spouse, parent, or immediate family member. In addition, dietary habits and water sources are important risks for certain pathogens.

Travel history

Because certain opportunistic infections occur predominantly in particular geographic regions (e.g., southwestern United States for coccidiomycosis; Ohio River Valley for histoplasmosis), place of birth and a complete travel history are particularly useful in formulating an accurate differential diagnosis. History of travel to developing or tropical countries may raise suspicion of travelers' diarrhea, malaria, leishmania, kala-azar, strongyloidiasis, *Penicillium* infection (Southeast Asia), HIV-2, etc.

Pets

Certain opportunistic infections have been associated with particular animals. Patients should be queried regarding exposure to animals and advised about methods of avoiding zoonoses. *Bartonella* (formerly *Rochalimaea*) species have been associated with cat-scratch disease and bacillary angiomatosis. Exposure to cat feces as well as dirt and unwashed ground foods is associated with toxoplasmosis.

Laboratory studies

Laboratory testing is sometimes the only way to absolutely establish or confirm a diagnosis. Laboratory studies should be individualized, but several general principles apply (Box 97.3 and Table 97.2).

A CBC may reveal mild normocytic, normochromic anemia, which often develops as HIV progresses. Macrocytosis frequently develops while on zidovudine, which is rarely prescribed any more. Pancytopenia may suggest bone marrow involvement or infiltration, isolated thrombocytopenia may be an early finding of HIV infection, and leukopenia and/or a blunted neutrophil response to infection is a common finding. Neutropenia often becomes more pronounced with various drug therapies (e.g., zidovudine, trimethoprim-sulfamethoxazole, pentamidine) and may require treatment with colony-stimulating factors.

Assessment of chemistries, liver function tests, and hepatitis serologies/viral levels are useful in diagnosing new or chronic illnesses, making vaccination recommendations, and as a guide to monitoring drug toxicities. Hepatitis A, B, C, and others are more

BOX 97.3

Purposes of laboratory testing in HIV infection

1. Establish baseline parameters
2. Identify underlying disease
3. Determine appropriate therapy
4. Estimate the likelihood and rate of disease progression
5. Monitor response to therapy
6. Monitor adverse reactions and toxicities
7. Screen for common/preventable illnesses

Abbreviation: HIV = human immunodeficiency virus

TABLE 97.2 **ROUTINE LABORATORY STUDIES GUIDELINES FOR HIV-INFECTED ADULTS**

Test	Indication	Interval
Antitoxoplasma IgG antibody	Screening for previous exposure Guide diagnostic and empiric management	Baseline Yearly in patients with negative results
Chemistry and liver functions	Evaluation of baseline renal and liver function, and nutritional status Diagnosis of concurrent hepatitis Monitoring of drug toxicities Monitoring of efficacy of therapy	Baseline q6–12mo More frequently in patients with advanced disease, baseline abnormalities, or with drug toxicity
Chest radiograph	Screening for disease Diagnosis of active disease	Baseline If pulmonary disease suspected
Complete blood count	Evaluation of anemia, leukopenia, or thrombocytopenia Monitoring of drug toxicities	Baseline q6mo More frequently in patients with abnormalities
Hepatitis profile	Diagnosis of viral hepatitis Evaluation for vaccination Response to vaccination	Baseline During potential acute infection Postvaccination
Lymphocyte subset testing (CD4 cells)	Guiding initiation of prophylactic therapy Prognostic information Monitoring of efficacy of therapy	Baseline q6mo if >500 q3mo if <500
HIV viral load	Diagnostic in acute infection before seroconversion (>10,000/mL) Monitoring of HIV activity Monitoring of efficacy of therapy	Baseline Every month until antiretroviral therapy efficacy is established q3mo if clinically stable
RPR or VDRL	Screening for syphilis Monitoring response to therapy Use specific test (i.e., FTA) for confirmation and/ or false-negative specimen	Baseline Yearly (at least) in patients at risk/prior infection Monthly for 6 mo, and at 9 and 12 mo after therapy
Tuberculosis skin test (TST; purified protein derivative)	Screening for infection or previous exposure	Baseline, then yearly More frequently if at risk
IGRA (interferon-γ release assay)	Identification of new converters Exposed to active tuberculosis (TB) and TST is negative; Those with anergy	

Abbreviations: HIV = human immunodeficiency virus; TB = tuberculosis.

common in HIV infection based upon underlying risk behaviors, and the choice of initial ART may be influenced by coinfections, especially hepatitis B.

Nonspecific syphilis (RPR or VDRL) tests, with confirmatory fluorescent treponemal antibody absorbed (FTA-ABS) tests, should be performed initially and repeated annually in patients at risk. Lumbar puncture may be indicated for patients with reactive serologies (RPR of 1:16 and above), for patients with positive treponemal tests of uncertain duration, late latent syphilis, and/or secondary to symptoms.

A tuberculin skin test (TST) should be placed on initial evaluation and at least annually except in patients with a history of tuberculosis or known prior reactive TST. An induration of 5 mm or more is considered positive in an HIV-infected individual and must be followed by a chest x-ray. Interferon-γ release assay (IGRA; QuantiFERON-TB, TSPOT) is recommended when TST is negative but the HIV-infected patient was exposed to an active tuberculosis patient or is at high risk of tuberculosis infection. Those also with known anergy to TST should receive IGRA testing. An initial chest radiograph is still often obtained to establish baseline status, regardless of TST or IGRA status.

Baseline antitoxoplasma immunoglobulin G (IgG) antibodies may influence prophylaxis decisions and help with the evaluation and empiric treatment of central nervous system mass lesions should they occur. Baseline CMV and EBV serologies, and cryptococcal antigen testing have no value.

Pap smears are recommended initially, at 6 months, and thereafter annually if normal. For high-risk patients based on sexual activity, more frequent evaluation may be prudent, with referral to a gynecologist for atypia or other Bethesda scale findings. The role of screening HPV testing has not yet been finalized, but will possibly replace Pap testing in the future. An anal Pap or equivalent screening test is recommended in those who have engaged in anal sex. The recommended frequency of such testing remains to be finalized.

Testing for STDs including gonorrhea, chlamydia, trichomonas, and syphilis should be performed at initial presentation and then at least annually thereafter. More frequent screening might be appropriate depending on individual risk behaviors and the local epidemiology. Type-specific HSV serologic testing should be considered at initial evaluation as well as at any time the patient presents for concerning lesions.

Cholesterol, lipid, and blood sugar evaluations are important to monitor for the metabolic abnormalities common in patients with HIV, especially those on ART.

CD4 lymphocyte counts (marker of immune status) and viral load counts (marker of disease status and response to therapy) should be obtained initially and at 3-month intervals as a guide for treatment and prophylactic interventions. Resistance status should be obtained at initial evaluation and thereafter as appropriate based on ART, compliance, and other clinical and laboratory factors. There is significant variability in CD4 cell counts; the aggregate picture over time is more useful than a single reading for major therapy decisions.

Viral load testing is essential for monitoring the efficacy of ART, and the most ultrasensitive assays, capable of detecting as low as 10 viral particles per mL, should be used. Viral genotyping and phenotyping are commonly used to detect resistance and to guide the choice of individual ART regimens in treatment-naïve patients and in patients who fail therapy.

Vaccinations

Patients should receive appropriate immunizations as early as possible in the course of HIV infection to optimize response. While clinical efficacy is difficult to prove or even assess, it is assumed that higher CD4 cell counts, preferably >500/mm^3, are associated with better vaccine efficacy (Table 97.3).

In previously unvaccinated patients, pneumococcal vaccine PCV13 (Prevnar 13) is administered first, followed by PPSV23 (Pneumovax 23) 8 weeks thereafter. Some recommend an additional booster PPSV23 after 5 years. If previously vaccinated with PPSV23, PCV13 should be administered 1 year later. Efficacy is very questionable if the CD4 cell count is <200 cells/mm^3. *Haemophilus influenzae* vaccination is not indicated as per the latest recommendations.

Patients without serologic evidence of hepatitis B infection or immunity should be given hepatitis B vaccine. Booster vaccinations, while not proved, are sometimes recommended for healthcare workers (and others) no earlier than 5 years after the initial vaccination series is completed.

TABLE 97.3 **VACCINATION GUIDELINES FOR HIV-INFECTED ADULTS**

Vaccine	Frequency
Pneumococcal vaccine Naïve patients Exposed to PPSV23 All patients	PCV13 first; PPSV23 8 weeks later PCV13 after 1 year PPSV23 booster at 5 years
Hepatitis B vaccine series	Series of three (0, 1, and 6 months) (booster in 5 years)
Influenza	Yearly, only injectable; no live attenuated
Human papillomavirus (HPV4; HPV2)	Three doses: both females and males (through age 26); (males receive HPV4 only)
Diphtheria/tetanus/pertussis	1 shot Tdap, then Td booster every 10 years
Measles (MMR), varicella	1–2 shots, if CD4 >200
Haemophilus influenzae, zoster, anthrax, small pox	Not recommended
Meningococcal, hepatitis A	Vaccination when CD4 cell count is >200 cells/mm^3
VZV	Shingrix only (inactivated); Zostavax contraindicated

Abbreviations: HIV = human immunodeficiency virus; MMR = measles, mumps, and rubella vaccine; CDC = Centers for Disease Control and Prevention, VZV = varicella zoster virus.

Influenza vaccine (*only inactivated*) is recommended annually. Mumps-measles-rubella (MMR) and Zostavax (live, attenuated VZV) are contraindicated in severely immunocompromised patients. On the other hand, Shingrix, an inactive, subunit vaccine for VZV, is considered safe in immunocompromised patients and has better immunogenic potential and should be considered. Inactivated polio vaccine, standard childhood vaccinations, and booster diphtheria and tetanus immunizations can be given as per published guidelines. Hepatitis A vaccine may also be indicated among selected at-risk populations.

Treatment considerations for both HIV and non-HIV infected individuals

Except for certain, rare circumstances, it is now recommended that patients begin ART at the *time of diagnosis* for the best long-term outcomes and survival rates. Careful consideration of the patient's compliance, lifestyle, comorbid conditions and medications, and socioeconomic factors must be made when deciding on what antiretroviral regimen is appropriate.

It is also important to be aware of *immune reconstitution inflammatory syndrome* (IRIS). While not occurring post initiation of therapy for acute initial HIV acquisition, this does occur when patients with particularly severe levels of immunosuppression are started on ART. As their immune systems get a "boost," they may develop on inflammatory response to underlying infections. Such underlying infections may be known and under treatment or previously unknown and first discovered due to IRIS. Patients with IRIS may experience symptoms such as rash, diarrhea, malaise, etc. It is important to differentiate between IRIS and drug allergy or intolerance. IRIS symptoms typically last no more than 4 weeks, and this usually occurs in patients with long-standing HIV illness.

Pre-exposure prophylaxis (PrEP) is now indicated for non–HIV-infected individuals who are at high risk for acquiring HIV. It is recommended that any HIV-negative individual who is in an ongoing sexual relationship with an HIV-positive partner receive PrEP. Other high-risk individuals include

- men who have unprotected anal sex with men
- those with a history of STDs
- heterosexual men and women having unprotected intercourse or a recent bacterial STD
- bisexual males engaging in unprotected intercourse
- injection drug users sharing needles and/or engaging in unsafe sexual practices.

PrEP consists of a combination pill of two nucleoside reverse transcriptase inhibitors, tenofovir disoproxil and emtricitabine, taken as a single daily dose. When taken consistently on a daily basis, PrEP has been shown to reduce the risk of HIV transmission by up to 92%. It is recommended that PrEP be combined with condoms and other prevention tools to provide even greater protection from acquiring HIV. PrEP should only be prescribed to those who will be compliant with the daily regimen as well as with quarterly physician follow-ups.

Guidelines for follow-up

Patients receiving ART need to be followed closely to ensure compliance, efficacy, and optimal management. Stable asymptomatic patients on ART without significant lab abnormalities can be seen every 3 to 4 months if they have no complications and are compliant. Symptomatic HIV patients should be examined and reevaluated as frequently as indicated, and testing should occur when immune status worsens. Most patients have numerous psychosocial needs that also must be addressed; referral to the appropriate staff is essential for complete and compassionate care.

HIV

Antiretroviral therapy

Amy L. Brotherton and Joseph M. Garland

Introduction

The syndrome now known as AIDS was first described in 1981 in Centers for Disease Control and Prevention (CCD) journal, *Morbidity and Mortality Weekly Report* (MMWR) through a case series of five young gay men in Los Angeles who were diagnosed with *Pneumocystis carinii* pneumonia. This was quickly followed by other reports from around the country of unusual infections usually found in extreme immune suppression now occurring in other populations with no known cause of immunosuppression. The causative agent of this immunosuppression, the HIV virus, was discovered in 1984 by Francoise Barré-Sinoussi and Luc Montagnier, a discovery for which they would later win the Nobel Prize. No effective treatment was available for this deadly virus until 1987, when zidovudine (AZT) was approved by the US Food and Drug Administration (FDA); its discovery, clinical trials, and approval were pushed forward by people living with HIV. The approval of zidovudine ushered in a new age in HIV management and brought new hope for a cure or for long-term viral suppression. Single-drug therapy was quickly found to lack long-term durability however, as treatment-associated resistance began to emerge, usually in 6 to 12 months after initiation of the drug. Luckily, the advent of new agents led to dual and then triple therapy as new options, and these were able to demonstrate long-term suppression. With the approval of the first protease inhibitor (PI) in 1995 and the first non-nucleoside reverse transcriptase inhibitor in 1996, triple therapy became the standard of care. At the time called *highly active antiretroviral therapy* (HAART) and later *combination antiretroviral therapy* (cART)—and now simply referred to as ART—this multiple-drug approach to treatment brought long-term viral suppression to patients and has remained the standard of care for nearly all patients.

The growing pantheon of drugs used to treat HIV brought with them new challenges as well—side effects, high pill burdens, drug toxicities, and drug-resistant viral strains all emerged. Initial regimens often required dosing multiple times daily with multiple pills and were often associated with both immediate side effects—nausea, diarrhea, and rash were common—and long-term effects that could be disfiguring and permanent, among them lipodystrophy, lipoatrophy, neuropathies, and loss of bone density. Refining these regimens to simplify dosing requirements, reduce toxicities and drug–drug interactions, and raise the genetic barrier to resistance have all been significant advances to transforming HIV from a deadly disease to a chronic disease that can be well-managed with a very tolerable, often single-pill, daily regimen. The first once-monthly injectable therapy was recently approved, and will usher in a new era of even more treatment options for people living with HIV. We do not yet have a cure for HIV, but the goal of long-term viral suppression with simple, well-tolerated regimens has in many ways been achieved.

This chapter provides a brief overview of HIV replication along with a more detailed review of the commonly prescribed, currently approved ART medications and classes, and their indications and combinations.

Use of ART in the setting of a variety of host and viral characteristics, monitoring, and a brief discussion of the immune reconstitution inflammatory syndrome (IRIS) are included as well.

HIV replication cycle

The HIV replication cycle is illustrated in Figure 98.1. Defining and understanding the HIV viral replication cycle has led to the identification of unique drug targets specific to the HIV virus or host proteins that are necessary for viral replication. Current ART medications inhibit entry of virus into host cells, reverse transcription of viral DNA from an RNA template, integration of this viral DNA into the host genome, and processing of newly transcribed viral proteins.

The viral replication cycle begins with attachment and fusion of the HIV virus to the host cell membrane. The attachment and fusion process is complex, orchestrated by viral glycoproteins 120 and 41 attaching to host cell CD4 receptors and CCR5 or CXCR4 co-receptors (Figure 98.2). Once attachment occurs, the viral membrane fuses to the cellular membrane, and release of the contained viral RNA and viral proteins into the host cell occurs. Within the host cytoplasm, viral RNA undergoes reverse transcription via the viral reverse transcriptase enzyme (RT). RT utilizes host cell nucleotides to construct a viral complementary DNA (cDNA). Viral cDNA interacts with the viral integrase protein in the host cell cytoplasm. Viral cDNA is then transported into the nucleus of the host cell, where integrase incorporates viral cDNA into the host DNA genome. Once incorporated into the host genome, viral DNA is transcribed and translated into polyproteins using host enzymes and ribosomes. Viral proteases then cleave these polyproteins into functional and mature viral proteins. Full HIV virions are constructed. These new virions then bud from the host cell surface, detach, and infect new host cells, repeating the cycle (Figure 98.1).

HIV pharmacotherapy

Pharmacotherapy for the treatment of HIV includes eight pharmacologic classes, each disrupting one of the critical steps in the viral replication cycle. Classes include fusion inhibitors, CCR5 antagonists, post-attachment inhibitors, and attachment inhibitors, collectively known as the "entry inhibitors"; reverse transcriptase inhibitors, including both nucleoside and non-nucleoside reverse transcriptase inhibitors (NRTIs and NNRTIs); integrase strand transfer inhibitors (INSTIs) or "integrase inhibitors"; and PIs. Pharmacokinetic (PK) enhancers, or "boosters," are combined with PIs and the integrase inhibitor elvitegravir to allow for once daily dosing but are not considered active agents within a regimen.

Modern-day regimens generally combine an NRTI pair, most commonly tenofovir/emtricitabine or abacavir/lamivudine, with an additional active agent from the INSTI, PI, or NNRTI class. Integrase inhibitors have become the preferred third agent for most treatment-naïve individuals owing to the excellent tolerability and efficacy of this class. Entry inhibitors are not recommended for use as initial therapy, and all are only used in the setting of salvage therapy. Though the majority of first-line regimens combine three agents, select two-drug regimens are approved for use in certain scenarios; these regimens combine an agent with a high genetic barrier to resistance with an additional agent from another class, such as a second-generation INSTI with an NRTI or NNRTI, or an INSTI with a PI.

Newer agents within each class often demonstrate significant advantages over first-generation antiretrovirals in terms of tolerability, safety, efficacy, and pill-burden. The following sections will review the pharmacologic classes and individual agents with a focus on modern ART and regimens that are most frequently prescribed today. Fixed-dose combinations (FDCs), which comprise part of a regimen, and single-tablet regimens (STRs), which are considered a complete regimen alone, will be referenced throughout. Tables 99.5 and 99.6 provide a detailed description of the available products and their co-formulations.

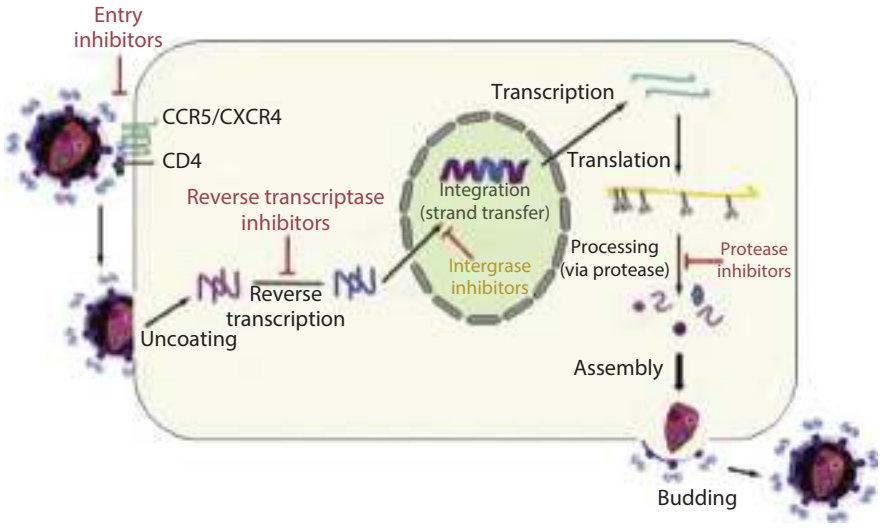

FIGURE 98.1 HIV replication cycle

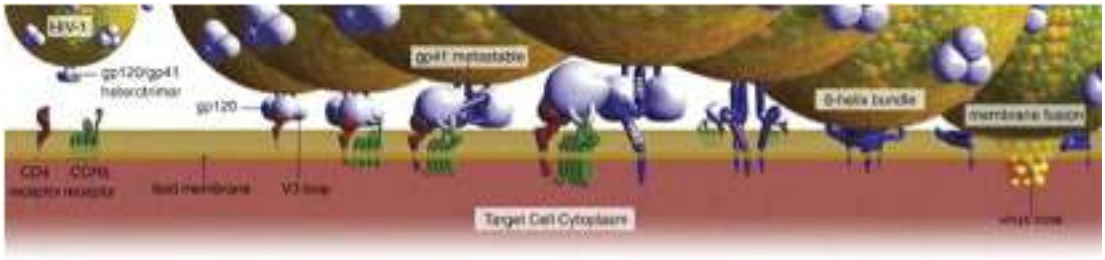

FIGURE 98.2 Fusion of the viral and host membranes

Nucleoside and nucleotide reverse transcriptase inhibitors

NRTIs are chemical derivatives of native nucleosides or nucleotides and inhibit reverse transcription of viral cDNA from HIV RNA. Apart from tenofovir, all NRTIs lack a 3′-hydroxyl (OH) group on their ribose ring, which prevents chain elongation and terminates proviral cDNA synthesis. NRTIs include the cytosine analogs lamivudine (3TC) and emtricitabine (FTC); adenosine analogs didanosine (ddI), tenofovir disoproxil fumarate (TDF), and tenofovir alafenamide (TAF); the guanosine analog abacavir (ABC); and the thymidine analogues stavudine (d4T) and zidovudine (AZT or ZDV). First-generation NRTIs (specifically ddI, d4T, and AZT) have a high affinity for host cellular mitochondrial DNA polymerase in addition to viral RT and consequently are associated with mitochondrial toxicities, including peripheral neuropathy, pancreatitis, lactic acidosis, hepatic steatosis, and lipoatrophy. They have largely been replaced by the second-generation class, which are better tolerated with fewer toxicities.

Apart from two-drug regimens, a dual NRTI backbone comprises two of the three agents in an ART regimen for a treatment-naïve individual. Preferred NRTI pairs include tenofovir/emtricitabine and abacavir/lamivudine. Due to their chemical similarities, emtricitabine and lamivudine are utilized interchangeably and therefore should never be combined. Table 98.1 presents a summary of the preferred NRTIs that will be discussed in this section.

Lamivudine and emtricitabine (3TC and FTC)

Lamivudine (3TC, trade name Epivir) and emtricitabine (FTC, trade name Emtriva) are structurally similar, roughly interchangeable cytosine analogs. Lamivudine is administered 300 mg orally once daily, while emtricitabine is administered 200 mg orally once daily. The cytosine analogs are very well-tolerated, with the rare exception of hyperpigmentation or skin discoloration of the palms and the soles with FTC. Both agents undergo renal elimination and require renal dose adjustment per package labeling, which typically necessitates breaking up FDCs or STRs into their individual components. However, results from a Phase 3b single-arm switch study in a small number of patients receiving chronic hemodialysis (HD) on the STR elvitegravir 150 mg/cobicistat 150 mg/tenofovir alafenamide 10 mg/emtricitabine 200 mg (trade name Genvoya) demonstrated that these agents are tolerable without renal dose adjustment. Based on limited data, this practice might be considered in scenarios where maintaining an STR is preferable for adherence. Both medications have activity against hepatitis B virus (HBV) and can be utilized in combination with tenofovir for HIV/HBV coinfection. Monotherapy for HBV with FTC or 3TC is not recommended due to the rapid development of resistance.

Tenofovir (TFV)

Two tenofovir prodrug formulations are commercially available, TDF (trade name Viread) and TAF (trade name Vemlidy). TDF is administered 300 mg orally once daily in those with normal renal function, whereas TAF is administered 10 mg orally once daily when co-formulated with cobicistat and 25 mg once daily in all other scenarios. Tenofovir is most frequently co-formulated with FTC, but co-formulations with 3TC have recently been approved.

TDF has been associated with rare instances of kidney and bone disease, including new onset or worsening renal impairment, proximal renal tubulopathy, Fanconi syndrome, and bone demineralization. Adverse effects are more pronounced when TDF is combined with PK boosters (ritonavir or cobicistat) due to increased levels of TDF through inhibition of the drug transporter P-glycoprotein. Additional risk factors for toxicity include preexisting renal dysfunction, advanced HIV, longer treatment history, and low body weight. In comparison, TAF exhibits 6.5 times higher intracellular concentrations and 90% lower serum concentrations of the active moiety, tenofovir diphosphate, when compared to TDF, and, because of this, it has demonstrated more favorable effects on renal biomarkers and percentage change in bone mineral density in clinical trials. TDF has been noted to have a more favorable lipid profile than TAF; however, the clinical significance of this is unknown. TAF has been associated with greater weight gain than TDF and ABC in treatment-naïve individuals. This is an ongoing area of investigation, and additional data are needed to fully comprehend the pathophysiological mechanism and clinical impact of this finding.

TDF and TAF have differing PK properties and toxicity profiles and should not be considered interchangeable in every scenario. TAF is the preferred formulation in individuals with chronic kidney disease or osteoporosis; however, avoiding tenofovir products entirely and utilizing an NRTI-sparing

TABLE 98.1 SUMMARY OF PREFERRED NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NRTIS)

Generic (Abbreviation) *Trade Name* Analog	**Adult Dosing, Formulations, Coformulations** *Trade Name* (Abbreviation)	**Metabolism, Dose Adjustments, Major Drug-Drug Interactions**	**Resistance Pathways**	**Adverse Effects, Considerations for Use**
Abacavir (ABC) *Ziagen* Guanosine	Dosing: 600 mg PO qd, or 300 mg PO BID Formulations: 300 mg tablet 20 mg/ mL oral solution FDCs: *Epzicom* (ABC/3TC) *Trizivir* (ABC/ZDV/3TC) STRs: *Triumeq* (DTG/ABC/3TC)	Alcohol dehydrogenase and glucuronyl transferase; renal elimination Dose adjustment: Renal: N/A Hepatic: CTP A: 200 mg BID CTP B or C: **Contraindicated** Major DDIs: none	K65R L74V Y115F M184V 69 insertion Q151M	Headache, fatigue, nausea **HLA-B*5701 testing required prior to use**; avoid use if positive—highest risk for hypersensitivity reaction **Increased CV events** associated with ABC in some cohort studies; **avoid if high CV risk**
Emtricitabine (FTC) *Emtriva* Cytosine	Dosing: Capsule: 200 mg PO qd Oral solution: 240 mg (24 mL) PO qd Formulations: 200 mg hard gelatin capsule 10 mg/ mL oral solution FDCs: *Descovy* (TAF/FTC) *Truvada* (TDF/FTC) STRs: *Atripla* (EFV/TDF/FTC) *Biktarvy* (BIC/TAF/FTC) *Complera* (RPV/TDF/FTC) *Genvoya* (EVG/c/TAF/FTC) *Odefsey* (RPV/TAF/FTC) *Stribild* (EVG/c/TDF/FTC) *Symtuza* (DRV/c/TAF/FTC)	Renal elimination Dose adjustment: Renal: CrCl <50 mL/min: dose adjustment recommended; limited data suggest tolerability without adjustment Hepatic: N/A Major DDIs: None	M184V/I; (often continued in setting of M184V mutation) K65R 69 insertion Q151M	Minimal toxicity; Hyperpigmentation/skin discoloration HBV activity; not for HBV monotherapy (high resistance) Used interchangeably with 3TC
Lamivudine (3TC) *Epivir* Cytosine	Dosing: 300 mg PO qd, or 150 mg PO BID Formulations: 150 and 300 mg tablets 10 mg/ mL solution FDCs: *Cimduo* (TDF/3TC) *Combivir* (ZDV/3TC) *Epzicom* (ABC/3TC) *Temixys* (TDF/3TC) *Trizivir* (ABC/ZDV/3TC) STRs: *Delstrigo* (DOR/TDF/3TC) Dovato (DTG/3TC) *Symfi* (EFV/TDF/3TC) *Symfi Lo* (EFV/TDF/3TC) *Triumeq* (DTG/ABC/3TC)	Renal elimination Dose adjustment: Renal: CrCl <50 mL/min: dose adjustment recommended; limited data suggest tolerability without adjustment Hepatic: N/A Major DDIs: None	M184V/I; (often continued in setting of M184V mutation) K65R 69 insertion Q151M	Minimal toxicity HBV activity; not for HBV monotherapy (high resistance) Used interchangeably with FTC

TABLE 98.1 CONTINUED

Generic (Abbreviation) *Trade Name* Analog	Adult Dosing, Formulations, Coformulations *Trade Name* (Abbreviation)	Metabolism, Dose Adjustments, Major Drug-Drug Interactions	Resistance Pathways	Adverse Effects, Considerations for Use
Tenofovir alafenamide (TAF) *Vemlidy* Adenosine	Dosing: 25 mg PO qd, or 10 mg PO qd with cobicistat Formulations: 25 mg tablet FDC: *Descovy* (TAF/FTC) STRs: *Biktarvy* (BIC/TAF/FTC) *Genvoya* (EVG/c/TAF/FTC) *Odefsey* (RPV/TAF/FTC) *Symtuza* (DRV/c/TAF/FTC)	<1% renal elimination Dose adjustment: Renal: CrCl ≥15 mL/min or on HD; not required CrCl <15 mL/min and not on HD: use not recommended Hepatic: N/A Major DDIs: Avoid with **strong inducers**[a] rifapentine, and rifabutin	K65R TAM1 69 insertion	Diarrhea, nausea, headache Lower risk of renal insufficiency, Fanconi syndrome, or proximal renal tubulopathy than TDF Lower risk of osteomalacia or decreased BMD than TDF **HBV activity; preferred NRTI in HIV/HBV coinfection**
Tenofovir disoproxil fumarate (TDF) *Viread* Adenosine	Dosing: 300 mg PO qd 7.5 level scoops (300 mg) of oral powder PO qd Formulations: 150, 200, 250, and 300 mg tablets 40 mg/g oral powder FDCs: *Cimduo* (TDF/3TC) *Temixys* (TDF/3TC) *Truvada* (TDF/FTC) STRs: *Atripla* (EFV/TDF/FTC) *Complera* (RPV/TDF/FTC) *Delstrigo* (DOR/TDF/3TC) *Stribild* (EVG/c/TDF/FTC) *Symfi* (EFV/TDF/3TC) *Symfi Lo* (EFV/TDF/3TC)	Renal elimination Dose adjustment: Renal: CrCl <50 mL/min: required Hepatic: N/A Major DDIs: HIV/HCV protease inhibitors and PK boosters may increase levels of TDF; TDF reduces levels of unboosted atazanavir	K65R TAM1 69 insertion	Diarrhea, nausea, vomiting, flatulence, headache, asthenia Renal insufficiency, Fanconi syndrome, proximal renal tubulopathy; avoid in CKD Osteomalacia, decreased BMD; avoid in osteoporosis **HBV activity; preferred NRTI in HIV/HBV coinfection** Preferred tenofovir formulation in pregnancy, PEP, or with concomitant strong inducers[a]

Abbreviations: BMD = bone mineral density; CKD = chronic kidney disease; CrCl = creatinine clearance; CTP = Child-Turcotte-Pugh; CV = cardiovascular; FDC = fixed-dose combination; HBV = hepatitis B virus; HCV hepatitis C virus; HD = hemodialysis; NRTI = nucleoside and nucleotide reverse transcriptase inhibitor; PEP = post-exposure prophylaxis; P-gp = p-glycoprotein; PK = pharmacokinetic; STR = single-tablet regimen; TAM1 = thymidine analog mutation 1 pathway (positions 41, 210, and 215)
[a]Examples of strong inducers include rifampin, carbamazepine, oxcarbazepine, phenobarbital, and phenytoin
The NRTI class also includes zidovudine (AZT or ZDV), didanosine (ddI), stavudine (d4T), and zalcitabine (ddC). These agents are no longer in clinical use except in very rare instances (usually based on patient preference not to change from an older regimen). Given their extremely limited clinical use in the modern era, they have not been included in this table.

regimen would also be clinically appropriate. TDF requires renal dose adjustments, while TAF does not, with <1% renal elimination. TDF is currently the preferred formulation in pregnancy, for post-exposure prophylaxis, and in the setting of concomitant P-glycoprotein inducers. In the future, it may be important to consider an individual's risk for weight gain when selecting between TAF and TDF in certain patient populations; studies are ongoing to determine the significance of this effect. Both formulations have excellent activity against HBV and are preferred NRTIs in the setting of HBV coinfection. Caution is advised when discontinuing tenofovir products in those with chronic HBV due to risk of hepatitis flare.

Abacavir (ABC)

Abacavir (trade name Ziagen) is most frequently paired with 3TC (FDC trade name Epzicom). ABC is administered 600 mg orally once daily but requires dose reduction to 200 mg twice daily in mild hepatic impairment (Child-Turcotte-Pugh A), and its use is contraindicated in those with moderate to severe hepatic impairment (Child-Turcotte-Pugh B or C). ABC is metabolized in part by alcohol dehydrogenase, and levels may be increased in the setting of concomitant alcohol consumption. ABC lacks activity against HBV, and regimens including tenofovir are preferred in the scenario of HIV/HBV coinfection.

Common side effects of ABC include headache, fatigue, and nausea. The most well-known toxicity linked to ABC is a potentially fatal hypersensitivity reaction (HSR) in the presence of human leukocyte antigen allele, HLA-B*5701. Testing for HLA-B*5701 allele must be performed prior to use of ABC. If the result is positive, the risk of HSR is approximately 50%, and ABC therapy should be avoided and listed as an allergy in the medical record. For this reason, ABC-containing regimens are not commonly utilized when rapid initiation of ART is desired. A controversial association exists between ABC use and myocardial infarction, which was first reported in a large multinational observational study. Since the initial report, some cohorts have corroborated this finding whereas others have not. The US Department of Health and Human Services (DHHS) Guidelines recommend cautious use or avoidance of ABC in those with known high cardiovascular risk.

An abacavir-based NRTI backbone may be inferior to a tenofovir-based NRTI backbone in certain scenarios. The AIDS Clinical Trials Group (ACTG) 5202 trial compared the NRTI backbones ABC/3TC versus TDF/FTC when given in combination with efavirenz or ritonavir-boosted atazanavir. Results demonstrated higher virologic failure with ABC/3TC compared to TDF/FTC in patients with pretreatment viral loads of >100,000 copies/mL. Of note, this outcome was not observed in other trials, including a separate trial when ABC/3TC was given in combination with dolutegravir (this regimen is co-formulated and marketed as Triumeq). However, based on these data, in patients with high pretreatment HIV RNA, the combination of ABC/3TC with efavirenz or atazanavir/ritonavir, specifically, should be avoided.

NRTI administration requirements and interaction potential

All second-generation NRTIs can be administered without regard to meals. Limited drug–drug interactions exist for the NRTI class; however, it is important to note that the two tenofovir pro-drugs differ in interaction profiles. For example, the combination of TDF with nephrotoxic medications may increase risk for renal injury, particularly in those with additional underlying risk factors. Additionally, certain medications and combinations can increase TDF levels thereby increasing risk for TDF toxicity, such as the combination of TDF with ritonavir- or cobicistat-boosted darunavir or atazanavir. Due to lower peripheral exposure, these concerns are not clinically relevant with TAF. On the other hand, TAF should not be combined with P-glycoprotein inducers, including rifamycins, carbamazepine, oxcarbazepine, phenobarbital, phenytoin, or St. John's Wort, a drug–drug interaction that is not clinically relevant with TDF or any other preferred NRTI. Concomitant administration could lead to reduced TAF concentrations, therapeutic failure, and HIV resistance.

NRTI resistance mechanisms

Resistance to NRTIs occurs most frequently through single point mutations, thymidine analog mutations (TAMs), and β3-β4 insertions and/or deletions. M184V and K65R are the most commonly encountered clinically significant single-point NRTI resistance mutations. M184V confers high-level resistance to 3TC and FTC, whereas K65R confers high-level resistance to tenofovir and intermediate resistance to ABC, 3TC, and FTC. Tenofovir resistance can also occur through the presence of TAMs, which are selected for by thymidine analogs (d4T, AZT). TAMs can occur at positions 41, 210, and 215 (TAM1 pathway) or at positions 67, 70, 215, and 219 (TAM2 pathway). The TAM1 pathway impacts tenofovir activity more significantly than the TAM2 pathway. Presence of the Q151M complex reduces susceptibility to all currently approved NRTIs except tenofovir, and pan-NRTI resistance can occur through the 69 Insertion Complex.

The M184V mutation merits further discussion due to its unique clinical properties. Upon development of the M184V mutation, FTC or 3TC will often be continued in order to maintain its presence as it decreases viral fitness and results in a 0.3 to 0.6 $\log_{10}$ reduction in plasma HIV RNA levels. M184V can also hypersensitize HIV to tenofovir, restore partial sensitivity to tenofovir in the presence of TAMs or K65R, and delay the emergence of additional TAMs.

Non-nucleoside reverse transcriptase inhibitors

NNRTIs are noncompetitive inhibitors of RT that bind to the enzyme at an allosteric site, inducing a conformational change and thereby reducing its activity. In current practice, NNRTI-based regimens are only recommended as initial therapy in certain clinical scenarios due to a lower genetic barrier to resistance, poorer tolerability, and proven inferiority when compared to INSTI-based regimens. The risk for transmitted resistance in ART-naïve individuals is highest with the NNRTI class; therefore, NNRTI-based regimens should not be prescribed without a baseline genotype demonstrating susceptibility. Like NRTIs, the NNRTIs are also divided into two distinct groups, the first- and second-generation NNRTIs. Second-generation NNRTIs were structurally altered to theoretically increase efficacy in resistant HIV, but their most clinically meaningful benefit is an improved safety and tolerability profile. Table 98.2 presents a summary of the NNRTIs that will be discussed in this section.

First-generation NNRTIs

First-generation NNRTIs include delavirdine (DLV), efavirenz (EFV), and nevirapine (NVP). DLV and NVP are not utilized frequently in the United States largely due to inferior clinical efficacy, higher pill burden, and severe toxicities compared to other agents within the class.

Efavirenz at a dose of 600 mg orally daily, in combination with TDF/FTC (trade name Atripla), was the first STR approved for use in 2006, revolutionizing the approach to HIV management at that time. EFV-based regimens have since been removed from the recommended initial treatment options for most people with HIV due to high discontinuation rates and the development of more tolerable and durable agents and classes. This change was driven by an accumulation of data including results from the SINGLE trial,

TABLE 98.2 **SUMMARY OF NON-NUCLEOSIDE REVERSE TRANSCRIPTASE INHIBITORS (NNRTIS)**

Generic Name (Abbreviation) *Trade Name* Generation	**Adult Dosing, Formulations, Coformulations** *Trade Name* (Abbreviation)	**Metabolism, Dose Adjustments, Major Drug–drug Interactions**	**Resistance Pathways**	**Adverse Effects, Considerations for Use**
Doravirine (DOR) *Pifeltro* Second generation NNRTI	Dosing: 100 mg PO qd Formulations: 100 mg tablet STR: *Delstrigo* (DOR/TDF/3TC)	Hepatic through CYP3A4 Dose adjustment: Renal: N/A; not studied in ESRD Hepatic: N/A; not studied in CTP C Major DDIs: **Contraindicated with strong inducers[a] and rifapentine** Increase DOR to 100 mg BID with rifabutin	V106A/M Y188L M230L G190E	Nausea, dizziness, abnormal dreams Less neuropsychiatric adverse effects than EFV Administer without regard to meals; does not require acid for absorption
Efavirenz (EFV) *Sustiva* First generation NNRTI	Dosing: 600 mg PO qd, or 400 mg PO qd (low-dose) Formulations: 50 mg and 200 mg capsules 600 mg tablet STRs: *Atripla* (EFV/TDF/FTC) *Symfi* (EFV 600 mg/TDF/3TC) *Symfi Lo* (EFV 400 mg/TDF/3TC)	Hepatic through CYP2B6, 3A4, and 2A6 Dose adjustment: Renal: N/A Hepatic: use with caution in hepatic dysfunction Major DDIs: Induces CYP2B6, 2C19, 3A4 **Extensive DDIs** **EFV, ETV, and NVP reduce levels of many medications**, including certain anxiolytics, antidepressants, antipsychotics, alpha-adrenergic antagonists, anticoagulants, anticonvulsants, antifungals, antiplatelets, cardiac medications, contraceptives, HCV Direct Acting Antivirals, treatments for opioid dependence, and statins ETV, EFV, and NVP levels may be reduced with strong inducers[a], however, EFV 600 mg can be given with rifampin and rifapentine	**K103N/S** K101P L100I V106M V108I Y181C/I Y188L G190S/A P225H M230L	Rash, neuropsychiatric effects, vivid dreams, hepatotoxicity, hyperlipidemia **Take at bedtime on an empty stomach** (to decrease side effects); does not require acid for absorption Lower virologic efficacy when combined with ABC/3TC when HIV RNA >100,000 copies/mL
Etravirine (ETV) *Intelence* Second generation NNRTI	Dosing: 200 mg PO BID Formulations: 25, 100, and 200 mg tablets	Hepatic through CYP3A4, 2C9, 2C19 Dose adjustment: Renal: N/A Hepatic: N/A Major DDIs: Induces CYP3A4 Inhibits CYP2C9 and 2C19 **Extensive DDIs** Similar in profile to EFV, however ETV should not be coadministered with rifampin or rifapentine	Y181C/I/V L100I K101P G190A	Nausea, rash, including SJS, hepatotoxicity **Requires food for absorption**; does not require acid for absorption **Reserved for multidrug resistant HIV**

TABLE 98.2 CONTINUED

Generic Name (Abbreviation) *Trade Name* Generation	Adult Dosing, Formulations, Coformulations *Trade Name* (Abbreviation)	Metabolism, Dose Adjustments, Major Drug–drug Interactions	Resistance Pathways	Adverse Effects, Considerations for Use
Nevirapine (NVP) *Viramune*, *Viramune XR* First generation NNRTI	Dosing: 200 mg PO qd for 14 days followed by 200 mg PO BID, or 400 mg XR PO qd Formulations: 200 mg tablet 50 mg/5 mL oral suspension 400 mg XR tablet	Hepatic through CYP3A4, 2B6 Dose adjustment: Renal: N/A; administer additional 200 mg after HD Hepatic: contraindicated in CTB B or C Major DDIs: Induces CYP3A4, 2B6 **Extensive DDIs S**imilar in profile to EFV, however, NVP should not be coadministered with rifampin or rifapentine	**K103N** V106A/M Y181C Y188L G190A/S	Rash, including SJS Hepatotoxicity, including fatal hepatic necrosis Symptomatic hepatitis may occur in ARV-naïve females with pre-NVP CD4 counts >250 cells/mm^3 and in ARV-naïve males with pre-NVP CD4 counts >400 cells/mm^3 Administer without regard to meals
Rilpivirine (RPV) *Edurant* Second generation NNRTI	Dosing: 25 mg PO qd Formulations: 25 mg tablet STRs: *Complera* (RPV/TDF/FTC) *Juluca* (DTG/RPV) *Odefsey* (RPV/TAF/FTC)	Hepatic through CYP3A4 Dose adjustment: Renal: N/A Hepatic: N/A; not studied in CTP C Major DDIs: **Requires acid for absorption; contraindicated with PPIs**, and must be appropriately timed with antacids and H2RAs **Contraindicated with strong inducers[a] and rifapentine** Increase RPV to 50 mg daily with rifabutin	**E138K/G** K101E/P/T V90I V179I/L Y181I/C V189I H221I F227C/L M230L	Rash, depression, insomnia, headache, hepatotoxicity May artificially increase creatinine without decreasing renal function **Requires food for absorption**; administer with high calorie meal (390 kilocalories) Avoid use if pretreatment CD4 <200 cells/mm^3 or HIV RNA >100,000 copies/mL Small tablet size, favorable lipid profile

Abbreviations: ARV = antiretroviral; CTP = Child-Turcotte-Pugh; CYP = cytochrome P450; DDI = drug–drug interactions; ESRD = end stage renal disease; HD = hemodialysis; H2RA = histamine type-2 receptor antagonist; NNRTI = non-nucleoside reverse transcriptase inhibitor; PPI = proton pump inhibitor; SJS = Stevens-Johnson syndrome; STR = single-tablet regimen

[a]Examples of strong inducers include rifampin, carbamazepine, oxcarbazepine, phenobarbital, and phenytoin

The NNRTI class also includes delavirdine (DLV). This agent is no longer in clinical use except in very rare instances (usually based on patient preference not to change from an older regimen). Given extremely limited clinical use in the modern era, DLV has not been included in this table.

where EFV in combination with TDF/FTC demonstrated inferiority to dolutegravir in combination with ABC/3TC, a finding that was mainly driven by discontinuations due to adverse effects in the EFV arm.

Adverse effects from EFV leading to discontinuation are typically central nervous system (CNS)-related and may include vivid dreams, insomnia, dizziness, and difficulty concentrating. Depression, suicidal ideation, and psychosis have also been reported, and EFV should be avoided in those with preexisting psychiatric conditions. EFV may also cause dyslipidemia, including elevations in LDL and triglyceride levels. Although EFV has multiple other drug–drug interactions, it has minimal interaction with rifamycins, and efavirenz-based STRs are an option for individuals with mycobacterial coinfection.

In addition to co-formulation with TDF/FTC, EFV is also co-formulated with TDF/3TC (trade name Symfi). A reduced dose of EFV (400 mg) has been co-formulated with TDF/3TC to reduce adverse effects (trade name Symfi Lo). EFV is also available as a non–co-formulated product under the trade name Sustiva.

Second-generation NNRTIs

Second-generation NNRTIs include doravirine (DOR), etravirine (ETV), and rilpivirine (RPV). RPV and DOR are commonly used in scenarios where INSTI-based regimens are non-preferred, poorly tolerated, or contraindicated based on patient-specific factors. RPV and DOR have been associated with fewer adverse CNS effects and more favorable lipid profiles when compared to EFV-based regimens. However, cautious use of RPV is still recommended in those with preexisting psychiatric conditions.

RPV (trade name Edurant), at a dose of 25 mg orally once daily, is co-formulated with both TDF/FTC (trade name Complera) and TAF/FTC (trade name Odefsey). The combination of RPV with the INSTI dolutegravir (trade name Juluca) was recently approved as the first dual-therapy STR indicated for use in individuals with 6 months or more of virologic suppression based on data from the SWORD-1 and SWORD-2 trials (as a so-called *stable switch*). Additionally, clinical trials evaluating RPV as a component of the first dual-therapy long-acting injectable ART regimen (in combination with the novel INSTI cabotegravir) demonstrated efficacy in the ATLAS and FLAIR trials, and this combination (trade name Cabenuva) has been FDA-approved as the first once-montly injectable regimen; it is also approved only for stable-switch. RPV-based regimens should be avoided in patients with high pretreatment viral loads (>100,000 copies/mL) and low CD4 counts (<200 cells/mm^3) due to lower virologic efficacy noted in this population in clinical trials.

DOR (trade name Pifeltro), dosed 100 mg orally once daily, is a novel NNRTI that is co-formulated with TDF/3TC (trade name Delstrigo) and has demonstrated noninferiority to both EFV and ritonavir-boosted darunavir in the DRIVE-AHEAD and DRIVE-FORWARD trials. DOR has a unique resistance profile and has an interaction profile and administration requirements that are pharmacokinetically more appealing when compared to its counterpart, RPV.

ETV (trade name Intelence) is reserved for use in multidrug-resistant (MDR) HIV and is largely known for comprising part of the TRIO regimen during a time period where limited options existed for individuals with MDR HIV.

NNRTI administration requirements and interaction potential

When selecting an NNRTI-based regimen it is important to be mindful of administration requirements and drug interaction profiles due to the varying requirements among the individual agents.

EFV should be administered on an empty stomach to reduce untoward effects, as concentrations are increased when administered with food. Additionally, dosing at bedtime is recommended to limit CNS toxicities during the daytime.

Alternatively, RPV and ETV should be administered with food for optimal absorption and efficacy. RPV requires administration with a high-fat meal, including at least 390 kilocalories. NVP and DOR are the only NNRTIs that can be administered without regard to meals.

Rilpivirine is the only NNRTI that requires an acidic gastric pH for absorption; antacids and H_2-receptor antagonists must be appropriately timed for adequate absorption, and concomitant use with proton pump inhibitors is contraindicated.

NVP, EFV, and ETV are all inducers of cytochrome P450 (CYP)3A4, leading to potential for decreased levels and therapeutic failure of concomitant medications metabolized through this pathway, including select antidepressants, antipsychotics, anticoagulants, hepatitis C direct-acting antivirals, hormonal contraceptives, statins, and treatments for opioid use disorder.

NNRTI resistance mechanisms

The activity of first-generation NNRTIs can be completely diminished by a single-point mutation, most commonly K103N. For second-generation NNRTIs, rilpivirine resistance occurs most frequently through the single-point mutation E138K. Point mutations including V106A, Y188L, and M230L are associated with a 10-fold or greater reduced susceptibility to doravirine. ETV is considered to have a higher barrier resistance than all other NNRTIs; however, single-point mutations (i.e., Y181C or Y188L) in RT can decrease susceptibility to all members of the NNRTI class, including ETV.

Protease inhibitors and pharmacokinetic boosters

PIs prevent HIV aspartyl protease from cleaving polyproteins into their structural and enzymatic components, which results in immature and noninfectious viral particles. PIs are well-known for their high genetic barrier to resistance and low potential for transmitted resistance and have proved effective in treatment-experienced individuals with MDR HIV. However, the use of PI-based regimens as initial therapy has fallen out of favor due to a high toxicity profile and interaction potential, especially in an aging patient population with multiple comorbidities and potential for polypharmacy. The clinical role for PI-based regimens is most appreciated in individuals who cannot receive an INSTI- or NNRTI-based regimen due to concerns for poor adherence or resistance.

PIs are metabolized through CYP3A4 and are commonly administered in combination with a CYP3A4 inhibitor (also known as a PK booster), either cobicistat or ritonavir (RTV). The combination serves to prolong the half-life of the PI, increase virologic potency, and allow for once-daily dosing. Ritonavir (trade name Norvir) at a dose of 100 mg and cobicistat (trade name Tybost) at a dose of 150 mg are both utilized as PK boosters in combination with PIs. RTV was originally marketed as a PI at a dose of 600 mg twice daily. Due to pill burden, toxicity, and multiple drug–drug interactions, RTV is now exclusively utilized at a lower dose as a PK booster. Cobicistat has no antiviral activity. Cobicistat is also used as a booster for the INSTI elvitegravir, again to allow once-daily dosing. PIs and PK boosters are associated with multiple drug–drug interactions not limited to CYP3A4 inhibition, which can lead to toxicity from and/or therapeutic failure of concomitant medications. PK boosters are summarized in Table 98.3.

Older PIs (amprenavir, fosamprenavir, indinavir, lopinavir, nelfinavir, saquinavir, tipranavir) require more frequent dosing and are associated with higher rates of toxicity. Preferred PIs, including atazanavir and darunavir, are the focus of this section. Their drug characteristics are summarized in Table 98.3.

Atazanavir (ATV) and darunavir (DRV)

Atazanavir (trade name Reyataz) has been studied unboosted at a dose of 400 mg orally once daily in treatment-naïve individuals and in combination with ritonavir 100 mg or cobicistat 150 mg at a dose

of 300 mg once daily for treatment-naïve and treatment-experienced individuals. Unboosted atazanavir was associated with more treatment failures and atazanavir resistance in clinical trials; therefore, boosted atazanavir is preferred.

Darunavir (trade name Prezista) was first approved for use in treatment-experienced individuals at a dose of 600 mg orally twice daily in combination with ritonavir 100 mg twice daily. This remains the recommended dosing regimen in those with one or more darunavir-associated resistance mutations and in pregnant women due to metabolic changes of pregnancy. Darunavir 800 mg once daily in combination with cobicistat 150 mg or ritonavir 100 mg can be utilized in all other individuals. The virologic benefit of darunavir has only been established when given concomitantly with RTV or cobicistat; therefore, unboosted DRV is not recommended.

FDC tablets are available for cobicistat-boosted darunavir (trade name Prezcobix) and cobicistat-boosted atazanavir (trade name Evotaz) to decrease pill burden. Cobicistat-boosted darunavir is combined with TAF/FTC to form the only PI-based STR (trade name Symtuza).

PIs and boosters have been associated with gastrointestinal adverse effects, including nausea, vomiting, and diarrhea. Many PIs have been associated with metabolic derangements, including dyslipidemia, insulin resistance, and fat maldistribution. Adverse effects that are specific to atazanavir include indirect hyperbilirubinemia with jaundice and scleral icterus, cholelithiasis, and nephrolithiasis. The structure of darunavir contains a sulfonamide moiety, and cross-allergenicity may occur in those with sulfonamide allergies. Stevens–Johnson syndrome, toxic epidermal necrolysis, and erythema multiforme have been reported. Observational cohort studies have reported an association between darunavir, indinavir, fosamprenavir, and lopinavir/ritonavir and an increased risk of myocardial infarction. Cautious use or avoidance is recommended in those with high cardiovascular risk.

TABLE 98.3 **SUMMARY OF PREFERRED PROTEASE INHIBITORS AND BOOSTERS**

Generic Name (Abbreviation) *Trade Name*	**Adult Dosing, Formulations, Coformulations** *Trade Name* (Abbreviation)	**Metabolic Pathway, Dose Adjustments, Major Drug–drug Interactions**	**Resistance Pathways**	**Adverse Effects, Considerations for Use**
Protease Inhibitors				
Atazanavir (ATV) *Reyataz*	Dosing: *ARV-naïve:* 300 mg PO qd boosted with RTV 100 mg or COBI 150 mg PO qd, or 400 mg PO qd unboosted *With TDF or ARV-Experienced:* unboosted ATV not recommended Formulations: 150, 200, and 300 mg capsules 50 mg single packet oral powder FDC: *Evotaz* (ATV/c)	Hepatic through CYP3A4 Dose adjustment: Renal: Baseline CrCl <70 mL/min: avoid ATV/c with TDF Hepatic: Avoid boosted ATV Major DDIs: Inhibits CYP3A4 **Extensive DDIs** **Requires acid for absorption**, dose limitations of acid-reducing agents exist and must be appropriately timed **Contraindicated with strong inducers[a] and rifapentine** Administer rifabutin at a dose of 150 mg PO daily **DRV and ATV may affect levels of many medications** including certain anxiolytics, antidepressants, antipsychotics, alpha-adrenergic antagonists, anticoagulants, antifungals, antiplatelets, cardiac medications, contraceptives, corticosteroids, HCV direct-acting antivirals, treatments for opioid dependence, and statins The degree of interaction depends on specific PI and booster **Many contraindications exist**	I50L I84V Minor mutations at 10, 16, 20, 24, 32, 33, 34, 36, 46, 48, 53, 54, 60, 62, 64, 71, 73, 82, 85, 90, 93	Nausea, hyperbilirubinemia with jaundice/scleral icterus, nephrolithiasis **Requires food for absorption** Less adverse metabolic effects than other PIs; more favorable option than DRV if high cardiac risk Lower virologic efficacy when combined with ABC/3TC when HIV RNA >100,000 copies/mL

TABLE 98.3 CONTINUED

Generic Name (Abbreviation) *Trade Name*	Adult Dosing, Formulations, Coformulations *Trade Name* (Abbreviation)	Metabolic Pathway, Dose Adjustments, Major Drug–drug Interactions	Resistance Pathways	Adverse Effects, Considerations for Use
Darunavir (DRV) *Prezista*	Dosing: *ARV-naïve:* 800 mg PO qd boosted with RTV 100 mg or COBI 150 mg PO qd *DRV resistance mutations or during pregnancy:* 600 mg PO Q12H boosted with RTV 100 mg PO Q12H Formulations: 75, 160, 600, and 800 mg tablets 100 mg/mL oral suspension FDC: *Prezcobix* (DRV/c) STR: *Symtuza* (DRV/c/TAF/FTC)	Hepatic through CYP3A4 Dose adjustment: Renal: Baseline CrCl <70 mL/min: avoid DRV/c with TDF Hepatic: avoid boosted DRV in CTP C Major DDIs: Inhibits CYP3A4 Induces CYP2C9 **Extensive DDIs** **Contraindicated with strong inducers[a] and rifapentine** Administer rifabutin at a dose of 150 mg PO daily DRV and ATV may affect levels of many medications (see ATV for further information)	I50V V11I I54L L89V V32I L33F I47V I54M I76V I84V	Diarrhea, nausea, headache, hyperlipidemia **Requires food for absorption** **Increased CV events** associated with DRV in some cohort studies; **avoid if high CV risk**
Pharmacokinetic Enhancers/Boosters				
Cobicistat (COBI, c) *Tybost*	Dosing: 150 mg PO qd in combination with ATV, DRV, or EVG Formulations FDCs: *Evotaz* (ATV/c) *Prezcobix* (DRV/c) STRs: *Genvoya* (EVG/c/TAF/FTC) *Stribild* (EVG/c/TDF/FTC) *Symtuza* (DRV/c/TAF/FTC)	Hepatic through CYP3A4 Dose Adjustment: Renal: CrCl <70 mL/min: Not recommended when used with TDF Hepatic: not studied in CTP C Major DDIs: Inhibits CYP3A4, 2D6 and OAT1B1/B3 **Extensive DDIs**, increases levels of many medications leading to toxicity (see DDIs for DRV and ATV for classes that may be affected) Avoid with rifamycins	N/A	Not considered an active agent within a regimen; utilized as a CYP3A4 inhibitor to boost levels of PIs, EVG to allow for once-daily dosing Diarrhea, nausea, hyperlipidemia May artificially increase creatinine without decreasing renal function Requires food for absorption
Ritonavir (RTV, r) *Norvir*	Dosing: 100 mg PO qd or BID in combination with PI (refer to ATV and DRV for specific dosing recommendations) Formulations: 100 mg tablet 100 mg soft gel capsule 80mg/mL oral solution 100 mg single packet oral powder FDC: *Kaletra* (LPV/r)	Hepatic through CYP 3A4, 1A2, 2B6, 2D6 Dose Adjustment: Renal: N/A Hepatic: avoid in CTP C Major DDIs: Inhibits CYP3A4, 2D6 and P-pg Induces CYP 2B6, 1A2, 2C19, 2C9 and UGT1A1 **Extensive DDIs**, may increase or decrease levels of medications depending upon dominant metabolic pathway and concomitant PI Contraindicated with strong inducers Administer rifabutin 150 mg PO qd	M46L V82A I84V Minor mutations at 10, 20, 24, 32, 36, 54, 71, 73, 76, 77, 90	Not considered an active agent within a regimen; utilized as a CYP3A4 inhibitor to boost levels of PIs to allow for once-daily dosing Diarrhea, nausea, dyslipidemia Requires food for absorption

Abbreviations: ARV = antiretroviral; CrCl = creatinine clearance; CTP = Child-Turcotte-Pugh; CV = cardiovascular; CYP = cytochrome P450; DDI = drug–drug interaction; FDC = fixed-dose combination; P-gp = p-glycoprotein; STR = single-tablet regimen; UGT = uridine diphosphate-glucuronosyltransferase

[a]Examples of strong inducers include rifampin, carbamazepine, oxcarbazepine, phenobarbital, and phenytoin

The PI class also includes amprenavir, fosamprenavir, indinavir, lopinavir, nelfinavir, saquinavir, and tipranavir. These agents are no longer in clinical use except in very rare instances (usually based on patient preference not to change from an older regimen). Given their extremely limited clinical use in the modern era, they have not been included in this table.

PI administration requirements and interaction potential

All PIs and boosters require food for adequate absorption and efficacy. Atazanavir also requires an acidic gastric pH for absorption and should be separated appropriately from acid-reducing medications. Drug–drug interactions with PIs and boosters are extensive, and each agent may differ significantly in their interaction profile.

In general, PIs and boosters may increase (or sometimes decrease) levels of many medications, including certain antidepressants, antipsychotics, anticoagulants, antimycobacterials, antiarrhythmics, hepatitis C direct-acting antivirals, hormonal contraceptives, statins, benzodiazepines, treatments for opioid dependence, and corticosteroids. Interactions can lead to serious toxicities. For example, concomitant use of boosted PIs and intranasal or inhaled corticosteroids can lead to significant increases in corticosteroid levels, systemic exposure, and Cushing's syndrome. Beclomethasone is the only inhaled/intranasal corticosteroid that can be safely coadministered due to limited CYP3A4 metabolism.

The nature of each interaction may also be influenced by the concomitant booster. While both ritonavir and cobicistat inhibit CYP3A4, ritonavir also induces CYP1A2, CYP2B6 CYP2C19, and CYP2C9, and this may lead to increased or decreased levels of concomitant medications depending on the dominant metabolic pathway. For example, warfarin is an anticoagulant that is metabolized through multiple CYP enzymes. Concomitant cobicistat and warfarin may increase warfarin concentrations due to CYP3A4 inhibition, leading to increased risk for bleeding. However, concomitant ritonavir and warfarin may decrease warfarin concentrations through CYP1A2 and CYP2C9 induction, leading to increased risk for thrombosis.

It is essential to consult drug–drug interaction resources, including the US DHHS HIV Guidelines and the University of Liverpool website (www.hiv-druginteractions.org) to evaluate the potential for drug–drug interactions prior to the addition or discontinuation of a boosted PI.

PI resistance mechanisms

Resistance to PIs occurs through the development of multiple minor mutations or single major mutations. Primary resistance to atazanavir occurs through the presence of I50L, I84V, and/or N88S. Two or more resistance mutations are often required to substantially impact virologic response to boosted darunavir; major darunavir mutations are I50V, I54M, L76V, and I84V. In the setting of multiple PI mutations, phenotypic testing can be performed to determine the clinical utility and predicted effectiveness of darunavir.

Integrase strand transfer inhibitors (INSTIs)

INSTIs exert their activity by blocking HIV integrase-mediated incorporation of HIV cDNA into the host DNA genome. First-generation INSTIs include raltegravir (RAL) and cobicistat-boosted elvitegravir (EVG/c). Second-generation INSTIs, including dolutegravir (DTG) and bictegravir (BIC), are easier to administer and have a higher genetic barrier to resistance when compared to the first-generation class. In head-to-head clinical trials, INSTIs have demonstrated either noninferiority or superiority to NNRTI- and PI-based regimens. Their high tolerability and virologic efficacy support their place as first-line treatment options worldwide. Table 98.4 presents a summary of the INSTIs.

Raltegravir (RAL)

Raltegravir (trade name Isentress) was the first INSTI to receive FDA approval in 2007 and has the most cumulative clinical data of the class. RAL is administered 400 mg orally twice daily in most individuals, 1,200 mg (two 600-mg tablets) once daily (trade name Isentress HD) in non-pregnant individuals, and 800 mg (two 400-mg tablets) twice daily with potent inducers such as rifampin. RAL is not available as a co-formulated product.

For the combined endpoint of virologic efficacy and tolerability, RAL-based regimens have demonstrated superiority to EFV- and PI-based regimens in treatment-naïve individuals (STARTMRK and ACTG A5257). Additionally, when compared to EFV-based regimens, RAL- and DTG-based regimens have demonstrated a faster reduction in viral load and greater proportion of viral suppression at delivery in women who presented for treatment late in pregnancy (IMPAACT 1081 and DolPHIN-2). Switch studies for RAL have yielded disparate results. In SWITCHMRK 1 and 2, switching from a PI-based regimen to a RAL-based regimen demonstrated improved lipid profiles but increased virologic failure rates, thus highlighting the low genetic barrier with first-generation INSTIs. In a second study with lower rates of individuals who had previously experienced virologic failure, a switch from a PI-based regimen to RAL met noninferiority criteria for virologic efficacy. RAL does not require dose adjustments in renal or mild to moderate hepatic impairment.

RAL in combination with a tenofovir pro-drug and FTC or 3TC remains a recommended treatment option as initial therapy for most individuals in the DHHS Guidelines. Additionally, RAL is currently the recommended INSTI in individuals who are trying to conceive. In clinical practice, however, RAL is not widely used mainly due to its low genetic barrier to resistance, lack of a co-formulated product, and high pill burden relative to other options within the class.

Cobicistat-boosted elvitegravir (EVG/c)

Elvitegravir was the second INSTI to gain FDA approval in 2012 and is the only agent within the class that requires boosting with cobicistat. The pharmacologic concepts of boosting with PIs can be applied to EVG/c, including the high potential for drug–drug interactions, with the caveat that EVG is never combined with RTV. EVG is administered 150 mg orally once daily in combination with cobicistat 150 mg and is only available as a co-formulated product with TDF/FTC (trade name Stribild) and TAF/FTC (trade name Genvoya).

EVG-based regimens have demonstrated noninferior virologic suppression rates when compared to EFV- and PI-based regimens in treatment-naïve individuals (GS-102 and GS-103) and superiority to a boosted ATV-based regimen in treatment-naïve women (WAVES). The STR containing EVG/c with TDF/FTC should not be initiated in patients with a creatinine clearance of <70 mL/min and should be discontinued once the creatinine clearance decreases below 50 mL/min. EVG/c with TAF/FTC can be administered without dose adjustment in those on chronic hemodialysis, but use is not recommended in those with creatinine clearances below 30 mL/min who are not receiving chronic HD. Dose adjustment is not required for either regimen in mild-moderate hepatic impairment.

TABLE 98.4 **SUMMARY OF INTEGRASE STRAND TRANSFER INHIBITORS (INSTIS)**

Generic Name (Abbreviation) *Trade Name* Generation	**Adult Dosing, Formulations, Coformulations** *Trade Name* (Abbreviation)	**Metabolism, Elimination, Dose Adjustments, Major Drug–drug Interactions**	**Resistance Mutations and Pathways**	**Adverse Effects, Considerations for Use**
Bictegravir (BIC) Second generation INSTI	Dosing: 50 mg PO qd Formulations: BIC is only available as part of a STR STR: *Biktarvy* (BIC/TAF/FTC)	Hepatic through CYP3A4 and UGT1A1-mediated glucuronidation Dose adjustment: Renal: CrCl <30 mL/min: avoid BIC/FTC/TAF Hepatic: avoid in CTP C Major DDIs: Inhibits OCT2 and MATE1 transporters **Contraindicated** with dofetilide May increase levels of metformin (monitor) Polyvalent and divalent cations reduce absorption of all INSTIs through chelation; must be appropriately timed **Avoid with strong inducers[a], rifabutin, and rifapentine**	Q148H/K/R plus 1 or more INSTI mutation	Headache, nausea, diarrhea, weight gain May artificially increase creatinine without decreasing renal function High barrier to resistance Small tablet size
Dolutegravir (DTG) *Tivicay* Second generation INSTI	Dosing: 50 mg PO qd *INSTI-Experienced with certain INSTI mutations, or if coadministered with rifampin (without INSTI resistance)*: 50 mg PO BID Formulations: 50 mg tablet STRs: *Dovato* (DTG/3TC) *Juluca* (DTG/RPV) *Triumeq* (DTG/ABC/3TC)	Hepatic through CYP3A4 and UGT1A1/3/9-mediated glucuronidation Dose adjustment: Renal: caution if CrCl <30 mL/min in those who require BID DTG Hepatic: avoid in CTP C Major DDIs: Inhibits OCT2 **Contraindicated with dofetilide** May increase levels of metformin (titrate carefully and monitor) Polyvalent and divalent cations reduce absorption of all INSTIs through chelation; must be appropriately timed Can be administered with certain strong inducers at a dose of 50 mg BID (carbamazepine, rifampin); avoid with other strong inducers[a] and rifapentine	Q148H/K/R plus 1 or more INSTI mutation	Headache, insomnia Weight gain Depression and suicidal ideation (rare) CK elevations and myopathy (rare) May artificially increase creatinine without decreasing renal function High barrier to resistance

Abbreviations: CK = creatine kinase; CrCl = creatinine clearance; CTP = Child-Turcotte-Pugh; CYP = cytochrome P450; DDI = drug–drug interaction; MATE = multidrug and toxin extrusion protein; OCT = organic cation transporter; SJS = Stevens Johnson Syndrome; STR = single-tablet regimen; UGT = uridine diphosphate-glucuronosyltransferase

[a]Examples of strong inducers include rifampin, carbamazepine, oxcarbazepine, phenobarbital, and phenytoin

EVG-based regimens are no longer recommended as initial therapy for most people with HIV due to a low genetic barrier and limitations in side-effect and interaction profiles when compared to RAL-, DTG-, and BIC-based regimens.

Dolutegravir (DTG)

Dolutegravir (trade name Tivicay), a second-generation INSTI, is administered 50 mg orally once daily or 50 mg twice daily in individuals with first-generation INSTI resistance or in combination with potent inducers, such as rifampin. DTG is co-formulated with ABC/3TC (trade name Triumeq), 3TC (trade name Dovato), and RPV (trade name Juluca).

DTG/3TC was the first dual-therapy regimen approved for use in treatment-naïve individuals with baseline HIV RNA levels of <500,000 copies/mL based on data from the GEMINI-1 and GEMINI-2 trials. However, it should not be used in individuals with HBV coinfection or without baseline HIV genotypic resistance testing demonstrating 3TC susceptibility.

DTG-based regimens have demonstrated noninferiority to RAL-based regimens (SPRING-2) and superiority to EVF- and PI-based regimens (SINGLE and FLAMINGO, ARIAS) in treatment-naïve individuals. In treatment-experienced individuals, DTG-based regimens have outperformed RAL-based regimens, with higher rates of virologic suppression and lower rates of virologic failure due to treatment-emergent INSTI resistance (SAILING). DTG has also demonstrated an effective role in heavily treatment-experienced individuals, including those with NRTI or first-generation INSTI resistance (VIKING). DTG does not require dose adjustment in renal or mild to moderate hepatic impairment. However, cautious use is recommended in individuals with a creatinine clearance <30 mL/min when twice-daily dolutegravir is indicated because there may be a loss of therapeutic effect.

Based on its robust clinical efficacy and tolerability, DTG is a component of multiple regimens recommended as initial therapy in most individuals with HIV.

Bictegravir (BIC)

Bictegravir, a novel second-generation INSTI, is structurally similar to dolutegravir and was approved by the FDA in 2018 as part of a once-daily STR including bictegravir 50 mg and TAF/FTC (trade name Biktarvy). Similar to EVG/c, BIC is only available as a component of a STR and not as a standalone product. The slight structural differences between BIC and DTG increase the in-vitro potency of BIC against select INSTI mutations; however, an improved resistance profile has not yet been proved clinically.

BIC in combination with TAF/FTC has demonstrated noninferior virologic suppression rates when compared to DTG-based regimens in treatment-naïve individuals and noninferiority to DTG- and PI-based regimens in treatment-experienced individuals. BIC in combination with TAF/FTC does not require dose adjustment in individuals with mild to moderate hepatic impairment. Use is currently not recommended in those with a creatinine clearance of <30 mL/min. BIC should not be used in those with first-generation INSTI resistance; DTG administered twice daily or a non–INSTI-based regimen is preferred in this scenario.

BIC in combination with TAF/FTC is a recommended initial regimen for most individuals with HIV and has several advantages over other INSTI-based regimens, including a high genetic barrier, limited drug–drug interactions, co-formulation with an NRTI backbone with HBV activity, appropriateness for use in rapid initiation of ART, and small tablet size.

INSTI adverse effects

Adverse effects that are linked to the INSTI class include headache, insomnia, rash, and rare neuropsychiatric side effects. Recently, INSTI-based regimens have been associated with the potential for increased weight gain in clinical trials when compared to NNRTI- or PI-based regimens. This effect has been most pronounced with DTG and BIC when combined with TAF and appears to disproportionately affect black and Hispanic women. As described previously with TAF, the clinical significance of and mechanistic explanation for this finding is currently unknown, including whether reversibility of weight gain is possible on discontinuation of therapy.

DTG, BIC, and cobicistat can inhibit tubular secretion of creatinine without affecting glomerular filtration rate. An increase in creatinine of 0.1 to 0.4 mg/dL is expected. RAL and DTG have been associated with rare elevations in creatine kinase and proximal myopathy.

Boosted EVG is the most poorly tolerated agent of the class, with a side-effect profile like that of boosted PIs, including nausea, diarrhea, and dyslipidemia.

INSTI administration requirements and interaction profile

RAL, BIC, and DTG can be administered without regard to meals, whereas boosted EVG requires food for adequate absorption. As EVG is co-formulated with cobicistat, it has the highest potential for drug–drug interactions and may increase levels of medications metabolized through CYP3A4, thus increasing risk for toxicity. A close evaluation of the medication profile should be performed prior to the initiation or discontinuation of boosted EVG. BIC and DTG are minor substrates of CYP3A4 and are inhibitors of the renal transporter organic cation transporter 2 (OCT2). When combined with medications that are renally eliminated through this pathway (metformin and dofetilide), this can result in increased exposure and potential for toxicity. RAL is metabolized by uridine diphosphate-glucuronosyltransferase (UGT) enzymes and has the fewest drug–drug interactions of the class.

The most commonly overlooked but clinically significant drug–drug interaction with the INSTI class is the potential for chelation and reduced INSTI absorption when coadministered with polyvalent and divalent cations. Antacids and cation-containing supplements must be appropriately timed or avoided in certain scenarios. The percentage decrease in bioavailability varies, depending on the INSTI and concomitant cation. For instance, the bioavailability of DTG and BIC is relatively unchanged when coadministered simultaneously with iron or calcium supplements with food. However, EVG/c and RAL should be administered at least 2 hours before or at least 6 hours after iron and calcium supplements.

When coadministered with rifampin, DTG should be administered at a dose of 50 mg twice daily, and RAL should be administered at a dose of 800 mg twice daily in individuals without INSTI resistance. BIC- and EVG-based regimens should not be coadministered with any rifamycins.

INSTI resistance mechanisms

Resistance to INSTIs can occur through primary single-point mutations or the combination of primary and accessory mutations. Primary single-point mutations in the integrase enzyme, such as Q148H/R/K, N155H, or E92Q/V, can reduce the activity of first-generation INSTIs. EVG and RAL commonly demonstrate cross-resistance, and EVG should not be used in those with prior RAL resistance. Lower rates of DTG susceptibility and antiviral activity have been shown when one or more additional INSTI mutations are present with Q148H/K/R. That said, several mutations are required to confer high-level resistance to DTG or BIC. For example, Q148H/R and G140S in combination with mutations L41I/M, E92Q, T97A, E138A/K, G140A, or N155H are associated with 5- to 20-fold reduced susceptibility to DTG. The combination of G140S and Q148H decreases bictegravir susceptibility 4.8-fold; with additional E138K, susceptibility is reduced even further.

Entry inhibitors

Entry inhibitors target various steps in the process of HIV entry into host CD4+ cells. Enfuvirtide (ENF), maraviroc (MVC), ibalizumab (IBA), and fostemsavir (FTR) are the antiretrovirals that make up this class. These agents are reserved for use in individuals with limited treatment options due to MDR HIV and are not recommended as a component of initial drug therapy.

Enfuvirtide (T-20; trade name Fuzeon), a fusion inhibitor, received FDA approval in 2003 as a salvage drug for treatment-experienced patients with advanced HIV. ENF blocks the conformational change in glycoprotein (gp) 41 required for membrane fusion and HIV entry into the CD4+ cell and is available as a 90 mg subcutaneous injection administered twice daily. Injection site reactions occur in 98% of patients and may manifest as pain, nodules, cysts, or pruritus. Additional adverse effects include nausea, vomiting, diarrhea, fatigue, and insomnia. Dose adjustment is not required for hepatic or renal impairment, and clinically significant drug interactions have not been reported. Resistance to ENF can occur with amino acid substitutions on viral gp41, usually at positions 36, 38, 40, and 43.

Maraviroc (trade name Selzentry) is an allosteric antagonist of the host cell coreceptor CCR5 and prevents the essential interaction between CCR5 and viral gp120 and the conformational change required for viral attachment, fusion, and entry. HIV strains may utilize different host coreceptors for entry, either CCR5, CXCR4, or both. CCR5 antagonists are only effective against R5 virus and not X4 or mixed R5/X4 virus. A phenotypic viral tropism assay must be performed prior to initiation of MVC to determine if the circulating virus is R5-tropic, X4-tropic, or dual/mixed R5/X4-tropic. Individuals may have low levels of X4-tropic virus that circulate below the detection limit of the tropism assay, which can lead to virologic escape and therapeutic failure. Selection of X4-tropic virus may have additional consequences, including a faster decline in CD4 count and progression to AIDS. MVC is administered 300 mg orally twice daily without regard to meals, and dose adjustment is required when given with concomitant CYP3A4 inducers or inhibitors. Side effects of MVC include rash, upper respiratory tract infection, and fever. Resistance to MVC can occur through amino acid substitution on viral gp120 or when selection of CXCR4-binding virus occurs.

Ibalizumab (trade name Trogarzo), a post-attachment inhibitor, is a humanized monoclonal antibody that binds to domain 2 of the CD4+ cell receptor, inducing a conformational change that blocks the interaction between gp120 and HIV co-receptors. Ibalizumab is administered as an intravenous infusion at a loading dose of 2,000 mg followed by a maintenance infusion of 800 mg every 2 weeks thereafter. Clinical experience with ibalizumab is limited to a single-arm, 40-participant study in adults harboring MDR HIV who were failing salvage therapy. When combined with an individually optimized background regimen including at least one fully active agent, 43% of individuals achieved a viral load of <50 copies/mL at week 25. Common side effects of IBA include diarrhea, dizziness, nausea, rash, and creatinine elevations. There are no known clinically significant drug–drug interactions with IBA, and renal or hepatic impairment is not expected to alter its pharmacokinetic parameters.

Fostemsavir (trade name Rukobia), a pro-drug of temsavir, is a gp120 attachment inhibitor. Once hydrolyzed to the active moiety, temsavir binds directly to the viral gp120 subunit near its CD4-binding site, causing a conformational change that inhibits viral attachment to the CD4+ cell. Fostemsavir is administered 600 mg orally twice daily without regard to meals. Results from the BRIGHTE study demonstrated efficacy of FTR in highly treatment-experienced patients failing their current regimen with only one or two antiretroviral classes remaining. When administered in combination with an optimized background regimen including at least one fully active agent, 60% of individuals achieved an HIV RNA <40 copies/mL at week 96. The most common adverse reaction observed in clinical trials was nausea. Fostemsavir is a substrate of CYP3A4 and should not be coadministered with strong CYP3A4

inducers, such as rifampin, carbamazepine, and phenytoin. Additionally, levels of ethinyl estradiol and statins may be increased when administered concomitantly with FTR. Dose adjustment is not required in renal or hepatic impairment. The presence of gp120 resistance-associated polymorphisms at sites S375, M426, M434, or M475 has been associated with a reduced virologic response to fostemsavir.

New and investigational medications

Cabotegravir + Rilpivirine intramuscular formulation

Cabotegravir, a new INSTI that is an analog of dolutegravir, has a long half-life that allows for once-monthly intramuscular dosing. Rilpivirine, an NNRTI, can also be formulated as a once-monthly nanosuspension. The combination of these two agents as a once-monthly injection has demonstrated success both in treatment-naïve (the LATTE and FLAIR trials) and patients already on therapy ("stable switch"; the ATLAS trial), provided that the patient does not have preexisting INSTI and rilpivirine resistance. This combination was recently approved in January 2021 as the first fully non-oral treatment option for patients.

Islatravir

Islatravir, also called MK-8591, is a nucleoside reverse transcriptase translocation inhibitor (NRTTI). It represents a new class of agents and has the potential for less frequent dosing due to its long half-life. It is now in clinical trials in combination with doravirine and lamivudine.

Other agents

There are a number of other agents in development, several of which represent new classes of agents and which will further strengthen the HIV armamentarium. Maturation inhibitors, CCR5 antagonists, capsid inhibitors, and several monoclonal antibodies are in development and represent exciting future directions for treatment.

Use of ART therapy

Guidelines for ART initiation

Treatment with ART is now recommended for all people living with HIV regardless of CD4 count and HIV viral load. These recommendations are supported by results from high-quality, randomized controlled trials (RCTs) that have demonstrated conclusively a mortality benefit to people living with HIV with initiation of ART and a dramatic reduction in transmission risk with treatment of people living with HIV.

Treatment guidelines have evolved over the years. With the advent of ART, treatment was focused largely on prevention of opportunistic disease. The benefits of treatment had to be balanced with the side effects, high pill burdens, drug toxicities, and risk of development of drug resistant viral strains all seen with earlier regimens. Initiation of treatment was therefore initially driven by CD4 count. Numerous large clinical trials and new drug development have led to evolution in treatment guidelines, shifting from the use of CD4 cutoffs to determine timing of treatment initiation to now recommending universal, lifelong treatment for all patients. The SMART trial, published in 2006, clearly demonstrated a mortality benefit with continuous ART therapy once initiated rather than intermittent, CD4-driven treatment. Prior to that, some clinicians favored a "drug conservation" approach (sometimes called "structured treatment interruptions") in which ART was used to "boost" patients' CD4 counts and then stopped to minimize toxicity; therapy was reinitiated once the CD4 count fell below 350 cells/mm^3. The SMART trial randomized patients to this approach versus continuous therapy and demonstrated lower mortality to continuous therapy. Several trials followed, demonstrating a mortality benefit to treatment initiation at higher and higher CD4 counts. This progression culminated in 2015 with the publication of the START and TEMPRANO trials, which both demonstrated a clear reduction in AIDS-related events, serious non–AIDS-related events, or death from any cause in patients started on ART even at high CD4 counts. Following this, all major guidelines-defining bodies have changed treatment recommendations to encourage treatment initiation as soon as patients are ready, regardless of CD4 count.

Early treatment initiation is not only beneficial to the individual. Treatment is also prevention, and numerous trials have demonstrated conclusively that people living with HIV who are treated with ART and have an undetectable HIV viral load (<200 copies/mL) cannot transmit HIV to others. Aggregate data from the HPTN 052, PARTNER, PARTNER-2, and Opposites Attract trials have demonstrated conclusively that transmission does not occur from patients living with HIV to their HIV-negative partners if the virus remain undetectable, often described as "undetectable = untransmittable." This concept, popularized as "U = U," has become a major public health and empowerment message for people living with HIV. The demonstration of this public health benefit across numerous trials was also a major factor in driving all treatment guidelines to recommend universal treatment of patients living with HIV.

A number of trials have also looked at "rapid start" protocols. Though this is defined slightly differently in different studies, it can be conceptually explained as either initiation of ART at time of diagnosis ("same day ART") or within a brief window after diagnosis, generally 7 days. These trials have demonstrated a shorter time to viral suppression, which is of benefit to decreasing risk of transmission. Data from lower- and middle-income countries also demonstrate higher rates of linkage-to-care, higher rates of people achieving viral suppression, and better health outcomes, including lower rates of severe illness and death. Data from higher income

countries, where diagnosis at higher CD4 counts is more common and more infrastructures may exist to aid in patient retention, are still accumulating. Though there is insufficient broad evidence for guidelines to recommend universal "rapid start" or "test-and-treat" for all patients in all settings, this is an area of active investigation and guideline development.

Selection of regimen for treatment-naïve patients

Treatment guidelines have evolved over the years based on a number of factors, and choice of a regimen may still be influenced by co-occurring medical conditions, patients' current (non-HIV) medications, pregnancy status or desire to become pregnant, medication cost and access to coverage, and transmitted resistance. In spite of these nuances, treatment has become increasingly straightforward, with first-line recommended regimens across both higher- and low/moderate-income countries favoring treatment with two classes of medications, generally two NRTIs paired with an INSTI. See Box 98.1 for recommended initial regimens for most people with HIV and Box 98.2 for recommended regimens for some people with HIV.

A treatment regimen selection should always include assessment of resistance, and all patients initiating therapy should have an HIV-1 genotype assay performed to look for baseline resistance. In most cases, patients can be initiated on therapy before results have returned from this assay, and adjustments can be made if necessary should concerning resistance mutations be present. Most treatment regimens for treatment-naïve patients recommend the use of tenofovir with emtricitabine.

Integrase inhibitors have repeatedly demonstrated superiority over other classes (including NNRTIs, PIs, and entry inhibitors) in terms of sustained viral suppression and/or tolerability. Therefore, all first-line regimens pair NRTIs with an integrase inhibitor.

BOX 98.1

Recommended initial regimens for most people with HIV

- Bictegravir/tenofovir alafenamide/emtricitabine (AI)
- Dolutegravir/abacavir/lamivudine—only for patients who are HLA-B*5701 negative (AI)
- Dolutegravir (DTG) plus tenofovir plus emtricitabine or lamivudine (AI)
- Raltegravir plus tenofovir plus emtricitabine or lamivudine (BI for tenofovir disoproxil fumarate, BII for tenofovir alafenamide)
- Dolutegravir plus lamivudine—except for patients with an HIV VL >500,000, or if resistance testing is unknown, or HBV co-infected (AI)

As per US Department of Health and Human Services (DHHS) guidelines.

BOX 98.2

Recommended initial regimens in certain clinical situations

- INSTI plus 2 NRTIs:
- EVG/c/tenofovir/FTC (BI for both TAF/FTC and TDF/FTC)
- Boosted PI plus 2 NRTIs: (In general, boosted DRV is preferred over boosted ATV)
- (DRV/c or DRV/r) plus tenofovir/FTC (AI)
- (ATV/c or ATV/r) plus tenofovir/FTC (BI)
- (DRV/c or DRV/r) plus ABC/3TC—if HLA-B*5701 negative (BII)
- NNRTI plus 2 NRTIs:
- DOR/TDF/3TC (BI) or DOR plus TAF/FTC (BIII)
- EFV plus TDF/FTC (BI for EFV 600 mg/TDF/FTC or EFV 600 mg/TDF/3TC, BII for EFV 600 mg plus TAF/FTC)
- RPV/tenofovir/FTC (BI)—if HIV RNA <100,000 copies/mL and CD4 cell count >200 cells/mm^3
- Regimens to Consider when ABC, TAF, and TDF Cannot be Used or Are Not Optimal:
- DTG plus 3TC (AI)
- DRV/r plus RAL BID (CI)—if HIV RNA <100,000 copies/mL and CD4 cell count >200 cells/mm^3
- DRV/r once daily plus 3TC (CI)

Abbreviations: INSTI = integrase strand transfer inhibitors, NRTI = nucleoside reverse transcriptase inhibitor, NNRTI = non-nucleoside reverse transcriptase inhibitor, PI = protease inhibitor.

Personalized pharmacotherapy

With the shift to life-long treatment for all, the tolerability and durability of ART is now even more essential. With numerous effective and acceptable options to choose from, initiating or adjusting ART should always be based on regimen- and patient-specific factors. The concept and application of "personalized pharmacotherapy," including selection of ART based on pre-ART characteristics, patient-specific factors and preferences, pregnancy considerations, and additional scenarios, is discussed next.

Pre-ART characteristics

Some regimens have been associated with an increased risk of virologic failure in the setting of high pretreatment HIV RNA levels or low pretreatment CD4 count. For example, RPV-based regimens should not be initiated in those with baseline CD4 counts of <200 cells/mm^3. Additionally, RPV-based regimens and the combination of ABC/3TC with EFV or ATV/r should not be initiated in those with pretreatment HIV RNA of >100,000 copies/mL. Dual therapy with DTG/3TC should not be initiated in those with pretreatment HIV RNA of >500,000 copies/mL due to limited data in this population.

Rapid ART

If rapid initiation of ART is desired, ABC-based regimens should be avoided where HLA-B*5701 results are not readily available. Additionally, NNRTI-based regimens and dual-therapy with DTG/3TC should not be initiated without baseline HIV genotypic resistance testing demonstrating 3TC susceptibility. Preferred regimens for rapid initiation or if poor adherence or resistance is anticipated include a second-generation INSTI (DTG or BIC) or boosted darunavir in combination with tenofovir/FTC as these regimens have a high genetic barrier to resistance and will also cover HBV coinfection.

Ease of administration

Options for STRs are listed in Table 98.5. For individuals who prefer a regimen that can be administered without regard to meals, BIC-, DTG-, RAL-, and DOR-based regimens are appropriate. Boosted regimens (EVG/c and boosted PIs) and RPV-based regimens require food for absorption, and EFV-based regimens must be administered on an empty stomach to avoid adverse effects. RPV and ATV also require an acidic environment for absorption and may not be an optimal selection in individuals who require long-term acid-reducing agents.

Polypharmacy

Boosted regimens (EVG/c and boosted PIs) have the highest potential for drug–drug interactions. Therefore, BIC-, DTG-, RAL-, and DOR-based regimens are optimal in individuals receiving multiple concomitant medications. A comprehensive medication list should be obtained, and drug interactions should be assessed prior to initiation or adjustment of ART.

Concomitant disease states

Cardiovascular disease

ABC, DRV/r, and LPV/r have been associated with potential for increased risk of myocardial infarction, and cautious use or avoidance is recommended in those with high cardiovascular risk.

If a boosted PI is required, an ATV-based regimen may be preferable to a DRV-based regimen. BIC-, DTG-, RAL-, RPV-, and DOR-based

TABLE 98.5 **SINGLE-TABLET REGIMENS**

Trade name (abbreviation)	**Components and dosing**
INSTI plus Two NRTIs	
Biktarvy (BIC/TAF/FTC)	Bictegravir 50 mg/tenofovir AF 25 mg/emtricitabine 200 mg: 1 PO qd
Genvoya (EVG/c/TAF/FTC)	Elvitegravir 150 mg/cobicistat 150 mg/tenofovir AF 10 mg/emtricitabine 200 mg: 1 PO qd with food
Stribild (EVG/c/TDF/FTC)	Elvitegravir 150 mg/cobicistat 150 mg/tenofovir DF 300 mg/emtricitabine 200 mg: 1 PO qd with food
Triumeq (DTG/ABC/3TC)	Dolutegravir 50 mg/abacavir 600 mg/lamivudine 300 mg: 1 PO qd
INSTI plus One NRTI	
Dovato (DTG/3TC)	Dolutegravir 50 mg/lamivudine 300 mg: 1 PO qd
INSTI plus One NNRTI	
Juluca (DTG/RPV)	Dolutegravir 50 mg/rilpivirine 25 mg: 1 PO qd with food
Boosted PI plus Two NRTIs	
Symtuza (DRV/c/TAF/FTC)	Darunavir 800 mg/cobicistat 150 mg/tenofovir AF 10 mg/emtricitabine 200 mg: 1 PO qd with food
NNRTI plus Two NRTIs	
Atripla (EFV/TDF/FTC)	Efavirenz 600 mg/tenofovir DF 300 mg/emtricitabine 200 mg: 1 PO QHS on an empty stomach
Complera (RPV/TDF/FTC)	Rilpivirine 25 mg/tenofovir DF 300 mg/emtricitabine 200 mg: 1 PO qd with food
Delstrigo (DOR/TDF/3TC)	Doravirine 100 mg/tenofovir DF 300 mg/lamivudine 300 mg: 1 PO qd
Odefsey (RPV/TAF/FTC)	Rilpivirine 25 mg/tenofovir AF 25 mg/emtricitabine 200 mg: 1 PO qd with food
Symfi (EFV/TDF/3TC)	Efavirenz 600 mg/tenofovir DF 300 mg/lamivudine 300 mg: 1 PO QHS on an empty stomach
Symfi Lo (EFV/TDF/3TC)	Efavirenz 400 mg/tenofovir DF 300 mg/lamivudine 300 mg: 1 PO QHS on an empty stomach

Abbreviations: AF = alafenamide; DF = disoproxil fumarate; INSTI = integrase strand transfer inhibitors, NRTI = nucleoside reverse transcriptase inhibitor, NNRTI = non-nucleoside reverse transcriptase inhibitor, PI = protease inhibitor.

TABLE 98.6 **FIXED-DOSE COMBINATIONS**

Trade name (abbreviations)	**Components**	**Dosing**
Two NRTIs		
Cimduo (TDF/3TC)	Tenofovir DF 300 mg/lamivudine 300 mg	1 PO QD
Combivir (ZDV/3TC)	Zidovudine 300 mg/lamivudine 150 mg	1 PO BID
Descovy (TAF/FTC)	Tenofovir AF 25 mg/emtricitabine 200 mg	1 PO QD
Epzicom (ABC/3TC)	Abacavir 600 mg/lamivudine 300 mg	1 PO QD
Temixys (TDF/3TC)	Tenofovir DF 300 mg/lamivudine 300 mg	1 PO QD
Truvada (TDF/FTC)	Tenofovir DF 300 mg/emtricitabine 200 mg	1 PO QD
Protease inhibitor/booster		
Evotaz (ATV/c)	Atazanavir 300 mg/cobicistat 150 mg	1 PO QD with food
Prezcobix (DRV/c)	Darunavir 800 mg/cobicistat 150 mg	1 PO QD with food

Abbreviations: AF = alafenamide; DF = disoproxil fumarate; INSTI = integrase strand transfer inhibitors, NRTI = nucleoside reverse transcriptase inhibitor, NNRTI = non-nucleoside reverse transcriptase inhibitor, PI = protease inhibitor.

regimens may also be considered. For individuals receiving ABC-containing regimens, such as DTG/ABC/3TC, simplifying to DTG/3TC or DTG/RPV or switching to a tenofovir-based NRTI backbone may be appropriate. Certain antiretrovirals have also been associated with dyslipidemia, including EFV, EVG/c, and boosted PIs. TDF has been associated with lower lipid levels than TAF or ABC. BIC, DTG, RAL, DOR, and RPV are considered lipid neutral.

Renal disease

TDF and ATV have been associated with an increased risk for kidney toxicity. In individuals with chronic kidney disease (CrCl <60 mL/min), ABC- and TAF-based regimens are considered safer for use than TDF. TAF has been approved for use in patients with a CrCl of ≥15 mL/min and has been studied in a small population of patients on hemodialysis; however, its use has not been studied in those with a CrCl of <15 mL/min who are not yet on HD. NRTI-sparing regimens, such as DTG/3TC or DTG/RPV (only in stable switch) may also be considered. DTG, BIC, RPV, and cobicistat may artificially increase serum creatinine without reducing GFR. An increase of up to 0.4 mg/dL can be expected.

Osteoporosis

People living with HIV are at increased risk for low bone mineral density and bone fractures. Certain ARVs, including TDF, have been associated with progressive decline in bone mineral density, urinary phosphate wasting, and resultant osteomalacia. TAF and ABC have lesser impact on BMD than TDF and are preferred in postmenopausal women or those at high risk for osteoporosis. An NRTI-sparing regimen (DTG/3TC or DTG/RPV) could also be an optimal choice in this scenario.

Psychiatric illnesses

Certain regimens have been associated with adverse psychiatric effects and even suicidality, mainly EFV-based regimens and less frequently RPV-based regimens. INSTI-based regimens have also been implicated in causing mild to moderate adverse neuropsychiatric events, including insomnia and sleep disorders in retrospective cohort studies and case series. Certain ARVs, such as boosted PIs, EVG/c, and EFV, may increase or decrease levels of medications utilized for psychiatric illnesses. An appropriate assessment of potential for drug–drug interactions should be performed prior to initiation or discontinuation of any ARVs.

ART selection in pregnancy

All pregnant women with HIV should initiate on ART as soon as possible, regardless of their CD4 count or HIV viral load, both for their own health and to prevent maternal-to-child transmission of virus. To minimize risk of transmission, antiretrovirals should be given to women both prior to and following delivery, and they should be given to the neonate postnatally. Resistance testing should be sent prior to initiating therapy in pregnant women, but therapy should then be initiated *before results are available* because earlier viral suppression has been associated with lower risk of transmission to the fetus. Choice of treatment initiation regimen remains an area of active research. In general, recommendations for the use of ART in pregnant women are the same as those who are not pregnant; however, in some instances, recommendations have been modified based on concerns about drugs or due to limited experience with newer agents in pregnancy.

While a detailed discussion of antiretroviral choice during pregnancy is beyond the scope of this chapter, a few preferred regimens will be noted. Importantly, the DHHS panel recommends that women who are already on fully suppressive ART regimens when pregnancy occurs *should continue on those regimens* unless there are specific concerns about safety or inferior efficacy during pregnancy. If initiating therapy in a pregnant woman, the DHHS recommends a few preferred regimens based on currently available safety and pharmacokinetic data. All regimens pair a dual-NRTI backbone

with either an integrase inhibitor (DTG or RAL) or boosted PI (ATV/r or DRV/r).

For NRTI backbones, TDF is preferred over TAF due to limited available data on TAF use in pregnancy, and TDF/FTC and TDF/3TC are recommended equally, with a recommendation for caution in patients with renal insufficiency. ABC/3TC is also recommended as a preferred NRTI backbone combination in patients who are HLA-B*5701 negative and who do not have an HIV viral load of >100,000 if used in combination with EFV or ATV/r.

Preferred options for a third agent to be given in combination with a dual-NRTI backbone include INSTIs or a boosted PI. For INSTIs, DTG and RAL are recommended as preferred regimens, with the important caveat that the use of DTG at conception and in very early pregnancy has been associated with a small but potential increase in the risk of neural tube defects. Therefore, in patients planning pregnancy, DTG use should be discussed with the patient to ensure informed decision-making. Of note, RAL must be given as twice-daily dosing. Regarding other INSTIs, BIC does not have data on use in pregnancy and is therefore not recommended as a preferred agent, and EVG/c have only limited data, but these include a concern about inadequate drug levels of both EVG and cobicistat in the second and third trimesters, thus limiting usage in pregnancy. If considering a boosted PI during pregnancy (again, with a dual-NRTI backbone), either ATV/r or DRV/r are recommended during pregnancy based on extensive experience. DRV/r must be used twice daily in pregnancy due to inadequate levels with once-daily dosing, particularly during the third trimester.

Alternative regimens to consider in pregnancy include ZDV/3TC as an alternative dual-NRTI backbone, and LPV/r, EFV, or RPV in combination with a preferred dual-NRTI backbone as alternative third agents. Drugs with insufficient data in pregnancy and therefore not preferred include BIC, DOR, IBA, and TAF. The use of cobicistat is not recommended due to inadequate serum levels in the second and third trimesters. Finally, agents not recommended for initial ART in pregnancy include ETR, MVC, NVP, and T-20. Furthermore, these agents are also not recommended for treatment-experienced women in pregnancy except in special circumstances.

ART selection in patients with multidrug-resistant HIV

In contrast to treatment-naïve patients, management of patients with MDR HIV is complex. MDR-HIV can be seen in patients who have failed two or more standard ART regimens and rarely can be seen in newly diagnosed patients who acquired a resistant strain of virus. Treatment in these settings often require a nonstandard regimen. Ideally, three active agents should be selected based on resistance testing, and potency of the drugs is considered an important factor in determining the best regimen. In general, PIs and second-generation integrase inhibitors (dolutegravir and bictegravir) have the highest barriers to resistance and are useful as backbones when selecting a regimen.

Understanding a patient's full resistance history often requires review of prior resistance testing and/or sending a new resistance test. A number of different resistance tests exist; they fall into two broad categories—genotyping and phenotyping. *Genotypes* are obtained by amplifying and sequencing circulating HIV RNA and looking for mutations known to be associated with resistance (e.g., the M184V mutation associated with the reverse transcriptase genome is associated with lamivudine and emtricitabine resistance). An HIV-1 genotype can be obtained for NRTI, NNRTI, PI, and INSTI resistance. Separate testing may be required for INSTIs, and also for entry inhibitors. In patients with an undetectable HIV viral load, a *genotype archive* can be obtained as genotypic and phenotypic testing is not possible since there is no circulating HIV RNA to amplify. The genotype archive test amplifies cellular-associated integrated viral DNA in infected CD4-positive cells to look for known resistance mutations. This test can provide useful information in patients who are virologically suppressed on complex regimens who want to simplify their pill burden or who are having side effects to their current regimen. *Phenotypic tests* report viral growth in the presence of drug exposure. This test is more costly and takes significantly longer to result, but may be useful particularly in cases of complex resistance patterns in which the interaction of multiple mutations may be difficult to predict purely through interpretation of genotyping.

Individual regimens should be tailored to the unique resistance pattern seen in the patient. Clinicians should perform a careful review of all known resistance testing because older resistance tests may reveal archived resistance that may not be present on most recent testing due to low circulating levels. Clinicians should also review treatment history because clinical failure on an agent also raises concern for underlying resistance even if a resistance test was not obtained at the time. Once a composite of the patient's known resistance mutations can be constructed, the clinician should look at remaining active agents and try to construct a regimen that prioritizes durability and simplicity and which minimizes drug–drug interactions.

A number of studies have looked at salvage regimens for patients on failing regimens or those with complex resistance. These have been instructive in determining some best practices. Second-generation NNRTIs can sometimes can be used. The TRIO study followed patients with complex resistance history (virologic failure with three or more primary PI and NRTI mutations and three or fewer darunavir and NNRTI mutations) and demonstrated that a regimen of etravirine, raltegravir, and darunavir (dosed 600 mg BID) in these patients maintained durable viral suppression of 86% at 48 weeks. This regimen is now rarely used, however, largely because of the significant pill burden. Similarly to etravirine, doravirine, another second-generation NNRTI, has been shown to have efficacy even in the presence of mutations that affect other NNRTI agents.

In general, PIs have a high genetic barrier to resistance and therefore are often still active in patients with baseline resistance. Darunavir has the strongest evidence for usage in a salvage regimen, even in highly treatment-experienced patients. The POWER 1 and 2 studies compared provider-chosen regimens versus a regimen

with darunavir/ritonavir (dosed BID) in extensively treatment-experienced patients and demonstrated significantly better virologic suppression with darunavir/ritonavir. As mentioned previously, in patients with no known major darunavir mutations (I50V, I54M, L76V, and I84V), once-daily dosing is preferred but if known major resistance mutations are present, twice-daily dosing has demonstrated superiority.

A number of studies have looked at integrase inhibitors as well for patients with treatment resistance. Raltegravir and elvitegravir were studied, including raltegravir in the previously mentioned TRIO study and elvitegravir in the GSK 119 study, and demonstrated excellent outcomes even in patients with multiple NRTI and NNRTI mutations when treated with the combination EVG/c/TAF/FTC plus darunavir 800 mg once daily. This two-tablet once-daily regimen greatly simplified pill burden for many patients but was limited by the study parameters that specified no major darunavir mutations and no baseline integrase mutations. With the rollout of second-generation INSTIs (dolutegravir and bictegravir), construction of regimens for resistant virus has largely shifted to use of these agents. The SAILING trial demonstrated superiority of dolutegravir over raltegravir for highly treatment-resistance patients. The VIKING trials demonstrated sustained activity of dolutegravir even in the presence of multiple INSTI resistance mutations, with dolutegravir dosing increased to twice-daily. Evidence is emerging with bictegravir as well.

For highly treatment-resistant patients, use of alternative agents such as maraviroc, enfuvirtide, ibalizumab, or fostemsavir, should be considered.

Important resources exist to help clinicians create composite resistance profiles and understand predicted drug activity. The IAS-USA publishes a helpful and freely available online resource and "pocket card" detailing known resistance mutations (https://www.iasusa.org/resources/hiv-drug-resistance-mutations/), and the Stanford University HIV Drug Resistance Database allows clinicians to input composite resistance mutations on a simple online form to generate predictions of drug susceptibility (https://hivdb.stanford.edu).

Laboratory testing

A new diagnosis of HIV should be confirmed with laboratory testing. In general, in the United States, clinical laboratories are using fourth-generation enzyme-linked immunosorbent assay (ELISA) tests for HIV screening. These tests detect antibodies to both HIV-1 and HIV-2, as well as the p24 antigen, an early antigen in HIV infection. Fourth-generation testing is generally positive within 14 to 30 days from infection, and 99% would be positive at 44 days after infection. Confirmation testing is achieved through use of a different assay for HIV-1 or HIV-2 antibodies. For patients with a positive screening test but negative confirmatory antibody testing, HIV-1 polymerase chain reaction (PCR) testing is performed to capture patients who may be in the "window" period of antigen positivity before antibody formation.

For newly diagnosed patients with HIV, initial laboratory testing should include a CD4 cell count and HIV viral load to establish baseline values. In addition, patients should undergo resistance testing to assess for acquisition of resistant virus; approximately 15% of treatment-naïve patients will have acquired a virus with preexisting drug resistance. Baseline laboratory testing including a CBC and differential, basic metabolic panel (BMP), liver function testing (LFT: ALT, AST, total bilirubin), urinalysis, and a random or fasting lipid profile is important. Testing for coinfections is also recommended, including hepatitis B (hepatitis B core and surface antibody testing and hepatitis B surface antigen testing), hepatitis C, and tuberculosis (purified protein derivative [PPD] or interferon-γ release assays [IGRA]). Patients should also undergo testing for sexually transmitted infections, including syphilis antibody testing, and testing for gonorrhea and chlamydia at all potentially exposed sites (typically oral and rectal swabs and a urine sample for PCR testing); women should also have trichomonas testing. HLA B*5701 testing should be tested in any patients who will be initiating on abacavir-based regimens.

In patients with very low CD4 counts (generally <100) at treatment initiation, additional laboratory testing should be considered, including toxoplasma immunoglobulin G (IgG) testing and cytomegalovirus (CMV) IgG testing to assess for prior infection and to gauge risk of reactivation. G6PD enzyme assay testing should be considered in patients who require prophylaxis against *Pneumocystis*, particularly in those with a known sulfa allergy. In patients with CD4 counts of <50, consideration should be given to workup of occult opportunistic infections; this often includes checking mycobacterial blood cultures (for *Mycobacterium avium* complex and other nontuberculous mycobacteria), CMV viral load and an ophthalmologic exam to rule out CMV retinitis, and cryptococcal antigen testing in patients who live or have had travel to endemic areas.

All patients should be treated with antiretrovirals as soon as they are ready, and, in many cases, treatment may be initiated even prior to return of all laboratory testing through rapid-start protocols. Once patients initiate medications, repeat laboratory testing should be performed at 2 to 8 weeks after treatment initiation to ensure viral response and monitor for potential toxicities. This testing includes an HIV viral load, BMP, and LFTs. Once patients are stable on therapy, repeat laboratory testing should be performed every 3 to 6 months, again monitoring HIV viral load, BMP, and LFTs. Annual lipid testing and CBC with differential testing is recommended for all patients; yearly urinalysis is additionally recommended in patients on tenofovir therapy. CD4 monitoring recommendations have changed over the years and generally are more limited in nature once immune recovery is observed and as long as viral load suppression is maintained. Generally, patients should have a CD4 cell count checked at treatment initiation, then every 3 to 6 months for the first 2 years of therapy as long as the CD4 count remains <300. After 2 years of therapy, CD4 monitoring can be performed annually for patients with a CD4 count between 300 and 500, and is considered optional in patients with a CD4 count >500 as long as the HIV viral load remains suppressed.

It is not uncommon for patients with a low CD4 nadir to have a more muted immunologic response to therapy, and patients who initiate therapy at a CD4 count of <200 often do not recover a CD4 count of >500 even after years of therapy. There is no known benefit to changing ART in these patients and generally no

clinical consequence to a lower CD4 count in otherwise virologically suppressed patients.

With the advent of more sensitive testing for HIV viral loads, "blipping" has become a more common phenomenon. "Blips" are temporary increases in viral loads from undetectable to 50 to 1,000 copies/mL. Blips do not represent virologic failure and patients should generally be continued on their current regimen without changes. Blips should prompt a discussion with the patient about medication adherence, drug–drug interactions, and taking medications properly with or without food as indicated. The viral load should be repeated in 2 to 4 weeks to ensure that the blip has resolved and the patient is not progressing to virologic failure.

Virologic failure represents sustained elevation in viral load. This can occur in patients initiated on therapy who fail to suppress 24 to 48 weeks after treatment initiation, or in patients who were previously virologically suppressed and develop a persistent viremia. In the setting of virologic failure, patients should undergo resistance testing to determine if a new regimen should be initiated, and they should be assessed for and counseled on barriers to medication adherence.

Postexposure prophylaxis

Healthcare personnel, persons who inject drugs (PWID), victims of sexual assault, and those who engage in unprotected sex are at risk for HIV exposure. After initial exposure, HIV remains localized within dendritic cells of the skin and mucosa before systemic spread and development of chronic infection. Post-exposure prophylaxis (PEP) is the immediate administration of ART to an exposed individual to prevent systemic HIV infection.

PEP is characterized further into nonoccupational exposure prophylaxis (nPEP) and occupational exposure prophylaxis (oPEP). Nonoccupational exposure to HIV occurs most frequently through sexual contact without barrier protection, sexual assault, or intravenous drug use. Occupational exposure to HIV occurs through parenteral exposure, via percutaneous injury from a needle stick or sharp object, or direct contamination of mucous membranes or nonintact skin with potentially infectious sources. Sources that should be considered potentially infectious in the healthcare setting include blood, tissue, semen, vaginal secretions, cerebrospinal fluid, synovial fluid, peritoneal fluid, pericardial fluid, and amniotic fluid. Saliva, sputum, sweat, tears, urine, feces, and vomitus are not considered infectious unless visibly bloody.

The estimated risk of HIV transmission is influenced by several factors, including the route of transmission, the inoculum of infectious virus, the viral load of the source patient, and the exposed individual's immunologic response. Estimated risk of transmission is 0.3% and 0.09% for parenteral and membrane exposures, respectively. Nonintact skin exposure is estimated to be even lower. Occupational HIV transmission has been associated with deep injuries, visible blood on the device, procedures involving inoculation into a vein or artery, and exposure to fluids from a source patient with terminal illness, likely reflective of the risk for transmission in the setting of a high viral load. For sexual exposures, highest per-act transmission risk occurs with receptive anal intercourse (0.5–3.38%) due to a higher density of lymphoid follicles in rectal mucosa and a higher potential for abrasions when compared to vaginal mucosa.

Guidelines for nPEP and oPEP were most recently updated in 2016 and 2013, respectively. As prospective RCTs have not been conducted, recommendations are based on efficacy studies in animal models, observational studies, epidemiologic studies, and expert consensus.

First-line regimens for PEP consist of triple-drug ART with tenofovir disoproxil fumarate and emtricitabine as the dual NRTI backbone in combination with twice-daily raltegravir or once-daily dolutegravir. Due to the potential risk for neural tube defects in the first trimester with dolutegravir therapy, raltegravir is currently the preferred INSTI early in pregnancy and in nonpregnant women of childbearing potential who are sexually active or who have been sexually assaulted and are not using effective birth control. Preferred and alternative regimens for PEP are listed in Box 98.3. For those with a CrCl of ≤59 mL/min, the alternative NRTI backbone, zidovudine in combination with lamivudine, should be prescribed and renally dosed as appropriate. Two-drug regimens are no longer recommended for PEP. Additionally, the use of nevirapine for PEP is contraindicated due to the risk of hepatotoxicity.

When therapy is indicated, PEP should be initiated as soon as possible and within 72 hours of exposure. Animal models demonstrate that prevention of HIV acquisition decreases substantially from 100% to 50% to 25% for therapy initiation at 24, 48, and 72 hours post-exposure, respectively. If the HIV status of the source patient is positive or unknown, therapy should be continued for a total of 28 days post exposure. In animal studies, all animals receiving PEP for 28 days remained uninfected; half of animals treated for 10 days remained uninfected; and no animals receiving 3 days were protected.

BOX 98.3

Combined recommendations for non-occupational and occupational post-exposure prophylaxis (PEP)

Preferred regimens
RAL or DTG + TDF/FTC
Alternative Regimens, INSTI-Based
EVG/c/TDF/FTC
RAL or DTG + AZT/3TC
Alternative Regimens, PI-Based
DRV/r + TDF/FTC or AZT/3TC
ATV/r +TDF/FTC or AZT/3TC
LPV/r + TDF/FTC or AZT/3TC
Alternative Regimens, NNRTI-Based
RPV + TDF/FTC or AZT/3TC

Abbreviations: INSTI = integrase strand transfer inhibitor; NNRTI = non-nucleoside reverse transcriptase inhibitor; PI = protease inhibitor.

HIV testing of the source patient should be conducted, if possible, and once consent is obtained. If the HIV status of the source patient is negative, PEP can be safely discontinued. HIV testing of the exposed individual should occur at baseline, 4 to 6 weeks, 3 months, and 4 to 6 months after exposure. Additional laboratory testing of the exposed individual should include screening for bacterial sexually transmitted infections, pregnancy, and hepatitis B virus and hepatitis C virus infection, if indicated. Follow-up should occur within 72 hours of exposure to provide additional counseling; ensure continued PEP is indicated; assess adherence, access, and tolerability; and manage side effects. Minimal laboratory testing to evaluate the safety of PEP includes serum creatinine and hepatic function tests at baseline and upon completion of therapy.

For individuals who report behaviors or situations that may result in an ongoing risk for HIV acquisition, risk reduction counseling and intervention services should be performed. If indicated, pre-exposure prophylaxis (PrEP) should be considered at the conclusion of their 28-day PEP course. PWID should be offered medication-assisted treatment, if appropriate, and counseled on safe injecting and sexual practices, including referral to syringe exchange programs where available.

Pre-exposure prophylaxis

PrEP is the administration of antiretrovirals to an HIV-negative patient who is at high risk for acquiring HIV infection. A number of trials have demonstrated efficacy in prevention of HIV acquisition in patients taking PrEP. Effective prevention of HIV transmission has been demonstrated in men who have sex with men (MSM) in the iPrEX study, serodiscordant couples in the PartnersPrEP study, heterosexual individuals (both men and women) in the TDF2 study, and PWID in the Bangkok Tenofovir study. Studies of single-drug TDF, the oral combination of TDF/FTC, and the oral combination of TAF/FTC have shown efficacy. In the United States, Truvada (TDF/FTC) and Descovy (TAF/FTC) are the only agents currently FDA-approved for use for PrEP. TDF/FTC is approved for all higher risk individuals; TAF/FTC is approved for MSM and transgender women who have sex with men (this was the population studied in the DISCOVER trial that demonstrated noninferiority of TAF/FTC to TDF/FTC as PrEP). In general, patient compliance in PrEP trials was not ideal; however, patients who adhered to their medication appeared to significantly reduce their risk of infection.

Concerns do exist with PrEP, especially in those patients who might still become infected with HIV despite taking PrEP. PrEP is not a full three-drug ART treatment regimen and therefore viral resistance may develop to the PrEP drugs should infection occur. A negative HIV status must be confirmed prior to PrEP initiation, and patients should undergo HIV testing frequently throughout therapy as a new positive result should prompt immediate full three-drug ART therapy. Patients who are unwilling or unable to undergo frequent monitoring may pose a risk to themselves (potential for development of a resistant HIV virus) and to the community (potential to transmit a resistant HIV infection).

Other considerations must be made prior to starting PrEP as well. A patient's hepatitis B status should be assessed, as should their baseline renal function. Willingness of patients to undergo interval lab testing should be evaluated (including both HIV testing, test of renal function, and testing for other sexually transmitted infections). Women taking PrEP who may become or recently became pregnant should have risks and benefits to the fetus clearly discussed. Ideally, uninfected women taking PrEP who become pregnant should abstain from further high-risk sexual contact to fully minimize their risk of contracting HIV during their pregnancy. Since tenofovir is a primary medication in this regimen, renal function should be monitored at baseline and periodically.

Immune reconstitution inflammatory syndrome

Patients with HIV who are initiated on ART at a low baseline CD4 count (usually <100 cells/mm^3) may be at risk for IRIS. In this patient population, hosts may be unable to mount an appropriate immune inflammatory defense response, and OIs may exist in the absence of significant symptoms. As the immune system is restored with ART treatment, these subclinical infections can stimulate an aggressive inflammatory reaction. This reaction usually involves infected organ systems and is generally more common and profound in patients with disseminated OIs and high titers of pathogen. Autoimmune IRIS reactions that are unrelated to a known OI have also been described.

IRIS is a clinical diagnosis that may be difficult to discern from a true new infection or drug reaction. IRIS is broadly divided into two types, *paradoxical IRIS* describes a paradoxical worsening of a treated, known OI, while *unmasking IRIS* describes the unmasking of a previously subclinical untreated infection. Both forms of IRIS are commonly seen and can co-occur (i.e., patients can have multiple OIs present, with a clinical worsening of known disease and the unmasking of a second OI). Diagnosis of IRIS involves workup for potential undiagnosed disease and treatment of any diagnosed diseases. Once IRIS is considered the most likely possibility, nonsteroidal anti-inflammatory drugs or corticosteroid medications may be considered depending on severity.

Though initiation of ART in a patient with a known OI may increase the risk of IRIS, studies have demonstrated that, in most cases, IRIS can be managed and a mortality benefit exists to starting ART promptly (generally within 2 weeks of initiating treatment of the OI). Exceptions to this "treat early" approach are cryptococcal meningitis and tuberculous meningitis. For patients with cryptococcal meningitis, trials in low- and moderate-income countries have demonstrated a mortality benefit to delayed ART initiation after 5 weeks of therapy. For tuberculous meningitis, one trial demonstrated an increase in grade 4 adverse events with early ART initiation. Aside from these specific diagnoses however, the evidence strongly supports prompt initiation of ART within 2 weeks of initiating treatment of an OI.

Immune reconstitution inflammatory syndrome

Suzaan Marais and Graeme Meintjes

Introduction

In the majority of patients with advanced HIV disease, treatment with antiretroviral therapy (ART) results in a decreased HIV viral load, increased CD4 count, improved immunologic function, and subsequently, reduced opportunistic infections (OIs) and mortality. During the early stages of immune recovery on ART, a subset of patients may experience clinical deterioration due to the immune reconstitution inflammatory syndrome (IRIS); this can be as high as 25% of patients in cohorts with advanced immunosuppression at the start of ART. IRIS typically occurs during the initial 3 months of ART (when there is rapid reversal of the immunosuppressed state) as the result of a dysregulated immune response directed at infective or, less commonly, noninfective antigens. The majority of IRIS cases are associated with mycobacterial, fungal, or viral infections. However, IRIS may also be associated with other diseases (Table 99.1). Selected significant IRIS manifestations are discussed in further sections. Cutaneous IRIS manifestations are common and are highlighted in Table 99.1.

Two forms of infective IRIS are recognized: (1) paradoxical IRIS (p-IRIS), in which an OI is diagnosed and treated appropriately prior to starting ART with the subsequent development of recurrent, worsening, or new symptoms and signs after starting ART; and (2) unmasking IRIS (u-IRIS), in which a previously present but clinically undetected and therefore untreated OI becomes apparent after starting ART, typically with an unusually exaggerated inflammatory presentation (Figure 99.1). In both scenarios the spectrum of IRIS manifestations vary considerably; these may be localized or involve multiple organ systems, and systemic inflammatory signs may be prominent. IRIS may be mild and self-limiting, lasting days to weeks, or infrequently persist for years. In a small proportion of cases IRIS may be life-threatening or fatal, particularly in forms that involve the central nervous system (CNS) and those that result in airway compromise, organ failure, or organ rupture (Table 99.2). Risk factors associated with IRIS include a low CD4 count (particularly <50 cells/mm^3), high HIV viral load (particularly >5 $\log_{10}$), high pathogen load related to the OI, a rapid decline in HIV viral load and/or rise in CD4 count on ART, and short interval between initiation of OI treatment and ART. As no confirmatory tests exist, the diagnosis of p-IRIS relies on identifying the characteristic sequence of clinical events and exclusion of other possible causes for clinical deterioration, such as drug reaction or toxicity, failure of treatment for the OI (due to poor adherence, drug malabsorption, or antimicrobial drug resistance), or an alternative/additional infection or malignancy. U-IRIS is diagnosed using standard diagnostic tests for the underlying infection.

General principles in infective IRIS prevention and management

Prior to starting ART, thorough screening for OIs and, when diagnosed, initiation of appropriate treatment will prevent some cases of u-IRIS. A short interval between OI treatment and ART initiation is a strong risk

TABLE 99.2 CAUSES AND MANIFESTATIONS OF IMMUNE RECONSTITUTION INFLAMMATORY SYNDROME (IRIS) REPORTED THAT ARE POTENTIALLY LIFE-THREATENING

Causes	Manifestations
Neurologic manifestations	
Tuberculosis	Meningitis, intracerebral space-occupying lesions, spinal epidural abscess
Nontuberculous mycobacteria	Meningoencephalitis, brain abscess
JC virus	Progressive multifocal leukoencephalopathy
Cytomegalovirus	Encephalitis, vasculitis, ventriculitis
Herpes simplex virus	Encephalitis
Herpes zoster virus	Meningoencephalitis, vasculitis
Candida	Meningitis, vasculitis
Parvovirus B19	Encephalitis
BK virus	Meningoencephalitis
Toxoplasma	Encephalitis
Autoimmune reaction	Demyelinating central nervous system disease, cerebral vasculitis, Guillain–Barré syndrome
HIV itself the target of IRIS	Encephalitis
Cryptococcus	Meningitis, intracerebral space-occupying lesions, cerebellitis
Coccidioides	Meningitis
Extraneural manifestations	
Kaposi's sarcoma	Pneumonitis, airway and gastrointestinal tract involvement
Tuberculosis	Splenic rupture, bowel perforation, airway compression by lymph nodes, pericardial effusion, and acute renal failure
Nontuberculous mycobacteria	Airway compression by lymph nodes, alveolitis
Hepatitis B and C virus	Fulminant liver failure, progression of liver cirrhosis
Bacille Calmette–Guérin	Disseminated disease
Pneumocystis	Pneumonitis

factor for p-IRIS. However, delaying ART comes at the cost of remaining vulnerable to HIV disease progression, additional OIs, and mortality, particularly in severely immunosuppressed patients. The optimal time for starting ART depends on the underlying OI and will be discussed in relevant upcoming sections.

A key component of management is optimal therapy of the OI. Anti-inflammatory therapy should be considered to alleviate symptoms and reduce inflammation particularly in more severe cases. Nonsteroidal anti-inflammatory drugs (NSAIDs) may provide symptomatic relief in patients with mild IRIS manifestations. Corticosteroids are the most frequently used anti-inflammatory drugs in cases of IRIS related to mycobacterial and fungal infections, particularly in severe cases, and are the only treatment modality for which supportive clinical trial data exist. However, corticosteroids should generally only be considered when the diagnosis of IRIS has been made with certainty, having excluded alternative causes for clinical deterioration. Corticosteroids should normally not be used in patients with Kaposi's sarcoma (KS) as they may worsen this condition. There are isolated case reports of clinical response when other immunomodulatory drugs such as thalidomide and adalimumab were used to treat IRIS, but such approaches remain experimental. ART should not be interrupted in IRIS cases as this may increase vulnerability to other OIs and predispose to ART drug resistance. IRIS may also recur after ART reinitiation. ART interruption may be considered, however, as a last resort for patients with life-threatening IRIS, particularly those nonresponsive to corticosteroid therapy.

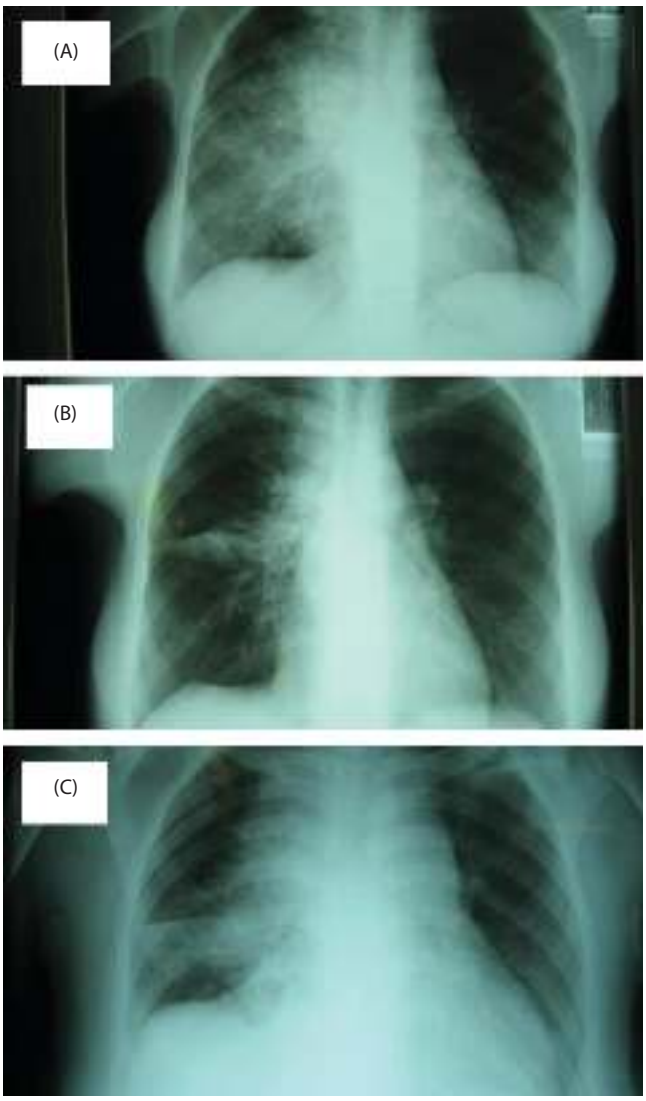

FIGURE 99.2 Chest radiograph sequence in a patient with paradoxical tuberculosis-immune reconstitution inflammatory syndrome (TB-IRIS): (A) at time of TB diagnosis, (B) improvement on TB treatment prior to antiretroviral therapy (ART), (C) worsening of pulmonary infiltrate and mediastinal lymph node enlargement at the time of IRIS presentation.

Pathogen-specific IRIS manifestations

Tuberculosis

Tuberculosis (TB)-IRIS is the most frequent form of IRIS in countries where TB/HIV coinfection rates are high. P-TB-IRIS occurs in 8% to 54% of patients who start ART while on TB treatment, typically 1 to 3 weeks, but up to 3 months, after starting ART. Presenting features relate to inflammation at previously recognized and/or new TB disease sites. Common symptoms and signs include fever, cough, tachycardia, lymphadenitis, pulmonary infiltrates (Figure 99.2), serous effusions, and tender hepatomegaly. Other manifestations include abscesses and osteitis. Neurologic TB-IRIS occurs in a substantial proportion of p-TB-IRIS cases (12% in one series) and presents as meningitis (Figure 99.3), intracranial tuberculomata, radiculomyelitis, spinal epidural abscesses, or brain abscesses. Although p-TB-IRIS is usually a self-limiting condition with an attributable mortality of 2%, neurologic forms are frequently fatal. The average symptom duration for p-TB-IRIS is 2 to 3 months, but in a minority TB-IRIS it is prolonged, lasting for months to years. Of particular importance in making the diagnosis is the exclusion of drug-resistant TB, which may present indistinguishably from p-TB-IRIS associated with drug-susceptible TB. Superficial and fluctuant lymph nodes can be aspirated and large deep collections, such as psoas abscesses, may be drained under ultrasound guidance to provide symptomatic relief and to obtain a specimen to rule out drug-resistant TB. The use of anti-inflammatory drug treatment depends on disease severity. Corticosteroid treatment (at a starting dose of 1–2 mg/kg/d of prednisone, or its equivalent, for 2–4 weeks and thereafter tapered based on individual clinical response) is indicated for life-threatening forms and may provide symptomatic relief for other cases with significant symptoms. The only randomized controlled trial (RCT) to assess treatment for any form of IRIS compared prednisone with placebo for the treatment of p-TB-IRIS, excluding patients with immediately life-threatening TB-IRIS. Patients in the prednisone arm received 1.5 mg/kg/d for 2 weeks followed by 0.75 mg/kg/d for a further 2 weeks. Prednisone was associated with a significant reduction in number of days hospitalized and also resulted in more rapid symptom and radiologic improvement.

FIGURE 99.3 CT brain findings in a patient who developed tuberculosis (TB) meningitis-immune reconstitution inflammatory syndrome (IRIS). Post-contrast imaging shows marked basal meningeal enhancement (*red arrow*) and multiple ring-enhancing lesions (*red and black arrow*) at IRIS presentation.

Evidence from three RCTs suggests that the optimal time to start ART in severely immunosuppressed TB patients (CD4 <50 cells/mm^3) is 2 to 4 weeks after TB treatment initiation. Starting ART at this time point (compared with 8–12 weeks) was associated with a survival benefit in one trial and a reduction in AIDS progression and mortality as a combined end point in the others, even though earlier ART increased the incidence of TB-IRIS two- to fivefold. Thus ART cannot be deferred for IRIS prevention in patients with very low CD4 counts. However, in such patients there is evidence for a strategy to prevent TBV-IRIS: an RCT demonstrated that in patients with HIV-associated TB and CD4 counts of ≤100 cells/mm^3, a 4-week course of prednisone (40 mg/d for 2 weeks followed by 20 mg/d for 2 weeks) reduced the incidence of TB-IRIS by 30% and was well tolerated. TB meningitis (TBM) patients are at higher risk of developing life-threatening neurologic TB-IRIS, and early ART was associated with more severe adverse events in an RCT of ART timing in TBM patients. Hence certain guidelines recommend deferring ART until 4 to 6 weeks after TB treatment initiation in TBM patients.

U-TB-IRIS is diagnosed in patients who present with unusually inflammatory or accelerated features of TB during the first 3 months of ART. Examples include unmasking pulmonary TB-IRIS presenting with rapid onset of respiratory symptoms and respiratory distress mimicking bacterial pneumonia, and suppurative lymphadenitis. A high index of suspicion for TB should be maintained in TB-endemic settings in all patients who present with clinical deterioration after starting ART. When diagnosed, standard TB treatment should be initiated.

Cryptococcosis

Cryptococcal IRIS most commonly presents with meningitis. Paradoxical cryptococcal meningitis (p-CM)-IRIS occurs in up to 30% of CM patients who commence ART, although it has been reported less frequently in recent cohorts. Other CNS manifestations include intracranial cryptococcomas or abscesses, cerebellitis, and spinal cord abscesses. Extra-CNS manifestations such as fever, lymphadenitis, soft tissue and skin lesions, cavitating or nodular pulmonary disease, and chorioretinitis have also been described. The majority of cases present 1 to 2 months after ART initiation, although a minority may present after more than a year on ART. P-CM-IRIS is associated with raised intracranial pressure (ICP) in up to 75% of cases and an increased inflammatory response with higher protein and white cell concentrations in cerebrospinal fluid (CSF) when compared to those from the pre-ART CM event. Diagnostic workup for p-CM-IRIS is directed at excluding other neuroinflammatory etiologies and cryptococcal relapse as causes for deterioration by CSF analysis. A cryptococcal relapse is indicated by a positive cryptococcal CSF culture after >3 months of antifungal therapy or an increase in quantitative culture from pre-ART culture. Amphotericin B plus flucytosine (where available) or fluconazole (induction phase doses of 800 mg/d) should be restarted pending fungal culture results in patients with severe deterioration. If the CSF is sterile, maintenance doses of fluconazole may be resumed. Intensive management of raised ICP with daily lumbar puncture, when required, is critical in the management of p-CM-IRIS. Although no clinical trial data exist, prednisone (1 mg/kg/d, or equivalent, tapered over 2–6 weeks) should be considered in patients with ongoing symptoms or life-threatening neurologic impairment, but ideally only after cryptococcal relapse has been excluded.

Starting ART early (within 1–2 weeks from CM diagnosis versus 4–5 weeks) is associated with increased mortality in CM patients, and ART should be deferred until 4 to 6 weeks of antifungal treatment have been received.

Unmasking cryptococcal IRIS presents during the initial months of ART with manifestations such as meningitis with a particularly high CSF white cell count (for example >50 cells × 10^6/L) or a raised opening pressure refractory to treatment, suppurative lymphadenitis, rapidly expanding CNS lesions (cryptococcomas), and cavitating or necrotic pneumonitis. A clear distinction between CM cases first diagnosed after ART that are related to immune reconstitution and those that are related to persistent immunosuppression may be difficult; therefore, these two groups are collectively referred to as "ART-associated CM." In resource-limited settings, currently, at least a third of all new CM cases are diagnosed in patients on ART. An important preventative strategy for ART-associated CM in high-burden settings involves screening patients with CD4 counts of <100 or <200 cells/mm^3 for subclinical cryptococcal infection prior to ART using blood cryptococcal antigen test. A positive test is highly predictive of subsequent ART-associated CM, and such patients should have meningitis excluded. If meningitis is excluded on CSF analysis they should be treated preemptively with fluconazole at a starting dose of 800 or 1,200 mg/d.

JC virus

Reactivation of the JC virus results in progressive multifocal leukoencephalopathy (PML), a demyelinating disease of the brain, usually diagnosed in patients with CD4 counts of <100 cells/mm^3. Both u-PML-IRIS and p-PML-IRIS are described, and both are associated with significant mortality. The majority of cases present within 3 months of ART initiation, but u-PML-IRIS may develop after >6 months on ART. Clinical deterioration during PML-IRIS is usually acute and may be transient, unlike the course of PML in patients not on ART. In >50% of PML-IRIS cases there is gadolinium enhancement on MRI, which is not observed outside the context of IRIS. The diagnosis cannot rely on detecting JC virus from CSF by polymerase chain reaction (PCR) as partial containment of viral replication by the recovering immune system can result in false-negative results, which is found in approximately 40% of PML cases receiving ART compared to approximately 5% of ART-naïve PML cases. Brain biopsy may be required to exclude other causes for deterioration (e.g., lymphoma). The treatment of PML-IRIS is particularly difficult as there is limited evidence regarding effective antiviral therapy for JC virus. Interruption of ART for 2 to 3 weeks has been associated with favorable outcome in isolated cases, but this is associated with risks, and PML-IRIS may recur when ART is resumed. The role of corticosteroids is controversial, given that there is no specific treatment for the underlying JC virus infection, but may be indicated in patients with severe neurologic deterioration and those with edema on brain imaging.

Cytomegalovirus

Cytomegalovirus (CMV)-IRIS usually presents with eye involvement. This can manifest as a first episode of retinitis after starting ART. More commonly though, CMV-IRIS presents as immune recovery uveitis (IRU), which usually occurs in patients diagnosed with CMV retinitis prior to ART who subsequently experience an increase in CD4 count on ART. IRU can also be unmasked by ART. Rarely, CMV-IRIS may affect other organs such as the colon, esophagus, or brain. The cumulative incidence of p-CMV-IRU is 38%, and patients with the greatest retinal involvement (>30% of the retinal surface) during the pre-ART retinitis episode are at highest risk for IRU. CMV-IRU is distinguished clinically from typical CMV retinitis by the abundance of intraocular inflammatory cells and inactive CMV retinitis in the former. The spectrum of IRU inflammation ranges from asymptomatic vitreitis to persistent uveitis with cystoid macular edema (CME) and epiretinal membrane formation. Worsening retinitis due to active CMV infection and persistent visual symptoms due to vitreous debris relating to previous CMV retinitis as well as new OIs should be considered in the differential diagnosis. The treatment of CMV-IRU varies according to disease severity. Cases with mild CME and visual acuity more than 20/30 can be observed without treatment. In more severe cases, periorbital or intravitreal corticosteroid injections usually result in decreased inflammation, but these treatments are not always associated with improved vision.

Hepatitis B and C viruses

ART initiation is frequently complicated by liver enzyme elevation (LEE). Patients coinfected with hepatitis B (HBV) or hepatitis C virus (HCV) are at increased risk because they are predisposed to drug-induced liver injury but also because of enhanced immune responses directed at the hepatitis virus. Hepatitis-IRIS is poorly defined, but significant LEE (rise of alanine aminotransferase [ALT] >5 × upper limit of normal, or >3 × of baseline if abnormal prior to ART), particularly within 3 months of starting ART, should prompt consideration of the diagnosis. Rarely, hepatitis-IRIS has been associated with severe hepatic dysfunction resulting in fulminant hepatic failure or life-threatening progression of cirrhosis. The diagnosis of hepatitis-IRIS is challenging as the most important differential diagnosis is drug-induced liver injury. Risk factors for hepatic flares on ART in HBV coinfection include high HBV DNA and ALT levels before ART. There are no evidence-based guidelines for managing hepatitis-IRIS. It has been suggested that HBV or HCV should be treated prior to ART initiation to minimize the risk of hepatitis-IRIS in high-risk cases (e.g., those with underlying liver cirrhosis). A pragmatic approach to a patient with chronic viral hepatitis with significant LEE on ART includes the following: (1) stop hepatotoxic non-ART drugs; (2) exclude alternative causes, as far as possible; (3) alter ART (if necessary) to exclude drugs with the highest risk for hepatotoxicity (especially nevirapine) and maintain patients coinfected with HBV on an effective ART regimen that contains two drugs also active against HBV (e.g., tenofovir and either lamivudine or emtricitabine); (4) monitor liver function tests and clinical status closely and consider liver biopsy if no improvement; and (5) interrupt ART if hepatic failure occurs and restart once liver enzymes are normalizing. In HBV coinfected patients, preferably two HBV active drugs should be continued during ART interruption to prevent viral rebound. None of the HIV drugs is effective against HCV, and treatment with anti-HCV therapy should be considered during ART interruption in affected patients. Corticosteroids and other immunosuppressive drugs should be avoided in hepatitis-IRIS as they may result in increased viral replication and hepatic deterioration.

Kaposi's sarcoma

KS is caused by the KS-associated herpesvirus (KSHV) and is the most common malignancy in HIV-infected persons. Although starting ART is associated with the resolution or improvement of KS lesions in most patients, p-KS-IRIS occurs in approximately 14% of patients with KS at a median time of 7 weeks on ART. U-KS-IRIS has also been reported. KS-IRIS cases present with new lesions or inflammation or enlargement of existing skin lesions. Lymphedema and oral, gastrointestinal, airway, and lung involvement are other manifestations. KS-IRIS is frequently fatal in settings with limited access to chemotherapy, with mortality of 48% reported for p-KS-IRIS in an African cohort. Pre-ART risk factors for p-KS-IRIS include more extensive KS disease, high plasma HIV-1 viral load (>5 $\log_{10}$), detectable plasma KSHV DNA, and not receiving KS treatment (chemotherapy). P-KS-IRIS might be prevented by administering chemotherapy, particularly in severe cases, prior to

ART. Treatment of KS-IRIS similarly includes systemic chemotherapy and/or localized radiotherapy. Corticosteroids may result in rapid progression of existing or new KS lesions and are therefore not used for KS-IRIS.

IRIS unrelated to HIV infection

IRIS is best described in the context of ART treatment of HIV infection, but it is also recognized in persons recovering from other causes of immune suppression, such as patients who interrupt immune suppressive drugs (e.g., tumor necrosis factor [TNF] inhibitors, natalizumab, and drugs used in solid organ/stem cell transplants). Further discussion is beyond the scope of this chapter, and the reader is referred to the review by Sun et al. (see Suggested reading).

IRIS pathogenesis

Central to the pathogenesis of most forms of ART-related IRIS is the rapid recovery of immune function in the presence of large amounts of infective antigen. Several components of the immune system have been implicated including activated antigen-specific CD4 and CD8 T lymphocytes, macrophages and monocytes, neutrophils, natural killer (NK) cells, and proinflammatory cytokines and chemokines. The hallmark of the tissue pathology associated with mycobacterial and fungal IRIS is granuloma formation, sometimes with suppuration. Viral forms of IRIS are characterized by CD8 T-cell infiltrates.

Conclusion

IRIS may complicate ART initiation in up to 25% of patients in cohorts starting ART with advanced immunosuppression. This is because the major determinant of IRIS is progression to advanced HIV disease that places individuals at risk of OIs. In resource-poor settings many patients still enter HIV care with advanced HIV and remain at risk for IRIS. Because there is no confirmatory test for IRIS, it is a clinical diagnosis and other causes of deterioration should be excluded before making the diagnosis of IRIS. In most cases ART is continued, treatment for the underlying infection should be optimized, and, for mycobacterial and fungal forms of IRIS, corticosteroids can be considered when symptoms are significant. There is RCT evidence to support the use of steroids for treatment and prevention of p-TB-IRIS, but in other forms of IRIS their use as treatment is based on anecdotal evidence of benefit.

Opportunistic infections in HIV

Anthony Ogedegbe and Marshall Glesby

Timely recognition and treatment of HIV-associated opportunistic infections (OIs) remains an important skill for practicing physicians worldwide. Whereas the overall incidence of these infections has fallen sharply since the advent of combination antiretroviral therapy (*aka* highly active antiretroviral therapy or HAART), OIs remain the most serious threat to well-being and survival among HIV-infected individuals with advanced immunosuppression. Despite improved access to screening globally, morbidity from OIs is often the first indication of previously undiagnosed HIV infection. Thus, familiarity of healthcare personnel with the presenting signs, symptoms, and treatment of OIs is key to improving HIV-related clinical outcomes at both the individual and community levels.

Fortunately, with most OIs, the likelihood of symptomatic disease correlates with CD4 count (Figure 100.1). Periodic CD4 measurements are, therefore, an integral part of OI surveillance, prevention and treatment. This chapter offers a clinical overview of the most frequently encountered OIs. Current concepts and approaches to management are also discussed.

Mucocutaneous infections

The largest threat to oral health in HIV-infected patients is oral candidiasis or "thrush." While not pathognomonic, the development of thrush in a young, otherwise healthy adult without known risk factors such as diabetes mellitus or recent antibiotic or inhaled steroid use should raise concern for undiagnosed HIV infection. Thrush typically presents as white, loosely adherent deposits on the dorsum of the tongue, but frequently extends posteriorly to involve the palate and oropharynx. Severe cases are associated with oral discomfort, dysgeusia, and nausea. Candidal angular cheilitis is also seen in HIV-infected patients but is rarer than thrush in this population. Clinically, it is indistinguishable from other causes of cheilitis, manifesting as painful, bleeding sores at the corners of the mouth. Treatment of both conditions consists of either oral or topical antifungal therapy (Table 100.1).

Seborrhea dermatitis is another common complication of HIV infection and presents as a greasy, flaky, and faintly erythematous rash with a predilection for the face. Areas rich in sebaceous glands—the hairline, eyebrows, nose, and nasolabial folds—are prime targets. The role of *Malassezia furfur* infection in pathogenesis remains uncertain. Topical antifungal and corticosteroid agents are used to treat this condition (Table 100.1).

Recurrent or multidermatomal cutaneous herpes zoster infections are sometimes the only outward indication of waning cell-mediated immunity in HIV-infected adults. Lancinating pain and paresthesias in the soon-to-be involved dermatome are followed days later by the sudden outcropping of vesicles on an erythematous base. Use of oral acyclovir or related agents (valacyclovir or famciclovir) within 72 hours improves symptoms, speeds up crusting, and may reduce the risk of postherpetic neuralgia (Table 100.1).

Painful, burning vesicular lesions in the perineum or perirectal region are most often due to herpes simplex virus (HSV) reactivation. Mucocutaneous HSV infections are more frequent at CD4 counts of ≤500

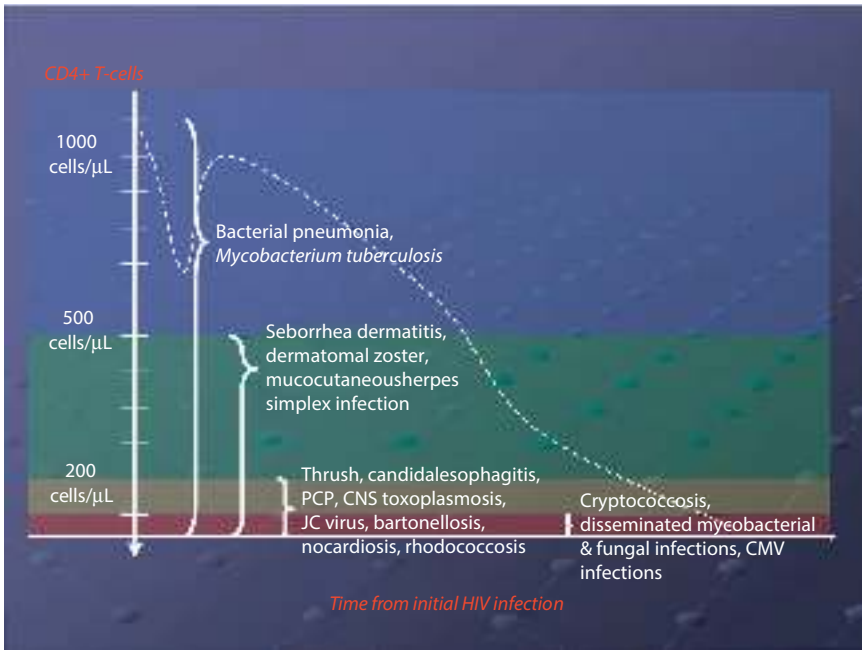

FIGURE 100.1 Spectrum of opportunistic infections in untreated HIV infection and the CD4 T-cell count ranges in which they manifest. CMV, cytomegalovirus; CNS, central nervous system; PCP, *Pneumocystis jirovecii* pneumonia.

cells/mm^3. Oral acyclovir, valacyclovir, and famciclovir are all effective in reducing the severity and duration of symptoms. They are also effective prophylactically (Table 100.1).

Skin lesions due to molluscum contagiosum, like the aforementioned OIs, also tend to be more frequent and severe in HIV-infected individuals. Molluscum contagiosum is caused by a poxvirus that causes characteristically firm, umbilicated, and sometimes pedunculated skin lesions (Figure 100.2). Intertriginous areas of the body, namely the axillae, perineum, antecubital, and popliteal fossae, are preferentially involved. Transmission requires intimate physical contact with an infected person. No specific chemotherapy exists; however, effective ART can hasten lesion regression. Alternatively, lesions can be removed by cryotherapy, curettage, or laser cautery (Table 100.1).

Oral hairy leukoplakia, caused by Epstein–Barr virus infection of lingual squamous epithelium, manifests as painless, white, tightly adherent, vertical ridges on the lateral aspect of the tongue. Lesions can be subtle so close inspection of the entire surface of the tongue and sublingual mucosa is warranted. Robust immune recovery through HAART is the most effective treatment for this condition (Table 100.1).

Pulmonary infections

Globally, *Mycobacterium tuberculosis* and *Pneumocystis jirovecii* remain the two most frequently identified causes of pneumonia in HIV-infected patients. They are also major causes of both morbidity and mortality in this population. Thus, the initial evaluation and management of lower respiratory tract infections in HIV-positive persons rests on the following principles: (1) prompt administration of empiric antibiotics against community- or hospital-acquired pneumonia pathogens, (2) immediate respiratory isolation of individuals presenting with either symptoms or chest imaging findings concerning for pulmonary tuberculosis (MTB), and (3) early administration of empiric treatments for *P. jirovecii* pneumonia (PJP) in individuals presenting with evidence of advanced HIV disease *plus* either acute respiratory failure and/or radiographic findings suspicious for PJP (discussed later).

The evaluation of pneumonia in HIV-infected individuals with low CD4 counts often requires CT scans of the chest in addition to chest x-rays (CXR). This is particularly true in cases where CXR findings—coupled with clinical inferences drawn from the history, physical exam, laboratory findings, and most recent CD4 count—do not comport with one specific cause of pneumonia. Given the myriad of possibilities in patients with AIDS (Table 100.2), cross-sectional imaging can be used to refine the initial differential diagnosis pending results of more definitive microbiologic and histopathologic tests.

Pneumocystis jirovecii pneumonia

Low-grade fever, dry cough, and progressive dyspnea are the cardinal symptoms of PJP. Risk factors include CD4 counts of ≤200 cells/mm^3, CD4 percentage of ≤14, prior PJP, or thrush at the time of presentation. Radiographically, PJP usually presents as symmetric, perihilar, interstitial, or alveolar infiltrates (Figure 100.3). However, excluding PJP purely on the basis of CXR findings can be risky. For example, follow-up CTs sometimes uncover classic PJP findings where prior CXRs had either been clear or suggestive of a bacterial process. Furthermore, a number of "atypical" radiographic

TABLE 100.1 **MANAGEMENT OF MUCOCUTANEOUS OPPORTUNISTIC INFECTIONS**

Condition/pathogen	First-line treatment	Notes
Thrush or candidal angular cheilitis	Fluconazole, 100 mg PO qd for 7–14 days	Alternative therapies include: Clotrimazole troches, 10 mg PO 5 × daily; nystatin solution, swish and swallow QID; or. In the event of azole resistance: amphotericin B suspension, 100 mg/mL PO QID; amphotericin B deoxycholate, 0.3–0.7 mg/kg IV qd; liposomal or lipid complex amphotericin, 3–5 mg/kg; voriconazole, 200 mg PO qd; or caspofungin 50 mg IV qd for 7–14 days.
Seborrhea dermatitis	Face: imidazole cream (ketoconazole 2% or clotrimazole 1%) plus hydrocortisone 1.0%–2.5% or desonide 0.05% cream BID Scalp/body: antidandruff shampoo (e.g., Selsun Blue or Head and Shoulders) plus triamcinolone 0.1% cream (body) or solution (scalp)	Severe cases may require addition of oral ketoconazole, 200–400 mg qd for 2–4 weeks.
Varicella-zoster virus	Acyclovir, 800 mg PO 5 × daily; famciclovir, 500 mg PO TID; or valacyclovir, 1000 mg PO TID for 7–10 days	(1) Trigeminal or disseminated cutaneous zoster; attendant meningoencephalitis; or evidence of visceral involvement (i.e., elevated transaminases and/or pancreatic enzymes) all merit IV acyclovir, 10 mg/kg q8h, until clinical resolution (minimum 14–21 days). (2) In the event of acyclovir resistance: foscarnet, 40–60 mg/kg IV q8h, or cidofovir plus IV hydration and oral probenecid to mitigate renal toxicity.
Herpes simplex virus	Acyclovir, 400 mg PO TID; famciclovir, 500 mg PO BID; or valacyclovir, 1000 mg PO BID for 7–14 days	In the event of acyclovir resistance: foscarnet, 40–60 mg/kg IV q8h, or cidofovir plus IV hydration and oral probenecid to mitigate renal toxicity.
Molluscum contagiosum	Laser, cryotherapy, and curettage plus HAART	
Oral hairy leukoplakia (OHL)	HAART	(1) OHL is pathognomonic of underlying HIV infection. (2) Rarely warrants specific therapy; but oral acyclovir 800 mg PO 5 × daily and podophyllin have been used with variable success in severe cases.

Abbreviations: PO = orally; QID = four times per day; qd = every day; BID = twice per day; TID = three times per day; HAART = highly active antiretroviral treatment; IV = intravenously.

findings—including cystic, apical, nodular, and cavitary infiltrates—have also been described in cytologically proven cases of PJP.

In managing suspected cases of PJP, it is imperative that prompt initiation of therapy always take precedence over making a definitive cytological diagnosis. Delays in PJP-specific therapy are the biggest threat to survival once the patient has sought medical care. And, contrary to notions held by some clinicians, treatment does not significantly reduce the yield of stainable pneumocystis organisms detectable in respiratory secretions within the first few days of therapy.

Intravenous (IV) trimethoprim-sulfamethoxazole (TMP-SMX) is the first-line agent for treating *severe* PJP (Table 100.3). In patients with sulfa allergies, IV pentamidine should be used instead. Pentamidine-related toxicities (e.g. acute pancreatitis, hypoglycemia, and renal failure) are, however, common and should be aggressively sought when using this drug. Adjunctive steroids have been shown to improve survival in individuals presenting with a PaO_2 of ≤70 mm Hg or alveolar–arterial (A-a) gradients of >35 mm Hg. Nonetheless, overall mortality rates, even in the post-HAART era, approach 30% and remain as high as 60% to 80% in ventilated patients.

In *mild to moderate* PJP, double-strength *oral* TMP–SMX is the drug of choice. Other effective oral regimens are available for individuals with sulfa allergies, including clindamycin plus primaquine, dapsone plus trimethoprim, and atovaquone (Table 100.3).

A definitive diagnosis of PJP is achieved with the identification of pneumocystis organisms in either sputum, bronchoalveolar lavage, or lung biopsy specimens. A variety of stains are commercially available, of which direct fluorescent antibodies to *P. jirovecii* organisms are the most sensitive and specific. Pneumocystis-specific polymerase chain reaction (PCR) of bronchoalveolar lavage fluid is also used for diagnosis, though it may not be able to distinguish between colonization and infection. Notably, in cases where the clinical index of suspicion for PJP as the sole cause of symptoms and radiological findings is high, elevated serum (1-3)-β-d-glucan levels may obviate the need for bronchoscopy or lung biopsy.

FIGURE 100.2 Molluscum contagiosum. Numerous flesh-colored umbilicated papules appeared on the face of a 33-year-old man with a 3 -year history of AIDS and a CD4 cell count of 60 cells/μL. Prominent lesions along the margin of the eyelids prevented him from closing his eyes completely.

FIGURE 100.3 Pneumocystis jirovecii pneumonia (PJP). Bilateral interstitial infiltrates on chest x-ray in a 39-year-old woman with AIDS and CD4 count of 33 cells/mm^3.

TABLE 100.2 **ETIOLOGIC CORRELATES OF RADIOLOGIC FINDINGS IN HIV-INFECTED PATIENTS WITH PNEUMONIA**

Chest x-ray or computed tomography findings	Common pathogens
(1) Focal/lobar asymmetric consolidation *without* intrathoracic lymphadenopathy	*Streptococcus pneumoniae, Moraxella catarrhalis, Haemophilus influenzae; Mycobacterium tuberculosis* in individuals with primary infection or CD4 counts >350 cells/mm^3.
(2) Diffuse interstitial or alveolar infiltrates *without* intrathoracic lymphadenopathy	*Pneumocystis jirovecii*, respiratory viruses (e.g., influenza virus and respiratory syncytial virus), *Mycoplasma pneumoniae.*
(3) Reticulonodular and/or cavitating nodular infiltrates *without* intrathoracic lymphadenopathy (*acute presentations*)	*Mycoplasma pneumoniae, Staphylococcus aureus*, *Klebsiella pneumoniae, Pseudomonas aeruginosa.*
(4) Reticulonodular and/or cavitating nodular infiltrates *plus* intrathoracic lymphadenopathy (*indolent presentations*)	*Mycobacterium tuberculosis, Nocardia asteroides, Aspergillus fumigatus*, *Rhodococcus equi, pulmonary Kaposi's Sarcoma (due to Human herpesvirus 8).*

Clinical improvement in severe cases of PJP is typically protracted and can take as long as a week. Only patients failing to show improvement beyond this time period are deemed treatment failures. We advocate the following approach to such cases: (1) starting adjunctive corticosteroid therapy in situations where the initial PaO_2 or A-a gradient had suggested otherwise, (2) switching to *IV* TMP-SMX (or IV pentamidine in patients allergic to sulfa) if either *oral* TMP-SMX or a second-line agent had been used initially, and/or (3) repeating bronchoscopy to obtain additional bronchoalveolar lavage samples (as well as transbronchial lung tissue specimens if not previously obtained). These can then be used to identify pathogens that may have been missed during the initial round of testing.

Mycobacterial infections

Unlike PCP, the risk of active *Mycobacterium tuberculosis* (MTB) infection in HIV-infected individuals is high even at normal CD4 counts. However, lower lobe, noncavitary, and extrapulmonary disease are more frequent at CD4 counts of ≤350 cells/mm^3. Chemotherapy recommendations are identical to seronegative patients with pulmonary MTB except clinicians have to be mindful of higher rates of treatment failure and drug resistance in HIV-positive patients. Furthermore, dose adjustments of HAART and/or anti-tuberculous agents are frequently necessary to avoid adverse drug interactions in patients being treated for both infections concurrently (Table 100.3).

The leading nontuberculous mycobacterial pulmonary pathogen in HIV-positive patients is *Mycobacterium avium* complex (MAC). Such cases are distinct from *disseminated* MAC (discussed later) in which severe CD4 lymphopenia and mycobacteremia are the rule. In the post-HAART era, the majority of cases of pulmonary MAC manifest within weeks of initiating HAART, leading some to posit an immunologic mechanism. Combination therapy comprising clarithromycin or azithromycin, ethambutol, and rifabutin is the treatment regimen of choice (Table 100.3).

Rarer mycobacterial causes of pneumonia in HIV-infected patients are *Mycobacterium kansasii* and the so-called *rapid-grower*

TABLE 100.3 **MANAGEMENT OF PULMONARY OPPORTUNISTIC INFECTIONS**

Pathogen	First-line treatment	Notes
Pneumocystis jirovecii	Mild to moderate disease: TMP–SMX-DS, 2 tabs PO TID; dapsone, 100 mg PO qd, plus TMP, 5 mg/kg PO q8h; clindamycin, 450 mg PO or 600 mg IV q8h, plus primaquine, 15 mg qd; or atovaquone, 1500 mg qd for 21 d Severe disease: TMP–SMX, 15 mg/kg IV (TMP component) qd in 3–4 divided doses, or, in patients with sulfa allergy, pentamidine, 4 mg/kg IV qd, plus prednisone (40 mg BID × 5 d; 20 mg BID × 5 d; 20 mg qd × 11 d) for 21 d	(1) Caution must be taken with the use of primaquine or dapsone in patients at risk for G6PD deficiency because of the risk of hemolytic anemia. Such individuals should be tested for G6PD deficiency in anticipation of exposure to these drugs. (2) May discontinue *secondary* prophylaxis after CD4 >200 cells/mm^3 for >3 mo.
M. *tuberculosis*	Isoniazid, 5 mg/kg/d, plus rifampin, 600 mg PO qd, plus pyrazinamide, 15–30 mg/kg PO qd, plus ethambutol, 15–25 mg/kg/d as initial therapy	Clinically significant drug-drug interactions between rifampin and antiretroviral medications (e.g. protease and integrase inhibitors) have been reported and should be researched thoroughly prior to adding rifampin to any antiretroviral regimen. Rifabutin, 150–300 mg PO qd, may be used in lieu of rifampin in such cases.
M. *avium* complex	Clarithromycin, 500 mg PO BID, or azithromycin, 600 mg qd, plus ethambutol, 15–25 mg/kg/d, plus rifabutin, 300 mg PO qd for a minimum of 12 mo	In patients on efavirenz, azithromycin is preferred over clarithromycin as part of the 3-drug regimen because efavirenz lowers the serum levels of the latter.
M. *kansasii*	Isoniazid, 5 mg/kg/d, plus rifampin, 600 mg PO qd, plus ethambutol, 25 mg/kg/d (× 2 months then 15 mg/kg) for 15–18 mo	If patient is taking a protease inhibitor, replace rifampin with rifabutin, 150–300 mg PO qd, because rifampin significantly lowers serum levels of protease inhibitors.
M. *abscessus*	Amikacin plus either cefoxitin or imipenem plus macrolide for 4–8 wk, followed by macrolide plus second agent for 6–12 mo	Monitor for inducible macrolide resistance.
M. *fortuitum*	Amikacin or tobramycin plus 2 of cefoxitin or imipenem or levofloxacin for 2–6 wk followed by 2 oral agents for 12 mo	
Histoplasma capsulatum (pulmonary and non-CNS disseminated disease)	Mild-to-moderate disease: itraconazole, 200 mg PO TID for 3 d, followed by itraconazole, 200 mg BID for 12 wk Severe illness: amphotericin B deoxycholate, 0.7 mg/kg IV qd, or liposomal or lipid complex amphotericin, 3–5 mg/kg, until clinically improved followed by itraconazole, 200 mg q12h for 12 wk	
Coccidioides immitis (pulmonary and non-CNS disseminated disease)	Mild-to-moderate disease: fluconazole, 400–800 mg PO qd Severe illness: amphotericin B deoxycholate, 0.5–1.0 mg/kg IV qd, followed by fluconazole, 400–800 mg PO qd	Lifelong suppression with fluconazole, 400 mg PO qd, is recommended, even with CD4 >200 cells/mm^3 on HAART.
Blastomycosis dermatitidis (pulmonary and non-CNS disseminated disease)	Amphotericin B deoxycholate, 0.7–1.0 mg/kg IV qd, or liposomal amphotericin, 3–5 mg/kg, until clinically improved, followed by itraconazole, 200 mg for 12 wk	
Aspergillus fumigatus (pulmonary and non-CNS disseminated disease)	Voriconazole, 6 mg/kg IV × 1, followed by either 4 mg/kg IV or 100–200 mg PO BID for 2–3 wk; oral voriconazole for suppression	(1) Alternatives to voriconazole: amphotericin B deoxycholate; liposomal or lipid complex amphotericin 3–5 mg/kg; or caspofungin +/− voriconazole (2) Also note: when using voriconazole with efavirenz, voriconazole dose should be increased to 400 mg q12h and decrease the efavirenz to 300 mg QD.
Nocardia asteroides (pulmonary and non-CNS disseminated disease)	TMP-SMX (15 mg/kg/d TMP; 75 mg/kg/d SMX) × 3 wk followed by 10 mg/kg/d TMP component PO	In severe cases: add amikacin or imipenem or third-generation cephalosporin when limited by aminoglycoside toxicity.
Rhodococcus equi (pulmonary and *non-CNS* disseminated disease)	Erythromycin or imipenem, 0.5 g IV q6h, plus rifampin, 600 mg PO qd for 2 wk, followed by oral clarithromycin or azithromycin plus rifampin for suppression	Alternative agents: ciprofloxacin or linezolid.

Abbreviations: TMP–SMX = trimethroprim-sulfamethoxazole; DS = double strength; PO = orally; TID = three times a day; IV = intravenously; qd = every day; BID = twice a day; CNS = central nervous system; G6PD = glucose-6-phosphate dehydrogenase; HAART = highly active antiretroviral therapy.

mycobacteria; namely *M. abscessus, M. fortuitum*, and *M. chelonae*. *M. kansasii* lung infections often mimic pulmonary MTB clinically as well as radiographically (see Table 100.3 for treatment recommendations).

Endemic mycoses

Pulmonary coccidioidomycosis, histoplasmosis, and blastomycosis primarily affect individuals with CD4 counts of ≤250 cells/mm^3. Rates of infection are higher in endemic areas. In the case of coccidioidomycosis, this comprises the San Joaquin valley (i.e., central and southern parts of California), southern Arizona, southwestern New Mexico, and west Texas. Histoplasmosis and blastomycosis, on the other hand, are both endemic to the Ohio and Mississippi River basins. However, blastomycosis is also found in northwestern New York as well as in the south-central and southeastern regions of the United States.

Previous or current residence in these regions is the main risk factor for all of these infections. In patients with higher CD4 counts, focal alveolar or nodular/cavitary infiltrates with or without intrathoracic lymphadenopathy are the common radiographic finding. Diffuse reticulonodular infiltrates, indicative of hematogenous dissemination, are, however, more common in individuals with very advanced immunodeficiency (i.e., CD4 counts ≤100 cells/mm^3). Life-threatening infections require induction chemotherapy with amphotericin-B-based drugs followed by maintenance treatment with oral triazoles (Table 100.3).

Pulmonary aspergillosis

Severe CD4 lymphopenia is one of several risk factors associated with pulmonary aspergillosis; others include neutropenia, recent exposure to corticosteroids, and marijuana use. Two distinct clinical syndromes have been described: isolated tracheobronchitis and pneumonitis. Symptoms in both cases include fever, productive cough, chest pain, and hemoptysis. Wheezing is more indicative of tracheobronchial involvement. Bronchoscopy in such cases reveals airway-obstructing mycelia and mucous balls. However, airway invasion can also occur, resulting in the formation of pseudomembranes and ulcerations. Radiographically, a variety of patterns have been observed with parenchymal disease, including subpleural focal opacities, diffuse reticulonodular infiltrates, and cavitary apical lesions. Treatment comprises voriconazole and/or amphotericin B-based drugs (Table 100.3).

Filamentous bacteria

Pulmonary nocardiosis and rhodococcosis are rare complications of AIDS in the post-HAART era. *Nocardia* and *Rhodococcus* are gram-positive, weakly acid-fast, filamentous bacteria. Both are associated with indolent to subacute lower respiratory infections. Radiographic features include nodular/cavitary pulmonary infiltrates with or without abscess formation. Concurrent mediastinal lymphadenopathy is also common. Disseminated disease with a predilection for brain and skin lesions has been observed with these organisms. Unlike nocardia, where blood cultures rarely turn positive, the yield of standard blood cultures approaches 50% in rhodococcal infections. The diagnosis of pulmonary nocardiosis, on the other hand, typically requires detection of branching, filamentous, acid-fast organisms either in sputa, bronchoalveolar lavage, or lung biopsy specimens. Chemotherapy is protracted in both diseases, and relapse is common in the absence of durable immune recovery from HAART (Table 100.3).

Gastrointestinal infections

Infections of the esophagus

Candidal esophagitis is a very common AIDS-defining OI. It manifests at CD4 counts of ≤200 cells/mm^3 and presents primarily as dysphagia and/or odynophagia. These symptoms are sometimes accompanied by chest pain or fever. In rare instances esophageal perforation can occur, usually as a complication of delayed or inadequate treatment. Triazoles are the mainstay of therapy (Table 100.4). Azole resistance may occur, particularly with recurrent episodes and in patients with very advanced HIV disease. In such cases, amphotericin-B-based therapies or echinocandins are usually effective (Table 100.4).

Rarely, herpes simplex virus (HSV) or cytomegalovirus (CMV) may infect the esophagus, causing symptoms indistinguishable from those encountered with candidal disease. Patients with the former are, however, usually more immunodeficient (i.e., CD4 counts ≤100 cells/mm^3). In patients presenting with esophageal symptoms but without evidence of thrush, it is customary to institute empiric candidal treatment and only pursue alternate causes (through endoscopically guided biopsy) with treatment failures (Table 100.4).

Diarrheal illness

Patients on HAART, particularly protease inhibitor-containing regimens, often experience treatment-related diarrhea. However, protracted symptoms or evidence of intestinal inflammation or invasion (i.e., fever, hematochezia, or abdominal pain) mandates an infectious workup.

Common community-acquired enteric pathogens, such as norovirus, *Salmonella*, *Campylobacter*, *Shigella*, *Yersinia*, and *Giardia*, are the usual culprits in individuals with CD4 counts >200 cells/mm^3. Invasive salmonellosis, campylobacteriosis, and shigellosis are, however, more frequent relative to the general population. Consequently, antibiotic treatment for these infections, whereas discretionary in otherwise healthy, HIV-seronegative persons, is recommended when these infections occur in the context of HIV disease (Table 100.4).

Patients with CD4 counts of ≤100 cells/mm^3 may experience severe, protracted watery diarrhea as a result of *Cryptosporidium, Microsporidia, Cyclospora*, or *Isospora* intestinal infections. Although much less frequent in the post-HAART era, effective chemotherapeutic agents against these organisms (with the exception of *Isospora* and *Cyclospora*) are sorely lacking. Antispasmodics and immune reconstitution via HAART are the mainstays of management (Table 100.4).

Symptomatic gastrointestinal CMV infections present most often in the large bowel. CMV colitis typically occurs at CD4 counts of ≤100 cells/mm^3 and presents as fever, bloody diarrhea, and abdominal pain. Treatment comprises 2 to 3 weeks of induction

TABLE 100.4 **MANAGEMENT OF OPPORTUNISTIC INFECTIONS OF THE DIGESTIVE TRACT**

Condition/pathogen	First-line treatment	Notes
Candidal esophagitis	Fluconazole, 200–400 mg PO qd for 14–21 d	In the event of azole resistance: amphotericin B suspension, 100 mg/mL PO QID; amphotericin B deoxycholate, 0.3–0.7 mg/kg IV qd; liposomal or lipid complex amphotericin, 3–5 mg/kg; voriconazole, 200 mg PO BID; or caspofungin, 50 mg IV qd, micafungin 150 mg IV qd, or anidulafungin 100 mg IV x 1 then 50 mg IV qd for 14–21 d.
Herpes simplex esophagitis	Acyclovir, 5 mg/kg IV, followed by acyclovir, 400 mg PO TID; famciclovir, 500 mg PO BID; or valacyclovir, 1000 mg PO BID for 7–14 d once patient is tolerating oral therapy	In the event of acyclovir resistance: foscarnet, 40–60 mg/kg IV q8h, or cidofovir, IV plus IV hydration, and oral probenecid to mitigate renal toxicity.
Cytomegalovirus esophagitis	Ganciclovir, 5–6 mg/kg/d IV, or valganciclovir, 900 mg PO BID, once patient tolerating oral therapy, for 2–3 wk followed by half-dose valganciclovir for chronic suppression	In the event of ganciclovir resistance: foscarnet, 90 mg/kg IV q12h, or cidofovir, IV plus IV hydration, and oral probenecid to mitigate renal toxicity.
Salmonellosis	Ciprofloxacin, 500–750 mg BID, or levofloxacin, 500 mg qd for 7–14 d	(1) Relapse is common and may necessitate chronic suppression; therefore, treat for 4–6 weeks in patients with CD4 count ≤200 cells/mm^3 or bacteremia. (2) Fluoroquinolone resistance is increasing, in which case azithromycin should be used.
Shigellosis	Ciprofloxacin, 500 mg BID, or levofloxacin, 500 mg qd for 3 d	(1) Treat for up to 14 d in patients with CD4 count ≤200 cells/mm^3 or bacteremia. (2) Alternative agent: azithromycin.
Campylobacteriosis	Ciprofloxacin, 500 mg BID, or azithromycin, 500 mg qd for 3 d	(1) Treat for up to 14 d in patients with CD4 count ≤200 cells/mm^3 or bacteremia. (2) Fluoroquinolone resistance is increasing rapidly, particularly in Southeast Asia.
Cryptosporidiosis	HAART *plus* antispasmodic +/− nitazoxanide 500 mg PO q12h for 14 d	
Microsporidiosis	Albendazole, 400 mg q12h for 3 wk	The most common cause of diarrheal illness, *Enterocytozoon bieneusi*, is the least susceptible species to albendazole.
Cyclosporidiosis	TMP–SMX-DS q6h for 10 d then 1 tab 3×/wk	Alternative agent: ciprofloxacin.
Isosporosis	TMP–SMX-DS q6h for 10 d then 1 tab 3×/wk	Alternative agents: ciprofloxacin, pyrimethamine plus folinic acid.

Abbreviations: PO = orally; qd = every day; QID = four times a day; IV = intravenously; BID = twice a day; TID = three times a day; HAART = highly active antiretroviral therapy; TMP–SMX-DS = trimethoprim–sulfamethoxazole-double strength.

therapy with IV ganciclovir or oral valganciclovir with half the induction dose as maintenance therapy thereafter (Table 100.4).

HIV cholangiopathy

Some intestinal pathogens (primarily *Cryptosporidium parvum* but also *Microsporidia*, CMV, and *Cyclospora*) are also able to infect the biliary tract, giving rise to a syndrome known collectively as *HIV cholangiopathy*. Typically a complication of very advanced HIV disease (CD4 counts ≤100 cells/mm^3), HIV cholangiopathy presents as right upper quadrant discomfort (rarely accompanied by fever or jaundice) and serum alkaline phosphatase elevation. Endoscopic retrograde cholangiopancreatography (ERCP) findings include papillary stenosis, biliary stricture, and/or biliary obstruction. Symptoms, while usually refractory to antimicrobial therapy, are often relieved by biliary stenting and sphincterotomy. Ursodeoxycholic acid (300 mg orally TID) is effective for symptom relief in patients with lesions not amenable to endoscopic intervention.

Neurologic infections

Meningitis

Cryptococcus neoformans is the most commonly identified cause of meningitis among HIV-infected patients. *C. gattii* has been

implicated in the Pacific Northwest of the US, Australia, and subtropical regions and is managed the same way as *C. neoformans*. Patients present subacutely with headache, fever, and lethargy. Other manifestations of increasing intracranial pressure (the most feared complication of this disease) include nausea, emesis, blindness, obtundation, and coma. Delays in therapy can be fatal. Management is three-pronged: (1) prompt initiation of induction antifungal therapy with an amphotericin-B-based drug *plus* 5-flucytosine for 14 days (Table 100.5), (2) serial lumbar punctures to alleviate excess intracranial pressure. and (3) consolidation as well as maintenance therapy with oral fluconazole. Similar clinical presentations, including a propensity for elevated intracranial pressure, are seen with MTB, histoplasma, and coccidioides meningitis (see Table 100.5 for treatment recommendations).

Encephalitis

Progressive multifocal leukoencephalopathy (PML) is caused by reactivation of previously latent JC virus infection within the brain parenchyma. Although much less frequent in the post-HAART era, PML remains one of the most disheartening complications of advanced HIV disease (i.e., CD4 counts ≤200 cells/mm^3). No effective antiviral therapies have been identified for this highly debilitating and often lethal disorder. Immune recovery through HAART remains the only recourse. Patients present with nonenhancing, periventricular, subcortical white matter lesions devoid of mass effect or surrounding edema. Lesions are more likely to enhance in patients who develop symptoms in the context of HAART (i.e., as part of an immune recovery inflammatory syndrome [IRIS]). Symptoms in either case include progressive focal motor-sensory deficits; visual field cuts; cerebellar findings such as ataxia, dysmetria, and vertigo; and seizures.

CMV meningoencephalitis is a marker of very advanced HIV immunodeficiency (≤100 cells/mm^3). Rapid cognitive deterioration marked by fever and headache is the usual presentation. The classic, almost pathognomonic, finding on MRI is a symmetric, T2-bright ventriculitis with extension to the adjacent periventricular white matter. However, nonspecific white matter changes are more common. Progressive cognitive decline in the face of antiviral treatment is common. Combination therapy comprising IV ganciclovir and foscarnet may improve outcomes (Table 100.5).

Varicella-zoster virus (VZV) brain infections are typically observed at CD4 counts of ≤200 cells/mm^3. Several variants have been described including focal as well as diffuse meningoencephalitis, cerebritis, and CNS vasculitis. Patients present with fever, encephalopathy, and/or focal motor-sensory deficits that typically follow, but may also precede, a dermatomal zoster outbreak. Treatment comprises IV acyclovir for a minimum of 2 to 3 weeks (Table 100.5).

Brain abscess

The most common cause of space-occupying brain lesions in HIV-infected patients with CD4 counts of ≤200 cells/mm^3 is toxoplasmosis (Figure 100.4). Patients present with headache, fever, confusion, and sometimes seizure. CNS toxoplasmosis is rare in toxoplasma-seronegative patients. In cases where primary CNS lymphoma is deemed less likely (i.e., patients seropositive for toxoplasma with multiple ring-enhancing brain lesions on MRI), an empiric trial of toxoplasma antibiotics (Table 100.5) is instituted in lieu of brain biopsy. Individuals who fail to improve after 10 to 14 days of treatment are subjected to stereotactic brain biopsy for a definitive histopathologic diagnosis.

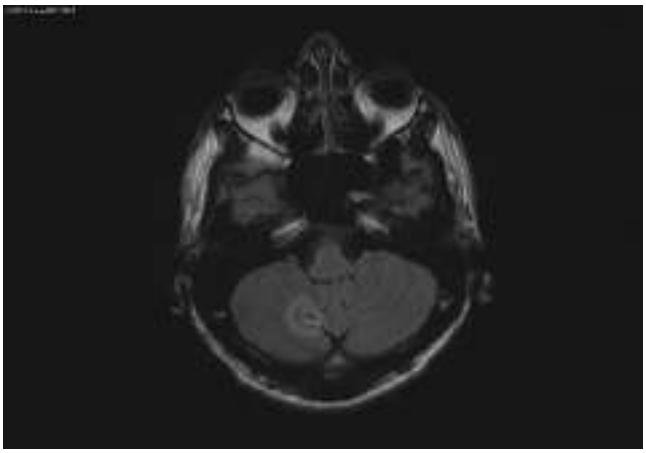

FIGURE 100.4 Cerebral toxoplasmosis. MRI reveals a 2.5 cm ring-enhancing lesion in the right cerebellar hemisphere.

Rarer causes of brain abscess in HIV-positive individuals include MTB, *Cryptococcus*, *Aspergillus*, the endemic mycoses, *Nocardia*, and *Rhodococcus* infections (see Table 100.5 for treatment recommendations). Concomitant pulmonary involvement, whereas rare with toxoplasmic brain infections, is a frequent finding with all these other pathogens.

Retinitis

CMV is the main infective threat to vision in patients with AIDS. Thus, acute blurry vision, photopsia, and/or scotomata in a patient with ≤100 cells/mm^3 merits emergent evaluation for CMV retinitis. Left untreated, symptoms quickly progress to blindness within days to weeks. Mechanisms for decreased visual acuity in CMV retinitis include retinal detachment (a consequence of large, peripheral lesions), involvement of the macula, and extension of lesions to the optic nerve. Funduscopically, CMV retinitis appears as multiple pale, yellow exudates against a red background. Retinal hemorrhages are also a common finding. Ganciclovir-impregnated retinal implants combined with oral valganciclovir is first-line therapy (Table 100.5).

VZV is a less common cause of acute retinal necrosis (ARN) in patients with HIV. Like CMV retinitis, permanent visual loss rapidly ensues if left untreated. Unlike the latter, however, VZV-related ARN can occur at any CD4 count. Progressive outer retinal necrosis (PORN), on the other hand, is a variant of VZV retinitis that targets individuals with very low CD4 counts, typically ≤100 cells/mm^3. (More recently, HSV and CMV have been implicated in isolated cases of PORN; however, VZV is generally thought to be the culprit in the majority of cases.) The lesions expand and coalesce in the periphery of the retina; thus, visual loss in VZV-related

TABLE 100.5 **MANAGEMENT OF NEUROLOGIC OPPORTUNISTIC INFECTIONS**

Pathogen/condition	First-line treatment	Notes
Cryptococcus neoformans	Amphotericin B, 0.7 mg/kg IV qd, plus 5-flucytosine (5-FC), 25 mg/kg q6h, or liposomal or lipid complex amphotericin, 4 mg/kg, plus 5-flucytosine, 25 mg/kg q6h for 2 wk, followed by 10 wk of fluconazole, 400 mg PO qd, followed by chronic suppression with fluconazole, 200 mg PO qd	Note: monitor 5-FC serum levels—peak and trough levels >80 mg/L and 40 mg/L, respectively, are associated with significant bone marrow toxicity.
M. *tuberculosis*	Isoniazid, 5 mg/kg/d, plus rifampin, 600 mg PO qd, plus pyrazinamide, 15–30 mg/kg PO qd, plus ethambutol 15–25 mg/kg/d for a minimum of 12 mo	Clinically significant drug-drug interactions between rifampin and antiretroviral medications (e.g. protease and integrase inhibitors) have been reported and should be researched thoroughly prior to adding rifampin to any antiretroviral regimen. Rifabutin, 150–300 mg PO qd, may be used in lieu of rifampin in such cases.
Histoplasma capsulatum meningoencephalitis	Amphotericin B deoxycholate, 0.7 mg/kg IV qd; liposomal or lipid complex amphotericin, 3–5 mg/kg, until clinically improved followed by itraconazole, 200 mg for 12–16 wk. Chronic suppression with 200 mg qd thereafter	Blood cultures, and even DuPont fungal isolators, are often negative in systemic histoplasma infections. However, a urinary histoplasma antigen-based test is >90% sensitive in patients with AIDS.
Coccidioides immitis meningoencephalitis	Fluconazole 400–800 mg IV or PO qd	Lifelong suppression with fluconazole, 400 mg PO qd, is recommended, even with CD4 >200 cells/mm^3 on HAART.
Blastomycosis dermatitidis meningoencephalitis	Amphotericin B deoxycholate, 0.7–1.0 mg/kg IV qd, or liposomal amphotericin, 3–5 mg/kg, until clinically improved, followed by itraconazole, 200 mg for 12 wk	
JC virus (progressive multifocal leukoencephalopathy)	HAART	
Varicella-zoster virus	Meningoencephalitis: acyclovir, 10 mg/kg IV for 14–21 d Acute retinal necrosis: intravenous acyclovir as above followed by chronic suppression with valacyclovir or famciclovir	In the event of acyclovir resistance: foscarnet 40–60 mg/kg IV q8h or cidofovir IV plus IV hydration and oral probenecid to mitigate renal toxicity.
Cytomegalovirus	Meningoencephalitis/polyradiculitis: ganciclovir, 5–6 mg/kg/d IV, or valganciclovir, 900 mg PO BID, +/− IV foscarnet, 90–120 mg/kg/d, until clinical improvement Retinitis: as above plus sustained-release ganciclovir intraocular implant q6–9 mo	(1) Lifelong chronic suppression with valganciclovir is recommended. (2) Under supervision of a qualified ophthalmologist, may discontinue maintenance therapy after maximal improvement and CD4 count has been >150 cells/mm^3 for >6 mo.
Toxoplasma gondii brain abscess	Pyrimethamine, 200 mg PO 1×, then 50–75 mg qd plus sulfadiazine, 1.0–1.5 g PO QID, plus folinic acid, 10–20 mg PO qd for 6 wk, followed by half-dose of all 3 drugs as chronic suppression	(1) Primary CNS lymphoma is the other leading cause of brain mass in this population but is more often unifocal, >4 cm, and distinguishable from cerebral toxoplasmosis on single-photon emission computed tomography and positron emission tomography. (2) In patients with sulfa allergy: replace sulfadiazine with clindamycin, dapsone, or atovaquone.
Aspergillus fumigatus	Voriconazole, 6 mg/kg IV 1×, followed by either 4 mg/kg IV or 100–200 mg PO BID for 2–3 wk; oral voriconazole for suppression	Less preferred agents: (1) amphotericin B deoxycholate; (2) liposomal or lipid complex amphotericin, 3–5 mg/kg; or (3) caspofungin +/− voriconazole.
Nocardia asteroides	TMP-SMX (15 mg/kg/d TMP; 75 mg/kg/d SMX) plus ceftriaxone, 2 g IV qd × 6 wk, followed by reduced doses of both drugs IV for 6–12 mo	In sulfa-allergic patients: substitute TMP–SMX with amikacin.
Rhodococcus equi	Erythromycin, 0.5 g IV q6h, plus imipenem, 0.5 g IV q6h, plus rifampin, 600 mg PO qd for 2 wk, followed by oral clarithromycin or azithromycin plus rifampin for suppression	Alternative agents: ciprofloxacin and linezolid.

TABLE 100.6 **MANAGEMENT OF DISSEMINATED INFECTIONS**

Pathogen/condition	First-line treatment	Notes
M. *avium* complex	Clarithromycin, 500 mg PO BID, or azithromycin, 600 mg qd, plus ethambutol, 15–25 mg/kg/d, plus rifampin, 600 mg PO qd, for a minimum of 12 mo	(1) In patients on efavirenz, azithromycin is preferred over clarithromycin as part of the 3-drug regimen; because efavirenz lowers drug levels of the latter. (2) If patient is taking a protease inhibitor, replace rifampin with rifabutin, 150–300 mg PO qd, because rifampin significantly lowers serum levels of protease inhibitors.
Histoplasma capsulatum	Mild to moderate disease: itraconazole, 200 mg PO TID for 3 d, followed by itraconazole, 200 mg BID for 12 wk Severe illness: amphotericin B deoxycholate, 0.7 mg/kg IV qd; amphotericin liposomal or lipid complex, 3–5 mg/kg, until clinically improved followed by itraconazole, 200 mg for 12 wk	
Talaromycosis	Amphotericin B deoxycholate, 0.6 mg/kg IV qd for 2 wk, followed by itraconazole, 200 mg q12h for 10 wk and then 100 mg PO q12h for suppression	
Bartonellosis	Erythromycin, 500 mg PO q6h for 12 wk minimum and until CD4 count >200 cells/mm^3	(1) Doxycycline with or without rifampin is preferred for CNS involvement. (2) Alternative agents for non-CNS disease: clarithromycin, 500 mg PO BID; azithromycin, 600 mg PO qd; or ciprofloxacin, 500 mg PO BID.

PORN occurs primarily as a result of retinal detachment. Treatment for VZV-related ARN consists of IV acyclovir for 2 to 3 weeks followed by oral valacyclovir (Table 100.5). VZV-related PORN, however, carries a worse prognosis primarily because it is more often refractory to antiviral therapy. One approach has been to administer ganciclovir and foscarnet intravenously along with intravitreal injections of ganciclovir and/or foscarnet.

Disseminated infections

Mycobacterium avium complex

Patients with disseminated MAC characteristically present with high, spiking fevers; progressive weight loss; and sometimes diarrhea. Elevated alkaline phosphatase levels (present in approximately 50% of cases) and enlarged para-aortic lymph nodes are also observed. Treatment consists of clarithromycin (or azithromycin), weight-based ethambutol, and rifabutin (Table 100.6).

Histoplasmosis

Disseminated histoplasmosis is a rare but potentially lethal complication of HIV infection. Presentations can either be indolent (i.e. manifesting as progressive fever, weight loss, and pancytopenia) or fulminant. The latter cases often manifest as an Addisonian crisis, a direct consequence of the propensity for histoplasma organisms to infiltrate and damage adrenal tissue. Treatment comprises amphotericin B-based chemotherapy followed by prolonged suppression with oral itraconazole (Table 100.6).

Talaromycosis *Talaromyces (formerly Penicillium) marneffei* is a dimorphic fungal pathogen that converts to a yeast at human body temperature. Disseminated talaromycosis is the third most common OI (after cryptococcal and MTB infection) in HIV-infected patients residing in Southeast Asia. Patients at highest risk have CD4 counts of ≤50 cells/mm^3. Usual symptoms include fever, weight loss, dry cough, lymphadenopathy, hepatosplenomegaly, and a rash similar to the umbilicated lesions of molluscum contagiosum. Serum alkaline phosphatase levels are often elevated. Blood cultures turn positive within 5 to 7 days of incubation. Treatment is similar to that of disseminated histoplasmosis (Table 100.6).

Bartonellosis

Patients present with fever, rash, and abdominal and/or bone pain. Risk factors include CD4 count of ≤200 cells/mm^3 and prior cat contact (*Bartonella henselae*) or human body louse infestation (*B. quintana*). Mucocutaneous manifestations, known as bacillary angiomatosis, are variable in appearance but classically present as enlarging violaceous plaques or nodules that mimic Kaposi's sarcoma. Bartonella osteomyelitis, a complication of *B. quintana* infection, is rare and involves the long bones and sometimes underlies cellulitic plaques.

B. henselae infections are uniquely associated with hepatosplenic peliosis which comprises cystic blood-filled, endothelium-lined spaces that appear as focal, hypodense lesions on CT (Figure 100.5). Application of Warthin–Starry stain to tissue specimens reveals pleomorphic microorganisms. In the absence of diagnostic tissue samples, confirmation of bartonellosis rests on culture and serology. Blood cultures and subsequent chocolate or heart infusion agar subcultures, however, have to be held for a minimum of 21 days.

FIGURE 100.5 *Bartonella henselae* hepatosplenic peliosis. CT of the abdomen with intravenous contrast reveals multiple low-density lesions with central septations and surrounding halos (*arrows*) in the liver and spleen. An image obtained slightly below the image shown in Panel A (Panel B) shows larger lesions as well as lymphadenopathy around the celiac axis (*arrows*). An image obtained below the image shown in Panel B (Panel C) shows additional lymphadenopathy in the peri-pancreatic and periportal regions (*arrow*).

Prophylaxis of opportunistic infections in HIV disease

Brandi Manning, Robert L. Bettiker, and Jeffrey M. Jacobson

Introduction

The AIDS epidemic presented as severe manifestations of various opportunistic infections (OIs) in hosts whose immune systems were compromised. Individuals with AIDS succumbed to pneumocystic pneumonia, toxoplasmosis, disseminated *Mycobacterium* infection, and several other OIs and malignancies. Now, with the availability of potent, well-tolerated, and convenient antiretroviral therapy (ART), HIV-positive persons can be largely unaffected by these OIs as long as they remain well-adherent to ART. Nevertheless, OIs remain a common presenting feature at the time of initial diagnosis. Barriers to care and medication adherence can also allow HIV to progress, leaving patients susceptible to OI. For these reasons and others, prophylaxis for OI in HIV positive patients remains an important topic and cornerstone of providing care for this patient population.

Prophylaxis is commonly divided into two categories: primary and secondary. Primary prophylaxis serves the purpose of hopefully preventing an initial infection from occurring. Secondary prophylaxis, on the other hand, is given to patients who have been treated for an OI and are now vulnerable to relapse, recurrence, or repeat infection. Whether it is primary or secondary, any chemical prophylaxis prescribed should have a clear clinical benefit to the patient with regards to reduced morbidity and mortality without significant risk of adverse events or cost. Prophylaxis should always be presented to patients as an option, keeping risk and benefit in mind for shared decision-making.

Pneumocystis

Primary prophylaxis

Prior to the initiation of ART and primary prophylaxis, the incidence of *Pneumocystis jirovecii* infection was as high as 70% to 80% in patients with AIDS but has since decreased to less than one case per 100 person-years in the United States and Western Europe. Primary prophylaxis should be initiated in all HIV patients with a CD4 count of <200 cells/mm^3 or CD4% below 14%. Prophylaxis can also be considered for those patients with a CD4 count up to 250 cells/mm^3 who cannot have frequent close monitoring of CD4 counts. The preferred regimen for prophylaxis is one trimethoprim-sulfamethoxazole (TMP-SMX) double-strength tablet daily. Alternate dosing options of a single-strength daily tablet or a double-strength tablet three times weekly are also acceptable if the preferred regimen is not tolerated due to sensitivity. TMP-SMX is the most efficacious choice and adds protection for *Toxoplasma* and other bacterial infections. Adverse effects of rash, hepatitis, hyperkalemia, gastrointestinal upset, and fever are not uncommon. Nevertheless, if adverse events occur, continuing this preferred regimen with symptomatic care and alternative dosing may be considered. If

TABLE 101.1 **PRIMARY PROPHYLAXIS AGAINST *PNEUMOCYSTIS JIROVECII***

Agent	Notes	Discontinuation
Trimethoprim-sulfamethoxazole (TMP-SMX)	Double-strength daily dosing is the preferred regimen	CD4 ≥200 cells/mm^3 for >3 months *or*
	Mild adverse effects are common and decreased dosing should be attempted if necessary	CD4 ≥100 cells/mm^3 *and* the viral load is suppressed for >3 months
Dapsone	Contraindicated in G6PD deficiency and severe sulfa allergy	
Atovaquone	Cost-prohibitive and liquid only	
Aerosolized pentamidine	Via Respirgard II only	

a life-threatening reaction occurs, such as toxic epidermal necrolysis, TMP-SMX should be permanently discontinued.

If an alternate agent cannot be avoided, options include dapsone, atovaquone, or aerosolized pentamidine. Patients receiving dapsone should be screened for G6PD deficiency prior to initiation. Dapsone and atovaquone have similar prophylactic efficacy but atovaquone can be cost-prohibitive and is only manufactured in liquid formulation, making dapsone a more appealing option for most patients. Potential adverse effects of dapsone include rash, agranulocytosis, methemoglobinemia, and hepatic dysfunction. Dapsone should not be given to any patient who has a history of severe reaction to TMP-SMX. Aerosolized pentamidine is another—albeit rarely used—option, although this regimen will not offer protection against extrapulmonary pneumocystosis nor against toxoplasmosis and can also be expensive. Inhaled pentamidine distributes selectively to the lower lung fields, leaving the upper portions susceptible to pneumocystic infection. It is not recommended that clindamycin and primaquine be used for prophylaxis.

Women desiring pregnancy should be counseled to wait on pregnancy if possible until the CD4 count exceeds 200 cells/mm^3. If prophylaxis must be given during pregnancy, folate supplementation should be given with TMP-SMX during the first trimester.

Primary pneumocystic prophylaxis (Table 101.1) can be safely discontinued once patients on ART have a CD4 count of at least 200 cells/mm^3 for more than 3 months or if the CD4 count is >100 cells/mm^3 and the viral load is suppressed for more than 3 months.

Secondary prophylaxis

Secondary pneumocystic prophylaxis (Table 101.2) should be given to any HIV-positive patient diagnosed with a pneumocystic infection and started immediately upon completion of the treatment course, which is typically 21 days. The drug of choice for secondary prophylaxis remains TMP-SMX, just as for primary prophylaxis. Likewise, it should be continued until the CD4 count reaches >200 cells/mm^3 for 3 months or after 3 to 6 months of undetectable viral load with CD4 count >100 cells/mm^3.

Primary and secondary prophylaxis should be restarted if a patient's CD4 count drops to <100 cells/mm^3 regardless of the viral load or if the CD4 count is 100 to 200 cells/mm^3 with a detectable viral load. If a patient should acquire a pneumocystic infection with a CD4 count >200 cells/mm^3 and already on ART, lifelong prophylaxis should be considered.

Toxoplasmosis

Toxoplasma gondii is a protozoan that can cause encephalitis in HIV-positive patients as a reactivation of latent cysts in tissue. It can also cause disseminated disease as a primary infection. Prior to ART, one-third of *Toxoplasma* seropositive individuals with severe HIV developed toxoplasmosis within a year's time if not on chemoprophylaxis. The seroprevalence of *T. gondii* antibodies (IgG) is 11% in the United States and much higher in other parts of the world.

TABLE 101.2 **SECONDARY AND TERTIARY PROPHYLAXIS AGAINST *PNEUMOCYSTIS JIROVECII***

Agent	Notes	Discontinuation
Trimethoprim-sulfamethoxazole (TMP-SMX)	Start immediately after completing treatment for infection	CD4 ≥200 cells/mm^3 for > 3 months *or*
	Double-strength daily dosing is the preferred regimen	CD4 ≥100 cells/mm^3 *and* the viral load is suppressed for >3 months
Dapsone	Contraindicated in G6PD deficiency and severe sulfa allergy	
Atovaquone	Cost-prohibitive and liquid only	
Aerosolized pentamidine	Via Respirgard II only	

TABLE 101.3 **PRIMARY PROPHYLAXIS AGAINST *TOXOPLASMA GONDII***

Agent	Notes	Discontinuation
Trimethoprim-sulfamethoxazole (TMP-SMX)	Double-strength daily dosing is the preferred regimen	CD4 ≥200 cells/mm^3 for >3 months *or*
	Mild adverse effects are common and decreased dosing should be attempted if necessary	CD4 ≥100 cells/mm^3 *and* the viral load is suppressed for >3 months
Dapsone	Contraindicated in G6PD deficiency and severe sulfa allergy	
Atovaquone	Cost prohibitive and liquid only	

Primary prophylaxis

All HIV-positive patients should be assessed for IgG *T. gondii* antibodies at the time of diagnosis. In HIV-positive patients with CD4 counts <100 cells/mm^3 who are seropositive for *T. gondii* IgG, or when antibody levels are unknown, primary prophylaxis should be given (Table 101.3). The preferred regimen is one TMP-SMX DS tablet daily. As with Pneumocystis, alternate dosing options of a single-strength daily tablet or double-strength tablet three times weekly are also acceptable if the preferred regimen is not tolerated due to sensitivity. If an alternative agent cannot be avoided due to a life-threatening reaction, the options include dapsone and atovaquone with dapsone being the more affordable and preferable option for most patients who do not have G6PD deficiency.

If a seronegative patient is placed on an alternative pneumocystic prophylaxis regimen that does not cover toxoplasmosis, they should be retested if the CD4 count falls below 100 cells/mm^3.

As with Pneumocystis, toxoplasmosis prophylaxis can be discontinued once HIV-positive patients are taking ART and the CD4 count is >200 cells/mm^3 for 3 months. If the CD4 count is >100 cells/ mm^3 and the viral load is suppressed for >3 months, it is reasonable to stop primary prophylaxis. If, however, at any point the CD4 count falls below 100 cells/mm^3 again, primary prophylaxis should be resumed.

Secondary prophylaxis

Secondary prophylaxis (Table 101.4) against toxoplasmosis applies to patients who have successfully completed treatment for *Toxoplasma* encephalitis and are then appropriate for maintenance therapy. Unlike primary prophylaxis, the preferred regimen for secondary prophylaxis is pyrimethamine and sulfadiazine plus leucovorin. This will also provide protection against Pneumocystis. Twice-daily dosing of sulfadiazine (as opposed to four times daily dosing for treatment) is effective for prophylaxis. Higher dose clindamycin is an alternative option as a substitute for those unable to tolerate sulfadiazine. Atovaquone can be used as well (with or without pyrimethamine or sulfadiazine) and will also offer protection against Pneumocystis. Although not officially in the guidelines, there are data to suggest that TMP-SMX for secondary prophylaxis may be a valid option.

Secondary toxoplasma prophylaxis can be discontinued once the patient is symptom free, has a CD4 count of >200 cells/mm^3, and has been on ART for at least 6 months. Clinicians may also consider follow-up imaging for resolution of brain lesions prior to discontinuation. If the CD4 count declines below 200 cells/mm^3, secondary prophylaxis should be resumed. Unlike primary prophylaxis, there are insufficient data to withhold secondary prophylaxis in situations when the CD4 count is >100 but <200 cells/mm^3 and the viral load is suppressed.

TABLE 101.4 **SECONDARY PROPHYLAXIS AGAINST TOXOPLASMA GONDII**

Agent	Notes	Discontinuation
Pyrimethamine, sulfadiazine, and leucovorin	Start immediately after completing treatment for infection	Once patient is symptom free *and*
	This preferred regimen also protects against Pneumocystis	CD4 ≥ 200 cells/mm3 *and* has been on antiretroviral therapy (ART) for at least 6 months
Atovaquone and pyrimethamine	Used in patients who cannot tolerate sulfa	Consider repeat imaging prior to discontinuation
	Add sulfadiazine or inhaled pentamidine for Pneumocystis protection	
Clindamycin	High dose for use in patients who cannot tolerate sulfa	
	More affordable than atovaquone	

Invasive mycoses: Cryptococcosis, histoplasmosis, coccidioidomycosis

Cryptococcosis

Cryptococcus neoformans (and the geographically restricted *C. gattii*) is a yeast that caused disease in approximately 1 in 12 HIV infected individuals in developed countries prior to the institution of ART. Persons with CD4 counts of <100 cells/mm^3 are at greatest risk for disseminated disease. Cryptococcosis most often presents as subacute to acute meningitis, but can infect any organ.

Prophylaxis with fluconazole can decrease the risk of cryptococcosis in patients with CD4 counts of <100 cells/mm^3, but it is not often done due to the lack of survival benefit from the treatment, relatively low incidence of the disease, and cost.

Treatment of *C. neoformans* meningitis and other disseminated disease involves induction, consolidation, and maintenance (secondary prophylaxis) phases. Maintenance therapy with fluconazole 200 mg/d should continue for 1 year and can then be discontinued as long as the CD4 count is >100 cells/mm^3 and the HIV viral load has been undetectable for >3 months. Secondary prophylaxis with fluconazole should be reinitiated if the CD4 count falls below 100 cells/mm^3 again.

Histoplasmosis

Histoplasma capsulatum is a dimorphic fungus endemic in the Ohio and Mississippi River valleys, southeastern US, Puerto Rico, and Latin America. In these areas, histoplasmosis may occur in up to 5% of HIV-infected individuals, especially those with CD4 counts of <150 cells/mm^3. Infection is controlled via cellular immunity, and disease may represent a new infection or reactivation of a latent infection acquired years earlier. Histoplasmosis may present with fever, fatigue, weight loss, and hepatosplenomegaly. End-organ disease most commonly occurs in the lung, skin, and central nervous system (CNS). Gastrointestinal disease may present as diarrhea or as a mass mimicking a malignant tumor.

Primary prophylaxis (Table 101.5) should be considered in anyone with a CD4 count of <150 cells/mm^3 and is at risk due to occupational exposure or to living in an hyperendemic area (>10 cases of histoplasmosis/100 patient-years). Itraconazole 200 mg/d is the preferred regimen, although fluconazole 400 mg/d may have some efficacy. The newer azoles—voriconazole, posaconazole, and isovuconazonium—have not been evaluated for prophylaxis. Itraconazole requires acidic stomach conditions to be absorbed.

Prophylaxis may be discontinued in patients on ART once the CD4 count rises above 150 cells/mm^3 for 6 months. It should be restarted if the CD4 count falls below 150 again.

TABLE 101.5 **PRIMARY PROPHYLAXIS AGAINST HISTOPLASMOSIS IN ENDEMIC REGIONS**

Agent	Notes	Discontinuation
Itraconazole	Daily dosing of 200 mg is the preferred option	CD4 >150 cells/mm^3 *and* on highly active antiretroviral therapy (HAART) for 6 months
	Must be taken on an acidic stomach	
Fluconazole	Daily dosing of 400 mg is the second option	

Coccidioidomycosis

Coccidioides spp. are dimorphic fungi endemic in southwestern United States. Similar to *Histoplasma*, waning cellular immunity may allow disease to develop from either new or latent infections. Coccidioidomycosis may present as diffuse or focal pneumonia, meningitis, arthritis, or osteomyelitis. HIV-infected individuals exposed to this fungus are at increased risk of developing disease when the CD4 count falls below 250 cells/mm^3.

Primary prophylaxis for individuals at risk for coccidioidomycosis who are antibody negative for *Coccidioides* is *not recommended*. Serologic testing every 6 to 12 months in an individual at risk for the disease (living in an endemic area and CD4 <250) is reasonable. A newly positive test represents an infection, and, if there is no evidence of active disease, prophylaxis with fluconazole 400 mg/d can be started. Fluconazole can be discontinued once the CD4 count rises above 250 cells/mm^3 and HIV has been suppressed with ART.

Patients who had focal pulmonary disease should remain on antifungal therapy for at least 6 months. Twelve months or more of secondary prophylaxis (Table 101.6) is recommended for those who

TABLE 101.6 **PRIMARY AND SECONDARY PROPHYLAXIS AGAINST COCCIDIOIDOMYCOSIS IN ENDEMIC REGIONS**

Agent	Notes	Discontinuation
Fluconazole	400 mg/d for patients with CD4 <250 cells/mm3 and positive serologies against Coccidioides spp.	CD4 >250 cells/mm^3 *and* undetectable HIV viral load
Fluconazole	400 mg/d as secondary prophylaxis after treatment of mild disease	After 6 months *and* CD4 >250 cells/mm^3 *and* undetectable HIV viral load
Fluconazole or Itraconazole	400 mg/d fluconazole or 200 mg twice daily itraconazole	After 12 months *and* CD4 >250 cells/mm^3 *and* undetectable HIV viral load
	Secondary prophylaxis after treatment of diffuse pneumonia or systemic (non-central nervous system [CNS]) disease	
Fluconazole	400 mg/d as secondary prophylaxis after CNS disease	Lifelong therapy

had diffuse pulmonary disease or extrathoracic (other than CNS) disease. CD4 counts should be >250 cells/mm^3 and the viral load suppressed prior to discontinuation. Since relapse of CNS disease is common even in individuals without HIV, lifelong secondary prophylaxis is the norm for those with meningitis.

Cytomegalovirus

Cytomegalovirus (CMV) is a β-herpesvirus causing a latent infection in roughly half of adults by age 40. Patients with severe cellular immunosuppression (e.g., patients with a CD4 count <50 cells/mm^3) are at risk of end-organ disease, usually by reactivation of the virus but also through new infections. Retinitis is the most common manifestation of CMV disease in individuals with HIV/AIDS, but CMV can also cause esophagitis, colitis, pneumonitis, and CNS disease (encephalitis, ventriculitis, lumbar radiculopathy).

Prior to ART, roughly one in three persons with HIV would develop CMV retinitis before dying. In that era, daily oral ganciclovir (no longer available) was shown to prevent retinitis, but CMV prophylaxis never was the standard of care due to cost, toxicity, and the high number needed to treat to prevent the disease. With the institution of ART, the incidence of CMV retinitis decreased by >95%. A more recent prophylaxis trial with oral valganciclovir in individuals at risk of disease failed to show a benefit, and CMV primary prophylaxis is currently *not recommended*.

Patients who have had CMV retinitis treated and controlled should be placed on maintenance therapy to prevent relapse. Therapies may be administered orally, parenterally, or intravitreally, and the choice should be made with the consultation of an HIV expert and an ophthalmologist (Table 101.7). Other end-organ disease need not be secondarily prophylaxed, unless there is evidence of retinitis or a relapse. Intravitreal prophylaxis will not prevent systemic disease or disease in the contralateral eye.

Secondary prophylaxis may be discontinued safely once three conditions have all been met: (1) after 3 to 6 months of prophylaxis, (2) when all retinal lesions are deemed inactive, and (3) CD4 count has risen to >100 cells/mm^3 for 3 to 6 months. Relapses can occur at any CD4 count; patients should have periodic retinal exams.

TABLE 101.7 **OPTIONS FOR SECONDARY PROPHYLAXIS AGAINST CYTOMEGALOVIRUS**

Route of administration	Agent
Oral	Valganciclovir
Parenteral	Ganciclovir
	Foscarnet
	Ganciclovir plus foscarnet
	Cidofovir
Intravitreal	Ganciclovir
	Foscarnet
	Cidofovir
	Fomivirsen (not available in the United States)

Tuberculosis

Mycobacterium tuberculosis kills well over 1 million persons worldwide every year and is a leading cause of death among persons with HIV. Tuberculosis (TB) is acquired through inhalation of infectious droplets and is often contained by cellular immunity. Persons may have latent TB infection (LTBI) for decades. Persons with HIV have a high risk of reactivating their LTBI, and there appears to be no CD4 cell count threshold associated with TB disease. Nevertheless, the lower the CD4 count the higher the risk.

All persons with HIV should be screened for LTBI upon presentation to medical care (as all patients with TB should be screened for HIV). Two types of screens are currently used: the Mantoux tuberculin skin test (TST) and the interferon-γ release assay (IGRA) blood test. Either is acceptable, although the sensitivity of both decreases with increased immune suppression. Only one test need be performed; administering both tests is currently not recommended.

Individuals with HIV testing positive either via the TST (skin induration >5 mm) or IGRA should have active TB ruled out. At a minimum, a chest x-ray should be obtained looking for active pulmonary disease. If there is no evidence of active TB, then the LTBI should be treated. Nine months of daily isoniazid plus pyridoxine remain the mainstay of LTBI therapy, although compliance tends to decrease in the last months of therapy. Three months of isoniazid plus rifapentine (and pyridoxine) given once weekly under directly observed therapy (DOT) appears to be as safe and efficacious as 9 months of isoniazid. Other alternative regimens are listed in Table 101.8.

Patients should be monitored every few weeks for adherence and toxicity. Medications should be discontinued if liver enzymes rise above five times the upper limits of normal. Patients should be cautioned to avoid alcohol, and clinicians should watch for drug interactions.

Once LTBI or active TB has been treated, reinfection occurs rarely in the United States. Secondary prophylaxis is not needed.

Disseminated mycobacterium avium complex

Organisms belonging to the *Mycobacterium avium* complex (MAC) can be found throughout the environment. HIV-infected individuals

TABLE 101.8 **LATENT TUBERCULOSIS TREATMENT IN PERSONS LIVING WITH HIV**

Agent	Duration
Isoniazid 300 mg/d plus pyridoxine 25–50 mg/d	9 months
Rifapentine (750 mg for 32–50 kg, 900 mg for >50 kg) weekly *plus* isoniazid 900 mg weekly plus pyridoxine 50mg weekly	12 weeks
Rifampin 600 mg/d	4 months

are at high risk of MAC disease, either localized (e.g., lymphadenitis) or disseminated, when the CD4 cells fall to <50 cells/mm^3. Disseminated disease often presents with fever, weight loss, or diarrhea. Patients with low CD4 counts and symptoms of MAC should have active disease ruled out prior to prophylaxis initiation.

MAC prophylaxis is currently not recommended in patients on suppressive ART. It is likewise not recommended in persons initiating ART regardless of CD4 count. Prophylaxis is only indicated in individuals with a CD4 count <50 cells/mm^3 whose viral load is not suppressed while on HAART. Medications include azithromycin 1,200 weekly or clarithromycin 500 mg twice daily. Rifabutin is an alternative for those who cannot tolerate the macrolides, but drug interactions can make administration difficult. Primary prophylaxis can be stopped once viral suppression has been achieved with ART.

For patients with MAC disease, full therapy against this mycobacterium should be continued for at least 1 year as secondary prophylaxis or maintenance therapy. Secondary prophylaxis can be discontinued after 12 months as long as the patient has no evidence of MAC disease, is on ART, and the CD4 count is > 100 cells/mm^3 for 6 months.

Vaccinations

Persons living with HIV who are older than age 13 should receive vaccinations against *Streptococcus pneumonia*. If never previously vaccinated, administer 1 dose of 13-valent pneumococcal conjugate vaccine (PCV13) followed at least 8 weeks later by 1 dose of 23-valent pneumococcal polysaccharide vaccine (PPSV23). Patients should receive a second dose of PPSV23 at least 5 years later and again at age 65 as long as the previous dose was given more than 5 years before. If the patient has already received the PPSV23 prior to receiving the PCV13, then defer administration of PCV13 at least 1 year after the PPSV23. Of note, administering the PPSV23 once the CD4 count is at least 200 cells/mm^3 will increase efficacy.

If not previously vaccinated and immune to hepatitis B, all persons living with HIV should complete the vaccine series with a three-dose series of single-antigen hepatitis B vaccine or combined hepatitis B and hepatitis A vaccine if the patient is also at risk for hepatitis A. Risk factors for hepatitis A in HIV-positive patients include MSM, injection drug use, and chronic liver disease. Patients should be assessed for immunity after completing the hepatitis B vaccine series, and nonresponders should repeat the series once there is a sustained increase in CD4 count.

All persons living with HIV should be offered the inactivated influenza vaccine annually. The live-attenuated vaccine is contraindicated in this patient population. Follow Advisory Committee on Immunization Practices (ACIP) guidelines for further details regarding age appropriate vaccinations.

Nosocomial infection

102

Percutaneous injury

Risks and management

David Kuhar and Krista Powell

Healthcare personnel (HCP) are at risk of occupational exposure to bloodborne pathogens such as hepatitis B virus (HBV), hepatitis C virus (HCV), and HIV from needlesticks and injuries from sharp objects. Risk factors for transmission of bloodborne pathogens as a result of occupational exposure are related to the source patient (e.g., titer and infectivity of the virus in his or her blood or body fluid), the injury (e.g., quantity of blood or body fluid transferred during the exposure), and the recipient individual (e.g., immunologic status).

Percutaneous exposures are the most common mechanism for transmission of bloodborne pathogens in healthcare settings. Hospital-based HCP in the United States have previously been estimated to sustain an average of 384,325 (range: 311,091–463,922) percutaneous injuries annually. Data from several surveillance systems have demonstrated that the majority of reported injuries occur in the acute care setting, particularly medical floors, operating rooms, and intensive care units.

Prevention of bloodborne pathogen transmission through exposure prevention requires a diversified approach following the occupational health and safety hierarchy of controls. Measures include the development of improved engineering controls (e.g., safer medical devices), work practices (e.g., technique changes to reduce handling of sharp objects), and infection control measures, including use of personal protective equipment. Another important pre-exposure strategy to prevent infection includes HBV immunization.

Although preventing exposures is the primary means of preventing bloodborne pathogen infection, appropriate post-exposure management is an important element of workplace safety. The Occupational Health and Safety Administration's bloodborne pathogens standard requires employers to develop written exposure control plans to protect all employees at risk of exposure to blood or other potentially infectious materials and to provide job-related post-exposure evaluation and follow-up to all employees. Healthcare organizations should have a system that includes written protocols for prompt confidential reporting, evaluation, counseling, treatment, and follow-up of any occupational exposures that may place HCP at risk for acquiring bloodborne infection. Each incident of occupational exposure to blood or body fluid that may contain HBV, HCV, or HIV should be evaluated as rapidly as possible and should include testing of the source patient for the appropriate bloodborne pathogens, testing of the exposed person for prior infection, and prompt administration of prophylactic agents when indicated.

Initial exposure management and evaluation

Wounds should be washed with soap and water. There is no evidence that the use of antiseptics for wound care or expressing fluid by squeezing the wound further reduces the risk of bloodborne pathogen transmission. However, the use of antiseptics is not contraindicated. The exposure should be evaluated for potential to transmit HBV, HCV, and HIV based on the type of potentially contaminated source body substance involved and the route and severity of the exposure. Blood, fluid containing visible blood, or other potentially infectious fluid (including semen; vaginal secretions; and cerebrospinal, synovial, pleural, peritoneal, pericardial, and amniotic fluids) or tissue can be infectious for bloodborne pathogens.

The person whose blood or body fluid is the source of a percutaneous injury should be evaluated for HBV, HCV, and HIV infection. Information available in the medical record at the time of exposure (e.g., laboratory test results, admitting diagnosis, or past medical history) or from the source individual may help determine the likelihood of bloodborne virus infection. If the HBV, HCV, and/or HIV infection status of the source is unknown, the source person should be informed of the incident and tested for evidence of bloodborne virus infection as soon as possible, including preferably using a nucleic acid test for HCV. Procedures should be followed for testing source persons, including obtaining informed consent, in accordance with applicable state and local laws. If the exposure source's infectious status cannot be determined (e.g., unknown source patient), decisions about post-exposure management should be made on a case-by-case basis after considering the type of exposure and the clinical and/or epidemiologic likelihood of infection with HBV, HCV, or HIV.

Bloodborne pathogens

Hepatitis B virus infection

HBV infection is a well-recognized occupational risk for HCP. The risk of HBV infection is primarily related to the degree of contact with blood and also to the hepatitis B e antigen (HBeAg) status of the source patient. In studies of unvaccinated HCP who sustained injuries from needles contaminated with blood containing HBV, the risk of developing clinical hepatitis from exposure to hepatitis B surface antigen (HBsAg)- and HBeAg-positive blood was 22% to 31%, and the risk of developing serologic evidence of HBV infection, 37% to 62%. By comparison, the risk of developing clinical hepatitis from a needle contaminated with HBsAg-positive, HBeAg-negative blood was 1% to 6%, and the risk of developing serologic evidence of HBV infection, 23% to 37%.

All HCP at risk for contact with contaminated blood or body fluids should be vaccinated against HBV. Pre-vaccination serologic testing for previous infection is not performed for the majority of persons being vaccinated because of occupational risk unless the hospital or healthcare organization considers testing cost-effective. Regardless of vaccination history, testing is cost-effective for high-risk HCP populations, including those born in geographic regions with high (≥8%) and intermediate (2–7%) HBsAg prevalence, unvaccinated US-born HCP whose parents were born in regions of high HBsAg prevalence, HIV-positive HCP, HCP who have disclosed having engaged or currently engaging in high-risk substance abuse or sexual behaviors, and HCP who require immunosuppressive therapy or who are on hemodialysis. These HCP should be tested for HBsAg and antibodies to hepatitis B core antigen (anti-HBc)/antibody to HBsAG (anti-HBs) to determine infection status. Hepatitis B vaccine can be administered at the same time as other vaccines. Vaccination options include a two-dose series (administered at time zero and 1 month) and a three-dose series (administered at time zero, 1 month, and 6 months). Two doses of Heplisav-B (HepB-CpG) administered <4 weeks apart should be repeated. Both doses of the two-dose series should consist of HepB-CpG. If the three-dose series is interrupted after the first dose, the second dose should be administered as soon as possible. The second and third doses should be separated by at least 2 months. If only the third dose is delayed, it should be administered when convenient. To determine the need for revaccination and to guide post-exposure prophylaxis, post-vaccination serologic testing should be performed for all HCP at risk for occupational exposure to blood or body fluids 1 to 2 months after completion of the vaccination series for a protective concentration of anti-HBs (≥10 mIU/mL). Persons who do not respond to the primary vaccine series should complete a second vaccine series or be evaluated to determine if they are HBsAg positive. Revaccinated persons should be retested at the completion of the second vaccine series.

HCP with previous documentation of a complete vaccine series, but no documentation of anti-HBs of ≥10mIU/mLmay be at risk for HBV infection. Some experts suggest that they undergo anti-HBs testing upon hire or matriculation. Vaccinated HCP without previous anti-HBs testing who sustain an occupational exposure should be tested for anti-HBs as soon as possible after the exposure. Completely vaccinated HCP with anti-HBs <10mIU/mL should receive additional vaccination. For HCP who received two doses of HepB-CpG, revaccination may consist of a second complete HepB vaccine series followed by anti-HBs testing 1 to 2 months after the final dose. Alternatively, revaccination may consist of administration of an additional single HepB vaccine dose followed by anti-HBs testing 1 to 2 months later (and, if anti-HBs remains <10 mIU/mL, completion of the second HepB vaccine series followed again by anti-HBs testing 1–2 months after the final dose). For HCP who received the three-dose series, revaccination may consist of an additional dose of HepB vaccine, followed by anti-HBs testing 1 to 2 months later. HCP whose anti-HBs remain <10mIU/mL could receive two additional vaccine doses (to complete a second vaccine series), followed by repeat anti-HBs testing 1 to 2 months after the last dose.

Primary nonresponders to vaccination who are HBsAg negative should be considered susceptible to HBV infection and counseled regarding the need to obtain hepatitis B immunoglobulin (HBIG) prophylaxis for any known or probable exposure to HBsAg-positive

TABLE 102.1 **RECOMMENDED POST-EXPOSURE PROPHYLAXIS FOR PERCUTANEOUS EXPOSURE TO HEPATITIS B VIRUS (HBV), UNITED STATES**

Vaccination and antibody response status of exposed person[a]	**Treatment when source is found to be:** HBsAg[b] positive	HBsAg negative	Source not tested or status unknown
Unvaccinated/incompletely vaccinated or vaccine refusers	HBIG[c] × 1 and complete HB vaccine series[d]	Complete HB vaccine series	Complete HB vaccine series
Previously vaccinated			
Known responder[e]	No treatment	No treatment	No treatment
Known nonresponder[e]			
After complete series	HBIG × 1 and initiate revaccination	Initiate revaccination	If known high-risk source, treat as if source were HBsAg positive
After two complete series	HBIG × 2 (separated by 1 month)	No treatment	If known high-risk source, treat as if source were HBsAg positive

[a] Persons who have previously been infected with HBV are immune to reinfection and do not require post-exposure prophylaxis.
[b] Hepatitis B surface antigen.
[c] Hepatitis B immunoglobulin; dose 0.06 mL/kg intramuscularly.
[d] Hepatitis B vaccine series. Healthcare personnel should be tested 1 to 2 months after completion of the vaccination series for anti-HBs.
[e] A seroprotective (adequate) level of anti-HBs after completion of a vaccination series is defined as anti-HBs ≥10 mIU/mL; a response <10 mIU/mL is inadequate and is not a reliable indicator of protection.
[f] Antibody to HBsAg.

blood (Table 102.1). Any blood or body fluid exposure of an unvaccinated susceptible person should lead to initiation of the hepatitis B vaccine series.

For percutaneous exposures to HBV-infected blood, the decision to provide prophylaxis must take into account several factors, including the HBsAg status of the source and the hepatitis B vaccination and vaccine-response status of the exposed person. The hepatitis B vaccination status and the vaccine-response status (if known) of the exposed person should be reviewed. Table 102.1 summarizes prophylaxis recommendations for percutaneous exposure to blood according to the HBsAg status of the exposure source and the vaccination and vaccine-response status of the exposed person. When HBIG is indicated, it should be administered as soon as possible after exposure (preferably within 24 hours). The effectiveness of HBIG when administered >7 days after exposure is unknown. Hepatitis B vaccine, when indicated, should also be given as soon as possible (preferably within 24 hours) and can be given simultaneously with HBIG (though it should be administered intramuscularly at a separate site, with vaccine always given in the deltoid muscle). For exposed persons who are in the process of being vaccinated but have not completed the vaccination series, vaccination should be completed as scheduled and HBIG added. HBV testing should be performed on any exposed person who has an illness compatible with hepatitis.

Hepatitis C virus infection

HCV is not transmitted efficiently through occupational exposures to blood. The average incidence of anti-HCV seroconversion after accidental percutaneous exposure from an HCV-positive source is 1.8% (range, 0–7%). The risk for transmission after exposure to fluids or tissues other than HCV-infected blood has not been quantified but is thought to be low.

HCP who provide care to persons exposed to HCV in the occupational setting should be knowledgeable regarding the risk for HCV infection and appropriate counseling, testing, and medical follow-up. Immunoglobulin and antiviral agents are not recommended for post-exposure prophylaxis (PEP) after exposure to HCV. For the person exposed to a source with HCV viremia or for whom HCV infection status is unknown, testing for anti-HCV should be performed within 48 hours of exposure. A reflex HCV RNA test should be performed if anti-HCV testing is positive. If anti-HCV testing is negative, or if reflex HCV RNA is negative after positive anti-HCV testing, then HCV RNA testing should be repeated ≥3 weeks after exposure. If RNA testing is negative, many experts recommend testing for anti-HCV at 4 to 6 months post-exposure; a reflex HCV RNA test should be performed if anti-HCV testing is positive. All persons with current HCV infection as evidenced by a positive HCV RNA test should be referred for evaluation by a practitioner with expertise in liver disease and HCV treatment. Spontaneous clearance of infection may occur up to 6 months after exposure, so persons with positive HCV RNA testing <6 months after exposure should be tested again ≥6 months after exposure to determine infection status.

Human immunodeficiency virus infection

In 2014, the US Centers for Disease Control and Prevention (CDC) updated the 2005 risk estimate of HIV transmission after a percutaneous exposure to HIV-infected blood. Based on a meta-analysis and systematic review of 21 published studies, estimated average risk is approximately 0.23% (95% confidence interval: 0%, 0.46%). Fourteen of the 21 studies reported no transmissions. These and other studies suggest that infection risk is increased by factors that increase the "effective" viral dose, such as exposure to a larger quantity of blood (e.g., a device visibly contaminated with the patient's

blood, a procedure that involved a needle placed directly in a vein or artery, a deep injury) and a source patient with a high viral load.

After exposure, timely receipt of HIV post-exposure prophylaxis can reduce the risk for HIV transmission. HCP exposed to HIV should be evaluated as soon as possible (within hours) after their exposure and should be tested for HIV at baseline (i.e., to establish infection status at the time of exposure). Whenever possible and according to applicable state and local laws, the HIV status of the exposure source patient should be determined to guide appropriate use of HIV PEP. Administration of PEP should not be delayed while waiting for test results. If the source patient is determined to be HIV-negative, PEP should be discontinued and no follow-up HIV testing for the exposed provider is indicated.

After exposure to HIV, PEP should be initiated as soon as possible. PEP should be administered for 4 weeks, if tolerated. The drug regimen selected for HIV PEP should have a favorable side-effect profile as well as a convenient dosing schedule to facilitate both adherence to the regimen and completion of 4 weeks of PEP. Given the complexity of choosing and administering HIV PEP, whenever possible, consultation with an infectious diseases specialist or another physician who is an expert in the administration of antiretroviral agents is recommended. Such consultation should not, however, delay timely initiation of PEP.

Box 102.1 lists the preferred regimen for HIV PEP, alternative regimens, medications to be used only in consultation with an expert, and medications that are not recommended for use as PEP. A regimen containing three (or more) antiretroviral drugs is now recommended routinely for all occupational exposures to HIV. Tenofovir (TDF) plus emtricitabine (FTC) plus raltegravir (RAL) is recommended as the preferred regimen for occupational exposures

BOX 102.1

Recommended HIV post-exposure prophylaxis (PEP) regimens

Preferred HIV PEP regimen

Raltegravir (Isentress; RAL) 400 mg PO twice daily
Plus
Truvada,1 PO once daily
(Tenofovir DF [Viread; TDF] 300 mg + emtricitabine [Emtriva; FTC] 200 mg)

Alternative regimens

(May combine one drug or drug pair from the left column with one pair of nucleoside/nucleotide reverse transcriptase inhibitors from the right column. Prescribers unfamiliar with these agents/regimens should consult physicians familiar with the agents and their toxicities.)[a]

Raltegravir (Isentress; RAL) Tenofovir DF (Viread; TDF) + emtricitabine (Emtriva; FTC); available as Truvada
Darunavir (Prezista; DRV) + ritonavir (Norvir; RTV) Tenofovir DF (Viread; TDF) + lamivudine (Epivir; 3TC)
Etravirine (Intelence; ETR) Zidovudine (Retrovir; ZDV; AZT) + lamivudine (Epivir; 3TC); available as Combivir
Rilpivirine (Edurant; RPV) Zidovudine (Retrovir; ZDV; AZT) + emtricitabine (Emtriva; FTC)
Atazanavir (Reyataz; ATV) + ritonavir (Norvir; RTV)
Lopinavir/ritonavir (Kaletra; LPV/RTV)
The following alternative is a complete fixed-dose combination regimen and no additional antiretrovirals are needed: Stribild (elvitegravir, cobicistat, tenofovir DF, emtricitabine)

Alternative antiretroviral agents for use as PEP *only* with expert consultation

Abacavir (Ziagen; ABC)[b]
Efavirenz (Sustiva; EFV)
Enfuvirtide (Fuzeon; T20)
Fosamprenavir (Lexiva; FOSAPV)
Maraviroc (Selzentry; MVC)
Saquinavir (Invirase; SQV)
Stavudine (Zerit; d4T)

Antiretroviral agents generally not recommended for use as PEP

Didanosine (Videx EC; ddI)
Nelfinavir (Viracept; NFV)
Tipranavir (Aptivus; TPV)

Antiretroviral agents contraindicated as PEP

Nevirapine (Viramune; NVP)

[a] The alternative regimens are listed in order of preference; however, other alternatives may be reasonable based on patient and clinician preference.

[b] Abacavir hypersensitivity reaction can be fatal and is associated with the HLA -B*5701 allele. HCP considered for treatment with abacavir should first undergo screening for the HLA -B*5701 allele.

to HIV. This regimen is tolerable, potent, conveniently administered, and has been associated with minimal drug interactions. Tenofovir, a component of Truvada, is not indicated for HCP with an estimated creatinine clearance (eCrCl) of <60 mL/min. Some experts recommend using antiretroviral drugs for PEP after occupational exposure that were approved for use after the release of the US Public Health Service (USPHS) 2013 guidelines for the management of occupational exposure to HIV and recommendations for PEP. For example, tenofovir alafenamide (TAF) has been used instead of TDF in PEP regimens. The once-daily integrase strand transfer inhibitor, dolutegravir (DTG), has been used instead of twice-daily RAL as part of occupational PEP regimens, however, concerns have been raised about use of DTG during the perinatal period. Because many antiretroviral agents can have adverse effects in pregnancy or have insufficient data, they may not be recommended for use in pregnancy. When prescribing PEP, anticipating and preemptively treating side effects (e.g., nausea, diarrhea, etc.) commonly associated with taking antiretroviral agents is encouraged. (Findings from

TABLE 102.2 **PRACTICE RECOMMENDATIONS FOR HEALTHCARE FACILITIES (HCFS) IMPLEMENTING GUIDANCE FOR MANAGEMENT OF OCCUPATIONAL EXPOSURES TO BLOODBORNE PATHOGENS (BBPS)**

Practice recommendation	Implementation checklist
Establish a BBP management policy	All institutions where HCP may experience exposures should have a written policy for management of exposures
	The policy should be reviewed periodically to ensure it is up to date
Implement management policies	HCFs should provide appropriate training to all personnel on the prevention of and response to occupational exposures
	HCFs should establish hepatitis B vaccination programs
	HCFs should establish exposure-reporting systems
	HCFs should have personnel who can manage an exposure readily available at all hours of the day
	HCFs should have ready access to post-exposure prophylaxis (PEP) for use by exposed personnel as necessary
Establish laboratory capacity for BBP testing	HCFs should provide prompt processing of specimens from exposed and source persons to guide management of occupational exposures
	Testing should be performed with appropriate counseling and consent
Select and use appropriate PEP regimens	HCFs should develop a policy for the selection and use of PEP antiretroviral regimens for HIV exposures within their institution
	Hepatitis B vaccine and hepatitis B immunoglobulin (HBIG) should be available for timely administration
	HCFs should have access to resources with expertise in the selection and use of PEP
Provide access to counseling for exposed healthcare personnel (HCP)	HCFs should provide counseling for healthcare personnel (HCP) who may need help to deal with the emotional impact of an exposure and who should be instructed to use precautions to prevent secondary transmission during the follow-up period
	HCFs should provide medication adherence counseling to assist HCP complete HIV PEP as necessary
Monitor for adverse effects of PEP	HCP taking antiretroviral PEP should be monitored periodically for adverse events through clinical evaluation, including blood testing, at baseline and 2 weeks post-exposure
Monitor for seroconversion	HCF should develop a system to encourage exposed HCP to return for follow-up testing
Monitor exposure management programs	HCFs should develop a system to monitor reporting and management of occupational exposures to ensure timely and appropriate response
	Evaluate:
	Exposure reports for completeness and accuracy
	Access to care (i.e., the time of exposure to the time of evaluation)
	Laboratory result reporting time
	Review:
	Exposures to ensure that HCP exposed to sources not infected with BBPs do not receive PEP or PEP is stopped
	Monitor:
	Completion rates of HBV vaccination and HIV PEP
	Completion of exposure follow-up

an African observational study suggesting that perinatal exposure to DTG-containing antiretroviral regimens was associated with neural tube defects have prompted recommendations that HCP prescribing PEP should avoid use of DTG for non-pregnant women of childbearing potential who are sexually active or who have been sexually assaulted and who are not using an effective birth control method and pregnant women early in pregnancy, since the risk of an unborn infant developing a neural tube defect is during the first 28 days. See: https://stacks.cdc.gov/view/cdc/38856 "Update: Interim Statement Regarding Potential Fetal Harm from Exposure to Dolutegravir—Implications for HIV Post-exposure Prophylaxis (PEP)."

Re-evaluation of the exposed person should be performed within 72 hours post-exposure, especially as additional information about the exposure or source person becomes available. HCP with occupational exposure to HIV should receive follow-up counseling regarding precautions to prevent secondary transmission during the follow-up period, post-exposure testing, and medical evaluation regardless of whether they receive PEP. HIV testing should be performed for 6 months post-exposure (e.g., at 6 weeks, 12 weeks, and 6 months). Use of fourth-generation combination HIV p24 antigen–HIV antibody immunoassays allow for earlier detection of HIV infection. If the clinician is certain that a fourth-generation combination HIV p24 antigen–HIV antibody test is being utilized, then HIV testing could be performed at baseline, 6 weeks, and concluded at 4 months post-exposure. If PEP is used, the HCP should be monitored for drug toxicity by medical evaluation and by checking, at a minimum, CBCs and renal and hepatic function tests at baseline and again 2 weeks after starting PEP. The scope of post-exposure blood testing should be based on medical conditions in the exposed person and the anticipated toxicities of the drugs included in the PEP regimen. Further testing may be indicated if abnormalities were detected. HIV testing should be performed on any exposed person who has an illness compatible with HIV seroconversion.

Guidance for healthcare facilities

In Table 102.2, specific practice recommendations for the management of occupational bloodborne pathogen exposures are outlined to assist healthcare institutions with the implementation of established exposure management guidelines. All recommendations given are valid as of February 2019.

Hospital-acquired fever

Susan K. Seo and Arthur E. Brown

Fever is a common clinical problem in hospitalized patients. Although the development of fever in a hospitalized patient may be the clinical expression of a community-acquired infection that has completed its incubation period, this chapter focuses on the possible causes of new-onset fever occurring at least 48 hours after hospital admission. The reader, however, should keep other diagnoses in mind and inquire about the patient's history of travel, pet and animal exposure, hobbies (e.g., gardening, whitewater rafting, and other adventure sports), sexual activity, dietary preferences, occupational exposures, recent immunizations, drug (including corticosteroids) and herbal ingestion within the past month, recent contact with febrile or ill individuals, and other epidemiologic factors such as season of the year.

Nosocomial fever occurs in 2% to 31% of medical inpatients. The wide range in prevalence rates has been attributed to differences in definition of fever, methods of temperature measurement, study population (e.g., general medical patients, geriatric patients), and healthcare setting (e.g., county, university, or Veterans Affairs hospital). Hospital-acquired fever may be due to an infectious and/or noninfectious cause, either happening alone or concurrently. An etiology can be identified after appropriate workup in 73% to 88% of patients. It is not uncommon for length of stay and resource utilization to be increased due to the management of the febrile episode.

Not surprisingly, nosocomial infections account for 56% to 74% of causes of fever in hospitalized patients, with the most common infectious causes being bloodstream infections, upper and lower respiratory tract infections, and urinary tract infections (Box 103.1). There has been a steady increase in the rates of nosocomial infections due to multidrug-resistant organisms (MDROs). Knowledge of local surveillance data, including antibiotic resistance patterns, and patient risk factors for acquisition of MDROs is important as one considers choice of empiric antimicrobial therapy. Noninfectious causes comprise 14% to 31%. These are usually related to some form of vascular disruption (e.g., myocardial infarction, pulmonary embolism), inflammatory (e.g., gout) or collagen vascular disease (e.g., lupus), endocrine disorder (e.g., adrenal insufficiency), malignancy, or drug (Box 103.2). In some instances, the only identifiable factor may be an invasive procedure (e.g., surgery, bronchoscopy) performed within 24 hours of fever onset.

A comprehensive review of the patient's history and a full physical exam should be performed to find clues to the source(s) of fever. Disorders of immune function, valvular heart disease, history of previous placement of prosthetic devices (e.g., orthopedic), prior illness and treatment including for MDROs, drug allergies, and history of transplantation should be reviewed with the patient. Attention should also be paid to risk factors for hospital-acquired fever such as recent surgical, endoscopic, or interventional radiologic procedures; recent urinary and respiratory tract instrumentation; intravascular devices; drug therapy; blood transfusions; and immobilization. The physical examination should be complete but focus on vital signs; general appearance; signs of toxicity; skin rash; presence of genital, mucosal, and/or conjunctival lesions; presence of cardiac murmur or rub; new crackles; decreased breath sounds; egophony and/or pleural friction rub on lung auscultation; abdominal tenderness; hepatosplenomegaly; costovertebral angle tenderness; arthritis; spinal tenderness; meningismus; and/or neurologic dysfunction.

Obviously, the postoperative patient will have special attention given to the operative site and wounds. Consultation with the surgeon regarding the operative findings, technical difficulties, and complications is essential. Similarly, conferring with the endoscopist after bronchoscopy, endoscopic retrograde

BOX 103.1

Infectious causes of hospital-acquired fever

Bloodstream
- Intravascular device-related (e.g., triple-lumen central venous catheter, Hickman, Broviac, Port)
- Sepsis due to bacterial or fungal organisms

Central nervous system
- Epidural abscess
- Meningitis

Gastrointestinal
- Cholangitis
- Diverticulitis
- Intra-abdominal abscess
- Pseudomembranous colitis

Respiratory tract
- Aspiration pneumonia
- Empyema
- Hospital-acquired pneumonia
- Sinusitis
- Ventilator-associated pneumonia

Skin and soft tissue
- Cellulitis
- Myonecrosis
- Necrotizing fasciitis

Surgical site (incisional, deep space, or abscess)

Urinary tract
- Catheter-related
- Post instrumentation (e.g., cystoscopy)

Other
- Endocarditis
- Prosthetic device infection
- Suppurative thrombophlebitis
- Transfusion-related (bacterial, fungal, viral, parasitic)

BOX 103.2

Examples of noninfectious causes of hospital-acquired fever

Biologic agents (e.g., vaccines, cytokines)/drugs
- Alcohol or drug withdrawal
- Drug fever
- Drug overdose (e.g., anticholinergic agents)
- Neuroleptic malignant syndrome

Cardiac causes
- Myocardial infarction
- Pericarditis

Collagen vascular diseases
- Vasculitis

Endocrine disorders
- Adrenal insufficiency
- Thyroid storm

Factitious fever

Inflammatory diseases
- Gout, pseudogout
- Nonviral hepatitis

Intra-abdominal conditions
- Acalculous cholecystitis
- Acute pancreatitis
- Mesenteric ischemia
- Upper or lower gastrointestinal bleeding

Malignancy
- Tumor fever

Neurologic conditions
- Intracranial or subarachnoid hemorrhage
- Seizures
- Stroke
- Subdural hematoma

Procedure-related
- Benign postoperative fever
- Endobronchial intubation
- Transfusion reaction

Thromboembolic disease
- Deep venous thrombosis
- Pulmonary embolus
- Superficial thrombophlebitis

Vascular conditions
- Sickle cell crisis

cholangiopancreatography, colonoscopy, or cystoscopy may reveal information regarding the etiology of post-endoscopic fever in such a patient. The patient with cancer may receive a significant amount of blood products over time and may develop transfusion-related infections (see Chapter 104, "Transfusion-related infection"). Infections found in the alcoholic, drug abusing, thermally injured, diabetic, elderly, or immunocompromised patient require special consideration (see chapters covering these topics). The immunocompromised patient with cancer in particular may have a variety of possible infectious etiologies to consider (see Chapter 85, "Infections in patients with neoplastic disease").

The investigation of hospital-acquired fever should take into consideration possible foci of infection. The initial evaluation typically includes a CBC, urinalysis, chest radiograph, and cultures of blood, urine, and, if indicated, sputum. Adequate sputum for microbiologic evaluation should contain few epithelial cells and numerous polymorphonuclear neutrophils if the patient is not neutropenic. However, obtaining a good specimen, particularly in critically ill and/or neutropenic patients, might be difficult. Appropriate cultures of wound sites and drainage are also important. It is essential to obtain fresh material from the drainage site rather than the material that has been dwelling in the collection apparatus. In the patient with diarrhea, stool specimens should be obtained and tested for *Clostridium difficile*. When a rash is present, a biopsy of the skin should be obtained for both histologic and microbiologic

examination. Vascular access devices are suspect. If possible, these should be removed and the tips sent for culture.

It is important that the specimens are obtained correctly and are transported to the microbiology laboratory quickly. This aids in the recovery of fastidious organisms, particularly anaerobic bacteria. Examination of the Gram-stained specimen is useful in judging the adequacy of the specimen and aids in the presumptive etiologic diagnosis. There is also increasing adoption of rapid diagnostics (e.g., peptide nucleic acid fluorescence in situ hybridization [PNA FISH], matrix-assisted laser desorption ionization-time of flight [MALDI-TOF] mass spectrometry, and multiplexed nucleic acid amplification tests) by clinical microbiology laboratories, as these technologies expedite time to organism identification and, when combined with antimicrobial stewardship, improve time to appropriate therapy. Procalcitonin is a serum biomarker that rises with systemic inflammation, especially from bacterial origin, but false-positive and false-negative results can occur, necessitating careful interpretation within the clinical context. Certainly, decisions regarding antimicrobial therapy should not be solely based on procalcitonin levels. In addition, the degree to which procalcitonin rises varies among pathogens, and it is unclear how to interpret results in patients with renal failure, immunocompromised patients, post-surgical patients, and others under severe physiologic stress. That being said, procalcitonin-based algorithms in non–critically ill patients with suspected or proven respiratory infections or critically ill patients with suspected sepsis have been shown to be useful, particularly in guiding early discontinuation of antibiotic therapy.

Further radiographic studies may be needed depending on the clinical situation. Appropriate CT scans should be conducted to locate a deep (i.e., pelvic) source of fever in a postoperative patient who underwent abdominal surgery. Ultrasonographic studies help in evaluating the liver and spleen and the vascular system. Sometimes, gallium scans or indium-labeled white blood cell scans may assist in locating occult foci of infection. Once located, radiographically guided drainage or open drainage of the abscess can be achieved.

In summary, determining the cause of fever in hospitalized patients can be very challenging. Although infection is common, the clinician needs to be aware that hospital-acquired fever may constitute a variety of other conditions.

Transfusion-related infection

William R. Jarvis and Virginia R. Roth

The transfusion of blood and blood components is associated with a very low but ever-present risk of infection. It is estimated that 1 in every 2000 units of blood may carry an infectious agent and that about 4 in 10 000 recipients develop a chronic disease or die as a result of receiving contaminated blood. A wide variety of viral, bacterial, and parasitic agents have been associated with blood transfusion (Box 104.1). Concerns have also been raised about the potential for transmission of Creutzfeldt–Jakob disease (CJD) and its new variant (vCJD) through blood products. However, no human episodes of CJD or vCJD have been definitively linked to blood or blood component transfusion to date, and case–control studies have not found blood transfusion to be a risk factor for CJD. The risk of viral transmission has been markedly reduced with improved screening, particularly using nucleic acid testing (NAT). The risk is now estimated to be 1 in 2 million units for human immunodeficiency virus (HIV) or hepatitis C virus (HCV) and approximately 1 in 200 000 units for hepatitis B virus (HBV). Because the risk of viral or parasitic infection is very low and blood is screened for HCV, HBV, HIV, and human T-cell lymphoma/leukemia virus (HTLV) 1, the remainder of this chapter focuses on bacterial complications of blood transfusion, which can be diagnosed and treated.

Although the rate of bacterial contamination of blood products is unknown, the rate of bacterial infection associated with blood products is estimated to be similar to that of viral infection. The Bacterial Contamination of Blood Products (BaCON) study, a collaboration among the Centers for Disease Control and Prevention (CDC), American Red Cross, American Association of Blood Banks (AABB), and Department of Defense, conducted active surveillance for transfusion-transmitted bacteremia between 1998 and 2000. There were 34 bacteremic episodes and 9 deaths. The rate of transfusion-transmitted bacteremia (events per 106 units) was 9.98 for single-donor platelets, 10.64 for pooled platelets, and 0.21 for red blood cell units; for fatal reactions, the rates were 1.94, 2.22, and 0.13, respectively. The fatality rate associated with transfusion-related sepsis has been estimated to be 1 in 6 million transfused units. Transfusion-transmitted bacterial sepsis is the second most common cause of transfusion-related fatality (after clerical error). Between October 1995 and September 2004, 85 (13%) of 665 transfusion fatalities reported to the Food and Drug Administration were due to bacteria; 58/85 (68%) were due to gram-negative bacteria. In 2008, there were approximately 24 million blood components transfused. During FY2008, there were 46 FDA-reported transfusion-related fatalities, with subsequent reports of 44 in FY2009, 40 in FY2010, and 30 in FY2011. Of these, 5 (11%), 2 (5%), and 4 (13%) in FY 2009, FY2010, and FY2011, respectively, were traced to microbial infection. In FY2010 and FY2011, *Babesia*, *Staphylococcus aureus*, *Escherichia coli*, *Morganella morganii*, and *Klebsiella pneumoniae* accounted for all the fatalities. However, more common nonfatal episodes of transfusion reaction, which may result from bacterial contamination of blood or blood components, often are assumed to be an immune response to transfused leukocytes and are not fully investigated for contamination.

BOX 104.1

Infections transmissible by blood transfusion

Viruses
- Hepatitis
- Hepatitis A virus (HAV)
- Hepatitis B virus (HBV)
- Hepatitis C virus (HCV)
- Hepatitis D virus (HDV)
- Hepatitis E virus (HEV)
- Hepatitis G virus (HGV)
- Cytomegalovirus (CMV)
- Epstein–Barr virus (EBV)
- Nonhepatitis
- HIV-1 and -2
- HTLV-1 and -2
- Human herpesvirus 8 (HHV-8)[a]
- Parvovirus B19
- Colorado tick fever virus
- West Nile virus

- *Toxoplasma* spp.
- *Leishmania* spp.
- Nematode (loasis, other microfilaria)
- *Treponema pallidum* (syphilis)

Abbreviations: HIV = human immunodeficiency virus; HTLV = human T-cell lymphoma/leukemia virus.

[a] Potential risk only, no reported case.

Whole blood and erythrocytes

After collection, whole blood may be maintained at room temperature for ≤8 hours before being stored at 1°C to 6°C (33.8°F to 42.8°F) up to 35 to 42 days, depending on the additives used (Table 104.1). Erythrocytes may be prepared from whole blood at any point during the normal storage period of the whole blood. Then, the erythrocytes may be stored at 1°C to 6°C up to the expiration date of the whole blood unit from which they were prepared. The growth of psychrophilic organisms, such as *Yersinia enterocolitica* or *Pseudomonas* species, is favored by these storage conditions, accounting for most erythrocyte transfusion-related sepsis episodes (Table 104.2). These episodes tend to occur with units that have been stored for >14 to 25 days, which reflects a growth lag of about 7 to 14 days followed by exponential growth of the organism; levels of 10^9 organisms/mL are reached by 38 days, and 315 ng of endotoxin/mL (approximately 4000 EU/mL) by 28 to 34 days. Transfusion of such units can lead to both septic and endotoxic shock.

Platelets

Each year, approximately 9 million platelet-unit concentrates are transfused in the United States. Platelets are stored in oxygen-permeable containers with agitation at 20°C to 24°C (68°F to 75.2°F) for ≤5 days. The most common transfusion-associated infection reported in the United States is bacterial contamination of platelet components. Bacterial contamination is estimated to occur at the incidence rate of 1:1000 to 1:3000 platelet units. Platelet transfusion-related sepsis usually involves common skin organisms, e.g., *Staphylococcus epidermidis, S. aureus*, or other aerobic bacteria that can grow rapidly at room temperature (Table 104.2). Sepsis episodes related to platelet transfusion also tend to occur with units

TABLE 104.1 **BLOOD COMPONENT STORAGE CONDITIONS AND ESTIMATED BACTERIAL CONTAMINATION RATES**

Component	Storage conditions	Estimated contamination rate
Whole blood	≤8 h at room temp	0.03%
CPDA-1	≤35 d at 1°C–6°C	
CPD plus AS	≤45 d at 1°C–6°C	
Packed red blood cells	≤35 d at 1°C–6°C	≤0.5%
CPDA-1	≤45 d at 1°C–6°C	
CPD plus AS		
Platelets	≤5 d at 20°C–24°C	Single donor, ≤2.5% Pooled, ≤10%
Plasma	Frozen, stored ≤18°C	≤0.1%
	For use, thawed and stored ≤24 h at 1°–6°C	

Abbreviations: CPDA = citrate-phosphate-dextrose-adenine (additives); CPD = citrate-phosphate-dextrose; AS = adenine saline (additives).

TABLE 104.2 **REPORTED EPISODES OF TRANSFUSION-ASSOCIATED SEPSIS**

		Duration in days from collection to transfusion	
PATHOGEN	**PERCENTAGE**	**MEDIAN**	**RANGE**
Erythrocytes			
Yersinia enterocolitica	49.0	24	7–41
Pseudomonas fluorescens	23.5	24	16–32
Serratia liquefaciens	7.8	21	17–26
Treponema pallidum	2.0	≤1	–
Pseudomonas putida	2.0	–	–
Other species	15.7	23	20–26
Platelets			
Staphylococcus epidermidis	33.3	4	3–5
Salmonella choleraesuis	11.7	≤1	–
Serratia marcescens	8.3	2	1–3
Staphylococcus aureus	5.0	5	3–6
Bacillus cereus	5.0	–	–
Streptococcus viridans group	3.3	3	1–6
Salmonella enteritidis	3.3	5	3–5
Other species	23.3	4	2–6

that are late in the storage period (around 4 to 5 days), when there may be a higher titer of organisms than early in the storage period. In addition, sepsis episodes occur more frequently with pooled platelet units than with single-donor apheresis units. A pooled platelet unit is prepared by combining 6 to 10 random donor platelet concentrates up to 4 hours before transfusion. In contrast, an apheresis unit is prepared by separating platelets from the whole blood of a single donor and returning other blood components to the donor. The higher rate of sepsis associated with pooled platelets primarily is seen because, on average, pooled platelets are stored longer than apheresis platelets. With pooled platelets, there also is a higher risk of contamination associated with the exposure to multiple donors or with the manipulation of the concentrates. In March 2004, an AABB standard was introduced that required routine quality control testing for bacterial contamination of apheresis platelet products. On January 31, 2011, a new AABB Standard, 5.1.5.1.1, specified that bacterial detection methods for PLT components shall use assays either approved by the Food and Drug Administration (FDA) or validated to provide sensitivity equivalent to these FDA-approved methods. These were implemented in many US and Canadian blood centers and have reduced the risk of platelet-associated bacterial infection.

Plasma and plasma-derived products

Plasma is either collected by apheresis or prepared from whole blood and is stored at below −18°C (−0.4°F) within 6 hours of collection. It can be thawed in a water bath using a plastic overwrap or in a microwave and subsequently stored at 1°C to 6°C up to 24 hours before transfusion. The survival of bacteria is not supported by these storage conditions. However, equipment may carry contamination; for example, one reported episode of sepsis associated with a plasma transfusion was attributed to a contaminated water bath used for thawing the unit.

Contamination of plasma-derived products also is thought to be rare. They are prepared from plasma stored under very stringent conditions, and many of the products also undergo viral inactivation procedures. However, contamination may still occur, as demonstrated by outbreaks of hepatitis C virus infections associated with the administration of contaminated intravenous immunoglobulin or hepatitis A virus associated with plasma-derived products.

Sources of contamination

Contamination of blood or blood components may occur intrinsically if a donor is bacteremic or viremic at the time of donation; it may also occur extrinsically from the skin during phlebotomy or from containers and other equipment used during processing and storage. The infecting organism may reflect the source of contamination. With *Y. enterocolitica*-contaminated erythrocytes, the implicated source is often an asymptomatic episode of gastrointestinal (GI) illness within the previous month. Because the GI illness is usually mild, the donor may not recall or may neglect to report the episode during prescreening.

Clinical management

Although these contamination episodes are rare, it is important to consider the possibility of blood and blood component contamination when a patient develops a fever during or soon after a transfusion (Figure 104.1). If bacteremia cannot be ruled out, the transfusion should be stopped immediately. Any residual blood product or administration set should immediately be quarantined and refrigerated. A Gram-stain and/or acridine orange-stain smear of the blood product should be performed. Stain and/or culture of blood component segments usually are negative, even when the unit itself is positive; this may reflect low-level contamination of the unit at the time of donation. Cultures of the blood product in the bag, the patient's blood before antimicrobials are begun, and any intravenous solution used during transfusion should be obtained promptly. Information about the donor should be reviewed completely. If organisms are recovered from the recipient and blood product, molecular typing of patient and donor isolates may prove causality.

After appropriate cultures are obtained, broad-spectrum empiric antimicrobial therapy should be started. Empiric treatment of suspected sepsis associated with blood products must be based on the component. Because most reported sepsis episodes associated with erythrocyte transfusion have been caused by *Y. enterocolitica* or *Pseudomonas* species, particularly *Pseudomonas fluorescens*, initial therapy may include trimethoprim–sulfamethoxazole or an antipseudomonal β-lactam plus an aminoglycoside. Because infectious complications associated with platelets usually are caused by

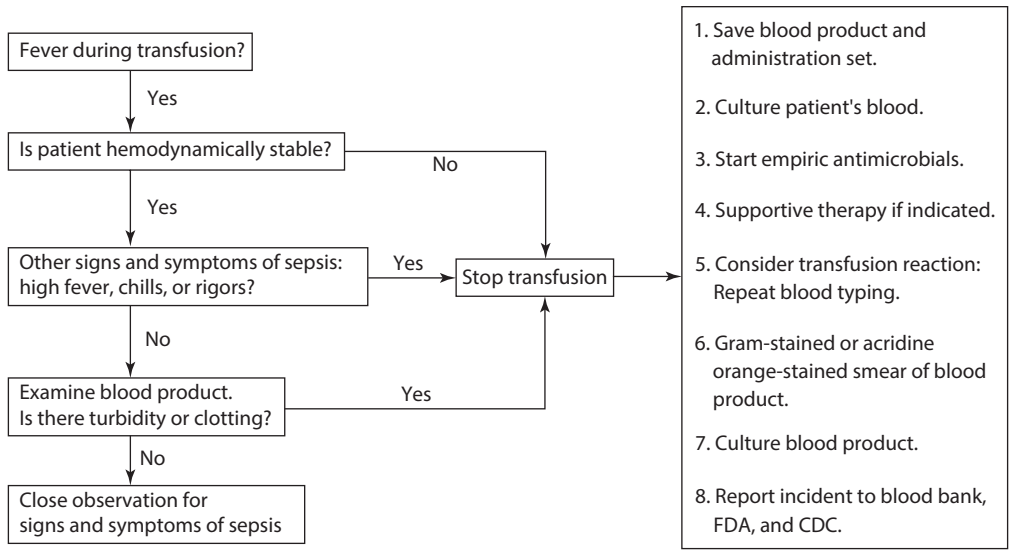

FIGURE 104.1 Management of Fever During Transfusion

aerobic bacteria, e.g., coagulase-negative staphylococci or *S. aureus* and occasionally gram-negative organisms, initial empiric therapy may include a penicillinase-resistant penicillin and an aminoglycoside. Empiric therapy should be narrowed as soon as an infecting pathogen is identified and antimicrobial susceptibility results are available.

Prevention

Sensitive, rapid diagnostic tests for detecting bacterial contamination are not yet available. Therefore, minimizing the risk of transfusion-associated sepsis depends on appropriate donor screening, donor site inspection and preparation, and proper handling of the blood components (Box 104.2). Detection of infectious complications associated with blood products may be increased by educating the medical and blood bank staff about the signs and symptoms of patients with transfusion reactions, the importance of immediately reporting transfusion reactions to the blood bank, promptly culturing the blood of the recipient, promptly performing stains and culture of the blood component, and ensuring quarantined refrigerated storage of the unit and administration set until contamination has been excluded.

BOX 104.2

Prevention of transfusion-associated sepsis

Donors

Screen for infectious diseases (health questionnaire); inquire about travel, behaviors, dental work, signs and symptoms of recent illness

Phlebotomy

Inspect site; avoid dimpled areas of the skin
Prepare site properly
Use aseptic techniques

Bag and component preparation

Use aseptic techniques
Perform proper cleaning and disinfection of processing equipment; use plastic overwraps in water baths for thawing
Use appropriate storage conditions
Visually inspect contents before transfusion

Intravascular catheter-related infection

Johny Fares, Alexandre E. Malek, and Issam I. Raad

Introduction

Central venous catheters (CVC) are essential in securing vascular access for fluids, medications, blood products, total parenteral nutrition (TPN), and hemodialysis. They are employed for both inpatients and outpatients. Central line-associated bloodstream infections (CLABSI) are major healthcare-associated infections, especially in high-risk patients. According to the US Centers for Disease Control and Prevention (CDC), the incidence of CLABSIs has dropped by around 50% between 2008 and 2016. However, according to the National Healthcare Safety Network (NHSN), these infections are still associated with a high mortality rate of 12% to 25% and the high healthcare cost of $45,814 per CLABSI in the United States.

Pathogenesis

Colonization is universal after insertion of a CVC, occurring as early as 1 day after insertion, and is independent of catheter-related infection. Electron microscopy studies of catheter surfaces show that adherent microorganisms can be found in either a free-floating form or a sessile form embedded in a biofilm.

The process of adherence results from the interaction of three factors: intrinsic properties of the catheter, host-derived proteins, and microbial factors. The surface irregularities and charge difference of the catheter facilitate bacterial adherence. Some microorganisms adhere better to polyvinyl chloride, silicone, and polyethylene surfaces than to Teflon polymers and polyurethane. In addition, thrombogenesis is more commonly seen with certain catheter materials that are associated with higher risk of colonization and catheter-related infections. Host factors consisting of plasma proteins such as fibrinogen, fibronectin, laminin, and thrombospondin result in the formation of a thrombin sheath on the internal and external surfaces of the catheter. Then, colonizing microorganisms adhere via secretion of extracellular, polysaccharide-rich material, or glycocalyx, leading to a biofilm formation on the external surface of short-term catheters and internal surface of long-term catheters (dwell time of at least 30 days). This biofilm enables bacteria to adhere to the catheter and resist antibiotics, making their eradication difficult.

Microorganisms colonize vascular catheters through different sources. For short-term catheters, the skin of the site of insertion is the major source for colonization; bacterial skin flora migrate along the external surface of the catheter. The hub of the vascular device is the most common source of colonization for long-term catheters, with microorganisms introduced from the hands of medical personnel. In this case, colonizing bacteria migrate along the internal surface of the catheter. Hematogenous seeding from a secondary source of infection and contamination of the infusate or additives, such as contaminated heparin flush, are rare causes of colonization and infection of vascular devices.

Other CLABSI risk factors: femoral catheterization has higher rates of infections and thrombotic complications than subclavian catheterization and, compared to gauze dressing, transparent occlusive dressing is associated with significantly increased rates of insertion site colonization, local catheter-related infection, and CLABSI when CVCs remain for >3 days.

The causative microorganisms associated with CLABSI are primarily gram-positive bacteria, followed by gram-negative bacteria and *Candida* spp. Skin flora such as *Staphylococcus epidermidis* and *S. aureus* remain the predominant source of CLABSI, followed by *Enterococcus faecalis*, *Klebsiella* spp. (*pneumoniae/oxytoca*), *Enterococcus faecium,* and *Escherichia coli.* Microorganisms that contaminate the hands of medical personnel, such as *Pseudomonas, Acinetobacter, Stenotrophomonas maltophilia*, and *Candida* are also common causative organisms. Emerging pathogens such as *Achromobacter*, rapidly growing mycobacteria (*M. chelonae* and *M. fortuitum*), and fungal elements such as *Fusarium, Malassezia furfur*, and *Rhodotorula* spp. have been described in *specific* conditions (i.e., hyperalimentation, interleukin-2 therapy).

Organisms such as *E. coli*, *Enterococcus faecium*, and *Streptococci viridans* are more commonly seen in oncology patients as compared to non-oncology patients. This predominance is attributed to the mucosal barrier injury seen in cancer patients, leading to the translocation of these organisms from the gastrointestinal tract.

Clinical manifestations and diagnosis

The clinical presentation of CLABSI consists of nonspecific systemic signs and local manifestations at the skin insertion site.

The systemic features include fever and chills, which may be accompanied by hypotension, hyperventilation, altered mental status, and nonspecific gastrointestinal manifestations such as nausea, vomiting, abdominal pain, and diarrhea. Deep-seated infections such as endocarditis, osteomyelitis, retinitis, and organ abscess may complicate CLABSI caused by virulent organisms such as *S. aureus*, *Pseudomonas aeruginosa*, and *Candida albicans*. Local manifestations are neither sensitive nor specific. On one hand, they may be absent, especially in immunocompromised patients. On the other hand, peripherally inserted central catheter (PICC) lines may produce sterile exit site inflammation (26%).

The CDC and the Infectious Diseases Society of America (IDSA) definitions of intravascular catheter-related bloodstream infections (CRBSI) are summarized in Table 105.1.

The CLABSI definition may lack specificity. For example, in some cancer patients, particularly those with compromised mucosal barrier, some laboratory-confirmed bloodstream infections (LCBI) that are labeled CLABSI may have resulted from bacteria translocation from the gastrointestinal tract. To distinguish LCBI related to central lines from those due to unapparent sources, the CDC developed a new definition termed mucosal barrier injury LCBI (MBI-LCBI) whereby a recognized intestinal organism is cultured from the blood of patients with clues to mucosal barrier injury such as gastrointestinal graft-versus-host disease, diarrhea, or neutropenia.

CRBSI as defined by the IDSA more specifically identifies the CVC as the source of the bacteremia.

Preventive strategies

CVCs should only be used when medically necessary and should be removed as soon as possible. The subclavian site is preferred for non-tunneled CVC. Femoral sites should be avoided in adult patients.

TABLE 105.1 **DIAGNOSIS OF CENTRAL LINE-ASSOCIATED BLOODSTREAM INFECTION (CLABSI) ACCORDING TO THE CENTERS FOR DISEASE CONTROL AND PREVENTION (CDC) DEFINITION AND INFECTIOUS DISEASES SOCIETY OF AMERICA (IDSA) 2009 GUIDELINES FOR THE DIAGNOSIS AND MANAGEMENT OF INTRAVASCULAR CATHETER-RELATED INFECTIONS**

CDC definition of central line-associated bloodstream infections (CLABSIs)[a]	IDSA 2009 definition of intravascular catheter-related bloodstream infection (CRBSI)
Patient has a CVC that was in place for >2 days and CVC was present on the date of the LCBI or the day before. In addition, the LCBI must not be related to an infection at another site and must meet one of the following criteria: • A recognized pathogen cultured from one or more blood cultures • A common skin contaminant cultured from *two* or more blood cultures drawn on separate occasions within 2 days of each other and at least *one* of the following clinical signs or symptoms: fever (>38°C/100°F), chills, or hypotension *and* signs and symptoms • For patient ≤1 year of age, a common skin contaminant is cultured from two or more blood cultures drawn on separate occasions within 2 days of each other and the patient has at least one of the following clinical signs or symptoms: fever (>38°C/100°F core), hypothermia (<36°C/97°F core), apnea, or bradycardia	• **Diagnostic method sparing the catheter**: A definite CRBSI requires one of the following to be present: • The same organism is cultured from two simultaneous quantitative blood cultures drawn from the catheter and peripheral site with a CVC/peripheral colony count ratio ≥3:1 • The differential time to positivity of at least 2 hours (microbial growth from blood drawn from a catheter is detected at least 2 hours before microbial growth from blood drawn from the peripheral site) • **Diagnostic method implicating catheter removal**: A definite CRBSI requires that the same organism is cultured from at least one percutaneous blood culture and from a culture of the catheter tip (in semiquantitative catheter culture ≥15 CFU per catheter segment, or in quantitative catheter culture ≥10^2 CFU per catheter segment)

[a] CDC definition of CLABSI does not require catheter removal.
Abbreviations: CVC = central venous catheter, LCBI = laboratory-confirmed bloodstream infection.

Guidelines for the prevention of intravascular catheter-related infections emphasize the importance of educating and training healthcare personnel who insert and maintain catheters. Hand hygiene with soap and water or alcohol-based rubs should be performed before and after inserting, replacing, accessing, or dressing a CVC. The use of maximal sterile barrier precautions that includes the use of a cap, mask, sterile gown, and a sterile full body drape is recommended for CVC insertion.

Skin cleansing using chlorhexidine preparation before CVC insertion reduces the risk of CVC colonization and CLABSI. Alternatively, tincture of iodine or 70% alcohol could be used when chlorhexidine is contraindicated.

Dressing choice may vary: sterile, transparent dressing allows visual monitoring of the CVC and requires less frequent changes than sterile gauze. The use of chlorhexidine-impregnated dressing is recommended in patients >2 months of age, for short-term catheters. Regular monitoring of CVC by visual inspection or by palpation through the dressing is recommended.

Antimicrobial-coated catheters have also been introduced to reduce the incidence of CLABSIs. They are recommended by the CDC for prevention of catheter-related infections for CVCs that are expected to remain in place for >5 days if rates of CLABSI remain elevated despite the implementation of aseptic techniques including maximal sterile barrier precautions. CVCs coated with minocycline and rifampicin (M-R) were found to be the most successful in doing so. They provide an antimicrobial protection for several weeks (28–50 days) and were shown to decrease the incidence of CLABSI in cancer patients with no increase in the rate of resistance of staphylococcal species against minocycline and rifampicin. Chlorhexidine-/silver sulfadiazine-coated catheters could also be used. However, they provide a shorter duration of protection and a 12-fold lower reduction in CLABSI incidence compared to the M-R coated catheters.

Antimicrobial catheter lock and flush solutions are recommended by CDC in patients who have long-term catheters and a history of multiple CRBSIs. Catheter lock solution technique consists of flushing the catheter lumen and then filling it with 1 to 3 mL of a combination of an anticoagulant plus an antimicrobial agent. The lock dwell time in the lumen of the CVC may vary from 2 to 12 hours depending on the solution. Initially, heparin was widely used as an antithrombotic agent to maintain catheter patency, but it has been shown to enhance staphylococcal biofilm formation at the concentration of 1,000 U/mL used in catheter locks. Currently, other chelators, such as citrate and ethylenediamine-tetraacetic acid (EDTA) are widely used as a component of catheter lock solutions due to their very potent anticoagulant effect, their ability to prevent the biofilm formation, and their synergistic antimicrobial activity. A minocycline-EDTA combination was shown to be very effective in preventing CLABSIs in patients with long-term CVCs, especially in cancer patients and hemodialysis patients. Nitroglycerin-citrate-ethanol (NiCE) lock solution is also effective in reducing the rate of CLABSI as shown by multiple in vitro and in vivo studies. With the emergence of resistant microorganisms, such non-antibiotic antimicrobial lock solutions are preferred over antibiotic lock solutions as CLABSI prophylaxis. In addition, many studies showed that they are superior to the antibiotic lock solutions in preventing CLABSIs. For example, Minocycline and EDTA (M-EDTA) solution was superior to vancomycin–heparin lock solution, both in an in vitro biofilm model and an animal model.

The CDC does not recommend routine catheter exchange and guidewire exchange as CLABSI preventive measures. However, the guidewire may be used to (1) replace a malfunctioning catheter, (2) convert an existing catheter to a different type, and (3) salvage the vascular access as an alternative strategy in patients with limited venous access along with the use of systemic antimicrobial therapy.

A summary of the preventive strategies are listed in Box 105.1.

Therapy

After confirming that the catheter is the source of the bloodstream infection, treatment of CLABSI involves catheter management (removing, exchanging, or salvaging the line) and systemic antimicrobial therapy. A summary of therapies are listed in Table 105.2.

Catheter management

Catheter removal is the most popular approach in the management of catheter-related infections. The IDSA recommends the removal of long-term catheters (indwelling for ≥14 days) in patients with

BOX 105.1

Measures for the prevention of central line-associated bloodstream infection (CLABSI)

- **Traditional measures:**
- Education of healthcare personnel on vigilant catheter insertion and care
- Use the subclavian vein as the preferred insertion site for nontunneled CVCs and avoiding femoral insertions
- Hand hygiene
- Use of maximal sterile barrier precautions during CVC insertion (includes the use of a cap, mask, sterile gown, and a sterile full body drape)
- Skin cleansing using chlorhexidine before CVC insertion
- Skilled infusion therapy team
- Removal of unnecessary CVCs
- **Novel technology:**

Strongly recommended or well-supported evidence:

- Antimicrobial coating of catheters particularly if the catheter is expected to remain in place >5 days
- Prophylactic antimicrobial catheter lock solutions particularly in patients who have long-term catheters and a history of multiple CLABSI
- Chlorhexidine bathing
- Topical antibiotics at the insertion site, only for hemodialysis patients

Abbreviation: CVC = central venous catheter.

TABLE 105.2 **MANAGEMENT OF CATHETER-RELATED INFECTIONS**

Microorganism	Duration of systemic therapy	Catheter management
Coagulase-negative staphylococci		Catheter removal or salvage
CVC removed	5–7 d	
CVC retained	10–14 d	
Staphylococcus aureus		Catheter removal
Uncomplicated	14 d	
Complicated If catheter retained	4-6 wk 4 wk	
Gram-positive bacilli	7 d	Catheter removal. Could attempt salvage
Enterococcus	7-14 d	Catheter removal. Could attempt salvage
Gram-negative rods	7–14 d	Catheter removal. Could attempt salvage depending on the causative organism.
***Candida* species**		Catheter removal
Uncomplicated	14 d	
Complicated	6 wk	
Mycobacterium	14 d	Catheter removal

Abbreviation: CVC = central venous catheter.

complicated CRBSI (severe sepsis, suppurative thrombophlebitis, endocarditis); in cases of persistent bloodstream infection after >72 hours of antimicrobial therapy to which the infecting microbes are susceptible; or if the causative organism is *S. aureus, P. aeruginosa*, a fungus, or a mycobacterium. Short-term catheters (indwelling <14 days) should be removed if the causative organism is a gram-negative bacilli, *S. aureus*, enterococci, fungi, or mycobacteria.

However, catheter removal and replacement is costly, and it is associated with many complications in high-risk patients (e.g., cancer patients and hemodialysis patients, who are often thrombocytopenic and have limited vascular access). Catheter salvage, when possible, can reduce the risks and cost associated with catheter removal. In fact, IDSA guidelines recommend catheter salvage in patients with uncomplicated long-term catheter-related bloodstream infections who have limited vascular access that is critical for their survival.

Antimicrobial lock therapy is an effective alternative. It consists of locking a highly concentrated antibiotic-based solution into the infected line for several hours daily. Many lock solutions have been tried. Some were found to be ineffective, such as vancomycin-based lock solutions that were associated with high risk of failure, especially with *S. aureus*. New lock solutions, such as ethanol (25%)-minocycline-EDTA combination, show very promising results in vitro and clinically and have been shown to eradicate multidrug-resistant (MDR) organisms (i.e., methicillin-resistant *S. aureus* [MRSA], ESBL gram-negative organisms) and *Candida* spp.

Catheter exchange over a guidewire is also an available alternative for the management of the CVC in CRBSI. Using an antibiotic-coated catheter for such an exchange could improve the overall outcome of CLABSI. Multiple studies showed that catheter exchange over guidewire using minocycline-rifampicin–coated CVC may improve the overall response rate and prevent cross-contamination during the exchange procedure.

Systemic therapy

The choice and duration of antibiotic therapy depend on many factors such as the causative organism and its antibiotic susceptibility, presence or absence of any deep-seated infections, and the management of the catheter itself. Most of the CLABSIs will be treated for a period of 5 to 14 days, depending on the isolated microorganisms. However, in cases of complicated CLABSI (i.e., septic thrombophlebitis, endocarditis, or metastatic infection) or if the CLABSI persists beyond 72 hours of initiation of appropriate antimicrobial therapy, the vascular catheter should be removed and the infection should be treated with parenteral antibiotics for at least 4 weeks.

When determining the duration of antimicrobial therapy, the first day on which blood cultures are negative is counted as day 1.

Coagulase-negative staphylococci

Coagulase-negative staphylococcus (CoNS) is the most common causative organism of CLABSI. However, due to the high contamination rate of blood cultures by this organism, a single positive blood culture growing CoNS is not enough to prove a true bloodstream infection. The IDSA recommends obtaining additional blood cultures from the CVC and peripheral vein to prove that it is a true CoNS bloodstream infection rather than a contamination. Once proved, the usual management is catheter removal and systemic therapy. Because most CoNS are nosocomially acquired and are resistant to penicillins, the choice of a glycopeptide (i.e., vancomycin) is recommended pending susceptibility. Antibiotic therapy is then tailored according to the susceptibility testing. Methicillin-susceptible CoNS are treated with nafcillin or oxacillin (first-generation cephalosporins are a good alternative), whereas methicillin-resistant CoNS are treated with vancomycin. Daptomycin or quinupristin-dalfopristin could be used as alternative antimicrobial agents. Duration of therapy is usually 5 to 7 days if the catheter is removed and there is no complications. If the catheter is retained, treatment should be for 10 to 14 days, and the catheter should be treated with an antibiotic lock solution. For patients with an endovascular implant or orthopedic hardware, the catheter is usually removed and a systemic therapy of at least 14 days is recommended. However, if the catheter is retained in this group of patients, 14 to 21 days of antimicrobial therapy is recommended. Note that *Staphylococcus lugdunensis* CRBSI could lead to serious complications such as endocarditis and thus should be managed in same way as *S. aureus* CRBSI.

Staphylococcus aureus

According to the CDC vital signs report, the rate of CLABSI caused by *S. aureus* in the ICU was reduced by 73% between 2006 and 2011. However, *S. aureus* CLABSI is still common and is associated with high rates of deep-seated infection such as osteomyelitis, septic phlebitis, and endocarditis. Management usually consists of line removal and systemic antibiotic therapy. Failure to remove the catheter is associated with persistent bacteremia, relapse, and increased mortality. The CVC should be removed unless there are major contraindications, in which case the patient should either receive an antibiotic lock therapy or have his or her CVC exchanged over a guidewire with an antimicrobial-impregnated CVC, along with 4 weeks of systemic antimicrobial therapy. For methicillin-sensitive *S. aureus*, nafcillin or a first-generation cephalosporin is the first choice. Vancomycin, daptomycin, or quinupristin-dalfopristin could be used for the treatment of MRSA. Strains resistant to linezolid have been reported.

A14 days course of intravenous therapy is enough if the CVC is removed, no deep-seated infection is present, follow-up blood cultures after 48 to 96 hours of the initiation of the antibiotic therapy are negative, and the patient defervesced within 48 to 72 hours of therapy. If fever or bacteremia persists for >72 hours or if the patient has another prosthetic device or there is evidence of endocarditis, suppurative thrombophlebitis, or metastatic infection, the intravenous therapy duration should be expanded to at least 4 to 6 weeks.

Echocardiography should be performed for all patients with *S. aureus* CLABSI, starting with transthoracic echocardiography (TTE) and proceeding to transesophageal echocardiography (TEE) if a vegetation is identified on TTE. However, TTE is not enough to rule out infective endocarditis, particularly for those with persistent fever or bacteremia beyond 72 hours of initiation of antimicrobial therapy.

Gram-positive bacilli

Vancomycin remains the antibiotic of choice in the treatment of CLABSI caused by gram-positive bacilli such as *Bacillus* and *Corynebacterium* species. Removal of the catheter is recommended.

Enterococcus

CRBSI caused by enterococcus is usually managed with catheter removal and systemic antibiotic therapy. However, catheter salvage using an antibiotic lock therapy is an alternative as long as there are no associated complications (i.e. deep-seated infections, persistent bacteremia, catheter site inflammation signs). The duration of systemic therapy for uncomplicated CRBSI is 7 to 14 days, independently of the catheter management. The choice of antibiotic depends on the susceptibility of the organism; ampicillin for susceptible enterococci and vancomycin for resistant organisms.

Gram-negative bacilli

Over the past decade, the incidence of CLABSI caused by gram-negative rods has increased, especially in cancer patients. The most common gram-negative organisms associated with CLABSI are *Klebsiella pneumoniae, Enterobacter* spp., *P. aeruginosa, Acinetobacter* spp., and *Stenotrophomonas maltophilia*. Management involves catheter removal and systemic antibiotic therapy for 7 to 14 days. Salvaging the catheter with an antibiotic lock solution could be attempted in cases of uncomplicated CLABSI. High-risk patients (i.e., previous history of MDR bacteremia, neutropenia, and previous antibiotic therapy) should be started on empiric antibiotic therapy that covers MDR gram-negative organisms; these include fourth-generation cephalosporin, β-lactam/β-lactamase inhibitors, or carbapenem with or without aminoglycoside. A combination of two antibiotics as empiric therapy for high-risk patients is an alternative. Trimethoprim-sulfamethoxazole is the drug of choice for *S. maltophilia* CLABSI.

Candida

IDSA guidelines recommend removing the CVC and treating for 14 days after the first negative blood culture in uncomplicated cases of *Candida* infection. Endophthalmitis (15% of untreated cases) merits 6 weeks of therapy. Fluconazole or echinocandin (caspofungin, micafungin, or anidulafungin) should be considered in documented cases of catheter-related candidemia. If the rates of fluconazole-resistant *C. glabrata* and *C. krusei* in the hospital are high, or the patient was exposed to azoles in the previous 3 months, an echinocandin is the drug of choice.

Mycobacterial disease

Catheter removal is recommended and surgical intervention may be needed in long-term catheters infected with *M. chelonae* or *M. fortuitum*. A 14-day course of antimicrobials is suggested. However, a longer duration of therapy is required in complicated cases.

Infections associated with urinary catheters

Lindsay E. Nicolle

Urinary tract infections (UTIs) are a common and clinically important outcome of the use of urinary catheters. Urinary catheters may be (1) short-term (<30 days) indwelling urethral catheters, (2) long-term (>30 days) indwelling urethral or suprapubic catheters, or (3) used for intermittent catheterization. UTI with a catheter in situ is usually asymptomatic and referred to as *catheter-associated asymptomatic bacteriuria* (CA-ASB). Symptomatic infection is referred to as *catheter-acquired urinary infection* (CA-UTI). Different types of catheter are indicated for different populations and have different risks for the occurrence of infection (Table 106.1).

Pathogenesis

Acquisition of urinary infection with catheter use is virtually always through ascending infection (Box 106.1). For indwelling urethral catheters, bacteria usually ascend into the bladder on the biofilm that forms on the external and internal surfaces of the catheter tubing but may also ascend through reflux of contaminated urine up the drainage tubing. Disruption of the closed drainage system from the bladder to the drainage bag may also introduce bacteria, and there is a high incidence of new bacteriuria which develops within 24 hours following such a break in the system. Bacteria introduced at the time of catheterization account for <5% of infections.

Bacteriuria is a predictable consequence when an indwelling catheter remains in situ for a long enough time. The likelihood of developing bacteriuria is 3% to 7% per day while the catheter remains in situ. The determinants of symptomatic infection are not well described, but trauma to the mucosa or catheter obstruction may precipitate CA-UTI.

With intermittent catheterization, organisms are repeatedly introduced into the bladder at catheterization. Individuals managed with intermittent catheterization usually have a neurogenic bladder with incomplete bladder emptying so organisms, once introduced, may persist in the bladder. The organisms that cause bacteriuria are usually present as colonizing bacteria in the periurethral area but may also be introduced by contamination of the catheter or on the hands of the individual performing catheterization.

Bacteriology

Urinary infection identified in the setting of urethral catheterization is considered complicated UTI. *Escherichia coli* remains an important pathogen in these infections, but other organisms are also frequently isolated. These include other Enterobacteriaceae such as *Klebsiella pneumoniae*, *Citrobacter* spp., *Enterobacter* spp., and *Serratia marcescens*. For long-term indwelling catheters, in particular, infections with urease-producing organisms such as *Proteus mirabilis*, *Morganella morganii*, or *Providencia stuartii* are common. *Pseudomonas aeruginosa* and other gram-negative nonfermenters such as *Acinetobacter* spp. may be isolated, as well as gram-positive organisms, particularly enterococci and coagulase-negative staphylococci.

TABLE 106.1 **TYPES OF CATHETER USE AND FREQUENCY OF URINARY INFECTION IN CATHETERIZED POPULATIONS**

Catheter	Usual population	Infection rate
Indwelling urethral		
Short-term	Acute-care facility	5% per day
	Output monitoring	Women > men
	Postsurgical	
	Acute retention	
Long-term	Long-term care:	100% prevalence
	5–10% of residents	
	Chronic retention—men	
	Healing of pressure ulcer	
Intermittent catheter	Neurogenic bladder	1–3% per
	Spinal cord injury	catheterization
	Multiple sclerosis	
	Other impaired bladder emptying	

Candida albicans and other yeast species also occur, usually isolated from subjects receiving antimicrobials. The high frequency of recurrent infection and repeated courses of antimicrobials promote the emergence of more resistant organisms.

Polymicrobial bacteriuria is characteristic of infection in subjects with long-term indwelling catheters but may also occur with other types of catheterization. Long-term indwelling catheters or short-term catheters in situ for more than a few days are covered with a bacterial biofilm on both interior and external surfaces. This biofilm is composed of microorganisms, bacterial extracellular glycopolysaccharides, and protein and minerals incorporated from the urine. There is a complex microbial flora with multiple organisms growing in the biofilm; usually two to five organisms are present in a mature biofilm. The biofilm is an environment within which microorganisms are relatively protected from both antimicrobials and the host inflammatory and immune response. Urine specimens obtained for culture through the biofilm-laden catheter are contaminated by organisms present in the biofilm which may not be present in bladder urine. The number, type, and quantity of organisms isolated from these specimens may differ from a specimen of simultaneous bladder urine.

BOX 106.1

Methods by which organisms gain access to the bladder in catheter-acquired urinary infection

Ascending infection

- Introduced when the catheter is placed in the bladder
- Ascending from periurethral area on biofilm on mucous sheath on external catheter surface
- Ascending from interior drainage bag or tubing on biofilm
- Intraluminal from drainage bag with urine reflux
- Introduced with breaks in closed drainage

Other (uncommon)

- Hematogenous from another body site

Morbidity and mortality

Most catheter-acquired urinary infections are asymptomatic. However, catheterized subjects are at risk for increased morbidity from symptomatic UTI. Pyelonephritis, fever, and bacteremia may require hospitalization or result in extended hospitalization when nosocomially acquired. Local complications including prostatitis and epididymitis, purulent urethritis, urolithiasis, and urethral abscesses may occur. Crystalline biofilm formed by urease-producing organisms, principally *P. mirabilis*, is the most common cause of catheter obstruction. Acute urinary infection in subjects with spinal cord injury or other neurologic diseases may present as increased lower limb spasticity or autonomic hyperreflexia. Urinary infection in residents with chronic indwelling urethral catheters is the most frequent cause of bacteremia in long-term care facilities, with these residents experiencing three times the incidence of fever as bacteriuric long-term care facility residents without an indwelling catheter. Occasionally, acute urosepsis occurs, but mortality directly attributable to urinary infection is uncommon relative to the high frequency of bacteriuria.

Diagnosis

A diagnosis of urinary infection in a catheterized patient requires microbiologic confirmation. Clinical findings will then determine whether infection is symptomatic or asymptomatic. Culture of an appropriately collected urine specimen is essential. The specimen must be collected before antimicrobial treatment is initiated. It may be obtained directly at the time catheterization is initiated, by intermittent catheterization, from a newly placed catheter in subjects with long-term indwelling urethral catheters, or by aspiration from the catheter port of a short-term indwelling catheter. Quantitative criteria for the microbiologic diagnosis of urinary infection are shown in Table 106.2. Lower quantitative counts in subjects with indwelling catheters often reflect contamination from catheter biofilm rather than bladder bacteriuria.

A diagnosis of symptomatic urinary infection requires a positive urine culture. However, a positive urine culture is common in catheterized patients at any time. Patients with short-term indwelling catheters have an increasing prevalence of bacteriuria the longer the catheter remains in situ; those maintained on intermittent catheterization have a prevalence of about 50% at any time. Virtually all individuals with chronic long-term indwelling catheters are persistently bacteriuric. Thus, although a positive urine culture is necessary for diagnosis of urinary infection, it is not sufficient to identify symptomatic infection—clinical symptoms must also be present.

TABLE 106.2 **MICROBIOLOGIC DIAGNOSIS OF URINARY INFECTION IN SUBJECTS WITH CATHETER**

Clinical presentation	Quantitative count of bacteria
Asymptomatic	$\geq 10^5$ CFU/mL single specimen
Symptomatic	
In and out catheter	$\geq 10^2$ CFU/mL[a]
Indwelling catheter	$\geq 10^5$ CFU/mL

[a] Including subjects with intermittent catheterization.
Abbreviation: CFU = colony-forming unit.

Clinical presentations consistent with urinary infection are listed in Box 106.2. Localizing genitourinary symptoms or signs such as flank pain and tenderness, fever with an obstructed catheter, acute hematuria, or recent catheter trauma support a diagnosis of symptomatic urinary infection with a high degree of confidence. However, most patients with indwelling catheters and symptomatic urinary infection will not have localizing genitourinary symptoms. A frequent clinical scenario is fever and a positive urine culture without localizing findings to the genitourinary tract or another potential site of infection. Catheterized patients often present with fever alone as a manifestation of urinary infection, but other potential sources must always be considered. In one study of subjects with long-term indwelling catheters, only 33% of such episodes were confirmed to be due to a urinary source. Thus, in the absence of localizing genitourinary findings or bacteremia with the urinary isolate, symptomatic urinary infection is a diagnosis of exclusion.

BOX 106.2

Clinical presentations of acute urinary infection in subjects with bladder catheters

Asymptomatic
Symptomatic
Systemic
- Acute pyelonephritis
- Fever with catheter obstruction
- Fever with acute hematuria
- Bacteremia with urinary isolate
- Increased lower leg spasms or autonomic hyperreflexia in spinal cord injury
- Fever without genitourinary localizing findings and no alternate source (≤50% urinary source)

Local[a]
- Urethritis
- Epididymitis
- Urethral abscess
- Bladder or kidney stones
- Catheter obstruction
- Prostatitis
- Scrotal abscess

[a] Local complications are primarily seen with long-term indwelling urethral catheters.

Pyuria is a universal accompaniment of bacteriuria in individuals with indwelling catheters and is also present in most bacteriuric patients who use intermittent catheterization. Pyuria may also be present in the absence of bacteriuria due to irritation of the bladder by the catheter. The presence of pyuria or level of pyuria associated with bacteriuria has not been shown to have any prognostic clinical significance. Thus, pyuria is insufficient to make a diagnosis of urinary infection, and the presence of pyuria is not, by itself, an indication of symptomatic infection.

Treatment

Treatment of asymptomatic bacteriuria is not indicated for subjects managed by intermittent catheterization or with an indwelling urethral catheter. For subjects with long-term indwelling catheters, antimicrobial treatment of CA-ASB does not decrease the frequency of subsequent symptomatic episodes but leads to recurrent bacteriuria with more resistant bacteria. As previously noted, pyuria by itself or with bacteriuria is not an indication for treatment in an individual who is asymptomatic. For women, if catheter-acquired bacteriuria persists for 48 hours after removing a short-term indwelling catheter, treatment may be indicated. This clinical question has not been addressed for men, and no definitive recommendation can be given.

When symptomatic infection is diagnosed clinically, a urine specimen for culture should be obtained in every case before initiation of antimicrobial therapy. For individuals with catheters in situ for ≥2 weeks, the catheter should be replaced and a specimen for culture obtained from the newly placed catheter before initiating antimicrobial therapy. This allows collection of a urine specimen that is representative of bladder organisms without biofilm contamination. Replacing the catheter immediately prior to antimicrobial therapy has also been shown to shorten the time to defervescence and decrease the likelihood of symptomatic relapse in short-term follow-up. It is assumed that these beneficial effects result from removal of the biofilm with its high concentration of organisms. For short-term indwelling catheters where mature biofilm formation is less likely, catheter replacement prior to initiating antimicrobial therapy is not recommended.

Oral antimicrobials appropriate for treatment of urinary infection are listed in Table 106.3, and parenteral antimicrobials are listed in Table 106.4. Parenteral therapy should be initiated in patients who are hemodynamically unstable, are vomiting or otherwise unable to take oral medications, have impaired gastrointestinal absorption, or have a high likelihood of being infected with an organism resistant to oral agents.

If symptoms are mild but persistent, antimicrobial therapy should not be initiated until the urine culture results are available. This allows for selection of antimicrobial therapy specific for the infecting organism. Empiric antimicrobial therapy should be initiated pending urine culture results when a patient is significantly ill with fever or other systemic symptoms or when the patient has other severe symptoms attributable to urinary infection.

TABLE 106.3 **ORAL ANTIMICROBIALS FOR TREATMENT OF URINARY TRACT INFECTION IN CATHETERIZED PATIENTS WITH NORMAL RENAL FUNCTION**

Antimicrobial	Dosage
Penicillins	
Amoxicillin	500 mg TID
Amoxicillin-clavulanic acid	500/125 mg TID or 875/125 mg BID
Cephalosporins	
Cephalexin	500 mg QID
Cefaclor	500 mg QID
Cefadroxil	1 g OD or BID
Cefuroxime axetil	250 mg BID
Cefixime	400 mg OD
Cefpodoxime proxetil	100–400 mg BID
Fluoroquinolones[a]	
Norfloxacin	400 mg BID
Ciprofloxacin	250–500 mg BID
Ofloxacin	200–400 mg BID
Levofloxacin	250–500 mg OD
Other	
Nitrofurantoin	50–100 mg QID
Trimethoprim	100 mg BID
Trimethoprim–sulfamethoxazole	160/800 mg BID

[a] Recommended for oral empiric therapy.

TABLE 106.4 **PARENTERAL ANTIMICROBIALS FOR TREATMENT OF URINARY TRACT INFECTION IN INDIVIDUALS WITH NORMAL RENAL FUNCTION**

Antimicrobial	Dosage
Aminoglycoside	
Amikacin[a]	5 mg/kg q8h or 15 mg/kg q24h
Gentamicin[a]	1–1.5 mg/kg q8h or 4–5 mg/kg q24h
Tobramycin[a]	1–1.5 mg/kg q8h or 4–5 mg/kg q24h
Penicillin	
Ampicillin	1–2 g q6h
Piperacillin	3 g q4h
Piperacillin/tazobactam	4 g/500 mg q8h
Ticarcillin/clavulanic acid	50 mg/kg q6h
Cephalosporins	
Cefazolin	1–2 g q8h
Ceftriaxone	1–2 g q24h
Cefotetan	1 g q12h
Cefotaxime	1–2 g BID or TID
Cefepime	2 g q12h
Ceftazidime	0.5–2 g q8h
Ceftazidime-avibactam	2g/500 mg q8h
Ceftolozane-tazobactam	1.5g q8h
Other	
Aztreonam	1 g q6h
Imipenem/cilastatin	500 mg q6h
Ertapenem	1g q24h
Meropenem	500 mg q8h
Doripenem	500 mg q8h
Vancomycin	500 mg q6h or 1 g q12h

[a] Recommended for initial empiric therapy with ampicillin if renal function is normal.

The selection of initial empiric therapy should consider recent antimicrobial therapy prescribed to the patient; bacteriology and susceptibilities of previous urine cultures from the patient, when available; and resistance patterns of endemic flora in an institution in addition to patient tolerance. An aminoglycoside, with or without ampicillin for enterococci, is usually appropriate for initial empiric parenteral therapy. In the presence of moderate to severe renal failure, an extended-spectrum β-lactam antimicrobial or fluoroquinolone may be preferred rather than an aminoglycoside. When there is a concern about resistant organisms, alternative empiric therapy with coverage specific for the expected susceptibilities should be selected. Once urine culture and susceptibility results from the pretherapy urine specimen are available, usually 48 to 72 hours after initiation of therapy, the antimicrobial regimen can be reassessed and, if appropriate, changed to alternative specific therapy. This should include a change to oral therapy, whenever possible, for patients in whom parenteral therapy was initiated.

If the patient continues to require an indwelling catheter, the treatment duration should be for as short a period as possible (5–7 days). Longer courses of therapy will promote the emergence of organisms of increasing resistance, potentially increasing the difficulty in treating future episodes of symptomatic infection. If the catheter is removed, 7 to 14 days of therapy should be given. For subjects managed with intermittent catheterization, 7 days is recommended for lower tract symptoms and 10 to 14 days for systemic infection.

Prevention

The most effective means of preventing catheter-associated infection is not to use a catheter or, if there is a clear clinical indication for use, to limit the duration of catheterization to as short a period as possible (Box 106.3). When feasible, alternate strategies to

BOX 106.3

Prevention of catheter-acquired urinary tract infection

Effective

- Restrict indications for catheter use
- Limit duration of catheter use
- Daily review of continuing need for catheter
- Aseptic insertion (for indwelling catheter)
- Maintain closed drainage system
- Antibiotics first 4 days (not recommended)[a]
- Antibiotics at removal (not recommended)[a]

Not effective

- Bladder irrigation with antimicrobial
- Periurethral care with soap or disinfectant
- Routine catheter replacement
- Disinfectant in drainage bag
- Coating of catheter with antimicrobial substances[b]
- Antimicrobial prophylaxis

[a] Not recommended because of emerging antimicrobial resistance.

[b] Nitrofurazone coating may decrease symptomatic infection but has increased adverse effects.

manage voiding, such as a condom catheter for men, should be used. For short-term indwelling catheters, the maintenance of a closed drainage system is important in delaying acquisition of infection. Antimicrobial therapy given during the first 3 days of catheterization or at the time of catheter removal is associated with a decreased frequency of infection. However, these antimicrobial strategies are not recommended because they are associated with an increased frequency of reinfection with more resistant organisms. Other interventions that have been systematically evaluated, such as daily periurethral cleaning with either soap or a disinfectant and addition of disinfectants to the drainage bag, are not effective in decreasing the frequency of symptomatic infection.

It is not clear that any interventions will decrease the frequency of bacteriuria in subjects with chronic indwelling urethral catheters. Preventive strategies in these patients must focus on limiting symptomatic infection through early identification of catheter obstruction and prevention of catheter trauma to the genitourinary mucosa. Routine replacement of chronic indwelling catheters is not recommended. The catheter should be replaced only if there is obstruction or other catheter malfunction or prior to treatment of symptomatic urinary infection.

For spinal cord-injured patients managed with intermittent catheterization, use of prophylactic antimicrobials may decrease the frequency of infection in the early postinjury period but is not effective in the long term as infection with organisms of increased antimicrobial resistance occurs. Thus, prophylactic antimicrobials are not recommended in patients using intermittent catheterization. Maintenance of bladder volumes of <500 mL in these subjects may decrease the frequency of symptomatic infection. For nursing home patients, rates of infection with intermittent catheterization are similar if either a clean or sterile catheter technique is used. Thus, clean technique is recommended because it is less costly.

Antimicrobial therapy should be given to subjects with asymptomatic bacteriuria before an invasive genitourinary procedure, such as transurethral prostatic resection or stone extraction, where there is a high likelihood of mucosal trauma. Antimicrobial therapy is initiated before the surgical procedure and is conceptually "prophylaxis" to prevent bacteremia and sepsis rather than treatment of asymptomatic bacteriuria. Antimicrobial therapy is not indicated before a chronic indwelling urethral catheter change because this is not a high-risk procedure.

UTI in catheterized patients is primarily a technologic problem of biofilm formation on inert devices. Thus, substantive progress in preventing these infections will require technologic development of devices resistant to biofilm formation. Many antimicrobial-coated or -impregnated urinary catheters have been developed, and some of these are widely used. Nitrofurazone-coated catheters may be associated with a small decrease in the incidence of symptomatic infection in hospitalized patients with short-term catheters but there is an increased frequency of adverse effects with these catheters. Silver alloy catheters have not consistently been shown to improve outcomes. Catheters using other biomaterials or coatings are under further development, but none of these has yet been documented to decrease morbidity.

Section 14

Infections related to surgery and trauma

107

Postoperative wound infection

E. Patchen Dellinger

Postoperative wound infection or surgical site infection (SSI) is the archetypal surgical infection because it follows a surgical procedure and requires surgical intervention for resolution. As with many infections, best results are obtained by prompt diagnosis and treatment, which is facilitated by understanding the risk factors. The most obvious factor influencing risk of infection is the density of bacterial contamination of the incision. This was recognized several decades ago in the wound classification system that divides all surgical wounds into the following four categories: clean, clean-contaminated, contaminated, and dirty. Clean wounds result from an elective procedure without break in technique that does not involve any area of the body other than skin normally colonized by resident bacteria. Clean-contaminated wounds result from a procedure such as elective bowel resection that intentionally opens the gastrointestinal (GI) tract or other colonized region such as the female genital tract but does not result in grossly visible spill of contents during the procedure. Contaminated procedures are those with gross spill from the GI tract or trauma and emergency procedures in which a wound has been created without normal antisepsis and sterile technique. A dirty wound is one that results from an operation in an area of active infection or previous bowel injury and leak. Among these categories, infection risk ranges historically, before modern understanding and practice of perioperative antibiotic prophylaxis, from 2% for clean wounds to 30% to 40% for dirty wounds when the skin is closed primarily.

Studies done many decades ago demonstrate that essentially all surgical incisions, even in clean operations, have some bacteria in the wound at the end of the procedure. Clinicians have recognized that the nature of host defenses and the extent to which the operative procedure or preexisting disease impairs these defenses also influences the risk of wound infection. Modern wound classifications that include underlying risk as well as the risk of bacterial contamination predict infection more accurately. The first widely used system, developed by the National Research Council in 1964, divided all surgical wounds by inherent risk of contamination into clean, clean-contaminated, contaminated, and dirty. The next version assigned 1 point each for wound classification of contaminated or dirty, an operation lasting longer than the 75th percentile for that procedure, and an American Society of Anesthesiology (ASA) physical status classification of 3 or 4. In this system, the risk of postoperative wound infection for patients with risk points of 0, 1, 2, or 3 is 1.5%, 2.9%, 6.8%, and 13.0%, respectively. These data reflect modern use of perioperative prophylactic antibiotics, as discussed in Chapter 112, "Surgical prophylaxis." Efforts at the Centers for Disease Control and Prevention (CDC) and the National Healthcare Safety Network (NHSN), which is now the most prominent national surveillance system, have worked to develop more precise procedure-specific risk predictions for SSIs. They now report infection rates at participating hospitals in terms of Standardized Infection Ratios (SIR), which express the rate for a given hospital and given procedure as a ratio of observed divided by expected SSI rate. To report SIR, NHSN looks at data for 39 different specific procedure categories and applies between 1 to 11 specific risk factors taken from the list in Table 107.1 associated with each procedure category to calculate the expected SSI rate.

Diabetes	Spinal level

Diagnosis

The diagnosis of postoperative wound infection is obvious when the wound opens and discharges pus. However, the diagnosis is ideally made earlier and prompt therapeutic intervention undertaken. It is rare for a postoperative wound infection to be clinically evident before the fourth or fifth postoperative day. The sole exceptions to this are infections caused by β-hemolytic streptococci or by histotoxic *Clostridium* species and, more rarely, wound toxic shock. These infections can be clinically evident within fewer than 24 hours, and, although they are rare, they tend to be devastating. The wound of any patient with severe systemic signs of infection during the first few days after an operation should be inspected for signs of infection (Figure 107.1). Streptococcal infections are marked by local signs of inflammation and at times an exudate containing white blood cells (WBCs) and gram-positive cocci. Clostridial infections lack signs of inflammation and produce a thin exudate lacking WBCs because of the action of clostridial exotoxins, but gram-positive rods without spore formation are evident on Gram smear. Wound toxic shock due to toxin production by staphylococci or streptococci is a rare complication of SSI and represents <1% of all SSI. Most of these cases present within 48 hours of an operation. The earliest signs are fever, diarrhea, and vomiting. Profuse watery diarrhea, erythroderma, and hypotension are also characteristic. Initially, local signs of wound infection are often absent. Drainage and irrigation of the wound in combination with a systemic antistaphylococcal antibiotic is recommended. Although most wound infections are diagnosed between 5 and 15 days after the procedure, in some cases, diagnosis may be delayed considerably. This is more likely with wounds with a significant amount of tissue overlying the area such as abdominal wounds in morbidly obese patients and wound infections under chest wall musculature following a posterolateral thoracotomy.

Because most patients have some fever in the first several days after a major operative procedure such as abdominal exploration or thoracotomy, fever is not a specific sign of postoperative infection (Figure 107.2). It is tempting for the surgeon to continue prophylactic antibiotics or to restart antibiotics if the patient shows early postoperative fever, but this impulse should be resisted because these infections will not resolve without opening the wound. When antibiotics are given without a commitment to open the wound, the most likely results are a delay in diagnosis and definitive treatment, a consequent increase in morbidity, and risk of additional complication such as wound dehiscence or herniation. A few surgical wounds exhibit erythema adjacent to the incision, either concentrated around skin sutures or staples or diffusely. In the absence of marked induration and/or drainage, this erythema usually does not indicate wound infection. The average clinician will be sorely tempted to prescribe antibiotics for a patient with such a wound, but most resolve without any specific treatment, and no data suggest that administration of antibiotics in such a situation will prevent the need to open the wound for a real infection.

Therapy

Incisional drainage

The primary treatment for a wound infection is to open the wound and evacuate the infected material. Antibiotics are used as adjunctive treatment only for patients who exhibit signs of significant systemic response to the infection or in whom there is evidence of invasive soft tissue infection beyond the boundaries of the surgical incision. The evidence for infection may be most prominent in a portion of the incision, but in most cases, the entire incision will be involved under the skin and will have to be opened. If necrotic tissue is found in the wound, some preliminary debridement may be helpful, but small shreds of involved tissue will separate by themselves over time if the wound is left open and subjected to gauze dressing changes two to three times daily, decreasing in frequency as the wound clears. The importance of dressing changes is greater if the wound is deep, as in patients with severe obesity or in posterolateral thoracotomy wounds in muscular patients. If the wound is undermined, it is important to place the dressing so that gauze is in contact with all areas of the wound, but the dressings should not be put in forcefully or under pressure because this causes pain, inhibits drainage of exudate, and stimulates excess scar formation and slows wound closure, which occurs through the normal mechanism of contracture of granulation tissue.

When an incision is opened initially, it should be inspected by a physician who understands the procedure and the underlying anatomy. If the procedure was a celiotomy or a thoracotomy, the integrity of the closure of the abdominal or chest wall should be verified and evidence sought for purulent fluids originating deep to the abdominal or chest wall. In some cases, the incisional infection is not the primary event but is a signal of more severe and more extensive infection at a deeper level (see Chapters 55 and 57, "Abdominal abscess" and "Peritonitis," respectively).

Antibiotics

At the time of diagnosis and opening of the wound, empiric antibiotic administration should only occur when there are signs of a significant systemic reaction with temperature >38°C/100.4°F), elevated

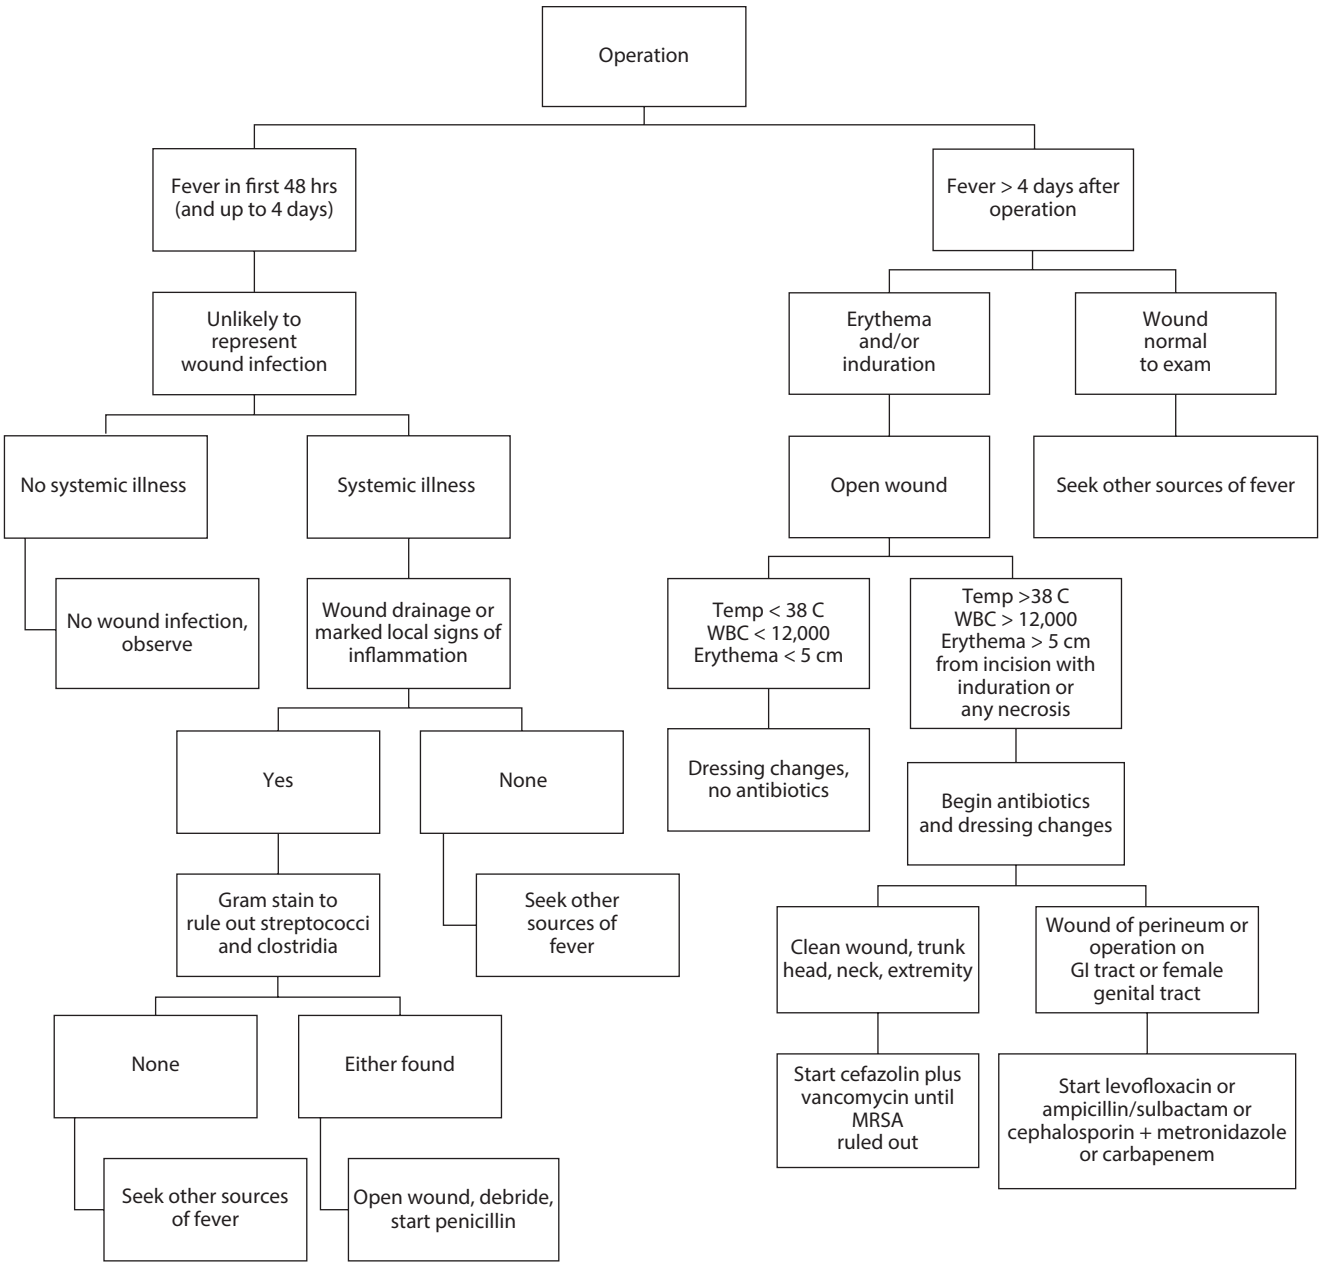

FIGURE 107.1

pulse rate, or absolute WBC count >12,000; when inspection of the wound reveals invasive infection in the subcutaneous space or at the fascial level; or when surrounding erythema and induration extend >5 cm from the line of incision. The agent chosen should be guided by Gram smear of the wound exudate and the nature of the procedure. Infections following clean operations that have not entered the GI tract and that involve the head and neck, trunk, or extremities tend to be caused by *Staphylococcus aureus* or, less commonly, streptococcal species. If Gram smear confirms gram-positive cocci and if antibiotics will be given, treatment is appropriate with an initial parenteral dose of cefazolin or oxacillin, 1 g intravenously (IV). For patients allergic to penicillin and cephalosporins, clindamycin, 900 mg, or vancomycin, 1 g IV, is acceptable. If the patient can take oral fluids and is not thought to have bacteremia, subsequent treatment can be with oral cephalexin or cephradine, 500 mg, or clindamycin, 450 mg four times daily. As community-acquired methicillin-resistant *S. aureus* (CA-MRSA) increase in frequency, consideration should be given to initiating treatment with sulfamethoxazole/trimethoprim, 800/160 mg orally (PO) every 12 hours; doxycycline, 100 mg PO every 12 hours; or vancomycin, 1 g IV every 12 hours; or linezolid, daptomycin, telavancin, or ceftaroline, until susceptibility data are available. Antibiotic treatment should be continued only as long as systemic signs of infection or local cellulitis continue to be present, usually 3 days or less.

For infections that follow operations in the axilla, gram-negative enteric bacilli are more commonly causative, and after operations on

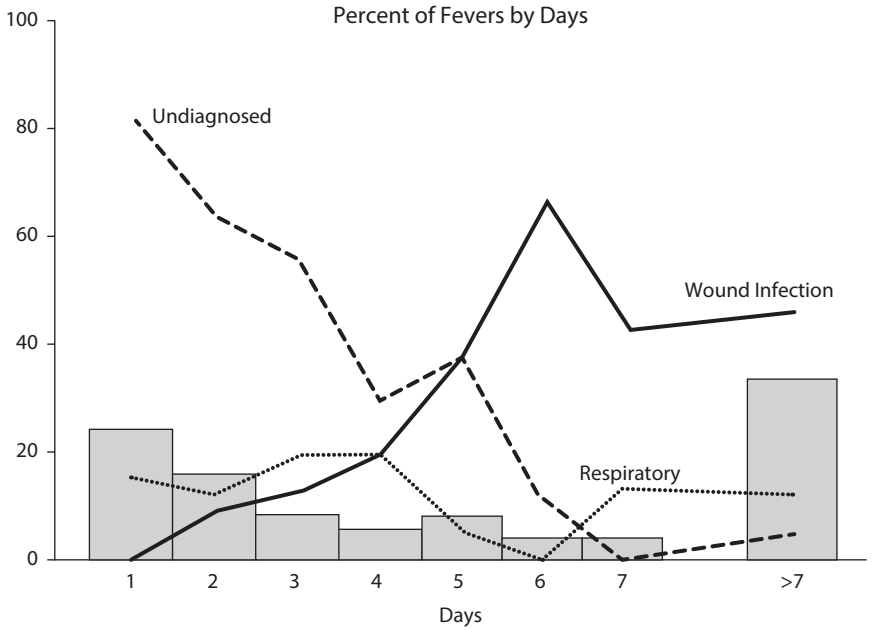

FIGURE 107.2 Bars represent the percent of all postoperative fevers occurring on the indicated day following an operative procedure. Lines indicate the percentage of fevers occurring on each day attributable to the cause indicated. (From Dellinger EP. Approach to the patient with postoperative fever. In: Gorbach SL, Bartlett JG, Blacklow NR, eds. *Infectious Diseases*, 3rd edn. Philadelphia, PA: Lippincott Williams & Wilkins; 2004:817–823).

the perineum or involving the GI tract or the female genital tract both facultative and obligate anaerobic bacilli and cocci are often involved. In these cases, if antibiotic treatment is thought necessary, initial treatment can be a cephalosporin or a fluoroquinolone combined with metronidazole. Patients allergic to penicillin and cephalosporins can receive levofloxacin, 500 mg IV every 12 hours, combined with metronidazole, 1 g IV every 12 hours. Again, the treatment should usually be for 3 days or less. If the patient is able to take oral agents, switching to an oral regimen of levofloxacin, 500 mg every 24 hours, combined with metronidazole, 500 mg every 6 hours, should be considered.

In the rare patient who has an invasive wound infection caused either by β-hemolytic streptococci or by a histotoxic *Clostridium* spp. diagnosed in the first 48 hours after operation, aggressive antimicrobial therapy is necessary in addition to opening the wound and inspecting it in the operating room under general anesthesia, with the option of aggressive soft tissue debridement if evidence of spreading soft tissue invasion and necrosis is found. Penicillin G, 4 million units IV every 4 hours, is appropriate if the diagnosis of streptococcal or clostridial infection is firm. If in doubt, cefazolin or vancomycin provides treatment for staphylococcal infections in addition to streptococcal and clostridial infections, but the addition of metronidazole for anaerobic coverage may be prudent. CA-MRSA have been reported to cause necrotizing soft tissue infections, so initial treatment of these infections with gram-positive cocci should include the use of vancomycin, 1 g IV every 12 hours.

Wound closure

The most reliable method for handling an infected wound that has been opened is to continue dressing changes and allow the wound to close spontaneously by secondary intention. In straightforward wound infections, this results in a very satisfactory result in most cases. In a minority of wounds, the incision can be reclosed, usually with tapes, after the incision has cleared up and is lined by healthy granulation tissue. The failures that occur at this time are as often caused by the geometry of the wound as they are by the bacterial content.

Trauma-related infection

Mark A. Malangoni

Infection is a serious complication of trauma, particularly among patients who have a greater severity of injury or suboptimal host defenses. Although exsanguination and central nervous system injury are the most common causes of mortality in the first 48 hours following injury, patients who die later often succumb to infectious complications or their consequences.

Trauma-related infection represents either infection at an original site of injury or infection that occurs as a direct result of injury. Examples of the former are an infected laceration or osteomyelitis at the site of an open fracture. The latter includes empyema after a penetrating wound to the chest and an intra-abdominal abscess that follows repair of a gunshot wound to the colon. Infection also can occur at sites remote from the area of injury; however, these infections usually are indirectly related to the immediate injury and will not be discussed further.

Similar to other infections, trauma-related infections occur when there is an imbalance in the normal relationship between microorganisms, the local environment, and innate or acquired host defenses. These infections can occur either from the introduction of small numbers of highly pathogenic bacteria or following contamination from a large inoculum of less pathogenic organisms. Common pathogens is various areas of the body are listed in Table 108.1.

Injury can lead to infection by (1) direct contamination of a sterile site with exogenous microorganisms; (2) disruption of the natural epithelial barriers of the gastrointestinal, respiratory, or gynecologic tracts, with contamination from endogenous microorganisms; (3) impairment of local antimicrobial clearance mechanisms by direct damage to tissues and the introduction of foreign bodies, hematomas, or seromas which act as adjuvants to promote infection; and (4) weakened systemic host defenses through secondary mechanisms that are either preexisting or secondary to the consequence of injury.

Various preexisting conditions may also contribute directly to the development of trauma-related infections through detrimental effects on local or systemic defense mechanisms. Examples include diabetes mellitus, obesity, malnutrition, advanced age, alcoholism, and single or multiple organ system dysfunction. Hyperglycemia, hypoxemia, and hypothermia also increase the likelihood of developing a trauma-related infection. Importantly, the adequacy of the blood supply to the injured area can affect the propensity to develop infection, and impaired perfusion because of preexisting disease or perturbations due to the injury per se increases the risk of developing an infection.

Necessary invasive and diagnostic interventions such as the placement of endotracheal tubes, intravascular catheters, and urinary catheters provide microorganisms with a portal of entry to sterile body sites, bypassing normal defenses. This can result in infection at the site of entry or may cause a distant infection following hematogenous dissemination of pathogens. Improper treatment can also predispose to infection by impairing the clearance of bacteria.

Efforts to prevent infection should begin immediately after injury. The general principles of initial management of injury include meticulous examination of external wounds to determine the extent and severity of injury. Bleeding should be controlled by application of direct pressure or by identification and ligation of major bleeding points. Control of bleeding, evacuation of hematomas, debridement of all devitalized soft tissues, removal of foreign material, and identification of bony fractures are essential to proper wound management. The injury site should be irrigated with a physiologic solution such as 0.9% normal saline. Wounds

TABLE 108.1 **POTENTIAL PATHOGENS BASED ON ANATOMIC LOCATIONS**

Skin	*Staphylococcus epidermidis* *Staphylococcus aureus* *Clostridium* species *Bacteroides species (non-fragilis)*
Oropharynx	*Staphylococcus epidermidis* *Staphylococcus aureus* β-hemolytic streptococci *Streptococcus pneumoniae* Anaerobic streptococci *Candida albicans* *Bacteroides species (non-fragilis)*
Upper gastrointestinal tract	Enterococci *Candida albicans* Enterobacteriaceae (e.g., Escherichia coli, Klebsiella, Enterobacter)
Distal gastrointestinal tract	Enterobacteriaceae Enterococci *Bacteroides fragilis* *Clostridia* species

should be covered with a sterile dressing, preferably moistened with 0.9% normal saline, as soon as possible in order to prevent further contamination and tissue desiccation; however, this process should not impede definitive care or transfer to a trauma center when indicated.

In traumatic wounds associated with fractures, there is a direct relationship between the risk of infection and the severity of related soft tissue injury. Early immobilization of fractures reduces additional soft tissue damage, limits hematoma formation, and can help decrease the risk of infection by preventing dissemination of contaminating bacteria when an open fracture is present. Fracture immobilization also helps promote restoration of normal homeostasis.

After appropriate cleansing, debridement, and hemostasis are completed, wound closure should be addressed. In general, simpler techniques are preferred over more elaborate ones. Traumatic wounds with a low risk for infection should undergo primary closure. Soft tissue injuries at increased risk for infection include those that have devitalized or ischemic tissue, are located at or near areas of heavy colonization such as the groin or perineum, have a delay of 6 hours or more to definitive care, or are complicated by the presence of associated diseases or conditions that compromise clearance of contaminating organisms. Crush injury, high-velocity and shotgun injuries, coexisting thermal injury, and irregular or stellate wound configurations are other indicators of high-risk wounds. Wounds that are heavily contaminated or at high risk for infection should not be closed primarily. In these situations, it is more prudent to repeat cleansing and debridement of the site of injury and delay closure until it can be done safely. Unless the wound environment is sufficient to allow for closure with a low risk of infection, wounds should be allowed to heal by secondary intention or have delayed primary closure. Although this may seem inconvenient for the patient, it often avoids substantial consequences associated with infection.

Stab wounds and low-velocity gunshot wounds can usually be irrigated and closed primarily as long as there has not been significant exogenous or endogenous contamination. When intestinal injury is present, there is an increased concentration of microorganisms contaminating the site of injury, particularly at the exit site, and these wounds should be left open. High-velocity missile track and shotgun wounds should not be closed primarily and are best managed by debridement and irrigation of entrance and exit sites, followed by coverage with sterile dressings. Complex wounds with extensive areas of devitalized soft-tissue are best managed by debridement and irrigation with dressing care. Exposed soft tissue can be managed with wet-to-dry dressing changes using 0.9% normal saline to promote a healthy granulating bed that can be covered later either with a split-thickness skin graft or with full-thickness skin or can be allowed to heal by secondary intention. Although it may be tempting to use antiseptic or antimicrobial-containing agents for irrigation, these substances offer no advantage in the early treatment of wounds and may impair healing. When wounds that are healing by secondary intention begin to granulate and contract, it may be appropriate to switch to hydrocolloid gels or alginates, which are associated with less discomfort and a less frequent need for dressing changes. Negative pressure wound therapy has been demonstrated to be useful for treatment of large open wounds once contamination has been minimized as it accelerates wound contraction and reduces the time to healing. It also has the advantages of requiring less frequent dressing changes and improved patient comfort.

Antibiotic therapy is not a substitute for sound clinical judgment, excellent local wound care, aseptic technique, and careful handling of tissues. For uncomplicated minor wounds with minimal contamination and a low risk of infection, antibiotic therapy is unnecessary. Empiric antibiotic therapy is beneficial when there is heavy bacterial contamination, an open fracture, involvement of a joint space, major soft tissue injury, or delay of initial management for >6 hours, as well as for patients with impaired local or systemic host defenses. Initial cultures of contaminated wound sites usually add little to treatment decisions. Tetanus toxoid and tetanus immunoglobulin should be administered in accordance with established guidelines for contaminated wounds.

Empiric antibiotic therapy should be directed primarily against gram-positive bacteria in most soft tissue wounds. When contamination with anaerobes and gram-negative enteric bacteria is suspected, such as with a farm-related injury or a human bite, the antimicrobial spectrum must include agents effective against these organisms. Treatment should be continued only for 24 hours in wounds with a minor or moderate degree of contamination; a longer duration of treatment is recommended when contamination is greater. Recommended antibiotic choices are listed in Table 108.2.

The high prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) in the community and among patients or those who reside in long-term care facilities mandates a reassessment of the approach to the treatment of patients who are potentially contaminated or infected with these organisms. When MRSA is

TABLE 108.2 **ANTIBIOTIC THERAPY FOR TRAUMATIC WOUNDS**[a]

Clean lacerations	No antibiotics recommended
Heavily contaminated lacerations or wounds at risk for infection	Cefazolin, 1–2 g IV q8h Amoxicillin-clavulanate, 500 mg PO q12h, or 250 mg PO q8h For penicillin-allergic patients, use ciprofloxacin 400 mg IV or 500 mg PO q12h plus metronidazole 500 mg IV or PO q6h or Moxifloxacin 400 mg IV or PO q24h
Farm injuries and human bites; soil contamination; delays in care of heavily contaminated wounds	Piperacillin-tazobactam, 3.375 g IV q6h, or amoxicillin-clavulanate, 500 mg PO q12h, or 250 mg q8h (see Chapter 23, "Human and animal bites") For penicillin-allergic patients, use ciprofloxacin 400 mg IV or 500 mg PO q12h plus metronidazole 500 mg IV or PO q6h, or moxifloxacin 400 mg IV or PO q24h
Penetrating abdominal injury[b]	Cefotetan, 2 g IV q8h, or piperacillin-tazobactam, 3.375 g IV q6h For penicillin-allergic patients, use ciprofloxacin 400 mg IV q12h plus metronidazole 500 mg IV q6h, or moxifloxacin 400 mg IV q24h

[a] Local infection data and resistance patterns may require additional coverage when methicillin-resistant *Staphylococcus aureus* (MRSA) is suspected (see text).
[b] Doses should be repeated for every 10 units of blood loss.

suspected, empiric therapy should be chosen based on whether this is considered a community-acquired or healthcare-acquired strain. Healthcare-acquired strains usually require treatment with vancomycin, linezolid, daptomycin, telavancin, or clindamycin whereas community-acquired MRSA is often susceptible to trimethoprim-sulfamethoxazole and tetracyclines in addition to the preceding agents. Cultures should be done at the time of drainage or debridement in patients who develop an infection in order to identify the antimicrobial susceptibility profile of these organisms and to direct therapy.

The occurence of intra-abdominal infection after penetrating abdominal trauma is a paradigm that defines risk factors for trauma-related infection in a single body cavity. Increased patient age, number and degree of organ injuries, units of blood products transfused, delays in treatment, and presence of severe contamination, such as with colon injury, identify patients at high risk for infection after penetrating abdominal trauma. These factors are indicators of diminished physiologic reserve, impairments that result from the systemic effects of injury, detrimental effects of hemorrhagic shock and transfusion, and the contribution of heavy bacterial contamination to the risk of infection. Because these risk factors cannot be completely defined before operation, empiric treatment with a broad-spectrum antimicrobial agent effective against gram-negative facultative organisms and anaerobes is indicated (Table 108.2). Patients with a low risk of infection need only a single dose of antibiotic, but those at greater risk, such as with colon injury, should be treated for 24 hours. Treatment >24 hours has repeatedly been demonstrated to be of no added value.

Fewer than 2% of patients operated for blunt abdominal injury are found to have contamination from injury to the gastrointestinal tract. In this circumstance, cefazolin alone is adequate empiric treatment. Metronidazole should be added when bowel injury is suspected or confirmed. Antimicrobials can be discontinued immediately if no hollow viscus injury is found.

Damage control laparotomy has gained utility in the management of patients with abdominal injury accompanied by hypothermia, metabolic acidosis, and excessive blood loss. Following correction of all deficits in the intensive care unit, these patients are usually reoperated within 24 to 48 hours. There is no evidence to support continuation of antibiotics in this situation.

Bullets or pellets that penetrate the gastrointestinal tract and lodge in soft tissues can result in soft tissue infections through a combination of direct tissue injury and bacterial contamination. In this situation, the contaminating foreign material should be removed, debridement done, and definitive closure delayed.

Intra-abdominal infection following penetrating trauma is a serious healthcare-acquired infection and often involves antimicrobial-resistant organisms. Recommended intravenous treatment regimens include either a carbapenem or piperacillin-tazobactam alone or cefepime in combination with metronidazole. Ciprofloxacin plus metronidazole or moxifloxacin alone are useful alternatives for patients who are allergic to β-lactams. Vancomycin or linezolid should be added when MRSA is suspected. Cultures must be done to identify pathogens and delineate their antimicrobial sensitivity profile, and therapy is adjusted based on culture results.

Approximately 3% to 5% of patients who incur a hemothorax will develop empyema. The main risk factors for this complication are retained hemothorax and prolonged tube thoracostomy use. While there is inconclusive evidence for the use of prophylactic antimicrobials for hemothorax, there is strong evidence that evacuation of retained hemothorax within 72 hours reduces the incidence of posttraumatic empyema.

Infected implants

Gordon Dickinson

This chapter addresses infections associated with artificial devices of a specialized nature. The rate of infection is generally low, but, collectively, there are millions of these devices implanted yearly, so the infections are not rare. Optimal treatment requires participation of surgical specialists experienced in the management of these difficult infections, especially for pseudophakic endophthalmitis, in which the mainstay of therapy is intraocular injections.

Intraocular lens-associated infections (pseudophakic endophthalmitis)

Pseudophakic endophthalmitis is thought to occur as a consequence of contamination with flora of conjunctival sac or lid margin at the time of surgery. There have been reports of infections arising from contamination of lenses and neutralizing and storage solutions.

The differential diagnosis of endophthalmitis following cataract extraction includes sterile inflammation as well as bacterial and fungal infection. The most common presenting signs and symptoms include pain in the involved eye, decreased visual acuity, red eye, lid edema, hypopyon, and absent or poor red reflex. A single bacterial strain is usually isolated; the most common pathogen is a coagulase-negative staphylococcus (approximately 50% in one large series) followed by *Staphylococcus aureus*. Virtually any microorganism can be implicated. Delayed-onset pseudophakic endophthalmitis has been reported after uncomplicated initial cataract surgery. This entity presents ≥1 months after surgery and is manifest by waxing and waning ocular inflammation. The leading cause of delayed-onset pseudophakic endophthalmitis is *Cutibacterium acnes* (formerly *Propionibacterium acnes)*. Diagnostic evaluation requires aqueous and vitreous samples for Gram stain and culture. Vitrectomy may have therapeutic as well as diagnostic value.

Patients should be seen by an ophthalmologist immediately. Antimicrobials administered intraocularly and topically are the mainstay of treatment for this localized infection. Because of unpredictable antibiotic penetration, systemic antibiotic are of secondary importance and generally unnecessary. (See also Chapter 15, “Endophthalmitis”).

Cochlear implants

Cochlear device implantation is available to adults and children as young as 1 year of age to correct severe hearing loss. The device consists of a subcutaneous receiver, a lead wire that passes through the middle ear, and fibers that contact the cochlear nerve. An external component with microphone and transmitter is positioned adjacent to the receiver. Infections, reported to occur in 1.5% to 4% of cases, may be classified as surgical wound infection, otitis media, or meningitis. Surgical wound infections generally arise in

the immediate postoperative period and are manifest by tenderness, erythema, and swelling. Meningitis may occur in the postoperative period, but also may be encountered in the months following implantation. Otitis media in an ear with a cochlear device may also occur either in the postoperative period or long afterward. Symptoms suggestive of a surgical wound infection or otitis media deserve immediate attention, with collection of a specimen for culture if possible and prompt initiation of antibiotics to minimize the infection and preserve the device. Many infections can be managed medically without removal of the device, although wound dehiscence over the receiver or progression of symptoms generally mandate device removal. Meningitis, encountered more frequently in children, may be associated with or without otitis media. The pathogens are typical of otitis-associated meningitis seen in children without cochlear implants. Because *Streptococcus pneumoniae* is a leading cause, empiric antibiotic therapy should include antimicrobials appropriate for this pathogen. Once an infection obviously involves the cochlear implant, it is difficult to salvage the device, a very serious matter because reimplantation may not be feasible. Prior to implantation of a cochlear device, both 13 valent conjugated polysaccharide and 23 valent polysaccharide pneumococcal vaccines should be administered according to current guidelines.

Breast implant–associated infections

Breast prosthesis implantation, for augmentation or reconstruction post-mastectomy, is a common procedure. In 2018, in the United States, an estimated 313,735 augmentation mammoplasty procedures were performed. Prostheses approved by the US Food and Drug Administration (FDA) consist of a silicone rubber shell filled with either saline or silicone polymer gel (in 2018, an estimated 88% were of the latter type). They are implanted in a subglandular or submuscular pocket through inframammary, periareolar, transaxillary, transareolar, or transumbilical approaches. Infection rates following augmentation mammoplasty range from 1.1% to 2.5% and are much higher following reconstruction. Vascular compromise of the soft tissue in mastectomy and longer operative times are thought to contribute to the overall higher incidence of infections in breast reconstruction. Intraoperative breakdown of sterile technique, contaminated supplies, and hematogenous seeding are all possible sources of implant-associated infection. Endogenous flora of human breast tissue is similar to skin flora and accounts for most infections. The most common pathogens are *Staphylococcus* spp. including *S. aureus* and *S. epidermidis,* followed by a broad spectrum of gram-positive and -negative organisms including *Serratia marcescens*, *Pseudomonas aeruginosa*, *Escherichia coli*, Group B streptococcus, *Enterobacter*, and *M. morganii*. Fungal infection is rare. A combination of patient comorbidities and surgical techniques are the major risk determinants. The signs and symptoms are variable, but common findings are malaise, fever, tenderness, induration, breast erythema, asymmetry, and ultrasonographic evidence of periprosthetic fluid accumulation. Severe sepsis can develop, and there are case reports of toxic shock syndrome occurring in the early postoperative period.

Clusters as well as sporadic infections caused by *Mycobacterium abscessus* and *M. fortuitum* have been reported. The source of the pathogen is usually not identified, but inadequate equipment sterilization is suspected. Local signs and symptoms are similar to other bacterial infections, with a more subtle or delayed onset and a lack of improvement on standard antibiotic therapy. Gram stain of the fluid usually reveals no organisms but many polymorphonuclear leukocytes. Stain for acid-fast bacilli is sometimes positive. A definitive diagnosis is established by culture of the organism.

Although oral fluoroquinolones have been suggested as treatment for early, subtle symptoms, breast implant–associated infections are treated with systemic antibiotics. As methicillin-resistant *S. aureus* and methicillin-resistant coagulase-negative staphylococci have become increasingly common, empiric regimens should include vancomycin along with coverage for gram-negative organisms such as imipenem. Subsequent adjustment is made according to culture results. Duration of the therapy will depend on the causative organism, severity of infection, and clinical response; it usually ranges from 10 to 14 days. Agents with potential activity for most atypical mycobacteria include amikacin, cefoxitin, fluoroquinolones, clarithromycin, azithromycin, doxycycline, and imipenem, but susceptibility studies should be obtained, and a combination of two or more effective agents is recommended to prevent development of resistance. Infections caused by mycobacteria require months of therapy. Although early aggressive antibiotic treatment of infections can sometimes preserve the implant, continued, severe, or systemic symptoms require implant removal with capsule debridement and postsurgical drain placement. Rarely will the contralateral implant have to be removed. Surgical replacement is possible once all symptoms resolve; most surgeons prefer to wait for 6 months to allow tissue recovery.

Penile implant–associated infection

Infection is a major complication for implantation of penile prostheses, occurring in an estimated 3% of cases. Most penile prosthesis–associated infections likely originate at the time of the implantation. Common sources of infection include skin, colorectal and perianal flora, urine, and operating room environment. Infection can present within days after surgery to several weeks or months post implantation. *S. epidermidis* is isolated in >50% of cases; other bacteria include *S. aureus* and gram-negative enteric bacteria such as *E. coli*, *P. aeruginosa, Klebsiella* spp. and *Proteus* spp. Gonococcal and fungal infections have been reported. Signs and symptoms of infections include new-onset pain, swelling, tenderness, erythema, induration, fluctuance, erosion, and extrusion of prosthesis. Infections caused by *S. epidermidis* are often subtle and may present with dysfunction of the prosthesis or pain upon manipulation of the device.

Empiric antibiotic therapy treatment should be directed at both gram-positive bacteria and gram-negative coliform bacteria pending isolation of the causative pathogen. There is universal consensus that if a penile implant–associated infection occurs, the implant and all associated foreign material should be removed. There are, however, diverging views about surgical management. The preferred approach is a two-stage operation with the infection-associated device removed, the wound allowed to heal, and then replacement 4 to 6 months later. Although this approach is usually successful, the penis may be shortened by scarring. For selected patients, surgeons may elect to remove the infection-associated device, debride the wound, and implant a new device in a single-stage operation. For uncomplicated infections with the device out, a 10- to 14-day course of systemic antibiotics is given, whereas for complicated infections or when the device is immediately replaced, antibiotic therapy should be continued for at least a week or more after all signs of infection have resolved.

Infection in the burn-injured patient

Roger W. Yurt and Rafael Gerardo Magaña

The diagnosis of infection in the patient with major burn injury is especially problematic because the signs of infection are the same as those of the response to injury.

The tissue injury that occurs with a major burn and the associated inflammatory response to it cause one of the greatest perturbations of homeostasis that occurs in any disease state. Thus the greatest challenge in developing a differential diagnosis in the burn-injured patient is to distinguish between the injury state and infection. That the manifestation of infection may be blunted by diminished immune response further complicates evaluation of the patient while also contributing to an increased susceptibility to infection.

The challenge posed in the clinical and laboratory evaluation of the burn-injured patient is summarized in the outline of injury-related changes in Table 110.1.

Injury pathophysiology and susceptibility to infection

The initial approach to the burn-injured patient is oriented toward limiting the progression of the injury by stabilization of the patient and maintenance of blood flow to the wound. The zone of coagulative necrosis consists of tissue that has been irreversibly damaged, whereas the surrounding zone of stasis contains areas of potentially reversible injury. Adjacent areas, known as the hyperemic zone, may also evolve to become necrotic if the blood flow is not maintained. For this reason, the primary goal of early burn therapy is to ensure adequate delivery of oxygen, nutrients, and circulating cells to the wound. In addition to prevention of progression of the injury, immediate burn care focuses on maintenance of a viable tissue interface at which both specific and nonspecific defenses against infection can be mounted.

The depth of burn injury is categorized as partial or full thickness. Full-thickness injuries will heal only by contraction, ingrowth of surrounding epidermis, or grafting of tissue because all epidermis in the wound has been destroyed. These wounds are leathery and dry, contain thrombosed vessels, and are insensate. Partial thickness wounds contain residual epidermis, which can close the wound if blood flow is maintained and infection does not supervene.

Partial thickness wounds are red and moist, and pain is elicited by touch. Deep partial-thickness wounds contain only epithelial elements associated with organelles of the skin. They take longer to heal (2 to 3 weeks) than superficial partial-thickness wounds, and there is a greater functional and cosmetic deformity if they are allowed to heal primarily. These wounds are difficult to differentiate by clinical evaluation from superficial partial-thickness injuries, which usually heal within 10 days to 2 weeks.

The dynamic aspect of burn wounds is dramatically seen when partial-thickness wounds convert to full-thickness wounds during a difficult resuscitation of a patient. Although this is rarely seen with current methods of resuscitation, resuscitation that is delayed or performed on patients at extremes of age occasionally will show this progression.

TABLE 110.1 CLINICAL AND LABORATORY SIGNS RELATED TO INJURY THAT COMPLICATE THE EVALUATION OF THE PATIENT WITH BURN INJURY

Sign	Abnormality
General condition	Lethargy-electrolyte imbalance
	Analgesic effects
	Hyperventilation
	Pain, topical agents
	Tachycardia
	Pain, volume depletion, hypermetabolism
Fluid balance	Hypovolemia
	Initial injury
	Delayed-evaporative loss
Fluid composition	Hypernatremia
	Free water loss
	Inadequate fluid replacement
	Hyponatremia
	Excessive free water
	Effects of topical silver nitrate
	Hyperglycemia
	Stress
Temperature	Hypothermia
	Heat loss to the environment
	Large fluid requirement
	Hyperthermia
	Hypermetabolism
	Endotoxin from the wound
Neutrophil response	Neutrophilia
	Acute
	5–7 days after injury
	Neutropenia
	2–3 days after injury

Any agent that causes cellular death can lead to a deeper wound. With this in mind, caustic topical agents and vasopressors are avoided, the wound is not allowed to desiccate, and the patient is kept warm.

Both mortality and susceptibility to infection correlate directly with the extent of the surface area injury. Distribution of surface area varies with age, so a chart is used to plot accurately the extent and depth of surface area burned. The rule of nines may be used to estimate the extent of injury as follows: torso, back and front, each 18%; each leg 18%; each arm 9%; and head 9%. Calculation of the extent of injury is helpful in estimating fluid requirements and prognosis. Patients with greater than 25% to 30% total body surface area burn exhibit the pathophysiologic features already described.

Prevention of infection

Current data do not support the general use of prophylactic systemic antibiotics in the inpatient population. Frequent evaluation of the wound and surrounding tissue allows early and appropriate therapy of cellulitis while sparing a majority of patients exposure to unnecessary antibiotics. However, some practitioners give systemic antibiotics (cephalexin) to outpatients with burns because it is not possible to observe closely and ensure appropriate care of the wound. The use of systemic antibiotics in these patients is individualized such that those who are likely to follow up with their care and recognize changes in their wounds are not given antibiotics. The one time that prophylactic systemic antibiotics are used in inpatients is at the time of surgical manipulation because this may cause bacteremia. Antibiotics are administered immediately before and during burn wound excision. The choice of antibiotics is dictated by knowledge of the current flora in the burn center or, more specifically, by the burn wound flora of the individual patient.

The mainstay of prevention of burn wound infection is aggressive removal of the necrotic tissue and closure of the wound with autograft. In the interim, topical antimicrobial prophylaxis will decrease the incidence of conversion of partial-thickness to full-thickness wound by local infection, and these agents may prolong the sterility of the full-thickness burn wound. Silver sulfadiazine is the most commonly used topical agent and is a soothing cream with good activity against gram-negative organisms. Because it does not penetrate the wound, it is used only as a prophylactic antimicrobial. Bacterial resistance to silver sulfadiazine has been reported, and it has been reported to cause neutropenia. Silver nitrate in a 0.5% solution is an effective topical agent when used before wound colonization. This agent does not penetrate the eschar, and therefore its broad-spectrum gram-negative effectiveness is diminished once bacterial proliferation has occurred in the eschar. Additional disadvantages of this agent include the need for continuous occlusive dressings, which limits the evaluation of wounds and restricts range of motion. The black discoloration of the wound, as well as the environment, contributes to the decrease in the use of silver nitrate. Mafenide acetate (Sulfamylon) cream has a broad spectrum of activity against staphylococci. A significant advantage of this agent is that it penetrates burn eschar and therefore is effective in the colonized wound. The disadvantages of Sulfamylon are a transient burning sensation, an accentuation of postinjury hyperventilation, and inhibition of carbonic anhydrase activity.

Recent experience with a new silver-impregnated dressing that does not have to be changed daily suggests that this agent is a good alternative for prophylaxis against infection in partial-thickness wounds.

The goal of burn therapy is to prevent burn wound infection by permanent closure of the wound as rapidly as possible. Early removal of necrotic tissue and wound closure has the advantages of removal of eschar before colonization, which typically occurs 5 to 7 days after injury, and of reduction of the overall extent of injury. A drawback of early excisional therapy is the possibility that burned tissue that may heal if left alone over a 2- to 3-week period may be unnecessarily excised.

Advances in resuscitation have led to the ability to salvage an increasing number of patients from the shock phase immediately

after injury and have resulted in a greater number of patients surviving to the time (3 to 4 days after the injury) when the effects of inhalation injury become clinically prominent. In patients without inhalation injury but with large burns, postinjury hyperventilation and subsequent decreases in tidal volume may lead to atelectasis and subsequent pneumonia. Diminished mucociliary function and destruction of the airways by inhalation of products of combustion lead to airway obstruction and infection.

Frequent diagnostic and therapeutic bronchoscopies are necessary in this group of patients. Attempts at specific prophylaxis of the sequelae of inhalation injury, such as nebulization of antibiotics and treatment with steroids, have failed to show any benefit.

Nosocomial infections are of even greater concern in the burn intensive care setting than other units because of the large open colonized wounds. Cross-contamination is avoided by use of gowns, gloves, and masks by nurses, medical staff, and visitors. The patient is not touched except with a gloved hand, and each patient is restricted to his or her own monitoring and diagnostic equipment. If adequate nursing care can be provided, it is preferable to isolate patients who have large open wounds in individual rooms. Cohort patient care has been shown to be effective in reducing endemic infections.

Diagnosis and treatment of infections

Wound infection

Because the full-thickness burn wound is at high risk for infection, routine clinical and laboratory surveillance of the wound is an absolute necessity. Daily observation of the wound for discoloration, softening or maceration of the eschar, or the development of cellulitis provides early detection of wound-associated infection. Although surface cultures of the burn wound provide insight into the organisms that are colonizing the wound, evaluation of a biopsy of the burn wound is the only way to obtain accurate assessment of the status of the wound. Systematic evaluation of burn wounds with quantitative culture of biopsies of all areas of wound change documents the clinical diagnosis of wound infection and provides identification and antimicrobial sensitivity of the involved organism. Routine biopsy of full-thickness burn wounds on an every-other-day schedule provides evidence of advancing wound infection and serves as a basis for initiating therapy. Arapid fixation technique allows histologic diagnosis of invasive infection within 3 hours, whereas quantitative counts and identification of the organism are available in 24 hours.

This combined use of histologic and culture techniques provides early diagnosis as well as the identity of the organism and its sensitivity to antimicrobials. When the findings are consistent with invasive infection (greater than or equal to 10^5 organisms/g of tissue), aggressive surgical therapy is instituted to excise the involved wound. In preparation for surgery or in patients who require stabilization before general anesthesia is given, a penetrating topical agent is used (Sulfamylon). The choice of antibiotic is based on previous biopsy sensitivity data or data accumulated on sensitivities of the current flora in the patient population.

A growing number of patients present with primary nonsuppurative gram-positive infections. These infections are often caused by methicillin-resistant *Staphylococcus aureus* (personal observation), and whether diminished neutrophil response or a change in the nature or the virulence of such organisms may explain this phenomenon is unknown.

Pulmonary infection

From a practical standpoint, inhalation injury is diagnosed by history, physical examination, and bronchoscopy. A history of exposure to fire in a closed space along with findings of carbonaceous sputum, singed nasal vibrissae, and facial burns are associated with a high incidence of inhalation injury. In the burn patient, pulmonary complications after injury are not uncommon and may increase the mortality rate of ventilator-associated pneumonia (VAP), which may increase from 40% to 77% in the presence of significant inhalation injury. Bronchoscopy reveals upper airway edema and erythema, whereas bronchorrhea, carbon in the bronchi, and mucosal slough suggest lower airway and parenchymal injury.

Carboxyhemoglobin levels may be elevated, but with a half-life of 45 minutes on 100% oxygen the level may be normal. Chest x-ray studies are of little value in making the diagnosis of inhalation injury because they are often normal for the first 72 hours after injury. Xenon ventilation–perfusion lung scan reveals trapping of xenon in the ventilation phase and is supportive of a diagnosis of small airway obstruction secondary to injury of the distal airways and parenchyma. Although hematogenous pneumonia is less common than in the past, it remains a significant problem in the patient with burns. When it occurs, the source (most commonly the wound or suppurative vein) must be defined and eradicated. Prophylactic antibiotics are not used for either bronchopneumonia or hematogenous pneumonia; specific therapy is based on knowledge of previous endobronchial culture, and sensitivity is substantiated by repeat cultures at the time of diagnosis. Diagnosing pneumonia in this population may be difficult. Different clinical scores have been developed to this end; however, they are of little value because they have low specificity and sensitivity when compared with specimens obtained via bronchoalveolar lavage. A culture with 10^4 organisms/mL is generally considered to be significant enough to warrant antibiotic therapy. Bronchoalveolar lavage with negative results also reduces the usage of unnecessary antibiotics.

Suppurative thrombophlebitis

Suppurative thrombophlebitis is mentioned in particular in relation to the patient with burn injury because it is the most common cause of repeatedly positive blood cultures in the presence of appropriate antibiotics in this population. These findings alone should lead to a presumptive diagnosis of a suppurative process in a previously cannulated vein. The process may be insidious, with only minimal clinical findings. Because of this complication, venous cannulation should be minimized, but when it is necessary catheters should be changed on a regular basis. In some centers this is done as often as every 3 days. Treatment consists of surgical excision of the entire involved vein to the level of normal bleeding vessel. In this setting the differential diagnosis should include endocarditis.

Chondritis/suppurative chondritis

Burn wounds that involve the ear are of particular concern, because its cartilage has no intrinsic blood supply and thus has the potential to develop chondritis and subsequent suppurative chondritis. Because the ear is covered only by skin and has no subcutaneous tissue, the cartilage is at risk for infection when there is a full-thickness burn causing local necrosis. This often leads to loss of tissue and permanent deformity and, in some cases, loss of the ear.

Damaged skin acts as a portal of entry. In addition, local edema may predispose to thrombosis of central vessels. *Pseudomonas* and *Staphylococcus* are the most common pathogens involved in this pathology.

Sulfamylon is of benefit in this condition because it can penetrate eschar to the level of cartilage and prevent bacterial invasion. Pressure-related damage to the ear must be avoided. Therefore, the ear should be dressed in topical only or topical and one layer of nonadherent gauze. To avoid pressure on the ear, a pillow for the head should not be allowed.

Once suppurative chondritis ensues, surgical intervention is mandatory and consists of drainage and debridement of all nonviable tissue. This can be accomplished by making an incision on the helical rim of the ear (bivalving), with subsequent drainage and excision of nonviable tissue. The ear is then dressed with an antibacterial solution, changed on a twice-daily schedule, and allowed to heal by secondary intention. Special attention should be given to avoid any form of compression to keep the dressings in place, because this may increase the extent of necrosis.

Section 15

Prevention of infection

111

Nonsurgical antimicrobial prophylaxis

Nadine G. Rouphael and Alexandra Wolcott Dretler

Prevention

Chemoprophylaxis is the use of an antimicrobial agent to prevent infection. Chemoprophylaxis is often administered after exposure to a virulent pathogen or before a procedure associated with risk of infection. Chronic chemoprophylaxis is sometimes administered to persons with underlying conditions that predispose to recurrent or severe infection. Antibiotics can also be used as preemptive therapy (sometimes referred to as *secondary prophylaxis*) to prevent clinical disease in persons infected with a microorganism such as *Mycobacterium tuberculosis*. Immunization, another excellent means of preventing infection, is discussed in Chapter 113. For information on prophylaxis of bacterial endocarditis, see Chapter 17, "Endocarditis"; for information on prophylaxis in persons infected with the human immunodeficiency virus (HIV), see Chapter 101, "Prophylaxis of opportunistic infections in HIV disease"; for malaria prophylaxis, see Chapter 199, "Malaria"; for prophylaxis related to transplant recipients and neutropenic patients, see Chapter 88, "Infections in transplant recipients," and Chapter 84, "Infections in the neutropenic patient"; and for surgical prophylaxis, see Chapter 112, "Surgical prophylaxis."

Several concepts are important in determining whether chemoprophylaxis is appropriate for a particular situation. In general, prophylaxis is recommended when the risk of infection is high or the consequences significant. The nature of the pathogen, type of exposure, and immunocompetence of the host are important determinants of the need for prophylaxis. The antimicrobial agent should eliminate or reduce the probability of infection or, if infection occurs, reduce the associated morbidity. The ideal agent is inexpensive, orally administered in most circumstances, and has few adverse effects. The benefit conferred by prophylaxis must be weighed against the risks of antimicrobial use, including alteration of the normal microbiota and selection for antimicrobial resistance. The ongoing crisis of antibiotic-resistant bacteria underscores the importance of rational and not indiscriminate use of antimicrobial agents.

The efficacy of chemoprophylaxis is well established in situations such as perioperative antibiotic administration, exposure to invasive meningococcal disease, prevention of recurrent rheumatic fever, and prevention of tuberculosis. Chemoprophylaxis is accepted in other situations lacking supporting data. When the risk of infection is low, as with bacterial endocarditis following dental procedures, randomized clinical trials of prophylaxis are not feasible. However, the consequences of infection may be catastrophic, providing a compelling argument for chemoprophylaxis despite the low risk of infection. When prophylaxis is advocated without data confirming efficacy, there should be a scientific rationale to support the use of a particular antimicrobial agent.

Table 111.1 lists the situations in which antimicrobial prophylaxis is indicated after exposure to certain pathogens. Because the duration of exposure is usually brief, the duration of chemoprophylaxis is

TABLE 111.1 **PROPHYLAXIS FOLLOWING SELECTED EXPOSURES**

Exposure	Pathogen	Prophylaxis[a]	Comments
Meningitis and meningococcal bacteremia	*Neisseria meningitidis* (see Chapters 141, "Meningococcus and miscellaneous neisseriae" and 74, "Bacterial meningitis")	Rifampin, 600 mg (5 mg/kg for children <1 mo and 10 mg/kg for children ≥1 mo) q12h for 4 doses (not recommended for pregnant women); Ciprofloxacin, 500 mg (single dose) (non-pregnant or lactating adults only—unless no acceptable alternative therapy available—and if not resistant to ciprofloxacin); Ceftriaxone, 250 mg IM 1 dose (125 mg for children <15 yr).	Recommended for close contacts only, including household members, child-care center contacts and anyone directly exposed to oral secretions (through kissing, mouth-mouth resuscitation, or intubation/endotracheal tube management). Only healthcare workers who managed an airway or were otherwise exposed to respiratory secretions of a patient with meningococcal disease require prophylaxis. For travellers on a prolonged flight (≥8 hours), prophylaxis should be considered for passengers seated directly next to an index patient or anyone who had direct contact with respiratory secretions of an index patient during the flight. Prophylaxis is not recommended for close contacts of patients with noninvasive disease (e.g. pneumonia, conjunctivitis, or nasopharyngeal carriage). Significant increased risk of meningococcal disease associated with use of eculizumab, a terminal complement inhibitor. Consider penicillin prophylaxis for the duration of eculizumab treatment.
Meningitis	*Haemophilus influenzae*	Rifampin, 20 mg/kg for individuals ≥1 mo (max dose 600 mg) (10 mg/kg for children <1 mo) daily for 4 d.	Recommended for all index patients (unless treated with cefotaxime or ceftriaxone) and household contacts (except pregnant women) in households with 1) children <4 years who are not fully vaccinated or 2) immunocompromised members <18 years regardless of vaccination status. Index patients aged <2 years treated with any antibiotic other than cefotaxime or ceftriaxone should receive rifampin prophylaxis prior to hospital discharge. In childcare centers, prophylaxis is recommended when two or more cases of invasive Hib disease occur in <60 days and unimmunized or underimmunized children attend the center; all attendees and childcare providers, regardless of age or vaccine status, should receive prophylaxis in this scenario. There are currently no guidelines for prophylaxis for close contacts of patients with nontypable (non type b) *Haemophilus influenza*.
Perinatal group B streptococcus (GBS)	Group B streptococcus	Penicillin G, 5 million units IV initial dose then 2.5 to 3 million q4h, or ampicillin, 2 g IV initial dose then 1 g IV q4h, until delivery. If penicillin or cephalosporin allergic but no history of anaphylaxis, angioedema, respiratory distress or urticaria use cefazolin, 2 g IV initial dose then 1 g IV q8h until delivery. If penicillin or cephalosporin allergic with a history of anaphylaxis, angioedema or respiratory distress and (1) isolate susceptible to clindamycin and erythromycin, use clindamycin, 900 mg IV q8h until delivery, or (2) isolate not susceptible to clindamycin or erythromycin use vancomycin, 1 g IV q12h until delivery.	Women should be screened with vaginal and rectal swabs at 35–37 wk of gestation and intrapartum prophylaxis given if GBS isolated. Prophylaxis should also be given if (1) GBS bacteriuria during any trimester of current pregnancy (with exception of circumstance where cesarean delivery is performed prior to onset of labor and with intact amniotic membranes) (2) previous infant with invasive GBS disease or (3) with unknown GBS status and intrapartum temperature ≥38°C or ≥18 h of ruptured membranes or delivery <37 wk of gestation or intrapartum nucleic acid amplification test (NAAT) positive for GBS.

TABLE 111.1 **CONTINUED**

Exposure	Pathogen	Prophylaxis[a]	Comments
Human bite	*Streptococcus viridans*, other streptococci, oral anaerobes, *Staphylococcus epidermidis, Corynebacterium* sp., *Staphylococcus aureus*, *Eikenella corrodens*	Amoxicillin–clavulanic acid, 875/125 mg BID or 500/125 mg TID for 5 d. For penicillin allergy, consider clindamycin, 300 mg QID, plus ciprofloxacin or levofloxacin.	Cleaning, irrigation, and debridement of human bite wounds are critical interventions to prevent infection. Risk of infection depends on the depth of the wound, extent of tissue damage, and the etiologic pathogen. *Eikenella* is resistant to clindamycin, nafcillin/oxacillin, first-generation cephalosporins, metronidazole, erythromycin and TMP-SMX. Clenched-fist and other hand injuries are at increased risk for deep infection; x-rays recommended.
Cat bite	*Pasteurella multocida*, *S. aureus*, streptococci	Amoxicillin–clavulanic acid, 875/125 mg BID or 500/125 mg TID for 3–5 d. For penicillin allergy, consider doxycycline, 100 mg BID, or cefuroxime axetil, 500 mg BID. If culture positive for only *P. multocida* can narrow treatment to Penicillin G IV or Penicillin VK PO.	The decision whether to give preemptive early antimicrobial therapy following dog or cat bite should be based on host immune competence and wound severity based on the latest IDSA guidelines. Antibiotics are recommended for patients who (1) are asplenic; (2) are immunocompromised; (3) have advanced liver disease; (4) have moderate to severe injuries, especially to the hand or face; (5) have preexisting or resultant edema of the injury site; (6) have injuries that may have penetrated the periosteum or joint capsule.
Dog bite	*S. viridans*, oral anaerobes, *S. aureus*, *P. multocida, P. canis, Capnocytophaga* sp.	Amoxicillin–clavulanic acid, 875/125 mg BID or 500/125 mg TID for 3–5 d For penicillin allergy, consider clindamycin, 300 mg QID, plus either ciprofloxacin, 500 mg BID, or TMP–SMX, 1 double-strength tablet BID	
Sexual assault	*Trichomonas vaginalis*, *Chlamydia trachomatis*, *Treponema pallidum*, *Neisseria gonorrhoeae* HIV (recommendations below in table)	Ceftriaxone, 250 mg IM single dose, plus azithromycin, 1 g single dose, plus metronidazole, 2 g single dose or tinidazole 2 g single dose. Assess risk for HIV in assailant and evaluate survivor for the need for treatment with nonoccupational HIV postexposure prophylaxis (nPEP)	See nPEP guidelines below for detailed discussion of evaluation and treatment in the setting of possible HIV exposure.
Nonoccupational HIV exposure (sexual, injection-drug use, or other exposure)	HIV	Preferred regimen for healthy adults and adolescents: Emtricitabine/tenofovir disoproxil fumarate (TDF/FTC) 300/200 mg plus dolutegravir 50 mg or raltegravir 400 mg BID. If within the first trimester of pregnancy or may become pregnant within the next 28 days, raltegravir preferred. Alternative regimen for adults and adolescents: TDF/FTC plus darunavir 800 mg and ritonavir 100 mg once daily. TDF/FTC contraindicated if CrCl <60 mL/min; expert consult recommended to advise on alternative regimen. First dose should be administered on site as soon as possible after negative rapid HIV test result or immediately after non-rapid HIV test sent. A 28-day prescription should be provided.	Rapid HIV Ag/Ab testing preferable; ideally wait for result prior to offering nPEP. If rapid HIV test is positive, nPEP should NOT be given. If only non-rapid testing available, start nPEP immediately and arrange follow up in 1-2 days for HIV test results. The National Clinician's Post Exposure Prophylaxis Hotline (PEP line), 1-888-448-4911, is a resource available to help clinicians with nPEP decisions. Additional STI testing should be performed and preemptively treated as indicated. For prophylaxis following occupational HIV exposure, see Chapter 104, Percutaneous injury: risks and prevention

(*continued*)

TABLE 111.1 CONTINUED

Exposure	Pathogen	Prophylaxis[a]	Comments
Sexual contacts	*T. pallidum*	Benzathine penicillin G, 2.4 million units IM	Treat if exposed within the previous 90 days. If >90 days after exposure, treat if serologic test results not available and follow-up is uncertain. Doxycycline is an alternative in nonpregnant patients allergic to penicillin.
	N. gonorrhoeae	Ceftriaxone, 250 mg IM single dose plus Azithromycin 1 g single dose.	Dual therapy now routinely recommended for gonococcal infectious due to worsening antimicrobial resistance.
	C. trachomatis	Azithromycin, 1 g single dose, or doxycycline, 100 mg BID for 7 d	Use azithromycin in pregnant women
	T. vaginalis	Metronidazole, 2 g single dose or tinidazole, 2 g single dose. Alternative regimen: metronidazole 500 mg BID for 7 days.	Treatment of sex partners is crucial to achieve cure and prevent reinfection.
Influenza	Influenza A and B	Oseltamivir (≥3 months)or inhaled zanamivir (≥5 years) once daily used after exposure to influenza or as pre-exposure prophylaxis for the duration of the influenza outbreak in the community in high-risk population. Start as soon as possible after exposure, ideally within 48 hours.	Postexposure chemoprophylaxis can be considered for the following groups of asymptomatic adults and children ≥3 months: (1) Those for whom vaccination is contraindicated, unavailable, or expected to have low effectiveness and who are at very high risk of developing complications from influenza and (2) Those who are unvaccinated and are household contacts of a person at very high risk of complications from influenza. Patient education and close follow up for early empiric antiviral initiation can also be considered. Chemoprophylaxis should not be a substitute for vaccination. Historically, amantadine and rimantadine have been used for prophylaxis for influenza A. However, resistance is now widespread. NAI resistance remains uncommon, but has occurred, most notably during the 2008-2009 season when an oseltamivir-resistant H1N1 virus strain was predominant.
Whooping cough	*Bordetella pertussis*	Azithromycin, 500 mg single dose on day 1 then 250 mg/d on days 2–5, or erythromycin, 500 mg QID for 14 d. Clarithromycin, 500 mg BID for 7 d or TMP–SMX, 160/800 mg BID for 7 d, are alternative regimen options.	Postexposure prophylaxis (PEP) recommended for: (1) all household contacts of a pertussis case, regardless of vaccine status and (2) people at high risk of developing severe illness or those who have close contact with people at high risk of developing severe illness. PEP ideally should be provided within 21 days of exposure. Use pediatric dosing for children.
Lyme disease	*Borrelia burgdorferi*	Doxycycline 200 mg single dose	Antimicrobial prophylaxis following tick bite is not recommended in most situations. However doxycycline is recommended (1) within 72 h of the removal of an adult or nymph *Ixodes scapularis* tick and (2) if the tick has been attached >36 h and (3) if the exposure occurred in a region where prevalence of *B. burgdorferi* in ticks is greater than 20%.

TABLE 111.1 CONTINUED

Exposure	Pathogen	Prophylaxis[a]	Comments
Anthrax	*Bacillus anthracis*	Ciprofloxacin, 500 mg BID, or doxycycline, 100 mg bid for 60 d; alternatives include levofloxacin, 500 mg daily, amoxicillin, 1,000 mg TID or Pen VK 500 mg Q6h (for penicillin susceptible strains), and clindamycin 30 mg/kg/day divided q8h (max 900 mg per dose). Two monoclonal antibodies, raxibacumab and obiltoxaximab, are options when alternative therapies are not available or not appropriate.	Inhalational anthrax is considered one of the major threats associated with bioterrorism. Post-event emergency use of anthrax vaccine was approved by the FDA in 2015 for exposed adults 18 through 65 years of age. Vaccine does not replace need for PEP. Use pediatric dosing for children.
Plague	*Yersinia pestis*	Doxycycline, 100 mg BID, or ciprofloxacin, 500 mg BID, for 7 d.	Incubation period for pneumonic plague is short (2–3 d); for established infection, streptomycin IM or gentamicin IM/IV remain the agents of choice. Use pediatric dosing for children.
Tularemia	*Francisella tularensis*	Doxycycline, 100 mg BID for 14 d, or ciprofloxacin, 500 mg BID	Prophylaxis recommended only in cases of laboratory inhalation or percutaneous exposure.

Abbreviation: TMP-SMX = trimethoprim–sulfamethoxazole.
[a] All regimens are administered orally unless otherwise specified.

short, which helps limit adverse reactions, minimizes the potential for resistance, and limits cost. Table 111.1 includes chemoprophylaxis for human, dog, and cat bites. It is important to remember that, aside from antibiotics, immunization (rabies and tetanus vaccines), irrigation, and debridement are crucial in the management of both animal and human bites. Table 111.1 also includes microorganisms that have gained notoriety as possible agents of biologic warfare or terrorism and infections that are sexually transmitted. Significant evidence supports the use of tenofovir-emtricitabine for the prevention of HIV infection in high-risk populations prior to exposure (pre-exposure prophylaxis or PrEP). This approach requires strict adherence, regular HIV and sexually transmitted disease testing, frequent monitoring, and carries the potential risk of developing HIV drug resistance. Pre-exposure prophylaxis should be used in combination with other methods to prevent HIV. See Chapter 101 for more information regarding PrEP guidelines.

Persons with an underlying predisposition to infection may benefit from prophylactic antimicrobial agents (Table 111.2). In contrast to short-term prophylaxis administered after exposures, chronic prophylaxis is often required. Because of the duration of antibiotic administration, the complications of chemoprophylaxis, including alteration of the microbiota and antibiotic resistance, are major considerations. Given these concerns, the decision to prescribe chronic chemoprophylaxis should be made on a case-by-case basis and should always involve a risk versus benefit conversation with the patient and/or family.

Chemoprophylaxis for *M. tuberculosis* is used to prevent acquisition of infection in high-risk groups following exposure to a patient with contagious tuberculosis disease. More commonly, preemptive therapy is given to those latently infected as demonstrated by a positive tuberculin or purified protein derivative (PPD) skin test or a positive interferon-γ release assay (IGRA) to prevent the development of tuberculosis disease. The regimens for chemoprophylaxis or treatment of latent *M. tuberculosis* infection are listed in Table 111.3. Prior to initiating prophylaxis for latent infection, the clinician should rule out active disease with a chest radiograph. In the setting of suspected infection with multidrug-resistant *M. tuberculosis*, the decision to provide chemoprophylaxis and the choice of regimen should be made by experienced healthcare professionals.

Chemoprophylaxis has been advocated for other situations, but, at this time, there is debate about the optimal role (Table 111.4). Although data are limited, it is likely that cost–benefit analyses may not favor routine prophylaxis in some of these settings or that the benefits of prophylaxis in the short term would be outweighed by long-term consequences, such as the development of antibiotic-resistant organisms.

TABLE 111.2 CHRONIC PROPHYLAXIS IN SPECIFIC CLINICAL SETTINGS

Underlying condition or recurrent infections	Pathogens	Prophylaxis[a]	Comments
Acute rheumatic fever (prevention of recurrences)	*Streptococcus pyogenes*	Penicillin G, 1.2 million units IM every 34 wk or penicillin V, 250 mg BID; alternatives include erythromycin, 250 mg BID or sulfadiazine, 1 g daily (0.5 g if weight ≤27 kg)	Risk diminishes with increasing age and time since initial attack; optimal duration unknown but continue prophylaxis at least until the early 20s or for 5 yr after most recent attack; some authorities advocate lifelong prophylaxis, especially after rheumatic carditis; 3-wk dosing of penicillin is recommended in particularly high risk populations, including those who have recurrent acute rheumatic fever while on an every-4-week regimen.
Asplenia, including sickle cell disease	Predominantly *S. pneumoniae;* also *H. influenzae Neisseria meningitidis*	Penicillin V, 250 mg BID (125 mg BID for children ≤5 yr), or amoxicillin 500 mg BID; prophylaxis generally continued at least 1 year after splenectomy; for children with sickle cell disease, prophylaxis continued at least until aged 5 yr. Alternative option instead of daily prophylaxis is to self-administer amoxicillin-clavulanate at onset of any febrile illness while seeking medical attention	Efficacy of chemoprophylaxis clearly established for children with sickle cell disease; chemoprophylaxis generally not recommended for adults (lower risk). Worsening antibiotic resistance rates diminish attractiveness of antibiotic prophylaxis and increases the importance of vaccination.
Lymphedema with recurrent cellulitis	*S. pyogenes*	Penicillin VK, 250 mg BID. In penicillin-allergic patients, use macrolides	Given only to patients with frequent episodes of erysipelas; efficacy is limited in patients with significant underlying disease and high BMI. Important to differentiate stasis dermatitis (non-infectious condition) from cellulitis.
Spontaneous bacterial peritonitis (SBP)	*Escherichia coli*, other *Enterobacteriaceae, Streptococcus* and *staphylococcus* sp. *enterococcus* sp.	Ciprofloxacin 500 mg daily, or TMP–SMX, 1 double-strength tablet daily. Patients with Child-Pugh class B or C cirrhosis and active gastrointestinal bleeding should receive Ceftriaxone 1 gm IV daily with eventual step down to oral options as above.	Used in persons with ascites protein concentration of ≤1 g/dL, with active variceal bleeding, and in persons with previous SBP.

Abbreviation: TMP-SMX = trimethoprim–sulfamethoxazole.
[a] All regimens are administered orally unless otherwise specified.

TABLE 111.3 REGIMENS FOR CHEMOPROPHYLAXIS[a] OR PREEMPTIVE THERAPY FOR *M. TUBERCULOSIS*

Drug(s)	Regimen	Duration	Comments
Isoniazid (INH)	300 mg (10–15 mg/kg children) daily or 900 mg (20–30 mg/kg children) twice weekly	6–9 months	9-month regimen preferred as more effective. 6-month regimen more cost-effective and has better compliance, but should NOT be used for HIV-infected patients, patients with evidence of healed TB on CXR and children Intermittent regimens provided by directly observed therapy (DOT).
Isoniazid and rifapentine (RPT)	900 mg INH and 900 mg RPT weekly	3 months	Alternative to INH with advantage of shorter duration, fewer doses, and higher rates of treatment completion. Can be self-administered or given by DOT. Use weight-based dosing for those under 50 kg, children 2–11 years. Not recommended for children under 2 years, pregnant women, or HIV-infected persons on antiretroviral medications with clinically significant or unknown drug interactions with RPT.
Rifampin (RIF)	600 mg daily	4 months	Use for those intolerant of INH or if exposed to INH resistant tuberculosis. Weight-based dosing in children. Not recommended for HIV-infected persons on antiretroviral medications with clinically significant or unknown drug interactions with RIF.

Abbreviations: TB = tuberculosis; CXR = chest x-ray; TNF-α = tumor necrosis factor-α.
[a] Chemoprophylaxis recommended for certain high-risk patients including children <5 years during the "window period" after exposure to active tuberculosis and before follow-up testing at 8–10 weeks, regardless of negative initial test result. Depending on intensity of exposure and rate of skin test conversion among others exposed, full course treatment should be considered in exposed persons with HIV infection, those on immunosuppressive therapy (including following transplantation) or in persons taking TNF-α antagonists.

TABLE 111.4 **CONTROVERSIAL AREAS REGARDING THE USE OF PROPHYLACTIC ANTIBIOTICS**[A]

Condition	Comments
Prosthetic device prophylaxis	Routine chemoprophylaxis before dental work, or other procedures that cause transient bacteremia in patients with prosthetic joints or vascular prostheses, is usually not warranted; prosthetic joint infections caused by oral microbiota, including α-streptococci, are uncommon, with a rate approaching that of endocarditis in patients with mitral valve prolapse without regurgitation, for which chemoprophylaxis is not recommended; coronary stents do not appear to be prone to infection
Recurrent urinary tract infection (UTI)	For selected patients with more than three infections yearly; consider prophylaxis for 6–12 mo. Prophylactic antibiotic choice should be tailored individually based on prior urinary bacterial isolates identity and susceptibility. Anatomic and functional causes of recurrent UTI should be investigated and treated as indicated.
Chronic bronchitis, bronchiectasis	May be useful in selected patients with frequent exacerbations (>4/yr); some authorities prefer antibiotics at first sign of infection. Azithromycin daily for 1 yr has been shown to decrease frequency of exacerbations and improve quality of life in patients with chronic obstructive pulmonary disease; hearing loss noted in some subjects. Consider inhaled antipseudomonal antibiotic in patients with chronic bronchiectasis.
IV catheter-associated infections	Antibiotic or ethanol "lock" therapy has been shown to prevent central venous catheter-associated bloodstream infections in some high-risk patients including those with recurrent catheter infections but data remains limited.
Pancreatitis	In severe pancreatitis with necrosis, antibacterial (as well as antifungal) prophylaxis has been suggested. However, even if antimicrobials appear to decrease mortality, in pancreatic necrosis they do not prevent infections

Abbreviations: UTI = urinary tract infection; IV = intravenous.

Surgical prophylaxis

Sonya Trinh and George A. Pankey

Introduction

Surgical site infections (SSIs) are infections related to operative procedures involving the incision site or surrounding tissues and organs. In the United States, an estimated 95 million operative procedures are performed annually in ambulatory settings and hospitals.[1] The annual incidence of SSIs in acute care hospitals has ranged from 2% to 5%; however, these rates are likely underestimates since 50% of SSIs are diagnosed after discharge.[2,3] According to national surveillance data from 2011 to 2014, SSIs were one of the most common hospital-acquired infections (HAI), accounting for 36.4% of HAIs.[4]

SSIs increase direct and indirect healthcare costs related to prolonged hospital stays, emergency room visits, readmissions for treatment, and repeat surgical procedures.[5] SSIs prolong the length of hospital stay by an average of 9.7 days and are the most common reason (19.5%) for unplanned readmission after surgical procedures.[6] Societal costs related to SSIs include loss of productivity and temporary or permanent disability. The annual cost of SSIs is an estimated $3.2 billion ($20,000 per case) and accounts for the largest proportion of costs related to HAIs (44.7%).[7] The healthcare and societal costs of SSIs are expected to increase since the number of operative procedures continues to rise each year and more procedures are performed on patients with complex comorbidities.[8]

The application of evidence-based strategies can prevent up to 55% of SSIs.[9] Starting in the early 2000s, the Centers for Disease Control and Prevention (CDC), the Centers for Medicare and Medicaid Services (CMS), healthcare facilities, and state health departments developed several measures to improve the safety and quality of surgical procedures. In 2005, the CDC established the National Healthcare Safety Network (NHSN) to track HAIs, including SSIs, to help healthcare facilities identify problem areas and measure the progress of prevention efforts. Since its inception, the NHSN has become the largest national surveillance system, with the participation of more than 17,000 healthcare facilities.[10] In 2006, the CDC and CMS created the Surgical Care Improvement Project to identify best practices for perioperative management including antimicrobial prophylaxis, glucose and temperature control, and venous thromboembolism prophylaxis.[11] CMS developed the Physicians Quality Reporting System to provide financial incentives to physicians meeting performance standards for quality measures, including measures related to surgical procedures. Based on physician performance, CMS and insurers can reduce or deny payments for surgical complications including SSIs.[12]

Definitions

Surgical site infections

SSIs are infections of the incision, surrounding tissues, or organs that occur within 90 days of an operative procedure.[13] For the purposes of research, quality improvement, and national surveillance, the NHSN has established a classification system for SSIs based on the degree of involvement: superficial incisional, deep incisional, and organ or space SSI (Box 112.1). *Superficial incisional* SSIs involve the skin and subcutaneous tissue surrounding the incision. *Deep incisional* SSIs extend to the fascia and muscle layers around the incision.

BOX 112.1

The National Healthcare Safety Network criteria for surgical site infections (SSI)[13]

Superficial incisional SSI

Date of event for infection occurs within 30 days after any operative procedure (where day 1 = the procedure date),

AND

Involves only skin and subcutaneous tissue of the incision,

AND

Patient has at least one of the following:

A. Purulent drainage from the superficial incision,

B. Organisms identified from an aseptically obtained specimen from the superficial incision or subcutaneous tissue by a culture- or nonculture-based microbiologic testing method which is performed for purposes of clinical diagnosis or treatment,

C. Superficial incision that is deliberately opened by a surgeon, attending physician, or other designee and culture- or nonculture-based testing is not performed,

AND

Patient has at least one of the following signs or symptoms: pain or tenderness; localized swelling; erythema; or heat,

D. Diagnosis of a superficial incisional SSI by the surgeon or attending physician or other designee.

Deep incisional SSI

Date of event for infection occurs within 30 or 90 days depending on the operative procedure (where day 1 = the procedure date),

AND

Involves deep soft tissues of the incision (for example, fascial and muscle layers),

AND

Patient has at least one of the following:

A. Purulent drainage from the deep incision,

B. A deep incision that spontaneously dehisces, or is deliberately opened or aspirated by a surgeon, attending physician or other designee,

AND

Organism is identified by a culture- or nonculture-based microbiologic testing method which is performed for purposes of clinical diagnosis or treatment culture or non-culture based microbiologic testing method is not performed,

AND

Patient has at least one of the following signs or symptoms: fever (>38°C); localized pain or tenderness. A culture- or nonculture-based test that has a negative finding does not meet this criterion,

C. An abscess or other evidence of infection involving the deep incision that is detected on gross anatomical or histopathologic exam, or on imaging test.

Organ/Space SSI

Date of event for infection occurs within 30 or 90 days depending on the operative procedure (where day 1 = the procedure date),

AND

Infection involves any part of the body deeper than the fascial/muscle layers, that is opened or manipulated during the operative procedure,

AND

Patient has at least one of the following:

A. Purulent drainage from a drain that is placed into the organ/space (for example, closed suction drainage system, open drain, T-tube drain, CT-guided drainage),

B. Organisms are identified from fluid or tissue in the organ/space by a culture- or nonculture-based microbiologic testing method which is performed for purposes of clinical diagnosis or treatment,

C. An abscess or other evidence of infection involving the organ/space that is detected on gross anatomical or histopathologic exam, or imaging test evidence is suggestive of infection.

Organ or *space* SSIs involve any area deeper than the fascia and muscle layer opened or manipulated during the operative procedure.[13]

Patients with SSIs may present with one or more of the following signs or symptoms: fevers (>38°C/100°F); pain or tenderness of the surgical site; localized swelling, erythema, or heat of the incision; purulent drainage from the superficial or deep incision; and spontaneous dehiscence of the deep incision. A microbiological diagnosis of SSIs is confirmed by obtaining an aseptic specimen from the superficial incision, subcutaneous tissue, or organ space and identifying organisms by culture or molecular testing. Imaging, gross anatomy, and histopathology are additional tools used to diagnose deep incisional and organ space infections.[13]

Surgical wound classification system

The American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) developed a surgical wound classification (SWC) system to assist with operative planning, develop perioperative protocols, and estimate infectious risk.[14] Surgeries are categorized at the time of the procedure into four SWCs based on the expected degree of contamination: class I clean, class II clean-contaminated, class III contaminated, and class IV dirty or infected (Box 112.2). In clean operations, the respiratory, alimentary, genital, or urinary tracts are not entered, and no inflammation is encountered during the procedure. During clean-contaminated procedures, the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions without contamination. Contaminated procedures include those with major breaks in sterile technique such as open cardiac massage or gross spillage from the gastrointestinal tract. Contaminated procedures also include surgeries traversing open, fresh, accidental wounds or acute, nonpurulent, and possibly necrotic incisions. Dirty or infected operations address existing clinical infections or perforated viscera. Dirty operations also include those performed on old traumatic wounds with retained devitalized tissue.[14]

BOX 112.2

The American College of Surgeons National Surgical Quality Improvement Program (ACS-NSQIP) surgical wound classification system[14]

Class I: Clean
An uninfected operative wound in which no inflammation is encountered and the respiratory, alimentary, genital, or urinary tracts are not entered. In addition, clean wounds are primarily closed and, if necessary, drained with closed drainage. Operative incisional wounds that follow nonpenetrating (blunt) trauma should be included in this category if they meet criteria.

Class II: Clean-Contaminated
Operative wounds in which the respiratory, alimentary, genital, or urinary tracts are entered under controlled conditions and without unusual contamination. Specifically, operations involving the biliary tract, appendix, vagina, and oropharynx are included in this category, provided no evidence of infection or major break in technique is encountered.

Class III: Contaminated
Open, fresh, accidental wounds. In addition, operations with major breaks in sterile technique (e.g., open cardiac massage) or gross spillage from the gastrointestinal tract and incisions in which acute, non-purulent inflammation is encountered are included in this category.

Class IV: Dirty or Infected
Includes old traumatic wounds with devitalized tissue and those that involve existing clinical infection or perforated viscera. This definition suggests that the organisms causing postoperative infection were present in the operative field before the operation

A cross-sectional study evaluated rates of SSI by wound class among 634,426 surgical cases reported to the ACS-NSQIP between 2005 and 2008.[14] The proportion of surgeries classified as clean was 49.7%, clean-contaminated was 35%, contaminated was 8.56%, and dirty was 6.7%. The rates of superficial, deep incisional, and organ/space SSIs were 1.8%, 0.5%, 0.3%, respectively, for clean; 3.9%, 0.9%, 1.9% for clean-contaminated; 4.8%, 1.3%, 2.6% for contaminated; and 5.2%, 2.1%, 4.5% for dirty procedures.[14]

Microbiology

According to the National Nosocomial Infections Surveillance System, the pathogens responsible for SSIs in US hospitals have shifted from primarily gram-negative to gram-positive organisms over the past three decades; the prevalence of SSIs caused by gram-negative bacilli decreased from 56.5% in 1986 to 33.8% in 2003.[15] Possible reasons behind the shift toward gram-positive organisms include the implementation of antimicrobial prophylaxis and the increased use of laparoscopy for intra-abdominal procedures.[15]

In clean procedures, the predominant organisms responsible for SSIs are skin flora including *Staphylococcus aureus* and coagulase-negative staphylococci (CoNS). In clean-contaminated procedures involving the respiratory, gastrointestinal, genital, or urinary tract, the main causative pathogens include skin flora, gram-negative bacilli, and *Enterococcus* species. Contaminated and dirty procedures are usually polymicrobial with organisms reflective of the endogenous flora of the manipulated organ system.[16]

Between 2011 and 2014, 149,009 pathogens from 133,080 SSIs across 4,515 hospitals were reported to the NHSN (Table 112.1). The most common pathogens across all surgeries were

TABLE 112.1 **SURGICAL SITE INFECTIONS (SSIS) REPORTED TO THE NATIONAL HEALTHCARE SAFETY NETWORK (NHSN) FROM 2011 TO 2014[4]**

Type of surgery	Number (%) of SSIs (*n* = 133,080)	Number (%) of pathogens (*n* = 149,009)
Abdominal	63,508 (47.7)	76,307 (51.2)
Breast	886 (0.7)	946 (0.6)
Cardiac	10,439 (7.8)	11,281 (7.6)
Kidney	251 (0.2)	285 (0.2)
Neck	146 (0.1)	212 (0.1)
Neurological	1,945 (1.5)	2,168 (1.5)
Obstetrical and gynecological	22.231 (16.7)	20,725 (13.9)
Orthopedic	31,539 (23.7)	34,341 (23.0)
Prostate	53 (<0.1)	61 (<0.1)
Transplant	644 (0.5)	815 (0.5)
Vascular	1,438 (1.1)	1,868 (1.3)

S. aureus (20.7%), *Escherichia coli* (13.7%), CoNS (7.9%), *Enterococcus faecalis* (7.5%), and *Pseudomonas aeruginosa* (5.7%) (Table 112.2). The operations accounting for the majority of SSIs were abdominal (47.7%), orthopedic (23.7%), obstetrics and gynecology (16.7%), and cardiac (7.8%) procedures. The most common pathogens isolated from SSIs after abdominal procedures were *E. coli* (19.6%), *E. faecalis* (9.4%), and *S. aureus* (9.1%). For orthopedic surgery SSIs, the most prevalent organisms were *S. aureus* (44.2%), CoNS (13.0%), and *P. aeruginosa* (4.9%).[4]

The number of SSIs caused by antibiotic-resistant organisms has increased since the 2000s. In a study of patients with culture-confirmed SSIs, the proportion of infections caused by methicillin-resistant *S. aureus* (MRSA) increased from 16.1% in 2003 to 20.6% in 2007 ($p < 0.0001$). MRSA infections were associated with higher mortality rates, longer hospital stays, and higher hospital costs compared with infections caused by other pathogens.[17] Among the SSI pathogens reported to the NHSN from 2011 to 2014, MRSA accounted for 43% of *S. aureus* isolates, and 60% of *E. faecium* isolates were vancomycin-resistant enterococci (VRE).[4]

Risk factors for surgical site infections

Several factors influence the risk of SSIs, including the patient's underlying medical condition, perioperative management, operative techniques, and the operating room environment (Box 112.3). Patient-related risk factors include extremes of age, diabetes mellitus, obesity, tobacco use, nutritional status, and altered immune response. Perioperative risk factors include improper skin preparation, hair removal, antimicrobial prophylaxis, and glycemic and temperature control. Procedural risk factors include surgeon inexperience and poor technique, timing of the operation (emergency vs. elective), and the length of the procedure. Risk factors related to the operating room environment include improper surgical scrub, skin antisepsis, and equipment sterilization.[18]

Guidelines for prevention of surgical site infections

Three national guidelines were developed for the prevention of SSIs: the 2013 American Society of Health-System Pharmacists (ASHP) Clinical Practice Guidelines for Antimicrobial Prophylaxis in Surgery, the 2016 American College of Surgeons (ACS) and Surgical Infection Society (SIS) Surgical Site Infection Guidelines, and the 2017 CDC Guidelines for Prevention of Surgical Site Infection.[18–20] This section summarizes the guideline recommendations and highlights any meta-analyses or large, well-conducted, randomized controlled trials (RCTs) supporting the recommendation.

TABLE 112.2 **DISTRIBUTION OF PATHOGENS ASSOCIATED WITH SURGICAL SITE INFECTIONS REPORTED TO THE NATIONAL HEALTHCARE SAFETY NETWORK (NHSN) FROM 2011 TO 2014**[4]

Pathogen	Total number (%) of pathogens (*n* = 149,009)	Number of pathogens by surgery type (%)				
		Abdominal (*n* = 76,307)	Orthopedic (*n* = 34,341)	Ob/Gyn (*n* = 20,725)	Cardiac (*n* = 11,281)	Other (*n* = 6,355)
Staphylococcus aureus	30,902 (20.7)	6,922 (9.1)	15,163 (44.2)	3,680 (17.7)	3,430 (30.4)	1,707 (26.9)
Escherichia coli	20,429 (13.7)	14,955 (19.6)	1.625 (4.7)	2,787 (13.4)	647 (5.7)	2,038 (32.1)
Coagulase-negative staphylococci	11,799 (7.9)	3,273 (4.3)	4,461 (13.0)	1,520 (7.3)	1,641 (14.5)	904 (14.2)
Enterococcus faecalis	11,156 (7.5)	7,197 (9.4)	1,620 (4.7)	1,710 (8.3)	325 (2.9)	304 (4.8)
Pseudomonas aeruginosa	8,458 (5.7)	4,469 (5.9)	1,672 (4.9)	990 (4.8)	918 (8.1)	409 (6.4)
Klebsiella (*pneumoniae/oxytoca*)	7,067 (4.7)	4,318 (5.7)	943 (2.7)	856 (4.1)	650 (5.8)	300 (4.7)
Bacteroides spp.	7,041 (4.7)	5,690 (7.5)	128 (04)	1,108 (5.3)	40 (0.4)	75 (1.2)
Enterobacter spp.	6,615 (4.4)	3,475 (4.6)	1,401 (4.1)	741 (3.6)	650 (5.8)	348 (5.5)
Other *Enterococcus* spp.	6,410 (4.3)	4,692 (6.1)	592 (1.7)	806 (3.9)	160 (1.4)	160 (2.5)
Proteus spp.	4,196 (2.8)	1,473 (1.9)	1,108 (3.2)	919 (4.4)	516 (4.6)	180 (2.8)
Enterococcus faecium	4,140 (2.8)	3,451 (4.5)	271 (0.8)	152 (0.7)	105 (0.9)	161 (2.5)
Candida albicans	3,351 (2.2)	2,736 (3.6)	132 (0.4)	215 (1.0)	160 (1.4)	108 (1.7)
Virdans streptococci	2,639 (1.8)	1,849 (2.4)	254 (0.7)	368 (1.8)	81 (0.7)	87 (1.4)
Group B streptococci	1,879 (1.3)	291 (0.4)	765 (2.2)	680 (3.3)	80 (0.7)	63 (1.0)
Serratia spp.	1,857 (1.2)	333 (0.4)	527 (1.5)	235 (1.1)	579 (5.1)	183 (2.9)
Other pathogen	21,070 (14.1)	11,183 (14.7)	3,679 (10.7)	3,968 (19.1)	1,299 (11.5)	941 (14.8)

BOX 112.3

American College of Surgeons and Surgical Infection Society surgical site infection risk factors

Intrinsic (patient-related)
Nonmodifiable
Increased age
Recent radiotherapy
History of skin or soft tissue infection
Modifiable
Diabetes
Obesity
Alcoholism
Current smoker
Preoperative albumin <3.5 mg/dL
Immunosuppression
Extrinsic (procedure-related)
Procedure
Emergency
Increasing complexity
Higher wound classification
Facility
Inadequate ventilation
Increased operating room traffic
Contaminated environmental services
Nonsterile equipment
Preoperative
Preexisting infection
Inadequate skin preparation
Inappropriate antibiotic choice, timing, and weight-based dosing
Hair removal method
Poor glycemic control
Intraoperative
Longer procedure duration
Blood transfusion
Breach in asepsis
Inappropriate antibiotic redosing
Inadequate gloving
Inappropriate surgical scrub
Poor glycemic control

The first part of the section summarizes the 2014 ASHP Clinical Practice Guidelines for Antimicrobial Prophylaxis in Surgery developed jointly by ASHP, SIS, the Infectious Diseases Society of America, and the Society for Healthcare Epidemiology of America.[19] These guidelines provide recommendations on the safe and effective use of antimicrobial agents for the prevention of SSIs based on a systematic review of the primary literature from 1999 through June 2010.

The second part of the section is a combined review of the 2016 ACS/SIS and 2017 CDC guidelines on perioperative interventions to address patient- and procedure-related risk factors.[18] The CDC guidelines were developed by clinical experts in collaboration with the Healthcare Infection Control Practices Advisory Committee, a federal advisory committee of the CDC.[20] These guidelines update the 1999 CDC recommendations,[21] with a systematic review of the primary literature from January 1998 through April 2014.[20] The section highlights recommendations relevant to the clinical practice of the infectious diseases specialist.

Prophylactic antimicrobial agents

The goals of preoperative antimicrobial prophylaxis are to prevent SSIs, prevent morbidity and mortality related to SSIs, and reduce healthcare costs. The benefits of surgical prophylaxis need to be weighed against the risks of antibiotic exposure, such as adverse drugs reactions and alterations to the patient's microbial flora. For the majority of procedures, cefazolin is the recommended antimicrobial agent for surgical prophylaxis because it is a safe and inexpensive antibiotic with an appropriate duration of action and activity against the pathogens most likely to contaminate the surgical site. For patients with a documented β-lactam allergy, acceptable alternatives include vancomycin or clindamycin. Antimicrobial agents should be administered at the appropriate time and dosage so that an adequate concentration reaches the serum and tissue during the procedure.

Timing of initial dose

A single dose of cefazolin should be administered within 60 minutes prior to incision to ensure a bactericidal concentration is established in the serum and tissues during the procedure.[20] For vancomycin and fluoroquinolones, the initial dose should be administered within 60 to 120 minutes prior to incision.[19,22] The optimal timing for surgical antimicrobial prophylaxis was established in the Trial to Reduce Antimicrobial Prophylaxis Errors (TRAPE), a large prospective multicenter study of patients undergoing cardiac surgery, hysterectomy, or hip or knee arthroplasty (n = 4,472). Patients were categorized into four groups based on the timing of surgical prophylaxis: group 1 (n = 1,844) received either a cephalosporin within 30 minutes before incision or vancomycin or a fluoroquinolone within one hour before incision; group 2 (n = 1,796) received either a cephalosporin 31 to 60 minutes before incision or vancomycin or a fluoroquinolone 61 to 120 minutes before incision; group 3 (n = 644) received antimicrobials earlier than recommended; and group 4 (n = 188) received the initial antimicrobial dose after incision. The study found rates of SSI increased as the interval of time between the antibiotic infusion and incision increased (2.1% in group 1, 2.4% group 2, and 2.8% group 3).[23]

Dosing

The ASHP recommendations for prophylactic antimicrobial agent dosing are summarized in Table 112.3. The dose of preoperative antimicrobial prophylaxis should be increased in obese and morbidly obese patients. A cefazolin dose of 2 g is recommended for

TABLE 112.3 **AMERICAN SOCIETY OF HEALTH SYSTEM PHARMACISTS RECOMMENDED DOSES AND REDOSING INTERVALS FOR ANTIMICROBIALS USED IN SURGICAL PROPHYLAXIS[19]**

Antimicrobial	Dose in adults	Half-life with normal renal function, hr	Redosing interval, hr
Ampicillin-sulbactam	3 g	0.8–1.3	2
Ampicillin	2 g	1–1.9	2
Aztreonam	2 g	1.3–2.4	4
Cefazolin	2 g, 3 g if ≥120 kg	1.2–2.2	4
Cefuroxime	1.5 g	1–2	4
Cefotaxime	1 g	0.9–1.7	3
Cefoxitin	2 g	0.7–1.1	2
Cefotetan	2 g	2.8–4.6	6
Ceftriaxone	2 g	5.4–10.9	NA
Ciprofloxacin	400 mg	3–7	NA
Clindamycin	900 mg	2–4	6
Ertapenem	1 g	3–5	NA
Gentamicin	5 mg/kg	2–3	NA
Levofloxacin	500 mg	6–8	NA
Metronidazole	500 mg	6–8	NA
Moxifloxacin	400 mg	8–15	NA
Piperacillin-tazobactam	3.375 g	0.7–1.2	2
Vancomycin	15 mg/kg	4–8	NA

patients weighing >60 kg and 3 g if >120 kg. The use of ideal body weight versus actual body weight depends on the lipophilicity of the drug; ideal body weight for lipophilic drugs (vancomycin) results in subtherapeutic concentrations in serum and tissue, while actual body weight for hydrophilic drugs (aminoglycoside) results in excessive concentrations in serum and tissue. For aminoglycosides, dosing is calculated using the patient's ideal body weight plus 40% of the difference between the actual and ideal body weight. Vancomycin should be dosed at 15 mg/kg.[19,22]

A pharmacokinetic study investigated cefazolin concentrations in the serum and tissues of 38 morbidly obese patients undergoing Roux-en-Y gastric bypass surgery. The patients were classified into three groups based on their body mass index (BMI): (A) BMI = 40 to 49, (B) BMI = 50 to 59, (C) BMI ≥60. Two grams of cefazolin was administered to all patients 30 to 60 minutes before the incision and a second 2 g dose 3 hours later. Tissue antimicrobial concentrations exceeded the therapeutic levels in only 48.1%, 28.6%, and 10.2% of BMI groups A, B, and C, respectively. This study highlighted the need to increase the cefazolin dose in obese patients to achieve therapeutic levels in the serum and tissue at the time of incision.[24]

Redosing

The ASHP recommendations for prophylactic antimicrobial agent redosing are summarized in Table 112.3. Redosing of prophylactic antimicrobial agents is recommended when the procedure time exceeds the half-life of the antibiotic. Redosing is also appropriate in patients with major blood loss (>1,500 mL) or extensive burns. Redosing should be performed at intervals of one to two times the antibiotic half-life.[19,22] Among patients in the TRAPE study undergoing operations lasting more than 4 hours, patients given a second dose of prophylactic antibiotics had a threefold reduction in the risk of SSI compared to those who were not redosed.[23]

Duration

In clean and clean-contaminated procedures, additional doses of prophylactic antimicrobial agents are not recommended after the surgical incision is closed.[20] The duration of antimicrobial prophylaxis should be <24 hours for most procedures. A meta-analysis was performed of 21 RCTs comparing no postoperative antimicrobial prophylaxis to postoperative antimicrobial prophylaxis for <24 hours among patients undergoing cardiac; thoracic; vascular; ear, nose, and throat; gynecologic; orthopedic; or general surgery procedures (n = 14,285). The study found no benefit in continuing antimicrobial prophylaxis after intraoperative closure of the surgical incision (odds ratio [OR] 1.84, p = 0.14).[20]

Penicillin allergy

Patients with a type I immunoglobulin E-mediated allergy to β-lactams develop anaphylaxis, urticaria, and/or bronchospasm within 30 to 60 minutes of β-lactam administration. Patients with a documented β-lactam allergy should receive an alternative to cefazolin for the prevention of SSIs. Patients with a history of exfoliative dermatitis to β-lactams (Stevens-Johnson syndrome, toxic epidermal necrolysis) should also receive an alternative antimicrobial agent. Acceptable alternatives include vancomycin, clindamycin, fluoroquinolones, and aminoglycosides.

A careful history should be obtained preoperatively to determine if a true β-lactam allergy exists because alternative antimicrobial agents are associated with decreased efficacy, increased costs, and adverse events. A single-center retrospective cohort study found patients with reported penicillin allergy had increased odds of developing an SSI. Among patients undergoing hip arthroplasty, knee arthroplasty, hysterectomy, colon surgery, or coronary artery bypass grafting (CABG) from 2010 to 2014 (n = 8,385), 922 (11%) reported a penicillin allergy and 241 (2.7%) developed an SSI.[25] Patients with reported penicillin allergies were administered cefazolin less often and received clindamycin, vancomycin, or gentamicin more frequently compared to those without a reported allergy. Patients reporting a penicillin allergy had 50% increased odds of SSIs attributed to the receipt of second-line antimicrobial prophylaxis. Accordingly, the study concluded that clarifying the type of reaction to penicillin should be included in routine perioperative care to prevent SSIs.

Type of surgery

The ASHP recommendations for prophylactic antimicrobial agents based on the type of surgery are summarized in Table 112.4.

TABLE 112.4 AMERICAN SOCIETY OF HEALTH-SYSTEM PHARMACISTS RECOMMENDATIONS FOR SURGICAL ANTIMICROBIAL PROPHYLAXIS[19]

Type of procedure	Recommended agents	Alternative agents in patients with β-lactam allergy
Cardiac (coronary artery bypass, cardiac device insertion, ventricular assist devices)	Cefazolin, cefuroxime	Clindamycin, vancomycin
Thoracic (lobectomy, pneumonectomy, lung resection, thoracotomy, video-assisted thoracoscopic surgery)	Cefazolin, ampicillin-sulbactam	Clindamycin, vancomycin
Gastroduodenal	Cefazolin	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Biliary tract	Cefazolin, cefoxitin, cefotetan, ceftriaxone, ampicillin-sulbactam	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone Metronidazole + aminoglycoside or fluoroquinolone
Laparoscopic procedure		
• Elective, low-risk	None	None
• Elective, high-risk	Cefazolin, cefoxitin, cefotetan, ceftriaxone, ampicillin-sulbactam	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone Metronidazole + aminoglycoside or fluoroquinolone
Appendectomy for uncomplicated appendicitis	Cefoxitin, cefotetan, cefazolin + metronidazole	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone Metronidazole + aminoglycoside or fluoroquinolone
Small intestine		
• Nonobstructed	Cefazolin	Clindamycin + aminoglycoside or aztreonam or fluoroquinolone
• Obstructed	Cefazolin + metronidazole, cefoxitin, cefotetan	Metronidazole + aminoglycoside or fluoroquinolone
• Hernia repair	Cefazolin	Clindamycin, vancomycin
Colorectal	Cefazolin + metronidazole, cefoxitin, cefotetan, ampicillin-sulbactam, ceftriaxone + metronidazole, ertapenem	Clindamycin + aminoglycoside or aztreonam or fluoroquinolone Metronidazole + aminoglycoside or fluoroquinolone
Head and neck		
• Clean	None	None
• Clean with placement of prosthesis	Cefazolin, cefuroxime	Clindamycin
• Clean-contaminated	Cefazolin + metronidazole, cefuroxime + metronidazole, ampicillin-sulbactam	Clindamycin
Neurosurgery	Cefazolin	Clindamycin, vancomycin
Cesarean delivery	Cefazolin	Clindamycin, vancomycin
Hysterectomy	Cefazolin, cefotetan, cefoxitin, ampicillin-sulbactam	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone Metronidazole + aminoglycoside or fluoroquinolone
Ophthalmic	Topical neomycin-polymyxin B-gramicidin, gatifloxacin, moxifloxacin (given as 1 drop every 5-15 minutes for 5 doses)	

TABLE 112.4 **CONTINUED**

Type of procedure	Recommended agents	Alternative agents in patients with β-lactam allergy
Orthopedic		
• Clean (involving hand, knee, foot not involving implantation of foreign material)	None	None
• Spinal procedures, implantation of internal fixation devices, total joint replacement	Cefazolin	Clindamycin, vancomycin
Urologic		
• Lower tract instrumentation with risk factors for infection	Fluoroquinolone, trimethoprim-sulfamethoxazole, cefazolin	Aminoglycoside
• Clean without entry into urinary tract	Cefazolin	Clindamycin, vancomycin
• Clean with entry into urinary tract	Cefazolin	Fluoroquinolone, aminoglycoside
• Clean-contaminated	Cefazolin + metronidazole, cefoxitin	Fluoroquinolone, aminoglycoside
Vascular	Cefazolin	Clindamycin, vancomycin
Transplantation		
• Heart, lung, heart-lung	Cefazolin	Clindamycin, vancomycin
• Liver	Piperacillin-tazobactam, cefotaxime + metronidazole	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
• Pancreas, pancreas-kidney	Cefazolin	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone
Plastic surgery	Cefazolin	Clindamycin or vancomycin + aminoglycoside or aztreonam or fluoroquinolone

Cardiac procedures

Surgical prophylaxis is recommended for the following cardiac procedures: CABG, valve repair, ventricular assist device, and cardiac device insertion procedures (pacemaker, implantable cardioverter defibrillator, or cardiac resynchronization device). Infections complicating cardiac procedures have severe consequences including sternal wound infections, mediastinitis, and device pocket infections. *Staphylococcus* spp. (*S. aureus* and CoNS) are isolated in almost half of SSIs after cardiac procedures. A preoperative dose of cefazolin or cefuroxime with appropriate redosing is recommended as surgical prophylaxis in cardiac procedures. Vancomycin should be administered in patients with a history of MRSA colonization. Patients with a documented β-lactam allergy should receive vancomycin or clindamycin as an alternative agent. Patients with *S. aureus* colonization should be treated preoperatively with intranasal mupirocin.

In cardiac procedures, administration of antimicrobial prophylaxis for up to 48 hours postoperatively is accepted practice. However, the primary literature suggests the risk of prolonged antibiotics exposure outweighs any potential benefit of SSI prevention. A 4-year cohort study of 2,461 patients undergoing CABG found antimicrobial prophylaxis for an extended duration (>48 hours) compared to a shorter duration (<48 hours) failed to reduce the risk of SSI (OR 1.2, 95% confidence interval [CI] [0.8, 1.6]). Prolonged prophylaxis was associated with an increased risk of acquiring antimicrobial-resistant organisms, including cephalosporin-resistant Enterobacteriaceae and VRE (OR 1.6, 95% CI [1.1, 2.6]).[26]

Thoracic procedures

Surgical prophylaxis is recommended for noncardiac thoracic procedures including lobectomy, pneumonectomy, thoracoscopy, lung resection, and thoracotomy. Thoracic procedures can be complicated by SSIs, pneumonia, and empyema. Similar to cardiac procedures, half of SSIs after thoracic procedures are caused by gram-positive organisms (*S. aureus* and CoNS). Causes of pneumonia after thoracic procedures include gram-positive organisms (*Streptococcus* species, *Staphylococcus* species) and common respiratory pathogens (*Haemophilus influenzae*, *Moraxella catarrhalis*).[27] For surgical prophylaxis, cefazolin or ampicillin-sulbactam is recommended for patients undergoing thoracic procedures. Acceptable alternatives include vancomycin or clindamycin for patients with a documented β-lactam allergy.

Ampicillin-sulbactam is a recommended antimicrobial agent for prophylaxis in thoracic procedures because it targets the normal lung flora responsible for postoperative pneumonia. In a prospective study of 445 patients undergoing lung resections for noninfectious diseases, patients receiving amoxicillin-clavulanate had significantly decreased rates of postoperative pneumonia compared to those receiving cefamandole ($p = 0.0027$).[27]

Gastrointestinal procedures

The ASHP antimicrobial prophylaxis guidelines divide gastrointestinal (GI) procedures into the following sections: gastroduodenal (with or without entry into GI lumen), biliary (open, low-risk

laparoscopic, high-risk laparoscopic), appendectomy, small intestine (nonobstructive, obstructive, hernia repair), and colorectal procedures. The most common organisms isolated from SSIs after gastrointestinal procedures are gram-negative bacilli (*E. coli*, *Proteus* spp., *Klebsiella* spp.) followed by gram-positive cocci (*Enterococcus* spp., *Streptococcus* spp., *Staphylococcus* spp.) and anaerobic organisms (*Bacteroides* spp., *Clostridium* spp.).

Antimicrobial prophylaxis is not necessary in low-risk patients undergoing elective laparoscopic cholecystectomy. For the majority of gastrointestinal procedures, a single dose of cefazolin is recommended for antimicrobial prophylaxis. For patients with a documented β-lactam allergy, acceptable alternative regimens include (1) clindamycin or (2) vancomycin for coverage of gram-positive organisms plus (1) an aminoglycoside, (2) aztreonam, or (3) a fluoroquinolone for coverage of gram-negative bacilli. Antimicrobial prophylaxis with both aerobic and anaerobic coverage is recommended for colorectal procedures, appendectomy for uncomplicated appendicitis, open biliary tract procedures, and obstructed small intestine procedures. Recommended regimens including anaerobic coverage include (1) a second-generation cephalosporin (cefoxitin or cefotetan), (2) cefazolin plus metronidazole, or (3) ampicillin-sulbactam. Alternative regimens for patients with documented β-lactam allergy are (1) clindamycin plus an aminoglycoside, aztreonam, or a fluoroquinolone, or (2) metronidazole plus an aminoglycoside or a fluoroquinolone.

Meta-analyses performed for the following gastrointestinal procedures have found antimicrobial prophylaxis decreases the risk of SSIs: percutaneous endoscopic gastrostomy (OR 0.35, 95% CI [0.23, 0.48]),[28] appendectomy,[29] hernioplasty (prosthetic mesh repair of hernia) or herniorrhaphy (suture repair of hernia) (OR 0.64, 95% CI [0.50, 0.82]),[30] and colorectal surgery (risk ratio [RR] 0.30, 95% CI [0.22, 0.41]).[31]

For colorectal surgeries, multiple studies have found the addition of mechanical bowel preparation (MBP) and oral antimicrobial prophylaxis to routine perioperative intravenous prophylaxis further reduces postoperative infection rates. A Cochrane review found combined oral and intravenous antibiotic prophylaxis significantly decreased SSI rates compared to intravenous (RR 0.55, 95% CI [0.41, 0.74]) or oral prophylaxis alone (RR 0.34, 95% CI [0.13, 0.87]).[31] The combination of MBP, oral antibiotics, and intravenous antibiotics also significantly reduces the risk of anastomotic leaks, ileus, prolonged hospitalization, and readmission after colorectal surgery.[32,33] Oral antimicrobial prophylaxis should be administered 10 hours prior to the operation and after MBP. Appropriate oral regimens for prophylaxis include (1) neomycin plus erythromycin or (2) oral neomycin plus metronidazole.

Head and neck procedures

Head and neck procedures requiring an incision through the oropharyngeal mucosa are classified as clean-contaminated. The majority of SSIs after head and neck procedures are polymicrobial and involve the normal oropharyngeal flora including *Streptococcus* spp. and anaerobes (*Bacteroides* spp., *Peptostreptococcus* spp., *Prevotella* spp., *Fusobacterium* spp., *Veillonella* spp.). For clean-contaminated head and neck procedures, (1) cefazolin or cefuroxime plus metronidazole or (2) ampicillin-sulbactam are recommended for surgical prophylaxis. Clindamycin is an alternative agent for patients with a documented β-lactam allergy.

Based on the findings of several studies, antimicrobial prophylaxis is not required for clean (thyroidectomy, lymph node excision) and certain clean-contaminated head and neck procedures (adenoidectomy, tonsillectomy, endoscopic sinus procedure). In a multicenter RCT of 500 patients undergoing thyroidectomy for goiter or thyroid cancer, there was no significant difference in the rate of SSIs between patients who received antibiotic prophylaxis with ampicillin-sulbactam and those without antibiotic prophylaxis.[34] A Cochrane review of 10 trials comprising 1,035 patients found no clinically significant impact of antibiotics in reducing the main adverse outcomes related to tonsillectomy, including reduction of pain, need for analgesics, and secondary hemorrhage rates.[35]

Neurologic procedures

Infections related to neurologic procedures have severe consequences including repeat neurologic surgery, prolonged course of parenteral antimicrobials, and death. Gram-positive organisms (*S. aureus,* CoNS) are responsible for almost half of SSIs after neurologic procedures. A single dose of cefazolin is recommended for patients undergoing craniotomy, spinal procedures, cerebrospinal fluid shunt procedures, or intrathecal pump placement. Vancomycin and clindamycin are alternative agents for patients with a documented β-lactam allergy.

There are no guidelines on the use of antimicrobial agent prophylaxis for patients with external ventricular drains (EVDs) or intracranial pressure monitors. Many centers initiate antibiotics to prevent drain-related infections although no prospective trials support the practice. In an international survey of current practices, the majority of neurosurgeons reported continuing prophylactic antibiotics for the duration of EVDs.[36] A minority of infectious disease specialists and about half of intensivists routinely used prophylactic antibiotics for EVDs.[36] A retrospective single-center study of 308 patients with EVDs found no significant difference in the rate of bacterial ventriculitis between patients who received periprocedural antibiotics and those who received antibiotics for the duration of the EVD.[37] Prospective studies are needed to investigate the use of prophylactic antibiotics for the prevention of EVD-related infections.

Obstetric and gynecologic surgery

A serious infectious complication of cesarean delivery is endometritis, an infection of the uterine lining that presents with fever, abdominal pain, uterine tenderness, or foul-smelling lochia. Prolonged labor in the presence of ruptured membranes is the main risk factor for endometritis as the vaginal bacterial flora enter the uterus during periods of relaxation between contractions. Most postpartum infections are polymicrobial and involve the normal vaginal flora including aerobic (*E. coli*, *Enterococci* spp., *Streptococci* spp.) and anaerobic (*Bacteroides bivius*, *Peptococcus* spp., *Peptostreptococcus* spp.) organisms. A single dose of cefazolin timed before incision is recommended for women undergoing cesarean delivery.

Clindamycin plus gentamicin is an acceptable alternative agent for patients with a documented β-lactam allergy.

A Cochrane review of 81 RCTs including 11,937 women assessed the use of prophylactic antibiotics on infectious complications in women undergoing cesarean delivery.[38] Women who received prophylactic antibiotics had a significantly decreased risk of endometritis (RR 0.39, 95% CI [0.31, 0.43]) and wound infections (RR 0.41, 95% CI [0.29, 0.43]).[38] Prophylactic antibiotics have typically been administered after cord clamping to avoid altering the neonate's microbial flora and masking early signs of neonatal sepsis, but studies suggest antibiotic prophylaxis is most effective prior to skin incision. A meta-analysis reviewed three RCTs and two nonrandomized trials comparing prophylactic antibiotics for cesarean delivery before skin incision and after cord clamping. The risk of postpartum endometritis was significantly decreased with the administration of antibiotics before skin incision (RR 0.47, 95% CI [0.26, 0.85]).[39]

After cesarean delivery, hysterectomies are the second most common gynecologic procedure performed in the United States and involve removal of the uterus and occasionally removal of one or both ovaries and fallopian tubes. Hysterectomies are performed through the vagina or the abdominal wall using laparoscopic or robotic methods. Infectious complications of hysterectomies include vaginal cuff infection, pelvic cellulitis, and pelvic abscess. Infections are usually polymicrobial, involving the normal vaginal flora including aerobic (*Streptococci* spp., *Enterococci* spp., gram-negative bacilli) and anaerobic (*Bacteroides* spp.) pathogens. For coverage of the typical surgical pathogens, a single dose of cefazolin, cefoxitin, cefotetan, or ampicillin-sulbactam is recommended for women undergoing vaginal or abdominal hysterectomy. For patients with a documented β-lactam allergy, the alternative agents recommended include (1) clindamycin or vancomycin plus an aminoglycoside, aztreonam or a fluoroquinolone, or (2) metronidazole plus an aminoglycoside or a fluoroquinolone.

Orthopedic procedures

The ASHP antimicrobial prophylaxis guidelines classify orthopedic procedures into four groups: (1) clean orthopedic procedures, (2) spinal procedures with or without instrumentation, (3) repair of hip fractures or implantation of internal fixation devices, and (4) total joint replacement procedures. Infections related to orthopedic procedures are costly given the need for hospital readmission, repeat orthopedic procedures, and prolonged courses of intravenous antibiotics. Orthopedic infections also contribute to significant morbidity given the loss of functionality, possible limb loss, or paralysis. Given these risks related to infection, antimicrobial prophylaxis with orthopedic implantation is widely accepted and practiced. Skin pathogens (*S. aureus, S. epidermidis*) are responsible for more than half of infections from orthopedic procedures. Gram-negative organisms (*E. coli*, *P. aeruginosa,* and *Enterobacter* spp.) are also frequently isolated from orthopedic infections.

Antimicrobial prophylaxis is not recommended in clean orthopedic procedures without instrumentation or implementation of foreign materials given the low risk of infection. Cefazolin is recommended for antimicrobial prophylaxis in the other three groups of orthopedic procedures: spinal procedures with or without instrumentation, repair of hip fractures or implantation of internal fixation devices, and total joint replacement procedures. Acceptable alternative agents for patients with a documented β-lactam allergy include vancomycin and clindamycin. Patients with *S. aureus* colonization should be treated preoperatively with intranasal mupirocin.

Multiple studies have found antimicrobial prophylaxis effectively prevents organ space infections in spinal procedures, hip fracture repair, and total joint replacement. In an RCT of 1,237 patients undergoing surgery for herniated disk, patients receiving cefuroxime prophylaxis had a significantly decreased rate of spondylodiscitis or epidural abscess (0%) compared to patients with no antimicrobial prophylaxis (1.4%) ($p < 0.01$).[40] In a meta-analysis of 15 RCTs performed to assess the most effective antimicrobial prophylaxis in hip fracture surgery, the following comparisons were examined: antibiotics at any dose versus placebo, multiple doses (>24 hours) versus one dose of antibiotics, and multiple doses versus 24-hour antibiotic coverage.[41] The meta-analysis found patients with antibiotic prophylaxis had a significantly decreased risk of superficial and deep wound infections compared to placebo. Furthermore, there was no significant difference in receiving a single dose versus multiple doses of antimicrobial prophylaxis. For total joint arthroplasty, a meta-analysis of seven studies including 3,064 patients found antimicrobial prophylaxis decreased the relative risk of wound infections by 81% compared with no prophylaxis ($p < 0.00001$).[42] The US Food and Drug Administration has approved premixed aminoglycoside (gentamicin, tobramycin) in bone cement products in second-stage revision of total joint arthroplasty, but no evidence suggests this is an effective strategy for the prevention of infection in primary joint arthroplasty.

Solid organ transplantation

Solid organ transplant (SOT) recipients are at increased risk of infection related to drug-induced immunosuppression, reactivation of latent infections, donor-derived infections, and preoperative colonization of antibiotic-resistant organisms. Patients are at the highest risk of infection during the first year posttransplant when receiving the highest level of immunosuppression. Antimicrobial prophylaxis is routinely administered posttransplant for the prevention of opportunistic infections including cytomegalovirus, herpes simplex virus, *Pneumocystis jiroveci*, and *Aspergillus*. Most infections in the first month after transplantation are hospital-acquired including SSIs, pneumonia, urinary tract infections, and bloodstream infections. Antimicrobial prophylaxis for the prevention of SSIs after SOT is recommended given the high risk of infection and the severe consequences related to infection, including transplant rejection and death. However, there are a limited number of well-conducted prospective studies on the optimal regimen and duration for antimicrobial prophylaxis after SOT.

SSIs related to heart and lung transplantation include mediastinitis and sternal osteomyelitis. Gram-positive organisms (*S. aureus,* CoNS, *Enterococcus* spp.) are the most common pathogens isolated from SSIs after heart and lung transplant. Other frequently isolated pathogens include Enterobacteriaceae, *P. aeruginosa*,

Stenotrophomonas maltophilia, and *Candida* spp. Infectious complications unique to lung transplantation include bronchial anastomotic infections and pneumonia related to bacterial or fungal colonization of the donor or recipient upper and lower airways. Patients with a history of cystic fibrosis receive frequent courses of antibiotics to treat exacerbations, and, as a result, their sinuses and upper airways are colonized with multidrug-resistant gram-negative organisms (*P. aeruginosa*, *S. maltophilia*, *Burkholderia* spp.) and *Aspergillus* spp. These pathogens can be transmitted to the lower airways after lung transplantation and cause pneumonia.

Infectious complications after liver transplantation include SSIs, intra-abdominal infections, and biliary tract infections. After kidney transplant, the most common infections include SSIs and urinary tract infections. Normal bowel and skin flora are responsible for most infections after abdominal transplant including aerobic gram-negative bacilli (*E. coli*, *Klebsiella* spp., *Enterobacter* spp., *Citrobacter* spp.), *Enterococcus* spp., skin flora (*S. aureus*, CoNS), and *Candida* spp.

Cefazolin is recommended for antimicrobial prophylaxis in heart, lung, heart-lung, pancreas, kidney, and pancreas-kidney transplantation. Vancomycin or clindamycin are alternative agents for patients with a documented β-lactam allergy. In liver transplantation, (1) piperacillin-tazobactam or (2) cefotaxime plus ampicillin are recommended for antimicrobial prophylaxis. Alternative agents for patients with documented β-lactam allergy include (1) vancomycin or (2) clindamycin *plus* (1) an aminoglycoside, (2) aztreonam, or (3) a fluoroquinolone. Antimicrobial prophylaxis should be modified to cover any organisms isolated from the donor or recipient pretransplant.

Urologic procedures

Prophylactic antibiotics are administered in urologic procedures to prevent SSIs as well as postoperative bacteremia. *E. coli* is the most common pathogen associated with bacteriuria after urologic procedures. Gram-positive organisms (*S. aureus*, CoNS, *Streptococcus* spp.) are frequently associated with urologic procedures requiring skin incisions without entry into the urinary tract. Biofilm-producing pathogens (*Staphylococcus epidermidis*, *P. aeruginosa*) are a concern for urologic procedures involving placement of prosthetic material (penile prosthesis). Risk factors for postoperative infections include anatomic abnormalities of the urinary tract, urinary obstruction, urinary stones, and indwelling or externalized catheters.

Patients with preoperative bacteriuria are treated prior to urologic procedures to prevent postoperative infections. A single dose of cefazolin is recommended for clean urologic procedures with or without entry into the urinary tract. A single dose of an aminoglycoside is recommended in procedures involving placement of prosthetic material. Vancomycin and clindamycin are alternative agents for patients with a documented β-lactam allergy undergoing clean urologic procedures without entry into the urinary tract. Alternative agents for urologic procedures with entry into the urinary tract include (1) a fluoroquinolone, (2) an aminoglycoside plus metronidazole, or (3) an aminoglycoside plus clindamycin.

Vascular procedures

Infections after vascular surgery using prosthetic material can result in severe consequences including limb loss. The predominant pathogens include *S. aureus*, CoNS, and enteric gram-negative bacilli. Antimicrobial prophylaxis is used in vascular procedures with a high risk of infection, including procedures involving implantation of prosthetic material, aneurysm repair, thromboendarterectomy, and vein bypass. Cefazolin is the recommended regimen for those undergoing vascular procedures with a high risk of infection. Alternative agents for patients with a documented β-lactam allergy include clindamycin and vancomycin.

Perioperative management

The 2016 ACS/SIS and 2017 CDC guidelines recommend perioperative interventions to address patient and procedure-related risk factors (Box 112.4). This section highlights interventions relevant to the practice of an infectious diseases specialist. Modifiable

BOX 112.4

Summary of the 1999 and 2017 Centers for Disease Control and Prevention guidelines for the prevention of surgical site infections[20,21]

Preparation of the patient

a. Identify and treat all infections remote to the surgical site before elective operations. Postpone elective operations with remote site infections until the infection has resolved.
b. Do not remove hair preoperatively unless the hair at or around the incision site will interfere with the operation. If hair removal is necessary, remove immediately before the operation with clippers.
c. Encourage tobacco cessation for a minimum of at least 30 days before elective operations.
d. Ensure skin around the incision site is free of gross contamination before performing antiseptic skin preparation.[21]

Antiseptic prophylaxis

a. Advise patients to shower or bathe (full body) with soap (antimicrobial or nonantimicrobial) or an antiseptic agent on at least the night before the operative day.
b. Perform intraoperative skin preparation with an alcohol-based antiseptic agent unless contraindicated.[21]

Hand and forearm antisepsis for surgical team

a. Perform preoperative surgical hand and forearm antisepsis according to manufacturer's recommendations for the product being used.
b. 2005 Guidelines for Hand Hygiene in Healthcare Settings provide additional surgical hand antisepsis recommendations.[56]

Operating room ventilation

a. Maintain positive pressure ventilation in the operating room and adjoining spaces.
b. Maintain the number of air exchanges, airflow patterns, temperature, humidity, location of vents, and use of filters in accordance with recommendations from the most recent version of the Facilities Guideline Institute—Guidelines for Design and Construction of Hospitals and Outpatient Facilities 2014.[57]

Cleaning and disinfection of environmental surfaces

a. Do not perform special cleaning or closing of operating rooms after contaminated or dirty operations.[21]

Reprocessing of surgical instruments

a. Sterilize all surgical instruments according to published guidelines and manufacturer's recommendations.
b. Immediate-use steam sterilization should never be used for reasons of convenience, as an alternative to purchasing additional instrument sets, or to save time. This practice should be reserved only for patient care items that will be used immediately in emergency situations when no other options are available.
c. Additional recommendations available at CDC and HIPAC Guideline for Disinfection and Sterilization in Healthcare Facilities 2008.[58]

Surgical attire and drapes

a. Wear a surgical mask that fully covers the mouth and nose when entering the operating room if an operation is about to begin or already under way, or if sterile instruments are exposed. Wear the mask throughout the operation.
b. Wear a new, disposable, or hospital-laundered head covering for each case, when entering the operating room. Ensure it fully covers all hair on the head and all facial hair not covered by the surgical mask.
c. Wear sterile gloves if serving as a member of the scrubbed surgical team. Put on sterile gloves after donning a sterile gown.
d. Use surgical gowns and drapes that are effective barriers when wet (i.e., materials that resist liquid penetration).
e. Change scrub suits that are visibly soiled, contaminated, and/or penetrated by blood or other potentially infectious materials.[21]

Sterile and surgical technique

a. Adhere to principles of sterile technique when performing all invasive surgical procedures
b. If drainage is necessary, use a closed suction drain. Place a drain through a separate incision distant from the operative incision. Remove the drain as soon as possible.[21]

Parenteral antimicrobial prophylaxis

a. Administer preoperative antimicrobial agents only when indicated based on published clinical practice guidelines and timed such that an inhibitory concentration of the agents is established in the serum and tissues when the incision is made.
b. In clear and clean-contaminated procedures, do not administer additional prophylactic antimicrobial agent doses after the surgical incision is closed in the operating room.[20]

Glycemic control

a. mplement perioperative glycemic control and use blood glucose target levels <200 mg/dL in patients with and without diabetes.[20]

Normothermia

a. Maintain perioperative normothermia.[20]

Oxygenation

a. For patients with normal pulmonary function undergoing general anesthesia with endotracheal intubation, administer increased FiO2 during surgery and after extubation in the immediate postoperative period. To optimize tissue oxygen delivery, maintain perioperative normothermia and adequate volume replacement.[20]

Postoperative incision care

a. Protect primarily closed incisions with a sterile dressing for 24–48 hours postoperatively.
b. Do not apply antimicrobial agents (i.e. ointments, solutions, or powders) to the surgical incision for the prevention of SSI.[21]

patient-related risk factors include tobacco use and colonization with microorganisms. Perioperative interventions that decrease the risk of SSIs include antiseptic prophylaxis, skin preparation, and glycemic and temperature control.

Tobacco cessation

Multiple studies have described the increased risk of SSIs among smokers after general and orthopedic surgery. Smoking induces vasoconstriction of the vessels in the surgical bed, leading to a reduction

in the oxygenation and nutrients needed for an immune response and wound healing. Tobacco cessation is recommended for a minimum of 30 days before elective operations.[21] A multicenter RCT of 120 smokers undergoing hip and knee replacement found patients randomized to the smoking cessation group 6 to 8 weeks before elective surgery had a significantly decreased incidence of SSIs (5%) compared to the control group (31%) (p = 0.001).[43]

Preoperative *Staphylococcus aureus* screening and decolonization

Nasal colonization with *S. aureus* occurs in approximately 30% of the US population and increases the risk of SSIs 2- to 14-fold.[44,45] Perioperative mupirocin ointment is a safe and inexpensive treatment that reduces the rates of *S. aureus* nasal carriage and postoperative infection. In an RCT of 891 patients with nasal carriage of *S. aureus* undergoing general, gynecologic, neurologic, or cardiothoracic surgery, patients randomized to mupirocin had a significantly decreased rate of *S. aureus* SSIs (4.0%) compared with those receiving placebo (7.7%) (p <0.02).[46] These results were confirmed in a meta-analysis of three randomized trials and four before-after trials assessing the risk of SSIs following perioperative intranasal mupirocin versus usual care in non-general surgery (cardiothoracic, orthopedic, and neurosurgery) patients.[47] The ASHP recommends preoperative *S. aureus* screening and nasal decolonization for all patients undergoing total joint replacement and cardiac procedures. A typical preoperative *S. aureus* decolonization protocol includes the application of 2% nasal mupirocin twice a day for 5 days. Because *S. aureus* can develop resistance to mupirocin, universal *S. aureus* screening and decolonization are not recommended in the general population.

Antiseptic prophylaxis

Patients are advised to shower or bathe their full body with antimicrobial or non-antimicrobial soap or an antiseptic agent on at least the night before the operative day.[20] Perioperative bathing or showering with chlorhexidine is a well-accepted practice for reducing skin bacteria; however, no evidence suggests a benefit of chlorhexidine compared to other wash products for the reduction of SSIs. A 2015 Cochrane Database Systematic Review examined six high-quality RTCs comparing the efficacy of perioperative 4% chlorhexidine gluconate washes to nonantiseptic shower or bathing products for preventing SSIs.[48] Chlorhexidine did not significantly reduce the risk of SSI compared to placebo in a meta-analysis of three RTCs comprising 7,791 patients. Similarly, a meta-analysis of three RTCs including 1,443 patients found no significant difference in SSI rates between chlorhexidine and bar soap.[48]

Hair removal and skin preparation

Removal of hair preoperatively is not recommended unless the hair at or around the incision site will interfere with the operation.[21] If hair removal is necessary, it should be performed immediately before the operation with clippers. Shaving with a razor is not advised as microscopic abrasions and cuts are created, allowing pathogens to cross the natural skin barrier. Intraoperative skin preparation with an alcohol-based antiseptic agent is recommended unless contraindicated.[21] Alcohol-based solutions have a rapid bactericidal effect but the antimicrobial effect is not as persistent as that of iodine- or chlorhexidine-based solutions.

Glycemic control

Perioperative glycemic control is recommended with a target blood glucose level of <200 mg/dL in diabetic and non-diabetic patients.[20] Hyperglycemia is associated with multiple adverse consequences including increased risk of mortality during surgical intensive care unit admissions. Multiple studies have found intensive perioperative glycemic control is associated with increased episodes of hypoglycemia without decreasing the risk of SSIs. In an RCT comparing intensive glycemic control (80–100 mg/dL) to conventional glycemic control (<200 mg/dL) among patients undergoing cardiac surgery ($n = 371$), intensive glycemic control increased the risk of mortality and stroke without reducing the length of intensive care unit and hospital stay.[49] A single-center RCT comparing intensive glycemic control (80–130 mg/dL) with conventional glycemic control (160–200 mg/dL) in cardiac surgery patients ($n = 109$) found no significant difference in the composite infection outcome, including pneumonia, urinary tract infection, sepsis, septic shock, wound infection, bloodstream infection, and catheter infection.[50] Both studies concluded that intensive glycemic control provides no additional morbidity or mortality benefit compared to conventional glycemic control.

Normothermia

Maintenance of perioperative normothermia is recommended for the prevention of SSI. Hypothermia triggers thermoregulatory vasoconstriction leading to a decrease in oxygen levels in the surgical bed. A reduced level of oxygen in the tissues impairs neutrophil production of superoxide radicals used in the oxidative killing of surgical pathogens. In addition, other immune functions are directly impaired by hypothermia, including chemotaxis and phagocytosis of granulocytes, motility of macrophages, and productions of antibodies.[51] Multiple studies have found normothermia decreases the incidence of SSI. In an RCT of 200 patients undergoing colorectal surgery, the normothermia group had a significantly lower rate of SSI (6%) compared to the hypothermia group (19%) (p = 0.009). The duration of hospitalization was also significantly reduced in the normothermia group by 2.6 days (p = 0.01).[51] In a study of 421 patients undergoing clean (breast, varicose vein, or hernia) surgery, the warmed group had significantly decreased rate of SSI (5%) compared to the nonwarmed group (14%) (p = 0.001).[52]

Oxygenation

Administration of increased fraction of inspired oxygen (FIO_2) during surgery and after extubation in the immediate postoperative period is recommended for patients with normal pulmonary function undergoing general anesthesia with endotracheal intubation. Maintenance of perioperative normothermia and adequate volume replacement optimize tissue oxygen delivery.[48] Neutrophil production of bactericidal superoxide radicals depends on the partial pressure of oxygen in tissues. Optimizing the partial pressure of oxygen in tissues

allows for neutrophilic oxidative killing for prevention of SSIs. Three double-blind RCTs found administering supplemental inspired oxygen was an effective intervention for reducing SSIs. In an RCT of 500 patients undergoing colorectal resection, the risk of SSI among patients receiving 80% FIO_2 was 50% lower compared to patients receiving 30% FIO_2 (11.2%).[53] An RCT of 300 patients undergoing elective colorectal surgery found administration of 80% FIO_2 was protective against SSIs (RR 0.61, 95% CI [0.38, 0.98]).[54] In an RCT study of 210 patients undergoing open appendectomy, oxygenation with 80% FIO_2 reduced the risk of SSI (5.6% versus 13.6%, p = 0.04) and the mean hospital stay (2.51 days versus 2.92 days, p = 0.01).[55]

Postoperative wound management

Protection of primarily closed incisions with a sterile dressing for 24 to 48 hours postoperatively is recommended. Triclosan antibiotic-coated sutures should be considered for the prevention of SSI. Topical antimicrobial agents (ointments, solutions, or powders) applied to the surgical incision for the prevention of SSI are not recommended. The literature is mixed regarding the use of intraoperative antimicrobial irrigation and antimicrobial dressing applied to surgical incisions after primary closure in the operating room for the prevention of SSI.

113

Immunizations

Elaine C. Jong

Long-lasting immunity against many serious infectious diseases can be elicited through *active immunization*, the administration of specific antigens (killed or attenuated microorganisms; purified polysaccharides, proteins, or other components; or recombinant antigens produced by genetic engineering) that stimulate the recipient host's production of protective antibodies. New vaccine technologies include using mRNA (messenger RNA) or DNA in vaccines that enable cells in recipients' bodies to produce the specific targeted antigens that will subsequently elicit a protective immune response. Vaccine doses may be given orally, administered as mucosal vaccines, or given by injection using intradermal, subcutaneous, or intramuscular routes. *Passive immunization* is the process by which protective immunity is obtained through transfer of preformed antibodies from an immune host to a nonimmune recipient, either as immunoglobulin or antibody-specific immunoglobulin.

Protective efficacy resulting from active immunization with a vaccine depends on several factors: the age of the host, with decreased efficacy of certain vaccines observed in the very young and very old; the immune status of the host, with decreased efficacy observed in persons with compromised immune status because of disease or therapy; and the characteristics of the vaccine product itself.

In active immunization, protective levels of specific antibodies usually develop within 2 to 4 weeks upon completion of the primary immunization regimen. The antibody response may be recalled and boosted when the immune system is challenged by additional "booster" doses of the vaccine antigen(s) or by exposure to the naturally occurring pathogen. Passive immunization can confer rapid protection, but serum levels of protective antibodies in recipients are highest immediately after receipt, decreasing with the passage of time, and there is no immune recall on challenge.

Several different vaccines may be administered concomitantly at separate sites without decreased efficacy, although the timing and sequence of vaccines have to be taken into account. For example, when immunoglobulin is given for passive immunization against hepatitis A, antibodies against several common infections in addition to antibodies against hepatitis A may be present in sufficient amounts to interfere with the response to the corresponding vaccines. Immunoglobulin should not be given for 3 months before or 3 weeks after measles, mumps, and rubella vaccine and not for 2 months after varicella vaccine. However, vaccines against tetanus, diphtheria, yellow fever, typhoid fever, hepatitis B, rabies, and meningococcal meningitis can be given on the same day as immunoglobulin. If immunoglobulin is given on the same day as hepatitis A vaccine, the vaccine is still efficacious, although the resulting peak antibody titer is lower than when the vaccine is given alone.

The US Food and Drug Administration (FDA) is responsible for licensure of all pharmaceuticals including vaccine products for use in the United States. The Advisory Committee on Immunization Practices (ACIP) at the Centers for Disease Control and Prevention (CDC) issues recommendations for routine use of vaccines in children and adolescents, harmonizing its recommendations to the greatest extent possible with those issued by the American Academy of Pediatrics (AAP), the American Academy of Family Physicians (AAFP), and the American College of Obstetrics and Gynecology (ACOG). The ACIP recommendations for routine use of vaccines in adults are harmonized with those of the AAFP, ACOG, and the American College of Physicians (ACP).

Federal law requires that potential vaccine recipients be informed of the potential benefits and possible adverse side effects of each vaccine. Vaccine Information Statements (VISs) prepared by the CDC are used for this purpose: these forms can be downloaded and copies printed for use in patient education from the CDC website (http://www.cdc.gov/vaccines/hcp/vis/index.html). The VISs are available in English and 40 additional languages.

Tolerance to minor adverse effects associated with each vaccine and the potential for more serious vaccine-associated symptoms must be taken into account in the person who is a candidate for multiple vaccine doses on the same day. If clinically significant adverse events are associated with any vaccination, such occurrences should be reported to the Vaccine Adverse Event Reporting System (VAERS) online (http://www.vaers.hhs.gov) or by telephone (800-822-7967).

Childhood and adolescent immunizations

The routine immunizations recommended during childhood and adolescence cover communicable diseases of public health importance that cause significant morbidity and mortality in susceptible populations. The ACIP immunization schedules are updated and published on an annual basis, and interim updated recommendations are published in the *Morbidity and Mortality Weekly Report* (*MMWR*) as needed. Figure 113.1 shows the immunization schedule for persons aged 0 through 18 years according to recommendations from the CDC ACIP (http://www.cdc.gov/vaccines/acip/index.html).

In the following summary, minimal ages for administration of the first dose of the various vaccines are given, and the detailed schedule for subsequent doses may be found in Figure 113.1. Figure 113.2 provides the CDC ACIP schedule for catch-up immunizations. The minimal interval between doses shown in this figure can be used to reset the schedule for a given vaccine series in persons aged 4 months through 18 years who start late or who are more than 1 month behind the recommended schedule. If more time elapses than the recommended interval between scheduled doses in a vaccine series, the series does not need to be restarted, but the next dose(s) should be administered according to the recommended intervals until the series is complete.

At birth, the first dose of the hepatitis B vaccine three-dose series (HepB: Recombivax HB, Merck; Engerix-B, GlaxoSmithKline) is initiated. At 2 months of age, the first doses of the following vaccine series are given: rotavirus (RV-1: Rotarix, GlaxoSmithKline; RV-5: RotaTeq, Merck), diphtheria, tetanus and acellular pertussis (DTaP: Daptacel, Sanofi Pasteur; Infanrix, GlaxoSmithKline), *Haemophilus influenzae* type b conjugate (Hib PRP-T: ActHIB, Sanofi Pasteur; Hiberix, GlaxoSmithKline; or Hib PRP-OMP: PedvaxHIB, Merck), pneumococcal conjugate (PCV13: Prevnar 13, Sanofi Pasteur) and inactivated poliovirus (IPV: Ipol, Sanofi Pasteur).

At 6 months of age, annual flu vaccination commences with inactivated influenza vaccine (IIV: Fluarix, Glaxo-SmithKline; Fluvirin, Chiron; Fluzone, Sanofi Pasteur) or live attenuated influenza vaccine administered intranasally (LAIV4: FluMist Quadrivalent, AstraZeneca). At 12 months of age, the first doses of measles, mumps, and rubella (MMR: M-M-R II, Merck), varicella (VAR: Varivax, Merck) and hepatitis A (HepA: Havrix, GlaxoSmithKline; Vaqta, Merck) vaccines are recommended. Varicella vaccine may be administered at the same time as the MMR vaccine. Both VAR and MMR are live-virus vaccines administered by injection. If the two vaccines are not given simultaneously at different sites, the vaccine doses should be separated by 28 days if possible to reduce or eliminate possible interference of the vaccine given first with the vaccine given second. A second dose of MMR and VAR vaccines is recommended for children, between 4 and 6 years old on entry into school to boost waning immunity from the first dose received in infancy.

The ACIP recommends *routine* vaccination of adolescents at 11 to 12 years of age with quadrivalent meningococcal conjugate vaccine (MenACWY) against meningococcal serogroups A, C, Y, W-135 disease, with a booster dose at 16 years old. MenACWY vaccines available in the US are: meningococcal groups ACWY polysaccharide diphtheria toxoid conjugate vaccine (MenACWY-D: Menactra, Sanofi Pasteur) meningococcal groups ACWY polysaccharide CRM197 conjugate vaccine (MenACWY-CRM: Menveo, Novartis), and meningococcal groups ACWY polysaccharide tetanus toxoid conjugate vaccine (MenACWY-TT: MenQuadfi, Sanofi Pasteur) If the first dose of MenACWY vaccine is received between 13 and 15 years old, a booster should be given at 18 years of age. MenACWY vaccine is also recommended for some infants and children with certain medical conditions. Meningococcal group B (MenB) vaccination is recommended only for *selected* groups of children, adolescents and adults (10 through 25 years of age) and certain adults ≥26 years of age at increased risk for meningococcal serogroup B disease due to certain underlying chronic medical conditions (complement component deficiencies; anatomic or functional asplenia, including sickle cell disease; treatment with eculizumab) or persons who are at increased risk of exposure (laboratory personnel; community or institutional outbreak of meningococcal serogroup B disease). At the time of writing, two MenB vaccines are commercially available (MenB-4C: Bexsero, Novartis; MenB-FHbp: Trumenba, Wyeth).

The immunization status of tetanus, diphtheria, and acellular pertussis vaccine should be reviewed among 11- to 12-year-olds as well. The ACIP recommends a single dose of the tetanus toxoid, reduced diphtheria toxoid, and acellular pertussis (Tdap) vaccine for persons aged 11 through 18 years who completed the recommended childhood DTP/DTaP vaccinations series. There are two Tdap vaccines: one is licensed for use in persons aged 10 through 64 years (Boostrix, GlaxoSmithKline) and the other is licensed for use in persons aged 11 through 64 years (Adacel, Sanofi Pasteur), and both are licensed for use at an interval of at least 5 years between the Td and Tdap dose. However, due to the poor control of pertussis observed in the United States in recent years, ACIP now recommends expanded use of Tdap. Tdap vaccine may be given *regardless of interval* since the last tetanus-toxoid- or diphtheria-toxoid-containing vaccine, it may be used in undervaccinated children aged 7 through 10 years, and it may be used in certain adults aged ≥65 years according to current ACIP recommendations.

Table 1 Recommended Child and Adolescent Immunization Schedule for ages 18 years or younger, United States, 2021

These recommendations must be read with the notes that follow. For those who fall behind or start late, provide catch-up vaccination at the earliest opportunity as indicated by the green bars. To determine minimum intervals between doses, see the catch-up schedule (Table 2). School entry and adolescent vaccine age groups are shaded in gray.

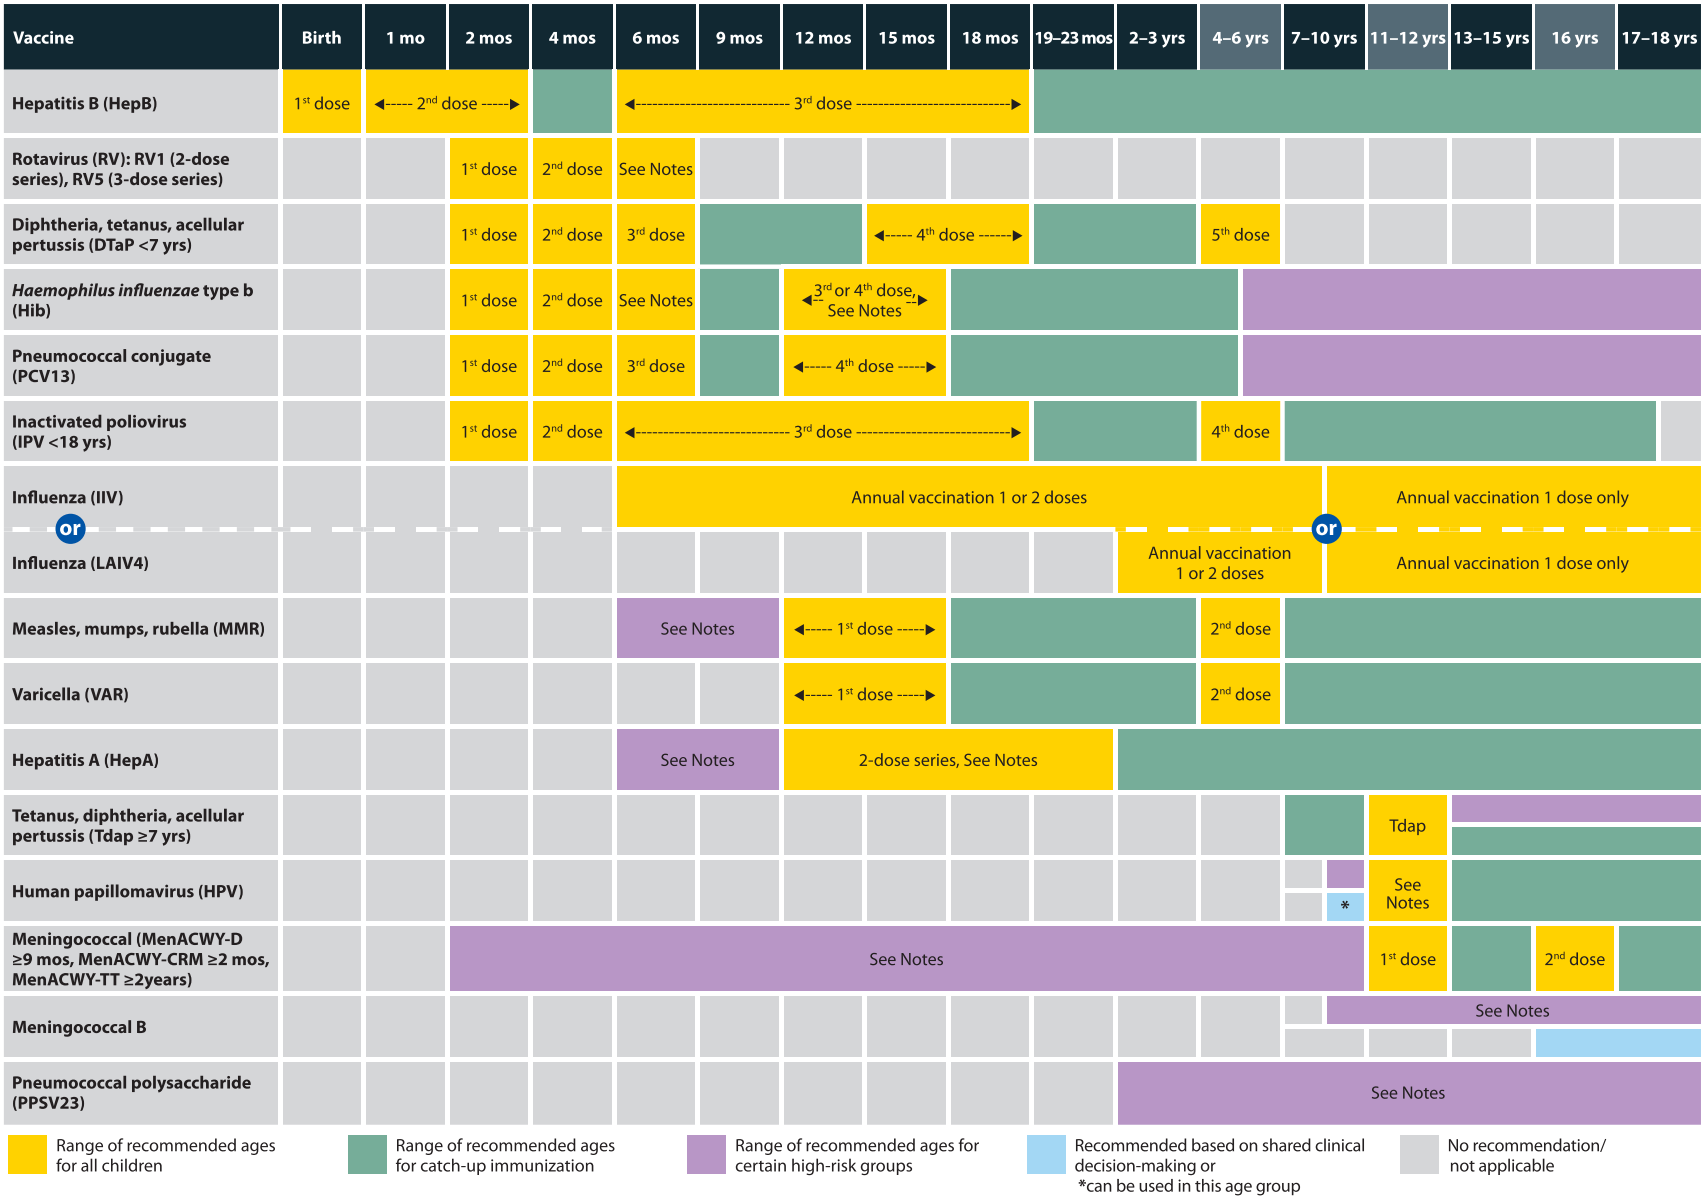

FIGURE 113.1

Table 2 Recommended Catch-up Immunization Schedule for Children and Adolescents Who Start Late or Who Are More than 1 month Behind, United States, 2021

The table below provides catch-up schedules and minimum intervals between doses for children whose vaccinations have been delayed. A vaccine series does not need to be restarted, regardless of the time that has elapsed between doses. Use the section appropriate for the child's age. **Always use this table in conjunction with Table 1 and the notes that follow.**

Children age 4 months through 6 years					
Vaccine	**Minimum Age for Dose 1**	**Minimum Interval Between Doses**			
		Dose 1 to Dose 2	**Dose 2 to Dose 3**	**Dose 3 to Dose 4**	**Dose 4 to Dose 5**
Hepatitis B	Birth	**4 weeks**	**8 weeks *and* at least 16 weeks after first dose.** Minimum age for the final dose is 24 weeks.		
Rotavirus	6 weeks Maximum age for first dose is 14 weeks, 6 days.	**4 weeks**	**4 weeks** Maximum age for final dose is 8 months, 0 days.		
Diphtheria, tetanus, and acellular pertussis	6 weeks	**4 weeks**	**4 weeks**	**6 months**	**6 months**
Haemophilus influenzae type b	6 weeks	**No further doses needed** if first dose was administered at age 15 months or older. **4 weeks** if first dose was administered before the 1st birthday. **8 weeks (as final dose)** if first dose was administered at age 12 through 14 months.	**No further doses needed** if previous dose was administered at age 15 months or older. **4 weeks** if current age is younger than 12 months ***and*** first dose was administered at younger than age 7 months ***and*** at least 1 previous dose was PRP-T (ActHib, Pentacel, Hiberix) or unknown. **8 weeks *and* age 12 through 59 months (as final dose)** if current age is younger than 12 months ***and*** first dose was administered at age 7 through 11 months; OR if current age is 12 through 59 months ***and*** first dose was administered before the 1st birthday ***and*** second dose was administered at younger than 15 months; OR if both doses were PRP-OMP (PedvaxHIB, Comvax) ***and*** were administered before the 1st birthday.	**8 weeks (as final dose)** This dose only necessary for children age 12 through 59 months who received 3 doses before the 1st birthday.	
Pneumococcal conjugate	6 weeks	**No further doses needed** for healthy children if first dose was administered at age 24 months or older. **4 weeks** if first dose was administered before the 1st birthday. **8 weeks (as final dose for healthy children)** if first dose was administered at the 1st birthday or after.	**No further doses needed** for healthy children if previous dose was administered at age 24 months or older. **4 weeks** if current age is younger than 12 months and previous dose was administered at <7 months old. **8 weeks (as final dose for healthy children)** if previous dose was administered between 7–11 months (wait until at least 12 months old); OR if current age is 12 months or older and at least 1 dose was administered before age 12 months.	**8 weeks (as final dose)** This dose only necessary for children age 12 through 59 months who received 3 doses before age 12 months or for children at high risk who received 3 doses at any age.	
Inactivated poliovirus	6 weeks	**4 weeks**	**4 weeks** if current age is <4 years. **6 months (as final dose)** if current age is 4 years or older.	**6 months** (minimum age 4 years for final dose).	
Measles, mumps, rubella	12 months	**4 weeks**			
Varicella	12 months	**3 months**			
Hepatitis A	12 months	**6 months**			
Meningococcal ACWY	2 months MenACWY-CRM 9 months MenACWY-D 2 years MenACWY-TT	**8 weeks**	See Notes	See Notes	
Children and adolescents age 7 through 18 years					
Meningococcal ACWY	Not applicable (N/A)	**8 weeks**			
Tetanus, diphtheria; tetanus, diphtheria, and acellular pertussis	7 years	**4 weeks**	**4 weeks** if first dose of DTaP/DT was administered before the 1st birthday. **6 months (as final dose)** if first dose of DTaP/DT or Tdap/Td was administered at or after the 1st birthday.	**6 months** if first dose of DTaP/DT was administered before the 1st birthday.	
Human papillomavirus	9 years	**Routine dosing intervals are recommended.**			
Hepatitis A	N/A	**6 months**			
Hepatitis B	N/A	**4 weeks**	**8 weeks *and* at least 16 weeks after first dose.**		
Inactivated poliovirus	N/A	**4 weeks**	**6 months** A fourth dose is not necessary if the third dose was administered at age 4 years or older and at least 6 months after the previous dose.	A fourth dose of IPV is indicated if all previous doses were administered at <4 years or if the third dose was administered <6 months after the second dose.	
Measles, mumps, rubella	N/A	**4 weeks**			
Varicella	N/A	**3 months** if younger than age 13 years. **4 weeks** if age 13 years or older.			

FIGURE 113.2

ACIP recommends routine human papilloma virus (HPV) vaccination of females aged 11 or 12 years old, catch-up vaccination for females aged 13 to 26 years old, and administration as early as 9 years old if the girl is at risk of exposure. HPV vaccine is contraindicated in pregnancy, but may be used in lactating women. ACIP also recommends routine HPV vaccination of males aged 11 to 12 years, and males 13 to 21 years not vaccinated previously. Additionally, the ACIP recommends routine HPV vaccination through the age of 26 years for men who have sex with men (MSM) because of increased risk for disease associated with HPV, and for immunocompromised males (including those with HIV infection).

The HPV vaccine (HPV: Gardisil 9, Merck) is an inactivated recombinant nine-valent vaccine directed against nine HPV types associated with human disease. The vaccine is given as a series of two or three doses depending on age at initial vaccination, and it is given by intramuscular injection. All nine HPV types covered by the vaccine (Types 6, 11, 16, 18, 31, 33, 45, 52, and 58) may cause precancerous or dysplastic genital lesions in both males and females; Types 16, 18, 31, 33, 45, 52, and 58 may cause cervical, vulvar, vaginal, and anal cancers in females and anal cancer in males; Types 6 and 11 are associated with genital warts.

Although clinical trials of concomitant administration of HPV vaccine with the other vaccines recommended for adolescents have not been performed, there are no theoretical reasons not to administer the first dose of HPV during the same clinic visit as MenACWY and Tdap vaccines, with the vaccines being administered at different anatomic sites.

Combination vaccines

The number of recommended early childhood immunizations creates issues of compliance and scheduling for parents, patients, and healthcare providers. Several commercially prepared combination vaccines are available for pediatric use (Table 113.1), and their use, when appropriate, instead of individual vaccines administered by separate injections is encouraged to promote patient and parent compliance. However, special care must be taken in terms of scheduling missed doses, completing a vaccine series with a different vaccine product than originally used, and recognizing differences in antigen content and dose scheduling between monovalent vaccines and corresponding combination vaccines. For more details pertaining to adaptation of the recommended vaccine schedule for special situations, see Figure 113.2, Figure 113.3, and 113.4.

Adult immunizations

Recommendations for adult immunizations are based on the history of immunizations received in the past and on the need to give booster doses for certain vaccines. A detailed review of the personal immunization history is indicated for international travelers, healthcare workers, and other persons who have risks of exposure related to occupational activities, advanced age, or compromised immune status due to disease (HIV), medications, cancer, or other chronic medical conditions.

The immunization history should be updated and documented at the time of initial intake into a primary care practice, during interim health maintenance visits, on employment in one of the healthcare or social services professions, and/or prior to international travel. Travel immunizations will be covered in Chapter 114, "Advice for travelers." If the immunization history of the person is uncertain or unknown, a conceptual framework of the prevalent practices pertaining to childhood, school, military service, and occupational immunization programs and standards will be helpful for assessing the current immunization status. The recommended adult immunization schedule is given in Figure 113.5. The recommended adult immunization schedule by medical condition and other indications and detailed notes are given in Figures 113.6 and 113.7.

Routine immunizations for adults

Tetanus and diphtheria and acellular pertussis vaccine

The combined diphtheria and tetanus toxoids and acellular pertussis vaccine (DTaP) series is a routine immunization of childhood. A formulation of the tetanus and diphtheria vaccine (Td) (Tenivac, Sanofi

TABLE 113.1 **SELECTED FDA-LICENSED COMBINATION VACCINES**[a]

Vaccine product	Age range
DTaP-IPV-HepB (Pediarix, GlaxoSmithKline)	6 weeks through 7 years
DTaP-IPV-Hib-HepB (Vaxelis, MSP Vaccine)	6 weeks through 4 years
DTap-IPV/Hib (Pentacel, Sanofi Pasteur)	2 months through 5 years
DTaP-IPV (Kinrix, GlaxoSmithKline; Quadracel, Sanofi Pasteur)	4 through 6 years
HepA-HepB (Twinrix, GlaxoSmithKline)	18 years or older
Hib-HepB (Comvax, Merck)	6 weeks through 5 years
MMRV (ProQuad, Merck)	12 months through 12 years

[a] Consult the package insert for details of licensed use for each combination vaccine.

Table 3 Recommended Child and Adolescent Immunization Schedule by Medical Indication, United States, 2021

Always use this table in conjunction with Table 1 and the notes that follow.

VACCINE	INDICATION									
	Pregnancy	Immunocompromised status (excluding HIV infection)	HIV infection CD4+ count[1]: <15% and total CD4 cell count of <200/mm³	HIV infection CD4+ count[1]: ≥15% and total CD4 cell count of ≥200/mm³	Kidney failure, end-stage renal disease, or on hemodialysis	Heart disease or chronic lung disease	CSF leak or cochlear implant	Asplenia or persistent complement component deficiencies	Chronic liver disease	Diabetes
Hepatitis B										
Rotavirus		SCID[2]								
Diphtheria, tetanus, and acellular pertussis (DTaP)										
Haemophilus influenzae type b										
Pneumococcal conjugate										
Inactivated poliovirus										
Influenza (IIV)										
or										
Influenza (LAIV4)						Asthma, wheezing: 2–4yrs[3]				
Measles, mumps, rubella	*									
Varicella	*									
Hepatitis A										
Tetanus, diphtheria, and acellular pertussis (Tdap)										
Human papillomavirus	*									
Meningococcal ACWY										
Meningococcal B										
Pneumococcal polysaccharide										

- Vaccination according to the routine schedule recommended
- Recommended for persons with an additional risk factor for which the vaccine would be indicated
- Vaccination is recommended, and additional doses may be necessary based on medical condition. See Notes.
- Not recommended/ contraindicated—vaccine should not be administered.
- *Vaccinate after pregnancy.
- Precaution—vaccine might be indicated if benefit of protection outweighs risk of adverse reaction
- No recommendation/not applicable

1 For additional information regarding HIV laboratory parameters and use of live vaccines, see the *General Best Practice Guidelines for Immunization*, "Altered Immunocompetence," at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/immunocompetence.html and Table 4-1 (footnote D) at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/contraindications.html.
2 Severe Combined Immunodeficiency
3 LAIV4 contraindicated for children 2–4 years of age with asthma or wheezing during the preceding 12 months

FIGURE 113.3

Notes

Recommended Child and Adolescent Immunization Schedule for ages 18 years or younger, United States, 2021

For vaccination recommendations for persons ages 19 years or older, see the Recommended Adult Immunization Schedule, 2021.

Additional information

COVID-19 Vaccination

ACIP recommends use of COVID-19 vaccines within the scope of the Emergency Use Authorization or Biologics License Application for the particular vaccine. Interim ACIP recommendations for the use of COVID-19 vaccines can be found at www.cdc.gov/vaccines/hcp/acip-recs/.

- Consult relevant ACIP statements for detailed recommendations at www.cdc.gov/vaccines/hcp/acip-recs/index.html.
- For information on contraindications and precautions for the use of a vaccine, consult the *General Best Practice Guidelines for Immunization* at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/contraindications.html and relevant ACIP statements at www.cdc.gov/vaccines/hcp/acip-recs/index.html.
- For calculating intervals between doses, 4 weeks = 28 days. Intervals of ≥4 months are determined by calendar months.
- Within a number range (e.g., 12–18), a dash (–) should be read as "through."
- Vaccine doses administered ≤4 days before the minimum age or interval are considered valid. Doses of any vaccine administered ≥5 days earlier than the minimum age or minimum interval should not be counted as valid and should be repeated as age appropriate. **The repeat dose should be spaced after the invalid dose by the recommended minimum interval.** For further details, see Table 3-1, Recommended and minimum ages and intervals between vaccine doses, in *General Best Practice Guidelines for Immunization* at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/timing.html.
- Information on travel vaccination requirements and recommendations is available at www.cdc.gov/travel/.
- For vaccination of persons with immunodeficiencies, see Table 8-1, Vaccination of persons with primary and secondary immunodeficiencies, in *General Best Practice Guidelines for Immunization* at www.cdc.gov/vaccines/hcp/acip-recs/general-recs/immunocompetence.html, and Immunization in Special Clinical Circumstances (In: Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2018 Report of the Committee on Infectious Diseases*. 31st ed. Itasca, IL: American Academy of Pediatrics; 2018:67–111).
- For information about vaccination in the setting of a vaccine-preventable disease outbreak, contact your state or local health department.
- The National Vaccine Injury Compensation Program (VICP) is a no-fault alternative to the traditional legal system for resolving vaccine injury claims. All routine child and adolescent vaccines are covered by VICP except for pneumococcal polysaccharide vaccine (PPSV23). For more information, see www.hrsa.gov/vaccinecompensation/index.html.

Diphtheria, tetanus, and pertussis (DTaP) vaccination (minimum age: 6 weeks [4 years for Kinrix or Quadracel])

Routine vaccination

- 5-dose series at 2, 4, 6, 15–18 months, 4–6 years
  - **Prospectively:** Dose 4 may be administered as early as age 12 months if at least 6 months have elapsed since dose 3.
  - **Retrospectively:** A 4th dose that was inadvertently administered as early as age 12 months may be counted if at least 4 months have elapsed since dose 3.

Catch-up vaccination

- Dose 5 is not necessary if dose 4 was administered at age 4 years or older and at least 6 months after dose 3.
- For other catch-up guidance, see Table 2.

Special situations

- Wound management in children less than age 7 years with history of 3 or more doses of tetanus-toxoid-containing vaccine: For all wounds except clean and minor wounds, administer DTaP if more than 5 years since last dose of tetanus-toxoid-containing vaccine. For detailed information, see www.cdc.gov/mmwr/volumes/67/rr/rr6702a1.htm.

Haemophilus influenzae type b vaccination (minimum age: 6 weeks)

Routine vaccination

- **ActHIB, Hiberix, or Pentacel:** 4-dose series at 2, 4, 6, 12–15 months
- **PedvaxHIB:** 3-dose series at 2, 4, 12–15 months

Catch-up vaccination

- **Dose 1 at age 7–11 months:** Administer dose 2 at least 4 weeks later and dose 3 (final dose) at age 12–15 months or 8 weeks after dose 2 (whichever is later).
- **Dose 1 at age 12–14 months:** Administer dose 2 (final dose) at least 8 weeks after dose 1.
- **Dose 1 before age 12 months and dose 2 before age 15 months:** Administer dose 3 (final dose) 8 weeks after dose 2.
- **2 doses of PedvaxHIB before age 12 months:** Administer dose 3 (final dose) at 12–59 months and at least 8 weeks after dose 2.
- **1 dose administered at age 15 months or older:** No further doses needed
- **Unvaccinated at age 15–59 months:** Administer 1 dose.
- **Previously unvaccinated children age 60 months or older who are not considered high risk:** Do not require catch-up vaccination
- For other catch-up guidance, see Table 2.

Special situations

- **Chemotherapy or radiation treatment:**
  12–59 months
  - Unvaccinated or only 1 dose before age 12 months: 2 doses, 8 weeks apart
  - 2 or more doses before age 12 months: 1 dose at least 8 weeks after previous dose

  Doses administered within 14 days of starting therapy or during therapy should be repeated at least 3 months after therapy completion.
- **Hematopoietic stem cell transplant (HSCT):**
  - 3-dose series 4 weeks apart starting 6 to 12 months after successful transplant, regardless of Hib vaccination history
- **Anatomic or functional asplenia (including sickle cell disease):**
  12–59 months
  - Unvaccinated or only 1 dose before age 12 months: 2 doses, 8 weeks apart
  - 2 or more doses before age 12 months: 1 dose at least 8 weeks after previous dose

  Unvaccinated persons age 5 years or older*
  - 1 dose
- **Elective splenectomy:**
  Unvaccinated persons age 15 months or older*
  - 1 dose (preferably at least 14 days before procedure)
- **HIV infection:**
  12–59 months
  - Unvaccinated or only 1 dose before age 12 months: 2 doses, 8 weeks apart
  - 2 or more doses before age 12 months: 1 dose at least 8 weeks after previous dose

  Unvaccinated persons age 5–18 years*
  - 1 dose
- **Immunoglobulin deficiency, early component complement deficiency:**
  12–59 months
  - Unvaccinated or only 1 dose before age 12 months: 2 doses, 8 weeks apart
  - 2 or more doses before age 12 months: 1 dose at least 8 weeks after previous dose

**Unvaccinated* = Less than routine series (through age 14 months) OR no doses (age 15 months or older)

FIGURE 113.4

Notes

Recommended Child and Adolescent Immunization Schedule for ages 18 years or younger, United States, 2021

Hepatitis A vaccination
(minimum age: 12 months for routine vaccination)

Routine vaccination
- 2-dose series (minimum interval: 6 months) beginning at age 12 months

Catch-up vaccination
- Unvaccinated persons through age 18 years should complete a 2-dose series (minimum interval: 6 months).
- Persons who previously received 1 dose at age 12 months or older should receive dose 2 at least 6 months after dose 1.
- Adolescents age 18 years or older may receive the combined HepA and HepB vaccine, **Twinrix®**, as a 3-dose series (0, 1, and 6 months) or 4-dose series (3 doses at 0, 7, and 21–30 days, followed by a booster dose at 12 months).

International travel
- Persons traveling to or working in countries with high or intermediate endemic hepatitis A (www.cdc.gov/travel/):
  - **Infants age 6–11 months**: 1 dose before departure; revaccinate with 2 doses, separated by at least 6 months, between age 12–23 months.
  - **Unvaccinated age 12 months or older**: Administer dose 1 as soon as travel is considered.

Hepatitis B vaccination
(minimum age: birth)

Birth dose (monovalent HepB vaccine only)
- **Mother is HBsAg-negative:** 1 dose within 24 hours of birth for **all** medically stable infants ≥2,000 grams. Infants <2,000 grams: Administer 1 dose at chronological age 1 month or hospital discharge (whichever is earlier and even if weight is still <2,000 grams).
- **Mother is HBsAg-positive:**
  - Administer **HepB vaccine** and **hepatitis B immune globulin (HBIG)** (in separate limbs) within 12 hours of birth, regardless of birth weight. For infants <2,000 grams, administer 3 additional doses of vaccine (total of 4 doses) beginning at age 1 month.
  - Test for HBsAg and anti-HBs at age 9–12 months. If HepB series is delayed, test 1–2 months after final dose.
- **Mother's HBsAg status is unknown:**
  - Administer **HepB vaccine** within 12 hours of birth, regardless of birth weight.
  - For infants <2,000 grams, administer **HBIG** in addition to HepB vaccine (in separate limbs) within 12 hours of birth. Administer 3 additional doses of vaccine (total of 4 doses) beginning at age 1 month.
  - Determine mother's HBsAg status as soon as possible. If mother is HBsAg-positive, administer **HBIG** to infants ≥2,000 grams as soon as possible, but no later than 7 days of age.

Routine series
- 3-dose series at 0, 1–2, 6–18 months (use monovalent HepB vaccine for doses administered before age 6 weeks)
- Infants who did not receive a birth dose should begin the series as soon as feasible (see Table 2).
- Administration of **4 doses** is permitted when a combination vaccine containing HepB is used after the birth dose.
- **Minimum age** for the final (3rd or 4th) dose: 24 weeks
- **Minimum intervals:** dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 8 weeks / dose 1 to dose 3: 16 weeks (when 4 doses are administered, substitute "dose 4" for "dose 3" in these calculations)

Catch-up vaccination
- Unvaccinated persons should complete a 3-dose series at 0, 1–2, 6 months.
- Adolescents age 11–15 years may use an alternative 2-dose schedule with at least 4 months between doses (adult formulation **Recombivax HB** only).
- Adolescents age 18 years or older may receive a 2-dose series of HepB **(Heplisav-B®)** at least 4 weeks apart.
- Adolescents age 18 years or older may receive the combined HepA and HepB vaccine, **Twinrix**, as a 3-dose series (0, 1, and 6 months) or 4-dose series (3 doses at 0, 7, and 21–30 days, followed by a booster dose at 12 months).
- For other catch-up guidance, see Table 2.

Special situations
- Revaccination is not generally recommended for persons with a normal immune status who were vaccinated as infants, children, adolescents, or adults.
- **Revaccination** may be recommended for certain populations, including:
  - **Infants born to HBsAg-positive mothers**
  - **Hemodialysis patients**
  - **Other immunocompromised persons**
- For detailed revaccination recommendations, see www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/hepb.html.

Human papillomavirus vaccination
(minimum age: 9 years)

Routine and catch-up vaccination
- HPV vaccination routinely recommended at **age 11–12 years (can start at age 9 years)** and catch-up HPV vaccination recommended for all persons through age 18 years if not adequately vaccinated
- 2- or 3-dose series depending on age at initial vaccination:
  - **Age 9–14 years at initial vaccination**: 2-dose series at 0, 6–12 months (minimum interval: 5 months; repeat dose if administered too soon)
  - **Age 15 years or older at initial vaccination**: 3-dose series at 0, 1–2 months, 6 months (minimum intervals: dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 12 weeks / dose 1 to dose 3: 5 months; repeat dose if administered too soon)
- **Interrupted schedules:** If vaccination schedule is interrupted, the series does not need to be restarted.
- No additional dose recommended after completing series with recommended dosing intervals using any HPV vaccine.

Special situations
- **Immunocompromising conditions, including HIV infection:** 3-dose series as above
- **History of sexual abuse or assault:** Start at age 9 years.
- **Pregnancy:** HPV vaccination not recommended until after pregnancy; no intervention needed if vaccinated while pregnant; pregnancy testing not needed before vaccination

Influenza vaccination
(minimum age: 6 months [IIV], 2 years [LAIV4], 18 years [recombinant influenza vaccine, RIV4])

Routine vaccination
- Use any influenza vaccine appropriate for age and health status annually:
  - 2 doses, separated by at least 4 weeks, for **children age 6 months–8 years** who have received fewer than 2 influenza vaccine doses before July 1, 2020, or whose influenza vaccination history is unknown (administer dose 2 even if the child turns 9 between receipt of dose 1 and dose 2)
  - 1 dose for **children age 6 months–8 years** who have received at least 2 influenza vaccine doses before July 1, 2020
  - 1 dose for **all persons age 9 years or older**
- For the 2021–22 season, see the 2021–22 ACIP influenza vaccine recommendations.

Special situations
- **Egg allergy, hives only**: Any influenza vaccine appropriate for age and health status annually
- **Egg allergy with symptoms other than hives** (e.g., angioedema, respiratory distress, need for emergency medical services or epinephrine): Any influenza vaccine appropriate for age and health status annually. If using an influenza vaccine other than Flublok or Flucelvax, administer in medical setting under supervision of health care provider who can recognize and manage severe allergic reactions.
- Severe allergic reactions to vaccines can occur even in the absence of a history of previous allergic reaction. All vaccination providers should be familiar with the office emergency plan and certified in cardiopulmonary resuscitation.
- A previous severe allergic reaction to influenza vaccine is a contraindication to future receipt of any influenza vaccine.
- **LAIV4 should not be used** in persons with the following conditions or situations:
  - History of severe allergic reaction to a previous dose of any influenza vaccine or to any vaccine component (excluding egg, see details above)
  - Receiving aspirin or salicylate-containing medications
  - Age 2–4 years with history of asthma or wheezing
  - Immunocompromised due to any cause (including medications and HIV infection)
  - Anatomic or functional asplenia
  - Close contacts or caregivers of severely immunosuppressed persons who require a protected environment
  - Pregnancy
  - Cochlear implant
  - Cerebrospinal fluid-oropharyngeal communication
  - Children less than age 2 years
  - Received influenza antiviral medications oseltamivir or zanamivir within the previous 48 hours,. peramivir within the previous 5 days, or baloxavir within the previous 17 days

FIGURE 113.4 Continued

Notes

Recommended Child and Adolescent Immunization Schedule for ages 18 years or younger, United States, 2021

Measles, mumps, and rubella vaccination (minimum age: 12 months for routine vaccination)

Routine vaccination
- 2-dose series at 12–15 months, 4–6 years
- Dose 2 may be administered as early as 4 weeks after dose 1.

Catch-up vaccination
- Unvaccinated children and adolescents: 2-dose series at least 4 weeks apart
- The maximum age for use of MMRV is 12 years.

Special situations
International travel
- **Infants age 6–11 months:** 1 dose before departure; revaccinate with 2-dose series at age 12–15 months (12 months for children in high-risk areas) and dose 2 as early as 4 weeks later.
- **Unvaccinated children age 12 months or older:** 2-dose series at least 4 weeks apart before departure

Meningococcal serogroup A,C,W,Y vaccination (minimum age: 2 months [MenACWY-CRM, Menveo], 9 months [MenACWY-D, Menactra], 2 years [MenACWY-TT, MenQuadfi])

Routine vaccination
- 2-dose series at 11–12 years, 16 years

Catch-up vaccination
- Age 13–15 years: 1 dose now and booster at age 16–18 years (minimum interval: 8 weeks)
- Age 16–18 years: 1 dose

Special situations
Anatomic or functional asplenia (including sickle cell disease), HIV infection, persistent complement component deficiency, complement inhibitor (e.g., eculizumab, ravulizumab) use:
- **Menveo**
  - Dose 1 at age 8 weeks: 4-dose series at 2, 4, 6, 12 months
  - Dose 1 at age 3–6 months: 3- or 4- dose series (dose 2 [and dose 3 if applicable] at least 8 weeks after previous dose until a dose is received at age 7 months or older, followed by an additional dose at least 12 weeks later and after age 12 months)
  - Dose 1 at age 7–23 months: 2-dose series (dose 2 at least 12 weeks after dose 1 and after age 12 months)
  - Dose 1 at age 24 months or older: 2-dose series at least 8 weeks apart
- **Menactra**
  - **Persistent complement component deficiency or complement inhibitor use:**
    - Age 9–23 months: 2-dose series at least 12 weeks apart
    - Age 24 months or older: 2-dose series at least 8 weeks apart
  - **Anatomic or functional asplenia, sickle cell disease, or HIV infection:**
    - Age 9–23 months: Not recommended
    - Age 24 months or older: 2-dose series at least 8 weeks apart
    - **Menactra** must be administered at least 4 weeks after completion of PCV13 series.
- **MenQuadfi**
  - Dose 1 at age 24 months or older: 2-dose series at least 8 weeks apart

Travel in countries with hyperendemic or epidemic meningococcal disease, including countries in the African meningitis belt or during the Hajj (www.cdc.gov/travel/)**:**
- Children less than age 24 months:
  - **Menveo (age 2–23 months)**
    - Dose 1 at age 8 weeks: 4-dose series at 2, 4, 6, 12 months
    - Dose 1 at age 3–6 months: 3- or 4- dose series (dose 2 [and dose 3 if applicable] at least 8 weeks after previous dose until a dose is received at age 7 months or older, followed by an additional dose at least 12 weeks later and after age 12 months)
    - Dose 1 at age 7–23 months: 2-dose series (dose 2 at least 12 weeks after dose 1 and after age 12 months)
  - **Menactra (age 9–23 months)**
    - 2-dose series (dose 2 at least 12 weeks after dose 1; dose 2 may be administered as early as 8 weeks after dose 1 in travelers)
- Children age 2 years or older: 1 dose Menveo, Menactra, or MenQuadfi

First-year college students who live in residential housing (if not previously vaccinated at age 16 years or older) or military recruits:
- 1 dose **Menveo, Menactra,** or **MenQuadfi**

Adolescent vaccination of children who received MenACWY prior to age 10 years:
- **Children for whom boosters are recommended** because of an ongoing increased risk of meningococcal disease (e.g., those with complement deficiency, HIV, or asplenia): Follow the booster schedule for persons at increased risk.
- **Children for whom boosters are not recommended** (e.g., a healthy child who received a single dose for travel to a country where meningococcal disease is endemic): Administer MenACWY according to the recommended adolescent schedule with dose 1 at age 11–12 years and dose 2 at age 16 years.

Note: Menactra should be administered either before or at the same time as DTaP. For MenACWY **booster dose recommendations** for groups listed under "Special situations" and in an outbreak setting and additional meningococcal vaccination information, see www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm.

Meningococcal serogroup B vaccination (minimum age: 10 years [MenB-4C, Bexsero; MenB-FHbp, Trumenba])

Shared clinical decision-making
- **Adolescents not at increased risk** age 16–23 years (preferred age 16–18 years) based on shared clinical decision-making:
  - **Bexsero:** 2-dose series at least 1 month apart
  - **Trumenba:** 2-dose series at least 6 months apart; if dose 2 is administered earlier than 6 months, administer a 3rd dose at least 4 months after dose 2.

Special situations
Anatomic or functional asplenia (including sickle cell disease), persistent complement component deficiency, complement inhibitor (e.g., eculizumab, ravulizumab) use:
- **Bexsero:** 2-dose series at least 1 month apart
- **Trumenba:** 3-dose series at 0, 1–2, 6 months

Bexsero and **Trumenba** are not interchangeable; the same product should be used for all doses in a series.
For MenB **booster dose recommendations** for groups listed under "Special situations" and in an outbreak setting and additional meningococcal vaccination information, see www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm.

Pneumococcal vaccination (minimum age: 6 weeks [PCV13], 2 years [PPSV23])

Routine vaccination with PCV13
- 4-dose series at 2, 4, 6, 12–15 months

Catch-up vaccination with PCV13
- 1 dose for healthy children age 24–59 months with any incomplete* PCV13 series
- For other catch-up guidance, see Table 2.

Special situations
Underlying conditions below: When both PCV13 and PPSV23 are indicated, administer PCV13 first. PCV13 and PPSV23 should not be administered during same visit.

Chronic heart disease (particularly cyanotic congenital heart disease and cardiac failure); chronic lung disease (including asthma treated with high-dose, oral corticosteroids); diabetes mellitus:

Age 2–5 years
- Any incomplete* series with:
  - 3 PCV13 doses: 1 dose PCV13 (at least 8 weeks after any prior PCV13 dose)
  - Less than 3 PCV13 doses: 2 doses PCV13 (8 weeks after the most recent dose and administered 8 weeks apart)
- No history of PPSV23: 1 dose PPSV23 (at least 8 weeks after completing all recommended PCV13 doses)

Age 6–18 years
- No history of PPSV23: 1 dose PPSV23 (at least 8 weeks after completing all recommended PCV13 doses)

Cerebrospinal fluid leak, cochlear implant:

Age 2–5 years
- Any incomplete* series with:
  - 3 PCV13 doses: 1 dose PCV13 (at least 8 weeks after any prior PCV13 dose)
  - Less than 3 PCV13 doses: 2 doses PCV13 (8 weeks after the most recent dose and administered 8 weeks apart)
- No history of PPSV23: 1 dose PPSV23 (at least 8 weeks after any prior PCV13 dose)

Age 6–18 years
- No history of either PCV13 or PPSV23: 1 dose PCV13, 1 dose PPSV23 at least 8 weeks later
- Any PCV13 but no PPSV23: 1 dose PPSV23 at least 8 weeks after the most recent dose of PCV13
- PPSV23 but no PCV13: 1 dose PCV13 at least 8 weeks after the most recent dose of PPSV23

FIGURE 113.4 Continued

Notes

Recommended Child and Adolescent Immunization Schedule for ages 18 years or younger, United States, 2021

Sickle cell disease and other hemoglobinopathies; anatomic or functional asplenia; congenital or acquired immunodeficiency; HIV infection; chronic renal failure; nephrotic syndrome; malignant neoplasms, leukemias, lymphomas, Hodgkin disease, and other diseases associated with treatment with immunosuppressive drugs or radiation therapy; solid organ transplantation; multiple myeloma:

Age 2–5 years

- Any incomplete* series with:
  - 3 PCV13 doses: 1 dose PCV13 (at least 8 weeks after any prior PCV13 dose)
  - Less than 3 PCV13 doses: 2 doses PCV13 (8 weeks after the most recent dose and administered 8 weeks apart)
- No history of PPSV23: 1 dose PPSV23 (at least 8 weeks after any prior PCV13 dose) and a 2nd dose of PPSV23 5 years later

Age 6–18 years

- No history of either PCV13 or PPSV23: 1 dose PCV13, 2 doses PPSV23 (dose 1 of PPSV23 administered 8 weeks after PCV13 and dose 2 of PPSV23 administered at least 5 years after dose 1 of PPSV23)
- Any PCV13 but no PPSV23: 2 doses PPSV23 (dose 1 of PPSV23 administered 8 weeks after the most recent dose of PCV13 and dose 2 of PPSV23 administered at least 5 years after dose 1 of PPSV23)
- PPSV23 but no PCV13: 1 dose PCV13 at least 8 weeks after the most recent PPSV23 dose and a 2nd dose of PPSV23 administered 5 years after dose 1 of PPSV23 and at least 8 weeks after a dose of PCV13

Chronic liver disease, alcoholism:

Age 6–18 years

- No history of PPSV23: 1 dose PPSV23 (at least 8 weeks after any prior PCV13 dose)

**Incomplete series* = Not having received all doses in either the recommended series or an age-appropriate catch-up series See Tables 8, 9, and 11 in the ACIP pneumococcal vaccine recommendations (www.cdc.gov/mmwr/pdf/rr/rr5911.pdf) for complete schedule details.

Poliovirus vaccination (minimum age: 6 weeks)

Routine vaccination

- 4-dose series at ages 2, 4, 6–18 months, 4–6 years; administer the final dose on or after age 4 years and at least 6 months after the previous dose.
- 4 or more doses of IPV can be administered before age 4 years when a combination vaccine containing IPV is used. However, a dose is still recommended on or after age 4 years and at least 6 months after the previous dose.

Catch-up vaccination

- In the first 6 months of life, use minimum ages and intervals only for travel to a polio-endemic region or during an outbreak.
- IPV is not routinely recommended for U.S. residents age 18 years or older.

Series containing oral polio vaccine (OPV), either mixed OPV-IPV or OPV-only series:

- Total number of doses needed to complete the series is the same as that recommended for the U.S. IPV schedule. See www.cdc.gov/mmwr/volumes/66/wr/mm6601a6.htm?s_%20cid=mm6601a6_w.
- Only trivalent OPV (tOPV) counts toward the U.S. vaccination requirements.
  - Doses of OPV administered before April 1, 2016, should be counted (unless specifically noted as administered during a campaign).
  - Doses of OPV administered on or after April 1, 2016, should not be counted.
  - For guidance to assess doses documented as "OPV," see www.cdc.gov/mmwr/volumes/66/wr/mm6606a7.htm?s_cid=mm6606a7_w.
- For other catch-up guidance, see Table 2.

Rotavirus vaccination (minimum age: 6 weeks)

Routine vaccination

- **Rotarix:** 2-dose series at 2 and 4 months
- **RotaTeq:** 3-dose series at 2, 4, and 6 months
- If any dose in the series is either **RotaTeq** or unknown, default to 3-dose series.

Catch-up vaccination

- Do not start the series on or after age 15 weeks, 0 days.
- The maximum age for the final dose is 8 months, 0 days.
- For other catch-up guidance, see Table 2.

Tetanus, diphtheria, and pertussis (Tdap) vaccination (minimum age: 11 years for routine vaccination, 7 years for catch-up vaccination)

Routine vaccination

- **Adolescents age 11–12 years:** 1 dose Tdap
- **Pregnancy:** 1 dose Tdap during each pregnancy, preferably in early part of gestational weeks 27–36
- Tdap may be administered regardless of the interval since the last tetanus- and diphtheria-toxoid-containing vaccine.

Catch-up vaccination

- **Adolescents age 13–18 years who have not received Tdap:** 1 dose Tdap, then Td or Tdap booster every 10 years
- **Persons age 7–18 years not fully vaccinated* with DTaP:** 1 dose Tdap as part of the catch-up series (preferably the first dose); if additional doses are needed, use Td or Tdap.
- **Tdap administered at age 7–10 years:**
  - **Children age 7–9 years** who receive Tdap should receive the routine Tdap dose at age 11–12 years.
  - **Children age 10 years** who receive Tdap do not need the routine Tdap dose at age 11–12 years.
- **DTaP inadvertently administered on or after age 7 years**:
  - **Children age 7–9 years**: DTaP may count as part of catch-up series. Administer routine Tdap dose at age 11–12 years.
  - **Children age 10–18 years**: Count dose of DTaP as the adolescent Tdap booster.
- For other catch-up guidance, see Table 2.

Special situations

- **Wound management** in persons age 7 years or older with history of 3 or more doses of tetanus-toxoid-containing vaccine: For clean and minor wounds, administer Tdap or Td if more than 10 years since last dose of tetanus-toxoid-containing vaccine; for all other wounds, administer Tdap or Td if more than 5 years since last dose of tetanus-toxoid-containing vaccine. Tdap is preferred for persons age 11 years or older who have not previously received Tdap or whose Tdap history is unknown. If a tetanus-toxoid-containing vaccine is indicated for a pregnant adolescent, use Tdap.
- For detailed information, see www.cdc.gov/mmwr/volumes/69/wr/mm6903a5.htm.

**Fully vaccinated* = 5 valid doses of DTaP OR 4 valid doses of DTaP if dose 4 was administered at age 4 years or older

Varicella vaccination (minimum age: 12 months)

Routine vaccination

- 2-dose series at 12–15 months, 4–6 years
- Dose 2 may be administered as early as 3 months after dose 1 (a dose administered after a 4-week interval may be counted).

Catch-up vaccination

- Ensure persons age 7–18 years without evidence of immunity (see *MMWR* at www.cdc.gov/mmwr/pdf/rr/rr5604.pdf) have a 2-dose series:
  - **Age 7–12 years**: routine interval: 3 months (a dose administered after a 4-week interval may be counted)
  - **Age 13 years and older**: routine interval: 4–8 weeks (minimum interval: 4 weeks)
  - The maximum age for use of MMRV is 12 years.

FIGURE 113.4 Continued

Table 1 Recommended Adult Immunization Schedule by Age Group, United States, 2021

Vaccine	19–26 years	27–49 years	50–64 years	≥65 years
Influenza inactivated (IIV) or **Influenza recombinant** (RIV4)	1 dose annually			
or		or		
Influenza live, attenuated (LAIV4)	1 dose annually			
Tetanus, diphtheria, pertussis (Tdap or Td)	1 dose Tdap each pregnancy; 1 dose Td/Tdap for wound management (see notes)			
	1 dose Tdap, then Td or Tdap booster every 10 years			
Measles, mumps, rubella (MMR)	1 or 2 doses depending on indication (if born in 1957 or later)			
Varicella (VAR)	2 doses (if born in 1980 or later)		2 doses	
Zoster recombinant (RZV)			2 doses	
Human papillomavirus (HPV)	2 or 3 doses depending on age at initial vaccination or condition	27 through 45 years		
Pneumococcal conjugate (PCV13)	1 dose			1 dose
Pneumococcal polysaccharide (PPSV23)	1 or 2 doses depending on indication			1 dose
Hepatitis A (HepA)	2 or 3 doses depending on vaccine			
Hepatitis B (HepB)	2 or 3 doses depending on vaccine			
Meningococcal A, C, W, Y (MenACWY)	1 or 2 doses depending on indication, see notes for booster recommendations			
Meningococcal B (MenB)	2 or 3 doses depending on vaccine and indication, see notes for booster recommendations			
	19 through 23 years			
***Haemophilus influenzae* type b** (Hib)	1 or 3 doses depending on indication			

Recommended vaccination for adults who meet age requirement, lack documentation of vaccination, or lack evidence of past infection

Recommended vaccination for adults with an additional risk factor or another indication

Recommended vaccination based on shared clinical decision-making

No recommendation/ Not applicable

FIGURE 113.5

Table 2 Recommended Adult Immunization Schedule by Medical Condition and Other Indications, United States, 2021

Vaccine	Pregnancy	Immuno-compromised (excluding HIV infection)	HIV infection CD4 count		Asplenia, complement deficiencies	End-stage renal disease; or on hemodialysis	Heart or lung disease, alcoholism[1]	Chronic liver disease	Diabetes	Health care personnel[2]	Men who have sex with men
			<200 mm³	≥200 mm³							
IIV or RIV4	1 dose annually										
or										or	
LAIV4	Not Recommended									1 dose annually	
						Precaution					
Tdap or Td	1 dose Tdap each pregnancy	1 dose Tdap, then Td or Tdap booster every 10 years									
MMR	Not Recommended*	Not Recommended	1 or 2 doses depending on indication								
VAR	Not Recommended*	Not Recommended			2 doses						
RZV					2 doses at age ≥50 years						
HPV	Not Recommended*	3 doses through age 26 years			2 or 3 doses through age 26 years depending on age at initial vaccination or condition						
PCV13		1 dose									
PPSV23		1, 2, or 3 doses depending on age and indication									
HepA					2 or 3 doses depending on vaccine						
HepB					2, 3, or 4 doses depending on vaccine or condition				<60 years		
									≥60 years		
MenACWY	1 or 2 doses depending on indication, see notes for booster recommendations										
MenB	Precaution	2 or 3 doses depending on vaccine and indication, see notes for booster recommendations									
Hib		3 doses HSCT[3] recipients only			1 dose						

- Recommended vaccination for adults who meet age requirement, lack documentation of vaccination, or lack evidence of past infection
- Recommended vaccination for adults with an additional risk factor or another indication
- Precaution—vaccination might be indicated if benefit of protection outweighs risk of adverse reaction
- Recommended vaccination based on shared clinical decision-making
- Not recommended/ contraindicated—vaccine should not be administered.
- No recommendation/ Not applicable

*Vaccinate after pregnancy.

1. Precaution for LAIV4 does not apply to alcoholism. **2.** See notes for influenza; hepatitis B; measles, mumps, and rubella; and varicella vaccinations. **3.** Hematopoietic stem cell transplant.

FIGURE 113.6

Notes

Recommended Adult Immunization Schedule for ages 19 years or older, United States, 2021

For vaccine recommendations for persons 18 years of age or younger, see the Recommended Child/Adolescent Immunization Schedule.

Additional Information

COVID-19 Vaccination

ACIP recommends use of COVID-19 vaccines within the scope of the Emergency Use Authorization or Biologics License Application for the particular vaccine. Interim ACIP recommendations for the use of COVID-19 vaccines can be found at www.cdc.gov/vaccines/hcp/acip-recs/vacc-specific/covid-19.html

Haemophilus influenzae type b vaccination

Special situations

- **Anatomical or functional asplenia (including sickle cell disease):** 1 dose if previously did not receive Hib; if elective splenectomy, 1 dose, preferably at least 14 days before splenectomy
- **Hematopoietic stem cell transplant (HSCT):** 3-dose series 4 weeks apart starting 6–12 months after successful transplant, regardless of Hib vaccination history

Hepatitis A vaccination

Routine vaccination

- **Not at risk but want protection from hepatitis A** (identification of risk factor not required): 2-dose series HepA (Havrix 6–12 months apart or Vaqta 6–18 months apart [minimum interval: 6 months]) or 3-dose series HepA-HepB (Twinrix at 0, 1, 6 months [minimum intervals: dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 5 months])

Special situations

- **At risk for hepatitis A virus infection:** 2-dose series HepA or 3-dose series HepA-HepB as above
  - **Chronic liver disease** (e.g., persons with hepatitis B, hepatitis C, cirrhosis, fatty liver disease, alcoholic liver disease, autoimmune hepatitis, alanine aminotransferase [ALT] or aspartate aminotransferase [AST] level greater than twice the upper limit of normal)
  - **HIV infection**
  - **Men who have sex with men**
  - **Injection or noninjection drug use**
  - **Persons experiencing homelessness**
  - **Work with hepatitis A virus** in research laboratory or with nonhuman primates with hepatitis A virus infection
  - **Travel in countries with high or intermediate endemic hepatitis A** (HepA-HepB [Twinrix] may be administered on an accelerated schedule of 3 doses at 0, 7, and 21–30 days, followed by a booster dose at 12 months)
  - **Close, personal contact with international adoptee** (e.g., household or regular babysitting) in first 60 days after arrival from country with high or intermediate endemic hepatitis A (administer dose 1 as soon as adoption is planned, at least 2 weeks before adoptee's arrival)
  - **Pregnancy** if at risk for infection or severe outcome from infection during pregnancy
  - **Settings for exposure, including** health care settings targeting services to injection or noninjection drug users or group homes and nonresidential day care facilities for developmentally disabled persons (individual risk factor screening not required)

Hepatitis B vaccination

Routine vaccination

- **Not at risk but want protection from hepatitis B** (identification of risk factor not required): 2- or 3-dose series (2-dose series Heplisav-B at least 4 weeks apart [2-dose series HepB only applies when 2 doses of Heplisav-B are used at least 4 weeks apart] or 3-dose series Engerix-B or Recombivax HB at 0, 1, 6 months [minimum intervals: dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 8 weeks / dose 1 to dose 3: 16 weeks]) or 3-dose series HepA-HepB (Twinrix at 0, 1, 6 months [minimum intervals: dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 5 months])

Special situations

- **At risk for hepatitis B virus infection:** 2-dose (Heplisav-B) or 3-dose (Engerix-B, Recombivax HB) series or 3-dose series HepA-HepB (Twinrix) as above
  - **Chronic liver disease** (e.g., persons with hepatitis C, cirrhosis, fatty liver disease, alcoholic liver disease, autoimmune hepatitis, alanine aminotransferase [ALT] or aspartate aminotransferase [AST] level greater than twice upper limit of normal)
  - **HIV infection**
  - **Sexual exposure risk** (e.g., sex partners of hepatitis B surface antigen [HBsAg]-positive persons; sexually active persons not in mutually monogamous relationships; persons seeking evaluation or treatment for a sexually transmitted infection; men who have sex with men)
  - **Current or recent injection drug use**
  - **Percutaneous or mucosal risk for exposure to blood** (e.g., household contacts of HBsAg-positive persons; residents and staff of facilities for developmentally disabled persons; health care and public safety personnel with reasonably anticipated risk for exposure to blood or blood-contaminated body fluids; hemodialysis, peritoneal dialysis, home dialysis, and predialysis patients; persons with diabetes mellitus age younger than 60 years, shared clinical decision-making for persons age 60 years or older)
  - **Incarcerated persons**
  - **Travel in countries with high or intermediate endemic hepatitis B**
  - **Pregnancy** if at risk for infection or severe outcome from infection during pregnancy (Heplisav-B not currently recommended due to lack of safety data in pregnant women)

Human papillomavirus vaccination

Routine vaccination

- **HPV vaccination recommended for all persons through age 26 years:** 2- or 3-dose series depending on age at initial vaccination or condition:
  - **Age 15 years or older at initial vaccination:** 3-dose series at 0, 1–2 months, 6 months (minimum intervals: dose 1 to dose 2: 4 weeks / dose 2 to dose 3: 12 weeks / dose 1 to dose 3: 5 months; repeat dose if administered too soon)
  - **Age 9–14 years at initial vaccination and received 1 dose or 2 doses less than 5 months apart:** 1 additional dose
  - **Age 9–14 years at initial vaccination and received 2 doses at least 5 months apart:** HPV vaccination series complete, no additional dose needed
- **Interrupted schedules:** If vaccination schedule is interrupted, the series does not need to be restarted
- **No additional dose recommended after completing series with recommended dosing intervals using any HPV vaccine**

Shared clinical decision-making

- **Some adults age 27–45 years: Based on shared clinical decision-making,** 2- or 3-dose series as above

Special situations

- **Age ranges recommended above for routine and catch-up vaccination or shared clinical decision-making also apply in special situations**

FIGURE 113.7

Notes Recommended Adult Immunization Schedule, United States, 2021

- **Immunocompromising conditions, including HIV infection**: 3-dose series as above, regardless of age at initial vaccination
- **Pregnancy**: HPV vaccination not recommended until after pregnancy; no intervention needed if vaccinated while pregnant; pregnancy testing not needed before vaccination

Influenza vaccination

Routine vaccination

- **Persons age 6 months or older:** 1 dose any influenza vaccine appropriate for age and health status annually
- For additional guidance, see www.cdc.gov/flu/professionals/index.htm

Special situations

- **Egg allergy, hives only:** 1 dose any influenza vaccine appropriate for age and health status annually
- **Egg allergy–any symptom other than hives** (e.g., angioedema, respiratory distress): 1 dose any influenza vaccine appropriate for age and health status annually. If using an influenza vaccine other than RIV4 or ccIIV4, administer in medical setting under supervision of health care provider who can recognize and manage severe allergic reactions.
- Severe allergic reactions to any vaccine can occur even in the absence of a history of previous allergic reaction. Therefore, all vaccine providers should be familiar with the office emergency plan and certified in cardiopulmonary resuscitation.
- A previous severe allergic reaction to any influenza vaccine is a contraindication to future receipt of the vaccine.
- **LAIV4 should not be used** in persons with the following conditions or situations:
  - History of severe allergic reaction to any vaccine component (excluding egg) or to a previous dose of any influenza vaccine
  - Immunocompromised due to any cause (including medications and HIV infection)
  - Anatomic or functional asplenia
  - Close contacts or caregivers of severely immunosuppressed persons who require a protected environment
  - Pregnancy
  - Cranial CSF/oropharyngeal communications
  - Cochlear implant
  - Received influenza antiviral medications oseltamivir or zanamivir within the previous 48 hours, peramivir within the previous 5 days, or baloxavir within the previous 17 days
  - Adults 50 years or older
- **History of Guillain-Barré syndrome within 6 weeks after previous dose of influenza vaccine:** Generally, should not be vaccinated unless vaccination benefits outweigh risks for those at higher risk for severe complications from influenza

Measles, mumps, and rubella vaccination

Routine vaccination

- **No evidence of immunity to measles, mumps, or rubella:** 1 dose
  - **Evidence of immunity:** Born before 1957 (health care personnel, see below), documentation of receipt of MMR vaccine, laboratory evidence of immunity or disease (diagnosis of disease without laboratory confirmation is not evidence of immunity)

Special situations

- **Pregnancy with no evidence of immunity to rubella:** MMR contraindicated during pregnancy; after pregnancy (before discharge from health care facility), 1 dose
- **Nonpregnant women of childbearing age with no evidence of immunity to rubella:** 1 dose
- **HIV infection with CD4 count ≥200 cells/mm^3 for at least 6 months and no evidence of immunity to measles, mumps, or rubella:** 2-dose series at least 4 weeks apart; MMR contraindicated for HIV infection with CD4 count <200 cells/mm^3
- **Severe immunocompromising conditions:** MMR contraindicated
- **Students in postsecondary educational institutions, international travelers, and household or close, personal contacts of immunocompromised persons with no evidence of immunity to measles, mumps, or rubella:** 2-dose series at least 4 weeks apart if previously did not receive any doses of MMR or 1 dose if previously received 1 dose MMR
- **Health care personnel:**
  - **Born in 1957 or later with no evidence of immunity to measles, mumps, or rubella:** 2-dose series at least 4 weeks apart for measles or mumps or at least 1 dose for rubella
  - **Born before 1957 with no evidence of immunity to measles, mumps, or rubella:** Consider 2-dose series at least 4 weeks apart for measles or mumps or 1 dose for rubella

Meningococcal vaccination

Special situations for MenACWY

- **Anatomical or functional asplenia (including sickle cell disease), HIV infection, persistent complement component deficiency, complement inhibitor (e.g., eculizumab, ravulizumab) use:** 2-dose series MenACWY-D (Menactra, Menveo or MenQuadfi) at least 8 weeks apart and revaccinate every 5 years if risk remains
- **Travel in countries with hyperendemic or epidemic meningococcal disease, microbiologists routinely exposed to *Neisseria meningitidis*:** 1 dose MenACWY (Menactra, Menveo or MenQuadfi) and revaccinate every 5 years if risk remains
- **First-year college students who live in residential housing (if not previously vaccinated at age 16 years or older) and military recruits:** 1 dose MenACWY (Menactra, Menveo or MenQuadfi)
- For MenACWY **booster dose recommendations** for groups listed under "Special situations" and in an outbreak setting (e.g., in community or organizational settings and among men who have sex with men) and additional meningococcal vaccination information, see www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm

Shared clinical decision-making for MenB

- **Adolescents and young adults age 16–23 years (age 16–18 years preferred) not at increased risk for meningococcal disease:** Based on shared clinical decision-making, 2-dose series MenB-4C (Bexsero) at least 1 month apart or 2-dose series MenB-FHbp (Trumenba) at 0, 6 months (if dose 2 was administered less than 6 months after dose 1, administer dose 3 at least 4 months after dose 2); MenB-4C and MenB-FHbp are not interchangeable (use same product for all doses in series)

Special situations for MenB

- **Anatomical or functional asplenia (including sickle cell disease), persistent complement component deficiency, complement inhibitor (e.g., eculizumab, ravulizumab) use, microbiologists routinely exposed to *Neisseria meningitidis*:** 2-dose primary series MenB-4C (Bexsero) at least one month apart or

FIGURE 113.7 Continued

Notes Recommended Adult Immunization Schedule, United States, 2021

- MenB-4C (Bexsero) at least 1 month apart or 3-dose primary series MenB-FHbp (Trumenba) at 0, 1–2, 6 months (if dose 2 was administered at least 6 months after dose 1, dose 3 not needed); MenB-4C and MenB-FHbp are not interchangeable (use same product for all doses in series); 1 dose MenB booster 1 year after primary series and revaccinate every 2–3 years if risk remains
- **Pregnancy:** Delay MenB until after pregnancy unless at increased risk and vaccination benefits outweigh potential risks
- For MenB **booster dose recommendations** for groups listed under "Special situations" and in an outbreak setting (e.g., in community or organizational settings and among men who have sex with men) and additional meningococcal vaccination information, see www.cdc.gov/mmwr/volumes/69/rr/rr6909a1.htm

Pneumococcal vaccination

Routine vaccination

- **Age 65 years or older** (immunocompetent—see www.cdc.gov/mmwr/volumes/68/wr/mm6846a5.htm?s_cid=mm6846a5_w): 1 dose PPSV23
  - If PPSV23 was administered prior to age 65 years, administer 1 dose PPSV23 at least 5 years after previous dose

Shared clinical decision-making

- **Age 65 years or older** (immunocompetent): 1 dose PCV13 based on **shared clinical decision-making** if previously not administered.
  - PCV13 and PPSV23 should not be administered during the same visit
  - If both PCV13 and PPSV23 are to be administered, PCV13 should be administered first
  - PCV13 and PPSV23 should be administered at least 1 year apart

Special situations

(www.cdc.gov/mmwr/preview/mmwrhtml/mm6140a4.htm)

- **Age 19–64 years with chronic medical conditions (chronic heart [excluding hypertension], lung, or liver disease, diabetes), alcoholism, or cigarette smoking:** 1 dose PPSV23
- **Age 19 years or older with immunocompromising conditions (congenital or acquired immunodeficiency [including B- and T-lymphocyte deficiency, complement deficiencies, phagocytic disorders, HIV infection], chronic renal failure, nephrotic syndrome, leukemia, lymphoma, Hodgkin disease, generalized malignancy, iatrogenic immunosuppression [e.g., drug or radiation therapy], solid organ transplant, multiple myeloma) or anatomical or functional asplenia (including sickle cell disease and other hemoglobinopathies):** 1 dose PCV13 followed by 1 dose PPSV23 at least 8 weeks later, then another dose PPSV23 at least 5 years after previous PPSV23; at age 65 years or older, administer 1 dose PPSV23 at least 5 years after most recent PPSV23 (note: only 1 dose PPSV23 recommended at age 65 years or older)
- **Age 19 years or older with cerebrospinal fluid leak or cochlear implant:** 1 dose PCV13 followed by 1 dose PPSV23 at least 8 weeks later; at age 65 years or older, administer another dose PPSV23 at least 5 years after PPSV23 (note: only 1 dose PPSV23 recommended at age 65 years or older)

Tetanus, diphtheria, and pertussis vaccination

Routine vaccination

- **Previously did not receive Tdap at or after age 11 years:** 1 dose Tdap, then Td or Tdap every 10 years

Special situations

- **Previously did not receive primary vaccination series for tetanus, diphtheria, or pertussis:** At least 1 dose Tdap followed by 1 dose Td or Tdap at least 4 weeks after Tdap and another dose Td or Tdap 6–12 months after last Td or Tdap (Tdap can be substituted for any Td dose, but preferred as first dose), Td or Tdap every 10 years thereafter
- **Pregnancy:** 1 dose Tdap during each pregnancy, preferably in early part of gestational weeks 27–36
- **Wound management:** Persons with 3 or more doses of tetanus-toxoid-containing vaccine: For clean and minor wounds, administer Tdap or Td if more than 10 years since last dose of tetanus-toxoid-containing vaccine; for all other wounds, administer Tdap or Td if more than 5 years since last dose of tetanus-toxoid-containing vaccine. Tdap is preferred for persons who have not previously received Tdap or whose Tdap history is unknown. If a tetanus-toxoid-containing vaccine is indicated for a pregnant woman, use Tdap. For detailed information, see www.cdc.gov/mmwr/volumes/69/wr/mm6903a5.htm

Varicella vaccination

Routine vaccination

- **No evidence of immunity to varicella:** 2-dose series 4–8 weeks apart if previously did not receive varicella-containing vaccine (VAR or MMRV [measles-mumps-rubella-varicella vaccine] for children); if previously received 1 dose varicella-containing vaccine, 1 dose at least 4 weeks after first dose
  - Evidence of immunity: U.S.-born before 1980 (except for pregnant women and health care personnel [see below]), documentation of 2 doses varicella-containing vaccine at least 4 weeks apart, diagnosis or verification of history of varicella or herpes zoster by a health care provider, laboratory evidence of immunity or disease

Special situations

- **Pregnancy with no evidence of immunity to varicella:** VAR contraindicated during pregnancy; after pregnancy (before discharge from health care facility), 1 dose if previously received 1 dose varicella-containing vaccine or dose 1 of 2-dose series (dose 2: 4–8 weeks later) if previously did not receive any varicella-containing vaccine, regardless of whether U.S.-born before 1980
- **Health care personnel with no evidence of immunity to varicella:** 1 dose if previously received 1 dose varicella-containing vaccine; 2-dose series 4–8 weeks apart if previously did not receive any varicella-containing vaccine, regardless of whether U.S.-born before 1980
- **HIV infection with CD4 count ≥200 cells/mm^3 with no evidence of immunity:** Vaccination may be considered (2 doses 3 months apart); VAR contraindicated for HIV infection with CD4 count <200 cells/mm^3
- **Severe immunocompromising conditions:** VAR contraindicated

Zoster vaccination

Routine vaccination

- **Age 50 years or older:** 2-dose series RZV (Shingrix) 2–6 months apart (minimum interval: 4 weeks; repeat dose if administered too soon), regardless of previous herpes zoster or history of zoster vaccine live (ZVL, Zostavax) vaccination (administer RZV at least 2 months after ZVL)

Special situations

- **Pregnancy:** Consider delaying RZV until after pregnancy if RZV is otherwise indicated.
- **Severe immunocompromising conditions (including HIV infection with CD4 count <200 cells/mm^3):** Recommended use of RZV under review

FIGURE 113.7 Continued

Pasteur; Td vaccine, Merck) with reduced content of diphtheria toxoid is used to boost immunity in persons 7 years of age or older, and booster doses of Td are recommended every 10 years throughout adult life.

Poor control of pertussis in the United States has been noted since the late 1990s, and epidemiologic studies suggest that waning immunity to pertussis over time following childhood DTaP immunization contributes to this. In partially immune adolescents and adults, pertussis often causes a prolonged respiratory illness without the characteristic "whooping cough" and thus may not be recognized as such. Adolescents and adults with undiagnosed pertussis may transmit the infection to infants at highest risk of serious complications from the infection. For this reason, ACIP currently recommends that a single dose of Tdap vaccine (tetanus toxoid with reduced diphtheria toxoid and acellular pertussis content) (Adacel, Sanofi Pasteur; Boostrix, GlaxoSmithKline) be used to replace the next booster dose of Td vaccine among persons 19 years or older to boost levels of pertussis immunity in the adult population. Depending on community outbreaks of pertussis, occupational exposures, and/or personal health risks, Tdap vaccine may be administered with no minimal interval from the last Td vaccine dose based on current vaccine safety data. In wound management, Tdap or Td may be administered if more than 5 years have elapsed since the last dose of tetanus toxoid-containing vaccine was received; Tdap is preferred for persons whose Tdap history is unknown.

Healthcare workers

Healthcare workers exposed to patients with confirmed pertussis infections may warrant antibiotic prophylaxis and should consult the facility's infection control or occupational health consultant. ACIP recommends the use of Tdap vaccine as a one-time substitute for a Td vaccine booster among healthcare workers, especially for those providing care to pediatric patients.

Measles, mumps, and rubella

The measles, mumps, and rubella vaccines are given as a combination vaccine (MMR) in early childhood, at 12 to 15 months of age. However, up to 5% of vaccine recipients may fail to respond to primary immunization and have inadequate or waning immunity to measles by young adulthood. For this reason, the ACIP and AAP recommend that a second dose of measles vaccine (as a component of MMR vaccine) be given in childhood at 4 to 6 years of age upon primary school entry. Outbreaks of measles among college-aged individuals in campus communities have occurred over the past two decades and have resulted in significant disruption of campus activities. At present, most American colleges and universities require documentation of receipt of a second dose of measles vaccine or evidence of immunity (obtained by a serum test for measles antibodies) for registration as a preventive measure against future outbreaks of measles on campus. There is no contraindication to using the MMR vaccine to boost measles immunity even if the recipient is already immune to mumps and rubella.

In recent years, an increase in mumps cases has been reported in the United States among young adults and their cohorts. Outbreaks of mumps have occurred at universities among students with high vaccine coverage rates from childhood immunization programs, suggestive that MMR vaccine-induced immunity to mumps also wanes in the years following vaccination, resulting in increased susceptibility to infection among adolescent and young adult populations. During outbreak situations, a third dose of MMR vaccine to boost immunity may be administered to persons at risk of exposure, as directed by local or state public health officers. Monovalent measles, mumps, and rubella vaccines are commercially available but are not commonly recommended, stocked, and/or used in vaccine immunization programs.

Potential vaccine adverse reactions include the rare occurrence of usually transient, but occasionally prolonged, arthralgias and arthritis attributed to the rubella component of the MMR vaccine in nonimmune women of reproductive age—the very group most likely to benefit from immunization against rubella. As with any vaccine, the potential risks versus benefits of immunization with MMR vaccine should be discussed with potential vaccine recipients, along with the VIS statements.

Contraindications

MMR vaccine is a live-virus combination vaccine. Women of childbearing age should not be pregnant at the time of receiving MMR vaccine and should defer pregnancy for 3 months after MMR immunization.

HIV-infected persons

MMR immunization is recommended for use in susceptible persons with asymptomatic HIV infection because the potential benefits of immunization appear to outweigh the serious course of natural measles infections in this population.

Healthcare workers

People born before 1957 are generally considered immune to measles, mumps, and rubella by virtue of having had the natural infectious diseases in the pre-MMR vaccine era. However, because a small percentage in this group did not acquire lasting immunity from historical accounts of diagnosed/presumed infections, and because healthcare workers may be at increased risk of acquiring measles and mumps infections and transmitting them to other patients/clients, healthcare workers should provide proof of prior receipt of two doses of MMR vaccine or serologic immunity to measles and mumps.

Varicella vaccine and zoster (shingles) vaccine

Varicella (chickenpox) infections are more likely to result in severe disease among adults compared to children, often accompanied by complications such as varicella pneumonia. A live attenuated viral

vaccine against varicella (VAR: Varivax, Merck) was released in the mid-1990s. The primary series for adults born in 1980 or later consists of two doses given by injection 1 month apart.

Varicella-zoster virus (VZV) causes varicella (chickenpox) and becomes dormant within the nerves following exposure but can reactivate later in life, usually around 50 years old. The risk of virus reactivation increases with age, causing herpes zoster or "shingles," a condition characterized by a vesicular rash that follows a dermatomal distribution that is often associated with debilitating chronic pain. For protection against shingles, the ACIP recommends that a two-dose series of zoster recombinant vaccine be given to persons aged ≥50 (RZV, Shingrix, GlaxoSmithKline).

Contraindications

Varicella vaccine is contraindicated in pregnant women. Women of childbearing age should not be pregnant at the time of receiving varicella vaccine and should defer pregnancy for 3 months after varicella immunization. Varicella vaccine is contraindicated in persons with compromised immunity, including individuals with HIV infection.

Healthcare workers

Current occupational health recommendations for healthcare workers include documentation of varicella immunity or varicella immunization as a condition for working in certain clinics and hospitals.

Polio vaccine

Immunization against polio is a part of the routine childhood immunization program, and booster doses are not given routinely in adulthood in the Western Hemisphere (North and South America) and Western Europe, where polio is considered eradicated. Current pediatric regimens use the enhanced inactivated polio vaccine (IPV: Ipol, Sanofi Pasteur) administered by injection for primary immunization. A single dose of IPV is recommended as a booster in adults when there is imminent risk of exposure, such as travel to certain regions of Africa and Asia where polio is still transmitted, or for occupational exposure (e.g., work in certain research laboratories).

Hepatitis B vaccine

Hepatitis B immunization has been included as one of the regular immunizations in the United States since 1991. Hepatitis B vaccine should be considered a "catch-up" immunization among young adults born before the hepatitis B vaccine was incorporated into the routine childhood immunization programs. Hepatitis B immunization should also be recommended to individuals at risk of exposure to hepatitis B virus through occupational risk; treatment with blood products; contact with infected family, friends, or others; or international travel.

The primary series for hepatitis B immunization consists of three doses given by intramuscular injection into the deltoid muscle at 0, 1, and 6 months (HepB: Recombivax HB, Merck; Engerix-B, GlaxoSmithKline). An accelerated schedule consisting of three doses of hepatitis B vaccine given at 0, 1, and 2 months, with a booster dose at 12 months, has FDA approval (Engerix-B).

The recombinant CpG-adjuvanted hepatitis B vaccine (HepB-CpG: Heplisav, Dynavax Technologies Corp.) was FDA-approved in 2018 for use in adults aged ≥18. HepB-CpG is given as two doses by intramuscular injection one month apart, and is highly efficacious. In limited clinical studies, the HepB-CpG vaccine elicits a high rate of seroprotection in vaccine recipients aged ≥40 years, an age group in which suboptimal seroprotection rates from HepB vaccine previously had been observed.

A combination vaccine against hepatitis A plus hepatitis B (HepA-HepB: Twinrix, GlaxoSmithKline) is licensed for those ≥18 years of age and is given on a standard schedule of 0, 1, and 6 months. An accelerated schedule for HepA-HepB is FDA-approved for administration on an accelerated dosing schedule of three doses given on 0, 7, and 21 to 28 days, followed by a fourth dose at 12 months. Protective immunity against hepatitis A and hepatitis B is elicited following receipt of the first three doses; the fourth dose is a booster dose given to assure long-lasting immunity. The accelerated schedule could be useful for international travelers with <1 month's time before departure and for healthcare workers who need rapid protection before duty assignments. The antibody response to hepatitis B is enhanced when A and B antigens are given simultaneously in the same syringe or concomitantly when monovalent hepatitis A and hepatitis B vaccines are given at the same time but at separate sites. The adjuvant effect of hepatitis A in the combination HepA-HepB vaccine is of potential benefit to hepatitis B-susceptible adults aged ≥30 years who tend to respond with lower antibody levels to monovalent hepatitis B vaccine compared with younger hepatitis B vaccine recipients.

Healthcare workers

Hepatitis B immunization or immunity is required for work in certain occupations, including healthcare workers, policemen, firemen, morticians, and others who are likely to have work-related contact with human blood and other bodily substances.

Pneumococcal vaccine

As of 2014, the ACIP recommends that all adults ≥65 years of age receive both PCV13 (pneumococcal conjugate vaccine 13-valent: Prevnar 13, Wyeth Pharmaceuticals Inc., a subsidiary of Pfizer Inc.) and PPSV23 (pneumococcal polysaccharide vaccine 23-valent: Pneumovax 23, Sanofi Pasteur). If not previously vaccinated with a pneumococcal vaccine, PCV13 should be administered first, followed by a dose of PPSV23 6–12 months later. If PPSV23 was previously received, then PCV13 should be administered 12 months or more after PPSV23.

The FDA licensed the 13-valent pneumococcal conjugate vaccine (PCV13) in 2010, and the ACIP recommended PCV13 for children ages 6 weeks through 71 months to prevent invasive

pneumococcal disease. In 2011, the FDA expanded the licensure of PCV13 to include adults aged ≥50 years, and, in 2012, the ACIP recommended routine use of PCV13 in adults aged ≥19 years with immunocompromising conditions, functional or anatomic asplenia, cerebrospinal fluid (CSF) leaks, or cochlear implants. In pneumococcal vaccine-naïve persons in the 19- to 64-year age group, it is preferable to administer PCV13 first, followed by PPSV23 at least 8 weeks later if additional immunization is desirable. If one or more PPSV23 doses have been previously received, the PCV13 should be given ≥1 year after the last PPSV23 dose was received. Any additional dose of PPSV23 should be separated by at least 5 years from the most recent dose of PPSV23.

Viral influenza vaccine

Viral influenza vaccine is reformulated annually based on recent worldwide epidemiology of influenza viruses according to World Health Organization data. Annual immunization with the "flu" vaccine is recommended for all persons ≥6 months of age, with rare exception, with priority given to infants aged 6–59 months and adults aged ≥50 years in case of vaccine shortage.

The flu vaccine distributed for a given season may not be totally protective against all strains of influenza viruses in circulation following the annual flu vaccine formulation, thus antiviral drugs may be considered a second line of defense. Prompt treatment within 48 hours after the onset of flu symptoms with oral oseltamivir (Tamiflu, Genentech) or inhaled zanamivir (Relenza, GlaxoSmithKline) during outbreaks of influenza A or B may ameliorate illness in breakthrough attacks. Other antiviral drugs used to treat the flu include peramivir (Rapivab, BioCryst Pharmaceuticals) administered intravenously by a health care provider, and baloxovir (XoFluza, Genentech) taken orally. Due to potential interference with vaccine efficacy, peramivir treatment should be avoided for two weeks after receipt of a live attenuated influenza vaccine (LAIV4) and should not be given for 48 hours before LAIV4.

Vaccines include inactivated influenza vaccine quadrivalent (IIV4); inactivated influenza vaccine trivalent (IIV3) standard dose, high dose, and intradermal dose; cell-cultured inactivated influenza vaccine trivalent (ccIIV3); recombinant influenza vaccine trivalent (RIV), and live attenuated influenza vaccine quadrivalent (LAIV4). LAIV4 (FluMist Quadrivalent, AstraZeneca) administered by a nasal spray, is licensed for recipients aged 2–49 years. Intradermal IIV3 (Fluzone Intradermal, Sanofi Pasteur) is licensed for use in persons aged 18–64 years, and high-dose IIV3 (Fluzone High Dose, Sanofi Pasteur) is licensed for persons ≥65 years. Current information on brands, manufacturers, dosage, and age range are posted on the CDC website http://www.cdc.gov/flu.

Hepatitis A vaccine

The conditions allowing transmission of hepatitis A are ubiquitous, although the relative risk appears to be highest in countries where sanitation and hygiene are suboptimal and there is widespread fecal contamination of food and water supplies. In countries of low endemicity for hepatitis A virus (HAV), outbreaks of the disease are related to contamination of food during preparation by infected food handlers and to ingestion of fresh or frozen fruits and vegetables imported from areas highly endemic for hepatitis A and contaminated during cultivation or processing. Shellfish from sewage-contaminated beds are another source of foodborne transmission.

In the United States, adults identified by the CDC as being at increased risk for hepatitis A or severe outcomes include international travelers, MSM, users of injecting and non-injecting drugs, persons who have clotting factor disorders, persons working with nonhuman primates, and persons with chronic liver disease. Hepatitis A outbreaks are increasingly reported in cities with large homeless populations living under poor conditions of sanitation and hygiene, so homelessness is another indication for HepA vaccine.

Children can serve as a significant reservoir of HAV in outbreaks and in endemic communities. Hepatitis A infections are mild and often anicteric in young children, so infected children are not detected. Fecal–oral transmission to other children and family members, as well as to adult teachers or caretakers, can easily occur in household, daycare, and institutional settings, especially if children in diapers are present. It is important to note that HAV case fatality rates in healthy individuals rise with age, so although the rate is 0.1% from younger than 1 to 14 years of age, it is 0.4% in those from 15 to 39 years of age, 1.1% in those older than 40 years, and 2.7% in persons older than 49 years.

A safe and highly efficacious inactivated hepatitis A vaccine became available with the 1994 release of Havrix (Smithkline Beecham; now, GlaxoSmithKline), an inactivated HAV vaccine derived from the HM-175 viral strain. VAQTA (Merck), an inactivated HAV vaccine derived from the CR-326 F strain, was licensed a few years later. Havrix and VAQTA are available in the United States and Canada as well as worldwide. Other hepatitis A vaccine products are also in use in Europe and Asia.

The immunization schedules for both hepatitis A vaccines licensed in the United States consist of a single primary dose given by intramuscular injection into the deltoid muscle, resulting in protective antibody titers within 4 weeks that confer protection for 6 months up to 1 year. The first vaccine dose is followed by a booster dose 6 to 12 months later, producing levels of antibody predicted by mathematical modeling to give protection up to 10 years or more. Vaccine protection against hepatitis A may also be obtained by receipt of the combined hepatitis A and B vaccine (HepA-HepB: Twinrix, GlaxoSmithKline) (see earlier discussion).

Immunoglobulin

Immunoglobulin (IG) is purified human immunoglobulin used to provide protection against HAV infection through the passive transfer of preformed antibodies against HAV present in the IG (at least 100 IU/μL). IG is recommended for prevention of hepatitis A following known exposure to a confirmed case of HAV (0.02 mL/kg) and in nonimmune travelers going to HAV-endemic areas when there is <2 weeks remaining before departure (0.02 mL/kg to 0.06 mL/kg).

Special considerations

Attenuated live viral or bacterial vaccines are generally contraindicated for pregnant women and patients with compromised immunity. Exceptions are the recommendations for giving the MMR vaccine to children with HIV infection and giving the yellow fever vaccine to a pregnant female traveler with imminent departure to a high-risk destination in a foreign country. In these cases, the theoretical risk of serious adverse vaccine complications may be outweighed by the anticipated benefits of vaccine-elicited protection.

Vaccine efficacy can be affected by various conditions (including age) and therapies that lead to compromise of the immune system. In persons >65 years, the high-dose IIV flu vaccine is used to elicit improved immunoprotection against influenza compared to the standard dose. In patients receiving hemodialysis, the suboptimal immune response to hepatitis A and B vaccines may necessitate higher than standard antigen doses, given as a special vaccine formulation or as additional doses after the standard series has been administered.

Limited data suggest that administration of toxoid, killed virus, and purified derivative vaccines to HIV patients as appropriate may elicit protective immunity in the vaccine recipient if the CD4 count is ≥200/mm^3. An observed rise in viral loads in some HIV patients following vaccination has been of some concern, but the phenomenon is thought to be frequently transient. The current consensus is that a severe infection with a given vaccine-preventable pathogen is more likely to be associated with a more detrimental rise in viral load than that seen secondary to the corresponding immunization. High-dose vaccine formulations or additional doses in certain vaccine series may be used in off-license protocols to improve vaccine efficacy in this group of patients and other groups with altered immune response (e.g., end-stage renal disease on hemodialysis, heart or lung disease, alcoholism, chronic liver disease, diabetes).

The conjugate vaccines against encapsulated bacteria (*H. influenzae* type b, pneumococcal, and meningococcal vaccines) are recommended for adults who have a history of functional or anatomic asplenia because of the risk of overwhelming sepsis associated with infections from these agents, although data on protective efficacy of these vaccines in this patient group are incomplete.

Travel immunizations

The patient seeking vaccine advice for international travel presents an opportunity to review and update routine immunizations as well as assess the risk of exposure to exotic diseases during the trip (see Chapter 114, "Advice for travelers").

Advice for travelers

Henry M. Wu and Jessica K. Fairley

Whether for business, tourism, study, or aid work, more individuals are traveling to more parts of the world. The World Tourism Organization estimates that, in 2015, there were 1.2 billion international tourist arrivals worldwide. Health problems associated with travel are common, especially in low-income countries where travelers frequently self-report a travel-associated health problem and often seek healthcare while traveling or after return. Healthcare providers can play a critical role in minimizing the risk of illness and injury during travel.

General approach

While administration of travel-related vaccinations and malaria prophylaxis remain cornerstones of the pre-travel consultation, providing advice on managing chronic medical conditions, food and water hygiene, physical safety, and disease vector avoidance is also important. Noninfectious causes of morbidity and mortality such as injury and exacerbation of chronic illness are typically the most common health issues travelers encounter. Important considerations include:

- Preexisting medical conditions, current medications, and allergies
- Itinerary, including details of travel within countries, duration of stay, and sequence of countries visited
- Purpose of travel, accommodations, and activities
- Previous vaccination history and recommended vaccines for the itinerary
- Need for prophylactic and self-treatment medications, including those for malaria prevention, treatment of travelers' diarrhea, and altitude sickness

Referral to a travel health specialist should be considered, particularly for medically complex travelers, for those traveling to low-income countries, and when travel-specific vaccines are indicated. Since vaccines typically take 10 to 14 days to elicit full immune responses, and some require multiple doses to complete a primary series, travelers should ideally be evaluated in a travel clinic at least 4 to 6 weeks prior to departure. However, when this is not possible, travelers should still be seen, even when travel is imminent.

Preexisting medical conditions

International travel is increasingly common among individuals of all ages and health statuses, including those with medical conditions that predispose to infection or injury. Exacerbations of underlying conditions are a common cause of morbidity; furthermore, individuals in these groups can be at increased risk for complications from infections including travelers' diarrhea, influenza, and malaria. Current medications

should be reviewed for drug interactions or contraindications with travel-related medications or vaccinations. Immunocompromising conditions are generally contraindications to live vaccine administration. Pregnancy presents a particular challenge for travel to malarious areas, as pregnancy is a risk factor for severe infection and a contraindication to some of the commonly used prophylaxis medications. Pregnancy is also a risk factor for severe complications of other infections potentially acquired during travel, including hepatitis E, toxoplasmosis, and Zika virus infection. The physical ability of the traveler to withstand environmental conditions at their destinations should also be considered. For example, travel involving high altitude, difficult terrain, and even commercial flying may be inappropriate for some. When risks of travel are significant, advising against nonessential travel can be important.

Itinerary and purpose of travel

Review of the traveler's itinerary is important to determine the specific infectious, environmental (e.g., altitude, climate, etc.), and public safety risks that will be encountered. Country-specific health advisories, vaccine recommendations, and malaria prophylaxis recommendations are available from the Centers for Disease Control and Prevention (CDC) Travelers' Health website and other online resources (Box 114.1). Although most recommended vaccinations are not required for entry, countries can have individual yellow fever or polio vaccination requirements. Timing and duration of travel is also important to consider when prescribing malaria prophylaxis (see Chapter 199, "Malaria").

The purpose of the trip, accommodations, and likely activities are essential considerations when providing individualized advice. Tourist and business travelers typically take short-term trips to visit major cities and often stay in high-end accommodations, while long-term travelers (e.g., missionaries, aid workers, business expatriates, students, etc.) stay for durations that make health problems more likely and often adopt accommodations and eating habits closer to that of locals. Similarly, immigrants visiting friends and relatives (VFRs) in their countries of origin often travel to non-tourist destinations and adopt local living conditions; however, many VFR travelers have barriers to accessing travel medicine providers or do not recognize the importance of malaria prophylaxis and vaccinations when visiting their countries of origin.

The usual activities of the business, tourist, and adventure travelers are very different, and each traveler should be counseled about the infections, injuries, and exposures that are most likely. For example, popular freshwater activities in Africa, such as white-water rafting in the Nile River in Uganda or diving in East African Rift Valley Lakes can result in schistosomiasis infection. Rural itineraries and direct animal contact can be risk factors for various vaccine-preventable (e.g., rabies, Japanese encephalitis [JE]) and nonvaccine preventable (e.g., avian influenza, African tick-bite fever) infections.

Travelers should be aware that blood- and bodily fluid-borne infections such as HIV, hepatitis B, and hepatitis C may be more prevalent in travel destinations than at home, and routine advice of avoiding unprotected sexual contact and percutaneous exposures (e.g., tattooing, piercings) is prudent. All travelers might encounter risk of bloodborne infections when seeking medical care, especially in areas where unsafe injection practices exist or when administration of inadequately screened blood products occurs. Those working in healthcare settings (i.e., medical missionaries, healthcare trainees, etc.) should be advised to investigate the availability of reliable HIV postexposure prophylaxis medications should an occupational percutaneous bodily fluid exposure occur.

BOX 114.1

Sources of information for travel health advisers

1. Centers for Disease Control and Prevention (CDC) Travelers' Health website. Provides country-specific immunization and malaria prophylaxis recommendations, as well as helpful links to locate travel medicine and insurance providers. The *Health Information for International Travel 2018* is also available online here. Website: www.cdc.gov/travel
2. US Department of State. Provides updated travel advisories and alerts, as well as country-specific advice for US travelers. Website: www.travel.state.gov
3. International Association for Medical Assistance to Travelers (IAMAT). Nonprofit organization providing travel health advice, country-specific recommendations, and listing of international clinics. Website: www.iamat.org
4. International Society of Travel Medicine (ISTM). Association of travel health advisors and publisher of the *Journal of Travel Medicine*. Provides a listing of travel clinics. Website: www.istm.org

Immunizations

When providing pre-travel advice, it is important to review both routine immunizations as well as those recommended or required for the particular itinerary. Travelers should be up to date on routine vaccinations (see Chapter 113, "Immunizations"). Some vaccinations, such as polio or meningococcal vaccination, are routinely administered to children and adolescents in the United States, although adult boosters are recommended for travel to specific areas. Measles and hepatitis A vaccination are also routine childhood vaccines in the United States; however, many adults are inadequately vaccinated. On the other hand, yellow fever, typhoid, cholera, and JE vaccinations are used in the United States and Europe almost exclusively for international traveler. Vaccination for tuberculosis with Bacille Calmette–Guérin (BCG) vaccination is rarely indicated for travelers. Table 114.1 lists the immunizations of special importance for travel and their schedules.

Unless required, immunizations should generally be recommended according to risk of disease. The risk of infections can vary significantly among different countries in a region, Furthermore,

TABLE 114.1 **IMMUNIZATIONS FOR FOREIGN TRAVEL**

Vaccine	Adult dosage	Duration of efficacy
Live attenuated		
Yellow fever	1 (0.5 mL) SC 10 days before travel	Lifelong immunity for most individuals (see exceptions in text)
Typhoid	1 enteric-coated capsule taken on alternate days for 4 doses with cool liquid 1 h before a meal[a]	Booster series q5yr
Cholera	Single oral dose prepared and administered in a healthcare setting	3 months (long-term data unavailable to guide booster recommendation)
Inactivated		
Typhoid	1 dose (0.5 mL) IM	Booster q2yr
Rabies pre-exposure	3 doses (1.0 mL) IM on days 0, 7, and 21 or 28	No boosters recommended for most travelers at routine exposure risk
Meningococcal (quadrivalent A/C/Y/W-135)	1 dose (0.5 mL) IM	Reimmunization recommended q5yr[b]
Japanese encephalitis, inactivated Vero cell culture-derived	2 doses (0.5 mL) IM on days 0 and 7 to 28	Booster recommended at 1 yr; data unavailable regarding efficacy of booster given ≥2 yrs after primary vaccination and need for subsequent booster doses
Hepatitis A	2 doses, at 0 and 6–12 mo (HAVRIX) or 0 and 6–18 mo (VAQTA)	Probable lifelong immunity
Passive prophylaxis		
Immunoglobulin for protection against hepatitis A[c]	0.1 mL/kg for travel ≤1 mo, 0.2 mL/kg for travel ≤2 mo (0.2 mL/kg q2 mo for travel ≥2 mo)	

Abbreviations: SC = subcutaneous; IM = intramuscular.
[a] Must not be taken while taking antibiotics, including doxycycline malaria prophylaxis.
[b] For participation in Hajj pilgrimage vaccination within previous 3 years and ≥10 days prior to arrival required.
[c] Must be administered at least 3 months prior to administration of measles or vaccination.

infection risk can vary with different activities, accommodations, and eating habits. Trip duration is also important to consider due to the increased risk of infection exposure over time, and some vaccinations such as JE, hepatitis B, or rabies vaccination, are of higher priority in long-term travelers.

Most vaccines can be administered simultaneously at separate sites, and this is often necessary when multiple are indicated. However, immunologic response to live-virus vaccines (i.e., MMR, varicella, yellow fever, or intranasal live attenuated influenza vaccines) might be attenuated when administered within 30 days of another live-virus vaccine. Therefore, live-virus vaccines should be administered on the same day or spaced apart at least 30 days.

Influenza

Though many travelers and physicians underrecognize the importance of influenza vaccination prior to travel, influenza is the most common vaccine-preventable illness seen in travelers, and vaccination is recommended for all travelers aged ≥6 months. Influenza occurs year-round in the tropics and from May through November in the southern hemisphere. For these reasons vaccine should be administered in the United States to all travelers until the vaccine expiration date (usually in May–June of the year following its availability). The southern hemisphere vaccine is not available in the United States.

Hepatitis A and immunoglobulin

Hepatitis A is one of the most common vaccine-preventable infections in travelers. While risk is higher in rural areas or for those with adventurous eating habits, many travel-related cases have occurred with typical tourist itineraries, and hepatitis A vaccination is strongly recommended for all travelers. Although vaccination is now routine for US children with a two-dose series, many adults have not been vaccinated. For routine vaccination, the minimum age for the first dose of hepatitis A vaccine is 12 months; however, infants aged 6 to 11 months traveling to higher risk areas may receive one dose of vaccine, followed by revaccination with the usual two-dose series after the infant reaches 12 months of age. Prior to the availability of the hepatitis A vaccine, immunoglobulin (IG), was used for protection. Though IG protects travelers immediately, its duration of protection is short and its availability is limited. IG is still recommended for travelers <6 months old or those with vaccine contraindications. IG can also be given in addition to vaccine to travelers aged >40, with chronic liver disease, or those who are immunocompromised when travel is imminent (in <2 weeks).

Hepatitis B

Although hepatitis B vaccination is now recommended in the United States for all infants, children, and adolescents, many adults have not been vaccinated. Among travelers, hepatitis B vaccination has typically been reserved for persons at higher risk of exposure, such as healthcare workers, those who may have casual sex, and for long-term travelers to high-prevalence countries. However, all travelers to low-resourced countries are at risk when seeking healthcare due to potentially unsafe injection practices and inadequately screened blood products. In addition to the recombinant hepatitis B vaccine, which is usually given in a three-dose series (over 6 months), a newer hepatitis B vaccination (HepB-CpG) is now available in the United States. HepB-CpG is given as a two-dose series given 1 month apart. This two-dose series might be favorable for travelers leaving too soon to consider the primary and accelerated vaccination schedules recommended for the recombinant hepatitis B vaccines. A combined hepatitis A and B vaccine is available in the United States, and an accelerated regimen is also approved for the combined vaccine (0, 7, 21–30 days). When using the accelerated schedule with combined vaccine, a booster dose should be given at 1 year to provide long-term immunity.

Measles, mumps, rubella, and varicella

Measles continues to be a major cause of morbidity and mortality in many regions of the world, including Europe, which has had recent increases in cases due to suboptimal vaccination coverage. Since measles is extremely transmissible, ensuring that travelers have immunity to measles is particularly important to prevent outbreaks resulting from its introduction into areas with susceptible persons. Although mumps and rubella are less of a health threat to travelers, both infections can have serious complications. For international travelers, two doses of the MMR vaccine are recommended for those without contraindications unless there is serologic evidence of immunity, prior history of disease, or birth prior to 1957. Of note, children between 1 and 4 years old may have only had one MMR dose. It is recommended that they get their second dose prior to travel (as long as it is administered at least 4 weeks after the first dose), and additional doses are unnecessary. For those under 1 year of age, immunization may be given between 6 and 12 months of age and is recommended for international travel. Two doses after age 12 months are still indicated in this circumstance. The combination MMRV vaccine (measles, mumps, rubella, and varicella), can be used when needed, although it is not licensed in the United States for infants <1 year.

Varicella does present a health risk to nonimmune individuals. International travelers should have evidence of immunity, which can include age-appropriate vaccination (one dose of varicella vaccine for children aged 1 to 4 years and two doses for individuals aged ≥4 years), history of chickenpox or zoster, serologic evidence of immunity, or birth before 1980 (not a criterion for healthcare workers, pregnant women, or immunocompromised individuals).

Typhoid

Although *Salmonella enterica* serotype Typhi is prevalent in many countries in Africa, Asia, and Central and South America, typhoid fever is not common in travelers. However, given the serious nature of the infection and availability of well-tolerated vaccines, live Ty21a oral capsular vaccine or the injectable inactivated vaccine should be considered in travelers to endemic areas. Immunocompromised travelers should receive the inactivated vaccine. While those traveling off usual tourist routes or adventurous eaters are at highest risk, long-term and frequent short-term travelers to developing countries are also at increased risk. Vaccine recipients should be aware that the vaccines are only 50% to 80% effective and do not prevent typhoid fever caused by *S. enterica* serotype Paratyphi; therefore, vaccination alone can not be relied on to prevent typhoid fever.

Cholera

Cholera, the severe diarrheal illness caused by *Vibrio cholerae* O-group 1 or O-group 139 is endemic in numerous countries in Africa, South Asia, and Southeast Asia. A large cholera epidemic also began in Haiti in 2010, and the disease is now endemic in Hispaniola. Transmission primarily occurs via drinking water with naturally occurring *V. cholerae* or water contaminated with feces from an infected person. Transmission can also occur from person to person during epidemics. Risk to travelers is primarily in those who travel to epidemic or endemic areas and do not practice to safe food and water hygiene or have close contact with cholera patients. Persons with low gastric acidity or type O blood are at higher risk for severe cholera illness.

A live attenuated single-dose oral cholera vaccine (CVD 103-HgR) was approved in the United States in 2016 for use in adults aged 18 to 64 years. Studies have demonstrated vaccine efficacy of 80% at 3 months after vaccination. Concurrent or recent use of antibiotics or chloroquine may diminish the immune response to CVD 103-HgR. Although travelers who follow safe food, water, and handwashing recommendations are at extremely low risk for cholera infection, vaccination can be can be considered in travelers who are traveling to areas of active cholera transmission, especially those without access to safe food and water, persons with risk factors for severe disease, or those will not have access to treatment if illness occurs. Healthcare workers in cholera endemic and epidemic areas might also consider vaccination. Safety and efficacy of CVD 103-HgR in immunocompromised or pregnant persons is not established. Data are also unavailable to guide any recommendation regarding the need and safety of revaccination. Studies in children are ongoing.

Polio

Infants and children should be current on routine polio immunizations prior to travel. Intervals between doses may be reduced to optimize immunization status before departure. Adults aged ≥18 years who are traveling to an endemic or epidemic area should complete a primary series prior to travel if they have never received one. Details on accelerated schedules are available from the CDC Health Information for International Travel (Table 114.1). Furthermore, as a precaution, all adults who have received the routine childhood series should also receive a single booster dose of the inactivated polio vaccine before travel to polio endemic or epidemic countries. A single booster dose might also be recommended for adults working in healthcare settings, refugee camps, or other

humanitarian aid settings in certain countries that share a border with endemic and epidemic countries. Long-term travelers staying >4 weeks in certain polio-affected countries may also be subject to recent requirements for proof of polio vaccination 1–12 months prior to departure from the affected country. Readers are encouraged to refer to the CDC Travelers' Health website for updated country-specific recommendations (Table 114.1). Oral polio vaccine is no longer available in the United States.

Tetanus, diphtheria, and pertussis

All travelers should be up to date with tetanus, diphtheria, and pertussis vaccination as per routine. Diphtheria continues to be endemic in many countries outside the United States and Western Europe. Pertussis is increasingly recognized worldwide, including in the United States. Adult travelers who have not previously received the combined tetanus/diphtheria/acellular pertussis vaccine (Tdap) should receive one dose of Tdap instead of tetanus and diphtheria toxoid (Td) for booster immunization.

Yellow fever

Yellow fever is a viral illness transmitted by mosquitoes in tropical Africa and South America. It is rare in travelers, but, because of its high mortality, vaccination is recommended for individuals visiting endemic areas. Some countries have specific yellow fever vaccination entry requirements, including some that require documentation of vaccination for all visitors, and others that require vaccination only when arriving from an endemic country. Country-specific entry requirements (available from the CDC Travelers' Health website and country embassies) should be reviewed for each international traveler. In the United States vaccination is available only at approved yellow fever vaccination clinics (see the CDC Travelers' Health website, Table 114.1, for a listing).

Vaccination is documented on an International Certificate of Vaccination or Prophylaxis (ICVP, "yellow card") and considered valid 10 days after the date of vaccination. Previous recommendations for routine boosting at 10 years have been revised, and now booster doses at 10 years are now only recommended for women who were pregnant when they received their first dose, those who received a hematopoietic stem cell transplant after yellow fever vaccination (if sufficiently immunocompetent to receive vaccine), those who were HIV-infected when receiving their last dose of vaccine, and travelers who may be in higher risk situations for yellow fever. In 2016, the International Health Regulations were amended by the World Health Assembly, and certificates of vaccination for yellow fever are now considered valid for life (for entry purposes). This amendment applies to new and existing certificates.

Yellow fever vaccine is a live-virus vaccine and is contraindicated in infants <6 months of age and individuals with thymus disorders or immunodeficiencies (including AIDS and those receiving immunosuppressive or immunomodulatory therapies for transplanted organs, malignancies, autoimmune disorders, or other conditions). Precautions to vaccination include ages between 6 and 9 months or >60 years, pregnant or breastfeeding women, and HIV-infected individuals without AIDS. Following yellow fever vaccination, rare cases of encephalitis or autoimmune neurologic disease have been reported, as well as multiorgan system illness similar to yellow fever illness. Although severe adverse events occur with an overall frequency of only 3.8 per 100,000 doses, risk is increased among those age ≥60 years. Individuals with vaccine contraindications who travel to countries with entry requirements should carry a waiver documented on the ICVP and physician's letterhead to avoid being denied entry or subject to penalty (or vaccination) upon arrival.

Meningococcal meningitis

Quadrivalent meningococcal vaccines protect against *Neisseria meningitidis* serogroups A, C, Y, and W-135. Routine vaccination in the United States is recommended for adolescents and other groups with increased risk of infection. Travelers to countries that are hyperendemic or epidemic are considered at increased risk, including travelers to the African "meningitis belt" during the dry season (December through June). Vaccination is also required by the Saudi Arabia government for those attending the Hajj pilgrimage in Mecca.

Japanese encephalitis

From 1973 to 2015, there were 79 reports of JE infection among travelers from nonendemic countries. JE transmission occurs in Asia during the summer to autumn in temperate regions, and during the rainy season or potentially year-round in the subtropics and tropics. JE is transmitted by night-biting *Culex* mosquitoes, typically in rural areas with rice cultivation and pig-farming. Up to 30% of symptomatic infections are fatal, and 30% to 50% of survivors have neurologic sequelae. Short-term urban travelers are at very low risk; however, travelers on prolonged itineraries to rural areas can have similar risks as that of the local population. Therefore, vaccination should be particularly considered in long-term travelers and those with extensive overnight rural exposures. The inactivated Vero cell culture-derived vaccine (Ixiaro) is licensed in the United States for individuals aged ≥2 months. Vaccine is given in a two-dose series 28 days apart (or 7 to 28 days apart for adults 18 to 65 years old).

Rabies

The decision to administer rabies pre-exposure vaccination should be based on various considerations including endemicity of rabies in the countries visited, exposure risk, duration of stay, and availability of postexposure biologics. Rabies is transmitted through inoculation of saliva from an infected mammal, typically resulting from a bite, though non-bite exposures can occur via mucous membranes or open wounds. All travelers should avoid contact with wild and feral mammals, as well as unvaccinated domesticated dogs and cats. Children have increased risk for animal bites and may potentially not report exposures. Any possible exposure should be washed immediately with soap and water, and medical care should be sought immediately to determine if postexposure prophylaxis is indicated. Although individuals who have received pre-exposure vaccinations do not need rabies immunoglobulin (RIG) following an exposure, booster doses of vaccine are still needed, so all travelers should be advised to seek urgent care following potential exposures.

Other advice

Malaria prophylaxis

Because malaria infection represents a significant risk to nonimmune travelers, prescription of malaria prophylaxis can be a critical part of the pre-travel consultation. For details, see Chapter 199, "Malaria."

Food and water hygiene

Prevention of travelers' diarrhea and other food- and waterborne gastrointestinal infections requires careful selection of food and beverages while traveling in the developing world. Foods that are well-cooked and still hot are safest. Fruits washed and peeled by the traveler are safe. Raw salads, salsas, and fruits eaten whole are risky. Commercially bottled carbonated beverages, alcohol, hot tea, and coffee are generally safe. Tap water consumption is generally unsafe (see www.cdc.gov/travel for country-specific recommendations), and only boiled, bottled (from reliable sources), or properly disinfected water should be consumed. Ice cubes are typically made from untreated tap water. Milk and dairy products should be pasteurized or cooked. For more details on the treatment and prevention of travelers' diarrhea, see Chapter 119, "Travelers' diarrhea."

Altitude illness

Acute mountain sickness (AMS) can occur with rapid ascent to altitudes >8,000 ft (2,500 m), and symptoms can include headache, fatigue, nausea, and loss of appetite. Symptoms usually resolve with acclimatization in 1 to 3 days or descent; however, progressive ascent (e.g., in mountain climbing) can cause persistent symptoms or increase the risk of high-altitude cerebral edema or high-altitude pulmonary edema. Since many popular high-altitude destinations such as Cusco, Peru, are reached by direct flight, travelers visiting these areas might be at particular risk for AMS. Susceptibility to AMS is unpredictable; therefore, prophylaxis medication such as acetazolamide should be considered for travelers going to these areas.

Injuries

Accidents can be the cause of nearly half of fatalities among international travelers. These can include traffic accidents, drownings, and other injuries resulting from outdoor activities. Travelers should be aware that traffic laws, road quality, fire codes, and other safety regulations in the developing world are typically at much lower standards or nonexistent. Alcohol consumption is a significant risk factor for travel-related injury, and individuals often consume more during travel. Crimes such as robberies, sexual assault, and homicide are worldwide problems. Politically unstable countries or those in the midst of social unrest can be particularly dangerous for travelers. The US State Department provides updated travel alerts and country-specific safety advice (www.travel.state.gov).

Jet lag

Travel across several time zones typically results in disrupted sleep as the traveler's internal body clock adjusts to the local time, a process that takes about 1 day for each time zone crossed. Adequate hydration, resting after arrival, and judicious use of sedatives can help with adjustment or symptom management. Bright light exposure can help reset the internal clock. For travel eastward, it is recommended that travelers seek bright light in the early morning, and, for westward travel, exposure should be in the late afternoon. Melatonin can be helpful for jet lag; however, it is considered a supplement in the United States and is not regulated by the US Food and Drug Administration (FDA).

Insect avoidance

Mosquito and other arthropod avoidance measures such as insect repellents, bednets, and permethrin-treated clothing can be important, particularly when visiting areas endemic for dengue, malaria, and other arthropod-borne infections including Zika virus infections. See Chapter 199, "Malaria," for insect avoidance recommendations.

Travelers' health kit

A travel health kit can be important and might include prescription medications, over-the-counter medications (analgesics and fever medications, antidiarrheals, antinausea medications, antihistamines, topical medications for insect bites and rashes, etc.), a digital thermometer, oral rehydration solution packets, and first-aid supplies. Travelers should anticipate airline security regulations that restrict carry-on items. Some over-the-counter or prescription medications may be subject to stricter regulations overseas (e.g., diphenhydramine is considered a controlled substance in Zambia). Prescription medications are best carried in the original containers with the patient's name and prescribing physician information. Carrying a physician's letter that lists medical conditions and medications (with generic names and dosages) is advised.

Health and evacuation insurance

If urgent healthcare is needed during travel, travelers should be advised to seek the best quality medical care available. Online resources for finding reliable providers of care overseas can be very helpful (Table 114.1). Travelers should be aware that healthcare obtained overseas might not be covered by their usual health insurance, and supplemental insurance might be prudent. Furthermore, medical evacuation by air ambulance is typically not covered, and travelers should consider purchasing evacuation insurance when traveling to countries where standards of care are significantly lower.

Fever in the returning traveler

Alimuddin Zumla

General considerations

Fever is a frequent problem in travelers returning from holidays, business trips, or employment outside their country of residence. In 2018, >1 billion people traveling for business or pleasure arrived at international destinations. Up to half of tourists to tropical countries become ill during or after travel. A wide range of infectious and parasitic diseases can cause fever, some of which can be rapidly fatal if not detected and treated early. For example *Plasmodium falciparum* malaria is a medical emergency, and prompt diagnosis and treatment is essential. All patients should be assessed for risk of malaria, viral hemorrhagic fever, dengue, and antibiotic-resistant urinary, gastrointestinal, or respiratory infections.

Fever in a traveler may not be specifically related to travel and may be related to more universal causes such as common cold, viral pharyngitis, sinusitis, influenza (Flu A and Flu B), Covid-19, bacterial pneumonia, otitis media, or urinary tract infections. The subject of this chapter is fever related to more "imported" diseases acquired during travel to which the physician practicing in the West may be unfamiliar (see Box 115.1). With the great increase in volume and speed of travel between developed and developing countries, physicians in the United States, Europe, and other developed countries are increasingly seeing more patients with imported infections.

Careful assessment of travelers with fever must involve a detailed history, a thorough examination, and targeted laboratory investigations. The following are essential in the clinical management of fever in the returning traveler:

1. A comprehensive history:
   a. Symptoms, time of onset, duration, and progression and evolution of symptoms over time. Try to localize symptoms to organ systems.
   b. Travel history: Destinations, type of accommodation, prophylaxis measures taken, activities (e.g., game viewing, camping, farms, caves, swimming in lakes/rivers, sex, drug abuse, consumption of uncooked or semi-cooked food, and water source), bites (insects, mosquito, tsetse flies, ticks, fleas, lice, mites, animal, other).
2. A complete physical examination of all systems: Clinical features to look for are: skin rash (maculopapular, petechiae, ecchymosis), skin lesions (eschars, insect bites, erythema nodosum, boils, erysipelas), lymphadenopathy, hepatomegaly, splenomegaly, jaundice, wheeze, crackles, crepitations, joint or muscle involvement, stiff neck, photophobia, conjunctivitis, neurologic signs, or evidence of bleeding.
3. Urgent investigations:
   a. CBC
   b. Malaria thin and thick blood films including rapid malaria diagnostic test
   c. Blood culture
   d. Urine culture and dipsticks analysis (blood, protein, sugar)
   e. Stool: Bacteriology, virology, and parasitology (ova, cysts, and parasites)
   f. Blood biochemistry (C-reactive protein, urea, electrolytes, creatinine, and liver function tests)

g. Chest x-ray
h. Specific polymerase chain reaction (PCR) tests on clinical specimens for those suspected of having rapidly fatal diseases (e.g., arboviruses, viral hemorrhagic fevers [VHF], Middle East respiratory syndrome [MERS]-coronavirus.

4. Other investigations in persisting fever:
   a. Serology: Bacterial, viral, fungal, spirochetal (save serum for paired serology)
   b. Bone marrow and/or lymph node aspirates: Microscopy and culture may be required if fever persists without localizing signs.
   c. Further imaging: CT scan, positron emission tomography (PET), PET/CT scans.

The most common tropical fevers in travelers are malaria, enteric fever, hepatitis, amebic liver abscess, and rickettsial and arboviral infections.

BOX 115.1

Causes of tropical fevers in travelers

Most common
- Cosmopolitan infections (common cold, sinusitis, upper respiratory tract infections, urinary tract infections, etc.)
- Malaria
- Enteric fever (typhoid and paratyphoid)
- Atypical pneumonia, acute respiratory tract infections (bacterial and viral pneumonia)
- Hepatitis (hepatitis A, hepatitis E)
- Rickettsial infections
- Arboviral infections (dengue, chikungunya, yellow fever, Western equine encephalitis [WEE], Eastern equine encephalitis [EEE], and others)
- Bacterial diarrhea or dysentery
- Viral gastroenteritis
- Protozoal diarrhea (giardiasis or amebiases)
- Amebic liver abscess
- Sexually transmitted diseases

Less common
- African trypanosomiasis
- Tuberculosis
- Human immunodeficiency virus (HIV)
- Brucellosis
- Leptospirosis
- Histoplasmosis
- Atypical pneumonia (Legionnaires' disease, pulmonary histoplasmosis, psittacosis)
- Acute schistosomiasis (Katayama fever)
- Leptospirosis
- Filariasis
- Drug fever

Uncommon
- Visceral leishmaniasis (kala-azar)
- Cutaneous leishmaniasis
- Lyme disease
- Relapsing fever (borreliosis)
- Melioidosis
- Middle East respiratory Syndrome coronavirus (MERS-CoV)
- Viral hemorrhagic fevers (e.g., Ebola, yellow fever, Crimean Congo hemorrhagic fever)
- Tropical pulmonary eosinophilia
- Cutaneous larva migrans
- Endocarditis
- Fungal infections (Histoplasmosis, Cryptococcosis)
- Noninfectious causes (malignancy, autoimmune)

Malaria

Malaria is the most important potentially fatal cause of fever in travelers returning from the tropics. Thus, all febrile travelers returning from malaria endemic areas must be evaluated for malaria, even those who have taken appropriate malaria chemoprophylaxis. Antimalarial prophylaxis regimens cannot be considered fully protective.

Nearly all malaria cases due to *Plasmodium falciparum* present with fever within 4 weeks of returning but could present several months after leaving a malarious area. *P. vivax* and *P. ovale* malaria may occur up to 3 years after exposure due to persistence of hypnozoites (latent parasites) in the liver. *P. malariae*, which does not have a latent liver phase, is the least common species causing fever in travelers but may present up to a year or longer (up to 20 years) after first infection. Typical symptoms are high fever, shaking, chills, sweats, headache, and myalgias. Symptoms may be modified or masked according to the immune status, as in an immune native of an endemic area or by the use of prophylactic antimalarial drugs. Severe *P. falciparum* infections can rapidly lead to such lethal complications as cerebral malaria, renal failure, severe hemolysis, and adult respiratory distress syndrome.

Diagnosis is by appropriately prepared and carefully examined Giemsa-stained thin and thick malaria smears. A single negative set of smears cannot rule out malaria; smears should be repeated at 6-hour intervals for at least 24 hours. Rapid malaria antigen detection tests are now available. Specific prophylaxis and therapy for malaria is discussed in Chapter 199, "Malaria."

Enteric fever (typhoid and paratyphoid)

Typhoid and paratyphoid fevers can be contracted from contaminated food or water where the prevalence of these bacteria is high. Typhoid vaccines offer protection to no more than 70% of recipients. Enteric fever should be suspected in travelers returning from an endemic area with fever, headaches, abdominal pain, diarrhea, or cough. Symptoms may not develop until several weeks after return. Diagnosis is confirmed by positive blood, stool, or

urine culture. The agglutinin test (Widal) lacks sensitivity and specificity and is not recommended. Newer rapid serologic tests that detect IgM antibodies to *Salmonella typhi* antigens are available. Blood and bone marrow cultures have the highest yield within 1 week of symptoms, and urine and stool cultures become positive after the first week. *S. typhi* worldwide has developed multiple antibiotic resistance, including to fluoroquinolones. See Chapter 148, "Salmonella," for specific therapy details.

Hepatitis

Travelers to the developing world who have not received hepatitis A vaccine or immune serum globulin (ISG) run a significant risk of contracting hepatitis A from ubiquitously contaminated water or food. Rare cases of hepatitis E have been contracted in South Asia and elsewhere, and this type of hepatitis may not be prevented by ISG. Hepatitis B is usually contracted from sexual contact and is uncommon in travelers. In the pre-icteric phase of acute hepatitis, fever, chills, myalgias, and fatigue may occur, and this syndrome can mimic malaria and other acute tropical fevers. Hepatitis serologic testing can confirm the type of infection, but when these tests are negative in a patient with apparent hepatitis, cytomegalovirus or infectious mononucleosis (Epstein–Barr virus [EBV]) should be considered.

Amebic liver abscess

A period of acute diarrhea often precedes development of an amebic liver abscess. A returned traveler with fever and right upper quadrant pain should be suspected of this infection. Stools are positive for *Entamoeba histolytica* in only 10% to 15%. Sonography or CT of the liver will show a filling defect, and an amebic serology test will confirm infection. Needle aspiration is seldom required for diagnosis or treatment. There is very rapid clinical response to metronidazole, 750 mg three times daily for 10 days, followed by a luminal drug such as paromomycin (Humatin), 500 mg three times daily for 7 days.

Rickettsial infections

Tick typhus can be contracted in West, East, and South Africa and in the Mediterranean littoral. Infection typically begins with a skin eschar at the tick bite site; fever, chills, and headache; and, in a few days, a diffuse papular rash can develop. Epidemic, scrub, and murine typhus and Q fever are much less commonly contracted by travelers. Diagnosis is made by indirect fluorescent antibody tests or PCR of eschar and skin lesion for specific rickettsial organisms. Tetracycline is highly effective, and response is generally rapid. A single 200 mg dose of doxycycline may be adequate, but 100 mg twice a day for 5 to 7 days may be required for some *Rickettsia* species.

Viral fevers

Dengue fever, endemic in most parts of the tropical world, especially Asia, Africa, and the Indian subcontinent, is the most commonly imported arbovirus infection. Symptoms include fever, fatigue, headache, body and bone aches, and eye pain. Typically, a diffuse rash appears on the third to fifth day as other symptoms abate. Chikungunya virus is a mosquito-borne disease that has similar clinical symptoms to dengue but differs in causing severe joint pains rather than deep bone pain. A recent outbreak of chikungunya in islands of the Indian Ocean has led to numerous imported cases into Europe, North America, and parts of Asia. Japanese B encephalitis is a rare infection of travelers to rural areas of the Far East. A number of other rarer acute viral illnesses have been imported from endemic areas, including lethal Lassa and Marburg fever viruses from West and Central Africa. Diagnosis is usually confirmed serologically; there is no specific treatment, and management is generally supportive. (See Chapter 181, "Dengue" and Chapter 193, "Viral hemorrhagic fevers.")

Less common febrile illnesses in travelers

African *trypanosomiasis* is uncommon in American travelers, although it has been reported from travelers to East Africa. Even short-term travelers to game parks of East and Central Africa should take precautions against tsetse fly bites. Travelers should inform their physician of exposure if symptoms such as trypanosomal chancre at a bite site, fever, evanescent rash, headache, and lethargy develop up to 4 weeks after returning home. (See Chapter 201, "Trypanosomiases and leishmaniases.")

Tuberculosis (both drug-sensitive and drug-resistant) remains a threat worldwide. Any returnee with fever, cough, and chest radiography evidence suggestive of pulmonary disease should be screened for tuberculosis. Screening with the interferon-γ release assay (IGRA) before and after travel is recommended.

Brucellosis is contracted from contaminated raw goat or cow milk or soft cheese. Presentation can be with fever, chills, sweats, body aches, headache, monoarticular arthritis, weight loss, fatigue, or depression. Diagnosis is by blood culture and/or specific agglutination tests. Treatment is with a tetracycline plus streptomycin or rifampin.

Leptospirosis is common in the tropics but is rarely contracted by travelers. Infection is acquired through direct or indirect contact (such as contaminated water) with infected animals. Recreational activities, such as water sports and adventure travel, are emerging as important risk factors for this infection. Most infections are anicteric and mild. Initial symptoms may include high remittent fever, chills, headache, myalgias, nausea, and vomiting. No more than 10% of patients develop jaundice. Diagnosis is usually made with serology. Early therapy with penicillin or tetracycline is usually beneficial.

Histoplasmosis, a cosmopolitan disease, has rarely infected travelers to Latin America. Visitors to caves contaminated with bat droppings are at particular risk. Consideration should be given to

histoplasmosis in a returned traveler with fever and pulmonary or, less likely, disseminated disease. Ketoconazole or itraconazole given for 3 to 6 weeks is effective treatment.

Visceral *leishmaniasis* (kala-azar) is extremely rare in American tourists, although European travelers have been infected around the Mediterranean littoral. Symptoms include fever, hepatosplenomegaly, and wasting. Diagnosis is confirmed by demonstrating leishmanial organisms in a biopsy specimen of liver, spleen, or bone marrow or detection of parasite DNA by PCR test. Pentavalent antimonial compounds (sodium stibogluconate [Pentostam] and meglumine antimonate [Glucantime]) are first-line drugs. Second-line drugs are amphotericin B and pentamidine.

Classically associated with tick bites during visits to forests, *Lyme disease* occurs in Europe and the United States and may also be present in other parts of the world. Hikers in particular should take precautions against tick bites in any recognized endemic area.

Relapsing fever is caused by a spirochetal organism of the *Borrelia* spp. and occurs in a louse-borne, primarily epidemic form and in a more widely scattered tick-borne, endemic form. The latter form is present in the western United States and has been diagnosed in returnees from that area to the eastern United States. Imported relapsing fever is uncommon, but cases have been contracted in West Africa, Spain, and Central America. Diagnosis is by finding the spirochetes in a thick or thin Giemsa-stained blood smear. Treatment is with a tetracycline.

Legionnaires' disease cases in travelers have continued to rise since its first identification in Philadelphia in 1976. Many cases are associated with travel on cruise ships, hotels, and aircraft within and outside Europe. Infection is acquired from contaminated air conditioning systems, whirlpool spas, or swimming pools. While diagnosis in suspected cases can be confirmed from culture, seroconversion, and urinary antigen detection, the mainstay of clinical management for Legionnaires' disease is prompt empiric administration of *Legionella*-specific antibiotic treatment for community-acquired pneumonia and *Legionella* spp. with azithromycin, levofloxacin, or tetracyclines.

Melioidosis is endemic primarily in Southeast Asia and sporadically occurs in other areas. The majority of imported cases are seen in refugees from Southeast Asia, in returned servicemen from that area, and occasionally in tourists. An asymptomatic form of infection is most common, but acute pneumonic and septicemic forms may occur. Chronic suppurative forms may also develop in various organs. These forms can lie dormant for many years and have the capacity to flare into acute fulminant symptoms. Any patient with a pneumonic process who is returning from rural areas of Southeast Asia should be considered to have possible melioidosis. Diagnosis is by special culture techniques or by serology. The most effective treatment is with intravenous ceftazidime, imipenem, or meropenem. Oral therapy is with trimethoprim-sulfamethoxazole or doxycycline.

HIV infection is a particular hazard from sexual contact, blood transfusion, or contaminated needle or syringe contact worldwide. A number of disposable syringes and needles should be carried by the traveler who may need injections while traveling in areas where only nondisposable products are used. HIV serology screening should be done on any traveler with such exposure. Postexposure prophylaxis (PEP) involves taking anti-HIV medications as soon as possible after exposure to HIV.

Most viral and bacterial causes of diarrhea, amebic dysentery, and occasionally parasitic diarrhea due to *Giardia lamblia* may often present as intermittent diarrhea, nausea, headache, and fatigue and also cause fever, which may precede diarrhea by some hours or days. Acute schistosomiasis, acute fascioliasis, and acute bancroftian filariasis are uncommon causes of fever in travelers.

Drugs used for prophylaxis or treatment of travel-related infections may themselves be a cause of fever. These include sulfonamide-containing drugs such as trimethoprim-sulfamethoxazole and pyrimethamine with sulfadoxine (Fansidar) (used for malaria treatment). Quinine and doxycycline may rarely cause fever. Drugs obtained abroad, often in combinations and without prescription, may cause a cryptic fever. It is worthwhile to stop all nonessential medications pending an etiologic diagnosis in febrile travelers.

While some illnesses with fever may begin during travel, others may occur days, weeks, or even years after return from travel. Thus travel history must be part of the routine medical history for every ill patient. Furthermore, clinicians should consider the public health implications of certain infections (such as drug-resistant tuberculosis, influenza, measles, viral hemorrhagic fever, and newer viral threats such as the Middle East respiratory syndrome coronavirus [MERS-CoV] and H7N9 influenza) and notify appropriate public health authorities in their home countries.

Systemic infection from animals

David J. Weber, Jonathan J. Juliano, and William A. Rutala

Introduction

Zoonoses are defined as diseases and infections that are transmitted between vertebrate animals and humans. Currently there are more than 200 recognized zoonotic diseases, and 75% of emerging infectious diseases fit into this category. Zoonotic diseases can be transmitted to humans through bites and scratches, direct contact, aerosols, arthropod vectors, or contamination of food or water. There are many reasons for the increased impact of zoonotics in current times. Contact with domestic animals continues to be frequent, even in urban centers. Pets are a major reservoir and source of zoonoses, especially for children. In 2011–2012, 62% of US households, or approximately 72.9 million total households, owned a pet: 39% of households owned a dog, 33% owed a cat, 5% owned a pet bird, and 4% owned a reptile. The total number of animals owned was 78 million dogs, 86 million cats, 16 million birds, and 4.6 million reptiles. Other common pets include fish, rabbits, hamsters, gerbils, mice, and farm animals such as horses.

Recent factors that have had a substantial impact on emergence of zoonotics are human encroachment on wildlife habitat, wildlife trade and translocation, the ownership of exotic pets, petting zoos, and ecotourism. The epidemics of severe acute respiratory syndrome (SARS), West Nile virus, and monkeypox in North America have demonstrated the role of wildlife and exotic pets in the emergence of zoonotic diseases in industrialized nations. Traditional leisure pursuits such as hunting, camping, and hiking are increasingly common and continue to bring people into close contact with wild animals, arthropods, and sometimes contaminated water. Occupational exposures to domestic animals or animal products, especially in backyard operations, remain a leading cause of zoonotic disease exposure.

For all of the reasons described above, it is increasingly important for physicians, veterinarians, and public health professionals to work together in recognizing and controlling zoonotic diseases. The Centers for Disease Control and Prevention (CDC) has become a World Organization for Animal Health (OIE) Collaborating Center for Emerging and Remerging Zoonoses and now dedicates an entire issue of the *Emerging Infectious Disease* journal to zoonotics. The key to controlling zoonoses continues to lie with the astute clinician diagnosing and reporting these diseases, and the goal of this chapter is to assist in these efforts.

Clinical approach

Zoonoses are caused by a diverse group of microorganisms. Infectious syndromes caused by zoonotic pathogens are equally diverse. Hence, classification of zoonoses is difficult for the clinician. Diseases may be classified by the nature of the pathogen, animal host, mode of transmission from animal to human, geographic range of host, or clinical syndrome (i.e., systemic disease or specific organ system of infection). Although most zoonoses are relatively unusual, they must be included in the differential diagnosis of many clinical syndromes. All patients with an infectious syndrome whose cause is not apparent after a standard

history and physical examination should be questioned to assess the possibility of a zoonosis. First, the clinician should question patients about exposure to pets and ask whether they own or have had recent contact with a dog, cat, bird, fish, reptile, or rodent. If contact may have occurred, the clinician should ask about a history of bites or scratches. Second, the patient should be asked about exposure to farm animals (which may also be pets) such as horses, pigs, cattle, and fowl (i.e., chickens and turkeys). The clinician should determine the amount and degree of exposure. Third, patients should be asked about leisure pursuits such as hunting, fishing, hiking, and camping. The clinician should assess specific animal contacts such as dressing or skinning animals, ingestion of water from streams and lakes, and bites by arthropods such as ticks (see also Chapter 119, Tick-borne disease). Fourth, the clinician should obtain a careful travel history to determine the risks of exposure to geographically limited zoonoses. In particular, it is important to ascertain whether a patient has had an animal bite or scratch while visiting an area endemic for rabies. Because the incubation period for rabies may extend for years, persons bitten or scratched by dogs or other possible rabid hosts should be considered for postinjury prophylaxis. In general, evaluation for specific zoonoses should be based on the possibility of exposure (Table 116.1).

A brief description of the approach to possible systemic infections caused by animals is provided in subsequent paragraphs. More detailed information may be found in specific chapters in this book or in the Suggested Reading at the end of this chapter.

Zoonotic diseases acquired by animal bite or scratch

Dog bites account for 70% to 90% of animal bites and cat bites account for 3% to 15%. Bites from wild animals constitute <1% of bite wounds. The infection rate from penetrating dog bites is approximately 3% to 12%. Cat bites are much more likely to become infected. Most dog and cat bites occur on the extremities. Males are more likely to be bitten by a dog than are females, whereas the opposite is true for cat scratches and bites. The highest incidence of dog bites is in children ages 5 to 9 years and the highest incidence of cat bites/scratches is now in adults >75 years of age. Approximately 1% of rodent bites become infected.

Although infections following animal bites may be caused by various flora, some generalizations can be made. The most common pathogen to cause infection following feline bites is *Pasteurella multocida* (see Chapter 23, Animal and human bites), which generally results in rapid progressive cellulitis similar to that caused by *Streptococcus pyogenes*. Occasionally sepsis may result, especially in the immunocomprised host. The agents of rat-bite fever, *Streptobacillus moniliformis* and *Spirillum minus*, may be transmitted by several small rodents, including the rat, mouse, and gerbil. Both agents cause a systemic illness. Infections with *Aeromonas hydrophila* may follow bites inflicted in fresh or brackish water or by aquatic animals such as snakes and alligators. Severe local infection progressing to crepitant cellulitis with systemic toxicity may occur. Although most cases of tularemia follow the handling of rabbits, infection may be transmitted by animal bites or scratches, especially domestic cats (other animals include the coyote, pig, and squirrel). *Capnocytophaga canimorsus* is an unusual systemic infection strongly associated with dog bites. More than 50% of patients have reported dog bites before clinical infection, although infection has also been reported following scratches from dogs, cat bites or scratches, and contact with wild animals. Approximately 80% of patients reported in the literature have a predisposing condition, most commonly splenectomy. Other predisposing conditions have included Hodgkin's disease, trauma, idiopathic thrombocytopenia purpura, alcohol abuse, steroid therapy, and chronic lung disease. Bites from seals, whales, and walruses may transmit a murine mycoplasma. *Erysipelothrix rhusiopathiae* is carried most commonly by swine but is also found in sheep, horses, cattle, chickens, crabs, fish, dogs, and cats. A local infection, erysipeloid, may result from bites or injury with these animals usually during occupational exposure. Thus, abattoir workers, butchers, fishermen, farmers, and veterinarians are at risk for infection with *E. rhusiopathiae*. Sepsis and endocarditis may result from local infection.

Zoonotic diseases acquired by arthropod bites

Due to major changes in the environment the incidence of zoonotic diseases vectored by arthropods has increased dramatically in recent years. The most significant of these diseases are vectored by ticks and include Rocky Mountain spotted fever (RMSF), Lyme disease, ehrlichiosis, and anaplasmosis. RMSF is caused by the rickettsial agent *Rickettsia rickettsii* and is the most severe rickettsial disease occurring in the United States. This disease is characterized with an acute onset of fever, malaise, headaches, chills, and in most cases a maculopapular rash. The rash of RMSF typically appears between the third and fifth days of illness but is absent in 5% to 15% of patients. Initially maculopapular, it begins on extremities, often around the wrist and ankles. As the rash progresses, it spreads centripetally to the trunk and characteristically involves the palms and/or soles. As it evolves, it becomes more clearly defined and more petechial and may rarely progress to skin necrosis and gangrene. RMSF has a case-fatality rate of 13% to 25% when untreated. Lyme disease has been reportable since 1992, and almost 10 000 cases were reported that year. In 2011 there were approximately 24 000 definite and 9000 probable cases of Lyme disease reported in the United States. Lyme disease is characterized by a distinctive circular rash, called erythema migrans (EM). Erythema migrans is characteristically an expanding annular erythematous plaque with central clearing, most commonly seen in the axilla, thigh, and groin. Color varies from pink to violaceous. Erythema migrans may last up to 4 weeks and may recur during the secondary stage of infection. Ehrlichiosis is a tick-borne disease caused by *Ehrlichia chaffeensis*, *E. ewingii,* and *E muris*-like which is characterized by fever, headache, malaise, mylagias, nausea/vomiting/diarrhea, and conjunctival injection and rash (in up to 60% of children, less than 30% of adults).

TABLE 116.1 **INFECTIOUS DISEASES ACQUIRED FROM ANIMALS**

Disease	Persons at risk[a]	Birds, fowl	Cats, dogs	Farm animals	Fish, reptiles,[b] water	Rabbits	Rodents	Arthropod vectors	Wild animals

TABLE 116.1 **CONTINUED**

Disease	Persons at risk[a]	Birds, fowl	Cats, dogs	Farm animals	Fish, reptiles,[b] water	Rabbits	Rodents	Arthropod vectors	Wild animals
Giardiasis	I, III, IV	+		++		+			+++
Toxocariasis	IV		++						
Toxoplasmosis	IV, IX		+++	+					
Trichinosis	Public			+					++

Abbreviation: SARS-coV = severe acute respiratory syndrome-coronavirus.
+, Rare source; ++, occasional source; +++, most-common source; (vector), not spread directly by animal but always via vector.
[a] Persons at risk: Group I (agriculture), farmers and other people in close contact with livestock and their products; group II (animal-product processing and manufacture), all personnel of abattoirs and of plants processing animal products or by-products; group III (forestry, outdoors), persons frequenting wild habitats for professional or recreational reasons; group IV (recreation), persons in contact with pets or wild animals in the urban environment; group V (clinics, laboratories), healthcare personnel who attend patients and healthcare workers, including laboratory personnel, who handle specimens, corpses, or organs; group VI (epidemiology), public health professionals who do field research; group VII (emergency), public affected by catastrophes, refugees, or people temporarily living in crowded or highly stressful situations; group VIII (fisherman), people catching or cleaning fish or engaging in recreational activities in the water; group IX (immunocompromised hosts), people who are immunocompromised because of immunodeficiency, cancer chemotherapy, organ transplants, immunosuppressive medications, liver and/or renal disease; group X (disaster responders, public), potential bioterrorist agent.
[b] Reptiles include lizards, snakes, and turtles.
[c] Rodents include hamsters, mice, and rats.

It is a serious disease with a case-fatality rate of 1.8%. Anaplasmosis is a tick-borne disease caused by *Anaplasma phagocytophilum*. Symptoms are similar to ehrlichiosis but rash is rare.

Mosquito-borne zoonotic diseases are common and significant throughout much of the world but play only a minor role domestically. The most common in the United States is West Nile virus. The vast majority of infected have subclinical or mild disease, whereas 1 in 150 infected will develop encephalitis. A unique feature is the ascending paralysis ("West Nile polio"). Other mosquito-borne zoonotics that occur in the United States are western equine encephalitis (WEE), eastern equine encephalitis (EEE), St. Louis encephalitis, and Lacrosse encephalitis. Other than EEE, these agents generally cause mild disease but can occasionally cause severe encephalitis in immunocompromised patients. EEE is rare but has a case-fatality rate of about 33%.

Plague, caused by *Yersinia pestis*, persists in wild rodents in the western half of the United States and is vectored by rodent fleas. Tularemia, caused by *Francisella tularensis*, occurs throughout the entire United States and is vectored by ticks, deer flies, and other insects. Tularemia also has several reservoirs such as rabbits, voles, and badgers. Both plague and tularemia may cause local skin and soft-tissue infection and serious systemic illness.

Zoonotic diseases acquired by inhalation

Although community-acquired pneumonia (CAP) is a common disease, few cases of pneumonia are due to zoonotic agents. Lower respiratory infection due to zoonotic agents generally causes an "atypical" pneumonia and may be mistaken for infection caused by *Legionella* spp., *Mycoplasma pneumoniae*, or *Chlamydia pneumoniae*. Zoonotic diseases that may be acquired in the home include *P. multocida* infection (cats and dogs), psittacosis (birds), and Q fever (parturient cats). Hunting or hiking in the United States may bring people into contact with animals capable of transmitting brucellosis (farm animals), plague (rodents, ground squirrels, prairie dogs), Q fever (farm animals, cats), tularemia (rabbits), and RMSF (ticks). The hantavirus cardiopulmonary syndrome (HCPS) due to Sin Nombre virus (SNV) results from inhalation of aerosols of excreta from infected rodents and is characterized by fever, headache, myalgias, and respiratory failure with a mortality rate of ~40%. In 2012 there was an outbreak in people visiting Yosemite National Park. Persons engaged in processing animal products such as hides are at risk for brucellosis and anthrax.

Few zoonotic pneumonias are capable of being transmitted from person to person. However, person-to-person transmission has been reported of avian influenza (H5N1 strain), *Coxiella burnetii* (Q fever), *Mycobacterium bovis*, and *Y. pestis* (plague). Avian influenza (H5N1) and pneumonic plague represent potentially serious nosocomial pathogens, and patients with these diseases should be placed on isolation precautions. Several zoonotic agents acquired via the respiratory route are potential agents of bioterrorism, including anthrax, brucellosis, plague, Q fever, and tularemia. Because of transmissibility and global migration, zoonotic pneumonias have the potential to cause significant epidemics across continents. A worldwide epidemic of SARS occurred in 2003 due to a novel coronavirus (SARS-coV). Molecular epidemiology suggested transmission from the palm civet and that the ultimate reservoir for the virus was bats. In 2009 a variant H1N1 triple assortment strain (human, avian, pig) led to a worldwide pandemic of influenza.

Zoonotic diseases acquired via ingestion

Zoonotic diseases acquired through ingestion are the most commonly acquired zoonotic diseases in the world. The main category is

bacterial diarrhea, with fever and abdominal cramps. *Campylobacter* is the most common agent and is normally found in the intestines of birds. Birds are also the primary reservoir of *Salmonella*, but it can also be found in many reptiles and mammals. The main reservoir of *Escherichia coli* O157:H7 is cattle and similar ungulates. One possible consequence of infection with *E. coli* O157:H7, especially in children and the elderly, is hemolytic-uremic syndrome (HUS), with hemolysis and renal failure. Brucellosis and listeriosis are bacterial foodborne zoonotic diseases of increasing importance in the United States due to the consumption of unpasteurized dairy products, causing a generalized febrile illness. Pregnant women are at higher risk for severe listeriosis.

There are also zoonotic agents that are transmitted via contaminated water. The most common disease is cryptosporidiosis, a protozoal disease spread by drinking and recreational water throughout the entire United States. Cryptosporidiosis generally causes a self-limited mild diarrheal illness. Giardiasis is also a protozoal waterborne zoonotic disease that is common and causes a mild diarrheal illness. Leptospirosis is generally transmitted through contaminated water. Although not common in the United States, there are sporadic outbreaks. Most cases produce a febrile illness that may progress to severe hepatic, renal, or neurologic disease. The reservoirs for leptospirosis are rodents, cattle, pigs, and small mammals (e.g., raccoons, opossums).

Systemic infections result from zoonotic diseases

Many zoonoses cause severe systemic symptoms. The range of possible pathogens can often be narrowed if the patient manifests specific organ involvement. Diseases to consider in patients with fever without focal signs on initial history and physical examination include *Aeromonas* sepsis, babesiosis, brucellosis, *C. canimorsus* sepsis, ehrlichiosis, cat scratch disease, leptospirosis, listeriosis, plague, Q fever, rat-bite fevers, relapsing fever, RMSF and other rickettsial infections, salmonellosis, tularemia, and viral hemorrhagic fevers.

Zoonoses may be associated with skin lesions. A generalized maculopapular rash may accompany cat scratch fever, Colorado tick fever, ehrlichiosis, leptospirosis, lymphocytic choriomeningitis, psittacosis, RMSF and other rickettsial infections (exceptions include Q fever and trench fever), rat-bite fever resulting from *Spirillum minus*, relapsing fever, and salmonellosis. Most rashes associated with zoonoses are too nonspecific to be of significant clinical utility. Crepitant or gangrenous lesions may complicate *Aeromonas*, *C. canimorsus*, or *Vibrio vulnificus* and related species. Petechial and purpuric lesions may occur with viral hemorrhagic fevers (e.g., dengue, yellow fever, Ebola, Lassa), RMSF, *Rickettsia prowazekii* infection, rat-bite fever resulting from *Streptobacillus moniliformis*, relapsing fever, and *C. canimorsus* sepsis. A local eschar often occurs with *Rickettsia conorii*, *Rickettsia australis*, *Rickettsia sibirica*, *Rickettsia akari*, and *Rickettsia tsutsugamushi*. Local skin lesions with or without lymphangitis may occur with cat scratch fever, rat-bite fever resulting from *Spirillum minus*, and tularemia.

Tick-borne disease

Steven C. Buckingham

Ticks can transmit numerous bacterial, parasitic, and viral pathogens to humans, and the secretions of some species can induce allergic reactions or cause paralysis. This chapter aims to provide a broad overview of tick-borne infections endemic to North America and to discuss general principles regarding their epidemiology, therapy, and prevention. Details about each of these infections are provided in their respective chapters.

Epidemiology

Tick-borne infections occur most often in the spring and summer, when ticks are most active, but are reported in colder months as well. Some patients with tick-borne infections will recall a recent tick bite, and many, but not all, report having spent time in a rural or wooded area within 2 to 4 weeks before the onset of illness. Frequently, however, patients are unaware of their recent tick exposure, for several reasons: Tick bites are usually painless, ticks may attach in sites covered by hair or clothing, and ticks in their larval and nymphal stages are very small but still capable of transmitting infection. Tick-borne infections have been reported in urban areas and, in endemic areas, among patients whose only outdoor exposures occurred in their own backyards. Thus the historical findings of tick bite or outdoor exposure may provide useful diagnostic clues, but their absence never excludes the possibility of a tick-borne illness.

Clinicians must understand the epidemiology of tick-borne infections to make presumptive diagnoses. The geographic distributions of tick-borne infections (listed in Table 117.1) correspond to the distributions of their associated tick vectors; thus, patients' geographic residence and travel history are keys to deciding which tick-borne illnesses are possible or likely.

Clinical manifestations

Most tick-borne infections present with nonspecific signs and symptoms, similar to those observed in viral syndromes (e.g., fever, malaise, headache, and myalgias). Sometimes, certain constellations of symptoms suggest a specific diagnosis. For example, the combination of erythema migrans, arthritis, and neurologic abnormalities suggests Lyme disease, whereas a cutaneous ulcer with associated regional adenopathy suggests tularemia.

Some of the typical physical and laboratory findings associated with specific tick-borne infections endemic to the United States are listed in Table 117.1. It must be emphasized, however, that not all patients with these illnesses will have all of their typical findings; for example, fewer than two-thirds of patients with Rocky Mountain spotted fever (RMSF) have the "classic triad" of fever, rash, and headache. Moreover, these illnesses have broad differential diagnoses; for example, the symptoms and signs of RMSF overlap considerably with those of ehrlichiosis, brucellosis, salmonellosis, Q fever, numerous viral infections (e.g., Epstein–Barr virus, cytomegalovirus, and enterovirus) and many other illnesses.

TABLE 117.1 **PRINCIPAL TICK-BORNE DISEASES OF THE UNITED STATES**

Disease	Organism	Geographic distribution and vector	Typical clinical findings[a]
Rocky Mountain spotted fever (RMSF)	*Rickettsia rickettsii*	Eastern United States: *Dermacentor variabilis* (dog tick) Mountain West: *Dermacentor andersoni* (wood tick) Southwestern deserts: *Rhipicephalus sanguineus* (brown dog tick)	Fever, headache, petechial rash, hyponatremia, thrombocytopenia
Rickettsia parkeri infection	*Rickettsia parkeri*	Southeastern United States: *Amblyomma maculatum* (Gulf Coast tick)	Similar to RMSF, but with eschar at inoculation site; rash may be vesicular or pustular; gastrointestinal symptoms less prominent
Human monocytotropic ehrlichiosis (HME)	*Ehrlichia chaffeensis*	Southeastern and southcentral states: *Amblyomma americanum* (Lone Star tick)	Similar to RMSF, but rash less common; leukopenia, thrombocytopenia, elevated transaminases
Human granulocytotropic anaplasmosis (HGA)[b]	*Anaplasma phagocytophilum*	Northeast and upper Midwest: *Ixodes scapularis* (blacklegged tick) Pacific coast: *Ixodes pacificus*	Similar to HME, but rash is rarely present
Ehrlichia ewingii infection	*Ehrlichia ewingii*	Southeastern and southcentral states: *A. americanum*	Same as HGA
Lyme disease	*Borrelia burgdorferi*	Northeast and upper Midwest: *I. scapularis* Pacific coast: *I. pacificus*	First stage: fever, erythema migrans Second stage: multiple skin lesions, conjunctivitis, arthralgias, myalgias, headache, cranial nerve palsies Third stage: arthritis; encephalopathy, dementia, peripheral neuropathy
Southern tick-associated rash illness	*Borrelia lonestari*	Southeastern and southcentral states: *A. americanum*	Rash similar to erythema migrans
Endemic relapsing fever	*Borrelia hermsii B. turicatae B. parkeri*	Western mountains and deserts: *Ornithodoros* species	Fever, chills, relapsing course
Tularemia	*Francisella tularensis*	Eastern United States: *D. variabilis* Mountain West: *D. andersoni* Southeastern and southcentral states: *A. americanum*	Fever, cutaneous eschar, lymphadenopathy, pulse–temperature dissociation
Babesiosis	*Babesia microti*	Northeast, Midwest, and West Coast: *I. scapularis*, other *Ixodes* species	Fever, malaise, headache, hepatosplenomegaly, thrombocytopenia, hemolytic anemia
Colorado tick fever	Coltivirus	Mountain West: *D. andersoni*	Fever, headache, leukopenia, thrombocytopenia; biphasic course
Powassan encephalitis	Powassan virus	Northeastern, north-central United States: *Ixodes* species, *D. andersoni*	Headache, seizures, altered sensorium, focal neurologic signs, meningismus
Tick paralysis[c]	Neurotoxin	Widespread: *Dermacentor* species, others	Ascending flaccid paralysis

[a] Not all patients will have all of the "typical" findings for these diseases. Many cases present simply with fever and vague constitutional symptoms.
[b] Formerly termed *human granulocytic ehrlichiosis*.
[c] Tick paralysis is not caused by an infection, but its epidemiology is similar to that of tick-borne infections.

Therapy

Tick-borne infections should, in general, be diagnosed presumptively, based on clinical findings and epidemiologic history. Because most specific tests yield negative results in early disease or must be sent out to a reference laboratory, the clinician often must prescribe antibiotics empirically (i.e., before a diagnosis is confirmed by laboratory testing). This is particularly true with regard to RMSF, in which mortality rates are significantly higher among patients who receive antirickettsial therapy on the fifth day of illness or later.

Details regarding the treatment of specific tick-borne infections are provided in the respective chapters. Generally speaking, doxycycline is appropriate for treatment of most tick-borne infections endemic to North America. At one time, chloramphenicol was

advocated for use in children younger than 8 years, owing to concerns over doxycycline's perceived potential to stain permanent teeth. Now, however, doxycycline is recognized as the drug of choice for the treatment of all suspected rickettsioses or ehrlichioses in North America, regardless of the patient's age. The principal reason for this change is that doxycycline treatment achieves superior outcomes in patients with RMSF or human monocytic ehrlichiosis, compared to chloramphenicol. Moreover, doxycycline does not penetrate teeth as well as tetracycline does; whereas repeated administrations of tetracycline to young children certainly can cause unsightly tooth discoloration, there is no evidence that a single course of doxycycline will do so.

Prevention of tick-borne diseases

Prevention of tick-borne diseases consists of avoidance of tick bites and prompt removal of attached ticks. During spring and summer months, it is prudent to examine persons and pets that have been outdoors at least daily for attached ticks. Wearing light-colored clothing will facilitate the identification of ticks. Nymphs and larvae are very small and may hide in areas such as the head, neck, axillae, belt line, or scrotum; thus, these areas must be scrutinized closely.

Attached ticks should be removed by grasping with tweezers close to the skin and pulling gently with steady pressure; the bite site should then be washed with soap and water. Attempts to detach ticks by applying petroleum jelly, fingernail polish, isopropyl alcohol, or a hot, extinguished kitchen match are discouraged, as these methods are both ineffective and potentially dangerous.

The repellant *N*,*N*-diethyl-*meta*-toluamide (DEET) is very effective for preventing tick, mosquito, chigger, and fly bites. Because protection increases with increasing concentrations, repellants containing 20% to 30% DEET are currently recommended for adults and children. When used appropriately, DEET is quite safe; concerns over its toxicity have been vastly overstated. Nevertheless, a few cautionary statements are in order. DEET must not be ingested and should be applied only to exposed, intact skin, or to clothing. It should not be introduced to the mouth, eyes, or other mucous membranes (and thus should not be applied to the hands of children). Children should not apply DEET-containing products to themselves, and DEET is not recommended for use on children younger than 2 months. DEET should not be overused; in most cases, one application per day is adequate. Treated skin should be washed with soap and water after coming indoors.

Permethrin is an insecticide that may be sprayed on clothing, providing an additional layer of protection against tick bites (and those of other arthropods). Clothes should be sprayed on each side of the fabric for 30 to 45 seconds and allowed to dry for 2 to 4 hours before wearing. Permethrin maintains potency for at least 2 weeks after application, even if clothes are washed. Although permethrin is occasionally associated with skin erythema or edema, systemic adverse effects have not been noted.

Recreational water exposure

Mary E. Wilson and Andrea K. Boggild

Many common forms of recreation involve water exposure. Pathogens in water infect susceptible humans by multiple routes: through skin and mucous membranes, via inhalation of aerosols, aspiration, and ingestion. Clinical manifestations of these infections range from superficial skin lesions to fatal, systemic infections. The survival of many water-associated pathogens is influenced by climate, season, other environmental conditions, and the level of sanitation. The types and abundance of organisms vary depending on the salinity, pH, temperature, and other characteristics of the water. Hence, many are found only or primarily in certain geographic regions or during some seasons of the year. The risk of infection by waterborne pathogens is a function of the duration and type of exposure, concentration density of organisms in water, and host immunity. This chapter describes the types of pathogens, geographic distribution, sources and routes of transmission, clinical presentations, and management of water-associated infections. Water can also be a source of toxins, including heavy metals. Oceans and beaches are the sites of marine envenomations. These topics are beyond the scope of this chapter.

Visits to recreational water venues are common, as are outbreaks of infections related to them. In the United States in 2011–2012, for example, 90 waterborne disease outbreaks in 32 states were reported to the Centers for Disease Control and Prevention (CDC). Almost 2,000 persons were affected by these outbreaks, with at least 95 associated hospitalizations and 1 death. Over the past 20 years, the number of reported diarrheal illnesses following recreational water exposure has steadily increased. Of the 90 outbreaks associated with recreational water exposure reported in 2011–2012, more than half (52%) were outbreaks of gastroenteritis specifically due to cryptosporidiosis. Cryptosporidiosis, giardiasis, *Escherichia coli* O157:H7 gastroenteritis, norovirus, shigellosis, leptospirosis, and *Pseudomonas* dermatitis have been the most commonly reported infections related to recreational water exposures in the United States in recent years. During the more prolonged reporting period of 2000–2014, almost 500 outbreaks associated with treated recreational waters were reported to the US CDC. The most common causes were *Cryptosporidium* (58%), *Legionella* (16%), and *Pseudomonas* (13%) (see Hlavsa 2018, in "Suggested Reading" section), pathogens characterized by chlorine-resistance and capacity to form biofilms. Outbreaks of adenoviruses (causing pharyngitis, conjunctivitis), cercarial dermatitis, and hepatitis A (public swimming pool) have also been reported. Chlorinated swimming pools, water parks, lakes, ponds, and whirlpools have been common sources. Although outbreaks related to recreational water use can occur throughout the calendar year, most occur in the summer months, with 61% of outbreaks associated with treated recreational water in 2011–2012 beginning in June, July, or August.

Patients typically do not volunteer specific descriptions of water exposures because they may not recognize their relevance. Box 118.1 lists several sources of water exposures that have been associated with infections and can be used as a checklist to help the clinician obtain relevant history. Most water-associated infections will become apparent within hours to days (usually ≤14 days) of exposure. An important exception is schistosomiasis, which may first manifest months or longer after exposure. Relevant history includes types of exposures; dates, duration, and location of exposures; and type of water (e.g., mountain stream, lake, hot tub, chlorinated pool, salt water). During participation in water sports, people commonly ingest water and inhale aerosols.

BOX 118.1

Types of activities associated with water exposure

Swimming, wading, diving
Near-drowning events
Fishing, hunting
Rafting, boating, kite sailing, sailing, surfing, windsurfing, water-skiing
Water parks (wave pools and water slides)
Sitting in hot tubs, whirlpools
Showering and bathing, ritual washing
Drinking water and water-containing beverages (untreated surface water consumed during hiking, camping)
Care of fish tanks, aquaria

Ingestion of contaminated water, whether during swimming, showering, or drinking, often causes infections manifested by diarrhea. Some pathogens have the capacity to cause systemic infection after ingestion. Fecally contaminated water may contain a potpourri of microbes—bacteria, viruses, protozoa, and helminths—causing a variety of illnesses with differing manifestations and incubation periods. Swimming at beaches near a sewage outlet, for example, leads to increased rates of conjunctivitis, otitis externa, skin, and soft tissue infections, as well as gastrointestinal infections. Interactive fountains are known to be particularly vulnerable to contamination as they are open to young children, the homeless, and animals and recirculate potentially contaminated water back onto users.

Recreational water activities are often group activities, so contaminated water may be associated with outbreaks, sometimes involving dozens or even hundreds of people. In addition to caring for the acutely ill patient, the clinician must consider the public health implications and alert the appropriate authorities. Early interventions may slow or halt an outbreak and allow early recognition of other cases. In many instances, outbreaks are the result of inadequate operation or maintenance procedures. For example, in a recent US-wide inspection of >5,000 spas, nearly 3,000 were found to be in violation of water quality and other maintenance parameters, resulting in the immediate closure of 11% of those inspected. As further illustration of this point, in August 2003, inadequate disinfection of an athletic facility spa resulted in an outbreak of methicillin-resistant *Staphylococcus aureus* (MRSA) skin infections among college football players, thus establishing this emerging pathogen as one with potential for waterborne transmission. A review of 18 outbreaks of *Pseudomonas* from spas implicated substandard levels of chlorination in each case. And, among almost 14,000 routine inspections of public hot tubs and spas conducted in 2013 across 16 jurisdictions, suboptimal disinfectant concentrations were noted in 20%.

The route of entry may influence the clinical findings for several of the water-associated pathogens, with skin penetration causing local wound infections and ingestion causing diarrheal infections. Box 118.2 lists the range of clinical manifestations of infections that follow water exposure. With some of the more virulent organisms or in the setting of immune compromise, infection may enter the bloodstream after any one of several entry points. Minor trauma, cuts, bites, and breaks in the skin can provide the portal of entry for many water-dwelling microbes. Table 118.1 summarizes infections and infestations that enter through the skin. Table 118.2 lists specific infections acquired via aspiration, inhalation, and ingestion.

BOX 118.2

Clinical manifestations of infections related to recreational water exposure

Skin and mucosal surface exposure
Conjunctivitis
Keratitis
Otitis externa
Dermatitis (including folliculitis)
Mastitis
Cellulitis
Fasciitis
Endometritis (reported after intercourse in water)
Systemic infection

Aspiration, inhalation, ingestion
Pharyngitis
Sinusitis
Meningoencephalitis
Pneumonitis
Gastroenteritis, colitis
Systemic infection

Several water-associated infections and intoxications can be rapidly progressive or can lead to serious complications. Because some of these are infrequent or rare, they may be unfamiliar to most physicians. The following section provides a brief summary of each. More common infections, such as shigellosis, campylobacteriosis, salmonellosis, and *E. coli* O157:H7 that can be acquired through water exposure are covered in more detail in other chapters of this book. Table 118.3 lists the recommended treatment for the less familiar water-associated infections and ones that are not covered in other chapters of the text.

Acquired by penetration through skin

Pseudomonas dermatitis or folliculitis

Use of hot tubs and whirlpools (spas), and, occasionally, swimming pools and water slides has been associated with development of a characteristic diffuse rash caused by the aerobic, gram-negative organism *Pseudomonas aeruginosa*. The rash, which is maculopapular or vesiculopustular and usually pruritic, develops within 48 hours of exposure and typically resolves within a week. Lesions are more prominent in areas covered by a bathing suit or clothing. Associated findings may include otitis externa, mastitis (in men and women), conjunctivitis, and lymphadenopathy. Infection is typically self-limited in healthy hosts; immunocompromised persons may

TABLE 118.1 **INFECTIONS AND INFESTATIONS ACQUIRED VIA PERCUTANEOUS AND PERMUCOSAL RECREATIONAL WATER EXPOSURE**

Pathogen or disease	Source
Bacteria	
Aeromonas hydrophila[a,b]	Freshwater streams, lakes, soil
Burkholderia pseudomallei (melioidosis)[a,b]	Fresh water, soil (tropics, subtropics)
Chromobacterium violaceum[a,b]	Freshwater rivers, soil (tropics, subtropics)
Leptospirosis[b]	Fresh water contaminated with animal urine (especially tropics, subtropics)
Mycobacterium marinum[a]	Fish tanks, swimming pools
Pseudomonas aeruginosa[a]	Hot tubs, whirlpools, swimming pools
Vibrio vulnificus, other vibrios[a,b]	Seawater
Tularemia[a,b,c] (*Francisella tularensis*)	Fresh water contaminated by infected animal; inoculation of skin, conjunctiva, oropharyngeal mucosa
Helminths	
Schistosomiasis[a,b]	Freshwater streams, lakes (focal in Asia, Africa, South America, parts of Caribbean)
Cercarial dermatitis (avian schistosomes)[a]	Fresh and salt water (worldwide)
Protozoa	
Acanthamoeba species[a,b] (keratitis); *Naegleria fowleri*[b]; *Balamuthia mandrillaris*[a,b]	Fresh water, especially stagnant ponds during hot summers; hot tubs, swimming pools, thermal springs
Viruses	
Adenovirus[a,b] (swimming pool conjunctivitis; pharyngitis)	Swimming pools; likely other freshwater sites
Coxsackieviruses[a,b]	Fresh water
Other	
Seabather's eruption[a]	Seawater

Pseudomonas dermatitis and *M. marinum* are rarely associated with systemic infection, primarily in compromised hosts.
[a] Skin and soft tissue.
[b] Systemic infection.
[c] Conjunctivitis.

develop hemorrhagic bullae, pneumonia, and bacteremia. From 2000–2014, 40 outbreaks caused by *Pseudomonas* were linked to hotel/motel pools or spas, leading to cases of skin- or ear-related disease. Infections can be prevented if water is maintained at a pH of 7.2 to 7.8 with adequate chlorination (free, residual chlorine levels should be in the range of 2.0 to 6.0 mg/L), with levels <0.5 mg/L consistently detected in outbreak situations.

Otitis externa (swimmer's ear)

Infection of the external ear canal, otitis externa, is common in swimmers. Usual symptoms are mild pain and pruritus around the ear. Pain may become more severe if infection progresses to involve deep tissues and bone, as more commonly occurs in patients with underlying medical conditions, such as diabetes mellitus. Common organisms are *S. aureus* and *P. aeruginosa*; multiple bacterial species are often recovered from cultures. Purulent drainage and local lymphadenopathy may develop. Occasionally infections progress to cellulitis that requires systemic antibiotic therapy. Topical therapy can be effective in early infections. See Chapter 6, "Otitis," for treatment.

Cercarial (schistosome) dermatitis

Cercarial dermatitis, also known as *swimmer's* or *clam digger's itch*, is caused by an allergic response to penetration of skin by cercariae of nonhuman larval trematodes of the genus *Schistosoma* (often avian schistosomes). A pruritic, maculopapular rash develops in water-exposed areas of the body (Figure 118.1). Both total duration of exposure and duration of exposure to shallow water correlate with increased likelihood of developing cercarial dermatitis. Shallow water exposure is a particular risk factor as this is where snail beds are most dense and cercarial accumulation is greatest. In 2011–2012, four outbreaks leading to 65 cases of cercarial dermatitis in the United States were linked to recreational water exposure.

Lesions appear hours to a day or more after water exposure and are often less prominent in areas covered by a bathing suit or other protective clothing. Papules may become vesicular. Secondary bacterial infection may result from scratching-related skin abrasions. Lesions peak in 2 to 3 days and typically resolve over 1 to 2 weeks without specific therapy. In persons with previous exposures lesions may develop sooner and may be more severe. Treatment is symptomatic and may include antihistamines and topical steroids. Systemic steroids have been used in severe cases. Nonhuman schistosomes are widely distributed, including in temperate areas, and may contaminate fresh, brackish, and seawater.

Schistosomiasis

Penetration of the skin by human schistosomes (e.g., *Schistosoma mansoni*, *S. haematobium*, *S. japonicum, S. mekongi*) may cause redness, urticaria, and pruritic papules, typically less severe than the cercarial dermatitis just described. Systemic manifestations of schistosomiasis may develop months or years later. Among 28 travelers who developed schistosomiasis after water exposure in Mali, 36% gave a history of schistosomal dermatitis. Infection can follow even brief water exposure, including river rafting. Attack rates have often been high in travelers who swim, wade, or bathe in infested water. An acute illness characterized by fever, malaise, and eosinophilia (Katayama syndrome) may develop 2 to 6 weeks after exposure and corresponds to larval migration following initial skin penetration. Dry cough, dyspnea, and pulmonary infiltrates may be present.

TABLE 118.2 **SPECIFIC INFECTIONS OR TOXINS ACQUIRED VIA INHALATION, ASPIRATION, OR INGESTION DURING RECREATIONAL WATER EXPOSURE**

Disease or pathogen	Main clinical finding
Adenovirus 3	Pharyngitis, fever, conjunctivitis
Amebiasis (*Entamoeba histolytica*)	Colitis, liver abscess
Aerosolized red tide respiratory irritation (ARTRI)	Rhinorrhea, cough, bronchospasm
Balantidiasis (*Balantidium coli*)	Diarrhea or dysentery
Campylobacteriosis	Diarrhea
Cholera (*Vibrio cholerae*)	Diarrhea, dehydration
Coxsackieviruses	Diarrhea
Cryptosporidiosis	Diarrhea, fever, nausea, vomiting
Cyclospora	Diarrhea, fever, nausea, vomiting
E. *coli* O157:H7	Bloody diarrhea
Free-living amoebae *(*especially *Naegleria fowleri)*	Meningoencephalitis
Giardiasis	Subacute diarrhea, fever, nausea, vomiting
Hepatitis A virus	Acute hepatitis
Hepatitis E virus	Acute hepatitis (potentially fatal in pregnancy)
Legionnaires' disease (*Legionella*)	Pneumonia
Leptospirosis	Fever, severe myalgia, conjunctival suffusion; may cause severe icterohemorrhagic fever
Melioidosis	Pneumonia, sepsis, skin lesions; protean manifestations
Norovirus ("Norwalk-like viruses")	Diarrhea, vomiting
Pfiesteria (possible estuary-associated syndrome)	Eye irritation, cough, rash, vomiting, abdominal cramps, neurocognitive changes
Poliovirus	Nonspecific febrile illness; flaccid paralysis 1%
Pontiac fever (*Legionella*)	Fever (self-limited)
Primary amebic meningoencephalitis (PAM)	See Free-living amoebae
Rotavirus	Watery diarrhea
Salmonellosis	Diarrhea; extraintestinal manifestations if bacteremic diarrhea; dysentery
Shigellosis	Diarrhea, dysentery
Toxoplasmosis	Fever, lymphadenopathy, lymphocytosis
Tularemia	Fever, lymphadenopathy, pneumonia; manifestations depend on route of transmission
Typhoid/paratyphoid fever (enteric fever due to *Salmonella enterica* serotype Typhi or Paratyphi)	Fever, systemic infection, gastrointestinal sequelae
Vibrio parahaemolyticus	Watery diarrhea; occasionally dysentery
Vibrio vulnificus	Sepsis, bullous skin lesions; high rate of hospitalization and mortality
Yersinia enterocolitica	Fever, diarrhea, acute mesenteric lymphadenitis

Neurologic complications (including transverse myelitis) can occur early or late. Clinical findings vary with the species of schistosome and are related to granulomatous reactions to eggs in tissue (Figure 118.2). Maps showing the geographic distribution of schistosomiasis are found on World Health Organization (WHO) and CDC websites and in the CDC reference.

Seabather's eruption (also marine dermatitis or sea lice)

Seabather's eruption is caused by penetration of the skin by *Linuche unguiculata*, *Edwardsiella lineata*, and other larvae of the phylum Cnidaria. Characteristic findings include an intensely pruritic, papular rash that begins 4 to 24 hours after swimming in the ocean. The

TABLE 118.3 **DIAGNOSIS AND TREATMENT OF SELECTED INFECTIONS**

Pathogen or disease	Diagnosis[a]	Treatment
Aeromonas hydrophila	C	TMP-SMX or FQ[b,c] (third-generation cephalosporins; AG; imipenem)
Burkholderia pseudomallei	C	Ceftazidime[b,c] (imipenem[b,c] or meropenem; TMP-SMX + doxycycline[c])
Chromobacterium violaceum	C	Limited clinical data; may be sensitive to FQ, TMP-SMX, tetracyclines, AG, extended-spectrum penicillins
Francisella tularensis (tularemia)	S, C	Gentamicin,[b] streptomycin,[b] or tobramycin[b] (doxycycline or ciprofloxacin; chloramphenicol)
Leptospirosis	S, C	Penicillin G[b,c] or doxycycline[b]
Mycobacterium marinum	C (at 30°C/86°F), M	Minocycline or clarithromycin (TMP-SMX; rifampin + ethambutol; doxycycline)
Primary amebic meningoencephalitis (due to free-living amoebae)	Visualization of trophozoites in CSF; C, M	*Naegleria*[d]: miltefosine; amphotericin B IV and IT *Acanthamoeba*: miltefosine; itraconazole, TMP-SMX, rifampin; pentamidine *Balamuthia*: miltefosine; pentamidine + fluconazole + sulfadiazine + flucytosine + clarithromycin
Schistosomiasis	Demonstration of eggs in tissue, urine, or stool; S	Praziquantel[b,c]
Vibrio vulnificus	C	Doxycycline + ceftazidime[b] (cefotaxime; ciprofloxacin; doxycycline + AG [FQ])

Abbreviations: AG = aminoglycoside; CSF = cerebrospinal fluid; FQ = fluoroquinolone; IT = intrathecal; IV = intravenously; TMP–SMX = trimethoprim–sulfamethoxazole.
[a] Method of diagnosis: C = culture, M = molecular testing (such as PCR), S = serology.
[b] Considered first-line therapy at time of printing.
[c] Randomized controlled trial level of evidence for therapy.
[d] Reports of treatment success are scant.

lesions are found in areas covered by a bathing suit and at points of contact (e.g., flexural areas, wristbands of diving suits). The tiny larvae are entrapped by the bathing suit, which acts as a mechanical stimulus for the release of nematocysts and injection of toxin by the larvae. Outbreaks are sporadic. Persons with extensive involvement may have systemic symptoms, including fever. Lesions usually clear within 10 days. Antihistamines and topical steroids may provide symptomatic relief. Systemic steroids have been used in severe cases.

Vibrio soft tissue infections

As resident marine flora, *Vibrio vulnificus*, *V. parahaemolyticus*, *V. alginolyticus*, and other *Vibrio* spp. can cause soft tissue infections through recreational water exposure. In 2007–2008, 236 cases of vibrioses linked to recreational water exposure were reported from 25 states, which represents one-fifth of the total cases of vibrioses in the country over that period of time. Almost one-third required hospitalization, and nine patients died. Organisms can be introduced by injuries (often on the lower extremity) that break the skin during swimming in the ocean or walking on beaches or can enter via preexisting open skin lesions. After trauma, *V. vulnificus* can cause pustular lesions, lymphangitis, and cellulitis, which may be mild or rapidly progressive, causing pain, myositis, skin necrosis, and gangrene. Surgical debridement (or amputation) in addition to antibiotic therapy and general support may be necessary. Of all *Vibrio*-associated illnesses secondary to recreational water exposure reported to the CDC in 2007–2008, *V. vulnificus* carried the highest rate of hospitalization and mortality.

Vibrio soft tissue infections, including necrotizing fasciitis, can also follow ingestion of contaminated food (commonly raw shellfish). Many vibrios, in addition to *V. cholerae*, can cause diarrheal illness, and gastroenteritis may be associated with high-grade bacteremia and high mortality. Large bullous skin lesions may occur with primary *Vibrio* bacteremia (especially *V. vulnificus*). Severe infections are more common in persons with chronic liver disease or other underlying diseases that compromise immune function.

FIGURE 118.2 Egg of *Schistosoma mansoni* from stool.

Vibrios are found in seawater or brackish water and are part of the usual bacterial flora of coastal waters in the United States and elsewhere. They are more abundant in warmer months, and most reported infections occur in the summer. Rising water temperatures in the Baltic Sea over the past three decades have led to an increase in the number of outbreaks due to *Vibrio* spp. in countries that have been historically protected from these organisms due to their cooler climate.

Treatment of soft tissue and systemic infections following seawater exposure should include coverage for *Vibrio* species.

Aeromonas hydrophila

Aeromonas hydrophila is a non–spore-forming, motile, facultatively anaerobic gram-negative organism found in freshwater lakes, streams, and soil. Puncture wounds or soft-tissue injury in contaminated water may lead to cellulitis that can resemble acute streptococcal infection with lymphangitis and fever. If not treated with effective drugs, it can progress to bullae formation and necrotizing myositis with gas in soft tissues. Findings can mimic gas gangrene. Soft tissue infections may require local debridement along with systemic antibiotic therapy.

Ingestion of *Aeromonas* may cause diarrhea. Although *Aeromonas* is frequently isolated from environmental waters, evidence of clearly defined outbreaks of diarrhea attributable to aeromonads is lacking. Aspiration of *Aeromonas*-contaminated water may lead to *Aeromonas* pneumonia and bacteremia.

Melioidosis (*Burkholderia pseudomallei*)

This water- and soil-associated gram-negative organism, found especially in tropical and subtropical areas, is a common cause of pneumonia, skin lesions, and sepsis predominantly in Southeast and South Asia and Australia, though also in Oceania, the Caribbean, and South America. The organism can be acquired through minor skin wounds or via aspiration or ingestion. Infection can be acute, subacute, or chronic and has protean manifestations, including cavitary lung disease, splenic abscesses, and osteomyelitis. The organism can persist silently in the human host and reactivate decades after acquisition, mimicking tuberculosis.

Acanthamoeba infections, including primary amebic meningoencephalitis

Free-living amebae of the genus *Acanthamoeba*, found in soil and fresh water, can enter human tissues and cause local or disseminated infection. Several species of *Acanthamoeba* have been reported to cause keratitis and granulomatous inflammation, which may be acute or subacute. Soft tissue infections have also been reported, although are more likely to result from infection with the related free-living ameba *Balamuthia mandrillaris*. Minor trauma to the cornea, as may occur in persons who wear contact lenses, predisposes to infection. The diagnosis is confirmed by finding *Acanthamoeba* on biopsy, corneal scrapings, or culture (Figure 118.3). Treatment typically requires both debridement and topical therapy (several agents have been tried: combination of miconazole nitrate, propamidine isethionate, and Neosporin; propamidine isethionate and dibromopropamidine; oral voriconazole and miltefosine; among others, although level of evidence is case series only).

The free-living ameba, *Naegleria fowleri*, may cause primary amebic meningoencephalitis (PAM) following recreational water exposure, typically in young healthy persons. Trophozoites enter the nasal passages during swimming or diving, penetrate the cribriform plate, and invade the central nervous system via olfactory neuroepithelium, causing rapid destruction of gray and white matter. Symptoms usually begin 3 to 7 days after exposure to water. Infection causes high fever, headache, and stiff neck, resembling bacterial meningitis, which rapidly progresses to coma and, usually, death. Diagnosis is confirmed by detection of trophozoites in the cerebrospinal fluid (CSF) (wet mount, Giemsa staining after fixation, or by culture) or by polymerase chain reaction (PCR) of CSF, although in most cases of PAM, diagnosis is postmortem. Infections have followed exposures in lakes, rivers, stagnant ponds, thermal springs, canals, and hot tubs and are more common during very warm periods, due to the thermophilic nature of these free-living protozoa. Disruption of lake or riverbed sediment by deep swimming or digging is a particular risk factor for PAM and may therefore serve as an important historical clue for clinicians. Ritualistic washing before prayers, which involves sniffing water to cleanse the nose, has also emerged as a risk factor for PAM in rural Nigeria. In 2007–2008, eight fatal cases of PAM due to *N. fowleri* were reported from Florida, Texas, Arizona, California, and Oklahoma.

Chromobacterium violaceum

This gram-negative organism is found in abundance in tropical and subtropical freshwater rivers and soils. The rarely reported infections have usually followed penetrating skin injury and are typically bacteremic. Persons with chronic granulomatous disease are at risk for

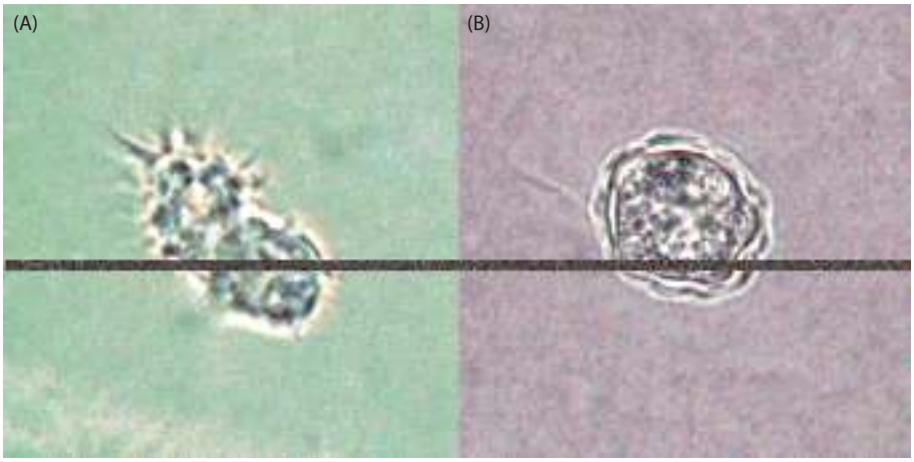

FIGURE 118.3 (A) Trophozoite and (B) cyst of *Acanthamoeba* spp. from corneal specimen, wet mount.

severe infection. Clinical data are limited, and evidence to guide management decisions is lacking.

Leptospirosis

Spirochetes of the genus *Leptospira* cause leptospirosis, a zoonosis of global significance. Leptospirosis has caused outbreaks in swimmers (lake, stream, other fresh water), kayakers, whitewater rafters (e.g., in Costa Rica), and, more recently, in 2011, among members of the French Armed Forces training in canyon rescue along the Absalon River of Martinique. Fresh water becomes contaminated with the urine of infected domestic and wild animals. Humans become infected when organisms enter through skin (especially if abraded) or mucous membranes, or after ingestion of contaminated water or food. Infections are more common in tropical and subtropical areas and during warm seasons in temperate regions. In the United States, infections have been especially common in Hawaii, although sporadic infections and occasional clusters occur in other areas, primarily in warmer months. In July 1998, an outbreak of leptospirosis occurred in Springfield, Illinois, primarily affecting triathletes who swam in Lake Springfield. Imported cases in travelers, however, can be seen throughout the year in North America. The single outbreak of leptospirosis (n = 2 cases) reported to the CDC in 2014 was related to lakewater exposures in a state park.

Infected persons can develop a systemic infection with protean manifestations, commonly including fever, headache, severe myalgia, and conjunctival suffusion. The spectrum of clinical disease can range from asymptomatic or mild infection to the most serious form, Weil's disease, characterized by an icterohemorrhagic fever. A biphasic course is classic, and complications such as aseptic meningitis, pneumonia, and acute renal failure are seen in one-quarter to one-third of all cases of leptospirosis. A large flood in Metro Manila, Philippines, in 2009 led to 471 hospitalizations and 51 deaths, with a case-fatality rate of 8%. A recent systematic review and meta-analysis estimated the overall mortality rate of untreated leptospirosis to be 2.2%, with a range of 0% to almost 40%, and mortality was almost exclusively associated with icterohemorrhagic fever and advanced age, rather than non-icteric manifestations such as meningitis (see Taylor 2015).

Mycobacterium marinum

Mycobacterium marinum usually invades only superficial tissue after local inoculation. Infection manifests as red plaques, papules, or nodules (sometimes with sporotrichoid or lymphocuticular spread) (Figure 118.4). The infection is referred to as "swimming pool granuloma" and "fish tank granuloma" because of the associations with fish and water. This subacute infection, most often on the hand or arm, can occur after exposure to fresh or salt water in aquariums and in swimming pools. Because the organism is relatively chlorine-resistant, infection can follow exposures in chlorinated pools.

Tularemia

Tularemia, caused by *Francisella tularensis*, an organism that sometimes contaminates water (from infected animals), can infect via multiple routes, including through conjunctivae, skin, oropharynx, and gastrointestinal tract. Ticks and other arthropods can transmit infection. It is mentioned in this chapter because infection can be severe, even fatal, but does respond to appropriate antibiotic therapy.

Acquired by inhalation, aspiration, or ingestion

Legionnaires' disease

Legionella can infect susceptible hosts through inhalation of aerosols generated by showers, whirlpools/spas, and sinks. Temperature is the most important abiotic factor influencing survival and growth of *Legionella*, which proliferates in hot water tanks and heat-exchanging systems. Several outbreaks of Legionnaires' disease, an acute pneumonic process, have been traced to exposures in resort hotels and whirlpools on cruise ships. Hence, this is an infection to consider in persons with febrile illness and pneumonia after travel. Pontiac fever results from the aerosolized antigens of *Legionella pneumophila* and is characterized by a self-limited febrile illness. In 2011–2012, 11 outbreaks caused by *Legionella* were linked to pools

FIGURE 118.4 Cutaneous nodule of *Mycobacterium marinum* several months after repeated fish tank exposure.

or spas, leading to 85 cases of Pontiac fever or Legionnaires' disease. Randomized controlled trials support the use of either macrolides (clarithromycin, azithromycin) or fluoroquinolones (levofloxacin) for the management of Legionnaires' disease or for empiric coverage of *L. pneumophila* in cases of community-acquired pneumonia.

Cryptosporidiosis

Cryptosporidium, an apicomplexan protozoan, has eclipsed *Giardia* as the most common parasitic cause of gastroenteritis outbreaks following recreational water exposure in the United States. Of 69 outbreaks related to treated recreational water reported in the United States in 2011–2012, 36 (52%) were caused by *Cryptosporidium*. Over the past 30 years, the number of annual outbreaks of cryptosporidiosis attributable to treated recreational water exposure (range 0–40 outbreaks) has steadily increased. Among 363 outbreaks with a confirmed pathogen reported to the CDC from 2000 to 2014, 212 (58%) were due to cryptosporidiosis, and, of these, 24 (11%) affected >100 people in each case, with four outbreaks affecting >2,000 people. In 2007, for instance, a single community-wide outbreak in Utah related to recreational water exposure led to almost 5,700 cases of cryptosporidiosis. Most cases of *Cryptosporidium* occur following exposure at treated water venues, such as swimming pools. A number of factors contribute to the spread and transmission of *Cryptosporidium*, notably the wide range of animal reservoirs; the large number of fully infectious oocysts excreted by human and animal hosts (Figure 118.5); the relative resistance of oocysts to standard disinfection practices, including chlorination; and a low minimum infective dose. Oocysts of *Cryptosporidium* may be difficult to distinguish from those of *Cyclospora cayetanensis* (Figure 118.6), which causes a similar clinical syndrome to cryptosporidiosis, although cyclosporiasis tends not to have the same association with recreational water exposures because the oocysts are not immediately infectious upon shedding; rather, they must undergo environmental sporulation over a 1- to 2-week period prior to being transmissible.

Although the clinical course is usually self-limited, severe and prolonged diarrhea may occur in young children and in those who are immunocompromised. Nitazoxanide has emerged through randomized controlled trials as an effective agent for the treatment of cryptosporidiosis in both healthy adults and children and in those who are immunocompromised.

FIGURE 118.5 Oocyst of *Cryptosporidium* spp. from stool, wet preparation.

Giardiasis

Since the first documented outbreak in 1965, >100 waterborne outbreaks have been attributable to the flagellated protozoan

FIGURE 118.6 Oocyst of *Cyclospora cayetanensis* from stool, wet preparation.

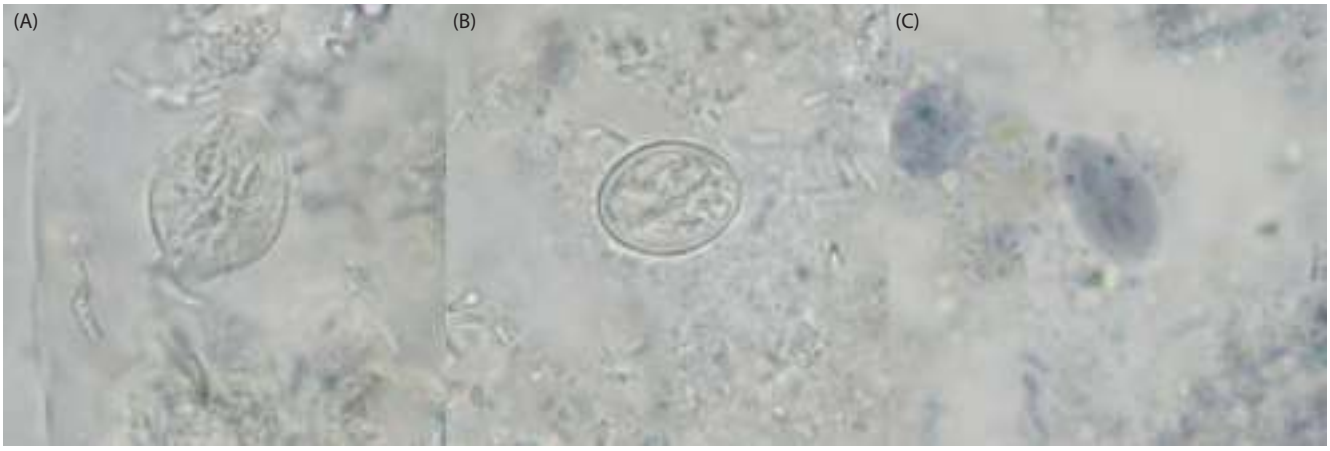

FIGURE 118.7 Trophozoite and cysts of *Giardia lamblia*, (A) wet preparation trophozoite; (B) wet preparation cyst; (C) iron–hematoxylin stain cyst.

Giardia. In 2011–2012, four outbreaks leading to 159 cases reported to the CDC were due to giardiasis acquired from recreational water exposure. Some outbreaks have been caused by both *Giardia* and *Cryptosporidium* (see Hlavsa 2018). Outbreaks of giardiasis have frequently been traced to ingesting unfiltered, unchlorinated, or inadequately chlorinated surface waters. Many infections in campers and hikers have followed drinking from mountain streams, even in remote wilderness areas. Like *Cryptosporidium*, *Giardia* has a broad mammalian host range, and cysts are excreted in fully infectious form (Figure 118.7). There are a number of effective therapeutic options for giardiasis that have been evaluated in randomized controlled trials, including metronidazole, nitazoxanide, tinidazole, mebendazole, albendazole, and furazolidone.

Norovirus ("Norwalk-like viruses")

In the 2011–2012 reporting period, norovirus was responsible for seven waterborne disease outbreaks, which caused 231 cases of gastroenteritis, rendering it second only to *Cryptosporidium* in the number of individuals who were sickened by a specific etiologic agent causing gastroenteritis. The majority of individuals were sickened by norovirus following exposure at treated water venues, notably swimming pools. Although community outbreaks of norovirus are often linked to transmission via doorknobs, toilets, and shared utensils, recreational water exposure significantly contributes to the overall case burden. The increasing number of cases reported over the past few years has been attributed to improved awareness and availability of viral detection methods, although diagnostic test underutilization is still likely to result in underreporting of viral agents of gastroenteritis. Visualization of norovirus in stool via electron microscopy is definitive (Figure 118.8). Management is supportive.

Chemical exposures and intoxications

Recreational use of marine water systems can lead to intoxications including, but not limited to, possible estuary-associated syndrome (PEAS) and aerosolized red tide respiratory irritation (ARTRI), caused by toxins liberated by the species of dinoflagellates, *Pfiesteria* and *Gymnodinium breve*, respectively. PEAS due to *Pfiesteria* leads to respiratory and eye irritation along with rash, vomiting, abdominal cramps, and cognitive changes, all of which appear to be self-limited. ARTRI occurs due to inhalation of brevetoxins present in sea spray during algal blooms and is characterized by a syndrome of rhinorrhea, cough, and bronchospasm. In both cases, treatment is supportive.

In 2011–2012, eight outbreaks following recreational water exposure to chemicals or toxins sickened 87 individuals. The largest such outbreak was associated with a wading pool, led to skin and eye symptoms in employees and patrons, and was caused by high free and combined chlorine levels. Other outbreaks related to recreational water exposure reported in the same time period were due to chlorine gas, trichloroamines, and microcystin toxin of cyanobacteria.

The recent phenomenon of *Sargassum* (seaweed) invasion throughout the Caribbean (Figures 118.9 and 118.10) has led to increasing reports of beachgoers and local hotel workers with acute and often severe inhalational poisoning due to hydrogen sulfide (H_2S) and ammonia, byproducts of *Sargassum* decomposition (see Resiere 2019). In addition to respiratory symptoms, chronic

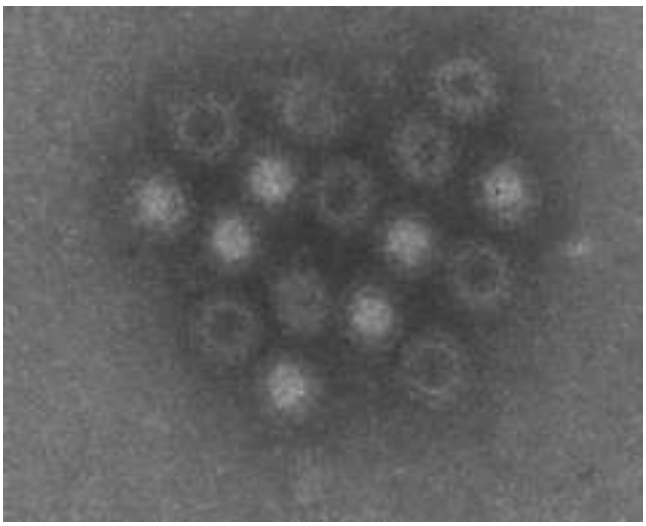

FIGURE 118.8 Electron micrograph of norovirus isolated from stool of a patient with acute gastroenteritis.

FIGURE 118.9 & 118.10 *Sargassum* weed befouling a beach in the Caribbean.

exposure to H_2S may lead to cardiac, neurologic, and neurocognitive manifestations. In the Caribbean, *Sargassum* weed incursion tends to peak during the months of January to April, precisely when tourist volumes are greatest. Consequently, in preparation for high tourist volumes, resorts and hotels grappling with *Sargassum* invasion retain more local workers to remove the weed, thereby also increasing the risk of occupational exposure among locals. While the mechanisms underpinning the huge global increases in "Yellow Tide" due to *Sargassum* weed are unclear, the scale of the economic, ecological, and health impacts of this phenomenon are enormous. Thus, efforts to remediate this situation are urgent and ongoing.

Travelers' diarrhea

Karen J. Vigil and Herbert L. DuPont

Diarrhea is the most frequent health problem encountered by persons going from industrialized to developing countries. Of the 100 million people traveling annually from industrialized to developing countries, approximately 40% will suffer from so-called travelers' diarrhea (TD), many more than once.

Classically, TD is defined as the passage of three or more unformed stools within 24 hours in association with at least one of the following symptoms of enteric infection: nausea, vomiting, abdominal pain or cramps, fever, fecal urgency, tenesmus, or the passage of bloody/mucoid (dysenteric) stools. This definition includes illness occurring up to 10 days after travelers return to their home countries.

Cases of TD can be categorized by severity as being mild (no disturbance in normal activities), moderate (modified travel activities required), or severe (illness requires confinement to bed). Fewer than 1% of patients are admitted to a hospital, but almost 40% are required to change their travel schedule.

Acute TD lasts for less than 2 weeks. Illness lasting more than 2 weeks is considered "persistent" and is seen in 2% to 10% of travelers. Possible etiologies of persistent diarrhea include intestinal infection by protozoal parasites, for example, giardiasis or cryptosporidiosis, and occasionally bacterial enteropathogens can cause a more protracted diarrhea. Unmasked gastrointestinal disease is seen in this setting occasionally, including irritable bowel syndrome, inflammatory bowel disease, and malabsorptive syndromes. Postinfectious irritable bowel syndrome, a recognized complication of bacterial enteric infection, has been shown to occur in as many as 10% of people after an episode of TD.

Food is the most important source of bacterial enteropathogens, which explains a majority of cases of TD. Water, which becomes more contaminated during rainy seasons, is often the source of viral gastroenteritis. Genetic factors contribute significantly to susceptibility to enteric infections. Fecal levels of inflammatory cytokines, including interleukin (IL)-8 and IL-1β, are often elevated in people who developed bacterial diarrhea. Host polymorphisms in the IL-8, IL-10, CD14, osteoprotegerin and lactoferrin genes were found to be associated with an increased susceptibility to TD.

Etiology

Bacterial enteropathogens cause up to 80% of TD cases. There is a relationship between geographic areas and the enteropathogens responsible for illness. For example, the diarrheagenic *Escherichia coli*, particularly enterotoxigenic *E. coli* (ETEC) and enteroaggregative *E. coli* (EAEC), are the major etiologic organisms in most areas of the developing world, responsible for ~50% to 60% of cases. Invasive pathogens, such as *Shigella, Salmonella*, and *Campylobacter*, represent 10% to 15% of cases but may account for up to 30% of cases in Asia, of which ciprofloxacin-resistant *Campylobacter* is of the greatest concern as it may not respond to customary self-treatment. Noncholera vibrios are found to cause TD in coastal areas of the world in a small number of cases. *Vibrio cholerae*, the causative agent of cholera, is a rare but serious cause of TD. *Klebsiella oxytoca, Laribacter hongkongensis*, enterotoxigenic *Bacteroides fragilis*, and *Arcobacter* have also been described as less frequent causes of TD.

Other than bacterial pathogens, parasites and viruses also cause TD. *Giardia* is an important pathogen in mountainous areas of North America and Russia. *Cryptosporidium* spp. are an important cause of diarrhea in travelers to Russia. *Cyclospora cayetanensis* has been found to be a causative organism of TD in Nepal, Haiti, and Peru. Rotavirus and norovirus are among the most common viruses described. Noroviruses have been identified in 10% to 20% of TD cases and remain a special problem on cruise ships.

The causes of TD in some areas of the world are also affected by the regional climate. ETEC was shown to be the major pathogen in the rainy, summer season in Mexico, with emergence of *Campylobacter jejuni* in the dry wintertime. In semitropical Morocco, *C. jejuni* was also found to be the most important pathogen in the dry winter season.

Prevention and chemoprophylaxis

Disease prevention is important to facilitate the purpose of the leisure or business trip and to prevent chronic enteric complications. Prevention measures consist of education for the future traveler on usually safe and occasionally unsafe foods and chemoprophylaxis.

Travelers should be instructed to avoid consuming moist foods served at room temperature and tap water (including ice). Food served steaming hot (>59°C), dry foods (e.g., bread), fruits that can be peeled, and foods with high sugar content (e.g., syrup, honey, or jelly) generally are safe.

Chemoprophylaxis may be used for short-term travel (≤3 weeks) in persons on a tight schedule (musicians, athletes, business persons, tourists, and politicians), in those who have experienced TD before (possibly related to genetic susceptibility), and for those who request it. Additional persons who might routinely employ chemoprophylaxis include those with underlying illness that might predispose them to increased risk of diarrhea or complications of illness, including persons with achlorhydria (from prior gastric surgery or regular use of proton pump inhibitors), inflammatory bowel diseases, human immunodeficiency virus (HIV) infection, transplant recipients or other immunosuppressions.

Bismuth subsalicylate (BSS) is modestly effective in the prevention of TD, with protection rates of approximately 65%. The dosage recommended for prophylaxis is two tablets (262 mg/tablet) orally with meals and at bedtime (eight tablets/day). Quinolones can prevent TD in up to 80% to 100% of cases. The emergence of quinolone-resistant *Campylobacter* spp. in South East Asia precludes their use in some areas of the world. Also, this class of drugs is too important for serious bacterial infection, and use for diarrhea prevention, which could encourage resistance development, cannot be justified. Rifaximin was shown to have a protection rate of 72% to 77% in a study in Mexico where diarrheagenic *E. coli* were the major pathogens. The drug was free of side effects when given for 2 weeks and was associated with minimal changes in fecal flora. We recommend rifaximin as the routine approach when chemoprophylaxis is desired because of its convenience and safety. It should not be given for trips longer than 2 to 3 weeks. The recommended dose is 200 mg (one tablet) with each of the major daily meals (usually two tablets a day) for as long as the person remains in the high-risk region.

Immunologic protection against ETEC diarrhea is feasible. An oral vaccine consisting of cholera toxin B subunit and inactivated whole-cell cholera strains has become available in some parts of the world. This vaccine confers protection against ETEC in up to 67%. However, it only has a 28% prevention rate for TD. A novel transcutaneous patch ETEC vaccine is also in development. Vaccination for TD with an anti-ETEC preparation can offer important protection from the major cause of the illness but cannot be completely protective because TD is a syndrome caused by multiple organisms.

Treatment

Hydration and dietary recommendations

Travelers' diarrhea can cause dehydration in infants, the elderly, or persons who have underlying medical illness. Fluids combined with electrolytes are the most important form of therapy. In the nondehydrated person without important underlying medical illness, commercially available sports drinks, diluted fruit juices, and other flavored soft drinks taken with saltine crackers and/or soups are usually enough to meet the fluid and salt needs during TD. Oral rehydration powders or solutions are also commercially available (e.g., CeraLyte).

During the early hours of diarrheal illness, it may be helpful to temporarily withhold solid foods that are complicated to absorb and that act as a stimulant of intestinal motility. In most cases of diarrhea, carbohydrates (noodles, rice, potatoes, oat, wheat, bananas) and steamed or baked white meats (fish and chicken) can be ingested. As illness improves and stools become formed, the diet can return to normal. In general, dairy products should be avoided in adults for the first day or two. It is important to feed patients with diarrhea to facilitate enterocyte renewal.

Nonantimicrobial therapy

Symptomatic therapy can be used in cases of mild TD. BSS is a commonly used antidiarrheal drug. This agent has antimicrobial, antisecretory, and anti-inflammatory properties. BSS can decrease the number of unformed stools passed in cases of TD by approximately 40%. BSS rarely causes mild tinnitus, and it commonly produces blackening of the tongue and stools from bismuth sulfide, a harmless salt of the nonabsorbed bismuth moiety. If a person is taking antimalarials for malaria prophylaxis, BSS should not be used concomitantly, because it can prevent absorption of the antimalarial drug.

Antimotility agents such as loperamide (Imodium) and diphenoxylate with atropine (Lomotil) are synthetic opioids that have selective effects on the intestine. These agents can improve diarrhea by slowing intestinal transit, leading to greater absorption of fluids and electrolytes. Loperamide is a drug of choice for symptomatic treatment of subjects without fever and not passing bloody

TABLE 119.1 **RECOMMENDED EMPIRIC TREATMENT OF TRAVELERS' DIARRHEA IN ADULTS**

Agent	Dosages	Comments
Loperamide	4 mg initially, then 2 mg after each stool, not to exceed 8 mg/d[a]	Should not be used in patients with fever and dysentery
Bismuth subsalicylate	30 mL or 2 tablets (262 mg/tablet) PO q 30 min up to 8 doses/d[a]	Should not be used with doxycycline when used for malaria prophylaxis Caution in people taking aspirin
Ciprofloxacin	500 mg PO BID or 750 mg PO qd for 1–3 d	Treatment failures most common because of resistant strains of *Campylobacter*
Rifaximin	200 mg PO TID for 3 d	Not recommended for febrile dysenteric diarrhea
Azithromycin	1000 mg single dose or 500 mg PO 1× and then 250 mg qd for 1 or 2 more d	Treatment of choice for febrile dysentery when *Campylobacter* is known to be the causative agent

[a] To be used for no more than 48 h.

stools. This agent will reduce the number of stools passed during a diarrhea episode by approximately 60%.

Antisecretory agents are being developed that work through a variety of pathways including calmodulin inhibition, chloride channel inhibition, and enkephalinase inhibition. In the United States a chloride channel inhibitor, crofelemer, is being developed for acute secretory diarrhea.

Antimicrobial therapy

Antimicrobial therapy in patients with TD shortens the duration of diarrhea and cures the disease. Clinical trials use time from initiation of therapy to passage of the last unformed stool (TLUS) as a primary parameter of efficacy. Antibiotic therapy is indicated in patients with moderate to severe disease because it has been shown to reduce TLUS by 1 to 3 days compared with placebo.

A variety of effective treatments for TD are available (Table 119.1). Rifaximin, 200 mg three times a day (TID) for 3 days, has a TLUS of 25.7 hours and a treatment failure of 10%, similar to ciprofloxacin, 500 mg twice a day (BID) for 3 days (25 hours and 6%, respectively), for treatment of noninvasive forms of the disease. Poorly absorbed (≤0.4%) rifaximin has an advantage for uncomplicated watery diarrhea in its safety profile. Rifaximin is not effective in the treatment of invasive forms of TD, particularly those associated with fever or dysentery.

For febrile dysenteric diarrhea, a systemic antibiotic, including the fluoroquinolones (ciprofloxacin, levofloxacin) or azithromycin, is preferred. Fluoroquinolones should not be used in children and pregnant women because they have been shown to damage articular cartilage in growing animals. These agents may interfere with xanthine metabolism, so patients taking theophylline may need to adjust their dosage of the drug. Fluoroquinolone resistance has become a problem with *Campylobacter* strains seen worldwide, which is a limitation of ciprofloxacin or levofloxacin.

Azithromycin is an azalide antibiotic related to macrolides and is more active than erythromycin against ETEC, *Salmonella* species, *Shigella* species, *V. cholerae*, and *C. jejuni*. In a clinical trial in Thailand, where *Campylobacter* has become resistant to ciprofloxacin, azithromycin was more effective than ciprofloxacin against *Campylobacter*. Azithromycin is effective against most forms of bacterial diarrhea and can be given as a single 1000-mg dose or daily in a lower dose for 3 days (see Table 119.1). Azithromycin may be the drug of choice for some regions of Asia where invasive pathogens are most common and is also the drug of choice for rescue therapy when rifaximin chemoprophylaxis is employed.

Travelers to high-risk areas should be encouraged to take with them an antibiotic for self-treatment of diarrhea that develops. It takes approximately 24 hours for a drug to cure the diarrhea. The antibiotic can be started after passage of the third unformed stool, to avoid unnecessary exposure to antibiotics for milder self-limiting syndromes. Some travel medicine experts prefer to begin the treatment with passage of the first unformed stool in a diarrheal episode to help reduce the duration of illness.

Combination therapy

Perhaps the optimal approach for empiric treatment of nondysenteric TD is to give the combination of loperamide with an antibiotic to combine a near-immediate effect of the loperamide with a curative effect of the antibiotic. This approach is not appropriate for patients with febrile, dysenteric diarrhea where a systemically absorbed antimicrobial agent alone should be used.

Bioterrorism

Megan C. Gallagher and Andrew W. Artenstein

Introduction

Bioterrorism (BT), the deliberate use of microbial agents or their toxins as weapons for political gain, continues to represent a persistent global threat due to the widespread availability of these substances and the opportunities for terrorists to deploy them against civilian targets. Despite the relative paucity of known BT events in the recent past, the potential for catastrophic consequences associated with exposure to biologic threat agents remains high. A precise calculation of "risk" as it relates to BT is not possible as the probability of exposure to these hazards is unknown—it remains in the unpredictable and malicious minds of terrorists. Nonetheless, due to the potential for devastating sequelae, it is important for clinicians to understand the diagnostic and therapeutic approach to illnesses caused by agents of BT in order to mitigate the effects of an attack.

BT agents are considered weapons of mass terror because of their potential for large-scale morbidity and mortality. For example, one early model predicted nearly 200,000 casualties from a release of 50 kg of aerosolized anthrax spores upwind of a population center of 500,000. Based on more recent experience—the US anthrax attacks of 2001 that resulted in 11 cases of systemic disease associated with 5 deaths—it is evident that even relatively small-scale events may cause mass terror.

Unlike conventional, chemical, and nuclear weapons, BT agents are associated with a clinical latency period during which transmission may occur and detection is difficult. The US Centers for Disease Control and Prevention (CDC) has classified BT threats into priority groupings based on their feasibility for deployment and their potential for mortality, morbidity, and public health impact; this categorization (Table 120.1) has continued to inform current biodefense strategies.

Clinical presentation

The clinical pictures of diseases caused by agents of BT are varied but, with few exceptions among the CDC category A and B threats, can be categorized into a limited number of syndromic presentations (Table 120.2). Unfortunately, there are scant pathognomonic features of BT-related illness, only suggestive ones, mandating a high index of suspicion among clinicians to capitalize on subtle clues, many of which may be epidemiologic in nature. However, the suggestive clinical and laboratory findings (Table 120.2) associated with the agents, when interpreted in the appropriate clinical and epidemiologic contexts, should prompt further, targeted evaluations and warrant empiric management. More detailed clinical information on each agent is covered in organism-specific chapters of this book.

TABLE 120.1 **AGENTS OF CONCERN FOR USE IN BIOTERRORISM**

Microbe/Toxin	Disease
Highest priority—Category A	
Based upon high potential mortality, morbidity, virulence, transmissibility, aerosolization feasibility, psychosocial implications of an attack, and major public health impact	
Bacillus anthracis	Anthrax: Inhalational, gastrointestinal, cutaneous, injection
Variola virus	Smallpox and its variants
Yersinia pestis	Plague: Pneumonic, bubonic, septicemic
Clostridium botulinum	Botulism
Francisella tularensis	Tularemia: Pneumonic, typhoidal
Viral hemorrhagic fevers	
Filoviruses	Ebola, Marburg
Arenaviruses	Lassa fever, South American hemorrhagic fevers
Bunyaviruses	Rift Valley fever, Congo–Crimean hemorrhagic fever
Moderately high priority—Category B	
Based upon moderate potential morbidity, aerosolization feasibility, dissemination characteristics, and diagnostic difficulty	
Coxiella burnetii	Q fever
Brucella species	Brucellosis
Burkholderia mallei	Glanders
Burkholderia pseudomallei	Melioidosis
Chlamydia psittaci	Psittacosis
Rickettsia prowazekii	Epidemic typhus
Alphaviruses	Viral encephalitides
Ricin	Ricin intoxication
Staphylococcus enterotoxin B	Staphylococcal toxin illness
Epsilon toxin of Clostridium perfringens	Intoxication
Salmonella species, Shigella dysenteriae, Escherichia coli 0157;H7, Vibrio cholerae, Cryptosporidium parvum	Food- and waterborne gastroenteritis
Emerging threat agents—Category C	
Based upon potential to be engineered due to ease of production and dissemination, availability, potential for high morbidity/mortality	
Hantaviruses	Viral hemorrhagic fevers
Flaviviruses	Yellow fever
Mycobacterium tuberculosis	Multidrug-resistant tuberculosis
Nipah virus	Systemic, flu-like illness
Miscellaneous	
Other examples of candidate threat agents that possess some elements of future BT concern	
Genetically engineered vaccine, and/or antimicrobial-resistant Category A or B agents	
Human immunodeficiency virus 1	
Adenoviruses	
Influenza	
Rotaviruses	
Hybrid pathogens: e.g., smallpox/plague, smallpox/Ebola	

Diagnosis

Rapid detection and accurate identification of BT agents is important not only for confirming that a BT event has occurred but also for treating individual patients and implementing appropriate public health measures. By definition, BT is insidious; in the absence of credible advance notification, it is likely that clustered, syndromic, clinical illness will be the initial manifestation of a BT attack. Although critical, early recognition is challenging for a variety of reasons: (1) targets of BT, especially in an open society, are myriad, diverse, and unpredictable; (2) the clinical latency of BT agents makes it likely that clusters of symptomatic individuals will present for medical care days to weeks after an "event" and at geographically diverse locations; (3) initial clinical manifestations of many BT-related illnesses are nondiagnostic and may be mistaken for other, more common but less impactful diagnoses; (4) clinicians are inexperienced with the clinical manifestations of these infections; and (5) even if the classic clinical findings are known, because BT agents are manipulated in the laboratory, their associated clinical syndromes may present differently from those arising from naturally occurring infection. Conversely, in the setting of a high level of suspicion, early recognition may be aided by a number of epidemiologic and clinical clues: (1) *case clustering*, which, because of the clinical latency of BT, requires attention to geographic surveillance and robust communications systems; (2) *unusual clinical presentations* of common syndromes, such as fulminant pneumonia in otherwise healthy young adults; or (3) *unusual disease patterns*, such as rare diseases occurring in traditionally nonendemic areas or concurrent disease in humans and animal populations.

The CDC has developed a national laboratory response network (LRN) for BT that integrates selected microbiologic laboratories across the United States into a network and mandates uniform practices for specimen collection, processing, shipping, security, and testing. Laboratories within the LRN consortium are designated as having screening, confirmatory, or reference functions. The network of laboratories is connected by a secure communications system, thus ensuring the timely flow of information among the CDC, other governmental agencies, state health authorities, and other laboratories. The mission of the LRN is to enable a rapid and organized response to BT; the CDC routinely audits the performance of network members using panels of unknown pathogens.

Although diagnostic tests are available for most BT agents, many are not readily available in clinical laboratories, are time-consuming, have less than optimal sensitivity and specificity, or cannot test for multiple agents simultaneously. Diagnostic platforms that can assess for the presence of multiple pathogens concurrently, so-called *multiplex strategies*, offer attractive advantages, especially in the arenas of environmental surveillance and in screening either patients presenting with nonspecific symptoms or asymptomatic individuals who have possible exposure to an unknown agent.

The preferred methods for the laboratory diagnosis of BT agents differ depending on the agent in question. For most bacterial agents the gold-standard diagnostic assay remains standard culture; other supporting assays include modified staining with light microscopy, motility testing, lysis by γ-phage, capsule production staining, hemolysis, wet mounts, staining for spores, slide agglutination, direct fluorescent antibody, enzyme-linked immunosorbent assay (ELISA), and rapid immunochromatography. Routine assays for viral agents include virus isolation through tissue culture or growth in eggs, direct and indirect immunofluorescence, immunodiffusion in agar, electron microscopy, modified staining and light microscopy, plaque reduction neutralization, hemagglutination inhibition, neuraminidase activity, complement fixation, and ELISA. Pathologic examination of tissues and immunohistochemistry also play an important role in diagnosing BT agents.

Molecular assays are becoming the new gold standard for BT detection, with sensitivities and specificities close to 100% when compared with culture or serologic assays. These assays detect infectious agents in humans through target nucleic acid isolation and amplification followed by specific pathogen identification. Several technologies and methods have been used for multiplex detection of different BT agents. Although still in the developmental stages, it is likely that DNA microfluidic devices will be commonly used diagnostic platforms in the future. These methods are sensitive and specific and theoretically can be used on unprocessed specimens in field settings, thus obviating laborious microbial isolation steps. However, several challenges, including sampling issues, data analysis, development of specific probes, quality control, cost containment, automation, performance, and integration, must be addressed before such methods replace the standard ones.

Laboratory diagnosis of specific Category A agents

Bacillus anthracis

Presumptive laboratory identification of *Bacillus anthracis* (Figures 120.1 and 120.2) is based on the presence of large gram-positive bacilli in either gram- or immunohistochemical-stained material from skin lesions, cerebrospinal fluid, pleural fluid, or blood in an appropriate clinical setting or on the growth of aerobic, nonhemolytic, large, catalase-positive, gray-white colonies on sheep-blood-agar cultures containing nonmotile, nonencapsulated, gram-positive, spore-forming rods. Although the diagnosis may be suspected at the screening laboratory level, confirmatory diagnostic tests must be performed in containment facilities of the LRN. Such tests include susceptibility to lysis by γ-phage and polymerase chain reaction (PCR); the US Food and Drug Administration (FDA) has approved a real-time PCR assay for the diagnosis of anthrax. There is ongoing investigation into rapid and point-of-care tests, including GeneXpert, a PCR-based test, and matrix-assisted laser desorption ionization-time-of-flight (MALDI-TOF), which uses mass spectrometry on peptides. Although there are no assays that have been rigorously and prospectively validated for the rapid diagnosis of inhalational anthrax during its early, nonspecific clinical stages, the development of assays that detect cell wall and capsular antibodies and anti-protective antigen responses should improve the outlook for early diagnosis of anthrax.

Serologic testing is of little value in the diagnosis of acute disease but may have some use in exposed survivors who demonstrate

TABLE 120.2 **SYNDROMIC DIFFERENTIAL DIAGNOSES AND CLINICAL CLUES FOR CATEGORY A AGENTS OF BIOTERRORISM (BT)**

Syndrome	Clinical presentation	Differential diagnosis	BT-associated disease	BT disease-specific clues
Influenza-like illness	Nonspecific constitutional and upper respiratory symptoms: malaise, myalgias, nausea, emesis, dyspnea, cough ± chest discomfort, without coryza or rhinorrhea → abrupt onset of respiratory distress ± shock ± mental status changes, with CXR abnormalities (wide mediastinum or infiltrates or pleural effusions)	Influenza, community-acquired bacterial pneumonia, viral pneumonia, *Legionella*, Q fever, psittacosis, mycoplasma, *Pneumocystis* pneumonia, tularemia, dissecting aortic aneurysm, bacterial mediastinitis, SVC syndrome, histoplasmosis, coccidioidomycosis, sarcoidosis, ricin, and *Staphylococcus* enterotoxin B (pulmonary edema/ARDS)	Inhalational anthrax	3-day average symptom duration before presentation Abdominal pain, headache, mental status abnormalities, hypoxemia common Mediastinal adenopathy: ~90% (Figure 120.1) Hemorrhagic pleural effusions: ~70% CT more sensitive than CXR in early hemorrhagic mediastinal adenopathy Meningoencephalitis: possibly ~50% Blood cultures positive in untreated; pleural fluid cultures or antigen-specific immunohistochemical stain usually positive
Skin lesions	Pruritic, painless papule on exposed areas→vesicle(s)→ulcer→edematous black eschar ± massive local edema and regional adenopathy, ± fever, evolving over 3–7 days	Recluse spider bite, staphylococcal lesion, atypical Lyme disease, Orf, glanders, tularemia, plague, rat-bite fever, ecthyma gangrenosum, rickettsialpox, atypical mycobacteria, cutaneous diphtheria, cutaneous leishmaniasis	Cutaneous anthrax	Painless; spider bite is painful lesion Nonpitting local edema may be massive (Figure 120.2) If untreated, may progress to systemic involvement Blood cultures, skin biopsy (from vesicular edge or erythema at edge of eschar)
Fulminant pneumonia	Abrupt-onset constitutional symptoms and rapidly progressive respiratory illness with cough, fever, rigors, headache, sore throat, myalgias, dyspnea, pleuritic chest pain, GI symptoms, lung consolidation, ± hemoptysis, ± shock; variable progression to respiratory failure	Severe community-acquired bacterial or viral pneumonia, inhalational anthrax, pulmonary infarct, pulmonary hemorrhage, influenza, mycoplasma pneumonia, *Legionella*, Q fever, SARS, tuberculosis	Pneumonic plague Pulmonary tularemia	Lobar or multilobar involvement ± buboes Hemoptysis common Characteristic sputum Gram stain Cough generally nonproductive Pulse–temperature dissociation in 40% Hilar adenopathy, pleural effusions Ulceroglandular form most common after natural or cutaneous exposures Erythema multiforme or nodosum in significant minority of systemic disease

TABLE 120.2 **CONTINUED**

Syndrome	Clinical presentation	Differential diagnosis	BT-associated disease	BT disease-specific clues
Sepsis with bleeding diathesis and capillary leak	Sepsis syndrome, GI symptoms, mucosal hemorrhage, altered vascular permeability, DIC, purpura, acral gangrene, hepatitis, hypotension, ± CNS findings, multiorgan system failure	Meningococcemia; gram-negative sepsis, streptococcal, pneumococcal, or staphylococcal bacteremia with shock; malaria, leptospirosis, typhoid fever, borrelioses, typhoidal tularemia; overwhelming postsplenectomy sepsis; acute leukemia; Rocky Mountain spotted fever; fulminant hepatitis, TTP, hemolytic-uremic syndrome, SLE, hemorrhagic smallpox; hemorrhagic varicella (in immunocompromised)	Septicemic plague Viral hemorrhagic fever	Occurs in minority of aerosol exposures Cutaneous findings as late sequelae ± buboes High-density bacteremia Maculopapular rash in Ebola, Marburg Certain organ systems preferentially involved with specific VHF etiologies
Febrile prodrome with generalized exanthem	Fever, malaise, prostration, headache, myalgias, and enanthema followed by development of synchronous, progressive, centrifugal papular→vesicular→pustular rash on face, mucous membranes, extremities→trunk→generalization ± hemorrhagic component, with systemic toxicity	Varicella, drug eruption, Stevens–Johnson syndrome, measles, secondary syphilis, erythema multiforme, severe acne, disseminated herpes zoster or simplex, meningococcemia, monkeypox, generalized vaccinia related to smallpox vaccination, insect bites, Coxsackievirus, vaccine reaction	Smallpox	Palms and soles involved Rash is denser peripherally even after fully evolved (Figures 120.3, 120.4) Lesions are well circumscribed, uniform, and almost nodular (Figure 120.5) Secondary bacterial infection common Hemorrhagic variant in pregnant and immunocompromised patients associated with severe systemic toxicity, bleeding diathesis, and early mortality
Progressive weakness	Acute onset of afebrile, symmetric, descending flaccid paralysis that begins in bulbar muscles, dilated pupils, diplopia or blurred vision, dysphagia, dysarthria, ptosis, dry mucous membranes→airway obstruction + respiratory muscle paralysis, clear sensorium and absence of sensory changes	Myasthenia gravis, brainstem CVA, polio, Guillain–Barré syndrome variant, tick paralysis, chemical intoxication	Botulism	Expect dearth of GI symptoms in aerosol attack as opposed to foodborne botulism Low-dose inhalation exposure may delay symptom onset Prominent anticholinergic effects

Abbreviations: CXR = chest x-ray; SVC = superior vena cava; ARDS = acute respiratory disease syndrome; CT = computed tomography; GI = gastrointestinal; SARS = severe acute respiratory syndrome; DIC = disseminated intravascular coagulation; CNS = central nervous system; TTP = thrombotic thrombocytopenic purpura; SLE = systemic lupus erythematosus; VHF = viral hemorrhagic fever; CVA = cerebrovascular accident.

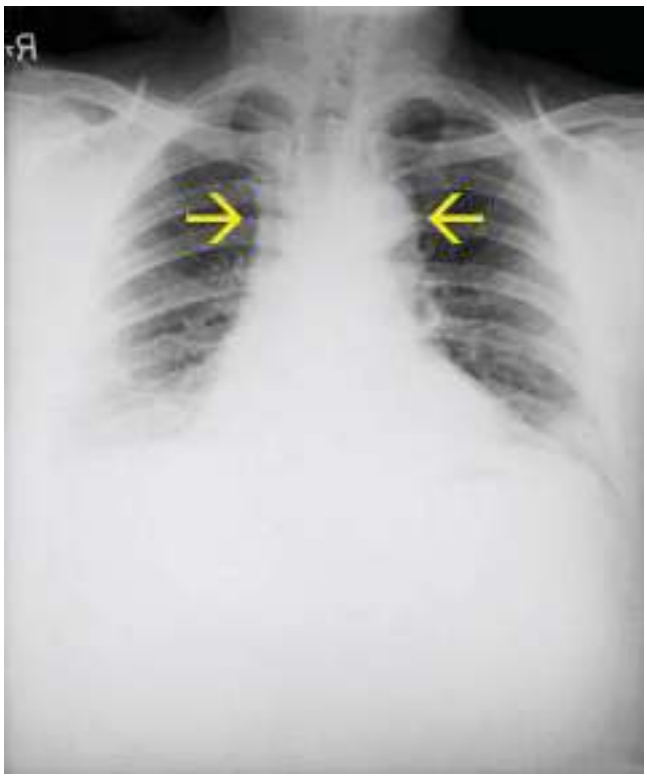

FIGURE 120.1 Inhalational anthrax. Note widened mediastinum (arrows). (Courtesy of Centers for Disease Control and Prevention).

seroconversion. The use of nasal cultures for detecting *B. anthracis* early after potential exposure may be of some use in defining the epidemiologic parameters of exposure but is not useful in making individual decisions about the use of treatment or prophylaxis.

Yersinia pestis

The gold standard for *Y. pestis* diagnosis remains standard microbiologic techniques such as microscopy of stained specimens and culture applied to expectorated sputum, bronchial washings, blood, or lymph node aspirates. The organism is suggested by its characteristic appearance as small gram-negative coccobacillary forms with bipolar, "safety-pin," uptake of Wright–Giemsa stain. *Y. pestis* grows slowly at routine incubation temperatures and may be misidentified by automated identification systems. Confirmation of the diagnosis requires the deployment of specialized testing: direct fluorescent antibody tests to detect the presence of F1 envelope antigen or PCR. Rapid tests to detect the F1 antigen are under investigation for potential field applicability on direct clinical specimens.

FIGURE 120.2 Cutaneous anthrax. (Courtesy of University of Heidelberg).

Francisella tularensis

Francisella tularensis appear as small, intra- and extracellular gram-negative coccobacilli in stains of clinical specimens. Because the organism does not grow readily in standard laboratory media and because it is highly infectious to laboratory personnel, specialized microbiologic and safety procedures must be instituted for this pathogen. For this reason, the diagnosis is usually based on clinical features, and cultures should be pursued in higher level laboratories of the LRN. Blood cultures are often negative, but samples that can be tested include swabs of skin lesions, lymph node aspirates, pharyngeal swabs, and sputum samples. Presumptive diagnosis can be made using direct fluorescent antibody, immunohistochemical staining, or PCR. Serology is generally useful only in retrospect as it takes >2 weeks to develop a serologic response in most individuals.

Clostridium botulinum

The diagnosis of botulism is largely based on epidemiologic and clinical features and the exclusion of other possible differential diagnoses. If laboratory diagnosis is necessary, the gold standard currently remains a mouse bioassay at a reference laboratory; PCR may have some utility in detecting *C. botulinum* nucleic acids in environmental samples.

Smallpox

The majority of smallpox cases present with a vesicular, centrifugal rash (Figures 120.3, 120.4, and 120.5) that, in the appropriate clinical and epidemiologic context, should prompt immediate notification of state or local public health authorities; specimens from suspected smallpox patients must be collected and transported under the direction of health authorities and in collaboration with the facilities of the LRN. Laboratory confirmation of the clinical diagnosis, especially in early or atypical cases in a suspected outbreak, is important; clinical diagnosis is probably sufficient in a confirmed outbreak. Infection control measures should be implemented prior to the acquisition of specimens in suspected cases.

Diagnostic assays in smallpox are typically performed on lesion scrapings, vesicular fluid, crusts, blood, or tonsillar swabs. A presumptive poxvirus diagnosis may be obtained by observing brick-shaped virions on electron microscopy of vesicular scrapings or by noting aggregations of virus particles, *Guarnieri bodies*, on histopathologic examination of tissue specimens. Isolation of variola virus in live cell cultures, followed by nucleic acid identification of specific orthopoxvirus species, is confirmatory but only performed in national reference laboratories with the highest level of biocontainment. The

FIGURE 120.3 Smallpox. Note heavy concentration of lesions on face and extremities compared to trunk. Compare also to the truncal concentration seen in varicella. (Courtesy of World Health Organization).

FIGURE 120.4 Progression of smallpox exanthem over the first eight days of illness. (Courtesy of World Health Organization).

FIGURE 120.5 Smallpox. Lesions are characteristically round, uniform in size, and at same stage of development. (Courtesy of Centers for Disease Control and Prevention).

development of standard and multiplexed PCR platforms promises a reliable and less cumbersome way to discriminate between variola and other orthopoxviruses in clinical specimens.

Viral hemorrhagic fevers

For Ebola virus, presumptive testing using real-time RT-PCR, preferably on whole blood, is available at more than 60 LRN laboratories. Confirmatory testing is then performed at the CDC. For other agents of viral hemorrhagic fevers (VHFs), clinical microbiology and public health laboratories are not currently equipped to make a rapid diagnosis; therefore, clinical specimens must be sent to the CDC or the US Army Medical Research Institute of Infectious Diseases (USAMRIID), the highest level laboratories in the LRN. Definitive diagnosis depends on identification of a specific viral etiology. Methods of early diagnosis at specialized laboratories include rapid enzyme immunoassays for antigen detection or viral immunoglobulin M (IgM), reverse transcriptase-PCR, and viral isolation in a biosafety level-4 facility. In general, serology is of limited value in early diagnosis because antibodies to these viruses usually do not appear until after the second week of illness.

Management

Once the diagnosis of BT-associated illness is considered, the initial step in the evaluation and management of an individual or group of patients is the immediate implementation of appropriate infection control measures according to the suspected agents (Table 120.3). This will ensure the maximal protection of first responders and healthcare workers as well as other patients in the healthcare environment. Empiric antimicrobial therapy of BT-associated illness should be initiated once the diagnosis is seriously considered as the early institution of appropriate therapy will not only potentially confer outcome advantages but may also potentially limit the spread of transmissible pathogens. The use of prophylactic antimicrobials is warranted for some agents. Recommendations for specific antimicrobial strategies for diseases caused by category A agents of BT are provided in Table 120.4.

Anthrax

Given the rapid clinical progression and attendant high mortality of inhalational anthrax, the early administration of appropriate, combination antimicrobials is essential and is likely to confer a survival advantage because patients appear to quickly reach a clinical threshold beyond which survival is unlikely. There have been no controlled clinical studies for the treatment of inhalational anthrax in humans because of its rare and sporadic occurrence in nature.

Many patients with cutaneous anthrax can be successfully treated as outpatients; however, those with cutaneous infection involving the head, neck, or upper torso areas or with signs of systemic inflammatory response syndrome or those with inhalational or injection anthrax generally require hospitalization. Although there are different pathophysiologic mechanisms underlying systemic anthrax and traditional severe sepsis, standard guidelines used for hemodynamic support in the latter condition should be followed. Additionally, aggressive and repeated drainage of pleural effusions may improve both ventilation and survival. Limited surgical debridement is indicated in cases of injection anthrax for diagnostic purposes and to debulk potential toxin reservoirs.

During the anthrax attacks in the United States in 2001, the CDC promulgated treatment protocols recommending combination antimicrobials for the initial management of suspected inhalational anthrax; these have recently undergone further refinement (Table 120.4). Reasons to empirically treat with multiple drugs include heightened concerns regarding the deployment of antimicrobial-resistant pathogens by terrorists; the high potential for meningeal involvement in victims of systemic anthrax, necessitating the achievement of adequate drug levels in the central nervous system; and the potential for additive or synergistic effects using multiple therapies with different targets.

Once the antimicrobial susceptibility profile of the organism has been determined and clinical improvement is evident, therapy may be tailored. Isolated cutaneous disease may be managed with single, oral antimicrobials but, as in other forms of anthrax, monotherapy using β-lactam agents is contraindicated due to resistance concerns. The recommended duration of therapy is 60 days for all BT-associated forms of anthrax due to presumed concomitant inhalational exposure to the primary aerosol and experimental animal data supporting a persistent risk of latent infection from delayed germination of spores.

Because anthrax is a toxin-mediated illness, some advocate the use of clindamycin as part of combination therapy despite the dearth of clinical data, citing the drug's theoretical benefit of diminishing bacterial toxin production, a strategy employed in some toxin-mediated streptococcal infections. Central nervous system penetration is another consideration in therapy selection and drives the preferential use of ciprofloxacin over doxycycline, plus augmentation with chloramphenicol, rifampin, or penicillin when meningitis is suspected. Corticosteroids have been used as adjunctive therapy in the setting of meningitis or severe mediastinal or head/neck edema, but there are scant data of their definitive efficacy.

Two new monoclonal antibodies, raxibacumab and obiloxaximab, directed against the protective antigen moiety of

TABLE 120.3 **EPIDEMIOLOGIC CHARACTERISTICS FOR SELECTED BIOTERRORISM-ASSOCIATED DISEASES**

Disease	Incubation period range (days)	Person-to-person transmission	Infection control precautions for patients	Case-fatality rate
Systemic anthrax with probable or confirmed meningitis	2–58[a]	No	Standard	81%[b]
Inhalational anthrax	2–58[a]	No	Standard	65%[b]
Gastrointestinal anthrax		No	Standard	57%[b]
Cutaneous anthrax	1–12	No	Standard	4%[b]
Botulism	12–72 hours	No	Standard	6%
Primary pneumonic plague	1–6	Yes	Droplet	Untreated: ~100% Treated: 57%
Bubonic plague	2–8	No	Standard	Untreated: 60% Treated: <5%
Smallpox	7–19	Yes	Contact + airborne	Unvaccinated: 30% Vaccinated: 3%
Tularemia pneumonia	1–21	No	Standard	Untreated: 60% Treated: <4%
Viral hemorrhagic fevers	2–21	Yes	Contact + airborne	Marburg: 23–70% Ebola: 20–40% with optimal supportive care Ebola: 75-90% without supportive care Other forms: 2%–30%
Viral encephalitides	1–14	No	Standard	10%–35%
Q fever	2–41	No	Standard	3%
Brucellosis	5–60	No	Standard	Untreated: 5%
Glanders	1–21	Yes	Contact + droplet	Untreated: approaches 100% Treated: low

[a] Based on limited data from human outbreaks and animal aerosol challenges.
[b] Based on a cumulative case series from 1941 to 2014, including those receiving a variety of antibiotic treatments

anthrax toxin, are now FDA-approved for the treatment of inhalation anthrax, in conjunction with antibiotics. These antibodies do not cross the blood–brain barrier, so they cannot be used for the treatment or prevention of meningitis.

Anthrax vaccine has been proved effective in preventing cutaneous anthrax in human clinical trials and in preventing inhalational disease after aerosol challenge in nonhuman primates. The vaccine, which acts by generating an immune response to protective antigen, a key component of anthrax toxin, has been generally found to be safe and has been recommended, in combination with antimicrobials, in a three-dose regimen as postexposure prophylaxis following exposure to aerosolized spores. The monoclonal antibodies can also be used as postexposure prophylaxis if elements of the first-line prophylaxis regimen are not available. Passive immunotherapy with anthrax immunoglobulin may serve an adjunct role to antimicrobials and may provide additional benefit in illness caused by multidrug-resistant pathogens.

Plague

Yersinia pestis is typically susceptible in vitro to penicillins, many cephalosporins, carbapenems, aminoglycosides, quinolones, and tetracyclines. It is variably susceptible to trimethoprim, chloramphenicol, and rifampin and is commonly resistant to macrolides and clindamycin. Recommended therapeutic approaches to plague in the BT setting are detailed in Table 120.4.

Naturally occurring antibiotic-resistant strains of *Y. pestis* have been reported in endemic areas of the world and are extremely concerning with respect to the development of biologic weapons.

Production of the currently licensed formalin-inactivated vaccine was discontinued by its manufacturers in 1999; this product had demonstrated efficacy in preventing or ameliorating bubonic disease but not primary pneumonic plague. A subunit vaccine using a bacterial capsular protein has demonstrated protective efficacy in an animal model of pneumonic plague.

TABLE 120.4 TREATMENT RECOMMENDATIONS FOR BIOTERRORISM CATEGORY A AGENTS IN ADULTS

	Anthrax-systemic
Treatment	Initial IV therapy when meningitis possible: ciprofloxacin 400 mg q8h *and* meropenem 2 g q8h *and* linezolid 600 mg q12h (levofloxacin or moxifloxacin as alternates to ciprofloxacin; imipenem, penicillin G, or ampicillin as alternates to meropenem; clindamycin or rifampin as alternates to linezolid) If meningitis is excluded, optimal first-line therapy is ciprofloxacin 400 mg q8h *and* clindamycin 900 mg q8h (PCN G, levofloxacin, moxifloxacin, ampicillin, or meropenem as alternates to ciprofloxacin; linezolid, doxycycline, or rifampin as alternates to clindamycin). Oral follow-up therapy using ciprofloxacin 500 mg q12h or doxycycline 100 mg q12h (levofloxacin, moxifloxacin, or clindamycin as alternatives) Raxibacumab and obiltoxaximab are anti-protective antigen monoclonal antibodies newly approved for the treatment of inhalation anthrax Administer with antibiotics They do not cross the blood-brain barrier, so cannot be used to prevent or treat meningitis Pre-medicate with diphenhydramine as hypersensitivity reactions can occur
Postexposure prophylaxis	Ciprofloxacin 500 mg orally q12h *or* doxycycline 100 mg orally q12h *plus* anthrax vaccine (unlicensed indication) Use levofloxacin or moxifloxacin as alternates • Amoxicillin 500 mg orally q8h for pregnant women Raxibacumab and obiltoxaximab can be used for prophylaxis of inhalation anthrax when alternatives are not available or cannot be used
Comments	IV treatment initially before switching to oral antimicrobial therapy when clinically appropriate; IV treatment should be used for 2 weeks or until patient is stable, whichever is longer Use of β-lactams should be informed by susceptibility profile Continue oral treatment to complete total of 60 days Treatment for immunocompromised individuals and pregnant women as above; recommendation based on life-threatening nature of illness
	Anthrax–cutaneous
Treatment	Oral therapy: ciprofloxacin 500 mg q12h or doxycycline 100 mg q12h (levofloxacin, moxifloxacin, or clindamycin as alternatives) for 60 days
	Botulism
Treatment	Early administration of antitoxin Supportive treatment (hydration, nasogastric suctioning for ileus, mechanical ventilation for respiratory failure)
Postexposure prophylaxis	Antitoxin administration
	Plague
Treatment	Preferred: streptomycin 1 g intramuscular BID *or* gentamicin 5 mg/kg intramuscular or IV once daily or 2 mg/kg loading dose followed by 1.7 mg/kg intramuscular or IV 3 times daily Alternative: doxycycline 100 mg IV BID or ciprofloxacin 400 mg IV BID or chloramphenicol 25 mg/kg IV 4 times daily
Postexposure prophylaxis	Preferred: doxycycline 100 mg orally BID *or* ciprofloxacin 500 mg orally BID Alternative: chloramphenicol 25 mg/kg orally 4 times daily

TABLE 120.4 CONTINUED

	Anthrax-systemic
Comments	10 days for treatment regimens 7 days for postexposure prophylaxis
	Smallpox
Treatment	Tecovirimat is a new, FDA-approved treatment for smallpox and other orthopoxviruses—600 mg BID for 14 days Antimicrobial agents effective against *Staphylococcus aureus* and streptococci should be used if smallpox lesions are secondarily infected, if bacterial infection endangers the eyes, or if the eruption is very dense and widespread Adequate hydration and nutrition for substantial fluid and protein losses Topical idoxuridine should be considered for the treatment of corneal lesions, although its efficacy is unproved for smallpox
Postexposure prophylaxis	Vaccination within 7 days of exposure unless contraindicated
	Tularemia
Treatment	Preferred: streptomycin 1 g intramuscular BID *or* gentamicin 5 mg/kg intramuscular or IV once daily Alternative: doxycycline 100 mg IV BID or ciprofloxacin 400 mg IV BID *or* chloramphenicol 15 mg/kg IV 4 times daily (not to be used in pregnancy)
Postexposure prophylaxis	Doxycycline 100 mg orally BID or ciprofloxacin 500 mg orally BID
	Viral hemorrhagic fevers
Treatment	Mainstay of treatment is supportive care—maintaining volume and electrolyte balance, correcting acid-base disturbances ZMapp is a cocktail of three neutralizing antibodies used to treat Ebola and is available in the US under an expanded access protocol Ribavirin for confirmed or suspected Bunyaviridae (Old World Hantavirus, Crimean–Congo hemorrhagic fever, Rift Valley fever) and Arenaviridae (Lassa virus) infections under an Investigational New Drug (IND) protocol Ribavirin not useful for Ebola or Marburg viral hemorrhagic fevers

Ribavirin	**Loading dose**	**Maintenance dose**
Intravenous	30 mg/kg IV (maximum 2 g) once	16 mg/kg IV (maximum 1 g per dose) q6h for 4 days followed by 8 mg/kg IV (maximum 500 mg per dose) q8h for 6 days
Oral	2000 mg orally once	Weight >75 kg: 600 mg orally bid for 10 days Weight ≤75 kg: 400 mg orally in a.m., 600 mg orally in p.m. for 10 days

	Convalescent plasma in Argentinian and Bolivian hemorrhagic fevers
Postexposure prophylaxis	Prophylactic ribavirin for Bunyaviridae and Arenaviridae infections, under IND status, may be useful

Tularemia

Francisella tularensis is generally susceptible in vitro to aminoglycosides, tetracyclines, rifampin, and chloramphenicol; however, many strains are resistant to β-lactams. Similar to the treatment of plague and lacking contraindications, therapy with streptomycin or gentamicin is preferred, although alternatives, such as ciprofloxacin, are effective. Because the use of drug-resistant organisms is possible in a bioterrorist event, empiric therapy should account for this, and antimicrobial susceptibility testing of isolates should be expeditiously accomplished. A live attenuated vaccine derived from the avirulent live vaccine strain has been used to protect laboratory personnel working with *F. tularensis* but is not approved for commercial use.

Botulism

Supportive medical care, airway protection, and mechanical ventilation represent the primary modes of therapy for botulism. Advancements in these modalities account for the improvements in clinical outcomes observed since the mid-1950s; the mortality rate from foodborne botulism in the United States has decreased from 60% to 6%. Passive immunization with equine antitoxin, early in the course of clinical illness, remains the specific treatment of choice to neutralize circulating toxin. Timely administration of this product may be neuroprotective and mitigate severity of disease but will not reverse extant paralysis. Antitoxin should be given to patients with neurologic symptoms as soon as possible after the diagnosis of botulism is suspected; treatment should not be delayed for definitive diagnosis. In the United States, antitoxin is available only from the CDC via state and local health departments. As with any equine-based antisera, anaphylaxis is a potential risk in allergic individuals. To screen for hypersensitivity, skin testing with escalating challenge doses may be necessary before proceeding to a full dose. Patients responding to intradermal challenge with systemic symptoms or signs of hypersensitivity may be desensitized with expert guidance and ready access to epinephrine and airway protection in the event of an adverse reaction.

Smallpox

A suspected case of smallpox warrants immediate implementation of stringent contact and airborne precautions in a negative-pressure, respiratory isolation setting and immediate engagement of public health authorities for diagnostic, forensic, and epidemiologic purposes. Vaccination of potential exposures, so-called *ring vaccination and containment*, must be expeditiously performed; vaccination of symptomatic individuals is indicated if in the early stages of illness, as this is known to be effective in controlling the spread of disease, may mitigate the individual course of disease, and/or may prevent death. The smallpox vaccine contains replication-competent vaccinia virus, which can be transmitted to non-vaccinated individuals and cause illness.

Tecorivirmat is a new antiviral, active against orthopoxviruses, that is now FDA-approved for the treatment of smallpox. Additionally, brincidofovir, a lipid conjugate of cidofovir, is currently under investigation for the treatment of smallpox based on promising in vitro studies. Topical idoxuridine may be useful in the setting of ocular involvement. Bacterial superinfection is a common complication of smallpox and a frequent cause of death in infected individuals. Aggressive deployment of penicillinase-resistant antimicrobial agents should be used to manage secondary infections with additional consideration given to the institutional and community prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA) in specific areas. Vaccinia immune globulin (VIG) is indicated for the management of specific, severe complications of smallpox vaccine; there is no evidence to support the use of VIG in either the treatment or prophylaxis of smallpox infections.

Viral hemorrhagic fevers

The mainstay of treatment for all etiologies of VHFs is supportive medical care, with special attention paid to hemodynamics, volume status, respiratory parameters, and acid–base balance. As many of these agents cause systemic hypotension while at the same time causing capillary leak syndromes, careful monitoring of fluid and electrolyte balance is an important component of patient management. Invasive hemodynamic monitoring, mechanical ventilation, blood product support, dialysis, and neurologic support are often needed.

Although there are no approved antiviral therapies for VHF, the nucleoside analog ribavirin has in vitro and in vivo activity against some arenaviral and bunyaviral etiologies of VHF, such as Rift Valley fever, Lassa fever, and Congo–Crimean hemorrhagic fever. The drug has been shown to reduce morbidity from hemorrhagic fever with renal syndrome caused by Old World hantaviruses and to probably reduce morbidity and mortality from Lassa fever. Intravenous ribavirin given within the first 6 days of fever to patients with Lassa fever who had high levels of viremia decreased mortality from 76% to 9%. The drug is available under investigational new drug (IND) status from the CDC and USAMRIID and is associated with significant hemolysis, cytopenias from marrow suppression, and is teratogenic in animals. Ribavirin has no clinical utility in infections caused by filoviruses, such as Marburg or Ebola, or flaviviruses.

ZMapp is a cocktail of three neutralizing monoclonal antibodies used for the treatment of Ebola. It remains under investigation, but is available in the United States under an expanded access protocol. There are two vaccines currently under investigation for Ebola. A ring vaccination trial using one of the vaccines, rVSV, in Guinea found no secondary cases of Ebola virus disease among those vaccinated. Active investigation into other therapeutics and vaccines is ongoing in naturally occurring outbreaks in Africa.

Section 18

Specific organisms: Bacteria

121

Actinomycosis

Thomas A. Russo and Grishma R. Trivedi

Etiologic agents

Actinomycosis is an indolent, slowly progressive infectious syndrome caused by anaerobic or microaerophilic bacteria, primarily from the genus *Actinomyces*. It is most commonly caused by *Actinomyces israelii*. However, *A. naeslundii*, *A. odontolyticus, A. viscosus, A. meyeri*, and *A. gerencseriae* are less common causes of infection. Infections due to *A. neuii* have been increasingly recognized. Advances in microbiologic taxonomy, using genotypic methods such as comparative 16S ribosomal RNA (rRNA) or sequencing of alternative genes, have led to the identification of many new *Actinomyces* species from both human and animal specimens. Presently 50 species and 2 subspecies have been recognized (http://www.bacterio.cict.fr/a/actinomyces.html). Although the syndrome of actinomycosis can be caused by these more recently described agents, most of the infections are not "classical" actinomycosis. Nearly all of actinomycotic infections are polymicrobial in nature where "companion organisms," such as *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans, Eikenella corrodens, Fusobacterium, Bacteroides, Capnocytophaga, Staphylococcus, Streptococcus*, and Enterobacteriaceae are commonly co-isolated with the agents of actinomycosis in various combinations depending on the site of the infection.

Epidemiology and pathogenesis

The etiologic agents of actinomycosis are members of the normal oral flora and are often isolated from the bronchi, gastrointestinal, and female genital tracts. Although males have a higher incidence of infection (unproved but probably due to more frequent trauma and poorer dental hygiene), actinomycosis occurs in all age groups and geographic locations. Disruption of the mucosal barrier is the critical step for the development of actinomycosis. Subsequently, a local infection may ensue, and, once established, if untreated spreads contiguously, ignoring tissue planes in a slow, progressive manner. Although acute inflammation may initially occur at the site of infection, the hallmark of classical actinomycosis is the characteristic chronic, indolent phase. This stage is manifested by lesions that usually appear as single or multiple indurations. Central necrosis develops that consists of neutrophils and sulfur granules (a finding virtually diagnostic of this disease). The walls of the mass are fibrotic and characteristically described as "wooden." Over time sinus tracts to the skin, adjacent organs, or bone may develop. Rarely, distant hematogenous seeding occurs. Foreign bodies appear to facilitate infection. This occurs most frequently with intrauterine contraceptive devices (IUCDs). Although actinomycosis has been described in the setting of various immunosuppressive therapies or states of host compromise, it remains unclear which arm(s) of host defense prevents/control infection. The contribution of the non-*Actinomyces* co-isolates or companion organisms to the pathogenesis of actinomycosis is also uncertain.

Infectious syndromes

Clinical presentations are myriad. Once common in the pre-antibiotic era, today the incidence of actinomycosis is diminished and, as a result, so is its timely recognition. It has been called "the most misdiagnosed disease" and some have stated that "no disease is so often missed by experienced clinicians." Actinomycosis remains a diagnostic challenge. Knowledge of the full spectrum of disease will expedite diagnosis and treatment and minimize the unnecessary surgical interventions, morbidity, and mortality that all too often occur with this disease. Three clinical presentations of this unique infection, in particular, warrant consideration. First, the combination of chronicity, progression across tissue boundaries, and masslike features mimic malignancy, with which it is often confused. Second, the cure of established actinomycosis requires prolonged treatment. Short courses of therapy with active agents usually result in only transient improvement. Therefore, actinomycosis should be thought of with refractory or relapsing infections. Last, development of a sinus tract, which may spontaneously resolve and recur, should prompt consideration of this disease.

Oral–cervicofacial disease

This is the most frequent site for actinomycosis, which usually presents as a soft tissue swelling, abscess, mass, or ulcer that is often mistaken for a neoplasm. The angle of the jaw is the most commonly involved site (Figure 121.1), but actinomycosis should be considered with any mass lesion or relapsing infection in the head and neck. Dental disease or procedures are a common precipitating factor. Rarely, otitis, sinusitis, and canniculitis can also occur. Isolated masses or ulcerative lesions of the tongue, vallecula, nasal cavity, nasopharynx, soft tissues of the head and neck, salivary glands, patent thyroglossal duct, thyroid, branchial cleft cyst, hypopharynx, or larynx also have been reported. Radiation therapy and particularly bisphosphonate treatment have been increasingly recognized for contributing to an increased incidence of actinomycotic infection of the mandible and maxilla. Pain, fever, and leukocytosis are variably present. Contiguous spread to the cranium, cervical spine, or thorax are potential sequelae.

FIGURE 121.1

Thoracic disease

The usual presentation is an indolent, progressive course that involves the pulmonary parenchyma and/or the pleural space. Thoracic actinomycosis may be facilitated by aspirated foreign material. Chest pain, fever, weight loss, and, less frequently, hemoptysis are prominent. A cough, when present, is variably productive. The most common radiographic appearance is either a mass lesion or pneumonia. Cavitary disease may develop, which can be demonstrated on CT scan. Hilar adenopathy may occur. Many cases have pleural thickening, effusion, or empyema. Lesions suggestive of pulmonary actinomycosis include those crossing fissures or pleura, mediastinal extension, spread to contiguous bone or chest wall (empyema necessitates), or the formation a sinus tract. In the absence of these scenarios, thoracic actinomycosis is often mistaken for malignancy, or empyema or pneumonia due to more usual causes. Although uncommon, the structures within the mediastinum and the heart, including heart valves, can be involved in various combinations, resulting in a variety of presentations. Isolated disease of the breast occurs rarely.

Abdominal disease

Abdominal actinomycosis is often unrecognized. Months to years usually pass from the inciting event (e.g., appendicitis, diverticulitis, peptic ulcer disease, spillage of gall stones or bile during cholecystectomy, foreign-body perforation, bowel surgery, or ascension from IUCD-associated pelvic disease) to diagnosis. Because of the flow of peritoneal fluid and/or direct extension of primary disease, virtually any abdominal organ, region, or space can be involved. It usually presents as an abscess or a mass lesion that is often fixed to underlying tissue and mistaken for a tumor. On CT, often heterogenous enhancement and thickening of bowel wall is seen. Sinus tracts to the abdominal wall, to the perianal region, or between bowel and other organs may develop mimicking inflammatory bowel disease. Hepatic infection usually presents as single or multiple abscesses or masses. Isolated disease is presumably via hematogenous seeding from cryptic foci. Imaging and percutaneous techniques have improved diagnosis and treatment. All levels of the urogenital tract can be infected. Bladder involvement, usually due to extension of pelvic disease, may result in obstruction or fistulas to bowel, skin, or uterus. Renal disease usually presents as pyelonephritis and/or renal and perinephric abscess.

Pelvic disease

Actinomycotic involvement of the pelvis is strongly associated with IUCDs but can also occur with other foreign bodies such as a surgical mesh. Although the magnitude of risk is unclear, it would appear to be small. The disease rarely occurs when an IUCD has been in place for <1 year; however, the risk of infection increases with time and is often seen in the setting of the "forgotten" IUCD. Symptoms are typically indolent with fever, weight loss, abdominal pain, and abnormal vaginal bleeding or discharge being most common. An endometritis, if untreated, may progress to a pelvic mass or a tubo-ovarian abscess. Unfortunately, diagnosis is often delayed, and a "frozen pelvis" mimicking malignancy or endometriosis will develop by the time of recognition, leading to unnecessary surgery. Ascites and pelvic lymphadenopathy are uncommon in this setting, in contrast to malignancy and tuberculosis.

Central nervous system

Central nervous system (CNS) infection is rare. Single or multiple brain abscesses are most common, usually appearing on CT as a ring-enhancing lesion with a thick wall that may be irregular or nodular. Rarely, primary meningitis, epidural or subdural space, or cavernous sinus infection occurs.

Musculoskeletal infection

Osteomyelitis is usually due to adjacent soft tissue infection but may be associated with trauma (e.g., fracture of the mandible), injections, surgery, osteoradionecrosis and bisphosphonate osteonecrosis, or hematogenous spread. The uncommon infection of the extremities is usually a result of trauma. Skin, subcutaneous tissue, muscle, and bone are involved alone or in various combinations. Cutaneous sinus tracts frequently develop. Actinomycotic infections of hip and knee prostheses have also been described.

Disseminated disease

Hematogenous spread of infection from any location may rarely result in multiorgan involvement, with the lungs and liver most commonly affected. The presentation of multiple nodules may mimic disseminated malignancy. *A. meyeri* appears to have the greatest capability of causing this syndrome.

Diagnosis

The diagnosis of actinomycosis is rarely considered. Often the first mention of actinomycosis is from the pathologist after extensive surgery (Figure 121.2). As medical therapy alone is often sufficient for cure, the challenge for the clinician is to consider actinomycosis so that this uncommon and unusual infection can be diagnosed in the least invasive fashion and to avoid unnecessary surgery. CT- or ultrasound-guided aspirations or biopsies are successfully being used to obtain clinical material for diagnosis, although surgery may be required. Of note, hypermetabolism has been demonstrated by ^{18}F-fluorodeoxyglucose positron emission tomography (FDG-PET) in actinomycotic disease. The diagnosis is most commonly made by microscopic identification of sulfur granules (an in vivo matrix of bacteria, calcium phosphate, and host material) in pus or tissues, although occasionally sulfur granules can be grossly identified from draining sinus tracts. Microbiologic identification is less frequent, due to either prior antimicrobial therapy or omission. To optimize yield, the avoidance of even a single dose of antibiotics is mandatory. Although some species can grow aerobically, isolation is maximized under anaerobic conditions, which require 5 to 7 days usually but can take up to 2 to 4 weeks. 16S rRNA gene amplification and sequencing has been successfully used by clinical microbiology laboratory to increase diagnostic sensitivity and specificity. MALDI-TOF MS is promising but databases are still in the process of being optimized.

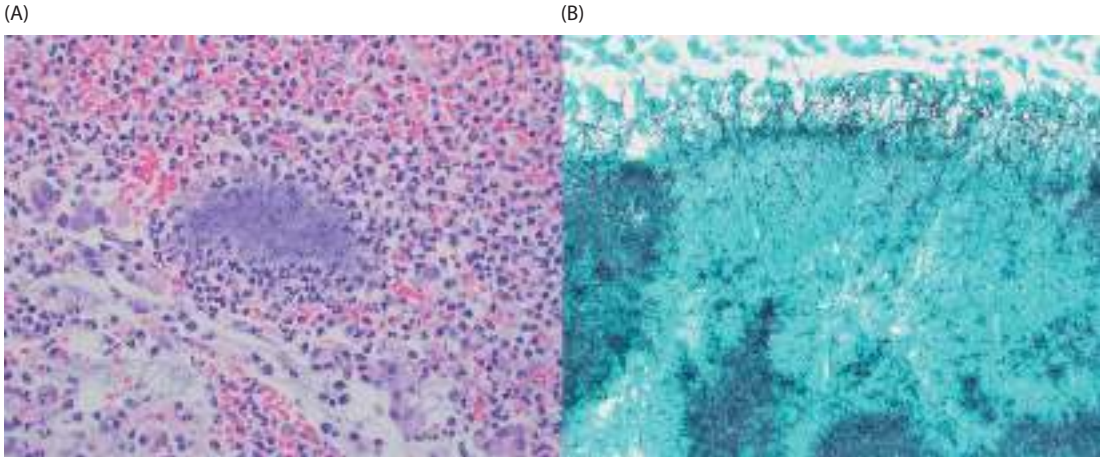

FIGURE 121.2

Because these organisms are normal oral and genital tract flora, their identification in the absence of sulfur granules from sputum, bronchial washings, and cervicovaginal secretions is of little significance.

Treatment

Antimicrobial therapy

Controlled trials either evaluating antimicrobials or designed to define duration of therapy in the treatment of actinomycosis have not been performed and unlikely will be done in future. Therefore, treatment decisions are based primarily on the collective clinical experience. Two principles of therapy have evolved. It is necessary to treat classical disease both with high doses and for a prolonged period. Presumably, this is because of the difficulties of antimicrobials penetrating the thick-walled masses that commonly occur with this infection and/or the sulfur granules themselves, which may represent a biofilm. Although therapy should always be individualized, 18 to 24 million units of intravenous (IV) penicillin for 2 to 6 weeks, followed by oral therapy with penicillin or amoxicillin for 6 to 12 months is justified for serious infections and bulky disease. For penicillin-allergic patients tetracyclines, ceftriaxone, or carbapenems are reasonable alternatives. Less extensive disease, particularly involving the oro-cervicofacial region, may require a shorter course of therapy. If the duration of therapy is extended beyond the resolution of measurable disease, then relapses, one of the clinical hallmarks of this infection, will be minimized. CT and MRI studies are generally the most sensitive and objective modalities to accomplish this goal. In the pregnant, penicillin-sensitive patient erythromycin is a safe alternative. Remarkably, little clinical information is available on the newer antimicrobial agents. Anecdotal successes have been reported with imipenem, ceftriaxone, ceftizoxime, and piperacillin–tazobactam (Box 121.1). Available data suggest that oxacillin, dicloxacillin, cephalexin, metronidazole, fluoroquinolones, and aminoglycosides should be avoided.

Home therapy

For home IV therapy, the ease of once-a-day dosing makes ceftriaxone appealing in certain circumstances; however, a greater body of literature supporting its efficacy would be desirable. The availability of portable infusion pumps for home therapy allows for both the appropriate dosing and practical administration of IV penicillin. For infections in critical sites (e.g., CNS) this approach remains the safest until more information is available on other agents. The pharmacokinetic properties, availability of oral and parenteral formulations, and potential efficacy of azithromycin also make this agent appealing. Unfortunately, few in vitro and no clinical data exist on its use to treat actinomycosis.

Treatment of co-isolates

It is unclear whether other bacteria frequently co-isolated with the etiologic agents of actinomycosis require treatment; however, many of them are pathogens in their own right. Designing a therapeutic regimen that includes coverage for these organisms during the initial treatment course is reasonable. If microbiology is not available, it is important to consider the site of infection when designing empiric coverage. For example, *Aggregatibacter actinomycetemcomitans, Eikenella corrodens, Fusobacterium*, and *Capnocytophaga* are more likely to be co-isolates in head and neck infection, whereas the Enterobacteriaceae are more commonly co-isolated in abdominal infection.

BOX 121.1

Appropriate and inappropriate antibiotic therapy for actinomycosis[a]

Group 1: Extensive successful clinical experience[b]
- Penicillin (3–4 million units IV q4h)[c]
- Amoxicillin (500 mg PO q6h)
- Erythromycin (500–1,000 mg IV q6h or 500 mg PO q6h)
- Tetracycline (500 mg PO q6h)
- Doxycycline (100 mg IV or PO q12h)
- Minocycline (100 mg IV or PO q12h)
- Clindamycin (900 mg IV q8h or 300–450 PO q6h)[d]

Group 2: Anecdotal successful clinical experience
- Ceftriaxone[c]
- Ceftizoxime
- Imipenam-cilastin
- Piperacillin-tazobactam

Group 3: Agents predicted to be efficacious based on in vitro activity
- Vancomycin
  - Linezolid
  - Quinupristin-dalfopristine
- Rifampin
- Ertapenem[c]
- Tigecycline
- Azithromycin[c]

Group 4: Agents that should be avoided
- Metronidazole
- Aminoglycosides
- Oxacillin
- Dicloxacillin
- Cephalexin
- Fluoroquinolones

[a] Additional coverage for concomitant "companion" bacteria may be required.

[b] Controlled evaluations have not been performed. Dose and duration require individualization depending on the host, site, and extent of infection. As a general rule, a maximum antimicrobial dose for 2–6 weeks of parenteral therapy followed by oral therapy for a total duration (6–12 months) is required for serious infections and bulky disease; whereas a shorter duration may suffice for less extensive disease, particularly in the oral–cervicofacial region.

[c] These agents can be considered for at-home parenteral therapy; penicillin requires a continuous infusion pump.

[d] Recent in vitro data have demonstrated resistance in up to 33% of isolates.

Surgery or percutaneous drainage

In the pre-antibiotic era, surgical removal of infected tissue was the only beneficial treatment. Despite the availability of effective antimicrobial therapy, combined surgical therapy is still advocated by some authorities. However, an increasing body of literature now supports the approach of initially attempting a cure with medical therapy alone. Successes have been reported in cases of extensive disease that initially appeared to be incurable using antibiotics alone. CT and MRI should be used to monitor the response to therapy. In most cases either surgery can be avoided or a less extensive procedure will be necessary. This approach is particularly important when the possibility of sparing critical organs is involved, such as the bladder or reproductive organs in women of childbearing age. In a patient with disease in a critical location (e.g., epidural space, selected CNS disease), with significant hemoptysis, or if suitable medical therapy fails, surgical intervention may be appropriate. In the setting of actinomycosis presenting as a well-defined abscess, percutaneous drainage in combination with medical therapy is a reasonable approach.

Treatment of the immunocompromised host

Actinomycosis has been described in association with HIV infection, steroid use, anti–TNF-α therapy, and lymphoproliferative tumors. Whether these infections were because of disease-associated disruptions of mucosa (e.g., cytomegalovirus infection with HIV infection), host defense abnormalities, immunosuppressive therapy, or some combination of these is unclear. From a treatment perspective it is reasonable to initially use the same approach as that for noncompromised hosts. Aggressive treatment directly against HIV (e.g., highly active antiretroviral therapy) and minimizing immunosuppressive therapy is also desirable if possible. Although prospective controlled data are not available, when actinomyces are identified in the setting of bisphosphonate-related osteonecrosis of the jaw (BRONJ) a prolonged course of antimicrobial therapy is reasonable and appears to be efficacious. The role of surgical debridement for BRONJ is less clear but resection of at least necrotic bone seems prudent.

Refractory disease

Usually actinomycosis responds well to medical therapy. However, refractory or perceived refractory disease has been described in HIV-infected individuals as well as in apparently normal hosts. In this setting basic principles of infectious disease apply. Exclude infection elsewhere (e.g., line-related, *Clostridium difficile* colitis) and/or non-infectious causes (e.g., drug fever, unrelated disease) as being responsible. Confirm that high-dose parenteral therapy is being utilized for initial treatment. Identify and drain significant purulent collections associated with the actinomycotic infection. Consider the possibility that untreated co-isolates (companion organisms) may be responsible. Although penicillin-resistant strains or evolution of resistance during therapy have not yet been clearly documented in vivo, this possibility should be considered when other more likely scenarios are excluded. Finally, surgery should be considered when infection is refractory to medical therapy, although, as stated, this usually can be avoided, at least initially.

Actinomyces-like organisms

An unresolved issue is whether screening cervical or endometrial specimens for *Actinomyces*-like organisms (ALOs) or their detection by immunofluorescence (IF) can predict/prevent IUCD-associated disease. Furthermore, a Papanicolaou smear may fail to detect ALOs even in the presence of active actinomycosis. Although the risk appears to be small, the consequences of infection are significant. Therefore, until more quantitative data become available, in the presence of symptoms that cannot be accounted for, regardless of whether ALOs or IF-positive organisms are detected, it would appear prudent to remove the IUCD and, if advanced disease is excluded, empirically treat for 14 days for possible early pelvic actinomycosis. The detection of ALOs or IF-positive organisms in the absence of symptoms warrants patient education and close follow-up but not removal of the IUCD unless an equally suitable means of contraception can be agreed upon.

Anaerobic infections

Itzhak Brook

Introduction

Infections caused by anaerobic bacteria occur frequently and can be serious and life-threatening. Because anaerobes colonize the skin and are the main component of mucous membranes flora[1] they are endogenous in nature. Because of their fastidiousness, anaerobes are difficult to isolate and are often unrecognized. Delay in implementing appropriate therapy may lead to clinical failures. Their isolation requires proper methods of collection, transportation, and cultivation of specimens. Treatment is complicated by their slow in vitro growth, the infection's polymicrobial nature, and the organisms' mounting antimicrobial resistance.

Epidemiology

Most infections are caused by normal flora anaerobes that contaminate a previously sterile body site or gain access to the body from an external source of normal flora such as a bite. They also occur when the local defenses are decreased. Some infections are caused by wound contamination by soil anaerobes (i.e., Clostridia). *Clostridium difficile* can lead to hospital epidemics when these bacteria are transmitted from patient to patient. Toxin-producing *Clostridium botulinum* causes food poisoning.

Microbiology

The clinically important anaerobes accounting for >95% of infections are:

- Gram-negative rods (*Bacteroides, Prevotella, Porphyromonas, Fusobacterium, Bilophila,* and *Sutterella* spp.);
- Gram-positive cocci (mainly *Peptostreptococcus* spp.);
- Gram-positive spore-forming (*Clostridium* spp.) and non–spore-forming bacilli (*Actinomyces, Propionibacterium, Eubacterium, Lactobacillus,* and *Bifidobacterium* spp.);
- Gram-negative cocci (mainly *Veillonella* spp.) (Table 122.1).

The recovery of anaerobes differs in various infectious sites (Table 122.2) and is influenced by their presence in the adjacent endogenous mucus membranes and skin flora. Polymicrobial synergistic infections caused by aerobic and anaerobic organisms are common.

Anaerobes taxonomy has changed because of improved characterization methods using genetic studies. Recent advances in direct detection of anaerobes from clinical samples include 16rRNA gene-based methods, DNA hybridization, matrix-assisted laser desorption/ionization time-of-flight mass spectrometry

TABLE 122.1 **ANAEROBIC BACTERIA PREDOMINATING IN INFECTIONS**

Gram-positive cocci	*Peptostreptococcus* spp.: *P. magnus, P. asaccharolyticus, P. prevotii, P. intermedius, P. anaerobius, P. micros* Microaerophilic streptococci (not true anaerobes)
Gram-positive non–spore-forming bacilli	*Propionibacterium* spp.: *P. acnes, P. propionicum, P. granulosum, Eubacterium tentum* *Bifidobacterium* spp.: *B. eriksonii, B. dentium* *Actinomyces* spp.: *A. israelii, A. naestundii, A. viscosus, A. odontolyticus, A. meyerii*
Gram-positive spore-forming bacilli	*Clostridium* spp.: *C. perfringens, C. ramosum, C. septicum, C. novyi, C. histolytica, C. sporogenes, C. difficile, C. bifermentans, C. butyricum, C. innocuum, C. sordellii, C. botulinum, C. tetani*

(MALDI-TOF MS) Biotyper, multiplex polymerase chain reaction (PCR), and oligonucleotide array technologies.[5] The ability to differentiate between similar strains enables better characterization of types of infection and anticipation of antimicrobial susceptibility.

Anaerobic spore-forming bacilli belong to the genus *Clostridium*. They are highly pleomorphic, ranging from short, thick bacilli to long filamentous forms, and are either ramrod straight or slightly curved. The most frequent Clostridia in clinical infections are

TABLE 122.2 **ANAEROBIC BACTERIA MOST FREQUENTLY ENCOUNTERED IN SPECIFIC INFECTION SITES**

Organism		***Infection site***
Gram-positive cocci	*Peptostreptococcus* spp. Microaerophilic streptococci (not obligate anaerobes)	Respiratory tract, intra-abdominal and soft tissue infections Sinusitis, brain abscesses
Gram-positive bacilli	Non–spore-forming: *Actinomyces* spp.	Intracranial abscesses, chronic mastoiditis, aspiration pneumonia, head and neck infections
	Propionibacterium	Shunt infections (cardiac, intracranial), infections associated with foreign body
	Bifidobacterium spp. *Acnes*	Chronic otitis media, cervical lymphadenitis, abdominal infections
	Spore-forming: *Clostridium perfringens*	Soft tissue infection, sepsis, food poisoning
	Clostridium septicum	Sepsis, neutropenic enterocolitis
	Clostridium difficile	Colitis, antibiotic-associated diarrheal disease
	Clostridium botulinum	Botulism
	Clostridium tetani	Tetanus
	Clostridium ramosum	Soft tissue infections
Gram-negative bacilli	*Bacteroides fragilis* group	Intra-abdominal and female genital tract infections, sepsis, neonatal infections
	Pigmented *Prevotella* and *Porphyromonas* spp. *Prevotella oralis, Prevotella oris-buccae,*	Orofacial infections, aspiration pneumonia, periodontitis Orofacial infections Orofacial infections, intra-abdominal infections
	Prevotella bivia, Prevotella disiens, *Fusobacterium nucleatum*	Female genital tract infections Orofacial and respiratory tract infections, brain abscesses, bacteremia
	Fusobacterium necrophorum	Aspiration pneumonia, mastoiditis, Lemierre's Syndrome, bacteremia

Clostridium perfringens, C. septicum, C. ramosum, C. novyi, C. sordellii, C. histolyticum, C. fallax, C. bifermentans, and *C. innocuum.*

C. perfringens is an often encapsulated, stout gram-variable rods of varying length, found in soil and human and animal intestines. It is the most commonly isolated histotoxic clostridia and produces several necrotizing extracellular toxins. It can cause devastating illness with high mortality rates and bacteremia associated with extensive tissue necrosis, hemolytic anemia, and renal failure.

C. septicum infection (mostly blood and subcutaneous tissue) is often association with occult colonic malignancy. *C. sordellii* infections often follow abortion, childbirth, and injection drug use.

C. botulinum can cause four syndromes: foodborne, wound, infant botulism, and adult intestinal toxemia. All of these produce the same clinical syndrome of symmetrical cranial nerve palsies followed by descending, symmetric flaccid paralysis of voluntary muscles, which may progress to respiratory compromise and death. Proteolytic strains of types A and B have been reported from food poisoning and wound infections. Infant botulism occurs with types A, B, and F.7 Disease caused by *C. botulinum* is usually an intoxication produced by ingestion of contaminated food (uncooked meat, poorly processed fish, improperly canned vegetables) containing a highly potent neurotoxin. *C. difficile* causes antibiotic-associated and spontaneous diarrhea and colitis. *C. tetani* is found in soil and rarely human feces. Infections can result from wound contamination with soil containing *C. tetani* spores that germinate in devitalized tissue and produce a neurotoxin.

Anaerobic gram-positive, non–spore-forming rods are part of gingival crevices, gastrointestinal tract, and vaginal and skin flora. They include Propionibacterium, Eubacterium, Bifidobacterium, Lactobacillus. Actinomyces, Arcanobacterium, Atopobium, Mobiluncus, and Pseudoramibacter.

The *Actinomyces, Arcanobacterium,* and *Bifidobacterium* spp. are gram-positive, pleomorphic, anaerobic to microaerophilic bacilli. *Actinomyces israelii, Actinomyces naeslundii* and *Propionibacterium propionicum*, members of the oral and throat flora, are the most frequent cause of actinomycosis. They have been isolated from intracranial abscesses, chronic mastoiditis, aspiration pneumonia, and peritonitis. Actinomycosis usually occurs in the face, neck, lungs, pleura, and genital and urinary tracts. Bone, pericardial, and anorectal lesions and bacteremia are less common, but all tissues may be involved.

Eubacterium and anaerobic lactobacilli are part of the oral, vaginal, and gastrointestinal flora. They are common in infections associated with malignancy, surgery, immunodeficiency, diabetes mellitus, foreign bodies, dental extraction, and broad-spectrum antibiotic therapy.

Propionibacterium spp., ordinarily nonpathogens, can cause implanted prostheses or central nervous system (CNS) shunt infection and endocarditis in previously damaged heart valves. They have been recovered from parotid and dental infections, brain abscesses, conjunctivitis associated with contact lens, peritonitis, and foreign body and pulmonary infections. *Propionibacterium acnes*, the commonest species, can be isolated from blood but is associated only rarely with bacteremia or endocarditis. Because these organisms are part of the normal skin flora, they are often a contaminant. *P. acnes* can cause bacteremia, especially in association with shunt and infections, and it plays a role in acne vulgaris.

Among *gram-negative bacilli*, the *Bacteroides fragilis* group are the most recovered Bacteroidaceae in clinical specimens. They resist penicillins, mainly through the production of β-lactamase. They include several members—the most commonly isolated ones are *B. fragilis* (the most commonly recovered member), *B. thetaiotaomicron, B. distasonis, B. ovatus,* and *B. vulgatus*. They are part of the normal gastrointestinal flora1 and predominate in intra-abdominal infections and other infections that originate from gut flora (i.e., perirectal abscesses, decubitus ulcers). The newly defined *Bilophila wadsworthia* and *Centipeda periodontii* are found in abdominal and endodontic infections, respectively.

Pigmented *Prevotella* (*Prevotella melaninogenica, Prevotella intermedia*), *Porphyromonas* (*Porphyromonas asaccharolytica*), and nonpigmented Prevotella (*Prevotella oralis, Prevotella oris*) are part of the oral and vaginal flora and are the predominant anaerobic gram-negative bacilli (AGNB) isolated from respiratory infections and their complications, aspiration pneumonia, lung abscess, chronic otitis media, chronic sinusitis, abscesses around the oral cavity, bite infection, paronychia, brain abscesses, and osteomyelitis. *P. bivia* and *P. disiens* predominate in obstetric and gynecologic infections.

Fusobacterium species are fusiform, moderately long, and thin organisms with tapered ends. *F. nucleatum, F. necrophorum, F. mortiferum,* and *F. varium* predominant in oral, pulmonary and intracranial infections. *Fusobacterium* spp. are also isolated from abscesses, obstetric and gynecologic infections, blood, and wounds.

A growing resistance of AGNB to penicillins has been noted in recent years.[20] Resistance was observed in pigmented *Prevotella* and *Porphyromonas, P. oralis, P. disiens, P. bivia,* and *Fusobacterium* spp. The main mechanism of resistance is through β-lactamase production.

The recovery AGNB in infected sites is similar to their distributions in the normal flora.[4–6] The *B. fragilis* group was more often found in sites proximal to the gastrointestinal tract, pigmented *Prevotella* spp. were more prevalent in infections proximal to the oral cavity, and *P. bivia* and *P. disiens* were more often isolates in obstetric and gynecologic ones (Table 122.2). Familiarity with this mode of distribution enables logical choice of antimicrobials adequate for the treatment of infections in or proximal to these sites.

The *predominate gram-positive cocci* are *Peptostreptococcus magnus, P. asaccharolyticus, P. anaerobius, P. prevotii,* and *Parvimonas micra* (*P. micros*). Other anaerobic cocci include *Coprococcus, Peptococcus, Ruminococcus sarcina,* and *Staphylococcus saccharolyticus.* They are part of the oral, upper respiratory tract, intestinal tract, vagina, and skin flora.

These organisms can be isolated in all types of anaerobic infection including respiratory infection (chronic sinusitis, mastoiditis, acute and chronic otitis media, aspiration pneumonia and lung abscess) and necrotizing, subcutaneous, and soft tissue infections. They can be isolated alone or mixed with other aerobic or anaerobic organisms. Microaerophilic streptococci are not true anaerobes and can become aerotolerant after subculture. They include the *Streptococcus anginosus* group (previously *Streptococcus milleri* group, which includes *S. constellatus* and *S. intermedius*) and *Gemella morbillorum* (previously *S. morbillorum*). Microaerophilic streptococci are common in chronic sinusitis and brain abscesses, obstetric and gynecologic infections, and abscesses.

There are three anaerobic *gram-negative cocci* genera: *Veillonella, Acidaminococcus,* and *Megasphaera* spp. *Veillonella* spp., the commonest of the three, are members of the oral, vaginal, and small intestinal flora. They are rarely isolated from almost every type of anaerobic infection.

Collection and transportation of specimens for anaerobic bacteria

Collection of specimens for anaerobic bacteria is important because documentation of an anaerobic infection is through isolation of organisms from the infected site. Appropriate documentation of anaerobic infection requires proper collection of appropriate specimens, expeditious transportation, and careful laboratory processing. Inadequate techniques or media can lead to missing the presence of anaerobic bacteria or the assumption that only aerobic organisms are present in a mixed infection.

Because anaerobes are present on skin and mucous membranes, even minimal contamination with normal flora can be misleading. Unacceptable or inappropriate specimens can yield normal flora and can be misleading and have no or little diagnostic value. Appropriate materials should be obtained by using techniques that bypass the normal flora.

Acceptable specimens include those obtained from normally sterile sites, such as blood or spinal, joint, or peritoneal fluids, or are collected after thorough skin decontamination. Two approaches are used to culture the maxillary sinus by aspiration following sterilization of the canine fossa or the nasal vestibule, via either the canine fossa or the inferior meatus. Urine is collected by percutaneous suprapubic bladder aspiration. Specimens can be collected from abscess contents, from deep aspirates of wounds, and via special techniques such as transtracheal aspirates or direct lung puncture. Specimens of the lower respiratory tract are difficult to obtain without contamination with indigenous florae. Double-lumen catheter bronchial brushing and bronchoalveolar lavage, cultured quantitatively, can be useful. Culdocentesis fluid obtained after decontamination of the vagina is acceptable.

Prompt delivery of specimens to the laboratory to allow for microbiologic processing is essential. Transportation of specimens should be prompt unless anaerobic transport devices are available. Transport devices generally contain oxygen-free environments provided by a mixture of carbon dioxide, hydrogen, and nitrogen, plus an aerobic condition indicator. Specimens should be placed into an anaerobic transporter as soon as possible.

Liquid or tissue specimens are always preferred to swabs. Liquid specimens are inoculated into an anaerobic transport vial or collected in a syringe and a needle. All air bubbles are expelled from the syringe. Insertion of the needle tip into a sterile rubber stopper is no longer recommended. Because air gradually diffuses through the plastic syringe wall, specimens should be processed in <30 minutes.

Swabs are placed in sterilized tubes that contain carbon dioxide or prereduced anaerobically sterile Carey and Blair semisolid media. Tissue specimens can be transported in an anaerobic jar or in a sealed plastic bag rendered anaerobic.

Virulence factors

Anaerobes possess a number of virulence factors including synergistic capability and production of toxins, polysaccharide capsules, and lipopolysaccharides.

Anaerobes possess several virulence factors that assist them to adhere to and invade epithelial surfaces. These factors include the presence of surface structures (such as capsule polysaccharide or lipopolysaccharide), production of superoxide dismutase and catalase, immunoglobulin proteases, coagulation promoting, spreading factors (such as hyaluronidase, collagenase, and fibrinolysin), adherence factors, and the production of toxins. Other factors that enhance the virulence of anaerobes include mucosal damage, oxidation–reduction potential drop, and the presence of hemoglobin or blood in an infected site.

Anaerobes contribute to the severity of infection through their synergy with their aerobic counterparts and with each other. Anaerobes generally take longer than aerobic bacteria to become virulent. This is because some of the major virulence factors of certain anaerobic bacteria (i.e., the production of a capsule) are expressed only after the infection has become chronic.

Predisposing conditions

Predisposing conditions include exposure of a sterile body site to a high inoculum of indigenous mucosal membrane flora, poor blood supply, tissue necrosis favoring the growth of anaerobes, or any condition that lowers the blood supply to an affected area such as trauma, foreign body, malignancy, surgery, edema, shock, colitis, and vascular disease. Other conditions include diabetes mellitus, splenectomy, immunosuppression, hypogammaglobinemia, neutropenia, leukemia, collagen vascular disease, and cytotoxic drugs. Infection with aerobic or facultative bacteria can be favorable for the growth of anaerobes. Anaerobic conditions and anaerobic bacteria can impair phagocytosis and intracellular killing through production of succinic acid, inhibition of chemotaxis, degradation of serum proteins by proteases and production of leukotoxins.

Suppuration, abscess formation, thrombophlebitis, and gangrenous tissue destruction associated with gas formation are the hallmarks of anaerobic infection. Anaerobes are commonly recovered in chronic infections and after failure of antimicrobial therapy with ineffective agents.

Some infections are likely to include anaerobes. These include brain abscess, oral and dental infections, bites, aspiration pneumonia, lung abscesses, peritonitis after perforation, amnionitis, endometritis, septic abortions, tubo-ovarian abscess, abscesses in and around the oral and rectal areas, pus-forming necrotizing infections of soft tissue or muscle, and postsurgical infections. Some solid

tumors (i.e., colonic, uterine, bronchial, carcinomas, head and neck) can become infected with anaerobes.

Prevention

Prevention and early therapy of conditions that can lead to anaerobic infection can reduce their rate. Examples include preventing oral flora aspiration by improving neurologic status, suctioning oral secretions, improving oral hygiene, and maintaining lower stomach pH to reduce the risk of aspiration pneumonia and its complications. Irrigation and debridement of wounds and necrotic tissue, drainage of pus, and improvement of blood supply help prevent skin and soft tissue infections.

Prophylactic antimicrobial therapy is recommended before surgery when the operative field is expected to be contaminated by mucosal membrane flora. Cefoxitin or ertapenem are used in procedures that involve the oral, rectal, or vulvovaginal. Vaccination with tetanus toxin can prevent *C. tetani* infection.

Signs and symptoms associated with anaerobic infections

Suppuration, abscess formation, thrombophlebitis, and gangrenous destruction of tissue associated with gas formation are the hallmarks of anaerobic infection. Clinical signs of anaerobic infection include:

- Infection adjacent to a mucosal surface
- Foul-smelling discharge
- Necrotic gangrenous tissue and abscess formation
- Free gas in tissue
- Bacteremia or endocarditis with no growth on aerobic blood cultures
- Infection related to the use of antibiotics effective against aerobes only
- Infection related to tumors or other destructive processes
- Infected thrombophlebitis
- Infection after bites
- Black discoloration of exudates containing *P. melaninogenica*, which may fluoresce under ultraviolet light
- Sulfur granules in discharges caused by actinomycosis
- Clinical presentation of gas gangrene
- Clinical condition predisposing to anaerobic infection (after maternal amnionitis, perforation of bowel, etc.)

Anaerobes are especially common in chronic infections and are commonly seen after failure of therapy with antimicrobials that are not effective against them, such as aminoglycosides, trimethoprim-sulfamethoxazole (co-trimoxazole), and older quinolones.

Certain infections are very likely to involve anaerobes as important pathogens, and their presence should always be assumed. Such infections include brain abscess, oral and dental infections, human and animal bites, aspiration pneumonia and lung abscesses, peritonitis after perforation of viscus, amnionitis, endometritis, septic abortions, tubo-ovarian abscess, abscesses in and around the oral and rectal areas, pus-forming necrotizing infections of soft tissue or muscle, and postsurgical infections following procedures on the oral or gastrointestinal tract or female pelvic area. Certain solid malignant tumors, such as colon, uterine, and bronchogenic carcinomas, and necrotic tumors of the head and neck, can become infected with anaerobes. The anoxic conditions in the tumor and exposure to the endogenous adjacent mucous flora may predispose to these infections.

Clinical infections

Anaerobes have been isolated from infections at all sites. However, the frequency and types of isolates vary and depend on the microbial flora at their source or the adjacent mucocutaneous sites.

Central nervous system

These include brain abscess (brain abscess), subdural empyema, epidural abscess, and meningitis. Brain abscess often originate from ear, mastoid, sinus, oropharynx, dental, or lung infection.[10] Ear or mastoid infection tends to spread to the temporal lobe or cerebellum, whereas facial sinusitis often causes abscess of the frontal lobe. Hematogenous spread often occurs after dental, oropharyngeal, or pulmonary infections, and rarely from endocarditis.

Meningitis can follow respiratory or cerebrospinal fluid shunt infection. Shunt infections are generally caused by skin flora (i.e., *P. acnes*) and in ventriculoperitoneal shunts that perforate the gut by enteric organisms (i.e., *B. fragilis*). *C. perfringens* can cause brain abscess and meningitis after head injuries or after intracranial surgery.

The anaerobes generally recovered from brain abscesses complicating respiratory and dental infections include *Prevotella, Porphyromonas, Bacteroides, Fusobacterium*, and *Peptostreptococcus* spp. Microaerophilic and other streptococci are also often isolated.

Early administration of antimicrobials at the stage of encephalitis can prevent abscess formation. Once an abscess has formed, surgical excision or drainage may be needed, combined with a long course of antibiotics (4–8 weeks). Some recommend evacuation of the abscess, whereas others advocate repeated aspirations. The procedures used are aspiration through a burr hole and complete excision after craniotomy. In multiple abscesses or abscesses in essential brain areas, repeated aspirations are preferred. Open craniotomy with debridement, intraventricular lavage, and intraventricular as well as intravenous anti-bimicrobial(s) are recommended after intraventricular rupture of the abscess. Prolonged high-dose antibiotics is an alternative approach replacing surgical drainage. Antimicrobials with adequate intracranial penetration are advocated for these infections: metronidazole, penicillins, meropenem, and chloramphenicol.

Head and neck and upper respiratory tract

Anaerobes can be recovered from a variety of head, neck, and upper respiratory tract infections especially in their chronic forms (Table 122.3). These include chronic otitis media, sinusitis and mastoiditis, tonsillar, peritonsillar and retropharyngeal abscesses, deep neck space infections, parotitis, sialadenitis, thyroiditis, odontogenic infections, and postsurgical and nonsurgical head and neck wounds and abscesses. The predominant isolates are *Prevotella, Porphyromonas, Bacteroides, Fusobacterium,* and *Peptostreptococcus* spp.

Most dental infections involve anaerobes; these include endodontic (e.g., pulpitis) and periodontal (gingivitis, periodontitis, and peri-implant) infections, periapical and dental abscesses, perimandibular space infection, and postextraction infection. Microaerophilic streptococci and *Streptococcus salivarius* can also be involved in dental infections. *Vincent's angina* is a distinct form of ulcerative gingivitis; the causative organisms include *Fusobacterium* spp. and anaerobic spirochetes.

Ludwig's angina is a connective tissue infection of the floor of the mouth, and *Lemierre's syndrome* is characterized by thrombosis and suppurative thrombophlebitis of the internal jugular vein that is

TABLE 122.3 **AEROBIC AND ANAEROBIC BACTERIA ISOLATED IN HEAD AND NECK AND UPPER RESPIRATORY TRACT INFECTIONS**

Type of infection	Aerobic and facultative organisms	Anaerobic organism
Otitis media and mastoiditis: acute Chronic	*Streptococcus pneumoniae* *Haemophilus influenzae* *Moraxella catarrhalis*[a] *Staphylococcus aureus*[a] *Escherichia coli*[a] *Klebsiella pneumoniae*[a] *Pseudomonas aeruginosa*[a]	*Peptostreptococcus* spp., Pigmented *Prevotella* and *Porphyromonas* spp.[a] *Bacteroides* spp.[a] *Fusobacterium* spp.[a] *Peptostreptococcus* spp.
Peritonsillar and retropharyngeal abscess	*Streptococcus pyogenes* *Staphylococcus aureus*[a]	*Fusobacterium* spp.[a] Pigmented *Prevotella* and *Porphyromonas* spp.[a]
Recurrent tonsillitis	*Streptococcus pyogenes* *Haemophilus influenzae*[a] *Staphylococcus aureus*[a]	*Fusobacterium* spp.[a]
Suppurative thyroiditis	Streptococcus pyogenes Staphylococcus aureus[a]	Pigmented *Prevotella* and *Porphyromonas* spp.[a] *Peptostreptococcus* spp.
Sinusitis: acute chronic	*Haemophilus influenzae*[a] *Streptococcus pneumoniae* *Moraxella catarrhalis*[a] *Staphylococcus aureus*[a] *Streptococcus pneumonia* *Haemophilus influenzae*[a]	*Peptostreptococcus* spp. Pigmented *Prevotella* and *Porphyromonas* spp.[a] *Fusobacterium* spp.[a] *Bacteroides fragilis* group[a]
Cervical lymphadenitis	*Staphylococcus aureus*[a] *Mycobacterium* spp.	Pigmented *Prevotella* and *Porphyromonas* spp.[a] *Peptostreptococcus* spp.
Postoperative infection disrupting oral mucosa	*Staphylococcus* spp.[a] Enterobacteriaceae[a] *Streptococcus pyogenes*	*Fusobacterium* spp.[a] *Bacteroides* spp.[a] Pigmented *Prevotella* and *Porphyromonas* spp.[a] *Peptostreptococcus* spp.
Deep neck abscesses and parotitis	*Streptococcus* spp. *Staphylococcus* spp.[a]	*Bacteroides* spp.[a] *Fusobacterium* spp.[a] *Peptostreptococcus* spp.[a]
Odontogenic complications	*Streptococcus* spp. *Staphylococcus* spp.[a]	Pigmented *Prevotella* and *Porphyromonas* spp.[a] *Peptostreptococcus* spp.
Oropharyngeal: Vincent's angina and necrotizing	*Streptococcus* spp. *Staphylococcus* spp.[a]	*Fusobacterium necrophorum*[a]

[a]Organisms that have the potential of producing β-lactamase.

associated with spread of septic emboli to the lungs and other sites; *F. necrophorum* is the prevalent species.

Deep neck infections (e.g., mediastinitis following perforation of the esophagus, extension of retropharyngeal abscess or cellulitis, dental abscess) are usually polymicrobial.

Otitis media

Peptostreptococcus spp. and *P. acnes* were found in 5% to 15% of acute otitis media. These organism and AGNB were present in 42% of culture-positive aspirates of patients with serous otitis media.

Anaerobes were recovered in half of the patients with chronic suppurative otitis media, mastoiditis, and infected cholesteatomas. The infection is often polymicrobial; the main isolates were AGNB, peptostreptococci, *Pseudomonas aeruginosa,* and *Staphylococcus aureus*. Anaerobes were isolated from 23 out of 24 (96%) specimens of chronic mastoiditis and from most intracranial abscesses complicating chronic suppurative otitis media. *Fusobacterium* spp. were also isolated from children with acute and chronic mastoiditis. Many of these organisms can produce β-lactamase that may contribute to the high failure rate of β-lactam antibiotics.

Rhinosinusitis

Streptococcus pneumoniae, Haemophilus influenzae, and *Moraxella catarrhalis* predominate in acute sinusitis. The bacterial sinus flora transitions from aerobic to anaerobic when the infection becomes chronic and oxygen levels decline. An elevated serum antibody level to *Prevotella* and *Fusobacterium* was demonstrated in patients with chronic sinusitis. Although anaerobes are generally isolated from only about 7% of acute sinusitis (mostly secondary to dental infection), they can be recovered from up to 67% of chronic infections.

Sinus infection may spread via anastomosing veins or contiguously to the CNS. Complications include orbital cellulitis, meningitis, cavernous sinus thrombosis, and epidural, subdural, and brain abscesses.

Parotitis

Acute suppurative parotitis is caused by aerobic (*S. aureus*, streptococci, gram-negative bacteria) and anaerobic (*Peptostreptococcus*, *Bacteroides*, and pigmented *Prevotella* and *Porphyromonas* spp.) bacteria. Empiric therapy should be directed against both. Drainage may be indicated when pus has formed.

Cervical lymphadenitis

The organisms causing acute unilateral infection associated with facial trauma or impetigo are *S. aureus* and group A β-hemolytic streptococci (GABHS). *Bartonella henselae* and mycobacteria are important in chronic infections. Anaerobes (mostly *Fusobacterium* and *Peptostreptococcus* spp.) were isolated in 25% and were associated with dental, periodontal, or tonsillar infection.

Head and neck infection after surgery

Postoperative head and neck infections are caused by the surgical site exposure to the oropharyngeal flora. Surgical wounds are generally infected by polymicrobial aerobic and anaerobic flora; the number of isolates varies from one to nine. The commonest isolates are peptostreptococci, *S. aureus*, AGNB, fusobacteria, and Enterobacteriaceae.

Tonsillitis

Clinical and laboratory data support the role of anaerobes in acute and chronic tonsillitis. Anaerobes were isolated from 25% of suppurative cervical lymph nodes, dental and tonsillar infections,[31] and internal jugular veins thrombophlebitis causing postanginal sepsis. Fusobacteria, peptostreptococci, and AGNB play a major role in complications of tonsillitis (e.g., bacteremia, abscesses). Polymicrobial flora predominate in peritonsillar and retropharyngeal abscesses. Anaerobes were isolated from the cores of tonsils of children with recurrent GABHS and non-GABHS tonsillitis.

The pathogenic role of anaerobes in tonsillitis is supported by their recovery in tonsillar or retropharyngeal abscesses, often without any aerobic bacteria; isolation in Vincent's angina[5]; recovery of encapsulated *Prevotella* and *Porphyromonas* in inflamed tonsils; isolation from the core of recurrently inflamed non-GABHS tonsils; and response to antibiotics in non-GABHS tonsillitis.

Immune response against *P. intermedia* can be detected in non-GABHS tonsillitis patients and against *P. intermedia* and *F. nucleatum* after recovery from peritonsillar cellulitis or abscesses, and infectious mononucleosis.

Metronidazole alleviated the symptoms of tonsillar hypertrophy and reduced fever in infectious mononucleosis. Since metronidazole has no antiviral or aerobic antibacterial efficacy, its suppression of oral anaerobes may reduce their secondary inflammation. This is supported by the increased recovery of *P. intermedia* and *F. nucleatum* during acute phases of mononucleosis.

Recurrent pharyngotonsillitis and failure of penicillin to eradicate GABHS can be a serious clinical problem. Penicillin therapy can select β-lactamase-producing bacteria (BLPB; e.g., *Prevotella, Porphyromonas, Fusobacteria*, *H. influenza*, *S. aureus*) found in the tonsils of three-quarters of children with recurrent GABHS tonsillitis. The ability to detect β-lactamase in the tonsillar core and the response to antimicrobials effective against BLPB (i.e., clindamycin or amoxicillin/clavulanate), highlights the role of aerobic and anaerobic BLPB in the inability of penicillin to eradicate GABHS tonsillitis.

Pleuropulmonary

Aspiration of oropharyngeal or gastric content and severe periodontal or gingival disease predispose for anaerobic pleuropulmonary infection. The infection can progress from pneumonitis to necrotizing pneumonia, pulmonary abscess, and empyema. The infection is usually polymicrobial and includes *Prevotella, Porphyromonas, Fusobacterium,* and *Peptostreptococcus* spp.; GABHS; and microaerophilic streptococci (Table 122.4). Anaerobes were recovered in most community-acquired and in one-third of

TABLE 122.4 **AEROBIC AND ANAEROBIC BACTERIA ISOLATED IN VARIOUS TYPES OF INFECTION**

Type of infection	Aerobic and facultative organisms	Anaerobic organism
Pleuropulmonary	*Staphylococcus aureus*[a] viridans streptococci *Pseudomonas aeruginosa*[a] Enterobacteriaceae[a]	Pigmented *Prevotella* spp. (*P. denticola, P. melaninogenica, P. intermedia, P. nigrescens, P. loescheii*) Nonpigmented *Prevotella* spp. (*P. oris, P. buccae, P. oralis*) *Fusobacterium nucleatum* *Peptostreptococcus* spp. (*P. micros, P. anaerobius, P. magnus*) *Bacteroides fragilis* group Non–spore-forming gram-positive rods (*Actinomyces, Eubacterium, Lactobacillus* spp.)
Intra-abdominal	*Escherichia coli* *Enterococcus* spp. *Pseudomonas aeruginosa*[a]	*Bacteroides fragilis* group *Bilophila wadsworthia* *Peptostreptococcus* spp. (especially *P. micros*) *Clostridium* spp.
Female genital tract	*Streptococcus* (groups A, B, others) *Escherichia coli* *Klebsiella pneumonia, Neisseria gonorrhoeae* (in sexually active patients) *Chlamydia* spp. (in sexually active patients) *Mycoplasma hominis* (in postpartum patients)	*Peptostreptococcus* spp. *Prevotella* spp. (especially *P. bivia, P. disiens*) *Bacteroides fragilis* group *Clostridium* spp. (especially *C. perfringens*) *Actinomyces* *Eubacterium* spp. (in intrauterine contraceptive device–associated infections)
Skin and soft tissue	*Staphylococcus aureus* *Streptococcus* (*Strep. milleri group*, groups A and B, viridans group) *Enterococcus* spp. Enterobacteriaceae, *Pseudomonas aeruginosa*[a]	*Peptostreptococcus* spp. (*P. magnus, P. micros, P. asaccharolyticus*) Pigmented *Prevotella* spp., *Actinomyces* spp. Fusobacterium nucleatum *Bacteroides fragilis* group[‡] *Clostridium* spp.

[a] Organisms that have the potential of producing β-lactamase.

nosocomial-acquired aspiration pneumonia and pneumonia associated with tracheostomy with and without mechanical ventilation.

Adequate cultures should avoid oral flora contamination by using bronchoalveolar lavage, bronchoscopy via bronchial brush protected in a double-lumen plugged catheter (using quantitative cultures in the last two methods), percutaneous transtracheal aspiration, lung biopsy, or thoracentesis (of empyema fluid). Management includes drainage of empyema and antimicrobials effective against anticipated anaerobic and aerobic bacteria.

Intra-abdominal

Most visceral abscesses (e.g., hepatic, splenic); chronic cholecystitis; perforated and gangrenous appendicitis; perforations resulting from obstruction, inflammatory bowel disease, trauma, diverticulitis, or infarction; and postoperative abdominal surgery wound infections and abscesses are polymicrobial due to gastrointestinal aerobic and anaerobic bacteria.

The initial infection following perforation is peritonitis, a synergistic polymicrobial infection. The predominant aerobic and facultatives are *E. coli* and *Streptococcus* spp. (including *Enterococcus* spp.), and the anaerobes are the *B. fragilis* group, and *Peptostreptococcus, Clostridium, Fusobacterium,* and *Eubacterium* spp. (see Table 122.4).

Intra-abdominal infections are biphasic: an initial peritonitis associated with *E. coli* sepsis, followed by abscess formation due to anaerobes (mainly *B. fragilis*). Biliary tract infection is usually caused by *E. coli, Klebsiella*, and *Enterococcus* spp. Anaerobes (mainly *B. fragilis* group and rarely *C. perfringens*) can be isolated in infections associated with carcinoma, recurrence, obstruction, and bile tract surgery or manipulation.

Appropriate management of intra-abdominal infections requires administrating antimicrobials effective against both aerobic and anaerobic bacteria, as well as surgical correction and drainage of pus. Single and easily accessible abscesses can be drained percutaneously. The outcome of the infection depends on a variety of factors that include the general condition of the patient (as measured by the Apache score), site of perforation, bacteriology, and antimicrobials given.

Antimicrobials should cover Enterobacteriaceae and anaerobes (mainly *B. fragilis* group). For mild to moderate community-acquired

infections in adults, the agents recommended are ticarcillin-clavulanate, cefoxitin, ertapenem, moxifloxacin, or tigecycline as single-agent therapy or combinations of metronidazole with cefazolin, cefuroxime, ceftriaxone, cefotaxime, levofloxacin, or ciprofloxacin. Agents no longer recommended are cefotetan and clindamycin (because of *B. fragilis* group resistance), ampicillin-sulbactam (*E. coli* resistance), and aminoglycosides (toxicity). For high-risk community-acquired infections in adults, recommended agents are meropenem, imipenem-cilastatin, doripenem, piperacillin-tazobactam, ciprofloxacin, or levofloxacin in combination with metronidazole, or ceftazidime or cefepime in combination with metronidazole. Quinolones should not be used unless hospital surveys indicate >90% susceptibility of *E. coli* to quinolones.

Female genital tract

These include soft tissue and perineal infections, bacterial vaginosis, vulvar and Bartholin gland abscesses, endometritis, pyometra, salpingitis, tubo-ovarian abscesses, adnexal abscess, pelvic inflammatory disease (including pelvic cellulitis and abscess), amnionitis, septic pelvic thrombophlebitis, intrauterine contraceptive device-associated infection, septic abortion, and postsurgical obstetric and gynecologic infections. Avoiding specimen contamination by normal genital flora can be achieved by use of culdocentesis, laparoscopy, or quantitative endometrial cultures of transcervical samples.

The predominant anaerobes in these polymicrobial infections include *P. bivia, P. disiens*, and *Peptostreptococcus, Porphyromonas,* and *Clostridium* spp. *Actinomyces* spp. and *Eubacterium nodatum* are isolated in infections associated with intrauterine devices. *Mobiluncus* spp. may be involved with bacterial vaginosis. The isolated aerobes include Enterobacteriaceae, *Streptococcus* spp., *Neisseria gonorrhoeae*, *Chlamydia* spp., and *Mycoplasma genitalium* (see Table 122.4).

Gas in the tissues, abscess formation, and foul-smelling discharge is often associated with the presence of anaerobes. Management includes administration of antimicrobials effective against potential aerobic, anaerobic, and sexually transmissible pathogens. Outpatient regimens include cefoxitin, ceftriaxone, or other parenteral third-generation cephalosporins plus doxycycline, with or without metronidazole. In-patient regimens include cefoxitin, cefotetan, or ampicillin-sulbactam plus doxycycline, and clindamycin or metronidazole plus doxycycline and gentamicin.

Skin and soft tissue infections

These include superficial infections, such as infected cutaneous ulcers, cellulitis, pyoderma, paronychia, hidradenitis suppurativa, and various secondary infected sites. Secondary sites include secondary infected diaper rash, gastrostomy or tracheostomy site, subcutaneous sebaceous or inclusion cysts, eczema, psoriasis, poison ivy, atopic dermatitis, eczema herpeticum, scabies, kerion, and postsurgical wound.

Subcutaneous tissue infections include cutaneous and subcutaneous abscesses, breast abscess, decubitus ulcers, diabetic (vascular or trophic) ulcers, bite wounds, anaerobic cellulitis, gas gangrene, bacterial synergistic gangrene, infected pilonidal cyst or sinus, Meleney's ulcer, and burns. Deeper soft tissue infections include necrotizing fasciitis, necrotizing synergistic cellulitis, gas gangrene, and crepitus cellulitis. These infections can involve the fascia and muscle, and cause myositis and myonecrosis. The isolated bacteria vary according to the type and circumstances leading to the infection and usually involve members of the normal flora of the region.

Aspirates from wounds and subcutaneous tissue infections and abscesses of the rectal area (i.e., decubitus ulcer, perirectal abscess) or those that originate from the gut flora (i.e., diabetic foot infection) often yield colonic flora. (i.e., *B. fragilis* group, *Clostridium* spp., Enterobacteriaceae, *Enterococcus* spp.). Infections in and around the oropharynx or that originate from that site (i.e., paronychia, bites, breast abscess) harbor oral flora. (i.e., *Prevotella*, *Porphyromonas, Fusobacterium*, and *Peptostreptococcus* spp.). Skin flora (i.e., *S. aureus*, *Streptococcus* spp.) and nosocomially acquired organisms can be found at all body sites (see Table 122.4). In addition to oral flora, human bite infections often contain *Eikenella* spp., and animal bites harbor *Pasteurella multocida*.

These infections are frequently polymicrobial and, in some (i.e., decubitus ulcers, diabetic foot ulcer), complicated by osteomyelitis or bacteremia. Deep tissue infections such as necrotizing cellulitis, fasciitis, and myositis often involve *Clostridium* spp., *S. pyogenes*, or polymicrobic aerobic and anaerobic bacteria. These often have gas in the tissues; putrid pus with a gray, thin quality; and are associated with a high rate of bacteremia and mortality.

Management includes surgical debridement and drainage; improving tissue oxygenation and administration of hyperbaric oxygen (HBO), especially in clostridial infection, may be helpful.

Osteomyelitis and septic arthritis

Anaerobes are notable in osteomyelitis of cranial and facial bones, long bones following trauma and fracture, osteomyelitis related to peripheral vascular disease, and decubitus ulcers. Cranial and facial bone osteomyelitis is usually caused by oral flora that spread from a contiguous soft tissue source or from sinus, ear, or dental infection. Intestinal anaerobes predominate in pelvic osteomyelitis that spreads from decubitus ulcers. Osteomyelitis of long bones is usually caused by hematogenic spread, trauma, or the presence of a prosthetic device.

Peptostreptococcus and *Bacteroides* spp. predominate at all sites; *Prevotella* and *Porphyromonas* spp. are prevalent in skull and bite infections, *B. fragilis* group is associated with vascular disease and neuropathy. Fusobacteria are often isolated from bites and cranial and facial infections. Clostridia are found in long bones, especially in association with wound contamination after trauma or exposure to gut flora.

Septic arthritis is rare and is frequently associated with hematogenous and contiguous spread, trauma, and prosthetic joints. Most infections are monomicrobial and the predominant isolates are peptostreptococci and *P. acnes* (often in prosthetic joint infection), *B. fragilis* and fusobacteria (often following hematogenic origin), and clostridia (associated with trauma).

Bacteremia

The incidence of anaerobes in bacteremia is 5% to 15%. Recent resurgence in anaerobic bacteremia is due to the greater incidence of anaerobic bacteremia in immunosuppressed and those with complex underlying disease. The common isolates are *B. fragilis* group (>75%), *Clostridium* (10–20%), *Peptostreptococcus* (10–15%), *Fusobacterium* spp. (10–15%), and *P. acnes* (2–5%).

B. fragilis group and clostridia are mostly associated with a gastrointestinal source; pigmented *Prevotella, Porphyromonas*, and *Fusobacteria* with oropharynx and pulmonary sources; fusobacteria with the female genital tract; *P. acnes* with foreign bodies; and peptostreptococci with all sources, but especially with oropharyngeal, pulmonary, and female genital tract sources.

Predisposing factors include malignancy; hematologic disorders; organ transplant; recent gastrointestinal, obstetric, or gynecologic surgery; intestinal obstruction; decubitus ulcers; dental extraction; the newborn; sickle cell disease; diabetes mellitus; splenectomy; and the use of cytotoxic agents or corticosteroids.

Typical features include metastatic lesions, hyperbilirubinemia, and suppurative thrombophlebitis. Mortality is 15% to 30% but improves with early and appropriate antimicrobials and resolution of the primary infection.

Management

Recovery depends on prompt and proper management. Treatment include neutralizing bacterial toxins produced and preventing local bacterial proliferation by changing the environment and hampering their spread.

Neutralization of toxins by specific antitoxins can be employed in clostridial infections (tetanus and botulism). Environmental control is achieved by debriding necrotic tissue, draining pus, improving circulation, alleviating obstructions, and increasing tissue oxygenation, sometimes by HBO. The primary role of antimicrobials is to limit local and systemic spread of the infection.

Hyperbaric oxygen

The use of HBO in gram-positive spore-forming anaerobic rods infection is controversial. Several uncontrolled reports demonstrated efficacy in individual cases,[3,5,74] however, since no controlled studies are available, HBO efficacy is unproved. Using HBO along with other therapeutic modalities is not contraindicated except when it delays other essential procedures.

Surgical therapy

Surgical therapy is often the most important and sometimes the only required treatment, whereas in others it is an important adjunct to antimicrobials. It is essential to drain abscesses, debride necrotic tissues, decompress closed space infections, and relieve obstructions. Without drainage the infection may persist and serious complications can arise.

Antimicrobial treatment

Appropriate management of mixed aerobic/anaerobic infection requires the administration of antimicrobials active against both components. A number of factors should be considered when choosing appropriate antimicrobials. They should be effective against all targeted organisms, induce minimal or no resistance, achieve adequate levels in the infected site, and induce minimal toxicity.

Antimicrobials may fail to clear the infection because of development of resistance, not achieving sufficient tissue levels, incompatible drug interaction, and development of an abscess. Antimicrobials are ineffective in treating abscesses. The abscess capsule reduces their penetration, and the low pH and the presence of binding proteins or inactivating enzymes (i.e., β-lactamase) can impair their activity. Low pH and the anaerobic conditions are detrimental for aminoglycosides and quinolones.

When choosing antimicrobials (see Table 122.5) for the therapy of polymicrobial infection, their aerobic and anaerobic spectrum and their availability in oral or parenteral form should be considered (Table 122.6). Some agents possess a limited range of efficacy. Metronidazole is effective only against anaerobes and therefore cannot be administered alone for mixed infections. Others (i.e., carbapenems) have broader spectra of activity.

Antimicrobials selection is easier when reliable culture results are available. However, this may be difficult to achieve, and most are treated empirically. Fortunately, the types of organism involved in many infections and their antimicrobial susceptibility patterns are predictable. However, antimicrobial resistance patterns may vary and may emerge during therapy.

B. fragilis group's susceptibility varies geographically and between institutions, and some antimicrobials used in the past are no longer adequate for empiric therapy. Many AGNB developed resistance to clindamycin, cefoxitin, and cefotetan, but most are uniformly susceptible to metronidazole, carbapenems, and chloramphenicol, and the combinations of a β-lactam/β-lactamase inhibitor. β-lactam/β-lactamase inhibitor combinations maintained good activity against the vast majority of anaerobes; 89% of *B. fragilis* strains are susceptible to ampicillin-sulbactam, 98% are susceptible to piperacillin-tazobactam.

Reports of a multidrug-resistant *B. fragilis* group underscores the importance of antibiotic stewardship. Clinicians can no longer rely on cumulative susceptibility data alone to select antimicrobials and should consider performing susceptibility testing when treating serious infections.

Additional factors influencing antimicrobial choice include drug pharmacology, toxicity, and effect on the flora. Although identification of the pathogen(s) and antimicrobial susceptibility may be required for selection of optimal therapy, the clinical setting and Gram stain of the specimen may suggest the types of organisms present.

Antimicrobials

Aminoglycosides, monobactams, and older quinolones possess poor activity against anaerobes. The agents adequate for treatment of anaerobic infections are discussed here.

TABLE 122.5 **ACTIVITY OF ANTIMICROBIAL AGENTS AGAINST ANAEROBES**

Agent	Comments
Nearly always active	
Metronidazole	Inactive versus microaerophilic streptococci (e.g., *Streptococcus milleri*), *Propionibacterium* and *Actinomyces* spp.; bactericidal versus most gram-negative anaerobic strains
Carbapenems	Resistant to most *Bacteroides* β-lactamases, although a novel β-lactamase that cleaves carbapenems was found in rare *B. fragilis* strains
β-Lactam plus β-lactamase inhibitors	The addition of a β-lactamase inhibitor to a β-lactam dramatically increases activity against anaerobes that produce a β-lactamase
Chloramphenicol	Good activity versus virtually all clinically significant anaerobes
Usually active	
Clindamycin	B. *fragilis* group: 15–40% of strains resistant; some clostridia other than *C. perfringens* are resistant
Cephamycins	B. *fragilis group*: 5–15% of strains resistant with considerable institutional variation at least partly reflecting use patterns; poor activity versus clostridia
Antipseudomonal	Relatively resistant to β-lactamases of *Bacteroides* spp; penicillins large doses usually employed
Variable activity	
Penicillin	Inactive versus some or most penicillinase-producing anaerobes, including most of the *B. fragilis* group and many strains of *Prevotella melaninogenica, P. intermedia, P. bivia, P. disiens,* and some clostridia
Cephalosporins	Less activity in vitro than penicillin G versus most anaerobes and limited other than cephamycins published clinical experience to document efficacy
Tetracycline	Inactive versus many anaerobes and most strains of *B. fragilis*; doxycycline and minocycline are somewhat more active than tetracycline
Vancomycin	Active against gram-positive anaerobes; inactive versus gram-negative anaerobes
Macrolides	Inactive versus many *Fusobacterium* spp. and some *B. fragilis* spp.; ketolides also show reduced activity versus fusobacteria
Fluoroquinolones	Third-generation (gatifloxacin, moxifloxacin, and gemifloxacin) show good in vitro activity; limited published data
Tigecycline	Active against nearly all anaerobes including strains of *B. fragilis* that are resistant to β-lactams, clindamycin, and quinolones. Minimum inhibitory concentrations are somewhat higher for clostridia
Poor activity	
Aminoglycosides	
Trimethoprim–sulfamethoxazole	
Monobactams (aztreonam)	

[†] While in vitro activity is excellent, clinical failures with chloramphenicol have been documented, rendering this drug less preferable to other active agents for the treatment of anaerobic infections.

Penicillins

Penicillin G is effective against *Peptostreptococcus* spp., most *Clostridium* spp., and nonsporulating anaerobic bacilli, and most non–β-lactamase-producing AGNB (i.e., *Bacteroides, Fusobacterium, Prevotella,* and *Porphyromonas* spp.). AGNB that exhibit increased resistance include *Fusobacterium*, *Prevotella*, and *Porphyromonas* spp., *P. bivia*, *P. disiens*, *Bilophila wadsworthia*, and *Bacteroides splanchnicus*. Resistance to penicillin by *C. ramosum, C. clostridioforme*, and *C. butyricum* through production of β-lactamase has also been observed.

Ampicillin and amoxicillin are equally effective to penicillin G, but the semisynthetic penicillins are less effective. Methicillin, nafcillin, and the isoxazolyl penicillins (oxacillin, cloxacillin, dicloxacillin) possess unpredictable activity and are inferior to penicillin G.

Penicillin therapy might be rendered ineffective by the presence of BLPB. The combinations of β-lactamase inhibitors (e.g., clavulanic acid, sulbactam, tazobactam) with a β-lactam antibiotic (ampicillin, amoxicillin, ticarcillin, or piperacillin) can overcome this phenomenon. Other mechanisms of resistance include

TABLE 122.6 **ANTIMICROBIAL DRUGS RECOMMENDED FOR THE THERAPY[A] OF SITE-SPECIFIC ANAEROBIC INFECTIONS**

	Parenteral	Oral
Intracranial	1. Metronidazole[4] 2. Chloramphenicol	1. Metronidazole[4] 2. Chloramphenicol
Dental	1. Clindamycin 2. Metronidazole,[4] Ticarcillin + CA, Ampicillin + SU[6]	1. Clindamycin, Amoxicillin + CA 2. Metronidazole[4]
Upper respiratory tract	1. Clindamycin 2. Ticarcillin + CA, Ampicillin + SU[6] 3. Metronidazole[4]	1. Clindamycin, Amoxicillin + CA 2. Metronidazole[5]
Pulmonary	1. Clindamycin[5] 2. Ticarcillin + CA, Ampicillin + SU,[6] Imipenem or Meropenem	1. Clindamycin[8] 2. Metronidazole,[5] Amoxicillin + CA
Abdominal	1. Metronidazole[3] 2. Imipenem or Meropenem Ertapenem, Piperacillin-Tazobactam, Tigecycline, Cefoxitin[3]	1. Metronidazole[8] 2. Amoxicillin + CA
Pelvic	1. Cefoxitin,[6] Clindamycin[3] 2. Piperacillin–Tazobactam,[6] Ampicillin + SU,[6], Metronidazole[6]	1. Clindamycin[6] 2. Amoxicillin + CA,[6] metronidazole[6]
Skin and soft tissue	1. Clindamycin, Cefoxitin 2. Metronidazole + Vancomycin 3. Tigecycline	1. Clindamycin, Amoxicillin + CA 2. Metronidazole + Linezolid
Bone and joint	1. Clindamycin, Imipenem, or Meropenem 2. Metronidazole + Vancomycin, Piperacillin-Tazobactam	1. Clindamycin 2. Metronidazole + Linezolid
Bacteremia with BLPB	1. Imipenem or Meropenem, Metronidazole 2. Cefoxitin, Ticarcillin + CA	1. Clindamycin, Metronidazole 2. Chloramphenicol, Amoxicillin + CA
Bacteremia with non-BLPB	1. Penicillin 2. Clindamycin, Metronidazole, Cefoxitin	1. Penicillin 2. Metronidazole, Chloramphenicol, Clindamycin

[a]Therapies are given as drug(s) of choice (alternative drugs). BLPB, β-lactamase-producing bacteria; CA, clavulanic acid; NA, not applicable; SU, sulbactam.
1, drug(s) of choice; 2, alternative drugs; 3, plus aminoglycoside; 4, plus a penicillin; 5, plus a macrolide (i.e., erythromycin); 6, plus doxycycline; 7, in location proximal to the rectal and oral areas use cefoxitin; 8, plus a quinolone (only in adults).

alteration in the porin canal and changes in the penicillin-binding protein.

In high concentrations, ticarcillin, piperacillin, and mezlocillin have good activity against Enterobacteriaceae and most anaerobes; however, about a third of *B. fragilis* group are resistant.

Cephalosporins

First-generation cephalosporins have similar activity against anaerobes similar to penicillin G. *B fragilis* group, *Prevotella*, and *Porphyromonas* are resistant to first-generation cephalosporins through cephalosporinase production. Cefoxitin is the most effective cephalosporin against the *B fragilis* group, although 5% to 15% may be resistant. It is not effective against clostridia, except *C. perfringens*. Cefotetan and cefmetazole (a second-generation cephalosporins) possess a longer half-life than cefoxitin. They are as effective against *B. fragilis*, but less efficacious against other members of the *B. fragilis* group. Consequently cefotetan is no longer recommended for treatment of intra-abdominal infections.

Carbapenems (imipenem, meropenem, doripenem, ertapenem)

Carbapenems possess excellent activity against aerobic and anaerobic bacteria and are often administered in serious infections. Resistance of the *B. fragilis* group is rare (<1%). Carbapenem resistance among anaerobes (1.1–2.5%) was found in a multicenter US survey. A higher rate (7–12%) was noted in a small number of isolates from Taiwan. Ertapenem has similar efficacy but is not active against *Pseudomonas* spp. and *Acinetobacter* spp.

Chloramphenicol

Chloramphenicol has excellent in vitro activity against most anaerobes, and resistance is uncommon. Its lipid solubility enables its penetration across lipid barriers, and it can gain high CNS concentrations. Its toxicity, the rare but fatal aplastic anemia, and the dose-dependent leukopenia, limit its use.

Clindamycin

B. fragilis resistance to clindamycin is increasing worldwide and reached about 40% in some locations. It is no longer recommended as empiric therapy for intra-abdominal infections. Up to 10% resistance was noted for *Prevotella*, *Fusobacterium*, *Porphyromonas*, and *Peptostreptococcus* spp., with higher rates for some *Clostridium* spp. (mostly *C. difficile*). Antibiotic-associated colitis due to *C. difficile,* although associated with most antimicrobials, was first described after clindamycin therapy.

Metronidazole and tinidazole

These nitroimidazoles possess excellent activity against anaerobes; however, they are ineffective against aerobes and facultatives. Microaerophilic streptococci, *P. acnes*, and *Actinomyces* spp. are often resistant, and adding antimicrobials effective against these organisms is often needed. Resistance among *B. fragilis* group is rare. Concern was raised about the carcinogenicity and mutagenicity of these drugs; however, these effects were found only in a single mice species and were never substantiated in other mammals or humans.

Macrolides (erythromycin, azithromycin, clarithromycin, fidaxomicin)

Macrolides have moderate to good activity against anaerobes other than *B. fragilis* group. They are active against pigmented *Prevotella* and *Porphyromonas* spp. and microaerophilic streptococci, gram-positive non–spore-forming anaerobic bacilli, and certain clostridia. They are less effective against *Fusobacterium* and *Peptostreptococcus* spp. They are active against *C. perfringens* and have poor or inconsistent activity against AGNB. Clarithromycin is the most active among macrolides against gram-positive anaerobes, including *Actinomyces, Propionibacterium,* and *Lactobacillus* spp. and *Bifidobacterium dentium*. Emergence of erythromycin-resistant isolates during therapy has been documented.

Fidaxomicin is a minimally absorbed narrow-spectrum macrolide effective against *C. difficile.*

Glycopeptides (vancomycin, teicoplanin)

Glycopeptides are effective against gram-positive anaerobes (including *C. difficile*) and inactive against AGNB.

Tetracyclines

Tetracycline is rarely used because of development of resistance by most anaerobes. Resistance in *P. acnes* has been related to previous use. The newer tetracycline analogues doxycycline and minocycline have better efficacy. Because of significant resistance, they can be used only when the isolates are susceptible or in less severe infections where a therapeutic trial is possible.

Tigecycline

This glycylcycline is active against aerobes and anaerobes and certain drug-resistant pathogens. It is active against *Streptococcus anginosus* group (includes *S. anginosus, S. intermedius*, and *S. constellatus*), *B. fragilis* group, *C. perfringens, C. difficile,* and *Parvimonas micra*. Resistance of members of the *B. fragilis* group is 3.3% to 7.2%.

Fluoroquinolones

Ciprofloxacin, ofloxacin, levofloxacin, fleroxacin, pefloxacin, enoxacin, and lomefloxacin are not very active against anaerobes; sparfloxacin, grepafloxacin. trovafloxacin, gatifloxacin, and moxifloxacin have considerable anti-anaerobic activity; and clinafloxacin and sitafloxacin have the greatest in vitro activity against anaerobes. Moxifloxacin monotherapy has been used in intra-abdominal infections in adults. However, concern over increasing resistance of *E. coli* and *B. fragilis* group has reduced its utilization. Quinolones use is restricted in growing children and during pregnancy because of their possible adverse effects on cartilage.

Other agents

Bacitracin is active against pigmented *Prevotella* and *Porphyromonas* spp. and is inactive against *B. fragilis* and Fusobacteria. Quinupristin-dalfopristin is active against *C. perfringens, Lactobacillus,* and *Peptostreptococcus* spp. Linezolid is active against *Fusobacterium, Porphyromonas, Prevotella,* and *Peptostreptococcus* spp.

Choice of antimicrobial agents

Parenteral antimicrobials (Tables 122.6 and 122.7) include metronidazole, a penicillin (i.e., ticarcillin, ampicillin, piperacillin) plus a β-lactamase inhibitor (i.e., clavulanic acid, sulbactam, tazobactam). Agents effective against gram-negative enteric bacilli (e.g., aminoglycoside, a fluoroquinolone) or an antipseudomonal cephalosporin (e.g., cefepime) are often added to metronidazole for treatment of intra-abdominal infection. Carbapenems (e.g., imipenem, meropenem, doripenem, ertapenem) are utilized as monotherapy.

Penicillin can be added to metronidazole in the therapy of intracranial, pulmonary, and dental infections to cover microaerophilic streptococci, *Actinomyces*, and *Arachnia* spp.; A macrolide can be added to penicillin to treat *S. aureus* and aerobic streptococci. Penicillin is added to clindamycin for supplemental coverage against *Peptostreptococcus* spp. and other gram-positive anaerobes.

Doxycycline is added to most regimens in pelvic infections to cover *Chlamydia* and *Mycoplasma*. Penicillin is still the drug of choice for bacteremia caused by susceptible non-BLPBs. However, other agents should be used for the therapy of bacteremia caused by BLPBs.

TABLE 122.7 **ANTIMICROBIAL DRUGS OF CHOICE FOR ANAEROBIC BACTERIA**

	Drug of choice	Alternative drugs
Peptostreptococcus spp.	Penicillin	Clindamycin, chloramphenicol, cephalosporins
Clostridium spp.	Penicillin	Metronidazole, chloramphenicol, cefoxitin, clindamycin
Clostridium difficile	Vancomycin, Fidaxomicin	Metronidazole, bacitracin
Fusobacterium spp.	Penicillin	Metronidazole, clindamycin, chloramphenicol
Bacteroides (BL-)	Penicillin	Metronidazole, clindamycin, chloramphenicol
Bacteroides (BL+)	Metronidazole, a carbapenem, a penicillin and β-lactamase inhibitor, clindamycin	Cefoxitin, chloramphenicol, piperacillin, tigecycline

Gram-negative bacilli include Bacteroides fragilis group and Prevotella, Porphyromonas, and Fusobacterium spp. BL, β-lactamase.

Because the duration of therapy is often longer than for infections caused by aerobic and facultative bacteria, oral therapy is often substituted for parenteral therapy. The available antimicrobials for oral therapy include amoxicillin plus clavulanic acid, clindamycin, chloramphenicol, and metronidazole. The duration of therapy of uncomplicated infection is generally 2 to 4 weeks. Some infections (i.e., osteomyelitis) require longer treatment. In some cases, such as lung abscesses, treatment may be required for as long as 6 to 8 weeks, but can often be shortened with proper surgical drainage.

Clinical judgment, personal experience, safety, and patient compliance should direct the physician in the choice of the appropriate antimicrobial agents.

Conclusion

Anaerobes are a frequent cause of endogenous infections in all body locations: the CNS, oral cavity, head and neck, chest, abdomen, pelvis, skin, and soft tissues. Management of these infection includes administration of effective antimicrobials, surgical drainage, and correction of the underlying pathology. Because these infections are often polymicrobial, the antimicrobial chosen should provide coverage of both the aerobic and anaerobic component of the infection. The most effective antimicrobials against anaerobes are metronidazole, the carbapenems (imipenem, meropenem, doripenem, ertapenem), chloramphenicol, the combinations of a penicillin and a β-lactamase inhibitor (ampicillin or ticarcillin plus clavulanate, amoxicillin plus sulbactam, and piperacillin plus tazobactam), tigecycline, cefoxitin, and clindamycin.

Anthrax

Tirdad T. Zangeneh, Marc Traeger, and Stephen A. Klotz

Introduction

Anthrax is a disease caused by the gram-positive, aerobic bacterium *Bacillus anthracis* and was recognized in antiquity. The disease figures prominently in the history of modern medicine because it was the first bacterial illness for which successful vaccines were prepared, almost simultaneously by William Smith Greenfield in London and Louis Pasteur in Paris. Anthrax is a zoonosis of herbivores encountered worldwide (except for Antarctica), and human cases continue to be seen in southern Europe, Eurasia, south Asia, and sub-Saharan Africa. Grazing wild ruminants and cattle are very susceptible, and human disease in animal husbandmen and herders is closely tied to exposure to infected beasts. It is reported that in some areas of rural Kenya 26% of animal husbandmen are serologically positive for *B. anthracis*. Propagating the bacteria in the spore form is used in bioterrorism, a novel and more recent form of human exposure to anthrax, utilizing delivery systems such as the postal service.

To understand anthrax one must keep in mind the natural cycle of disease in animals: spores survive prolonged periods in alkaline soils, rainwater concentrates spores in low-lying depressions, and susceptible herbivores gather in these locales during dry periods and inhale aerosolized spores or swallow spores loosely attached to forage. These geographic and climatic factors are usually present prior to animal outbreaks and may culminate in humans being infected accidentally. Spores arise from bacilli exposed to ambient air when blood from dying animals reaches the soil or carcasses are torn apart by scavengers. When the bacilli are exposed to air, spores form in the central and subterminal part of the bacillus. Spores may survive for prolonged periods (~90 years) in soil rich with organic material, a pH greater than 6.1 (alkaline soils), and with high concentrations of calcium ions (Ca^{++}). This characterizes a wide geographic swathe in the middle United States from Texas to North Dakota. It is also true for soils in the steppes of Asia and in sub-Saharan Africa, where anthrax remains common in wildlife. Although anthrax is considered an obligate pathogen, it is likely that in some circumstances a vegetative bacillus-spore cycle occurs independent of infection in the soil alone.

Currently, human anthrax infections in the resource-rich countries occur as a result of animal infection occurring thousands of miles away from the victim. Due to the worldwide trade in hides and wool, occasional occupational/recreational anthrax infections occur. There have even been recent reports of anthrax among intravenous drug users in Great Britain, their heroin contaminated at the source in Afghanistan. The widespread use of animal vaccines has reduced the number of livestock infections and, secondarily, human infections, but epizootics continue to occur in wildlife, particularly in South Africa and even in the United States and Canada.

Epidemiology of anthrax

Human anthrax infections related to the pursuit of agriculture most commonly take the form of cutaneous anthrax. This has been the pattern in Turkey and Zimbabwe, where the disease is endemic. Occasionally

gastrointestinal anthrax occurs and is almost always secondary to consumption of an animal dead from anthrax and usually in rural areas. Inhalational anthrax and meningitis are rare in the agricultural setting. Other persons at risk, apart from the animal husbandmen/herders, are veterinarians, slaughterhouse workers, and individuals handling bone meal.

Although anthrax occurs among wild animals in many resource-rich countries, human disease is almost always due to importation of contaminated animal products from resource-poor, rural areas of the world. Within the latter countries there are more than 1 billion livestock and 60 million poor rural livestock owners at risk for disease. The United States, Canada, and Europe are considered countries with only sporadic disease, although wildlife and cattle in Montana and northwestern Canadian provinces are endemic for animal anthrax. Research is being conducted to develop oral vaccines that to provide protection for wildlife where epizootics continue to occur.

Industrial anthrax is related to the use of animal products such as hair, wool, bone meal, and hides that are contaminated with spores of *B. anthracis*. This form of disease may occur years after the animals are slaughtered. Individuals at risk include tannery and textile workers and anyone using imported wool or yarn, hair, and hides from endemic areas. Disease is usually cutaneous (Box 123.1). Differential diagnoses are listed in Table 123.1.

TABLE 123.1 **DIFFERENTIAL DIAGNOSIS OF CUTANEOUS LESION OF ANTHRAX**

Zoonotic disease	Differentiating points
Tularemia (*Francisella tularensis*)	Prominent lymphadenopathy
Orf	Painless bullae
Cat scratch	Fleeting eschar
Tick-borne *Rickettsia: R. africae*, STARI, RMSF	Small eschar, often with body rash
Plague	Lymphadenopathy; Four Corners area of the United States

Abbreviations: STARI = Southern tick-associated rash illness; RMSF = Rocky Mountain spotted fever.

Pathogenesis of anthrax

Animal studies demonstrate that spores introduced through the skin rapidly germinate, and, within hours the subcutaneous lesions swell and numerous encapsulated gram-positive rods, often "box-car" in shape, are present. The capsule is composed of poly-D-glutamic acid and probably protects the bacterium from host recognition and attack by neutrophils (it is thought to be antiphagocytic). It is a bona fide virulence factor carried on a plasmid, pX02, and loss of the plasmid renders the bacterium less virulent (Table 123.2). The successful animal vaccine developed by Max Sterne uses a strain cured of pX02. Wildtype *B. anthracis* possesses a second plasmid, pX01, that controls toxin production of the vegetative state in the host. The toxin consists of three proteins, protective antigen (PA), edema factor (EF), and lethal factor (LF), typical binary toxins with an enzymatic site and binding site. After proteolysis of a small fragment from PA, the protein binds to six other PA fragments forming a heptameric channel to which LF and EF competitively bind and are then endocytosed. EF leads to increased levels of cyclic AMP and swelling whereas LF leads to cell death (Figure 123.1).

Spores inhaled into the lung reach the alveoli, where they are phagocytosed by macrophages. Macrophages then transit through the lymphatic system. Germination of the spores may occur up to 60 days following inhalation, as shown in monkeys. In gastrointestinal anthrax, hemorrhage and edema are located in the intestinal wall. In some animals, the M cell in Peyer's patches may be the site of entry of the microorganism.

BOX 123.1

Clinical clues that one may be dealing with anthrax

Think anthrax:
Employment history: Herdsman, veterinarian, textile worker, hide/wool worker
Chest x-ray findings: Widened mediastinum; pleural effusion (hemorrhagic)
Cutaneous lesions: Necrotizing ulcer with bullae; eschar (bacteria present beneath lesion)
Hemorrhagic meningitis: Gram-positive bacteria present in CSF

Clinical manifestations of anthrax

The clinical presentation of anthrax is variable and depends on the route of exposure. Presentations include cutaneous, inhalational, and enteric (gastrointestinal and oropharyngeal) forms, which may result in disseminated disease involving the central nervous system (CNS) (meningitis) and secondary bacteremia leading to sepsis. The majority of infections are due to cutaneous disease, and these infections have the lowest mortality. Cutaneous lesions, referred to as *eschars,* develop as single or multiple lesions after exposure to *B.*

TABLE 123.2 **VIRULENCE FACTORS POSSESSED BY *BACILLUS ANTHRACIS***

Virulence factor	Contribution to disease
Plasmid X02	Encodes for poly-D-glutamic acid capsule which may mask bacterium from host defenses
Plasmid X01	Encodes for tripartite toxin complex: protective antigen, lethal factor and edema factor
Spore	Survival of infectious propagule for up to ~90 years in conducive soils; exosporium allows for delay of germination within alveolar macrophages

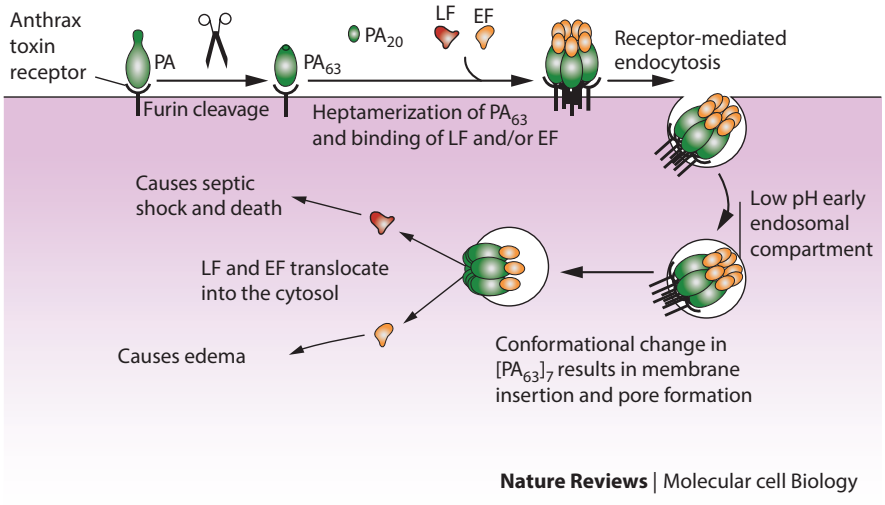

FIGURE 123.1

anthracis spores. Spores enter breaks in the skin, and, following an incubation period ranging from several hours to 3 weeks, the inoculum site develops into a papule followed by a ring of vesicles, accompanied by edema, regional lymphadenopathy, and necrosis. The lesion then forms the typical dark eschar, which is accompanied by profound edema usually from 5 to 7 days. Resolution occurs over a period of several weeks. Although the eschar is usually not painful most patients may experience constitutional symptoms or may present with sepsis, especially with lesions involving the face, neck, and upper chest. Infection involving the gastrointestinal tract occurs after ingestion of meat from animals dying of anthrax. The disease has an incubation period of 1 to 6 days and the presentation may initially include mild symptoms such as fever, nausea, vomiting, and mild diarrhea but then progresses to more severe symptoms of bloody diarrhea, acute abdominal pain, hematemesis, and ascites. Complications include obstruction, perforation, sepsis, and death. Pathologic evaluation demonstrates ulcerating, necrotizing lesions accompanied by regional lymphadenopathy. Inhalation anthrax is a rare but dangerous form of the disease with public health implications due to its association with bioterrorism. Infection involves lymph nodes rather than lung parenchyma, which makes the term "pulmonary" a misnomer since complications result from germinating spores transported to the lymphatic system by macrophages. The disease has a biphasic presentation with nonspecific initial symptoms of fever, headache, chills, malaise, and nonproductive cough followed by a more rapid progressive form when patients experience dyspnea, cyanosis, respiratory failure, sepsis, and death. The incubation period ranges from 4 to 11 days. The chest x-ray findings most consistent with inhalation anthrax include mediastinal widening, pleural effusions, and the presentation of hyperdense necrotic-appearing lymph nodes involving the mediastinum on CT. Infection of the CNS is a life-threatening complication of any of the major forms of anthrax and carries a poor prognosis. In contrast to common causes of bacterial meningitis, the cerebral spinal fluid contains large numbers of red blood cells, indicating a hemorrhagic component (Table 123.2).

Treatment of anthrax

Treatment for inhalational anthrax includes ciprofloxacin or doxycycline plus consideration of one or two other antimicrobials, such as rifampin, vancomycin, imipenem, chloramphenicol, penicillin or ampicillin, clindamycin, and clarithromycin. Doxycycline may be less optimal for cases with meningitis because of poor CNS penetration. For cutaneous anthrax, ciprofloxacin or doxycycline are recommended for initial therapy. Duration of combined intravenous and oral therapy should continue for 60 days for all anthrax cases because of the potential persistence of spores after an aerosol exposure. For additional details of antimicrobial regimens, see Chapter 120, "Bioterrorism." A new modality of therapy is the use of a monoclonal antibody (raxibacumab) that inhibits PA binding to anthrax toxin receptors.

However, reliance solely upon a monoclonal antibody against toxins in established anthrax bacteremia may not be efficacious. Animal studies show that antibodies to bacterial cell wall proteins may be needed in addition to anti-toxins to protect victims from the high-grade bacteremia that occurs in disseminated disease.

Bioterrorism and anthrax

The Working Group on Civilian Biodefense has identified *B. anthracis* as one of the most serious biologic weapon threats to cities or regions. Presentation of bioterrorism-related anthrax will typically result in inhalational and cutaneous cases. The sudden appearance of several cases of severe acute febrile illness with fulminant courses should prompt the clinician to consider anthrax—and therefore bioterrorism—as the etiology and delivery mechanism of the disease.

A cluster of cutaneous anthrax cases should also alert the clinician to the possibility of bioterrorism-associated anthrax. (See Chapter 120, "Bioterrorism.")

Prophylaxis of anthrax

Pre-exposure vaccination

An acellular vaccine against *B. anthracis* has been approved for human vaccination in the United States (anthrax vaccine absorbed or AVA, [BioThrax]). Pre-exposure vaccination is recommended by the Advisory Committee on Immunization Practices for adults, age 18–65 years, with specific occupational and laboratory exposures to *B. anthracis*. Laboratory personnel who work with high concentrations or pure cultures of *B. anthracis* spores, and/or with environmental samples associated with anthrax investigations, and/or in spore-contaminated areas or other settings with exposure to aerosolized *B. anthracis* are recommended to receive pre-exposure vaccination with AVA (BioThrax). Persons involved in environmental investigations or remediation efforts are also recommended to receive pre-exposure vaccination. Routine vaccination of those who handle animals or animal products in the United States is not recommended unless the person is handling potentially infected animals in research settings or in areas with a high incidence of enzootic anthrax or when standards and restrictions are insufficient to prevent exposure to *B. anthracis* spores. Pre-exposure AVA vaccination may be indicated for the military as recommended by the Department of Defense. Persons involved in emergency response activities are not routinely advised to receive pre-exposure vaccination but may be offered vaccine in specific circumstances. The recommended vaccination schedule includes five 0.5 mL doses administered intramuscularly at 0 weeks, 4 weeks, 6 months, 12 months, and 18 months; annual boosters are required every 3 years to maintain immunity.

Postexposure prophylaxis (PEP)

Those at risk for anthrax following a *B. anthracis* spore exposure are identified by public health officials depending on epidemiologic circumstances. Prophylaxis is indicated for those exposed to an airspace contaminated with aerosolized *B. anthracis*. Ciprofloxacin, doxycycline, and parenteral penicillin G procaine have been approved by the US Food and Drug Administration (FDA) for prophylaxis of inhalational *B. anthracis* infection. Although the optimal duration of prophylaxis is uncertain, antibiotics were recommended for 60 days for those exposed in the US anthrax attacks of 2001, based on animal studies of anthrax deaths and spore clearance after exposure, and the FDA has licensed a 60-day course for postexposure use. The Working Group on Civilian Biodefense recommends monotherapy with ciprofloxacin for adults, children, and pregnant women, recognizing that fluoroquinolones are not generally recommended for children or pregnant women because of risks of arthropathy in children. However, the working group determined that the risk of anthrax and its consequences outweighs the risks of fluoroquinolone use in these groups. Doxycycline is recommended as an alternative in all groups, with cautions and recommendations for its use in pregnant women and children similarly acknowledged. Amoxicillin is listed as an alternative 60-day prophylaxis option in pregnant women and children. The FDA has approved penicillin G, ciprofloxacin, levofloxacin, and doxycycline for antimicrobial posttexpoure prophylaxis of anthrax.

Postexposure vaccination of exposed persons is recommended in conjunction with a 42–60-day prophylactic antibiotic course (depending upon the demographics of those exposed) by the Advisory Committee on Immunization Practices. In contrast to pre-exposure vaccination, PEP vaccination is recommended as a three-dose subcutaneous series (at 0, 2, and 4 weeks) in conjunction with a 60-day course of appropriate antimicrobial agents. The vaccine is stored in the Strategic National Stockpile (SNS) to be used for postexposure prophylaxis in the event of a terrorist attack. In the event of a large-scale emergency response, in which the demand for vaccine exceeds the supply, dose-sparing regimens for AVA, and an alternative intramuscular administration route, have been shown to be protective and are available. PEP animal studies using monkeys support the use of vaccine *in conjunction* with antibiotics following exposure to aerosolized *B. anthracis* spores. Although 5 of 29 animals died after completing a 30-day course of antibiotics following *B. anthracis* spore exposure, none of 9 receiving doxycycline for 30 days plus vaccine at baseline and at day 14 following exposure died. However, 8 of 10 animals treated with vaccine only subsequent to aerosolized spore exposure died.

Laboratory diagnosis of anthrax

The most useful diagnostic laboratory test for anthrax is the blood culture. If drawn before antibiotics are started in those with inhalational anthrax, the standard blood culture may show growth of large gram-positive bacilli with preliminary identification of *Bacillus* species. During the US anthrax attacks, eight of eight case patients with inhalational anthrax who had blood cultures obtained prior to initiation of antibiotics had positive blood cultures for *B. anthracis*. *Bacillus* species are routinely identified in blood cultures within 24 hours following inoculation, but some laboratories do not further identify *Bacillus* species unless specifically requested because of the frequency of *Bacillus cereus* contaminants. If *B. anthracis* cannot be specifically excluded from cultures in a clinical laboratory, isolates can be transferred to a Laboratory Response Network (LRN) laboratory to identify or rule out *B. anthracis*. In specialized and LRN laboratories, other definitive diagnostic tests can be performed, such as immunohistochemical (IHC) staining or polymerase chain reaction (PCR) assays of biopsied tissue or body fluids. Cerebrospinal fluid (CSF) cultures may be useful for diagnosis.

For cutaneous anthrax, a Gram stain and culture of vesicular fluid should be obtained, and, if negative or if antibiotics were initiated prior to the sampling, a punch biopsy should be performed for IHC staining or PCR.

Nasal swabs are not used for diagnosis of inhalational anthrax since they may be negative in those with infection. However, they were useful as epidemiologic tools to identify the source and route of exposure and mechanism of release in the US anthrax attacks. A positive nasal swab indicates exposure to *B. anthracis* and is an indication for clinical or prophylactic treatment.

Sputum samples for Gram stain and culture are generally not helpful to diagnose inhalational anthrax due to the frequent lack of a pneumonic process. Antibody testing to the PA of *B. anthracis* has not been established as a diagnostic tool.

Non-*Anthrax bacillus* species and the diseases they cause

Bacillus cereus and other non–anthrax-related species are recognized contaminants but also clearly pathogenic. These bacteria, which are ubiquitous in the environment, are one of the most common microbes on the Earth's crust, present in wide diverse ecologic niches, and found in animal and plant food sources. Members of the genus are catalase-positive, spore-forming, aerobic or facultative anaerobic, gram-positive or gram-variable with close phenotypic and genetic similarities to one another, and they are easily grown on most culture media. Optimum temperature for growth is between 28°C/82°F and 35°C/95°F. The *B. cereus* group includes *B. cereus, B. anthracis, B. thuringiensis, B. mycoides, B. pseudomycoides*, and *B. weihenstephanesis*. The use of 16S rRNA for the comparison of the nucleotide sequences has highlighted the close relationship of *B. cereus, B. anthracis*, and *B. thuringiensis*. Other species, *B. subtilis*, *B. licheniformis*, *B. megaterium*, *B. pumilus*, and *B. sphaericus*, bear a more distant relationship and are clinically not as important in human infections. *B. cytotoxicus* belongs to the *B. cereus* group and was implicated in cases of severe food poisoning with a fatal diarrheal disease. It may have a lower cytotoxic potential than first reported. *B. cereus* has served as the model in several taxonomic studies and is the main focus of discussion in this section. *B. thuringiensis* is utilized as a biopesticide. *B. cereus* toxin is important in cases of foodborne illness. Additionally, intestinal and nonintestinal tissue destructive toxin production may occur secondary to hemolysins, phospholipases, emesis-inducing toxin, and pore-forming enterotoxins.

Recently anthrax-like infections affecting different wildlife species have been reported in several sub-Saharan African rainforests including the Taï National Park, Côte d'Ivoire, caused by *B. cereus* biovar *anthracis. B. cereus* biovar *anthracis* is a member of the *B. cereus* group and carries both *B. anthracis* virulence plasmids. *B. cereus* strain G9421, harboring two virulence plasmids, pBCXO1 and pBC210, has been linked to fatal anthrax-like pneumonias. The *B. cereus* isolate, BcFL2013, which is positive for the *B. anthracis* pXO1 toxin genes, has been associated with the development of lesions similar to the classic cutaneous anthrax eschar. (All three variants are discussed in the last reference of "Suggested reading"). *Bacillus cereus* harbouring *Ba813*, a chromosomal marker of *B. anthracis*, was reported to form a biofilm contributing to an outbreak of infections in patients with hematological malignancies.

Epidemiology of non-*Anthrax bacillus* species

Nosocomial infections include bacteremia and hospital-acquired pneumonias. These are usually due to microorganisms present in decaying organic matter, soil, fomites, water, and food sources. Foodborne outbreaks are due to the microorganism's presence in food sources and human intestinal flora. *B. cereus* species are often regarded as contaminants when recovered in blood cultures and have been implicated in cases of pseudo-outbreaks since the microorganism may survive usual disinfectants and inadequate sterilization techniques, and it has the capability to adhere to intravascular catheters. Populations at risk for disease include injection drug users, immunocompromised hosts, neonates, and long-term hospitalized critically ill patients with nosocomial infections.

Clinical manifestations of non-*Anthrax bacillus* infections

The clinical presentation of non-anthrax *Bacillus* infections is variable and includes wound and burn-related infections; endophthalmitis; bacteremia; CNS infections; intravascular infections including endocarditis; respiratory tract infections; complicated bone, skin and soft tissue infections; and toxin-mediated foodborne illnesses and chorioamnionitis with fetal demise. Most infections are due to *B. cereus*, but other species including *B. circulans, B. licheniformis, B. megaterium, B. pumilus, B. sphaericus*, and *B. subtilis* have been reported. While occupational exposure to *B. cereus* resulting in bacteremia and pneumonia has been reported, nosocomial infections such as ventilator-associated pneumonias, catheter-related bloodstream infections, and meningitis, through exposure to fomites, are increasingly being reported among immunocompromised hospitalized patients. Exotoxin-mediated tissue destructive ocular infections such as endophthalmitis resulting from exogenous (trauma) and endogenous (hematogenous) sources lead to rapid vision loss. These infections are typically more aggressive and rapid in nature in comparison to infections by other bacteria. CNS infections have been reported in immunocompromised patients who acquired the infections from hematogenous, intrathecal procedures, and possible gastrointestinal sources. Complicated skin and soft tissue infections due to penetrating trauma, surgery, injection drug use, or burns are associated with a high mortality, and, in some cases, have mimicked the eschars of *B. anthracis*. Cutaneous infections with necrotizing fasciitis and myonecrosis may resemble *Clostridium perfringens* gas gangrene infections. Intravascular infections including native valve and prosthetic valve endocarditis, and device-related infections, such as on pacemakers, have been described.

Gastrointestinal disease caused by *B. cereus* is due to the ability of the microorganism to survive heat and changes in environment and infiltrate human food sources. Its ability to cross-contaminate various food sources by spore formation indicates its ubiquitous presence in the food chain and opportunity for foodborne diseases. The most commonly reported clinical manifestations of foodborne illness with *B. cereus* are emetic and diarrheal syndromes mediated by various toxins. The presentations range from asymptomatic to mild to fatal cases. In emetic disease the incubation period ranges from 0.5 to 6 hours after ingestion of starchy foods such as rice contaminated by spores with an infective dose of 10^5 to 10^8 colony-forming units (CFU). Preformed toxins including cyclic peptide and cereulide mediate the disease process. The patients experience nausea, vomiting, and malaise with symptoms lasting from 6 to 24

hours. In diarrheal disease the incubation period ranges from 8 to 16 hours after ingestion of foods with high protein contents such as meat and milk products, mediated by hemolysin BL, nonhemolytic enterotoxin, and cytotoxin K enterotoxins in the small intestine. Patients often present with nausea, abdominal pain, and non-bloody diarrhea that lasts from 12 to 24 hours.

Treatment of non-*Anthrax bacillus* infections

Timely diagnosis and treatment of *B. cereus* infections is critical. Historically, culture methods are labor-intensive, costly and time-consuming. Recent advancements in the use of biosensors such as phage-based, cell-based, immunosensors and DNA biosensors allowTi for the rapid diagnosis of infections caused by *B. cereus* strains.

Through its production of β-lactamases, *B. cereus* is resistant to most β-lactam antibiotics including penicillins and cephalosporins. Reports of resistance to erythromycin, tetracycline, and carbapenems have created a problem for the clinician in choosing an initial treatment regimen. Some experts consider vancomycin the drug of choice, and there are multiple reports indicating that ciprofloxacin has been found to be effective in the treatment of skin and soft tissue infections. Antibiotic susceptibility methods should be performed to guide correct antibiotic selection even though studies have indicated uniform sensitivity to levofloxacin, moxifloxacin, rifampin, daptomycin, and linezolid. As is the case in most intravascular infections, removal of the source is key to achieving control of infection. Unfortunately, the reputation of *Bacillus* spp. as contaminants often leads to underrecognition, disregard of crucial information, and thus delay in treatment of severe, life-threatening infections. Treatment of gastrointestinal disease is supportive.

Bartonella bacilliformis

Nuria Sanchez Clemente

Introduction

Bartonella bacilliformis is a gram-negative, facultative intracellular, aerobic coccobacillus that is a member of the α-proteobacteria group along with *Rickettsia* and *Brucella*.

It is responsible for a spectrum of disease which, despite its limited distribution, have been given a multitude of names including *bartonellosis*, *Carrion's disease*, *Oroya fever*, and *verruga peruana*.

The disease is restricted to the Andean cordillera in Peru, Ecuador, and Colombia with sporadic cases being reported in Bolivia, Chile, and Guatemala. Classically, endemic areas are said to be confined to inter-Andean valleys at altitudes between 500 and 3,200 meters above sea level (Figure 124.1). This focality is mainly due to the characteristics of its putative principal sandfly vector, *Lutzomyia verrucarum*, which has a weak, hopping flight and is intolerant of extreme temperatures.

Young children under 10 are the most affected age group in endemic communities, partly because of a predominantly younger population but also due to the presumed protective immunity that develops with repeated infection.

B. bacilliformis is thought to be mainly transmitted to humans by sand flies belonging to the *Lutzomyia* genus. However, transmission via blood transfusion, tick bites, and vertical transmission have all been reported.

Clinical features

There are two well-described phases of the illness.

The initial intraerythrocytic acute stage, known as Oroya fever, occurs typically around 2 to 6 weeks after inoculation of the microorganism by the bite of an infected sandfly. It is characterized by fever, pallor, malaise, joint pain, headache, and anorexia. In severe cases, with high parasitemia, this progresses to severe hemolytic anemia.

High mortality rates of 44% to 88% have been reported in untreated individuals in endemic areas. Most deaths are associated with secondary bacterial infection, most commonly with *Salmonella* spp. but also with *Toxoplasma*, *Histoplasma*, mycobacteria, and fungi. Other complications include pericardial effusion, acute respiratory distress syndrome, hepatitis, convulsions, and coma. In pregnancy, infection can lead to miscarriage, premature labor, and maternal death.

Specific genetic variants of *B. bacilliformis* might account for the marked variability in mortality and morbidity observed in outbreaks.

B. bacilliformis may, in some cases, subsequently colonize the vascular bed of the skin, resulting in a chronic eruptive phase that can occur weeks to months after the acute illness. This stage is characterized by the eruption of crops of miliary, mular, or nodular verrugas or warts containing sero-sanguinous fluid. These occur mainly over the extremities but can also affect the face and trunk. Miliary lesions (Figure 124.2,

FIGURE 124.1

lower lesion) are the most common; occurring in the upper dermal layers they can crop in large numbers and can be pruritic. There may also be mucosal involvement. Mular lesions (Figure 124.2, upper lesion) are >5 mm in diameter and have an eroded center. Nodules are larger diffuse subdermal swellings. The latter two can be painful, especially if occurring over joints. Secondary bacterial infection is a recognized complication.

Due to the fact that *B. bacilliformis*, like all *Bartonella* spp., can circulate in the blood for the remaining life span of the infected erythrocyte, there is also a chronic and usually asymptomatic phase that can last several weeks or months.

The eponym Carrion's disease recognizes the contribution of Daniel Alcides Carrion, a Peruvian medical student who, in 1885, asked a fellow student to inoculate him with blood from a cutaneous lesion from a diseased patient in order to test his hypothesis that the two clinical entities were actually manifestations of the same disease. His hypothesis was proved tragically correct as he developed and soon after succumbed to the acute febrile form of the illness hitherto known as Carrion's disease, thus becoming a martyr of Peruvian medicine.

Diagnosis

In endemic areas, cases are treated empirically during outbreaks. However, the most frequently used diagnostic test is peripheral blood smear (Figure 124.3). When stained with Giemsa, the blue intra- and extraerythrocytic coccobacilli of *B. bacilliformis* can be seen microscopically. Few studies have looked at the sensitivity and specificity of this easy and affordable test. One study which used polymerase chain reaction (PCR) as a reference standard found a sensitivity of 36% and a specificity of 96% in patients with the acute form of the disease. In the chronic eruptive phase, the sensitivity of peripheral blood smear is even lower and therefore not usually carried out.

FIGURE 124.2

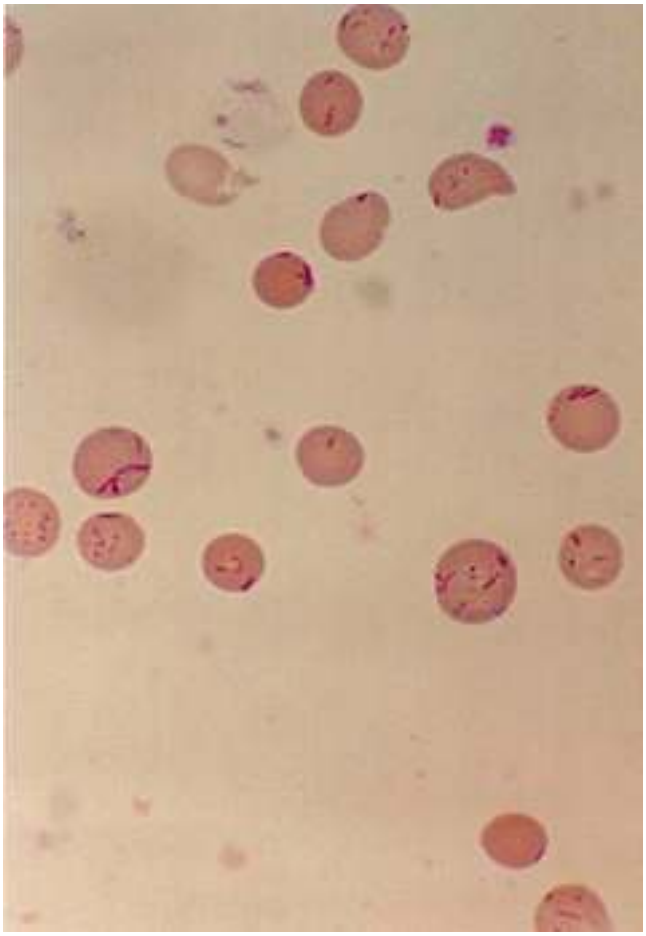

FIGURE 124.3

Blood cultures are rarely used as a diagnostic method as they require prolonged incubation for several weeks in blood-rich medium.

Histopathologic samples of the verrugas are rarely taken in the chronic eruptive phase if the diagnosis is unclear. Biopsy of the lesion classically shows angioblastic proliferation with copious macrophages and lymphocytes. Giemsa staining demonstrates *B. bacilliformis* in the endothelial cells and extracellular matrix.

Serologic methods such as indirect fluorescence antibody test (IFA) and enzyme-linked immunosorbent assay (ELISA) have been developed for use in both phases of the illness but are only available in tertiary centers away from endemic areas. Sensitivity using IgM is superior to IgG ELISA (85% vs. 70%); specificity has been quoted as 100% for both. IFA has a reported sensitivity of 85% and a specificity of 92%.

PCR tests also exist, and studies have shown 16S ribosomal RNA PCR tests to be superior in the detection of *B. bacilliformis* in peripheral blood samples and dried blood spots compared to other PCR techniques.

Management

There are no published controlled clinical trials of therapy for acute or chronic Carrion's disease. Treatment guidelines are based on observational studies and have not been updated since 2006 (Table 124.1).

Severe cases are those in which there are any of the following features: hemodynamic instability, metabolic acidosis, signs of cardiac failure, respiratory compromise, neurologic involvement, severe anemia, hepatitis, gastrointestinal involvement, renal failure, or raised inflammatory markers.

TABLE 124.1 **ANTIBIOTIC MANAGEMENT OF ACUTE AND CHRONIC BARTONELLOSIS ACCORDING TO SEVERITY**

Type of disease, severity	Antibiotic
Acute, mild to moderate	**Chloramphenicol** 50 mg/kg/d for first 3 d then 30 mg/kg to complete 14 d Ciprofloxacin 5 mg/kg BID for 14 d **Amoxicillin-clavulanate** 20 mg/kg BID for 14 d **Trimethoprim-sulfamethoxazole** 5 mg/kg BID for 14 d
Acute, severe	First line: ciprofloxacin 10–15 mg/kg BID for 14 d and ceftriaxone 70 mg/kg IV for 7–10 d Second line: ciprofloxacin (as above) and ceftazidime 30 mg/kg TID IV for 7–10 d or amikacin 7.5 mg/kg BID IV for 7–10 d
Chronic, all	**Azithromycin** 10 mg/kg/d for 7 d **Rifampin** 10 mg/kg/d for 21–28 d **Erythromycin** 12.5 mg/kg QID for 14 d **Ciprofloxacin** 5 mg/kg BID for 14 d

Prevention of the disease is mostly centered on vector control with the use of intra- and extradomiciliary DDT and pyrethroid sprays. Bed nets can also be efficacious but should be impregnated with insecticide as sandflies may penetrate the mesh due to their small size.

Due to its focal geographic nature and the fact that it affects small, isolated, rural communities, Carrion's disease has been truly neglected. Diagnostic and treatment guidelines are supported only by very low-evidence studies and expert opinion. Further research is needed to improve the understanding of this fascinating disease.

Cat scratch disease and other *Bartonella* infections

William A. Schwartzman

Introduction

Cat scratch disease (CSD) was first described in 1950 by Rene Debré as "La Maladie de Griff de Chat." Its cause remained a mystery until the late twentieth century, when amplification and sequencing of 16S rRNA genes was introduced as a method of identifying organisms that had not been successfully cultured. In 1992, David Relman and co-workers used this technique to identify the agent of CSD, and bacillary angiomatosis and parenchymal bacillary peliosis (BAP). He found that the causative organism was a small gram-negative coccobacillus closely related to the agents causing trench fever, brucellosis, and crown gall disease in plants (*Agrobacterium tumefaciens*).

The organism was first named *Rochalimaea henselae*, and was subsequently grouped within the family Bartonellaceae, along with a number of other organisms, including the agents of trench fever, *Bartonella quintana* (formerly *Rochalimaea quintana*). *Bartonella bacilliformis*, the agent of acute and chronic Carrión's disease is a related ancestor of modern members of the family Bartonellaceae. Recent reports suggest that similar clinical syndromes in the Andean highlands may also be caused by *Bartonella rochalimae* and possibly *Candidatus* Bartonella ancashi 20.0. These organisms, and probably others of the genus, share the ability to invade vascular endothelial cells, bone marrow erythroblasts, and mature erythrocytes. They also share the ability to induce macrophage-mediated secretion of proinflammatory cytokines (notably interleukin-10 [IL-10]) andvascular endothelial cell growth factor (VEGF) and the ability to suppress vascular endothelial cell apoptosis. These virulence factors give them the ability to disseminate within the host, causing proliferative vascular lesions and prolonged bacteremia in humans and mammalian reservoirs.

Since the identification of *Bartonella henselae*, there has been an explosion of knowledge about the manifestations of CSD and those of the expanding roster of *Bartonella* species that populate their mammalian reservoirs; from small rodents to horses, cows, kangaroos, and, in one report, porpoises (Table 125.1).

The clinical spectrum of CSD in the immunocompetent host includes classic CSD as well as ophthalmologic, neurological, cardiovascular, parenchymal, musculoskeletal, and immune complex–mediated syndromes such as glomerulonephritis; as well as prolonged fever without adenopathy or focal lesions. Parenchymal masses associated with CSD have been mistaken for malignancies such as breast cancer or lymphoma.

In hosts with compromised cell-mediated immunity, including patients with acquired immunodeficiency syndrome (AIDS), solid organ transplant recipients, and patients with hematologic malignancies, *B. henselae* and *B. quintana* cause vascular tumors called bacillary angiomas (BA) and blood-filled cavities of liver and spleen, termed bacillary peliosis hepatis; these lesions are referred to collectively as "BAP."

TABLE 125.1 *BARTONELLA* SPECIES CURRENTLY REPORTED TO HAVE CAUSED ZOONOTIC INFECTIONS

Species	Reservoir	Vector	Human disease
B. henselae	Cat, dog, raccoon	Cat flea *(Ctenocephalides felis)*, other?	CSD, retinitis, IE, myocarditis, encephalopathy, aseptic meningitis, myelitis, neuropathy, osteomyelitis, BAP, glomerulonephritis, purpura, pseudomalignancy, prolonged asymptomatic bacteremia
B. quintana	Rat, human?	Louse	CSD, IE, trench fever, encephalopathy, BAP, osteomyelitis, prolonged asymptomatic bacteremia
B. vinsonii subsp. *berkhoffii*	Coyote, dog	Unknown	IE
B. vinsonii subsp. *arupensis*	White-footed mouse	Unknown	IE, neurologic disorders
B. koehlerae	Cat, raccoon	Flea, *C. felis*	IE
B. elizabethae	Rat	Oriental rat flea *Xenopsylla cheopsis*	IE
B. washoensis	California ground squirrel *(Spermophilus beecheyi)*	Unknown	Fever, myocarditis
B. alsatica	Rabbit	Unknown	IE
B. grahamii	Wild mice	Unknown	Neuroretinitis
B. clarridgeiae	Cat, raccoon	Flea, *C. felis*	Possible CSD

Abbreviations: CSD = cat scratch disease; IE = infective endocarditis; BAP = bacillary angiomatosis and parenchymal bacillary peliosis.

Classic cat scratch disease

CSD is the most common cause of regional lymphadenitis in children and young adults. Approximately 24 000 cases occur each year with a prevalence of roughly 9.3/10 000 ambulatory patients per year and a seroprevalence ranging from 3% to 6%. CSD tends to occur in late summer or fall and to vary in frequency with the geographic distribution of the cat flea, *Ctenocephalides felis*.

The first clinical manifestations of CSD appear 5 to 7 days after the scratch or bite from an infected cat, kitten, or cat flea, with the appearance of a small erythematous nodule at the site of bacterial entry. Although this inoculation papule may go unnoticed, it is said to be present in 70% of CSD cases. This nodule represents the initial host response to bartonella and is characterized by palisading macrophages, acute and chronic inflammatory cell infiltration, as well as activation and invasion of vascular endothelial cells. Painful swelling of the proximal lymph nodes follows the appearance of the inoculation papule by 7 to 14 days and may be accompanied by constitutional symptoms and fever. The histopathology of the lymph node is highly characteristic of CSD, involving both acute and chronic inflammatory cells and the presence of microabscesses that are described as "stellate." Aggregates of small coccobacilli may be identified in these abscesses using either silver impregnation stains such as Warthin–Starry and Steiner stains or by immunofluorescent staining with commercially available monoclonal antibodies specific for *B. henselae* or *B. quintana*. The clinical diagnosis of classic CSD can also be confirmed by PCR of tissue or the demonstration of elevated immunoglobulin G (IgG) and IgM antibodies to *B. henselae* or *B. quintana*. Classic CSD usually resolves over several weeks to months without treatment. Although one prospective randomized controlled trial indicated that a 5-day course of azithromycin might hasten the resolution of lymph node swelling, most experts do not recommend antimicrobial therapy for mild to moderately severe CSD. Where lymph nodes become fluctuant and painful, needle aspiration may be all that is required to relieve discomfort and hasten resolution. The syndrome of classic CSD in immunocompetent hosts is thought to be due to an exuberant host response to relatively few organisms, which is one possible explanation for the relatively minor impact of antimicrobials in this setting (Table 125.2).

Ophthalmologic CSD

Approximately 3% of CSD patients develop ocular pathology. These manifestations may be unilateral or bilateral and include conjunctivitis, retinitis, choroiditis, iridocyclitis, endophthalmitis, or orbital abscess with osteomyelitis.

Most frequently patients present with retinitis and vision loss in the context of classic CSD; however, this may also appear without adenopathy. CSD retinitis may be indicated by the presence of characteristic exudates radiating from the macula, the so-called "macular star" or stellate retinitis.

The diagnosis may be confirmed by demonstrating elevated IgG or IgM antibodies to *B. henselae* or PCR of tissue biopsy specimens.

TABLE 125.2 **TREATMENT RECOMMENDATIONS FOR *BARTONELLA* INFECTIONS**

Clinical presentation	Adult treatment recommendations
Mild to moderate classic CSD	No antimicrobials recommended
Severe CSD with large painful lymphadenopathy	Azithromycin, 500 mg PO, d 1, 250 mg d 2–5, aspiration if fluctuant
Retinitis	Doxycycline[a], 100 mg PO BID for 4–6 wk, + rifampin, 300 mg PO BID for 4–6 wk; consider topical corticosteroids
Encephalopathy	Doxycycline[a], 100 mg PO or IV for 6 wk, + rifampin, 300 mg PO BID for 4–6 wk; duration is not a matter of consensus at this time
Suspected *Bartonella* BCNE	Gentamicin, 3 mg/kg/d × 14 d, + ceftriaxone, 2 g/d IV or IM × 6 wk
Confirmed *Bartonella* BCNE	Gentamicin, 3 mg/kg/d IV × 14 d, + doxycycline[a], 100 mg BID × 6 wk
Trench fever, prolonged *B. quintana* bacteremia	Gentamicin, 3 mg/kg/d IV × 14 d, + doxycycline[a], 200 mg/d PO × 4 wk
BA	Erythromycin, 500 mg PO QID × 3 mo, or doxycycline, PO QID 100 mg BID × 3 mo
PH	Erythromycin, 500 mg PO QID × 4 mo, or doxycycline[a], PO QID 100 mg BID × 4 mo

[a] Substitution of minocycline for doxycycline has not been addressed in published reports.
Abbreviations: CSD = cat scratch disease; BCNE = culture-negative infectious endocarditis; BA = bacillary angioma; PH = peliosis hepatitis.
Adapted from Rolain JM, Brouqui P, Koehler JE, Maguina C, Dolan MJ, Raoult D. Recommendations for treatment of human infections caused by Bartonella species. *Antimicrob Agents Chemother*. 2004;48:1921–1933.

Parinaud's oculoglandular syndrome (POGS) is a nodular, or "cobblestone," conjunctivitis accompanied by reactive preauricular lymphadenopathy. This is thought to represent the ocular equivalent of classic CSD, secondary to conjunctival inoculation of *B. henselae*.

Resolution of ocular CSD may be spontaneous; however, treatment with 4 to 6 weeks of doxycycline, with rifampin, with or without topical corticosteroids is recommended.

Neurologic CSD

Neurologic manifestations of CSD are relatively rare, accounting for 0.17% to 2% of cases. These include encephalopathy involving cortex, internal capsule, or midbrain; myelopathy; granulomatous cerebral angiitis; vertebral osteomyelitis; and peripheral neuropathy.

This encephalopathy may present with agitation, delirium, or new onset of seizures, including status epilepticus, coma, cerebellar ataxia, and disruptions of basal ganglia or midbrain. Anecdotal reports of successful treatment have included supportive measures with antiepileptic medication, usually accompanied by intravenous antibiotics with or without high-dose corticosteroids. A combination of intravenous or oral doxycycline with rifampin for at least 14 days is recommended; however, the most appropriate choice of antimicrobials, optimum duration of therapy, and the role of corticosteroids in these cases have not been resolved.

A number of mechanisms have been proposed for CSD encephalopathy, including direct bacterial involvement of neurons, host inflammatory response, autoimmune disease, and toxin production.

In immunocompromised patients, an acute psychiatric syndrome similar to acute mania may occur, which improves rapidly with antimicrobial therapy directed against *B. henselae*. An association has been reported between intrathecal synthesis of *B. henselae* antibodies and human immunodeficiency virus (HIV)-associated encephalopathy; although there is no evidence that this improves with treatment for bartonella.

Cardiovascular infections

Bartonella quintana and *B. henselae* are significant causes of blood culture-negative infectious endocarditis (BCNE). Estimates of the relative contributions of *Bartonella* species to these infections are based on several large case series from reference centers equipped to diagnose these relatively fastidious organisms, including the agent of Q fever, *Coxiella burnettii, Legionella pneumophila, Brucella* species, *Chlamydia psittaci, Tropheryma whipplei, Mycoplasma hominis*, nutritionally deficient streptococci, and the fungal causes of BCNE.

In a series of 349 cases of BCNE reported by Houpikian and Raoult in 2005, *Bartonella* species accounted for 29% of all cases. *Bartonella quintana* represented 75% of these and *B. henselae* 25%. As reported in previous series, *B. quintana* endocarditis was associated with body louse infestation, immunodeficiency, and chronic alcoholism, whereas *B. henselae* endocarditis was associated with cat contact and pre-existing valvular disease. The overall mortality was 7% with no difference between the two species. The aortic valve was the predominant site for both species, and valve replacement was performed in 75% of cases. Several cases of renal failure secondary to necrotizing crescentic glomerulonephritis have been reported in the context of both *B. henselae* and *B. quintana* endocarditis.

To date, four additional *Bartonella* species have been reported to cause infective endocarditis (IE) in humans: *Bartonella vinsonii, Bartonella vinsonii* subsp. *berkhoffii*, *Bartonella elizabethae,*

Bartonella koehlerae, and *Bartonella alsatica*. The diagnosis of *Bartonella* endocarditis was made by culture in roughly 30% of cases, whereas PCR of valvular tissue yielded 67%. Serologic demonstration of anti-*Bartonella* antibody titers ≤1:800 by direct fluorescent antibody (DFA) provided an acceptable noninvasive method of diagnosis in this series.

Suspected *Bartonella* BCNE should be treated with gentamicin for 2 weeks, combined with 6 weeks of intravenous or intramuscular ceftriaxone, to cover other possible causes of BCNE, with or without oral or intravenous doxycycline for 6 weeks. For proven *Bartonella* endocarditis, a combination of gentamicin for 2 weeks plus intravenous or oral doxycycline for 6 weeks is recommended.

Although rare, myocarditis has been associated with *Bartonella* infections. *Bartonella washoensis*-associated myocarditis was reported in a 70-year-old immunocompetent man, presumably associated with the presence of a large reservoir of the organism in the California ground squirrels (*Spermophilus beecheyi*) in recreational areas near Reno, Nevada. *Bartonella henselae* has been associated with a case of chronic active myocarditis in a 43-year-old immunocompetent man with classic CSD. An autoimmune reaction triggered by the *B. henselae* infection was postulated.

Prolonged bacteremia without endocarditis

Prolonged symptomatic or asymptomatic bacteremia is more frequently caused by *B. quintana* but may also be caused by *B. henselae* as well as other less common members of the genus. When accompanied by fever and constitutional symptoms, prolonged, relapsing *B. quintana* bacteremia was called trench fever in World War I and was at first thought to be a variant of endemic typhus, until Dr. Henrique da Rocha Lima determined it to be a distinct louse-borne infection. Following World War II, trench fever was considered to be an historical relic, until its resurrection in the late twentieth century as a significant cause of illness among the world's growing population of urban homeless, so-called urban trench fever.

Although the relation of prolonged bacteremia to infectious endocarditis has not been established, it is assumed that antimicrobial treatment of *B. henselae* and *B. quintana* bacteremia may have a role in preventing endocarditis. The currently recommended therapy for *B. henselae* and *B. quintana* bacteremia is intravenous gentamicin for 14 days with oral or intravenous doxycycline for 28 days. A thorough search for evidence of endocarditis should accompany the treatment of *Bartonella* bacteremia.

Parenchymal CSD

CSD with or without regional lymphadenopathy may be accompanied by hepatic or splenic foci of infection. The clinical presentation of hepatosplenic bartonellosis includes chronic or subacute course characterized by fever and abdominal pain that may be accompanied by nausea and vomiting. Hepatic transaminases may be elevated and may demonstrate disproportionate elevations of hepatic alkaline phosphatase over aspartate aminotransferase (AST) and alanine aminotransferase (ALT). Abdominal ultrasound or computerized axial tomography may demonstrate radiolucencies in liver and spleen. Histopathology of these lesions frequently demonstrates either necrotizing granulomas or stellate microabscesses similar to those described in the lymph nodes of classic CSD. Anecdotal reports suggest that doxycycline plus rifampin for periods of from 7 to 14 days may be effective in these cases, but spontaneous resolution has also been documented and there is currently no consensus favoring antimicrobial treatment.

Musculoskeletal

Bartonella henselae is a rare cause of osteomyelitis. *Bartonella quintana* has been linked to most bartonella-related cases, especially in children. Small case series describe typical presentations, including fever and bone pain in children or young adults with cat or kitten exposure, with or without associated lymphadenopathy. These may involve single or multiple foci of infection and frequently involve the axial skeleton or pelvic bones. The etiologic diagnosis in these cases was made by serology, histopathology, or PCR of bone biopsy specimens. There is no evidence beyond anecdotal reports that antimicrobial therapy is effective.

Bartonella in immunocompromised patients

Infections in immunocompetent hosts are characterized by an exuberant inflammatory response to relatively few organisms and a poor response to antimicrobial agents. However, in those with compromised cell-mediated immunity, such as individuals with AIDS or hematologic malignancies, organ transplant recipients, and those receiving immunomodulating agents for treatment of hepatitis C or rheumatologic diseases, the same organisms commonly cause systemic infections characterized by BAP lesions, which teem with organisms and respond dramatically to antimicrobial therapy.

BAP may develop in practically any anatomical site or organ, including skin, mucosa of the nasopharynx, gastrointestinal tract, central nervous system, bone, or lymph nodes. Cutaneous BA usually forms a 1-cm to 2-cm erythematous nodule with a surrounding collar of scaling skin (Figures 125.1 and 125.2). These are friable, bleed easily, and may itch.

The microscopic appearance of BA is of disorganized vascular channels, with prominent, rounded endothelial cells, projecting into irregular vascular lumens. These lesions are easily distinguished

FIGURE 125.1

FIGURE 125.2

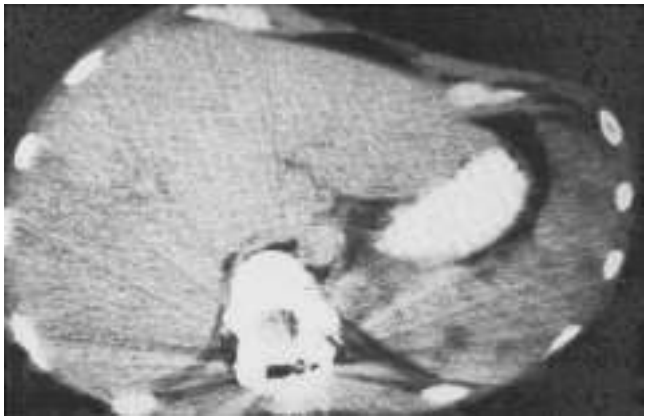

FIGURE 125.3

from the more organized spindle cells of Kaposi's sarcoma. When stained with hematoxylin and eosin, azurophilic granular material can be seen, representing clumps of bacteria. Although they may also be seen with Brown–Brenn tissue Gram stain or silver impregnation stains such as Steiner or Warthin–Starry, they are more easily visualized by immunofluorescent staining.

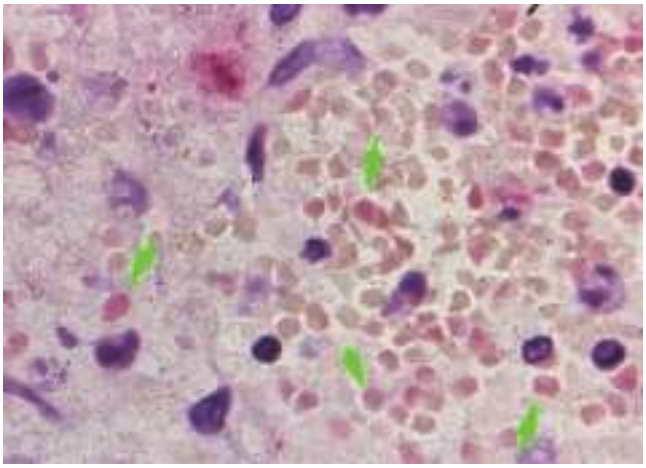

FIGURE 125.4

The second type of vascular lesion, bacillary parenchymal peliosis or peliosis hepatitis (PH), may involve liver or spleen. Computed tomography (CT) or magnetic resonance imaging may demonstrate hypodense lesions (Figure 125.3). Histologically, PH lesions are blood-filled cavities that appear to arise where normal sinusoidal endothelial cells have become disrupted by bartonella infection. The endothelial cells, erythrocytes, and macrophages of these lesions contain intracellular bacteria (Figures 125.4–125.6).

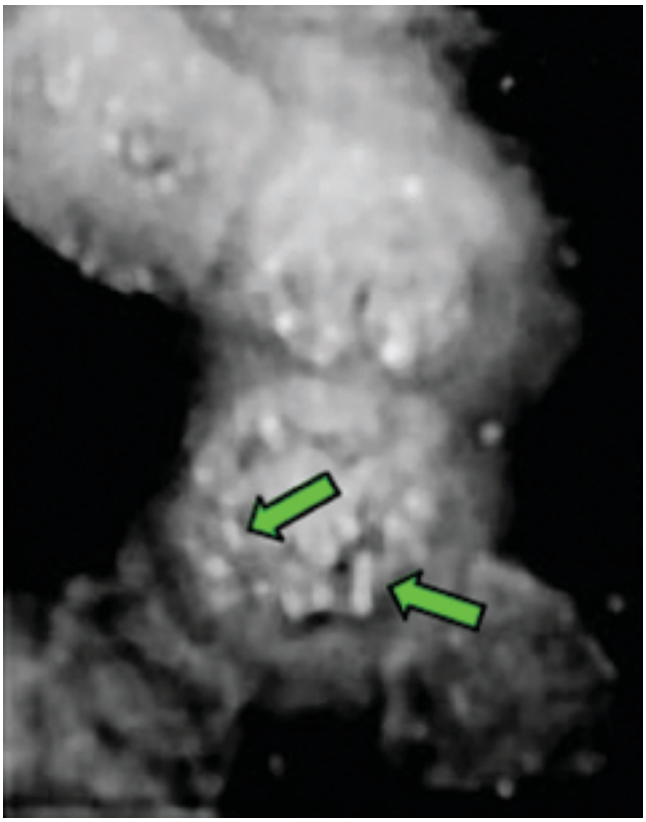

FIGURE 125.5

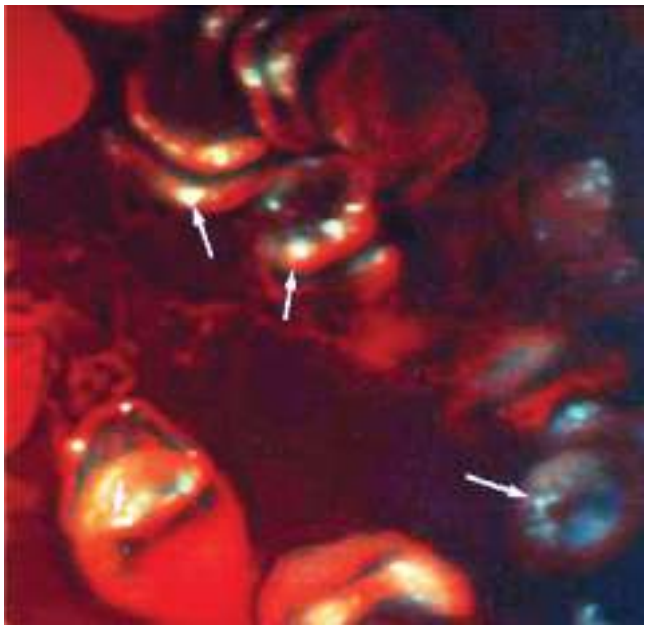

FIGURE 125.6

Treatment of patients with BAP usually results in a rapid clinical improvement. Treatment should continue for at least 3 months to avoid relapses. Although erythromycin is recommended, doxycycline appears to be as effective, with fewer gastrointestinal side effects.

Bordetella

Emily Souder and Sarah S. Long

Bordetellae are fastidious, non–carbohydrate-fermenting, tiny, gram-negative coccobacilli that grow aerobically on starch blood agar or synthetic medium supplemented with nicotinamide and amino acids for growth and charcoal or cyclodextrin resin for protection from fatty acids and other inhibitory substances. Bordetellae have multiple attachment proteins, including a 69-kDa outer membrane protein (pertactin), filamentous hemagglutinin, and fimbriae. *Bordetella pertussis* is the only species that expresses the major virulence protein, pertussis toxin. *B. pertussis* and *B. parapertussis* are exclusive human pathogens. *B. pertussis* is the cause of epidemic pertussis and the usual cause of endemic and sporadic pertussis. *B. parapertussis* is an infrequent cause of pertussis in the United States and is genetically more closely aligned with *B. bronchiseptica*, a common veterinary pathogen causing upper respiratory tract illnesses in animals. *B. holmesii*, first described as a cause of bronchitis, endocarditis, and septicemia in immunocompromised patients, infrequently can cause pertussis-like illness in otherwise healthy persons. Occasional case reports of *B. bronchiseptica* in humans include upper and lower respiratory tract illnesses, endocarditis, septicemia, posttraumatic meningitis, and peritonitis. *B. hinzii* has caused bloodstream infection in a handful of cases, usually associated with pulmonary symptoms. Asplenia or immunosuppression has been present in many adults infected with *Bordetella* non-*pertussis* and non-*parapertussis* species. Exposure to pets also is a factor.

Epidemiology and clinical manifestations

Pertussis is an unusual example among vaccine-preventable diseases for which universal immunization is given but for which incidence continues to be considerable. The >42,000 cases reported in the United States in 2012 were the highest number reported for any year in the past half-century. The actual number of cases likely is exponentially greater than that reported because pertussis is undersuspected, underdiagnosed, and underreported. During a prospective vaccine trial in adults, it was estimated that >600,000 cough illnesses due to *B. pertussis* likely occur in the United States annually. Age-related incidence of pertussis is highest in infants ≤2 months of age (~150 per 100,000), but the greatest number of cases and the reservoirs for *B. pertussis* are in school-aged children, adolescents, and adults who have waning vaccine immunity and lack the frequent natural subclinical reinfections that boosted immunity in a previous era. Additional factors in resurgence are speculated to include increased awareness, improved diagnostics, use of acellular vaccines for all doses, and pathogen adaptation.

Classic pertussis illness occurs almost exclusively in unimmunized older infants and children. It includes 2-week stages: an afebrile, upper respiratory tract illness with escalating cough (catarrhal stage) followed by paroxysms of machine-gun bursts of coughing, frequently with whoops and posttussive vomiting (paroxysmal stage), fading into fewer and less severe paroxysms (convalescent stage). Young infants have rapid onset of "fits" of gagging, gasping, and cyanotic or apneic episodes, with paroxysmal cough and whoop occurring only later, sometimes during convalescence. Adults do not have distinct stages, and at least one-third have only a prolonged nonspecific cough illness. Clues to pertussis in adolescents and adults are (1) pure or predominant cough illness that is escalating after 1 week, (2) cough illness in which there are sudden paroxysms

(repeated bursts of cough on one breath, bulging watery eyes, red face), or (3) cough illness associated with posttussive emesis. Several studies suggest that 13% to 32% of patients with this symptom complex have pertussis. Patients are afebrile, have few upper or lower respiratory tract signs or symptoms, do not have myalgia or malaise, and are well between paroxysms. Adults with pertussis describe a typical paroxysm as beginning with an aura of anxiety and fear to take a breath, followed by strangulating cough, feeling of suffocation, and posttussive exhaustion. Whoop is uncommon.

Diagnosis

Differential diagnosis predominantly includes other respiratory tract infection due to agents such as *Mycoplasma pneumoniae, Chlamydophila pneumoniae*, adenovirus, influenza, and parainfluenza. History of illness onset is most helpful. These other infections typically begin abruptly and include fever, systemic symptoms, multiple mucous membrane involvement, or rash—none of which is part of pertussis. Simple laboratory tests generally are not helpful in differentiating causes as only unimmunized persons with pertussis have remarkable lymphocytosis.

Current methods for confirmation of infection due to *B. pertussis* (i.e., culture, polymerase chain reaction [PCR], and serology) have limitations in sensitivity, specificity, or practicality; relative value depends on setting (sporadic vs. outbreak), phase of disease, and purpose of use (diagnostic vs. epidemiologic). Culture requires (1) collection of a posterior nasopharyngeal specimen obtained either by aspiration or with Dacron or calcium alginate swab, (2) use of Regan–Lowe transport medium, and (3) inoculation of specialized agar medium and incubation for up to 10 days. PCR is more sensitive than culture, averts difficulties of isolation, and has rapid result, but standardized validated primers should be used. Use of insertion sequence (IS) *481* increases sensitivity of PCR but does not distinguish between *B. pertussis* and *B. holmesii* nor will it detect *B. parapertussis* if used as the sole PCR target. Inclusion of multiple targets is necessary to detect and differentiate species. The PCR test is most sensitive during the first 2 weeks of cough illness, although some individuals may remain PCR positive for longer, and it requires similar collection of a posterior nasopharyngeal specimen using a Dacron swab (not a calcium alginate) or nasal wash technique. Serologic diagnosis is confirmed by an increase/seroconversion of immunoglobulin G (IgG) antibody to pertussis toxin (PT-IgG) between acute and convalescent samples in a previously unimmunized individual, or a single level in the second to third week of cough illness that is >2 standard deviations above the expected resting level in distantly immunized individuals. Generally, PT-IgG level >2 years after immunization of >90 EU/mL is highly suggestive, and levels >50 EU/mL are suggestive of symptomatic *B. pertussis* infection.

In unimmunized individuals, pertussis usually is confirmed easily by positive PCR and culture. However, these tests are positive in <20% of cough illnesses due to *B. pertussis* in adolescents and adults. A single elevated serum PT-IgG antibody level is the best diagnostic test in adolescents and adults.

Treatment

An antimicrobial agent is given when pertussis is suspected or confirmed, for potential clinical benefit and to limit the spread of infection to others (Table 126.1). In vitro, *B. pertussis* is susceptible to erythromycin, newer macrolides, fluoroquinolones, and third-generation cephalosporins. Ampicillin, rifampin, and trimethoprim-sulfamethoxazole have only modest activity, and first-and second-generation cephalosporins are not effective. In clinical studies, erythromycin is superior to amoxicillin for eradication of *B. pertussis*. Rare isolates resistant to erythromycin have been reported. Azithromycin is the drug of choice for all age groups. Idiopathic hypertrophic pyloric stenosis (IHPS) has been reported in up to 2% of neonates given azithromycin (this risk is less than that following erythromycin). The US Food and Drug Administration (FDA) also warns of risk of fatal heart rhythms with use of azithromycin in patients already at risk for cardiovascular events, especially prolongation of the QT interval. *B. parapertussis* is less susceptible in vitro to all agents except macrolides. *B. bronchiseptica* is susceptible in vitro to antipseudomonal penicillins, aminoglycosides, and fluoroquinolones but generally is not susceptible to cephalosporins; clinical failure has occurred with agents effective in vitro. *B. holmesii* has in vitro susceptibilities similar to *B. bronchiseptica*, but isolates have been susceptible to third-generation cephalosporins.

Secondary sinusitis, otitis media, bronchitis, or pneumonia can complicate *B. pertussis* infection, which denudes ciliated epithelium and inhibits local phagocytic function. Pathogens of secondary infections are *Streptococcus pneumoniae, Staphylococcus aureus, Haemophilus influenzae*, and *Moraxella catarrhalis*. Convalescence from uncomplicated pertussis is protracted, with exacerbations of paroxysmal cough during subsequent respiratory illnesses; these are not caused by reinfection or reactivation of *B. pertussis*.

Control and prevention

Postexposure prophylaxis (PEP) using the same agents, doses, and duration as for treatment (Table 126.1) should be given promptly to all household contacts and other close contacts regardless of their age or history of immunization. Benefits of PEP using azithromycin for infants far outweighs risk of IHPS. PEP of contacts has little effect if instituted ≥2 weeks after exposure to the index case. Healthcare personnel (HCP) not wearing a mask who were exposed at close range to an individual with pertussis before the fifth day of treatment should be given PEP promptly, especially if they have contact with young infants, regardless of receipt of Tdap (tetanus toxoid, reduced content diphtheria toxoid, and reduced content acellular pertussis vaccine). Cases and contacts with any respiratory tract illness should be excluded from high-risk settings (e.g., school, healthcare facilities) until the fifth day of treatment.

Five doses of DTaP vaccine should be given on the recommended schedule before 7 years of age. Since 2006, Tdap was recommended for universal immunization at 11 to 12 years of age (with catch-up of older adolescents), and for certain adults. By 2012, the Centers for Disease Control and Prevention (CDC) recommended a single

TABLE 126.1 **RECOMMENDED ANTIMICROBIAL AGENTS FOR TREATMENT AND POSTEXPOSURE PROPHYLAXIS OF PERTUSSIS[A]**

	Age group			
Agents	**≤1 Month**	**1–5 Months**	**≥6 Months and children**	**Adults**
Primary agents				
Azithromycin	Recommended agent 10 mg/kg/d, once daily ×5 d	10 mg/kg once daily ×5 d	10 mg/kg (max 500 mg) once on d 1; then 5 mg/kg (max 250 mg) once on d 2–5	500 mg once on d 1; then 250 mg once on d 2–5
Clarithromycin	Not recommended	15 mg/kg/d divided BID ×7 d	15 mg/kg/d (max 1 g/d) divided BID ×7 d	1 g/d divided BID ×7 d
Erythromycin	Not preferred Use if azithromycin unavailable; 40–50 mg/kg/d divided QID x 14 days	40–50 mg/kg/d divided QID ×14 d	40–50 mg/kg/d (max 2 g/d) divided QID × 14 d	2 g/d divided QID × 14 d
Alternate agent				
TMP–SMX	Contraindicated	Contraindicated at age <2 mo. At ≥2 mo, TMP 8 mg/kg/d–SMX 40 mg/kg/d divided BID ×14 d	TMP 8 mg/kg/d–SMX 40 mg/kg/d (max TMP 320 mg/d) divided BID ×14 d	TMP 320 mg-SMX 1,600 mg/d divided BID ×14 d

Abbreviations: TMP-SMX = trimethoprim–sulfamethoxazole; BID = twice a day; QID = four times a day; d=day.
[a] Recommendations of the Centers for Disease Control and Prevention and the American Academy of Pediatrics. *Morbid Mortal Weekly Rep*. 2005:54(RR-14):1–16.

dose of Tdap for *all* people 11 years of age and older (i.e., including those ≥65 years of age) regardless of time since Td and regardless of perceived risks of acquisition or transmission or the ages of likely contacts. Although Boostrix is the only licensed Tdap for use in those ≥65 years of age and is preferred, either Boostrix or Adacel can be used. In 2012, the CDC also recommended Tdap for pregnant women in the third trimester of *every* pregnancy (optimally early in the period between 27 and 36 weeks of gestation) to prevent infant deaths and severe morbidity by creating a passive antibody bridge until the infant can receive DTaP. When preparing for arrival of all newborns, and when pertussis is suspected or confirmed, immunization status of contacts should be sought and evaluated, and DTaP (for children ≤7 years) or Tdap (for people who have not previously received Tdap) should be given promptly if indicated. In 2018, Tdap (Adacel) was licensed for a second dose. However, because of rapid waning of protection following currently available acellular pertussis vaccines, there is no recommendation for Tdap revaccination for any age or risk group outside of pregnancy. However, when Td is indicated and only Tdap is available, Tdap can be given to a previously Tdap-immunized individual.

Branhamella-Moraxella

Lisa S. Hodges and Joseph A. Bocchini, Jr.

Moraxella catarrhalis is an important etiologic agent of otitis media in children, sinusitis in children and adults, and bronchopulmonary infection in adults with chronic obstructive pulmonary disease (COPD) or impaired host defenses.

Moraxella catarrhalis is a gram-negative unencapsulated diplococcus similar in morphology to the *Neisseria*. The bacterium was first described by Ghon and Pfeiffer as *Micrococcus catarrhalis* in 1902 and has since undergone several reclassifications. In 1970 it was placed into the genus *Branhamella* based on fatty acid content and DNA homology. *Moraxella (Branhamella) catarrhalis* is the most widely accepted nomenclature at this time.

Epidemiology

Moraxella catarrhalis is a normal inhabitant of the upper respiratory tract, but can be a pathogen in susceptible hosts. Colonization is seasonal, with an increase in prevalence during winter and spring months. Age and comorbidity are the major determinants of colonization. The mode of transmission is assumed to be direct contact with respiratory secretions or droplet spread. Approximately two-thirds of children become colonized during the first year of life. One prevalence study demonstrated that colonization with *M. catarrhalis* in infants occurs earlier than with *Streptococcus pneumoniae* or *Haemophilus influenzae*, and persists longer. Infants who become colonized with *M. catarrhalis* before 3 months of age are more likely to develop an episode of acute otitis media (AOM) or otitis media with effusion (OME) by the time they are 6 months old. Carriage rates in healthy adults are only 3% to 5%. In contrast, *M. catarrhalis* has been recovered in 5% to 32% of adults with COPD. Approximately half of adults with COPD who are newly colonized will develop an acute exacerbation of COPD.

The pneumococcal conjugate vaccine has altered patterns of nasopharyngeal colonization, permitting replacement with nonvaccine pneumococcal serotypes, nontypeable *H. influenzae*, and *M. catarrhalis*.

Pathogenesis

The pathogenesis of infection is complex with both host and bacterial factors determining the evolution from colonization to clinical disease. *Moraxella catarrhalis* expresses adhesion factors and several outer membrane proteins that facilitate preferential binding to mucosal surfaces of the upper and lower respiratory tract and to middle ear epithelial cells. Biofilm formation in sequestered sites such as the middle ear suggest its potential role in the development of AOM with effusion.

Prior colonization of the nasopharynx by *M. catarrhalis* appears to enhance the adherence and invasion of human epithelial cells by *Streptococcus pyogenes*.

Following infection, the organism has the ability to act through Toll-like receptors to induce proinflammatory cytokines in the bronchial epithelium that, in addition to causing acute exacerbations of COPD, may also be responsible for its pathogenesis. *Moraxella catarrhalis* also has the ability to inhibit this proinflammatory process and evade the host immune response, allowing for persistent mucosal colonization.

Clinical syndromes

Moraxella catarrhalis is the third most common etiologic cause of AOM and sinusitis in infants and children after *S. pneumoniae* and *H. influenzae*. Cultures of middle ear fluid and of sinus aspirates reveal that 15% to 20% of these infections are caused by *M. catarrhalis*. Most are mixed infections that resolve spontaneously. Suppurative complications are uncommon. *Moraxella catarrhalis* has also been recovered from children with OME.

Acute exacerbations of chronic bronchitis in adults with COPD and other chronic lung diseases is the most common lower respiratory tract infection caused by this organism. *Moraxella catarrhalis* is responsible for 30% of acute exacerbations of COPD, second only to *H. influenzae*. Exacerbations are characterized by cough, purulent sputum production, shortness of breath, low-grade fever, and a lack of leukocytosis. It is usually mild to moderate in severity with either patchy or lobar alveolar infiltrates on chest radiograph. CT findings include ground-glass opacities, bronchial wall thickening, and centrilobular nodules. Bacteremia is rare, and pleural effusion and empyema are uncommon.

Less common clinical syndromes associated with *M. catarrhalis* include conjunctivitis in infants that mimics the opthalmia neonatorum of *Neisseria gonorrhoeae*. Bacteremia in children may present like occult pneumococcal bacteremia but has also been reported in association with focal infections such as preseptal cellulitis, septic arthritis, osteomyelitis, and prosthetic vascular graft infection, and a purpuric rash similar to that seen in meningococcemia has been reported. Bacteremia in adults has been reported as a consequence of pneumonia and sepsis has been reported in patients with leukemia, AIDS, and agammaglobulinemia. Pancreatitis, peritonitis, and ventriculitis have also been described. Meningitis, especially in children, has occurred as a result of hematogenous spread from the nasopharynx, or as a consequence of ventriculoperitoneal shunt placement or surgery.

Nosocomial outbreaks with a single strain of *M. catarrhalis* have been reported, in respiratory units and healthcare facilities.

Diagnosis

A presumptive diagnosis can be made from a sputum smear that demonstrates many polymorphonuclear leukocytes with intracellular and extracellular gram-negative diplococci. Because *M. catarrhalis* is somewhat resistant to decolorization, this step in the Gram-stain procedure requires special attention. *M. catarrhalis* can be isolated on blood or chocolate agar media with the addition of CO_2.

Therapy

In many cases of otitis media and mild to moderate exacerbations of COPD, spontaneous resolution of *M. catarrhalis* infection occurs with the development of strain-specific immunity, an important consideration in determining the need for antimicrobial therapy in an individual patient.

Virtually all strains of *M. catarrhalis* now produce β-lactamase and are resistant to penicillin, amoxicillin, and ampicillin. The addition of a β-lactamase inhibitor (clavulanate, sulbactam, or tazobactam) to a penicillin restores its bactericidal activity against *M. catarrhalis*.

In addition, *M. catarrhalis* is susceptible to amoxicillin–clavulanate, ampicillin–sulbactam, piperacillin–tazobactam, second- and third-generation cephalosporins (including the oral agents), aminoglycosides, aztreonam, and carbapenems. It is also sensitive to macrolides, tetracyclines, trimethoprim–sulfamethoxazole (TMP–SMX), and fluoroquinolones.

Most infections caused by *M. catarrhalis* can be treated with oral antibiotics. For AOM or sinusitis (documented by tympanocentesis or sinus aspiration), amoxicillin–clavulanate administered for 10 days (otitis media) or 2 weeks (sinusitis) is the drug of choice. In patients with known penicillin allergy, macrolides, TMP–SMX, or fluoroquinolones may be used where appropriate.

Acute exacerbations of chronic bronchitis caused by *M. catarrhalis* can also be treated with a variety of oral antibiotics, including amoxicillin–clavulanate, second- or third-generation cephalosporins, TMP–SMX, macrolides, doxycycline, or fluoroquinolones.

Parenteral antibiotics are preferred for more invasive disease. The drug of choice for *M. catarrhalis* pneumonia is ampicillin–sulbactam; however, ceftriaxone could also be used. In patients with known penicillin allergy, a macrolide or a fluoroquinolone is an acceptable alternative.

In most patients with otitis, sinusitis, or an acute exacerbation of chronic bronchitis, the etiologic agent will not be known. The decision to treat and the choice of empiric therapy should consider *M. catarrhalis* but include all common pathogens associated with the specific infection syndrome.

Brucellosis

Carlo Carrillo and Eduardo Gotuzzo

Brucellosis is a zoonotic disease found in Latin America, Mediterranean countries (Spain, Italy, Greece), and Arabian countries (Iraq, Kuwait). According to the Centers for Disease Control and Prevention (CDC), the number of cases dropped from 6147 in 1947 to 104 in 1991 with modern bovine brucellosis eradication, mainly by pasteurization of milk or dairy products.

Most cases of brucellosis in the United States are related to occupational exposure to *Brucella abortus*. The affected are mainly men and occasionally laboratory and technical personnel. However, in Texas and Florida, the ingestion of unpasteurized dairy products is the common mechanism, and the pathogen responsible is *Brucella melitensis*, attacking men and women in equal proportion and sometimes children. *B. melitensis* produces a more severe clinical pattern and can even produce a chronic form. The attack rate is higher, especially in family outbreaks, with rare subclinical infections. *B. abortus* produces a mild disease with low attack rates (<10%) and more subclinical cases.

Clinical manifestations

Brucellosis is one of the most protean diseases because any system can be involved. We prefer to divide it into three forms.

Acute brucellosis

Usually, there is high fever, mainly in the evening, with malaise, headache, perspiration, arthralgias, and myalgias. In most cases, constipation, back pain, and loss of weight (as much as 20 pounds in 2 months) are found. Generally, granulomatous hepatitis, hematologic disorders, and articular compromise (especially, peripheral arthritis and sacroiliitis) are seen.

In this form of the disease, any of the routine agglutination assays produce an appropriate diagnosis (immunofluorescence [IF], enzyme-linked immunosorbent assay [ELISA], counterimmunoelectrophoresis [CIE], and Bengal rose test) with high specificity and sensitivity. Rarely, false-positive results may be caused by *Francisella tularensis* and *Yersinia enterocolitica*. With the epidemic of cholera in Latin America, the cross-reaction between *Vibrio cholerae* and *Brucella* is significant, producing false-positive serology to *Brucella* in patients with cholera. Even vaccines against cholera produce false-positive reactions transiently.

The medium Ruiz-Castañeda with Carrillo's modification (addition of 0.025% sodium phosphate sulfonate [SPS] and 0.05% of cysteine) increased the yield of *Brucella*. In the acute form, two blood cultures are as efficient as one bone marrow culture.

Subacute brucellosis (Figure 128.1)

Subacute form (undulant fever or Malta fever) is the typical and classic form described in endemic areas. There is intermittent low fever, often with articular compromise (peripheral arthritis, sacroiliitis, and/or

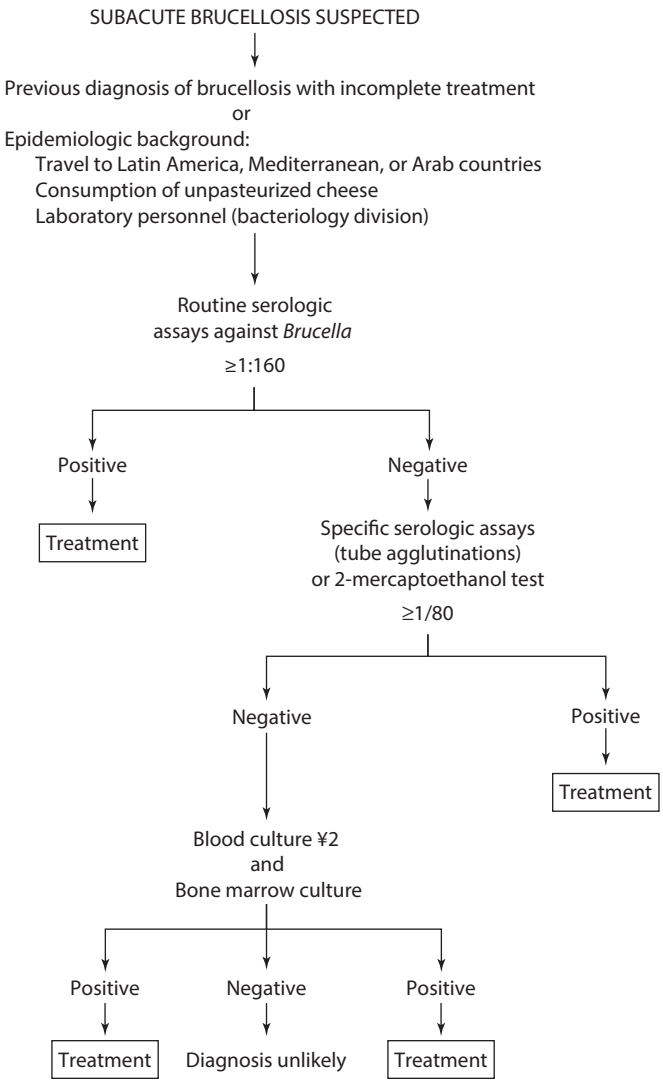

FIGURE 128.1 Algorithm for the evaluation and treatment of subacute brucellosis.

spondylitis), hematologic changes (e.g., pancytopenia, thrombocytopenia, hemolytic anemia), or hepatic damage (granulomatous hepatitis). Patients with incomplete treatment are also included in this form of brucellosis.

In this form of the disease, the 2-mercaptoethanol test detects IgG, and titer above 1:80 defines active infection. *Brucella* are isolated in 40% to 70% of serial blood cultures; the bone marrow culture (0.5 to 1 mL of aspirate from the iliac crest) permits isolation in 90% of these patients.

Chronic brucellosis (Figure 128.2)

In the chronic form with more than 1 year of illness, there usually is an afebrile pattern with myalgia, fatigue, depression, arthralgias, and so on. The most important differential diagnosis is chronic fatigue syndrome.

Other localized forms are granulomatous or recurrent uveitis and spondylitis. Peripheral arthritis and sacroiliitis are rare.

This form of disease is produced mainly by *B. melitensis*. It is found mainly in adults older than 30 years of age, especially older than 50 years old, and is rare in children.

The routine serologic tests and blood cultures give a diagnosis only 10% to 20% of the time. We recommend Coombs test specific for *Brucella* or blocking antibodies. The bone marrow in our experience produces a positive culture in 50% to 75% of patients.

Therapy

The intracellular character of *Brucella* results in an important therapeutic challenge, especially in subacute and chronic forms. Antibiotics should have in vitro activity, but the intracellular concentration must be adequate.

Tetracyclines have shown excellent in vitro activity throughout the world. The MIC90 (minimum inhibitory concentration required to inhibit growth of 90% of the organisms) was 2 μg/mL for tetracycline and 0.125 μg/mL for doxycycline in our surveillance in Peru. During the past 25 years, the antibiotic activity pattern of tetracycline against *B. melitensis* has not changed, which is remarkable because these are still our drugs of choice.

In addition, for oxytetracycline and doxycycline the minimal bactericidal concentration (MBC) was equal to MIC. All these features in conjunction with worldwide experience point to tetracyclines as the keystone of treatment.

The differences among tetracyclines are tolerance, dosage, and safety profile; however, the new ones have better tolerance and fewer side effects and can be used with meals without reducing efficacy. We prefer to use doxycycline or minocycline.

The other important aspect is the need to combine antibiotics to reduce the rate of relapse. Most antibiotics can reduce the fever, but recurrence is high.

Rifampin has been introduced as a preferential agent because of its excellent in vitro activity and intracellular concentration. The possibility of rapid resistance was shown in our strains when 5 of 10 strains exposed in vitro to rifampin developed resistance by the seventh day.

The third effective group of drugs against *Brucella* is the aminoglycosides, with good in vitro activity and good clinical response. The largest study was done with streptomycin; however, gentamicin, netilmicin, and amikacin showed the same and even better results in open trials.

Comparative studies have been done of doxycycline plus rifampin versus doxycycline plus streptomycin (D-S). Both schedules had a high cure rate (more than 95%); however, D-S had a lower relapse rate.

The doxycycline levels in the plasma of patients treated with rifampin were significantly lower than those of patients treated with D-S. Patients who were rapid acetylators had lower levels because they had higher clearance rates. In addition, the half-life

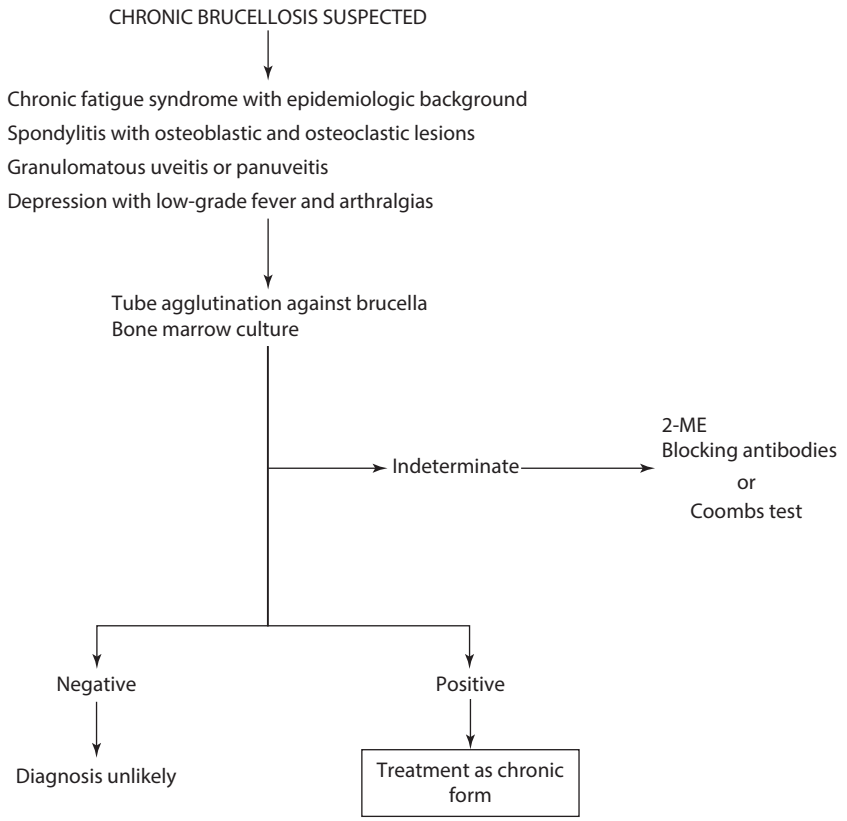

FIGURE 128.2 Algorithm for the evaluation and treatment of chronic brucellosis. 2-ME = 2-mercaptoethanol.

and the area under the curve were significantly lower in these patients. All these new data suggest that relapses may result from this interaction.

Adults

Our standard treatment for adult patients is oral doxycycline, 100 mg twice a day for 45 days, plus streptomycin, 1 g intramuscularly per day for 2 weeks (prolonging treatment with streptomycin for more than 2 weeks has not proved to be more effective); or doxycycline, 100 mg twice a day, plus rifampin, 600 mg once a day, both for 45 days. Only in a case of spondylitis, endocarditis, or brain abscess do we prolong treatment for 3 months.

In chronic brucellosis we prefer to use standard treatment for 45 days and then 3 months of doxycycline only. Some experts recommend adding levamisole for this special form during 3 months.

Children

In children younger than 8 years of age, tetracyclines cannot be used. The combination of rifampin, 15 to 20 mg/kg once a day for 4 weeks, and aminoglycosides at standard dose for 5 to 10 days is highly effective in children.

The use of trimethoprim–sulfamethoxazole (TMP–SMX) has also been recommended in children. TMP–SMX may be used at 240 mg for 4 weeks plus rifampin 20 mg/kg once a day for 4 weeks. This schedule has a high level of tolerance and few adverse effects; however, the efficacy is not as acceptable as with other schedules. Some report excellent results of TMP–SMX for 4 weeks plus gentamicin for 5 to 10 days.

Pregnancy and brucellosis

Brucellosis during pregnancy is a special problem because the best drug should be avoided and the clinical course and fetal prognosis are poor.

In our experience with more than 70% of women with brucellosis, early and adequate treatment showed excellent evolution of pregnancy, and the babies were normal. However, when antibiotic treatment is begun late, the prognosis is worse.

The best schedule is TMP–SMX plus rifampin for 6 weeks. Folic acid supplements should be given.

Another option is aminoglycoside for 10 days plus rifampin or TMP–SMX for 6 weeks.

Other antibiotics

Some drugs, such as chloramphenicol, erythromycin, ampicillin, and cephalosporins, showed moderate in vitro activity, but the clinical experience is not as good as with the other drugs.

Recently, the fluoroquinolones showed better in vitro activity, and they have good intracellular penetration. However, some trials showed that norfloxacin and ciprofloxacin had less clinical efficacy. Only ofloxacin in one trial showed good efficacy.

Steroids

We recommend corticosteroids only for 3 to 6 weeks for uveitis and for 2 to 10 weeks for severe thrombocytopenic purpura. If there is no response, we maintain steroids for 2 to 4 months. After this time if the thrombocytopenia is still evident, we recommend splenectomy.

Campylobacter

David W. K. Acheson

Campylobacter (Greek *campylo*, curved; *bacter*, rod) are motile, non-spore-forming gram-negative rods. Today they are recognized as a very common cause of gastrointestinal (GI) infection in humans in many parts of the world. *Campylobacter* organisms were first isolated in the early 1900s from aborted sheep fetuses. However, it was not until the 1970s that *Campylobacter* were isolated from stool.

While there are many members of the genus *Campylobacter*, the major enteric pathogen for humans is *Campylobacter jejuni*, although *Campylobacter coli*, *Campylobacter fetus*, *Campylobacter upsaliensis*, and *Campylobacter lari* are also pathogenic to humans. *C. jejuni* is most frequently associated with GI disease, and *C. fetus* usually causes systemic infection, often in debilitated patients. *Campylobacter* are microaerophilic, and although all will grow at 37°C (98.6°F), *C. jejuni* grows best at 42°C (107.6°F). A number of selective media are in use for the detection of *Campylobacter* spp. and the organisms grow optimally in a gas mixture of 5% to 10% oxygen, 1% to 10% carbon dioxide, and some hydrogen. Growth may be present following overnight incubation, but 2 days are needed before a negative report can be issued.

Although several serotypes of *C. jejuni* have been reported, there are few data regarding the relative virulence of these different types, although some appear to be more closely associated with the development of Guillain–Barré syndrome (GBS) than others.

Epidemiology

Campylobacter is one of the most commonly diagnosed enteric bacterial infections in many parts of the United States and Europe. It is estimated that there are more than 2 million cases per year in the United States. It is especially common in children younger than 1 year of age and in young adults, and it occurs most often in the summer. *Campylobacter* species are found in fowl and many wild and domestic animals, and most human infections probably result from contamination of milk and other animal food sources, especially poultry. The recent increase in consumption of raw milk has led to illness associated with *Campylobacter*. The organisms can also be transmitted by direct contact with infected animals and contaminated water, and cross-contamination between infected poultry and other foods is probably one of the most frequent modes of transmission. Small numbers of organisms may cause disease; as few as 800 have been shown to cause infection in volunteer studies, but the infecting dose is usually about 10^4. Although asymptomatic carriage of *Campylobacter* is thought to be uncommon in developed countries, in less developed nations carriage rates as high as 37% have been reported among children.

Clinical features

The incubation period for *C. jejuni* infection varies and is typically between 1 and 7 days, with most cases occurring 2 to 4 days after exposure. Very short incubation periods of fewer than 12 hours have been reported.

Campylobacter jejuni illness typically presents with a prodrome of fever, headache, myalgia, and malaise for up to 24 hours before intestinal symptoms develop. The fever may be as high as 40°C (104°F), and the diarrhea varies from a few loose stools to copious watery discharge. Blood is often present in the stool but varies in amount. The illness usually lasts less than a week, but patients untreated with antibiotics often continue to excrete the organisms for several weeks. Documented bacteremia is thought to occur in the early stages of infection in up to 1% of cases. Routine surveillance of infection in England and Wales detected 394 cases of *Campylobacter* bacteremia in 11 years that increased with age, with a range of 0.3/1000 in children aged 1 to 4 years to 5.9/1000 in patients aged 65 years or more. Overall 89% of the identified isolates were *C. jejuni* or *C. coli*. This may explain why focal infections such as endocarditis, meningitis, septic abortion, acute cholecystitis, pancreatitis, and cystitis have all been documented. Postinfectious reactive arthritis may also occur, especially in human leukocyte antigen (HLA)-B27-positive individuals. One of the most serious consequences of infection with *C. jejuni* is the development of GBS. This is an autoimmune disorder of the peripheral nervous system resulting in an ascending flaccid paralysis that carries a mortality rate of up to 5%. GBS is thought to be caused by molecular mimicry between polysaccharides on the outer surface of *C. jejuni* and gangliosides in the myelin sheaths of peripheral nerves.

In contrast to *C. jejuni, C. fetus* commonly produces systemic disease, often in vascular sites: endocarditis, pericarditis, and mycotic aneurysms of the abdominal aorta. Central nervous system infections such as meningoencephalitis also occur with *C. fetus*, as do other localized infections, including septic arthritis, spontaneous bacterial peritonitis, salpingitis, lung abscess, empyema, cellulitis, urinary tract infection, vertebral osteomyelitis, and cholecystitis. In patients with acquired immunodeficiency syndrome (AIDS), *Campylobacter* species other than *C. fetus* and *C. jejuni* may also cause bacteremia.

Diagnosis

Campylobacter have a characteristic darting motility, and a presumptive diagnosis of *Campylobacter* infection may be made by examination of stool passed within 2 hours using direct dark-field or phase-contrast microscopy. Leukocytes and red cells are also often seen in stool samples, with 75% of patients having polymorphonuclear leukocytes in their stool. Confirmation of the diagnosis of *C. jejuni* infection is based on a positive stool or blood culture as noted above, although *Campylobacter* is fastidious and may die during transport to the laboratory. DNA probes, polymerase chain reaction, and serologic testing all have been used to confirm diagnosis but are not routinely available. Direct detection of *Campylobacter* antigens in stool using enzyme immunoassays is a relatively new approach that is now commercially available. This method has the attraction of not requiring live organisms but has the detraction of not producing an isolate that will be available for antimicrobial sensitivity testing. *Campylobacter fetus* may be isolated from blood held in culture up to 14 days. The fastidious nature of the organisms means that failure to culture *Campylobacter* does not rule them out as the cause of significant clinical disease.

Therapy

As with all diarrheal diseases, fluid replacement and attention to electrolyte balance is the most important therapy in *Campylobacter* diarrhea. Oral rehydration is usually adequate, but patients with severe dehydration should be given volume replacement with intravenous solutions of electrolytes and water.

Most *Campylobacter* infections are mild and self-limited and do not result in a visit to a physician. These mild infections do not usually require antimicrobial therapy. Antimicrobial therapy should be reserved for patients who are severely ill, elderly, pregnant, or immunocompromised but may on occasion also be indicated in patients with bloody stools, high fever, extraintestinal infection, worsening symptoms or relapses, and those with symptoms lasting longer than 1 week. Treating patients later in the course of the disease (after several days of symptoms) will remove *Campylobacter* from the stool, but it is not likely to have a dramatic effect on the duration of symptoms. Person-to-person spread generally is not considered a major concern with *Campylobacter*, so treating to prevent this is not generally recommended (except in the case of food handlers). However, there may be exceptions to this, for example, the reduction of spread in day-care settings. Antibiotic therapy can have a dramatic positive effect on symptoms of *C. jejuni* infection, justifying a trial of therapy in severe or persistent illness.

Campylobacter jejuni is usually susceptible to many antimicrobial agents in vitro, including macrolides, tetracyclines, aminoglycosides, chloramphenicol, quinolones, and nitrofurans. The clinically important antibiotics include the macrolides, fluoroquinolones, aminoglycosides, and carbapenems. They are inherently resistant to trimethoprim and most cephalosporins except cefotaxime, ceftazidime, and cefpirone.

Erythromycin was, for years, the first-line drug to treat *Campylobacter*. However today the first-line agents for *Campylobacter* gastroenteritis include fluoroquinolones (if sensitive) or azithromycin. In patients with uncomplicated *Campylobacter* infection a first-line treatment would be levofloxacin or azithromycin 500 mg PO daily for 3 days or until signs and symptoms of disease have improved. For those with complications or underlying immunosuppression, a longer course (7 to 14 days) may be warranted. If a patient is not able to tolerate oral treatment or if they are severely ill other options include the use of an aminoglycoside or a carbapenem but it is recommended that susceptibility testing should be performed prior to their use.

Campylobacter resistance has not become a huge issue but is certainly more of a concern than it used to be. Generally the rate of macrolide-resistance among *Campylobacter* has remained stable at <5% in most parts of the world—but has been reported to be higher in Thailand and in Ireland. The prevalence of fluoroquinolone-resistant *Campylobacter* is rising. Resistance rates of greater than 50% have been reported in Spain, Hungary, and several developing countries. The rate of fluoroquinolone resistance is also increasing

in Southeast Asia and in the United States; in the United States, resistance increased from 0% to 19% between 1989 and 2001. This growing level of resistance to fluoroquinolones is important in the context of treating infections that may have been acquired in areas of high resistance or if treatment is appearing to fail.

Prognosis and prevention

Most patients recover totally following infection with *C. jejuni*. Complications such as reactive arthritis and GBS are unusual. Systemic *C. fetus* infections have a significant mortality, especially in patients with underlying disease such as diabetes mellitus or cirrhosis or who are immunocompromised. Transmission of *Campylobacter* infection can be reduced by careful food handling, with special attention to cross-contamination from poultry products. Proper cooking of food, pasteurization of milk, and protection of water supplies are all critical in preventing infection with *Campylobacter*.

Clostridium

Derek Forster

Introduction

The genus *Clostridium* contains many species of bacteria that cause human diseases. These bacteria produce some of the most deadly toxins ever discovered. Distinctive infections include botulism, tetanus, gas gangrene, and food poisoning from *Clostridium perfringens*. With few exceptions, clostridia are obligate, anaerobic, spore-forming bacilli that are ubiquitous in the environment, in soil and marine sediment. Although a member of the *Clostridium* genus, *Clostridium difficile* is discussed separately (Chapter 51, Antibiotic-associated diarrhea).

Botulism

Botulism is a rare but potentially fatal disease caused by *Clostridium botulinum* bacteria, which produce botulinum toxin, one of the most potent bacterial toxins ever described. It can be classified into four categories which reflect the mode of acquisition: foodborne botulism, infant and adult enteric botulism, wound botulism, and inhalational botulism. A recent category, iatrogenic botulism, has also been described in patients who have received botulinum toxin injections. All modes of acquisition can lead to the clinical syndrome of botulism, which manifests as symmetric flaccid paralysis of the voluntary musculature.

The word botulism is derived from the latin word *botulus*, which means sausage, and is a reference to an early investigation of "sausage poisoning" in a southern German town in which affected patients developed gastrointestinal and neuromuscular symptoms. This investigation is believed to be the first described outbreak of foodborne botulism.

There are eight strains of *C. botulinum* that are classified according to the type of toxin they produce. Of the eight toxin types, only types A, B, E, and occasionally F cause human disease. The spores are heat-resistant and able to survive at 100°C for several hours. In contrast to the spores, the toxins are heat-labile and are readily denatured by heating to temperatures above 80°C.

Epidemiology

Foodborne botulism

Foodborne botulism is caused by the ingestion of contaminated improperly cooked or raw foods containing preformed toxin. The toxin is absorbed in the small intestine whereby it enters the bloodstream and causes disease as it reaches the peripheral nervous system. The ingestion of spores alone does not cause botulism because the competitive environment of the gastrointestinal tract does not allow the spores to vegetate and produce toxin. The exceptions to this are infantile botulism and adult enteric botulism, which are discussed later.

Foodborne botulism represents the greatest public health concern related to botulism and is most frequently recognized in small outbreaks involving home-canned fruits and vegetables but has also been

associated with commercial products and restaurants. In the USA, 263 cases from 160 foodborne botulism events occurred between 1990 and 2000. Toxin type A was the most common, causing 51% of all cases. The highest percentage of cases occurred in Alaska where 103 (39% of cases) were due to ingestion of non-commercial fish and marine mammal products. Another study evaluated the epidemiology of endemic foodborne botulism among Alaskan natives from 1947 to 2007 and concluded that the incidence was decreasing but still remained >800 times the overall US rate.

Wound botulism

Wound botulism is caused by contamination of a wound with *C. botulinum* spores that germinate and produce toxin. Reported cases have increased dramatically over the last 20 years and are now mainly attributed to injection drug use. These cases have been associated with the use of "black tar" heroin administered subcutaneously or intramuscularly, a technique known as "skin popping." Wound botulism has also been described following open fractures and surgery.

Infant and adult enteric botulism

Infant botulism occurs when spores (not toxins) are ingested and then vegetate in the intestinal tract due to a lack of competing bacteria, producing toxin. It is the most common form of botulism in the United States with 2419 cases identified from 1976 to 2006. The main reservoir leading to infection is thought to be environmental dust containing spores. This correlates with the fact that states with high soil botulinum spore counts have the highest incidence of cases. California accounts for nearly 50% of all US cases. Honey remains the only identified food and the only avoidable source of infant botulism. Educational efforts have increased public awareness and ingestion of honey by infants has decreased markedly; however, significant decreases in cases have not been seen.

Adult enteric botulism, like infant botulism, occurs from infection of the intestinal tract with vegetative bacteria that leads to toxin production. It is considered rare in the adult but those at risk include patients with a disruption of their bowel flora due to anatomic abnormalities, functional disorders, or antibiotic use. Protracted symptoms and relapse due to persistent production of toxin may be seen.

Inhalational botulism

Inhalational botulism is not a naturally occurring disease. It has been described among users of intranasal cocaine, leading to a local wound infection in the sinuses where the bacteria ultimately germinate and produce toxin. This form also represents a potential route for bioterrorism attacks. A deliberate release of aerosolized toxin could produce an outbreak of botulism with considerable mortality.

Iatrogenic botulism

Iatrogenic botulism is a recently described entity that is caused by the direct injection of botulinum toxin for cosmetic purposes. In 2004, four cases of botulism were linked to the use of a highly concentrated, unlicensed botulinum toxin. These patients may have received doses nearly 3000 times the estimated human lethal dose by injection and had pretreatment serum toxin levels up to 43 times the estimated lethal human dose. All four patients survived but suffered a long hospital course.

Pathogenesis

Regardless of the mode of acquisition, once toxin has entered the bloodstream it reaches the peripheral cholinergic synapse where it eventually prevents the release of acetylcholine. It binds to a specific receptor called synaptotagmin on the pre-synaptic cleft of the synapse. Once bound, the toxin enters the cell via receptor-mediated endocytosis where it irreversibly disrupts the release of acetycholine. The exact mechanism of this action varies and depends on the type of toxin present. Return of function requires the formation of a new presynaptic terminal with a new synapse which generally takes 6 months or longer to occur. For this reason, clinical recovery is prolonged.

Clinical

The classic description of botulism is the acute onset of symmetric cranial nerve palsies with subsequent symmetrical descending flaccid paralysis that may progress to respiratory arrest. Fever is typically not present unless it is a component of a wound infection as with wound botulism. Sensory deficits are absent. Although botulinum toxin may be transported in a retrograde fashion via the nerves, central nervous system (CNS) involvement is rare and the patient almost always remains responsive.

As the disease progresses, descending paralysis of the neck, shoulders, upper extremities, and lower extremities can occur. Respiratory arrest can occur when the diaphragm and accessory breathing muscles become involved. Constipation is invariably present at later stages. The severity of disease ranges from mild involvement of the cranial nerves to full paralysis requiring mechanical ventilation and reflects the amount of toxin in the bloodstream.

Other symptoms depend on the mode of acquisition. With foodborne botulism, patients may have a prodrome of nausea, vomiting, abdominal pain, and dry mouth. In wound botulism, local wound infection with fever may be present. The incubation period is difficult to ascertain given the frequency of injection drug use but is generally longer than other forms of botulism (7 to 14 days) because of the time required for spores to vegetate, produce local infection, and generate toxin. At the time of evaluation, the local wound infection may have resolved, making history the key to diagnosis. The presentation of infantile botulism varies but may involve constipation, weakness, feeding difficulties, hypotonia, drooling, irritability, and a weak cry.

The major differential diagnoses are myasthenia gravis, Lambert–Eaton myasthenia syndrome, tick paralysis, Guillain–Barré syndrome and poliomyelitis. The edrophonium test may be positive in botulism and thus may not distinguish botulism from myasthenia gravis. Guillain–Barré syndrome frequently begins with sensory complaints and rarely as cranial nerve dysfunction. Fever is usually present in poliomyelitis but not in botulism. Cerebrospinal fluid (CSF) analysis is normal in botulism.

Diagnosis

The clinical syndrome of botulism is distinctive and thus a careful history and physical examination are essential to considering and making the diagnosis. Confirmation involves detection of the toxin in the patient's serum, gastric secretions, stool, or a food sample. This is done via mouse bioassay, which is performed in a limited number of public health laboratories.

Other diagnostic tools include anaerobic cultures of serum, stool, and implicated food if available; however, the strict anaerobic conditions needed for growth make isolation of *C. botulinum* difficult. Enzyme-linked immunosorbent assays and polymerase chain reaction have been used for detection in contaminated food samples but are not available for widespread use.

Treatment

The mainstay of therapy is supportive care with intubation and mechanical ventilation if necessary. The only specific therapy is botulinum antitoxin, which exists as two forms: equine serum heptavalent botulism antitoxin and human-derived botulism immune globulin. The equine antitoxin is used to treat adults and children > 1 year of age. Rates of hypersensitivity (including anaphylaxis) have been reported to be between 9% and 20% and thus a test dose is often given prior to administration. Human botulinum immune globulin (BabyBIG) is the recommended antitoxin for use in infantile botulism (children < 1 year of age). Antitoxin administration should not be delayed while awaiting the results of diagnostic testing. The antitoxin is available through the Centers for Disease Control and Prevention (CDC). A pentavalent antitoxin is only available through the department of defense.

Antibiotic therapy is often used for wound botulism. Penicillin G provides effective coverage of clostridial species with metronidazole a good alternative for penicillin-allergic patients. Wound debridement should be performed even if the wound appears unimpressive. A polymicrobial infection may be present, and thus broader coverage can be considered, but the use of aminoglycosides and clindamycin is contraindicated as they may induce neuromuscular blockade and thus worsen the effects of the toxin. Antibiotics are not recommended for infant botulism or adults with suspected enteric botulism as this may increase the toxin available for absorption. In the setting of foodborne botulism, laxatives, enemas, or other cathartics may be given if no significant ileus is present.

Prevention

A pentavalent botulinum toxoid vaccine was available for occupational exposure to botulinum toxins but was discontinued in 2011.

Tetanus

Tetanus is a neurologic disorder characterized by muscle spasms; it is caused by *Clostridium tetani*, an obligately anaerobic gram-positive bacillus found worldwide in soil. It has a characteristic "tennis racket" or "drumstick" appearance on Gram stain (Figure 130.1). Because of vaccination, the annual incidence of cases in the United States has decreased markedly from 1947 to 2008 (Figure 130.2). In the United States, there were 233 cases from 2001 to 2008. Most of the cases were in individuals over 65, reflecting waning immunity. In developing countries tetanus remains endemic with an estimated one million cases occurring worldwide annually with 300 000 to 500 000 deaths. Prevention of neonatal tetanus has been a target of the World Health Organization which has resulted in a decrease in the number of cases and deaths.

Pathogenesis

A wound infection with *C. tetani* is the first step of the disease process. Once the bacterium vegetates it produces tetanospasmin (tetanus toxin) and tetanolysin. Tetanospasmin enters the nervous system through presynaptic terminals and interrupts neuromuscular transmission whereby it can initially cause local paralysis. Once it enters the nervous system, retrograde transport facilitates its movement to the CNS where it prevents the release of inhibitory neurotransmitters, which results in an unopposed excitatory signal. This effect is also seen in the autonomic nervous system, causing a hypersympathetic state. Tetanospasmin binding is irreversible, and thus the effects last the lifetime of the neuron. The other toxin produced is tetanolysin, which causes tissue necrosis and thus a more favorable environment for growth of the bacterium.

Clinical

Tetanus exists in four clinical forms: generalized, local, cephalic, and neonatal. These forms reflect the location of initial involvement as well as the extent of disease. The incubation period is variable and can be as short as 1 day or as long as several months. The distance from the site of inoculation of the organism to the CNS is a major determinant of the incubation period, with longer distances resulting in a longer incubation period.

Generalized tetanus is the most commonly recognized form which often presents with trismus but later manifests as tonic contraction of skeletal muscles with intermittent muscular spasms.

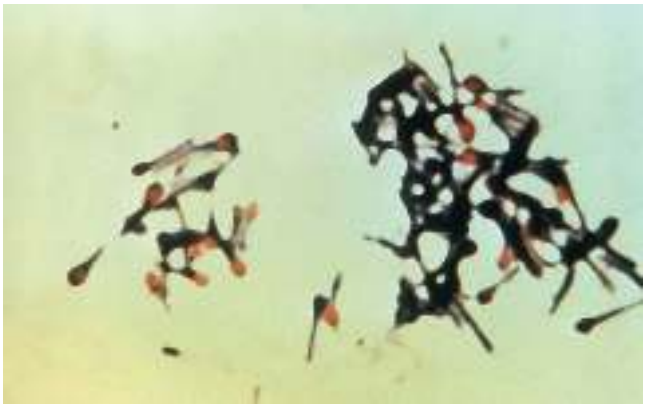

FIGURE 130.1 "Tennis racket" or "drumstick" appearance of Clostridum tetani. (http://www.cdc.gov/tetanus/about/photos.html)

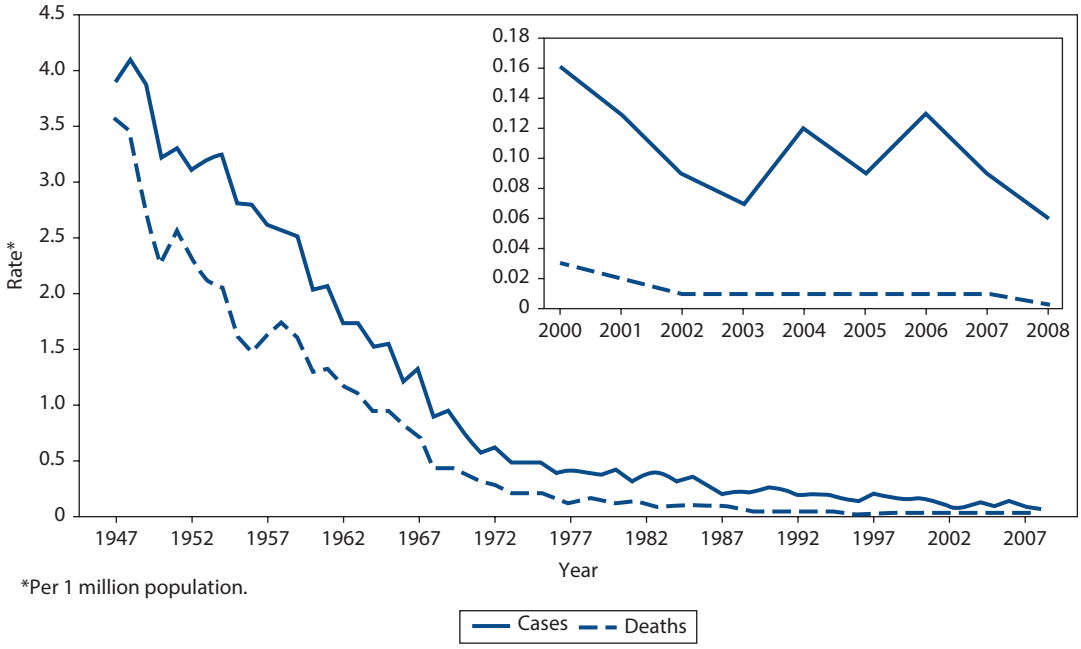

FIGURE 130.2 Annual rate of tetanus cases and tetanus deaths in the United States during 1947–2008, according to the National Notifiable Disease Surveillance System. From 1947–2008. (Centers for Disease Control and Prevention (CDC). Tetanus surveillance—United States, 2001–2008. MMWR Morb Mortal Wkly Rep. 2011;60 (12):365–369 available from: PM:21451446)

Decorticate posturing with flexion of the arms and extension of the legs is classically described with generalized spasms. There is no impairment in consciousness and thus the spasms are intensely painful. Symptoms of autonomic hyperactivity including irritability, restlessness, sweating, and tachycardia may be seen early in the course with progression to cardiac arrhythmias, labile blood pressures, and fevers in the later stages. This autonomic instability is the leading cause of death with a fatality rate of 11% to 28%.

Localized tetanus involves the muscles at the site of inoculation, presenting as tonic and spastic contractions. It may be mild and may persist for weeks to months. Although it may resolve spontaneously without long-term sequelae, it is often a prodrome of generalized tetanus. The reported incidence of localized tetanus is 13%.

Cephalic tetanus is a form of localized tetanus that involves the head or neck. Although it initially involves only the cranial nerves, it can be a prodrome of generalized tetanus. It can also spontaneously resolve without complications. The incubation period for progression to generalized tetanus is short due to its proximity to the CNS.

Neonatal tetanus typically occurs in the first 28 days of life. It develops in infants of unvaccinated mothers when infection of the umbilical stump with *C. tetani* occurs due to poor aseptic technique at delivery or contamination with dirt, straw, or other materials. Cultural practices involving the application of clarified butter, juices, and cow dung to the umbilical stump have also been implicated in the development of disease. It may manifest initially as general weakness and a failure to nurse but progresses to rigidity, spasms, trismus, and seizures. Sepsis, related to bacterial infection of the umbilical stump, occurs in about half of the patients and accounts for significant mortality which can exceed 90%.

Diagnosis

The diagnosis of tetanus is primarily based on the typical findings mentioned above. There is no definitive testing to confirm or exclude the diagnosis. Antitetanus antibodies are often undetectable in clinical disease. Culture for *C. tetani* is of little value because of poor sensitivity and specificity as positive cultures may be present without disease and represent colonization rather than true infection. Inadequate immunization and inadequate wound prophylaxis are important risk factors for the development of tetanus and thus, knowing a patient's prior vaccination status can be helpful when entertaining the diagnosis. Patients should also be questioned regarding prior tetanus prone injuries and physical exam should include evaluating for any possible inoculation sites.

There are several considerations in the differential diagnosis including drug-induced dystonia, trismus due to dental infections, strychnine poisoning, and neuroleptic malignant syndrome. Drug-induced dystonia, in contrast to tetanus, produces deviation of the eyes and an absence of tonic muscular contractions between spasms. Also, administration of anticholinergics will reverse the spasms in drug-induced dystonia but not in tetanus. Trismus due to dental infections is seen in the presence of an obvious dental abscess. Strychnine poisoning can cause a syndrome similar to tetanus. Testing of blood, urine, and tissue samples for strychnine can be done in settings when accidental or intentional poisoning is considered. Neuroleptic malignant syndrome can present with muscular rigidity and autonomic instability as well as fever and altered mental status, both of which are not seen in tetanus.

Treatment

The initial treatment of tetanus should include early and aggressive airway management. If endotracheal intubation is required, benzodiazepine sedation and neuromuscular blockade should be used because passage of the endotracheal tube can trigger spasms. Subsequent control of spasms requires the use of benzodiazepines at doses higher than typically required for sedation. Neuromuscular blockade may be required if adequate control is not achieved with benzodiazepines. Magnesium sulfate may be helpful as an adjunct to treatment. It blocks catecholamine release from nerves and reduces receptor responsiveness to catecholamines. It has been shown to reduce the use of other drugs for control of spasms and aid in the control of autonomic dysfunction but has not been shown to reduce mortality or the need for mechanical ventilation. Patients should be placed in darkened, quiet areas in the ICU to avoid triggering muscular spasms. This becomes more important in resource-limited settings where access to some medications and mechanical ventilation may not be available.

Passive immunization with human tetanus immune globulin (HTIG) to bind free toxin should be given as soon as the diagnosis of tetanus is considered. The dose for treating active tetanus is 3000 IU given intramuscularly. This shortens the course of tetanus and reduces the severity. Intrathecal administration may provide benefit when given in combination with intramuscular HTIG. Because infection does not confer immunity, active immunization with tetanus toxoid should also be initiated.

Antibiotics are generally recommended but their benefit is unclear. Antimicrobial susceptibilities demonstrate reliable sensitivity to penicillin and metronidazole as well as cephalosporins, imipenem, macrolides, and tetracycline. Favorable results with metronidazole compared to penicillin were described in one study with reduction in mortality and shorter hospitalization; however, subsequent studies have failed to show a difference. A possible explanation of poorer response to pencillin would be γ-aminobutyric acid (GABA) antagonism which is known to occur and results in CNS excitability. This effect is also seen with later-generation cephalosporins. Local wound management should be undertaken but surgical intervention, if necessary, should be performed after spasms are controlled.

Prevention

Tetanus is considered a preventable disease with vaccination. Current recommendations from the Advisory Committee on Immunization Practices (ACIP) include a combination vaccine containing diphtheria, tetanus, and pertussis (DTaP) as primary vaccination given at ages 2, 4, and 6 months, followed by a dose at age 15 to 18 months and again at age 4 to 6 years. A Tdap should be given for children ages 11 to 12. Adults should receive tetanus booster every 10 years with one booster being given as a Tdap to also provide boosted immunity for pertussis. Patients that sustain an unclean wound that is not considered minor should also receive a booster if more than 5 years has passed from their last immunization.

Clostridial myonecrosis (gas gangrene)

Clostridial myonecrosis is a deep space infection that results in destruction of healthy muscle tissue and causes systemic toxicity. It can result from trauma with direct inoculation or contamination and subsequent infection of a wound from *C. perfringens*. These account for about 70% of cases. It can also arise spontaneously from hematogenous seeding with *Clostridium septicum*. As with other species of clostridia, they are found commonly in soil. *Clostridium perfringens* is also found commonly in the intestines of humans and animals and requires a microaerophilic environment to thrive, which is in contrast to *C. septicum* which can grow in oxygen-rich environments. It is a life-threatening infection with mortality reported in 19% of traumatic cases and up to 81% of spontaneous cases. Other less common species that can cause disease include *C. sordelli*, *C. novyi*, *C. bifermentans*, and *C. histolyticum*.

Pathogenesis

Traumatic injury can result in vascular compromise to previously healthy tissue and provide an anaerobic environment which is ideal for the growth of *C. perfringens* as well as some other species listed above. Once the spores germinate, they produce alpha and theta toxin that cause tissue destruction, hemolysis, vasodilatation, and alterations in the extravascular migration of neutrophils. It is this alteration of neutrophil migration that accounts for the characteristic absence of purulence in the necrotic tissues. Alpha toxin can contribute to shock by suppressing myocardial contractility, which further compromises cardiac output in the setting of endothelial dysfunction and systemic vasodilatation.

Spontaneous clostridial myonecrosis is typically the result of hematogenous seeding from bacteria (usually *C. septicum*) that gain access to the bloodstream through the gastrointestinal tract. In stark contrast to *C. perfringens*, these bacteria do not require an anaerobic environment and thus can affect previously normal and healthy tissue. *C. septicum* also produces several toxins; however, their contribution to pathogenesis is less clearly known. As with *C. perfringens*, neutrophils are notably absent in the necrotic tissues. There are some predisposing factors which include colonic or hematologic malignancy, inflammatory bowel disease, recent gastrointestinal surgery, neutropenia, and acquired immunodeficiency syndrome.

Clinical

Severe pain is one of the hallmark findings in early disease and is present in both traumatic and spontaneous cases. In traumatic cases, erythema of the inoculation site may be seen. The classic skin findings include the rapid development of a bronze appearance, followed by purple or red discoloration with formation of fluid-filled blisters. As stated above, purulence is uncommon. The extremities become tense from progressive edema of the deeper structures and gas may be appreciated on palpation. Anemia may result from the hemolytic

effect of alpha toxin. Progression to sepsis and multiorgan failure may occur rapidly and can be seen within hours of the initial presentation.

Diagnosis and treatment

Early consideration of gas gangrene is critical to treatment success. The clinical signs mentioned above should point to the diagnosis. Gas in the tissues can be demonstrated by radiography, ultrasound, CT scan, or MRI; the latter two modalities also show deep structures in detail to determine if the infection is localized or if it is involving adjacent structures. Gram stain of involved tissue or fluid may demonstrate gram-positive or gram-variable rods with culture providing a definitive diagnosis.

The most essential component of therapy is early surgical debridement of the involved tissues. Antibiotics comprise another key component of therapy and reduce mortality when combined with early surgery. Penicillin remains one of the most widely used antibiotics to treat clostridial myonecrosis. The addition of clindamycin provides a highly active regimen and through its inhibition of protein synthesis may also decrease toxin production. Other antibiotics with activity include tetracyclines, metronidazole, erythromycin, and carbapenems. Hyperbaric oxygen has been used as an adjunct to therapy with reported improved survival rates; however, its use remains controversial. *Clostridum septicum* can survive and grow in an oxygen-rich environment and thus spontaneous cases caused by this organism would be unlikely to benefit from the use of hyperbaric oxygen.

Food poisoning caused by *clostridium perfringens*

C. perfringens is the second most common bacterial cause of foodborne illness in the United States, with one million cases each year. It results from the ingestion of a large inoculum of vegetative bacteria. Once ingested, the bacteria release an enterotoxin that causes watery diarrhea, abdominal cramping, vomiting, and fever. The incubation period is short, generally between 7 and 15 hours with spontaneous resolution of symptoms occurring at 24 to 48 hours. Meats are the most common contaminated foods with most cases occurring as a common source outbreak. Diagnosis requires the detection of bacterial toxin in stool or by detection of at least 10^6 *C. perfringens* spores per gram of stool in symptomatic patients. Therapy is supportive with hydration playing a major role. Of the five strains of *C. perfringens* (A through E) type A accounts for the majority of cases.

Other clostridial infections

Other clostridial infections may occur as part of a disease process described above or as part of a separate entity. For example, clostridial bacteremia may occur in the setting of clostridial myonecrosis, with *C. perfringens* and *C. septicum* accounting for the majority of cases. The association with *C. septicum* bacteremia and the presence of an underlying hematologic or colonic malignancy should be noted. Clostridia can also cause infections of the gallbladder with *C. perfringens* again accounting for the majority of cases. In this setting, gas may be demonstrated in the biliary tract and would be an indication for surgical intervention. Clostridia may be present as a component of polymicrobial abdominal infections that result from contamination of the peritoneum from intestinal contents. Although rare, they have also been described in anaerobic pulmonary infections.

Corynebacteria

Carlos H. Ramírez-Ronda and Carlos R. Ramírez-Ramírez

Corynebacterium diphtheriae (diphtheria)

Diphtheria is an acute, infectious, preventable, and sometimes fatal disease caused by *Corynebacterium diphtheriae*. The infection is usually localized to the upper part of the respiratory tract and/or the skin; from here it gives rise to local and systemic signs or it can be an asymptomatic carrier state. These signs are the result of a toxin produced by the microorganisms multiplying at the site of infection. The systemic complications particularly affect the heart (22%), the peripheral nerves (5%), and/or the kidneys (renal failure in severe cases).

Cause

Diphtheria is distributed worldwide, there are four biotypes: gravis, intermedius, mitis, and belfanti. All are associated with epidemic and endemic diphtheria. The highest incidence occurs in temperate climates. It occurs predominantly under poor socioeconomic conditions, where crowding is common and where many persons are either not immunized or inadequately immunized. In the United States 20% to 60% of adults are susceptible to diphtheria since the immunity wanes and it is not customary to receive boosters. In the 1990s there were reports of diphtheria outbreaks in the newly independent states of the former Soviet Union. Outbreaks were also experienced in other European countries and were characterized by a high fatality rate, and a large number of complications and adult cases. Diphtheria is seen in developed countries in people that travel to and return from endemic areas as well as in immigrants from endemic areas.

The only significant reservoir of *C. diphtheriae* is the human host. The organism is transmitted directly from one person to another, and intimate contact is required. Transmission is usually by way of infected droplets of nasopharyngeal secretions. Infective skin exudate has been involved in human-to-human transmission. Transmission may also occur via animals, fomites, or milk. The infectious period is usually 2 weeks from onset of symptoms, as long as 6 weeks, and, if treated with antibiotics, to less than 4 days.

Immunity depends on antitoxin in the host's blood. Antitoxin is formed by immunization or by clinical or subclinical infection, including skin infections. Immunity does not prevent carriage. Since immunity varies the Centers for Disease Control and Prevention (CDC) recommends that adults receive a diphtheria-toxoid-containing vaccine (Tdap) every 10 years after completing a primary childhood vaccination series. Despite incomplete immunity the rate of clinical disease is low, US incidence of ~0.001 cases/100 000 population.

Clinical features

Diphtheria may be symptomless or rapidly fatal. The incubation period varies from 1 to 7 days but is most commonly 2 to 4 days.

Respiratory diphtheria

Diphtheria infection of the respiratory tract is usually caused by toxin-producing strains of *C. diphtheriae*, rarely by toxigenic strains of *Corynebacterium ulcerans*, *Corynebacterium pseudotuberculosis* or *Corynebacterium hemolyticum*.

Anterior nares diphtheria

The infection is localized to the anterior nasal area and is manifested by unilateral or bilateral serous or serosanguineous discharge that erodes the adjacent skin, resulting in small crusted lesions. The membrane may be seen in the nose.

Tonsillar (faucial) diphtheria

Tonsillar diphtheria is the most common presentation and the most toxic form. The onset is usually sudden, with fever rarely exceeding 38°C (100.4°F), malaise, and mild sore throat. The pharynx is moderately infected, and a thick, whitish-gray tonsillar exudate is often seen. The tonsillar and cervical lymph nodes are enlarged. The exudate may extend to other areas and result in nasopharyngeal diphtheria and massive cervical lymphadenopathy (bull neck appearance also called malignant diphtheria). The most common complaints are sore throat (85%), pain on swallowing (23%), nausea and vomiting (25%), and headache (18%).

Pharyngeal diphtheria

Pharyngeal diphtheria is diagnosed when the membrane extends from the tonsillar area to the pharynx.

Laryngeal and bronchial diphtheria

Laryngeal and bronchial diphtheria involves the larynx. The voice becomes hoarse and inspiratory and expiratory stridor may appear; dyspnea and cyanosis occur, and the accessory muscles of respiration are used. Tracheostomy or intubation is needed.

Cutaneous diphtheria

Classically described as diphtheria in tropical areas, cutaneous diphtheria now is seen in nontropical areas as well. It takes the form of a chronic nonhealing ulcer, sometimes covered with a grayish membranous exudate. Another form is secondary infection of a pre-existing wound. Finally, superinfection with *C. diphtheriae* may occur in a variety of primary skin lesions, such as impetigo, insect bites, ecthyma, and eczema.

Complications of diphtheria

Myocarditis

Although electrocardiographic (ECG) changes have been described in up to 66% of cases, overt clinical myocarditis is less common (10%–22%). The onset is insidious, occurring in the second or third week of the infection. The patient exhibits a weak, rising pulse; distant heart sounds; and profound weakness and lethargy. Overt signs of heart failure can occur. The most common ECG changes are flattening or inversion of T waves, bundle branch block or intraventricular block, and disorders of rhythm. Serial determination of cardiac enzyme concentrations identifies most patients with myocarditis. The prognosis is poor, especially when heart block supervenes.

Peripheral neuritis

Neurologic toxicity has been described in about 5% of patients with diphtheria, but in severe diphtheria up to 75% of patients develop neurologic complications. The most common form of cranial nerve palsy is paralysis of the soft palate. There may be nasal regurgitation and/or nasal speech. This condition is usually mild, and recovery occurs within 2 weeks. Ciliary paralysis and oculomotor paralysis are the next most common forms. Peripheral neuritis affecting the limbs may appear during the fourth to eighth week. It is usually manifested by weakness of the dorsiflexors and decreased or absent deep-tendon reflexes. Diphtheritic polyneuritis has been described after cutaneous diphtheria.

Diagnosis

Diagnosis is made on clinical grounds and can be confirmed by laboratory tests (Figure 131.1). The clinical features of a fully developed diphtheritic membrane, especially in the pharynx, are sufficiently characteristic to suggest diphtheria and for treatment to be started immediately.

Specific diagnosis of diphtheria depends completely on demonstration of the organism in stained smears and its recovery by culture. In experienced hands, methylene blue-stained preparations are positive in 75% to 85% of cases. The bacilli can be recovered by culture in Loeffler's or Tindale's medium within 8 to 12 hours if patients have not been receiving antimicrobial agents. *Corynebacterium diphtheriae* can be seen as gram-positive bacilli in a "Chinese letter" distribution pattern on Gram or methylene blue stain (Figure 131.2); one can find metachromatic granules on Loeffler's stain and black colonies with halos with growth on Tindale's medium. The presence of β-hemolytic streptococci does not rule out diphtheria because such streptococci are recovered in up to 20% to 30% of patients with diphtheria.

Toxin detection should be performed to differentiate toxigenic from nontoxigenic strains, but is not the reason not to administer antitoxin. Toxin production can be demonstrated by the ELEK test and or rapid enzyme immunoassay (ELISA).

The differential diagnosis of tonsillar-pharyngeal diphtheria should include streptococcal pharyngitis, adenoviral exudative pharyngitis, infectious mononucleosis, and Vincent's angina, among others (Table 131.1).

Therapy

The best and most effective treatment of diphtheria is prevention by immunization with diphtheria toxoid. The most important aspect

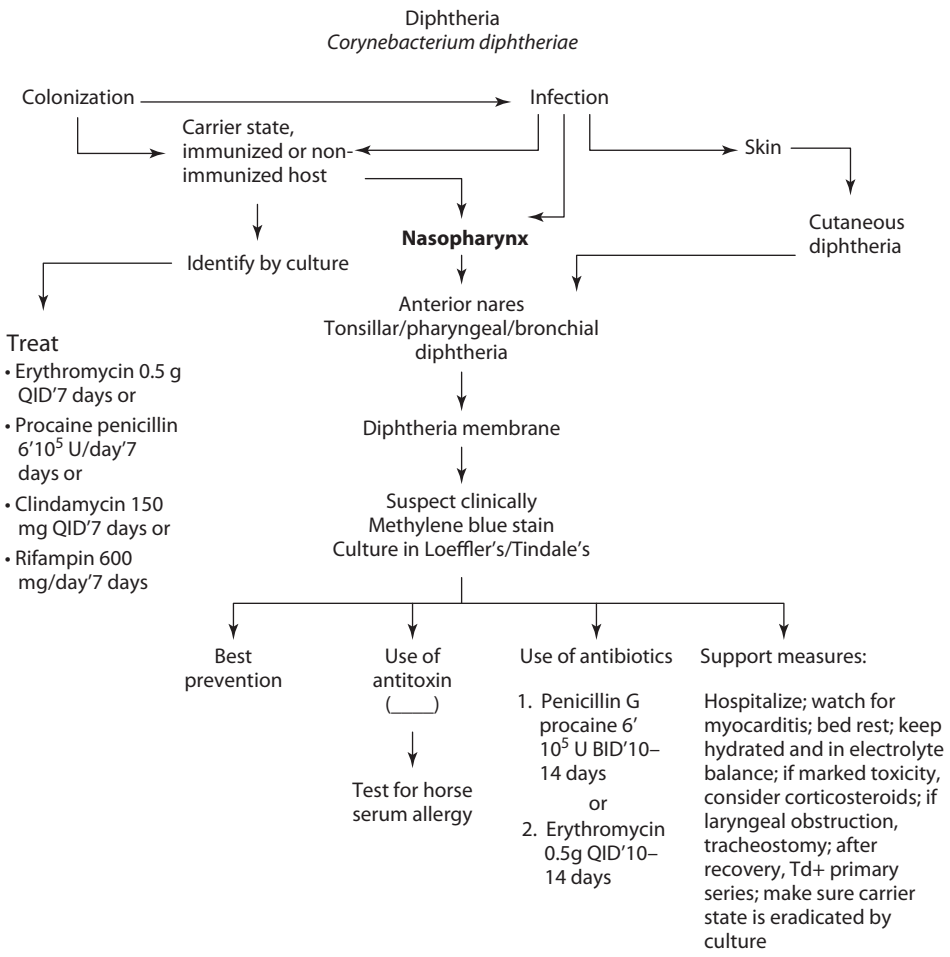

FIGURE 131.1 Diagnostic and treatment approach to diphtheria.

of treatment is to administer the antitoxin and antibiotics as soon as diphtheria is clinically suspected, without awaiting laboratory confirmation. The patient should be hospitalized, isolated, and kept in bed for 10 to 14 days (see Figures 131.1 and 131.3).

Use of antitoxin

The antitoxin is equine, and the minimal effective dose remains undefined; therefore, dosage is based on empiric judgment. It is usually accepted that for patients with mild or moderate cases, including those with tonsillar and pharyngeal membrane, 20 000 to 40 000 units for pharyngeal disease of <48 hours duration, 40 000 to 60

FIGURE 131.2 Gram-positive bacilli in a "Chinese letter" distribution pattern on Gram stain.

TABLE 131.1 **DIFFERENTIAL DIAGNOSIS OF DIPHTHERIA**

Affected area	Other conditions
Nose	Sinusitis, foreign body, snuffles of congenital syphilis, rhinitis
Fauces and pharynx	Streptococcal or adenoviral exudative pharyngitis, ulcerative pharyngitis (herpetic, Coxsackie-viral), infectious mononucleosis, oral thrush, peritonsillar abscess, retropharyngeal abscess, Vincent's angina, lesions associated with agranulocytosis or leukemia
Larynx	Laryngotracheobronchitis, epiglottitis
Skin	Impetigo, pyogenic ulcers, herpes simplex infection

000 units for nasopharyngeal disease, and 80 000 to 100 000 units for >3 days of illness or "bull neck" is appropriate. Doses should be given intravenously over 60 minutes as recommended by the American Academy of Pediatrics.

Before administration of the antitoxin, any history of allergy or reactions to horse serum or horse dander must be determined. All patients must be tested for antitoxin sensitivity with dilute horse antitoxin in saline 1:10 and an eye test. This is followed by a scratch test with a 1:100 dilution; if negative in half an hour, the scratch test is followed by an intradermal test, 1:100 dilution. If all tests are negative, antitoxin can be given. The intravenous route is recommended. A slow intravenous infusion of 0.5 mL antitoxin in 10 mL saline is followed in half an hour by the balance of the dose in a dilution of 1:20 with saline, infused at a rate not to exceed 1 mL/min. Others give the antitoxin dose intramuscularly in mild to moderate cases only.

If the patient is sensitive to horse serum, desensitization should be carried out with care, preferably in an intensive care unit. Epinephrine, intubation equipment, and respiratory assistance should be available. The following doses of horse serum antitoxin should be injected at 15-minute intervals if no reaction occurs:

1. 0.05 mL of 1:20 dilution subcutaneously
2. 0.10 mL of 1:10 dilution subcutaneously
3. 0.3 mL of 1:10 dilution subcutaneously
4. 0.1 mL of undiluted antitoxin subcutaneously
5. 0.2 mL of undiluted antitoxin subcutaneously
6. 0.5 mL of undiluted antitoxin subcutaneously
7. Remaining estimated therapeutic dose intramuscularly.

During all tests and on injection of antitoxin, a syringe containing epinephrine 1:1000 dilution in saline should be at hand to be used immediately in a dose of 0.01 mL/kg subcutaneously or intramuscularly at any sign of anaphylaxis. A good precaution is to have open venous access with normal saline prior to the test. If needed, a similar amount of epinephrine diluted to a final concentration of 1:10 000 in saline may be given slowly intravenously and repeated in 5 to 15 minutes. Other information and instructions in the package insert accompanying the antitoxin should be observed.

Antibiotics

Corynebacterium diphtheriae is susceptible to several antimicrobial agents. After cultures have been performed, antibiotics should be administered to prevent multiplication of the microorganism at the site of infection and to eliminate the carrier state. The antibiotics of choice are erythromycin (500 mg four times a day for 14 days) or penicillin G 25 000 to 50 000 units to a maximum of 1.2 million units IV every 12 hours until the patient can take oral penicillin V (250 mg QID) for a total of 14 days. Erythromycin has been favored since reports show greater efficacy than penicillin.

Supportive measures

Complications such as dehydration, malnutrition, and congestive heart failure should be diagnosed promptly and properly treated. In cases of severe laryngeal involvement, marked toxicity, or shock, corticosteroids (prednisone 3 to 5 mg/kg/day) have been advocated, but there are no hard data on their effectiveness. For laryngeal obstruction with respiratory stridor, a tracheotomy must be performed promptly.

Before the patient is discharged, specimens from throat and nose or suspected lesions should be cultured. At least two and preferably three consecutive negative cultures should be obtained.

After recovery, toxoid administration against tetanus and diphtheria (Td) should be administered to complete a primary immunization series if the patient has not been immunized.

Carriers

The chronic carrier state may occur despite immunity derived either from clinical disease or from immunization. The carrier state occasionally persists in the absence of antecedent disease. Erythromycin, 0.5 g orally four times a day for 7 days in adults, is the treatment of choice for the carrier state. Alternative antibiotics are procaine penicillin G, 600 000 U intramuscularly daily for 14 days, clindamycin, 150 mg orally four times a day for 7 days, or rifampin, 600 mg/day orally for 7 days.

Epidemics

The approach to epidemic disease is as follows:

1. Identify all primary cases, hospitalize, and treat.
2. Use toxoid in all the population at risk.
3. Culture all contacts for diphtheria, and treat all persons with *C. diphtheriae* in throat, nose, or skin lesions with erythromycin for 7 days to eliminate carrier state (Figure 131.3).
4. Watch primary contacts closely during the first week of exposure and treat at first signs or symptoms. Alternatively, all susceptible primary contacts can be given 1500 to 3000 U of diphtheria antitoxin, administered as previously described, in addition to toxoid. This low-level dose will boost them while they are forming their antibody.

Prevention

Children who have had a complete course of primary immunization with diphtheria–tetanus–pertussis (DTaP) vaccine may be given a booster injection on exposure to diphtheria. This is done in case of outbreaks but is not routine. Antibiotic prophylaxis is highly effective.

Household and other close contacts of a patient with diphtheria should be observed attentively for 7 days. They should receive either an intramuscular injection of 600 000 to 1.2 million units of benzathine penicillin or a 7- to 10-day course of erythromycin taken orally. Cultures should be performed before and after treatment. An injection of toxoid appropriate for age and immunization status can also be given. Susceptible close contacts who have had no (or only one) prior injections of toxoid should promptly be given 3000 to 10 000 units (depending on body size) of antitoxin, with the usual

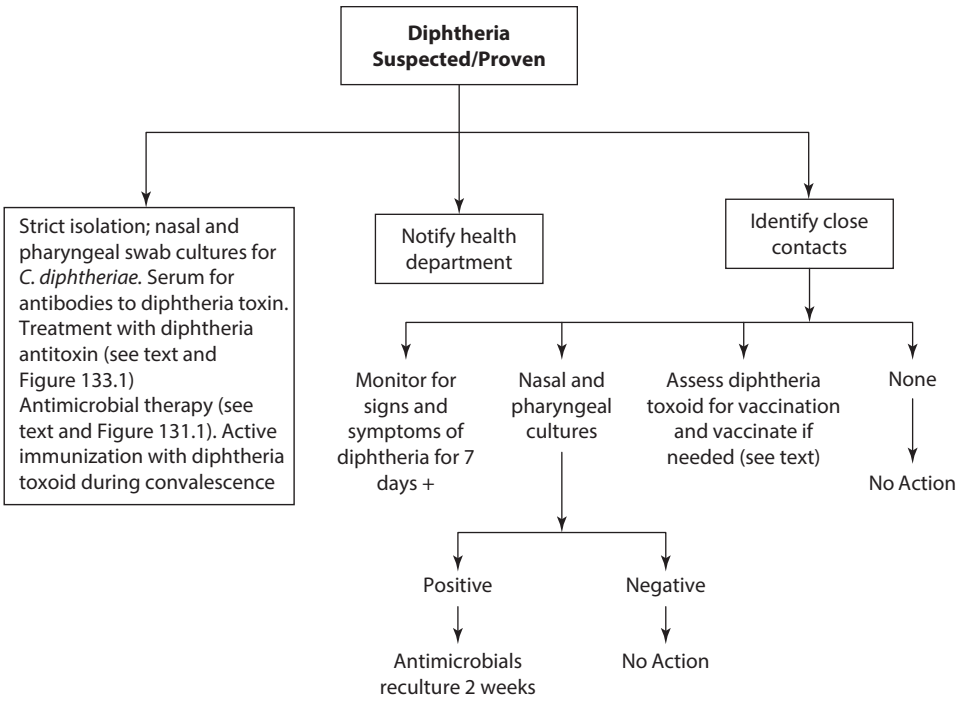

FIGURE 131.3 Public health management of diphtheria.[1]

precautions being followed. When indicated, active immunization with toxoid should be continued to completion. Routine immunization for diphtheria is discussed in Chapter 115, Immunizations.

Nondiphtheric corynebacteria

Nondiphtheric corynebacteria were once considered commensals. They are present in the skin and often are recovered from blood cultures. The presence of the microorganism in the blood has been considered contaminant, but there are many instances in which nondiphtheric corynebacteria are associated with bacteremias, sepsis, pneumonias, endocarditis, central nervous system infections, and intraocular infections, especially in immunocompromised patients and patients with vascular and central nervous system catheters and prosthetic devices. A common predisposing factor is neutropenia.

The diagnosis of infections with nondiphtheric corynebacteria usually involves their recovery from blood or other sterile body fluid. Corynebacteria can be identified by conventional methods; since 2000, a new system, the Rapid CORYNE System, was found to be excellent and an alternative to conventional methods.

Clinically, there are no specific findings that suggest nondiphtheric corynebacteria, but their association with central lines, skin, and subcutaneous infections in immunocompromised patients leads the clinician to associate a given infection with a gram-positive rod. Table 131.2 lists the epidemiology and clinical features of selected nondiphtheric corynebacteria.

TABLE 131.2 **EPIDEMIOLOGY AND CLINICAL FEATURES OF SELECTED NONDIPHTHERIC CORYNEBACTERIA**

Corynebacterium	Epidemiology	Clinical features
C. jeikeium	Skin, systemic	Soft-tissue, pneumonias, shunt infections; skin rash; endocarditis
C. minutissimum	Skin	Erythrasma, reddish-brown macular lesions, fluoresce under Wood's lamp
C. ulcerans	Skin, systemic	Cardiac and central nervous system involvement; diseases in horses and cattle
C. pseudotuberculosis	Skin exposure, farm animals, raw milk	Dermonecrotic toxin, suppurative granulomas, lymphadenitis, disease in farm animals
C. bovis	Shunts, skin	Meningitis, spinal epidural; abscess; ventriculoperitoneal or jugular shunts
C. pseudodiphtheriticum *C. striatum*	Systemic Immunosuppressed	Pneumonia endocarditis, tracheitis, urinary tract Pneumonias, meningitis, abscesses, bacteremias

Corynebacterium jeikeium

Corynebacterium jeikeium is a gram-positive coccobacillus or coccus resembling the streptococcus. Characteristically, it shows high-grade antibiotic resistance, being susceptible only to vancomycin in vitro and in vivo.

Clinical features

Diseases associated with *Corynebacterium jeikeium* include soft-tissue infections, pneumonitis with or without cavitation, continuous ambulatory peritoneal dialysis-related peritonitis, neurosurgical shunt infections, skin rash, catheter-related epicardial abscess, and endocarditis. It should always be considered a possible cause of sepsis in the neutropenic patient and in patients with prosthetic devices in place.

Therapy

Despite their high antibiotic resistance, these corynebacteria remain susceptible to vancomycin. Total effective duration of treatment has not been established. Clinical response must be followed, usually treating for 4 to 6 weeks. Newer fluoroquinolones, mainly ciprofloxacin, have also shown good results. Infected prosthetic material often requires removal.

Corynebacterium minutissimum

Infection with *C. minutissimum* usually involves the skin, and the classical disease entity is erythrasma. Erythrasma is a skin infection characterized by brownish-reddish macules that itch and when exposed to a Wood's lamp fluoresce. The most frequent location is the intertriginous areas.

Bacteremia with *C. minutissimum* has been described in patients with leukemia in blast crisis. There are also reports of trichomycosis axillaris associated with this corynebacterium.

Corynebacterium ulcerans

Corynebacterium ulcerans, like *C. diphtheriae*, produces diphtheria toxin by lysogeny but without apparent clinical consequences. However, there are documented reports of *C. ulcerans* bacteremias with cardiac and central nervous system involvement as well as pneumonia.

Corynebacterium pseudotuberculosis

Infection with *C. pseudotuberculosis* is associated with exposure to farm animals or consumption of raw milk. Clinically, it presents as a suppurative granulomatous lymphadenitis most likely related to the dermonecrotic toxin it produces. This organism responds to long-term treatment with erythromycin or tetracycline.

Corynebacterium bovis

Most infections reported with *C. bovis* are associated with central nervous system processes. There have been cases of meningitis, epidural abscesses, and shunt infections.

Corynebacterium pseudodiphtheriticum

Sites of infection caused by *C. pseudodiphtheriticum* include heart valves, wounds, urinary tract, and lungs, with pneumonia and necrotizing tracheitis. The susceptibilities of this microorganism are varied, with both susceptibility and resistance to erythromycin, clindamycin, and penicillin. There is a case of response to penicillin intravenously (12 million units daily for 14 days).

Corynebacterium striatum

Persons with an underlying immunosuppressive process are usually victims of *C. striatum*. There are reports of pneumonias, pulmonary abscesses, meningitis, and bacteremias with *C. striatum*. Most patients were treated with vancomycin.

Others

There have been reports of *Corynebacterium* CDC group A-4 associated with native valve endocarditis in immunocompetent patients as well as sepsis in immunocompromised hosts with infected Hickman catheters. *Corynebacterium aquaticum*, an environmental organism of fresh water, has been associated with septicemia in a neutropenic patient with an indwelling central venous catheter who used untreated stored rainwater to shower. *Corynebacterium afermentans* (CDC group ANF-1) was reported to cause endocarditis in a prosthetic valve.

Therapy

Some corynebacteria are susceptible to erythromycin, sulfonamides, chloramphenicol, gentamicin, imipenem, some of the newer fluoroquinolones, and vancomycin. For most serious and systemic infections, we prefer to use vancomycin at 1 g every 12 hours for at least 2 weeks in adults with normal renal function. In some patients, especially immunocompromised patients, combination therapy can be used with vancomycin plus imipenem at 500 mg intravenously every 6 hours, vancomycin plus rifampin at 600 mg daily orally, or vancomycin plus ciprofloxacin at 750 mg orally every 12 hours for 2 to 4 weeks. Erythromycin at a dosage of 2 to 4 g in divided doses can be used as an alternative regimen. The optimal effective therapy for these infections has not been determined, but 8 weeks of treatment are often required. For unresponsive cases, surgical consultation is recommended.

132

Enterobacteriaceae

Charles Stratton

The Enterobacteriaceae consist of a large, heterogeneous group of aerobic (facultatively anaerobic) gram-negative bacilli whose natural habitat is the gastrointestinal tract of animals and humans. Of the many members of the Enterobacteriaceae, there are three that are considered pathogens whenever they are isolated from humans. These three pathogens are *Salmonella*, *Shigella*, and *Yersinia*; their unique clinical features are considered in separate chapters. Many of the members of the Enterobacteriaceae are important causes of community- and hospital-acquired infections. Medically important Enterobacteriaceae are listed in Table 132.1.

Urinary tract infection

Members of the Enterobacteriaceae are the most important cause of both community- and hospital-acquired urinary tract infections (UTIs); *Escherichia coli* is the most frequently isolated pathogen and has been noted to have a unique pathogenesis in terms of its ability to cause UTIs. This pathogenesis involves adherent fimbriae and production of glycocalyx that allow it to adhere to normal bladder epithelium as well as the ability to invade bladder cells where this uropathogen is able to survive in biofilm colonies.

The symptoms of UTI are similar no matter which member of the Enterobacteriaceae is causing the infection; these symptoms can assist in differentiating upper UTI (i.e., pyelonephritis) from lower UTI (i.e., cystitis). Cystitis is characterized by frequency, urgency, dysuria, and suprapubic discomfort while pyelonephritis is characterized by fever, chills, nausea, vomiting, flank pain, and costovertebral angle tenderness. In male patients, involvement of the vesicles and/or prostate may occur with a UTI. Many of these symptoms may be absent in elderly patients or in patients with spinal cord injuries and/or indwelling urinary catheters. Perhaps the most distinct urinary tract pathogen is *Proteus* spp., which characteristically causes UTIs with an alkaline urine (pH of 8) and often is associated with the presence of staghorn calculi.

Asymptomatic bacteriuria is also important to understand when considering UTIs; asymptomatic bacteriuria is usually defined as $>10^5$ organisms/mL, with or without pyuria in the absence of symptoms. Asymptomatic bacteriuria infrequently results in symptomatic UTIs; treatment is indicated only in young children, pregnant women, or prior to instrumentation of the urinary tract, such as insertion of a Foley catheter.

The laboratory diagnosis of UTI typically involves a urine quantitative colony count, with 10^5 gram-negative (most often members of the Enterobacteriaceae) organisms/mL defining a UTI. However, as few as 10^2 gram-negative organisms/mL may be seen in symptomatic UTIs, particularly when the urine is collected by a suprapubic tap or by catheterization. It should be noted that quantitative colony counts have not been evaluated in a systematic manner for gram-positive organisms such as *Enterococcus* species, although 10^5

TABLE 132.1 **GENUS AND SPECIES COMMENTS**

Citrobacter diversus, *C. freundii, C. koseri*	Usually nosocomial, most frequently involving urinary tract, can cause neonatal meningitis and brain abscesses.
Cronobacter sakasakii	Causes meningitis and sepsis in neonates; associated with use of powdered infant formula.
Edwardsiella tarda	Associated with freshwater and fish; ingestion of fresh water can cause diarrhea. Soft tissue injuries while handling fish can lead to serious soft tissue infections.
Enterobacter cloacae	Colonizer of human colon, frequent cause of nosocomial infections, also noted for de-repression of AmpC beta-lactamase leading to high-level resistance to cephalosporins.
Escherichia coli	Most common cause of urinary tract infection. Six diarrheal pathotypes. Frequent cause of bacteremia related to urinary tract infection, ascending cholangitis, or intraabdominal infection. Cause of neonatal meningitis. Can cause pneumonia (both hospital-acquired and ventilator-associated). Important pathogen for community-acquired and hospital-acquired infections. Can have extended-spectrum β-lactamases.
Ewingella Americana	Rare cause of nosocomial infections.
Hafnia alvei	Rare cause of community-acquired and hospital-acquired infections.
Klebsiella pneumoniae, K. oxytoca, K. aerogenes	Common cause of community-acquired and hospital acquired infections. Urosepsis and bacteremia from ascending cholangitis are typical community-acquired infections. Can cause pneumonia. Hypermucoviscous strains associated with liver abscesses. High-level antimicrobial resistance possible due to extended-spectrum beta-lactamases, carbapenemases, or in the case of *K. aerogenes*, de-repressed AmpC β-lactamase.
Kluyvera ascorbate	Rare cause of nosocomial infections such as urinary tract infections.
Morganella morgani	Uncommon cause of community-acquired infections, more commonly seen in nosocomial infection, but still rarely seen causing infection.
Pantoea agglomerans	Plant pathogen that causes human infection after penetrating injuries with plant material such as wood splinters.
Plesiomonas shigelloides	Associated with fresh/brackish water as well as shellfish and oysters taken from brackish water; causes gastroenteritis in humans.
Proteus mirabilis, *P. vulgaris*	Common cause of urinary tract infections, particularly when renal calculi or indwelling catheters are involved. Also associated with fetid foot.
Providencia stuartii, *P. rettgeri*	Causes catheter-associated urinary tract infections.
Salmonella enterica	See Chapter 148, "Salmonella."
Serratia marcescens	Environmental pathogen associated with neonatal intensive care units and burn units, high-level resistance frequently seen.
Shigella species	See Chapter 153, "Shigella."
Yersinia species	See Chapter 158, "Yersinia."

gram-positive organisms/mL is often used as a definition of UTI. When in doubt, a repeat culture that grows the same organism can provide a clinically useful definition of UTI. When gram-positive organisms are suspected of causing a UTI, underlying urinary tract abnormalities should be considered and ruled out.

Gastrointestinal infections

Salmonella, *Shigella*, and *Yersinia* are considered pathogens whenever they are isolated from the human. These three pathogens often cause gastrointestinal infections and are discussed in separate

TABLE 132.2 **PATHOGENIC *ESCHERICHIA COLI* OF THE GASTROINTESTINAL TRACT**

Pathotype		Clinical illness	Comments
ETEC	Enterotoxigenic *E. coli*	Acute watery diarrhea, usually self-limited	Most common cause of travelers' diarrhea and in children worldwide
EAEC	Enteroaggregative *E. coli*	Mucoid diarrhea	May cause chronic diarrhea, emerging in travelers
EPEC	Enteropathogenic *E. coli*	Acute diarrhea and vomiting	Common in children in developing countries
EIEC	Enteroinvasive *E. coli*	Watery diarrhea or dysentery (fever, abdominal pain, tenesmus, blood)	Occurs in outbreaks
EHEC	Enterohemorrhagic *E. coli*	Watery and bloody diarrhea	Hemolytic-uremic syndrome

chapters. In addition, there are enteropathogenic forms of *E. coli* that can colonize the human gastrointestinal tract and cause diarrheal illnesses of the small and large intestines. These are listed in Table 132.2.

Given that *E. coli* is among the most common colonizers of the human gastrointestinal tract. It therefore is not surprisingly that there are five well-described mechanisms for enteropathogenic *E. coli* causing diarrheal illnesses. The most common of these mechanisms is enterotoxigenic *E. coli* (ETEC), which uses either a heat-labile toxin (LT) that interferes with cyclic adenosine monophosphate (AMP) or a heat-stable toxin (ST) that interferes with cyclic guanosine monophosphate (GMP). Both cholera-like toxins induce secretion of chloride anions into the small intestine and impede reabsorption of sodium chloride. The result is watery diarrhea that has been termed "traveler's diarrhea" or "Montezuma's revenge" and is the most common cause of diarrhea in children <2 years of age as well as in travelers to tropical regions where ETEC is commonly found in food and water supplies. ETEC is most easily diagnosed by molecular methods that detect the genes for LT or ST. The most serious of these five mechanisms is enterohemorrhagic *E. coli* (EHEC), which produce a Shiga toxin that inhibits host protein synthesis and induces apoptosis. This Shiga toxin also can be absorbed into the bloodstream and disseminated to other organs, causing acute renal failure, thrombocytopenia, and microangiopathic hemolytic anemia. This clinical constellation of organ dysfunction is collectively known as *hemolytic uremic syndrome* (HUS); treatment with antimicrobial agents is not indicated as this can make this syndrome worse.

Intra-abdominal infection

Because many of the Enterobacteriaceae are part of the normal gut flora, it is not surprising to find members of this group are the principal causes of intra-abdominal infections through a variety of different mechanisms. For example, obstruction of a diverticulum or of the appendix can lead to diverticulitis or appendicitis; both of these are polymicrobial infections in which members of the Enterobacteriaceae play an active role. Gut flora also plays an active role in peritonitis and/or abscesses anywhere in the abdominal or pelvic cavities when perforation of a viscus occurs. Members of the Enterobacteriaceae are commonly found in the biliary system, and, when obstruction by gall stones leads to cholecystitis, these gram-negative bacilli may cause ascending cholangitis or a liver abscess. Translocation of these gram-negative bacilli from the gut to the liver via the portal blood system also can result in a liver abscess. These biliary/liver infections are characterized by fever and abdominal pain that or may not be localized to the right upper quadrant. The likelihood of ascending cholangitis occurring with acute cholecystitis is roughly equal to the patient's age; if symptoms have been present for more that 3 days, then the likelihood of ascending cholangitis is almost 100%. Leukocytosis with a left shift is an important clue for the diagnosis of biliary/liver infections.

Cholecystitis and ascending cholangitis typically have an elevation of the total bilirubin if the common bile duct is involved and obstructed; if not obstructed, the total bilirubin is elevated 25% of the time. In two-thirds of liver abscesses, the alkaline phosphatase is elevated; usually there is little or no elevation of bilirubin or aminotransferases. Hypermucoviscous strains of *Klebsiella* spp. have been noted to cause liver abscesses; metastatic infections of the eye and central nervous system (CNS) also have been seen with these strains. The phenomenon was first described in East and Southeast Asia. More recently, this phenomenon has been reported from Europe and the United States.

Infection of the pancreas or of a pancreatic pseudocyst typically present with abdominal pain, nausea, vomiting, fever, and leukocytosis and can be difficult to diagnose; such pancreatic infections are often seen after pancreatic manipulations such as endoscopic retrograde cholangiopancreatography (ERCP). Suspicion of a possible pancreatic infection should result in serum amylase and serum lipase testing; if positive, these should be followed by appropriate imaging studies such as a CT or an MRI scan. Broad-spectrum empiric antimicrobial therapy should be directed at members of the Enterobacteriaceae as well as other gut flora such as anaerobes and enterococci.

Finally, members of the Enterobacteriaceae are the most common cause of *spontaneous bacterial peritonitis* (SBP), an infection of ascitic fluid without a concomitant intra-abdominal surgically treatable source of infection. Members of the Enterobacteriaceae are thought to cause 80% of SBP via bacterial translocation in which viable bacteria from the gastrointestinal lumen pass through the lumen to

extraintestinal sites. Nonenteric bacteria are the cause of SBP in about 20% and are thought to enter the peritoneal cavity from the bloodstream due to impaired liver function and altered portal circulation. Of these nonenteric bacteria, approximately 3% to 8% of culture-proven cases are caused by *Streptococcus pneumoniae*.

SBP is most often due to seeding of preexisting ascites, often in the setting of cirrhosis but occasionally in the setting of ascites due to nephritic syndrome or right-sided heart failure. Clinical manifestations include presence of ascites by physical exam or by imaging as well as fever, increasing abdominal girth, abdominal pain, and abdominal tenderness. Ascitic fluid should be obtained and the following tests done: aerobic and anaerobic cultures, cell count and differential, Gram stain, albumin, protein, glucose, lactate dehydrogenase, amylase, and bilirubin (if the fluid is dark orange or brown). If tuberculosis is suspected, a percutaneous biopsy of the peritoneum with a Cope needle should done.

Pneumonia and pleural space infections

Members of the Enterobacteriaceae cause between 5% and 15% of culture-proven pneumonias, regardless of whether the pneumonia is community-acquired or of nosocomial origin. Aspiration, older age, and comorbid conditions such as heart failure, renal disease, or diabetes tend to favor a gram-negative etiology; other clinical findings are not particularly useful in determining the etiological agent of bacterial pneumonia. Although production of dark-red mucoid sputum (termed "currant jelly sputum") has been associated with "Friedlander's bacillus" (i.e., *Klebsiella pneumoniae*), other clinical hallmarks of pneumonia caused by *K. pneumoniae* are nonspecific.

The imaging patterns from chest radiographs, CT scans, or MRI scans similarly are nonspecific and are not pathognomonic of gram-negative bacillary pneumonia, but this diagnosis should be considered whenever a necrotizing pneumonic process with pneumatoceles, cavitation, or empyema is noted. Gram-negative bacillary pneumonia is a well-recognized problem for patients with hospital-acquired and ventilator-associated pneumonia. The diagnosis should be made with Gram stains and cultures from expectorated sputum, deep lung suctioning via endotracheal tubes in intubated patients, or via bronchoscopy and bronchioalveolar lavage.

Skin and soft tissue infections

Although staphylococci and streptococci are the most common causes of skin and soft tissue infections, members of the Enterobacteriaceae are often involved in certain types of skin and soft tissue infections. Skin and soft tissue infections that typically involve members of the Enterobacteriaceae are surgical wound infections, particularly those involving abdominal or pelvic surgery. Such surgical wound infections are usually mixed infections and involve both gram-negative bacilli and anaerobic bacteria. Other skin and soft tissue infections that typically involve members of the Enterobacteriaceae include secondary infections of burns, infections of decubitus ulcers, the diabetic fetid foot, Fournier's gangrene, and other types of bacterial synergistic necrotizing fasciitis.

In general, these types of skin and soft tissue infections are complications arising from a preexisting wound or trauma, as well as arising from an enteric source such as a perforated intestine. Diabetes mellitus is a frequent comorbid factor, as exemplified by the fetid foot or Fournier's gangrene. Individuals with these types of skin and soft tissue infections are usually systemically ill-appearing with fever, leukocytosis, and often have accompanying bacteremia. These skin and soft tissue infections are characterized by moderate to severe pain, erythema, edema, crepitus on exam, tissue gas per radiographic, CT scan or MRI imaging, malodorous wound discharge, and evidence of skin/tissue necrosis. Empiric antimicrobial therapy along with surgical debridement is required for most of these types of skin and soft tissue infections.

Bone and joint infections

Septic arthritis, osteomyelitis, and prosthetic joint infections caused by members of the Enterobacteriaceae are well described in the medical literature. Overall, the involvement of gram-negative bacilli in these bone and joint infections is less frequent than is the involvement of gram-positive cocci and account for 5% to 25% of these infections. Osteomyelitis caused by a gram-negative bacillus may result from a focal soft tissue infection that has extended to involve the bone, as seen with the diabetic fetid foot. *E. coli, K. pneumoniae*, and *Proteus* spp. are the most common gram-negative bacilli involved in osteomyelitis of the diabetic foot. Seeding from the prostate or the bladder may lead to lumbar vertebral osteomyelitis; *E. coli* and *Proteus mirabilis* are the most common gram-negative bacilli involved in vertebral osteomyelitis. Hematogenous seeding of gram-negative bacilli can infect any bone or joint and are most often seen in septic arthritis and prosthetic joint infections in the elderly. The most common gram-negative bacillus isolated from such joint infections is *E. coli*.

The clinical presentations of gram-negative bacillary bone and joint infections is similar to that seen with bone and joint infections caused by gram-positive cocci. Joint infections are characterized by localized pain in the infected joint, joint swelling, joint erythema, and fever. Wound dehiscence and draining sinuses often are noted in cases of infections involving a recently implanted prosthetic joint. Vertebral infections typically have localized back pain with a radicular pattern; focal neurologic signs suggest an epidural abscess, which is a neurologic emergency requiring rapid diagnosis and appropriate decompressive surgery.

The clinical diagnosis of bone and joint infections relies on clinical suspicion that is usually strengthened by imaging studies such as radiographic studies, CT scans, MRI scans, and radionuclide white cell scans. The definitive diagnosis usually requires sterilely obtained cultures of joint fluid or bone; blood cultures should be done because approximately 50% of joint or bone infections will have an

accompanying bacteremia. Chronic draining sinuses are not appropriate sources for cultures as these sinus tracts may be colonized and not reveal the agents of deep infection.

Central nervous system infections

E. coli causes the majority of gram-negative bacillary meningitis due to members of the Enterobacteriaceae, although other members such as *Klebsiella pneumoniae*, *Citrobacter koseri*, *Enterobacter cloacae,* and *Cronobacter sakazakii* are occasionally seen. The majority of these gram-negative bacillary meningitis cases are seen in infants within the first weeks of life. Gram-negative bacillary infections of the CNS in adults are seen in the elderly or in patients with trauma, parenteral drug use, or neurosurgical procedures. Disseminated strongyloidiasis also may result in gram-negative bacillary meningitis when migrating *Strongyloides* larva bring colonic bacilli with them as they invade brain tissue. Due to the types of host that typically have gram-negative bacillary meningitis, the classic signs of fever and nuchal rigidity may not be seen. Analysis of cerebrospinal fluid (CSF) is needed to diagnose these cases of meningitis; the Gram stain may be difficult to read due to cellular and protein debris in the CSF. Blood culture should be done because >50% of these cases of gram-negative bacillary meningitis will have an accompanying bacteremia.

Focal suppurative gram-negative bacillary infections of the CNS, including brain abscesses, subdural empyema, and spinal epidural abscesses, are occasionally caused by members of the Enterobacteriaceae. In particular, ventriculitis and ventricular shunt infections can be seen and are difficult to treat because they act like abscesses. In addition, some of the gram-negative bacilli such as *Enterobacter* spp. that cause these infections have both intrinsic and acquired resistance to newer β-lactam agents. Indeed, members of the Enterobacteriaceae producing extended-spectrum β-lactamases (ESBLs), inducible AmpC-β-lactamases, and carbapenemases have become an increasing issue and have been seen in nosocomial infections such as ventriculitis and ventricular shunt infections.

Bacteremia, endovascular infection, and sepsis

A bacteremia caused by a member of the Enterobacteriaceae always should be considered a true-positive result, and a source of this bacteremia should be aggressively pursued. Most community-acquired infections with bacteremia caused by members of the Enterobacteriaceae will be due to pyelonephritis, ascending cholangitis, or diverticulitis. Hospital-acquired infections with bacteremia caused by members of the Enterobacteriaceae will be due to intravascular catheters, hospital-acquired pneumonia, or ventilator-assisted pneumonia. Intravascular catheters are particularly important causes of gram-negative bacteremia for patients receiving parenteral nutrition, hemodialysis, and chemotherapy for cancer, as well as for patients with long-term central venous catheters.

Infections caused by members of the Enterobacteriaceae can be seen with other intravascular devices such as vascular stints, prosthetic vascular grafts, and implanted transvenous pacemakers and defibrillators (automatic implantable cardioverter defibrillators; AICDs). The morbidity associated with infected intravascular devices is considerable, as is the morbidity of the intervention; this makes it imperative to establish a diagnosis. Unfortunately, the diagnosis of infections associated with these intravascular devices can be difficult; a tagged white blood cell (WBC) scan or the ^{18}F-FDG-PET/CT scan may be useful. The limited spatial resolution of the tagged WBC scan may decrease its sensitivity for low-grade infections; thus, a negative WBC scan does not rule out the possibility of this diagnosis.

Given the frequency of bacteremia due to members of the Enterobacteriaceae, a high percentage of native valve and prosthetic valve endocarditis would be expected to be seen yet only 2% to 5% of bacterial endocarditis are caused by gram-negative bacteria. *Salmonella* spp. and *Yersinia* spp. are the most common causes of Enterobacteriaceae endocarditis reported in the medical literature. Most members of the Enterobacteriaceae do not produce biofilm and are unable to adhere to damaged endothelium. *Salmonella* spp. seem to be an exception and are well-known causative agents of intravascular infections.

Bacteremia caused by members of the Enterobacteriaceae may rapidly progress to sepsis or septic shock. Sepsis is defined as "life threatening organ dysfunction caused by dysregulated host response to infection." Septic shock is defined as a "subset of sepsis with particular profound circulatory, cellular, and metabolic abnormalities associated with a greater risk of mortality than sepsis alone." Septic shock is usually accompanied by evidence of tissue hypoperfusion such as lactic acidosis, oliguria, or acute lung injury. Septic shock with fever and refractory hypotension may lead to organ failures. Therefore, the diagnosis of septic shock must be made in a timely manner.

The diagnostic criteria of septic shock are a "vasopressor requirement required to maintain a mean arterial pressure (MAP) of >65 mm Hg and a serum lactate level >2 mmol/L in the absence of hypovolemia." A qSOFA (quick SOFA) has been developed as a bedside tool to rapidly identify adult patients who are more likely to have a poor outcome; a qSOFA is considered to be positive if the patient has two of the following clinical criteria:

- Respiratory rate of 22/min or greater,
- Altered mentation (Glasgow Coma Scale of <15), or
- Systolic blood pressure of ≤100 mm Hg.

The qSOFA is also used to prompt clinicians to further investigate for organ dysfunction, initiate or escalate therapy as appropriate, and consider referral to critical care or increase monitoring frequency.
In addition, there are six management steps to be implemented within 1 hour of the onset of sepsis:

- Administer oxygen to maintain SpO_2 at >94%.
- Obtain blood cultures and consider infective source.
- Administer intravenous (IV) antibiotics.

- Consider IV crystalloid fluids.
- Check serial lactates.
- Commence hourly urine output measurement.

The window between the actual onset of sepsis and the clinical recognition of sepsis is often where significant delays in the management of sepsis occur; this time frame is also a critical time for appropriate management of sepsis. For example, IV antimicrobial agents (at least two classes of antimicrobial agents to cover known or suspected pathogens) should be started within 1 hour of recognition of sepsis. Patients who need vasopressors should receive norepinephrine as the first choice; vasopressin or epinephrine can be added. For patients who remain unstable, dobutamine is recommended. Finally, patients with hypoperfusion should receive 30 mL/kg of IV crystalloid, such as Ringer's lactate. All of these management steps hinge on the rapid recognition of sepsis and septic shock.

Principles of antimicrobial therapy

The principles of antimicrobial therapy, in part, require an understanding of the difference between empiric and definitive therapy, an appreciation of the role of the clinical microbiology laboratory in definitive therapy, acknowledging the importance of antimicrobial stewardship, and (most importantly) recognizing when to consult an infectious diseases specialist.

Under most circumstances, definitive antimicrobial therapy should be determined by the results of culture and susceptibility testing along with an appreciation of the pharmacokinetics and pharmacodynamics of the antimicrobial agents on the particular host to be treated. Factors such as allergies and toxicities, tissue penetration, presence of co-pathogens, renal and hepatic function, possible drug–drug interactions, dosing and ease of administration, and cost all must be considered. Empiric antimicrobial therapy must be guided by the clinical presentation, severity of illness, type and source of the infection, and local resistance patterns and/or available antibiograms that would predict potential resistance issues.

Unfortunately, increasing resistance found in members of the Enterobacteriaceae have made both empiric and definitive antimicrobial therapy more difficult in the 21st century. The successful development of novel antimicrobial agents, as well as novel β-lactamase inhibitors, has been impressive. These recent and future antimicrobial therapy options will be discussed in more detail in the next section. However, one of the major challenges of antimicrobial therapy is that many clinical microbiology laboratories do not have the technology to provide real-time information on the identification of bacteria as well as their susceptibility to antimicrobial agents and the presence of resistance markers. Susceptibility testing of these Enterobacteriaceae isolates often requires a send-out test to a reference laboratory, which may take several days. Finally, drug acquisition and costs must also be considered when adding new antimicrobial agents to the hospital formulary.

These issues addressed have greatly complicated empiric antimicrobial therapy in most hospitals in the United States because multidrug-resistant isolates of Enterobacteriaceae have a wide variety of resistance mechanisms. In particular, many different classes of β-lactamases may be seen in members of the Enterobacteriaceae. A brief review of these β-lactamase classes is found in Table 132.3. These multidrug isolates in the recent past often have been resistant to β-lactam agents due to ESBLs as well as the induction of chromosomal Class C (AmpC) β-lactamases. More recently, plasmid-borne Class C (Act1) β-lactamases have emerged in members of the Enterobacteriaceae, as have carbapenemase-producing strains. Carbapenemase-producing carbapenem-resistant Enterobacteriaceae are typically resistant due to the production of β-lactamases, such as Class A serine carbapenemases, Class D oxacillinases (OXA-48), or Class B metallo-β-lactamases. Non–carbapenemase-producing carbapenem-resistant Enterobacteriaceae have resistance mechanisms that include alterations in membrane permeability, development of drug efflux pumps, or alteration in binding site targets for antimicrobial agents. Moreover, resistance to aminoglycosides may be seen due to aminoglycoside-modifying enzymes.

Simple outpatient UTIs respond well to a short-course (3 days) of oral antimicrobial agents. The choice of therapy should be made on the basis of local susceptibility patterns for *E. coli*. Cultures often are not required unless the patient has a history of UTIs. Complicated UTIs (including pyelonephritis) often can be treated with an oral antimicrobial agent such as levofloxacin provided that nausea and vomiting do not prevent their use. Healthcare-associated or catheter-related UTIs may be caused by multidrug-resistant isolates of the Enterobacteriaceae, and cultures should be done. These patients often require hospitalization, and parenteral therapy is generally preferred.

Antimicrobial therapy for enteric infections caused by members of the Enterobacteriaceae is controversial. For patients with moderate to severe diarrhea, the most immediate goal of treatment is to restore and maintain electrolyte and fluid balance; this alone can be life-saving in elderly patients and infants. Empiric antimicrobial therapy is generally recommended for acute febrile dysentery; such therapy is clearly indicated in cases of bacteremic salmonellosis. However, antimicrobial therapy is indicated in only a small percentage of patients who have an established infectious cause of acute diarrhea. Most diarrheal illnesses caused by enteropathogenic *E. coli* are self-limited; cases of EHEC are thought to have a greater risk of HUS with antimicrobial administration.

The treatment of community-acquired gram-negative pneumonia caused by members of the Enterobacteriaceae has generally included β-lactam agents given for ≥3 weeks. Recent studies have demonstrated equivalent results with 8 days of therapy. Lung abscesses or empyema may require longer therapy as well as surgical intervention. Hospital-acquired and ventilator-associated gram-negative pneumonia may be caused by multidrug-resistant strains of Enterobacteriaceae; treatment of these pulmonary infections may be problematic and could require newer antimicrobial agents briefly reviewed in the following section.

TABLE 132.3 **SUGGESTED ANTIMICROBIAL REGIMENS FOR SELECTED INFECTIONS**

Infection	Typical pathogens	Recommended antibiotics	Alternatives	Treatment duration (days)
Urinary tract infection, uncomplicated	*E. coli, Klebsiella, Proteus*	Oral TMP–SMX, FQ	Ampicillin, cephalexin, nitrofurantoin	3
Urinary tract infection, complicated (including pyelonephritis, male UTI)	*E. coli, Klebsiella, Proteus*	Ceftriaxone, FQ	Pip/tazo, aminoglycosides, carbapenems, aztreonam	7–14
Urinary tract infection, recurrent catheter associated	All	Carbapenems, cefepime	Aminoglycosides	14
Diarrhea	*E. coli*	None	FQ, rifaximin, azithromycin	3–5
Spontaneous bacterial peritonitis	*E. coli, Klebsiella*	Cefotaxime	FQ, moxi, pip/tazo, ceph3, cefepime, carbapenems	10–14
Diverticulitis	*E. coli* + anaerobes	FQ or TMP–SMX + metronidazole, moxi	Pip/tazo, ceph3 + metronidazole	7–10
Cholangitis, cholecystitis, pancreatitis, other abdominal abscesses	All	Pip/tazo, cefepime + metronidazole, carbapenems	FQ + metronidazole, moxi, tigecycline	To resolution
Complicated skin/soft tissue	All	Pip/tazo, carbapenems	Tigecycline, FQ, moxi	To resolution + 2 days
Pneumonia, community acquired	*E. coli, Klebsiella*	Ceftriaxone, cefepime, FQ, moxi	Pip/tazo, carbapenems	≤21
Pneumonia, hospital or ventilator acquired	*E. coli, Klebsiella, Enterobacter, Serratia*	Carbapenems, cefepime, pip/tazo (usually with aminoglycoside or FQ as initial therapy)	Tigecycline	8
Meningitis	*E. coli*	Cefepime, ceftriaxone, meropenem		14
Meningitis/ventriculitis, shunt associated	*Enterobacter*	Cefepime or meropenem ± aminoglycoside	Ceph3	To normalization of CSF
Osteomyelitis, prosthetic joint infection	All	Ceftriaxone, cefepime	FQ, carbapenem, tigecycline	≥42
Bacteremia (line)	All	Cefepime	Carbapenem, pip/tazo,	10–14
Endocarditis, intravascular device	All	Cefepime or ceftriaxone ± aminoglycoside	FQ, moxi Pip/tazo ± aminoglycoside	42

Abbreviations: FQ = ciprofloxacin or levofloxacin; moxi = moxifloxacin; pip/tazo = piperacillin–tazobactam; ceph3 = ceftriaxone, cefotaxime, ceftazidime; TMP-SMX = trimethoprim–sulfamethoxazole; UTI = urinary tract infection; CSF = cerebrospinal fluid.

Therapy of gram-negative osteomyelitis and gram-negative infections involving orthopedic hardware generally requires 6 weeks of antimicrobial agents for acute infections and longer durations for chronic infections. The hardware should be removed if possible; if not possible, prolonged oral suppressive therapy may be needed. Parenteral cephalosporins with a long half-life may be preferable for these infections in comparison with fluoroquinolones or aminoglycosides. Fluoroquinolones may impede fracture healing, while aminoglycosides have toxicity issues when used for ≥6 weeks.

Suggested antimicrobial regimens for the infection discussed in this chapter are outlined in Table 132.4.

Recent and future antimicrobial therapy options

The antimicrobial management of serious infections caused by multidrug-resistant members of the Enterobacteriaceae has been improved in the past several years and promises to improve further because of the addition of new antimicrobial agents and/or β-lactamase inhibitors as therapeutic options. However, use of these newer antimicrobial agents against Enterobacteriaceae isolates in clinical practice requires a high level of antimicrobial stewardship so as to not promote overuse of these agents. These recent and

TABLE 132.4 **REVIEW OF B-LACTAMASE CLASSES THAT MAY BE FOUND IN ENTEROBACTERIACEAE ISOLATES**

Class	Examples with clinical relevance
Class A	TEM, SHV, CTX-M: ESBLs that hydrolyze β-lactam agents.
	KPC: Serine β-lactamase that hydrolyzes carbapenems.
Class B	IMP, VIM, SPM, NDM: Metallo-β-lactamases that require zinc for hydrolysis and hydrolyze both β-lactam agents and carbapenems.
	Metallo-β-lactamases are very resistant to β-lactamase inhibitors.
Class C	AmpC: Inducible chromosomal β-lactamases found in *Enterobacter*, *Serratia*, *Proteus*, and *Citrobacter*.
	Act1: Inducible plasmid-borne β-lactamases that produce AmpC β-lactamase.
Class D	OXA-48: Plasmid-borne β-lactamase found in some Enterobacteriaceae.

These β-lactamases have variable activity and may be able to hydrolyze carbapenems.

new antimicrobial agents/antimicrobial combinations are briefly reviewed.

Ceftolozane-tazobactam is a novel cephalosporin combined with a classic β-lactamase inhibitor (tazobactam). Ceftolozane, like other β-lactam agents, inhibits bacterial cell wall synthesis by binding to penicillin-binding proteins, while tazobactam extends the activity of ceftolozane to include the majority of Class A ESBL-producing Enterobacteriaceae as well as most *Bacteroides fragilis* isolates. Ceftolozane-tazobactam (ZERBAXA) was approved in the United States in 2014 for use in adults with complicated UTIs (including pyelonephritis) as well as for use in adults with complicated intra-abdominal infections (in combination with metronidazole). Ceftolozane-tazobactam is not active against gram-negative bacteria that produce Class B metallo-β-lactamases or Class A serine carbapenemases. Ceftolozane-tazobactam has limited activity against methicillin-susceptible *Staphylococcus aureus* (MSSA) and no activity against methicillin-resistant *S. aureus* (MRSA).

Ceftazidime-avibactam is a combination of the third-generation cephalosporin ceftazidime and a novel (non-β-lactam) β-lactamase inhibitor, avibactam. Ceftazidime, like other β-lactam agents, inhibits bacterial cell wall synthesis by binding to penicillin-binding proteins, while avibactam extends the activity of ceftazidime to include Class A ESBL-producing Enterobacteriaceae, Class A serine carbapenemase-producing Enterobacteriaceae, Class C (AmpC and Act1) β-lactamases, and some OXA-48 β-lactamase-producing Enterobacteriaceae. Ceftazidime-avibactam (AVYCAZ) was approved in the United States in 2015 for use in adults with complicated intra-abdominal infections (in combination with metronidazole) and in 2017 for complicated UTIs (including pyelonephritis). Ceftazidime-avibactam is not active against gram-negative bacteria that produce Class B metallo-β-lactamases and may not have activity against non–carbapenemase-producing carbapenem-resistant Enterobacteriaceae. Ceftazidume-avibactam has limited activity against gram-positive pathogens (e.g., MSSA and MRSA, as well as enterococci).

Meropenem-vaborbactam is a combination of the carbapenem meropenem and a novel boron-containing serine-β-lactamase inhibitor, vaborbactam. Meropenem, like other β-lactam agents, inhibits gram-negative bacterial cell wall synthesis by binding to penicillin-binding proteins, while vaborbactam extends the activity of meropenem to include Class A ESBL-producing and Class A serine carbapenemase-producing Enterobacteriaceae as well as Class C (AmpC and Act1) β-lactamase-producing Enterobacteriaceae. Meropenem-vaborbactam (VABOMERE) was approved in the United States in 2017 for use in adults with complicated UTIs (including pyelonephritis). Meropenem-vaborbactam has no activity against gram-negative bacteria that produce Class B metallo-β-lactamases or Class D OXA-48 β-lactamases. Meropenem-vaborbactam may not have activity against non–carbapenemase-producing carbapenem-resistant Enterobacteriaceae and has no activity against MRSA.

Plazomicin (Zemdri) is a novel semisynthetic parenteral aminoglycoside that, like other members of the aminoglycoside class, binds to the bacterial 30S ribosomal subunit and inhibits proteins synthesis. Plazomicin was approved in the United States in 2018 for once-daily use in adults with complicated UTIs (including pyelonephritis). Plazomicin was developed from sisomycin and is commonly referred to as a "next-generation" aminoglycoside. The enhanced activity of plazomicin against members of the Enterobacteriaceae is due to its being engineered to overcome the most commonly encountered aminoglycoside-modifying enzymes. However, plazomicin is not active against the less common 16S ribosomal RNA methyltransferases (16S-RMTase), which also modify the aminoglycoside target site. On occasion, plasmids carrying other resistant genes such as metallo-β-lactamases (MBL) will also carry the 16S-RMTase gene; because of this, there are some reports that plazomicin has no activity against some MBL producers. In summary, plazomicin displays potent in vitro activity against members of the Enterobacteriaceae, including both Class A ESBL-producing and Class A serine carbapenemase-producing isolates. Plazomicin does not offer improved activity over older aminoglycosides against *Pseudomonas aeruginosa* and *Acinetobacter baumannii*. Susceptibility testing is required for Class A serine carbapenemase-producing members of the Enterobacteriaceae to determine if these isolates are susceptible to plazomicin or resistant due to the plasmid carrying both the MLB gene and the 16S-RMTase gene.

Aztreonam-avibactam is a combination of the monobactam aztreonam with a novel (non–β-lactam) β-lactamase inhibitor avibactam. Aztreonam, like other β-lactam agents, inhibits bacterial cell wall synthesis by binding to penicillin-binding proteins, while avibactam extends the activity of aztreonam to include Class A ESBL-producing Enterobacteriaceae, Class A serine carbapenemase-producing Enterobacteriaceae, Class C (AmpC and Act1) β-lactamases, Class B metallo-β-lactamases, and some OXA-48 β-lactamase-producing Enterobacteriaceae. Aztreonam-avibactam is not active against gram-positive pathogens (e.g., MSSA and MRSA, as well as enterococci).

Imipenem-relebactam is a combination of the carbapenem imipenem-cilastatin with a novel (non–β-lactam) β-lactamase inhibitor, relebactam. The chemical structure of relebactam resembles that of avibactam; like avibactam, relebactam binds Class A and C β-lactamases. However, relebactam does not inhibit Class D OXA-48 β-lactamases, although avibactam does inhibit these OXA β-lactamases. Imipenem-cilastatin, like other β-lactam agents, inhibits bacterial cell wall synthesis by binding to penicillin-binding proteins, while relebactam extends the activity of imipenem-cilastatin to include Class A ESBL-producing- and Class A serine carbapenemase-producing Enterobacteriaceae as well as Class C (AmpC and Act1) β-lactamase-producing Enterobacteriaceae. Imipenem-relebactam has no activity against gram-negative bacteria that produce Class B metallo-β-lactamases or Class D OXA-48 β-lactamases. Imipenem-relebactam has no activity against MRSA.

Cefiderocol is an IV siderophore cephalosporin that inhibits gram-negative bacterial growth by both binding to PBP-3 as well as chelating iron ions within that organism that are essential to its survival. This unique property of cefiderocol is due to its catechol side chain that binds to ferric acid, which then allows the complex to be actively transported into the bacterium by bacterial iron transporters. The siderophore-like property results in chelation of iron ions that are essential to the cell's survival. Cepiderocol's chemical structure is similar to that of both ceftazidime and cefepime, but cefiderocol also has high stability to many β-lactamases, including extended-spectrum β-lactamases, AmpC-β-lactamases, and carbapenemases. In early clinical trials, cefiderocol has performed similarly to or has been superior to comparator agents in adults with complicated UTIs as well as in adults with hospital-acquired and ventilator-associated gram-negative bacillary pneumonia.

Eravacycline is a synthetic fluorocycline antimicrobial agent of the tetracycline class that structurally resembles tigecycline. Eravacycline has two modifications to the D-ring of its tetracycline core: a fluorine atom replaces the dimethylamine moiety at C-7, and a pyrrolidinoacetamido group replaces the 2-tertiary-butyl glycylamido at C-9. Like tigecycline, eravacycline binds to the 30S ribosome subunit and has activity against both clinically relevant gram-positive and gram-negative pathogens (except *Pseudomonas aeruginosa*), including anaerobes, as well as carbapenemase-producing members of the Enterobacteriaceae. Initial clinical studies investigating eravacycline in complicated intra-abdominal infections in adults have shown excellent efficacy. Eravacycline is available in IV and oral forms and should offer an alternate treatment option for adult patients with complicated intra-abdominal infections caused by multidrug-resistant gram-negative pathogens.

Conclusion

Clearly, the members of the Enterobacteriaceae cause a wide variety of infections and play a prominent role in UTIs, enteropathogenic *E. coli* diarrheal illnesses, gram-negative bacillary pneumonia, postoperative skin and soft tissue infections, and complicated intra-abdominal infections. These gram-negative bacilli play a lesser role in bone and joint infections and in CNS infections but are still important due to increasing resistance. The emergence of members of Enterobacteriaceae producing ESBLs, inducible AmpC-β-lactamases, and carbapenemases is a global problem that requires appropriate molecular and phenotypic methods for susceptibility testing and also may require the use of newer antimicrobial agents/antimicrobial combinations. These complex resistance mechanisms increasingly found in nosocomial gram-negative bacillary infections have created a challenge in selecting appropriate empiric antimicrobial therapy. Comprehensive microbial identification/antimicrobial susceptibility testing as well as a targeted approach to antimicrobial usage remain the keys to successful management of these infections.

Enterococcus

Ronald N. Jones and Rodrigo E. Mendes

Since the early 1970s, the enterococci have steadily emerged as important hospital-acquired (nosocomial) pathogens. In statistics from the National Nosocomial Infections Surveillance System (NNISS) and subsequent Centers for Disease Control and Prevention (CDC) programs (National Healthcare Safety Network), enterococci are the second most common gram-positive cause of nosocomial infections overall, and gram-positive isolates causing bloodstream infections. Data from the SENTRY Antimicrobial Surveillance Program also confirmed enterococci as the second most common gram-positive organisms responsible for bloodstream infections in US hospitals. In addition, enterococci rank first among gram-positive cocci in producing urinary tract infections (see Table 133.1). Increases in occurrence of this genus since the mid-1970s are related to patterns of general antimicrobial use in the hospital and in particular to widespread use of extended-spectrum cephalosporins, penicillin-β-lactamase inhibitor combinations, fluoroquinolones, and carbapenems, as well as the emergence of resistances in the genus. Cephalosporins are generally not active or bactericidal against enterococci, as are not fluoroquinolones, and they may promote a selective pressure advantage for this organism thereby contributing to the increased prevalence. However, recent evidence reported by Mendes et al. has demonstrated that the occurrence of enterococci overall, and *Enterococcus faecalis* and *E. faecium* causing bloodstream infections in US hospitals, are in decline.

According to the SENTRY Program, *E. faecalis* is responsible for approximately 65% of all human enterococcal infections, and *E. faecium* accounts for most (~29%) of the remainder. However, *E. faecium* may account for a greater proportion (>30%) of enterococcal bacteremias (see Table 133.2). Antimicrobial resistance is a particular problem among *E. faecium* isolates. Other species of interest are *E. casseliflavus* and *E. gallinarum*, not because of the frequency with which they are isolated (<5%), but because of the intrinsic low-level resistance to vancomycin (i.e., the *vanC* genotype and resultant generally intermediate susceptibility phenotype; minimum inhibitory concentrations [MICs], 4–8 μg/mL).

The therapy of enterococcal infections challenges the healthcare practitioners as resistance to ampicillin, high-level aminoglycosides resistance (HLAR; compromising bacteriocidal combination therapy), and glycopeptides (vancomycin and others) have occurred; emerging linezolid and tedizolid (oxazolidinones), daptomycin (a lipopeptide), tigecycline (a glycylcycline), and quinupristin-dalfopristin resistance have also narrowed the number of therapeutic options. In addition, the risk of failure of trimethoprim-sulfamethoxazole (TMP-SMX) in therapy for urinary tract infection has become widely recognized regardless of in vitro susceptibility, where some standard organizations recommend *not* testing TMP-SMX.

All enterococci are intrinsically resistant to achievable in vivo levels of aminoglycosides; however, synergic killing can occur when aminoglycosides are combined with a cell wall–active agent such as a penicillin or a glycopeptide. HLAR strains are not susceptible to the synergic co-drug effects of the aminoglycosides. It is clinically significant that cross-resistance to the synergic activity of the aminoglycosides is *not* complete between gentamicin (and the related compounds tobramycin, netilmicin, amikacin, kanamycin, and isepamicin) and streptomycin. Streptomycin may be used successfully in combination to treat some HLAR strains. The selection of the appropriate aminoglycoside co-drug should be directed by validated in vitro susceptibility tests and the availability of streptomycin for clinical use and testing for monitoring drug levels.

TABLE 133.1 **PERCENTAGE OF VARIOUS GRAM-POSITIVE PATHOGENS CAUSING NOSOCOMIAL INFECTIONS IN THE NNISS/NHSN (CDC) COMPARING 1975, 2003, 2008, AND 2013**

[a] Skin and skin structure infections (SSSI).
Abbreviations: CoNS = coagulase-negative staphylococci; NNISS = National Nosocomial Infections Surveillance System; NHSN = National Healthcare Safety Network; CDC = Centers for Disease Control and Prevention.

Resistance to vancomycin is much more common among *E. faecium* isolates than with *E. faecalis*. Reports in the United States in the late 1990s suggested that the overall vancomycin-resistant rate for enterococci was approximately 20% among isolates causing bloodstream infections and higher resistance rates for some other drugs and species limited therapeutic choices. These resistance rates have escalated through 2010–2012, and decreased afterward (Table 133.2). It was reported by Willems and colleagues that the high prevalence of vancomycin-resistant *E. faecium* in US hospitals were due the spread of a successful hospital-adapted clonal complex lineage (CC-17), which has evolved ampicillin-, vancomycin-, and fluoroquinolone-resistance phenotypes. Acquired vancomycin resistance is often associated with resistance to teicoplanin (Van A phenotype or *vanA* gene) or may occur in the absence of cross-resistance to teicoplanin (Van B phenotype or *vanB* gene). This difference can be clinically significant in nations where teicoplanin has been clinically available for >30 years and could also be relevant in the United States because telavancin and dalbavancin (long-acting lipoglycopeptide) are marketed and active against isolates exhibiting a VanB phenotype. Also, another lipoglycopeptide, oritavancin, retains activity against both VanA and VanB resistance phenotypes, as does daptomycin and the oxazolidinones.

For the clinician, the problems posed by the emergence of resistance have been exacerbated by the technical difficulties in reliable detection of these antimicrobial resistances. In vitro resistance to TMP-SMX as a result of the ability of the most prevalent enterococci to use thymidine or thymine in the susceptibility test medium (escapes bactericidal action) has been addressed by use of media free of or low in concentration for these antagonists. However, there can be significant amounts of antagonists in the urine, and therefore the meaning of in vitro test results performed in these "improved" standardized test conditions remains compromised. Routine testing against ampicillin without testing for organism β-lactamase production may result in false-susceptible results. However, β-lactamase production continues to be an exceedingly rare mechanism of resistance (≤0.1%) among *E. faecalis*. A number of problems with the detection of HLAR using the most prevalent automated and commercial broth microdilution susceptibility test systems (Vitek 2, MicroScan, BD Phoenix) have been reported, although these appear to have been resolved in recent years. Similarly, with vancomycin and other newer agent resistances reported from both automated susceptibility test systems, Etest and disk diffusion test interpretive criteria may continue to require modifications over time to enable

TABLE 133.2 **TRENDS IN VANCOMYCIN-RESISTANT ENTEROCOCCI (VRE) BACTEREMIA RATES IN THE SENTRY ANTIMICROBIAL SURVEILLANCE PROGRAM (USA; 2000–2019) HOSPITALS, QUANTITATING VANCOMYCIN RESISTANCE (VANA) PATTERNS**

2019	58.7 (96.3)	1.1 (100.0)

[a] A total of 753 other *Enterococcus* spp. were tested (data not shown) for a total of 11,092 US enterococcemia.
Modified from Arias et al., *Clin Infect Dis*. 2012;54(Suppl 3):S233–238 (data for 2000–2011) and Mendes et al., *J Chemoth*. 2018;30(5):280–289 (data for 2012–2016). Data on file (2017-2019), SENTRY Antimicrobial Surveillance Program (JMI Laboratories, North Liberty, IA). VanA phenotype defined as isolates displaying vancomycin and teicoplanin MICs of >4 μg/mL >8 μg/mL, respectively.

consistent, accurate detection of resistant strains. Lipoglycopeptide agents necessitate testing with surfactants (polysorbate-80) to prevent binding to reference test plastic labware and generally cannot be tested in widely available commercial testing systems.

Highly reliable, empiric therapy of enterococcal infection is not consistently satisfactory given the complexity and variability of resistance patterns, and therefore availability of prompt, reliable susceptibility test results is critical. At present, disk diffusion susceptibility testing, Etest, Vitek, or BD Phoenix Systems, and the reference broth microdilution or agar dilution methods are reliable methods for detection of important resistances. However, recent reports of false resistance have been reported for some newer agents, including oxazolidinones, caused by fuzzy zone diameter edges and trailing broth microdilution end points causing reading difficulties.

Enterococcal bloodstream infection

Isolation of enterococci from blood cultures may occur with or without endocarditis. In community-acquired enterococcal bloodstream infection approximately one-third of cases are concurrent with endocarditis, compared with fewer than 5% of nosocomial enterococcal bacteremias. These nosocomial infections are usually associated with urinary tract disease or instrumentation, intra-abdominal infection, infected intravascular devices, neoplastic disease, and significant neutropenia.

Infective endocarditis, even when caused by more susceptible strains of enterococci, tends to be more difficult to achieve clinical cure than those due to viridans group streptococci. Only two-thirds of patients will have favorable outcomes if a penicillin is used alone. Penicillin agents are not bactericidal, and a combination of a cell wall–active agent (a penicillin, usually ampicillin, or a glycopeptide) with an aminoglycoside for 4 to 6 weeks continues to be a recommended guideline for infections caused by *E. faecalis*. In general, ampicillin (two- or fourfold more active) is used in preference to penicillin. High-dose penicillin (ampicillin, 1-2 g q4-6h, or penicillin G, 18 to 30 million U/d) are considered appropriate, combined with gentamicin, 1 mg/kg every 8 hours or the use of the less toxic infusion pattern of 3 mg/kg once-daily dosing (Table 133.3). However, limited clinical information supports the use of once-daily aminoglycosides for endocarditis. Monitoring of aminoglycoside serum concentrations is essential to ensure adequate therapeutic levels and to minimize toxicity during the extended therapeutic course, as are vancomycin monitoring and stewardship if used (see also Chapter 37, "Endocarditis"). The choice of an aminoglycoside for combination therapy is between gentamicin and streptomycin (limited availability). Gentamicin is generally preferred because synergic killing is more consistent (see Table 133.4), ototoxicity is less frequent, and facilities to measure serum levels are more easily available. Enterococcal strains resistant to high levels of aminoglycoside in vitro are not susceptible to enhanced (synergistic) killing with a penicillin or vancomycin-like agents, and, in such patients, use of aminoglycosides constitutes exposure to potential toxicity (otic and renal) without apparent clinical benefit.

More recently, combinations of ampicillin and ceftriaxone to minimize gentamicin-caused renal toxicity and preserve higher cure rates have been successful for infections caused by *E. faecalis* (Table 133.3). In fact, the ampicillin and ceftriaxone combination therapy is the only option for the treatment of infective endocarditis and bacteremia due to HLAR *E. faecalis* with supportive clinical data. However, several clinical and observational studies implicated ceftriaxone as a major risk factor for occurrence of vancomycin-resistant *E. faecium* infection, including bacteremia. In addition, ceftriaxone is an independent risk factor for *Clostridium difficile* infections. Therefore, other alternative treatment options for *E. faecalis*, particularly combinations with newer cephalosporins (ceftaroline, ceftobiprole), as well as daptomycin, tigecycline, and fosfomycin have been suggested.

Unlike, ceftriaxone, other cephalosporins, such as cefepime and ceftaroline, do not appear to promote vancomycin-resistant enterococci (VRE) colonization/infection. Ampicillin plus ceftaroline demonstrated efficacy similar to ampicillin and ceftriaxone against *E. faecalis* in several in vitro pharmacodynamic studies. Other in vitro studies reported that the ampicillin-ceftriaxone activity was similar to ampicillin-ceftaroline and ampicillin-cefepime against *E. faecalis*. Daptomycin remains a very potent bactericidal agent against enterococci and is the treatment of choice for infections caused by *E. faecium*, where the majority of isolates in the United States are vancomycin-resistant (Table 133.2). Several studies have indicated that the daptomycin plus ceftaroline combination has been successful against *E. faecalis* and *E. faecium*, including isolates resistant to vancomycin. Although many studies reported success using a daptomycin dose of 6 mg/kg/d, there is evidence that higher doses of 8 to 12 mg/kg/d are associated with better clinical outcome and are recommended for serious and/or high-inoculum infections. The Clinical Laboratory Standards Institute (CLSI) MIC interpretative criteria for daptomycin was revised and published in May 2019 to include breakpoints for *E. faecium* and *Enterococcus* species other than *E. faecium*, and respective dosage regimens (Tables 133.4 and 133.5).

In serious infections caused by daptomycin-nonsusceptible *E. faecium*, linezolid has been recommended or daptomycin (high-dose) plus a β-lactam and another agent with in vitro activity, such as oritavancin, or an aminoglycoside if not a HLAR strain. Linezolid possesses US Food and Drug Administration (FDA) approval for treating VRE; however, this bacteriostatic agent offers a less desirable pathway for treating endovascular or serious infections. Tedizolid is a second-generation oxazolidinone recently approved for acute bacterial skin and skin structure infections, and clinical trial data indicate that tedizolid possesses an improved safety profile over linezolid (at the approved dose) with less likelihood of hematological and neurological toxicities and fewer drug–drug interactions. The use of this newest oxazolidinone for treating serious enterococci infections remains to be determined.

Older drugs such as chloramphenicol and doxycycline have demonstrated a variable degree of in vitro activity (<50% susceptible by CLSI criteria; data not shown) against the multidrug-resistant enterococci. Case reports indicate that these drugs used alone or with co-drugs can be successful in some cases, but each agent is

TABLE 133.3 **SUMMARY OF RECOMMENDED ANTIMICROBIAL TREATMENTS FOR INVASIVE ENTEROCOCCAL INFECTIONS**

Uncomplicated bacteremia			***E. faecium***	
		E. faecalis	**Vancomycin-susceptible**	**Vancomycin-resistant**
	1st options	Ampicillin	Vancomycin	Daptomycin or linezolid
	Alternatives	Piperacillin	Daptomycin	Daptomycin + β-lactams
		Imipenem	Linezolid	
		Vancomycin		
		Daptomycin		
		Linezolid		
Endorcaditis	1st options	Ampicillin + ceftriaxone	Vancomycin + gentamicin	Daptomycin or linezolid
		Ampicillin/penicillin + gentamicin		(Consider to add gentamicin or a β-lactam)
	Alternatives	Vancomicin + gentamicin	Linezolid	
		Daptomycin + β-lactams	Daptomycin + gentamicin	
			Daptomycin + β-lactams	

Table Modified from E. Rosselli Del Turco et al., *Clin Microbiol Infect*. 2021;27:364–371.
Dosages for the recommended antibiotics (all doses should be adjusted by kidney function):
Ampicillin: 1–2 g IV every 4 to 6 hours.
Piperacillin: 4 g IV every 8 hours.
Imipenem: 15–25 mg/kg IV every 6 hours.
Vancomycin: 25–30 mg/kg IV loading dose followed by 15 mg/kg every 8 hours.
Daptomycin: 6–8 mg/kg IV daily for uncomplicated non-vancomycin resistant enterococcal bacteraemia. At least 9 mg/kg IV daily for vancomycin-resistant enterococci.
Linezolid: 600 mg IV every 12 hours.
Ceftriaxone: 2 g IV every 12 hours.
Aqueous penicillin G sodium: 18–30 million U/24 h IV either continuously or in 6 equally divided doses.
Gentamicin: 3 mg/kg ideal body weight in 2–3 equally divided doses.

only bacteriostatic. Even with eradication of enterococci from the bloodstream, mortality remains high (30–50%). Furthermore, fluoroquinolones (ciprofloxacin, levofloxacin, and moxifloxacin) may have limited value for strains tested as susceptible (see Tables 133.4 and 133.5) because resistance may emerge rapidly when these drugs are used alone. Combinations of ampicillin and a fluoroquinolone or a cephalosporin have been found bactericidal for some strains in vitro. Quinupristin-dalfopristin is a generally bacteriostatic option available for use in therapy of *E. faecium* infection only (not *E. faecalis*).

A variety of other agents (see Tables 133.4 and 133.5) with activity against enterococci may have the potential to expand the enterococcal treatment. Dalbavancin and telavancin are active in vitro against vancomycin-susceptible *E. faecalis.* Oritavancin is active against both *E. faecium* and *E. faecalis*, regardless of vancomycin susceptibility, and single and case reports have documented the clinical experiences of oritavancin (see Table 133.5). New generation tetracycline agents, such as tigecycline, omadacycline, and eravacycline were designed to retain activity against common tetracycline resistance determinants, and offer potential options for the treatment of VRE infections. The agent with the most clinical experience, tigecycline, is approved for use in intra-abdominal and skin and soft tissue infections for vancomycin-susceptible *E faecalis*, and shows *in vitro* activity against VRE of both species. However, owing to low serum concentrations, tigecycline has been used only for intra-abdominal infections or as a part of combination therapy in recalcitrant enterococcal bacteremia and infective endocarditis. Omadacycline and eravacycline are the two most recent new generation tetracycline agents approved by the FDA with antimicrobial activity that includes enterococci (Table 133.5). However, several of these drugs demonstrate little bactericidal action against multidrug-resistant enterococci, and experience with their use alone or in combination awaits reports from structured clinical studies.

Therapy with dalbavancin or telavancin is not an option for VanA vancomycin-resistant *E. faecium* strains, which is the predominant pattern (>70% strains) among clinical isolates in the United States (Table 133.2). Some experimental and clinical experiences with lipoglycopeptides for treating gram-positive infections are starting to emerge. Bouza et al. showed successful clinical outcomes with dalbavancin in 72.7% patients having a variety of enterococcal infections, including endocarditis during an observational and retrospective study in 29 hospitals in Spain. Jones et al. also reported favorable outcome when treating an ampicillin- and

TABLE 133.4 **SUSCEPTIBILITY RATES OF ALL ENTEROCOCCAL STRAINS FROM THE SENTRY ANTIMICROBIAL SURVEILLANCE PROGRAM, HOSPITAL PATIENTS IN 2015–2019 (50–77 MEDICAL CENTERS IN THE UNITED STATES/YEAR)**[a]

[a] Data on file, SENTRY Antimicrobial Surveillance Program (JMI Laboratories, North Liberty, IA). Categorical criteria per Clinical Laboratory Standards Institute (CLSI, 2021). Daptomycin percentage susceptible results for *Enterococcus* spp. other than *E. faecium* were obtained according to a breakpoint of ≤2 μg/mL, which is based on a dosage regimen of 6 mg/kg/d. The daptomycin percentage susceptible results for *E. faecium* were obtained according to a breakpoint of ≤4 μg/mL, which is based on a dosage regimen of 8–12 mg/kg/d for serious infections.
[b] Gentamicin and streptomycin HL data from 1,628 and 3,170 isolates, respectively, collected during 2016–2017.

vancomycin-susceptible *E. faecalis* bacteremia case with dalbavancin. Similarly, Thompson et al. also reported successful telavancin treatment of endocarditis caused by vancomycin-susceptible *E. faecalis*. Animal model study results described by Tran et al. indicated that telavancin could be an alternative for deep-seated infections caused by vancomycin-susceptible *E. faecalis*.

Therapy for enterococcal bloodstream infection in the absence of endocarditis follows the same general principles as for endocarditis except that bactericidal therapy may not be required. Bactericidal effect should be sought in the immunocompromised patient, and empiric therapy for such patients should be initiated with the broadest spectrum anti–gram-positive agents (vancomycin or daptomycin) because patients likely to develop nosocomial enterococcal infection are also at risk for infection with methicillin-resistant staphylococci. As with all other pathogens, removal of potential foci of infection, such as an indwelling vascular device, and drainage of an abscess as source control is essential for successful therapy.

Therapy of nonsevere infections and urinary tract disease

In the absence of immediate susceptibility test results, ampicillin is still a reasonable option for therapy of mild to moderate infections and particularly for urinary tract infections, given the high levels of ampicillin achieved in the urine. Nitrofurantoin is also active against most enterococci (>90%; data not shown including VRE) but is useful in therapy of urinary tract infection only.

Clearly, these approaches must be modified in the context of local epidemiology (antibiogram) and emergence of resistant strains. In centers with very high incidence of infection with ampicillin-resistant enterococci, usually *E. faecium*, this may not be appropriate empiric therapy. For infection with drug-resistant organisms, the options are similar to those discussed for bloodstream infection except that synergic combinations are usually not advised.

Enterococcal carriage

There is no general acceptance that fecal carriage or colonization by multidrug-resistant enterococci is an indication for therapy; however, given the risk to the patient of subsequent disseminated infection, there is high epidemiologic interest in this issue. Studies of the intestinal tract reservoir/source of VRE have greatly increased our knowledge of colonization and factors leading to persisting carriage. The third-generation cephalosporins, but not all cephalosporins or β-lactams, have clearly been implicated in promoting enterococcal colonization, possibly due to the high biliary excretion of some third-generation cephalosporins, with levels that exceed concentrations of 5,000 μg/mL. Examples

[b] Categorical criteria per Clinical Laboratory Standards Institute (CLSI, 2021) or ≤0.25 μg/mL (susceptible) for dalbavancin and telavancin (vancomycin-susceptible *E. faecalis* breakpoint), and ≤0.12 μg/mL for oritavancin (vancomycin-susceptible *E. faecalis* breakpoint), ≤0.5 μg/mL for tedizolid (*E. faecalis* breakpoint), ≤2 μg/mL for daptomycin against *Enterococcus* spp. other than *E. faecium* when using a dosage regimen of 6 mg/kg/d and ≤4 μg/mL for daptomycin against *E. faecium* when using a dosage regimen of 8–12 mg/kg/d for serious infections, ≤0.25 μg/mL for tigecycline (vancomycin-susceptible *E. faecalis* breakpoint from the FDA package insert), ≤0.25 μg/mL for omadacycline (*E. faecalis* breakpoint from the FDA package insert), ≤4 μg/mL for ceftobiprole and ceftaroline.

of low-risk agents are aztreonam and cefepime, in contrast to cefoxitin, ceftriaxone, and clindamycin that have promoted VRE colonization. Some antimicrobials such as piperacillin-tazobactam inhibit establishment of VRE in the gut during therapy but promote overgrowth and persistence when exposed to VRE in the period of post-therapy recovery of normal flora. Data from clinical trials continue to be necessary to more adequately understand these complex interactions of antimicrobials, indigenous bowel flora, and colonizing resistant enterococci.

It seems reasonable to review the patient's therapy with a view toward discontinuation of any nonessential antimicrobials that might confer a selective advantage for the enterococci. However, relapses after discontinuation of selective intestinal tract decontamination remain high. The implications for infection control focus on (1) gastrointestinal selective decontamination; (2) antimicrobial use strategies (limit or restriction of selecting agents); (3) assuring persistence of the gastric acid barrier; (4) restoring indigenous colonic microflora; (5) assuring, where possible, decontamination of the hospital environment or patient's cutaneous surfaces; and (6) preventing patient-to-patient transmission via promoting handwashing/gloving by healthcare workers.

Conclusion

Therapy of enterococcal infections is one of the most challenging areas in the contemporary treatment of infectious disease. Quality laboratory support is essential to the management of these infections in the most appropriate manner while minimizing toxicity. Given the emerging inadequacies of our therapeutic armamentarium (ampicillin and glycopeptides) and the clear evidence that nosocomial spread of this pathogen can occur, an aggressive position with respect to hospital environment surveillance and infection control remains of critical importance. Also, more studies will be required to develop new, safe therapeutic agents and to focus our treatments on existing or newer antimicrobial agents (daptomycin, oxazolidinones, lipoglycopetides, tetracycline derivatives) used alone or in proven combinations that achieve acceptable enterococcus infection eradication with clinical safety.

Erysipelothrix

W. Lee Hand

Erysipelothrix rhusiopathiae is a pleomorphic, non-spore-forming, gram-positive bacillus. This organism causes both a self-limited soft-tissue infection (erysipeloid) and serious systemic disease. *Erysipelothrix rhusiopathiae* is widespread in nature and infects many domestic animals. Swine are probably the major reservoir of *E. rhusiopathiae*. The microorganism is also found in sheep, cattle, horses, chickens, and dogs, as well as in birds, fish, crustaceans, seals, and dolphins. Infection in humans is usually due to occupational exposure. Butchers, abattoir workers, fishermen, farmers, and veterinarians are at risk for *Erysipelothrix* infections. The clinical spectrum of human infection includes localized cutaneous infection, diffuse cutaneous disease, and systemic bloodstream infection.

Localized cutaneous infection

Erysipeloid of Rosenbach, the localized cutaneous form of illness, is the most common type of human infection caused by *E. rhusiopathiae* (Figure 134.1). Fingers and/or hands (sites of exposure) are almost always involved in this soft-tissue infection.

Mild pain may occur at the site of inoculation, followed by itching, throbbing pain, burning, and tingling. The characteristic skin lesion slowly progresses from a small red dot at the site of inoculation to a fully developed erysipeloid skin lesion, consisting of a well-developed purplish center with an elevated border. Patients often complain of joint stiffness and pain in the involved fingers, but swelling is minimal or absent. Small hemorrhagic, vesicular lesions may be present at the site of inoculation. Erysipeloid lesions do not resemble true cellulitis, as opposed to erysipelas, which is due to group A streptococcal infection. Thus, Rosenbach introduced the term *erysipeloid* for the human cutaneous disease caused by *Erysipelothrix*. Pain may be disproportionate to the degree of apparent involvement. Local lymphangitis and adenitis develop in 30% of patients. However, systemic symptoms such as high fever or chills are uncommon.

A provisional diagnosis is based on a history of contact with potentially contaminated materials or occupational exposure, plus compatible physical findings. Gram-stained smears and cultures of aspirated material from skin lesions are often negative because the organism is deep within the dermis.

Diffuse cutaneous disease

Most erysipeloid skin lesions resolve even without specific treatment. However, erysipeloid occasionally will progress to the diffuse cutaneous form in untreated patients. Eating of contaminated meat has also been reported as a cause of this clinical entity. The characteristic purplish skin lesions expand with gradual clearing of the center. Bullous lesions may appear at the primary site or at distant locations. These patients often have systemic symptoms such as high fever, chills, and arthralgias. Blood cultures are invariably negative.

FIGURE 134.1 Erysipeloid.
(From Gary M. White and Neil H. Cox, Diseases of the Skin, Philadelphia: WB Saunders; 1995.)

Systemic infection (bacteremia and/or endocarditis)

Bacteremic infection caused by *E. rhusiopathiae* is generally a primary infection and not the result of dissemination from localized cutaneous disease. Nevertheless, one-third of patients with bloodstream infection have skin lesions suggestive of erysipeloid. Persistent bacteremia with *E. rhusiopathiae* has been reported after eating contaminated seafood. Cutaneous serpiginous lesions or multiple bullous lesions over the trunk and extremities may be seen. Many patients have fever for 2 to 3 weeks before presentation. Fever and chills may resolve spontaneously, but relapse is to be expected.

Patients with severe underlying heart disease or liver disease may present with a clinical picture resembling gram-negative sepsis. More than one-third of patients with disseminated infection are alcoholics, and chronic liver disease is a major predisposing factor. Bacteremia has also been reported in immunocompromised individuals, who often are receiving corticosteroid and/or cytotoxic drug treatment for collagen vascular disease or malignancy.

Erysipelothrix rhusiopathiae bacteremia is usually associated with a severe clinical course and is frequently complicated by endocarditis. *Erysipelothrix* endocarditis often results in extensive destruction of cardiac valves, especially the aortic valve. Previous reports were that approximately one-third of endocarditis patients die, and an additional one-third require cardiac valve replacement. However, there are no recent data on mortality. Absence of typical findings of endocarditis on initial physical examination or echocardiography does not exclude this diagnosis in patients with positive blood cultures. Reported complications of endocarditis have included proliferative glomerulonephritis with acute renal failure and visceral botryomycosis.

Earlier publications indicated that 90% of bacteremic infections were associated with endocarditis. This perceived high frequency may, at least in part, be a result of reporting bias because a number of bacteremic cases without endocarditis have been reported more recently.

Unusual reported infections due to *Erysipelothrix* include necrotizing fasciitis (after local inoculation), septic arthritis of native and prosthetic knees, peritoneal dialysis-associated peritonitis, acute and chronic meningitis, intra-abdominal abscesses, and empyema in the spinal canal with paravertebral abscesses.

The diagnosis of disseminated *E. rhusiopathiae* infection depends on identification of this organism in blood cultures. Commercial media are satisfactory for isolation from blood, and growth is usually recognized in 2 or 3 days. The organism may initially be misidentified as a *Lactobacillus* species.

	Erythromycin (other macrolides may be used)	500 mg q6h PO	7 d
Severe bacteremic or endocarditis			
Primary	Penicillin G	2–4 million units q4h IV	4 wk
Alternatives	Ceftriaxone	2 g q24h IV	4 wk
	Imipenem	500 mg q6h IV	4 wk
	Ciprofloxacin (other IV fluoroquinolones may be used)	400 mg q12h IV	4 wk

Therapy

Erysipeloid may resolve spontaneously within 3 weeks, but treatment with appropriate antibiotic therapy hastens the healing process and prevents relapse. Local therapy with rest and heat is helpful for patients with painful, swollen lesions or arthritis. The involved hand or finger should be carried in a sling or splint. Surgical incision or debridement of local lesions is not necessary.

Penicillin and imipenem are the most active antibiotics against *Erysipelothrix* with in vitro testing. Penicillin is a time-tested, effective agent for treatment of all forms of *E. rhusiopathiae* infection. Other β-lactam antibiotics are also active against this organism. Fluoroquinolones and clindamycin demonstrate good in vitro activity. Macrolides, tetracyclines, and chloramphenicol have less predictable activity against *Erysipelothrix* and should not be used in the treatment of disseminated infection. *Erysipelothrix rhusiopathiae* is resistant to sulfonamides, trimethoprim–sulfamethoxazole, aminoglycosides, and vancomycin. Limited data indicated that daptomycin has good in vitro activity.

Antibiotic therapy should be based upon the clinical picture and results of blood cultures (Table 134.1). Oral antibiotic therapy is appropriate for localized cutaneous infection. Parenteral antibiotic treatment is indicated if patients have systemic infection or severe diffuse cutaneous disease. Penicillin G has been the historic drug of choice. Alternatives include ceftriaxone, imipenem, and fluoroquinolones. Patients with bacteremia or endocarditis should receive at least 4 weeks of intravenous antibiotic therapy.

HACEK

Vivian H. Chu

The acronym HACEK describes a heterogeneous group of organisms that share three major characteristics. First, they are small gram-negative rods that are commonly present as part of normal oral–pharyngeal or respiratory flora. Second, they are relatively fastidious microorganisms. Third, they have a predilection to infect heart valves. The HACEK group includes *Haemophilus* species (except *Haemophilus influenzae*), *Aggregatibacter* (formerly *Actinobacillus*) species, *Cardiobacterium hominis*, *Eikenella corrodens*, and *Kingella* species. These organisms are infamous for their ability to cause endocarditis although, rarely, they can also cause a variety of other infections (Table 135.1). For example, human bites can result in cellulitis or abscess formation resulting from HACEK organisms, especially *Eikenella* species, and various *Haemophilus* species can cause epiglottitis or brain abscesses.

Members of the HACEK group are normal indigenous flora of the oral cavity. Hematogenous seeding of the bloodstream may occur after dental manipulation, but is more likely to occur in the setting of ordinary daily activities, particularly among individuals with periodontal disease. Transient or sustained bacteremia puts individuals with underlying valvular heart disease at risk for developing infective endocarditis (IE). Antibiotic prophylaxis (AP) prior to dental manipulation has not been shown to protect against IE, therefore the guidelines for AP have been modified to include only individuals in the highest risk group. While millions of patients undergo dental procedures annually, cases of IE caused by HACEK group organisms are rare.

Diagnosis

Bacteria in the HACEK group are commonly but often erroneously considered in the differential diagnosis for culture-negative endocarditis. In the past the traditional method of increasing the recovery of HACEK bacteria was to extend the incubation of blood culture bottles from 5 to 7 days to 2 to 3 weeks. However, with improvements in blood culture methods, this practice is no longer recommended. A recent multicenter study showed that the mean and median times to detection of HACEK isolates using current laboratory methods and media were 3 and 3.4 days, respectively. In addition, none of the cultures that were held for prolonged incubation and terminal subculturing yielded additional growth. Several other studies have demonstrated that isolation of HACEK organisms usually occurs within 5 days, suggesting that prolonged incubation is no longer needed to detect HACEK bacteria.

HACEK organisms typically grow on 5% sheep blood and chocolate agar but not on Mac-Conkey's agar. Because growth is often poor or absent in an unenhanced atmosphere, incubation in 5% to 10% carbon dioxide (CO_2) is recommended. After growth is observed, standard biochemical tests will identify individual HACEK species. The use of 16S ribosomal RNA (rRNA) gene analysis may be useful for HACEK organisms that are not readily identified with standard biochemical tests.

TABLE 135.1 **HACEK-ASSOCIATED INFECTIONS**

Haemophilus aphrophilus, Haemophilus haemolyticus, Haemophilus parahaemolyticus, Haemophilus parainfluenzae, Haemophilus paraphrophilus, Haemophilus segnis	Brain abscess, endocarditis, endophthalmitis, epiglottitis, hepatic abscess, intra-abdominal infection, meningitis, neonatal sepsis, necrotizing fasciitis, otitis media, pneumonia, sinusitis, septic arthritis, urinary tract infection
Aggregatibacter actinomycetemcomitans	Brain abscess, cellulitis, empyema, endocarditis, endophthalmitis, osteomyelitis, periodontal infection, parotitis, pericarditis, pneumonia, synovitis, thyroid abscess, urinary tract infection
Cardiobacterium hominis	Endocarditis, meningitis
Eikenella corrodens	Abscessed tooth, Bartholin's gland abscess, brain abscess, cellulitis, conjunctivitis, dacryocystitis, empyema, endocarditis, endometritis, gingivitis, intra-abdominal abscess, intravascular space infections, keratitis, liver abscess, mediastinitis, meningitis, mycotic aneurysm, otitis externa, parotitis, pericarditis, pneumonia, septic pulmonary emboli, subdural empyema, thyroid abscess, thyroiditis
Kingella dentrificens, Kingella indologenes, Kingella kingae	Abscess, endocarditis, epiglottitis, intervertebral diskitis, meningitis, oropharyngeal infections, osteomyelitis, septic arthritis

Clinical features

Endocarditis caused by members of the HACEK group typically occurs in individuals with pre-existing valvular abnormalities and/or prosthetic valves. The results of a recent large, multicenter cohort showed that individuals with HACEK IE tend to be younger than those with non-HACEK IE with a median age of 47 years vs. 60 years, respectively. According to the afore-mentioned study, the most common members of the HACEK group identified were *Haemophilus* spp. (40%) followed by *Aggregatibacter* spp. (34%), *Cardiobacterium* spp. (14%), *Eikenella corrodens* (5%), and *Kingella* spp. (5%).

Endocarditis due to members of the HACEK group usually has a subacute course that may include frequent embolization due to the presence of large valvular vegetations. In the aforementioned cohort, stroke occurred in a significantly higher proportion of patients with HACEK IE compared to non-HACEK IE (25% vs. 17%, respectively; $p = 0.05$); however, the rates of in-hospital mortality (4% vs. 18%, respectively; $p < 0.01$) and 1-year mortality (11% vs. 39%, respectively; $p < 0.01$) were low. The high rate of stroke and paradoxically low rate of death is unique to HACEK IE.

Therapy

There have been no large trials to evaluate the best therapy for IE caused by HACEK group organisms. Currently available information on treatment is derived from in vitro susceptibility testing and the results of small case series or individual case reports. In the past, ampicillin plus an aminoglycoside was widely recommended as the therapy of choice. This treatment was advocated because synergy between β-lactams and aminoglycosides could often be demonstrated in vitro, but such synergy has not been conclusively proven to occur in vivo. Moreover, a number of case reports have documented therapeutic failures of combined therapy with ampicillin and gentamicin in the treatment of infections caused by *Aggregatibacter* (formerly *Actinobacillus*) *actinomycetemcomitans* and *Haemophilus*. In addition, authors of several recent reports have described β-lactamase production by numerous strains of HACEK group organisms. Because of their fastidious growth requirements, susceptibility testing for many members of the HACEK group is often difficult to obtain in routine microbiology laboratories. Taken together, HACEK group organisms should be considered ampicillin resistant unless proved otherwise; and the use of ampicillin as empiric or initial therapy for infections due to HACEK group organisms is not advised.

Most HACEK organisms, with the notable exceptions of *A. actinomycetemcomitans* and *E. corrodens*, are susceptible to first- and second-generation cephalosporins, and virtually all species are susceptible to third-generation cephalosporins. Therefore, cefotaxime or ceftriaxone is generally considered to be the best therapy for IE caused by HACEK group bacteria. The use of ceftriaxone, 2 g intravenously (IV) or intramuscularly (IM) once daily, is recommended because of its convenience and suitability for outpatient parenteral therapy (Table 135.2). The duration of therapy for native valve endocarditis should be at least 4 weeks; at least 6 weeks of therapy is recommended for prosthetic valve endocarditis.

TABLE 135.2 **ANTIBIOTICS RECOMMENDED FOR SERIOUS INFECTIONS**

	Antibiotic	Dosage and route	Length of therapy
First choice	Ceftriaxone	2 g IV or IM daily	4–6 wk
Alternative	Ciprofloxacin	750 mg PO every 12 h	4–6 wk

HACEK group organisms are also susceptible in vitro to most fluoroquinolones and aztreonam. Thus one of these agents may be used in the β-lactam-intolerant patient. There is a growing body of evidence to support the use of ciprofloxacin as outpatient therapy for HACEK endocarditis.

A number of investigators advocate empirical therapy with either ceftriaxone along with an aminoglycoside or ciprofloxacin until sensitivities return. A fluoroquinolone such as ciprofloxacin is the preferred alternative for patients who are allergic to a β-lactam. Ciprofloxacin is an appropriate choice for the outpatient segment of therapy because of its high bioavailability after oral ingestion and excellent safety profile. However, because of the lack of published data about fluoroquinolone therapy for HACEK group bacterial infections, ceftriaxone would still be considered first-line therapy. Careful follow-up of all patients undergoing treatment is also recommended, including periodic assessment of clinical and microbiologic response using careful examinations and follow-up blood cultures. Careful monitoring for compliance is advised for all patients treated with oral therapy.

HACEK group organisms are usually susceptible to tetracycline and chloramphenicol; however, both of these agents are bacteriostatic and thus are poor choices for endovascular infections. Most HACEK group members are resistant to metronidazole, vancomycin, erythromycin, and clindamycin.

Prognosis

Endocarditis caused by HACEK group organisms is associated with a favorable prognosis. Most infections can be cured with medical therapy or a combination of medical and surgical therapy.

Nonendocardial infections

Nonendocardial infections caused by HACEK group organisms are rare. Such infections are usually responsive to short courses of antibiotic therapy. Surgical drainage is indicated for abscesses. Most authorities recommend 3 to 4 weeks of parenteral therapy followed by an additional 3 weeks of antibiotics by mouth for treatment of septic arthritis caused by *Kingella kingae* and other HACEK group organisms. Two to four weeks of parenteral therapy followed by 1 to 6 months of oral therapy is recommended for the treatment of osteomyelitis caused by HACEK organisms. Management plans should include a careful assessment of the need for surgical debridement and monitoring for clinical response.

Helicobacter pylori

David Y. Graham and Emiko Rimbara

Introduction

Helicobacter pylori are gram-negative spiral shaped-bacteria that infect more than 50% of humans globally. *H. pylori* infection is a serious, chronic, transmissible infectious disease that causes progressive, destructive inflammation (e.g., gastritis) of the stomach. The infection is etiologically related to a number of important diseases including gastric and duodenal ulcer disease, gastric cancer, primary B-cell gastric lymphoma, atrophic gastritis, vitamin B_{12} malabsorption (pernicious anemia), iron deficiency anemia, idiopathic thrombocytopenia, and dyspepsia (i.e., *H. pylori* is a major cause of morbidity and mortality worldwide). The prevalence of *H. pylori* infection is inversely related to the general health, well-being, and degree of development of a society. Acquisition of the infection is often associated with transient symptoms that resolve. The process then becomes clinically latent; approximately 20% of infected individuals eventually develop clinically recognizable diseases.

Discovery of *H. pylori*

In the early 1980s, Robin Warren, a pathologist in Perth, Western Australia, teamed up with a young trainee in internal medicine, Barry Marshall, to investigate small curved bacteria seen on gastric biopsies from patients with gastritis. In 1982, the organism was eventually cultured and is now known as *Helicobacter pylori. H. pylori* is a microaerophilic, gram-negative, spiral rod approximately 0.6 × 3.5 μm with approximately seven unipolar flagellae. Biochemical features that help identify it are the presence of urease, oxidase, and catalase.

Warren and Marshall were able to prove that the organism was etiologically involved in gastritis and suggested it might also cause peptic ulcer and gastric cancer, which were both already established to be tightly associated with gastritis. In 2005, the Nobel Prize for Physiology and Medicine was awarded to Warren and Marshall for culture of the organism and proof of its relation to peptic ulcer disease. In 1994, the International Agency for Cancer Research defined *H. pylori* as a Class I carcinogen for gastric cancer, and the infection is now recognized as the primary etiologic factor for gastric cancer. Before 1950, gastric cancer was the most common cause of cancer deaths in most countries, and it still ranks as fifth most common with approximately 1 million deaths worldwide annually.

Epidemiology and transmission

H. pylori infection is typically acquired in childhood. It can be considered a situational opportunist as transmission can involve any route that allows bacteria from one person's stomach to gain access to another's.

H. pylori has also been cultured from stools and from vomit obtained from both infected young children and adults and from contaminated water and food. Most often transmission is person-to-person and tends to be transmitted within families. In countries with generally poor sanitation and unclean water supplies, waterborne transmission may also be important. Oral–oral transmission is unlikely except related to premastication of infant foods, which is still practiced in some societies. Overall, the major risk factors for *H. pylori* infection generally fall under the category of poor household hygiene and include birth in a developing country, low socioeconomic status, crowded living conditions, large family size, unsanitary living conditions, unclean food or water, presence of infants in the home, and exposure to gastric contents of infected individuals.

The prevalence of *H. pylori* infections varies by geographic location, ethnic background, and socioeconomic condition. As countries develop economically and sanitation improves, the incidence of *H. pylori* acquisition falls. For example, in the past 30 year *H. pylori* has almost disappeared from children in Japan (e.g., prevalence of ≤4%), and, except among the socially disadvantaged, this same process is occurring or has occurred in most developed countries. This change in *H. pylori* acquisition has resulted in an epidemiologic pattern of decreasing prevalence among successive birth cohorts. As a generalization, the prevalence in a birth cohort at about age 20 generally identifies the prevalence of *H. pylori* infections maintained by that birth cohort throughout life. In developing countries this is typically between 60% and 90%. In contrast, the *H. pylori* prevalence among middle-class white Americans born in the United States and whose parents were also born in the United States is now <15%, except in the elderly where the higher prevalence reflects the lower standards of living during their childhood. The general phenomenon of a declining prevalence of *H. pylori* infection in the United States is, however, now being offset by increasing immigration from high *H. pylori* prevalence regions.

Worldwide, improvements in sanitation and standards of living have resulted in a decline in the incidence of *H. pylori* infection and consequently of *H. pylori*-related diseases. However immigrants from developing countries will likely continue to provide a pool of *H. pylori*-related diseases even in the most advanced societies.

Pathogenesis of infection

After gaining access to the stomach, *H. pylori* urease helps protect the organisms from gastric acid while they use their flagella to "swim" to reach the mucus layer, which they burrow through to reach the mucosal surface where their adhesins attach, often at intercellular junctions. Here, they are protected both from acidic gastric contents and from being emptied from the stomach with meals. *H. pylori* possess many tools needed to evade host defenses, such as catalase, superoxide dismutase, and a poorly reactive lipopolysaccharide. Small numbers of *H. pylori* are also found within gastric epithelial cells, which may serve as a sanctuary to evade host defenses and may in part be responsible for the failure of topical antibiotic therapy. Attachment of *H. pylori* to the gastric mucosa is associated with local production of proinflammatory cytokines (e.g., interleukin-8), which induces infiltration of polymorphonuclear leukocytes and ultimately leads to the characteristic histologic pattern of an acute inflammatory reaction superimposed upon chronic inflammation which also includes organized lymphoid follicles.

The clinical outcome of *H. pylori* infection is determined by a complex interaction of the host, bacterium, and environmental factors. A number of putative *H. pylori* virulence factors have been described, including the *cag* pathogenicity island (PAI), the outer membrane inflammatory protein (OipA), a vacuolating cytotoxin (VacA), and a host of adhesins. The *cag* PAI region encodes a type IV bacterial secretion apparatus, which translocates or injects the CagA protein and possibly other proteins into host target cells. Phosphorylation of CagA activates a number of host signaling pathways that can subsequently influence host cellular functions, including proliferation, apoptosis, cytokine release, and cell motility. VacA is present in nearly all *H. pylori* strains but only about half of the *H. pylori* strains produce VacA toxin in vitro. Although VacA induces epithelial vacuolation in vitro, its function in vivo remains unclear; recent evidence suggests it may be critically involved in the intracellular survival of *H. pylori*.

A large number of descriptive epidemiologic studies have been done attempting to correlate specific *H. pylori* virulence factor genotypes and clinical outcome, especially in relation to *cagA* status and to genotypic variations in the *vacA* signal sequence (s1a, s1b, s1c) and mid-region of the *vacA* (m1, m2) gene. The presence of the putative virulence factors is typically linked (i.e., CagA positive strains also typically possess vacA m1,s1, OipA "on," etc.), but attempts to establish region-specific associations using samples of convenience produce confusing, conflicting, and inconsistent putative disease. It is important to note that *H. pylori* that lack all of the currently recognized putative virulence factors also result in increased mucosal inflammation, which in turn increases the risk of peptic ulcer disease and gastric cancer. No clinically avirulent *H. pylori* have been identified, and the risk of developing gastric cancer with the most virulent strains is only about twice that of infection with the least virulent strains. As such, testing for putative virulence factors has not proved to have clinical utility and is not clinically recommended.

Pattern of gastritis and clinical outcomes of *H. pylori* infection

The clinical outcome of an *H. pylori* infection is closely related to the anatomic pattern and severity of *H. pylori*-induced gastritis. The stomach is divided into two basic regions, an acid-secreting proximal portion, the corpus, and a distal non–acid-secreting region, the antrum. Although *H. pylori* colonizes the entire surface of the stomach, the acid-secreting corpus is relatively resistant, such that infection and inflammation in the corpus tends to be superficial. This pattern is because the organism is repelled from the gastric pits in the proximal stomach by the highly acidic fluid (pH <1) secreted from parietal cells, which is injected into the lumen through these pits and restricts *H. pylori* to the surface mucosa where they can

"hide" under the mucus layer. Inhibition of acid secretion, whether by highly selective vagotomy, use of an antisecretory drug, or during febrile episodes, allows the bacteria to invade into the pits and interact with the mucosa to produce inflammation deeper within the mucosa where the stem cells are located. Interleukin-1β, a potent natural antisecretory agent, is also produced in response to attachment of the bacteria and further reduces acid secretion, which may eventually allow the infection to become established in the depths of the corpus and result in pangastritis.

Antral inflammation affects the neuroendocrine G- and D-cells that affect acid secretion. Antral inflammation causes up-regulation of the gastrin-producing G-cells as well as inhibition of somatostatin secretion by D-cells resulting in deregulated acid secretion characterized by an increase in the amount and duration of gastric acid secretion in response to meals. In patients with antral-predominant gastritis, acid secretion from the corpus is relatively unpaired and sustained high acid secretion makes these patients at markedly increased risk of developing a duodenal ulcer. In contrast, hosts with low acid secretory capacity due to a low number of parietal cells or whose parietal cells are being inhibited (e.g., by antisecretory drugs) allow the organism to colonize a wider niche, producing pangastritis which may become corpus-predominant. The combination of both chronic and active inflammation of the corpus mucosa can eventuate in oxyntic gland atrophy, with the normal corpus mucosa being replaced by atrophy characterized by pseudopyloric metaplasia (spasmolytic polypeptide expressing mucosa) within which islands of intestinal metaplasia may develop, thus producing the characteristic phenotype of chronic atrophic gastritis. This low acid-secreting state is the phenotype associated with an increased risk of gastric cancer.

The rate and odds of progression from *H. pylori*-related chronic gastritis to gastric cancer is modulated by interactions between bacterial, environmental, and host factors. For example, and as noted earlier, the presence of the *cag* PAI signifies the presence of an infection associated with increased levels of inflammation and a corresponding increased risk of atrophy, genetic instability, and subsequently cancer. Diets high in salt and low in fresh fruits and vegetables accelerate the progression of mucosal damage and an earlier transformation from non-atrophic to atrophic gastritis. A number of host genetic factors, especially polymorphisms in the genes regulating the intensity of the inflammatory response to the infection, also influence outcome. For example, single-nucleotide polymorphisms in the genes encoding interleukin-1 are associated with an increased inflammatory response and an increased risk of developing gastric atrophy and gastric cancer. Environmental factors also play a key role. For example, in Japan, when the population experienced changes in diet and a decrease in smoking this resulted in a marked fall in the age-related incidence of gastric atrophy despite no change in the prevalence of CagA-positive infections or host genetics.

H. pylori infection is a necessary but not sufficient cause of gastric cancer. Eradication of the infection before the development of irreversible change can prevent development of gastric cancer despite the presence of the environmental and host risk factors that promote the disease. Even after atrophic gastritis develops, *H. pylori* eradication prevents further damage and prevents further increases in cancer risk but cannot return the risk to zero.

Gastric atrophy/atrophic gastritis also result in hypochlorhydria or achlorhydria which promote gastric colonization by enteric bacteria that produce carcinogenic substances (e.g., nitrosamines) from dietary and other sources. If some parietal cells remain intact or regenerate following *H. pylori* eradication, the patient can experience the return of at least partial acid secretion, which can either eliminate or reduce bacterial overgrowth and its associated production of carcinogens.

Diagnosis of *H. pylori* infection

H. pylori infection can be reliably diagnosed by a variety of tests including noninvasive assays (i.e., those not requiring obtaining gastric juice or a mucosal biopsy) and by those requiring a sample of the gastric mucosa or contents, which can be considered invasive or minimally invasive tests (Box 136.1). The noninvasive methods include detection of an immune response to the infection (e.g., IgG serologic tests), urea breath tests, and stool antigen assays. Invasive methods include rapid urease tests, histology, and culture. In addition, a number of tests currently used for research purposes, such as detection of the presence of *H. pylori* or its antimicrobial resistance using polymerase chain reaction on gastric biopsies or stools, are in trial for clinical use.

The method of choice clinically depends on availability, cost, and whether endoscopy is otherwise indicated. It is now agreed

BOX 136.1

Indications for testing for *Helicobacter pylori* infection[a]

Duodenal or gastric ulcer (present or history of)
Evaluate success of eradication therapy
Gastric low-grade MALT lymphoma
Atrophic gastritis
After endoscopic resection of early gastric cancer
Uninvestigated dyspepsia
Non-ulcer dyspepsia
Chronic NSAID/aspirin therapy[b]
Need for chronic proton pump inhibitor therapy
Relatives of patients with gastric cancer patients
Relatives of patients with duodenal ulcer
Relatives of patients with *H. pylori* infection
Patient desires to be tested
Individual from high-risk populations based on place of birth or groups locally recognized to have a high prevalence of the infection

[a] All proved to have an active *H. pylori* infection should be treated.

[b] When planning long-term therapy.

[c] When planning long-term antisecretory therapy.

Abbreviations: MALT = mucosa-associated lymphoid tissue, NSAID = nonsteroidal anti-inflammatory drug.

that the diagnosis of an active *H. pylori* infection should prompt eradication therapy, making a willingness to treat the infection if present the primary consideration for testing. Currently, testing for *H. pylori* infection is indicated in patients with a wide variety of conditions (Box 136.1).

Whenever possible noninvasive testing (e.g., the urea breath or stool antigen test) is preferred. Stool antigen tests using monoclonal antibodies are superior to stool antigen tests using polyclonal antibodies. While serologic testing is often the least expensive test, the sensitivity and specificity of serologic tests, particularly in-the-office tests, is typically lower than that of the urea breath test or stool antigen test. Because antibody titers fall slowly after *H. pylori* eradication, a fall in titer cannot be relied on to reliably assess post-eradication status of *H. pylori* infection. IgA and IgM *H. pylori* serologic tests are offered but are typically neither approved by the US Food and Drug Administration (FDA) nor accurate and are not recommended. Although IgG serology is no longer recommended as a single test, it can still be useful in conditions with high or low pretest probability. For example, a positive test in a patient with a known high-probability condition such as peptic ulcer disease would be considered indicative of an *H. pylori* infection, as would a negative test in a low *H. pylori* prevalence region in a patient with a low-probability condition such as gastroesophageal reflux disease. However, if one obtains a negative test in a high pretest probability situation, it would be prudent to retest using a test for active infection. In asymptomatic individuals and in the general population of most Western countries, most positive serologic tests will be false-positives, thus the admonition that treatment is not indicated unless the results are confirmed by a second test using different methodology and preferably one for active infection.

TABLE 136.1 **SUMMARY OF DIAGNOSTIC TESTS**

Test	Sensitivity (%)	Specificity (%)	Cost
Noninvasive tests			
Serology			
Laboratory, serum, ELISA	86–95	78–95	$$
In-office, serum	88–94	74–88	$
In-office, whole blood	67–88	75–91	$
Urea breath test			
^{13}C-urea breath test[a]	90–96	88–98	$$$
^{14}C-urea breath test[b]	90–95	90–95	$$
Stool antigen test	83–98	81–95	$$
Invasive tests			
Rapid urease test	88–95	93–100	$
Histology	93–98	95–99	$$$
Culture	77–98	100	$$$

[a] No radiation exposure.
[b] Low radiation exposure.

When endoscopy is clinically indicated, a rapid biopsy urease test, preferably using two specimens, one from the antrum and one from the corpus, can be used. Biopsy urease testing provides both a high sensitivity and specificity for the diagnosis of *H. pylori* infection but false-negatives are especially likely to occur if the patient is taking proton pump inhibitors (PPIs) or has atrophic gastritis with intestinal metaplasia. The result of the rapid urease test is generally not available during endoscopy and because false-negative biopsy urease tests occur, histology is generally obtained to confirm the results. Increasing antimicrobial resistance has reduced the interest in and use of rapid urease testing because the desire for rapid knowledge is now offset by the need for additional information, such as the results of susceptibility testing to choose the best therapy. Histology has the additional advantage of providing a permanent record and allowing identification and scoring of the pattern and severity of gastritis, which in turn allows risk stratification for gastric cancer using the Operative Link on Gastritis Assessment (OLGA) or OLGA for intestinal metaplasia (OLGIM) histologic cancer risk scoring systems.

Prospective studies have consistently shown that hematoxylin and eosin (H&E) staining of gastric mucosal biopsies has a relatively poor sensitivity and specificity for diagnosis of active *H. pylori* infections. The hallmark of *H. pylori* infection is mucosal inflammation, which should prompt a search for *H. pylori*. While organisms can be visualized with special stains such as the Genta or El-Zimaity triple stains, or the combination of H&E and the Diff-Quik stains, many patients are taking PPIs that allow some overgrowth and cause false-positive results. Currently, the best test to confirm the presence of *H. pylori* is by specific immunohistochemistry.

Culture of mucosal biopsies to establish antimicrobial susceptibility is extremely helpful in choosing an effective therapy and is clearly indicated in patients who failed to eradicate *H. pylori* using standard antimicrobial regimens. Cultures can also be obtained using minimally invasive methods with a brush or string test. Potentially, molecular testing of gastric juice, mucus, biopsies, or stool samples may allow rapid susceptibility testing but current methods have shown limited applicability.

Cautions about false-negative diagnostic tests

False-negative results are especially likely if the patient has taken drugs that reduce the bacterial load such as antibiotics, bismuth, or PPIs. In general, one should stop these drugs for 1 to 2 weeks before testing. H_2-receptor antagonists do not adversely affect any of these tests (although they may adversely affect the ^{14}C-urea breath test unless the test is administered along with citric acid) and can be used if needed to control symptoms. In clinical practice, post-eradication assessment for *H. pylori* infection should be routinely done but should be delayed at least 4 weeks following the completion of eradication therapy to avoid false-negative results. A 6-week delay is probably best when using the stool antigen test to confirm cure.

TABLE 136.2 **RECOMMENDED ANTIBIOTIC COMBINATIONS FOR *H. PYLORI* INFECTIONS**

Treatment	Drugs, dosages, and duration
Susceptibility-based	**No drug allergies**
Clarithromycin triple therapy (susceptible to clarithromycin)	Amoxicillin (1 g) and clarithromycin (500 mg) plus a PPI (40 mg omeprazole equivalent per dose) all given BID for 14 days
Metronidazole triple therapy (susceptible to metronidazole)	Amoxicillin (1 g) and metronidazole or tinidazole (500 mg) plus a PPI (40 mg omeprazole equivalent per dose) all given BID for 14 days
Fluoroquinolone triple therapy (susceptible to fluoroquinolones)	Fluoroquinolone (e.g., levofloxacin 500 mg once daily), plus a PPI (40 mg omeprazole equivalent per dose) and amoxicillin 1 g BID for 14 days
Susceptibility-based	**Allergic to penicillin**
Susceptible to clarithromycin and metronidazole	Clarithromycin (500 mg), and metronidazole or tinidazole (500 mg) plus a PPI (40 mg omeprazole equivalent per dose) all given BID for 14 days
Resistant to clarithromycin and/or metronidazole	Bismuth quadruple therapy (see **Susceptibility testing unavailable**)
Empiric therapies	**Susceptibility testing unavailable**
Bismuth quadruple therapy	Bismuth subsalicylate or bismuth subcitrate 2 tablets 2 or 4 times daily after meals plus tetracycline hydrochloride (500 mg) 4 times daily with meals and at bedtime plus metronidazole (400 or 500 mg) 4 times daily with meals and a PPI (40 mg omeprazole equivalent per dose) BID for 14 days
Prepackaged bismuth quadruple therapy	Pylera for 14 days; add a PPI twice daily (20–40 mg omeprazole equivalent BID)
New bismuth quadruple therapy (amoxicillin replaces tetracycline)	Bismuth 2 tablets 2 or 4 times daily after meals plus metronidazole (400 or 500 mg) four times daily with meals and amoxicillin 1 gm TID along with a PPI (40 mg omeprazole equivalent or more BID) for 14 days
New bismuth quadruple therapy (amoxicillin replaces metronidazole)	Bismuth 2 tablets 2 or 4 times daily after meals plus tetracycline HCl 500 mg four times daily with meals and amoxicillin 1 g TID along with a PPI (40 mg omeprazole equivalent or more BID) for 14 days
Furazolidone quadruple therapy	Furazolidone therapies are obtained by replacing metronidazole in bismuth quadruple therapies with furazolidone 100 mg TID
Empiric likely effective regimens	
Rifabutin triple therapy	Rifabutin (150 mg once or twice daily), amoxicillin (1 g TID and omeprazole 40 mg (or an equivalent PPI) q8h for 14 days
Rifabutin bismuth therapy	Add bismuth subcitrate or subsalicylate 2 tablets BID to preceding therapy
Experimental regimens	
High-dose PPI-amoxicillin dual therapy	PPI (e.g., rabeprazole 40 mg, esomeprazole 40 mg) plus amoxicillin (500–750 mg) all four times daily at approximately 6-hour intervals for 14 days (can use 8-hour interval at night)
Vonoprazan-amoxicillin dual therapy	Vonoprazan (the potassium competitive acid blocker) 20 mg BID plus 500–750 mg amoxicillin q6h for 14 days is recommended
Obsolete regimens	Sequential, hybrid, concomitant therapies, empiric use of triple therapies

Preferred PPIs: 40 mg omeprazole, 60 mg lansoprazole, 20 mg rabeprazole or esomeprazole, pantoprazole not recommended as 40 mg = 9 mg omeprazole.

Indications for *H. pylori* eradication

In developed countries, the recommendation is to treat and confirm cure for all diagnosed active *H. pylori* infections. Box 136.1 lists indications for testing for *H. pylori* in the United States and other developed countries. *H. pylori* causes gastric cancer and universally causes progressive damage to the structure and functions of the stomach. As with smallpox, polio, and syphilis, humans are the natural host; the world will be better off when all these diseases have been eradicated. In March 2013, Japan approved universal *H. pylori* eradication and is leading the way toward population-wide *H. pylori* eradication. However, developing countries with poor sanitation remain a challenge because of the high prevalence of the infection and the high rate of reinfection after eradication therapy. Elimination of this important pathogen will likely require an effective vaccine. However, progress in vaccine development has remained slow.

Gastroesophageal reflux disease, Barrett's esophagus, and adenocarcinoma of the esophagus

One source of early confusion and uncertainty regarding whom to treat was related to an early hypothesis that *H. pylori* infection might have beneficial effects. For example, soon after the discovery of *H. pylori* it was noted that those least likely to be infected in Western countries (e.g., white men) were also the group most likely to develop Barrett's esophagus and esophageal carcinoma, resulting in a suggestion that *H. pylori* might be protective. Barrett's esophagus occurs as a complication of the acid-related disease reflux esophagitis. Reflux esophagitis and Barrett's esophagus are rare wherever atrophic gastritis and gastric cancer are common. Those living in developed areas have experienced a marked decline in *H. pylori* infections, atrophic gastritis, and gastric cancer and an increase in symptomatic reflux esophagitis, Barrett's esophagus, and adenocarcinoma of the esophagus. The odds of developing gastric cancer by age 74 have been calculated for men worldwide and ranges from 0.6% in the United States to 22% in Yangcheng County, China. The increased risk of adenocarcinoma of the esophagus might be considered a tradeoff for the fall in gastric cancer, which resulted in the most common cause of cancer deaths becoming a rare disease while a heretofore very rare disease increased. The increase has now plateaued such that overall it remains an uncommon cause of cancer deaths.

It was also suggested that *H. pylori* infection in childhood might protect against atopy and asthma in children. In this scenario, *H. pylori* infection was related to the hygiene hypothesis, in which early exposure to antigens that regulate the immune response set the stage for subsequent development of allergic diseases. The protective role of *H. pylori* in atopic disease has not survived testing. While *H. pylori* infection is a surrogate for poor household hygiene, it is not directly involved in the development of or protection from atopic diseases. Of interest, and contrary to predictions from the *H. pylori* protective hypothesis, countries like Malaysia, where *H. pylori* was naturally absent, have not been plagued by any of the dire consequences predicted by those proposing that *H. pylori* eradication would result in a variety of new problems. The hypotheses regarding putative protective effects of *H. pylori* have all been falsified, with current evidence supporting the notion that *H. pylori* infection provides no meaningful benefits and should be eradicated.

Treatment of *H. pylori* infection

H. pylori infection has proved more difficult to cure than many other common bacterial infections. *H. pylori* occupy a number of niches and widely different environments in the stomach, including being intracellular. The gastric contents are highly acidic whereas most antibiotics function best at neutral or near-neutral pH. However, there are a number of therapeutic regimens that will reliably cure 95% of more susceptible infections in treatment-adherent patients. The main impediments to successful treatment has been lack of regional, local, or patient-specific *H. pylori* susceptibility data coupled with poorly designed antimicrobial regimens, poor patient adherence to complicated regimens, increasing antimicrobial resistance, and poor treatment recommendations. The history of the development of antimicrobial therapies for *H. pylori* is unique because it has largely been based on results of trial-and-error rather than a traditional susceptibility-based approach. Treatment trials and subsequent meta-analyses have usually involved populations uncharacterized in terms of the proportion with infections resistant to the antibiotics being tested. Because the proportions with resistance has varied and has not been assessed, the results of any study are at best population-specific and thus neither generalizable nor comparable. The focus has been on superiority trials, which were often done in populations where the results of the so-called standard therapy was known to be poor because local resistance ensured that the test regimen which contained drugs not affected by resistance that undermined standard therapy would be equal or superior. In addition, there was no defined clinically acceptable (e.g., ≥95%) result allowing low and clinically unacceptable treatment results to be compared and the winner chosen. Such studies were then combined in meta-analyses and used to produce consensus guidelines, as if meta-analysis was somehow able to transform uninterpretable studies with clinically unacceptable results into clinically meaningful treatment guidelines. The concepts and principles of antimicrobial stewardship so loved and respected by specialists in infectious disease have yet to take hold in the gastroenterology community and have resulted in guidelines based on experience rather than susceptibility data. As such, clinicians are required to make empiric choices regarding antibiotics, doses, and durations of therapy.

The *H. pylori*-infected stomach typically contains vast numbers of *H. pylori,* making it likely that a population of resistant strains is also present (the inoculum effect) especially with macrolides, nitroimidazoles, and fluoroquinolones. Worldwide, the unrestricted use of macrolides and fluoroquinolones resulted in a rapid increase in resistance among *H. pylori* so that now a relatively high proportion of treatment-naïve patients will have resistance to at least one

of these three antibiotics and thus the current recommendation to avoid regimens that use those drugs empirically (i.e., unless susceptibility has been confirmed). Molecular tests for susceptibility for clarithromycin and fluoroquinolones have been developed but are currently not reimbursed in the United States. Resistance to amoxicillin, tetracycline, bismuth, furazolidone, and rifabutin have remained rare, allowing continued use of these drugs. In contrast to macrolides and fluoroquinolones, metronidazole resistance is not all-or-none, so that resistance can often be overcome by adding bismuth and increasing the daily metronidazole/tinidazole dose to 1,500 to 2,000 mg and the duration of therapy to 14 days. As a general rule *H. pylori* therapy should be for 14 days, in part because of the presence of persistently resistant populations. The organism only replicates when the pH is 6 or 7, and this is difficult to achieve in vivo. PPIs are typically administered to reduce acid secretion and improve the effectiveness of most antimicrobials. They also reduce antibiotic washout from the stomach, increase the concentration of intragastric antibiotics, and promote *H. pylori* replication. In promoting the use of PPIs, the pharmaceutical industry used a shorter duration of treatment as a marketing point. However, PPIs require ≥3 days to reach full effectiveness, which hampers the effectiveness of these short-term therapies. Most regimens contain amoxicillin, and effectiveness is dose- and pH-dependent. The relative effectiveness of PPIs is measured as omeprazole equivalents, and best results with all therapies containing amoxicillin require 40 mg of omeprazole equivalent twice a day (i.e., 40 mg omeprazole, 20 mg esomeprazole, 20 mg rabeprazole, 45 mg lansoprazole, 180 mg of pantoprazole all BID) or more. The new class of PPI, the *potassium competitive acid blockers* (vonoprazan; P-CABs), is more potent than traditional PPIs and obtains full effectiveness on the first day of therapy. When these become widely available, this class of PPIs will likely supplant traditional PPIs whenever acid-sensitive antimicrobials are used, which may also allow shorter duration therapy while retaining high cure rates.

The lack of susceptibility data has resulted in consensus-based treatment guidelines that neither reflect local resistance patterns nor provide guidance to reliably and consistently achieve high cure rates. All recent guidelines also promote antimicrobial misuse. For example, they recommend a four-drug combination consisting of a PPI, amoxicillin, and clarithromycin plus metronidazole, called *concomitant therapy*. This regime effectively gives two triple therapies simultaneously (clarithromycin and metronidazole triple therapy) and is based on the hope that the infection will be susceptible to either clarithromycin or metronidazole. It is thus designed to, at a minimum, provide one unnecessary antibiotic, and, if dual clarithromycin and metronidazole resistance is present, it provides two unnecessary antibiotics. It has been calculated that each 1 million prescriptions results in a minimum of approximately 14,000 kilograms of unnecessary clarithromycin or metronidazole (a class I carcinogen). A similar pattern of antibiotic misuse was produced by the most commonly prescribed regimen in Japan (vonoprazan, amoxicillin, and clarithromycin). The cure rate with vonoprazan and amoxicillin alone for 7 days is approximately 80% and could be further improved by increasing the duration of therapy. Each year, more than 1 million prescriptions are given resulting in thousands of kilograms of unnecessary clarithromycin being prescribed. The rising concern regarding antimicrobial resistance related to excessive and inappropriate antibiotic use resulted in the World Health Organization in 2017 publishing a list of 16 antibiotic-resistant bacteria that pose the greatest threat to human health. *H. pylori*

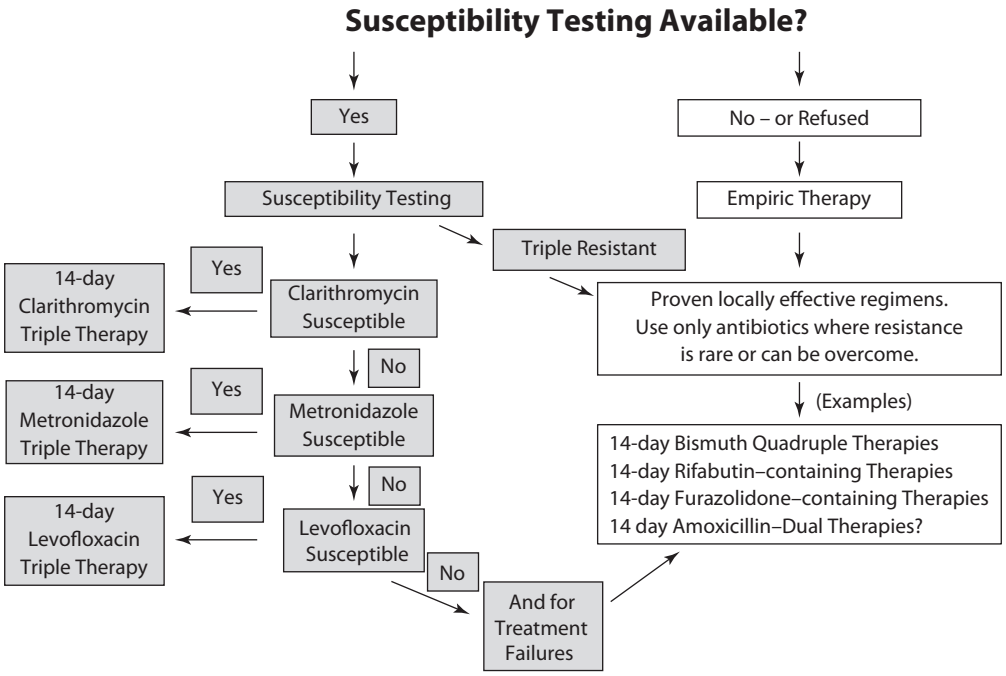

FIGURE 136.1 Algorithm showing idealized treatment scheme where local resistance patterns are known or patient-specific susceptibility is available. The concept is to either use susceptibility data or locally proven highly effective empiric regimens.

was categorized as a high-priority bacteria in the same tier as vancomycin-intermediate or –resistant bacteria and methicillin-resistant *Staphylococcus aureus*. Clearly, current recommendations for antimicrobial therapy of *H. pylori* contribute to the problem of antimicrobial resistance.

Which *H. pylori* therapies are best?

A successful regimen is defined as one that will reliably cure at least 95% of infections of susceptible strains in treatment-adherent patients. With susceptibility-based therapy this can easily be achieved, usually with a triple therapy. Clinically, it is prudent to use the regimen with highest patient acceptance and highest cure rates first (Figure 136.1). Levofloxacin has achieved black box status because of side effects by the FDA, moving it to third in the treatment order. For patients in whom susceptibility testing is unavailable, culture has failed, or multidrug resistance is present a four-drug bismuth-containing therapy is recommended (i.e., a triple therapy plus bismuth). Traditional bismuth quadruple therapy employs high doses of both tetracycline and metronidazole and has a high rate of side effects such that extra efforts in patient education are required to obtain adequate adherence. In the absence of metronidazole resistance, shorter duration therapy (e.g., 7 days) is sufficient. However, 14-day metronidazole triple therapy would be a better choice because it is better tolerated. A combination capsule formulation of bismuth quadruple therapy (Pylera) as been introduced but packaging was changed to a 10-day dose pack, requiring the patient to purchase two packages to obtain sufficient drug for the recommended 14-day therapy. This may be an example of the pharmaceutical industry rather than science deciding what is studied and what is offered. It is also an example of the failure of the regulatory agencies and opinion leaders to provide appropriate endpoints or advice.

The major issue with bismuth quadruple therapy is compliance because side effects are common and should be discussed (including the likelihood of black stools) before use. Studies are needed to test simplified bismuth-containing regimens, such as twice-a-day therapy instead of more frequent dosing.

Multiple treatment failures or salvage therapies

The best approach is to choose a regimen based on susceptibility testing, which currently may require referral to a *H. pylori* treatment specialist. Furazolidone is not widely available but, where available, is most often used as part of a 14-day bismuth-containing regimen (i.e., replacing the metronidazole) and given as 100 mg three times daily. It is highly effective but side effects are common, as are drug–drug interactions.

Confirmation of cure

Because the reasons that *H. pylori* was treated remain if therapy fails, it is important to confirm treatment success (i.e., therapy should always be followed by confirmation of cure). The confirmatory test should be delayed 4 to 6 weeks after the end of antimicrobial therapy to allow the bacteria, if still present, an opportunity to repopulate the stomach. Drugs that inhibit *H. pylori*, such as PPIs, should not be allowed for 1 and preferably 2 weeks prior to testing. The urea breath test is the ideal method of evaluating the outcome of therapy for those in whom follow-up endoscopy is not needed. An alternate approach would be to use the stool antigen test, but, in that case, testing should be delayed for 6 to 8 weeks.

Neisseria gonorrhoeae

Amy J. Mathers and Michael F. Rein

In 2018, *Neisseria gonorrhoeae* reportedly caused 583,405 infections in the United States, an increase of 63% since 2014. The gonococcus attaches primarily to columnar or cuboidal epithelial cells (Box 137.1) via pili and outer membrane proteins. It then penetrates between and through the cells to submucosal areas, where it elicits a neutrophilic host response. The clinical spectrum of primary infection with *N. gonorrhoeae* mirrors that of *Chlamydia trachomatis*.

Acute urethritis, manifesting as some combination of urethral discharge and dysuria, is the most common presentation of disease in men, although some infected men are asymptomatic. Epididymitis, usually unilateral and accompanied by urethral disease, sometimes occurs. Gram stain of urethral discharge may be used for presumptive diagnosis of gonococcal urethritis. Polymorphonuclear neutrophils (PMNs) with gram-negative, intracellular diplococci (GNID; Figure 137.1) are observed in 95% of infected, symptomatic men, and the finding is 98% specific. Observing PMN without GNID supports a diagnosis of nongonococcal urethritis (see Chapter 59, "Urethritis"), but the sensitivity of GNID in asymptomatic men is only about 75%, and Gram stain should not be used to screen such patients for gonorrhea.

In women, the primary site of infection is the endocervix, although the organism can be recovered from the urethra and periurethral (Skene's) and Bartholin's glands in adults and from the vagina itself in prepubescent girls. Asymptomatic infection is more common in women than men. Gram stains of cervical smears are insensitive. Untreated endocervical infection may ascend to the Fallopian tubes, causing pelvic inflammatory disease and perihepatitis (see Chapter 64). Gestational gonorrhea may result in ophthalmia neonatorum and, very rarely, neonatal gonococcal pneumonia.

Anorectal gonorrhea occurs in up to 40% of women with endocervical disease. It can also be an isolated finding in homosexual men or heterosexual women who practice receptive anal intercourse and in whom it may be the only infected site in about 20%. Most patients are asymptomatic, but some present with acute proctitis. Patients with pharyngeal infection acquired from fellatio are also typically asymptomatic, but pharyngitis may occur. Gonococcal conjunctivitis in adults, usually acquired by autoinoculation from a genital focus, produces varying degrees of inflammation.

Disseminated gonococcal infection occurs historically in perhaps 0.5% to 3% of infected patients. It usually presents as the arthritis–dermatitis syndrome, manifesting as asymmetric, migratory polyarthritis, arthralgias, or tenosynovitis. In 75% of cases, disseminated disease is accompanied by small papules or by vesicles with an erythematous base. Hereditary or chemotherapy-induced deficiency of the terminal components of complement or infection with organisms resistant to the bactericidal activity of serum predisposes to dissemination. Endocarditis and meningitis are very rare complications.

Diagnosis

Definitive diagnosis requires demonstrating the presence of the organism. Culture has been largely supplanted by molecular techniques. Nucleic acid amplification tests (NAATs) are those most widely used clinically in the United States and have high sensitivity and specificity. Performing a NAAT on urine has

BOX 137.1

Urethra
Pharynx
Cervix
Conjunctiva
Rectum
Vagina (in prepubescent girls)

adequate sensitivity in males and females, so a urethral swab or endocervical swab is no longer necessary. There have been some historic reports of decreased sensitivity in urine from women, and a vaginal swab, which can be self-collected, may be preferred in some settings. Although many NAATs are approved for urogenital specimens, only certain commercial laboratories are validated to test rectal or pharyngeal specimens. Clinicians should consult their local health departments regarding the current workup of extragenital sites. NAATs can detect free DNA from dead organisms for perhaps as long as 2 weeks after successful treatment and do not provide a specimen for testing antimicrobial sensitivity. Thus, in treatment failures, culture specimens should be obtained along with antimicrobial susceptibility testing. As the gonococcus is relatively unstable outside humans, one should contact the clinical laboratory for proper collection and transport procedures.

Therapy

There are several important and unique general principles to consider regarding treatment of gonococcal infections. Ideal treatment of uncomplicated infection should be single-dose, affordable, possessing a low side-effect profile, and, when possible, oral. Unfortunately, due to increases in antimicrobial resistance, there is no longer a first-line oral option for therapy. The treatment of uncomplicated infection is almost always performed without knowledge of antimicrobial susceptibility. There are few bacterial infections for which in vitro resistance correlates so tightly with clinical treatment failure. Resistance has emerged to all antimicrobial classes used to treat gonorrhea, and it is now considered one of the most urgent threats of antimicrobial resistance by the Centers for Disease Control and Prevention (CDC). Historically, one can follow the rapid appearance and dissemination of organisms resistant to penicillins, sulfonamides, tetracyclines, fluoroquinolones (FQ) and, most recently, cephalosporins. Gonococcal resistance is mediated by multiple chromosomal mutations and by acquisition of readily disseminated plasmids. This has now given rise to a handful of reports which describe isolates resistant to all recommended therapies.

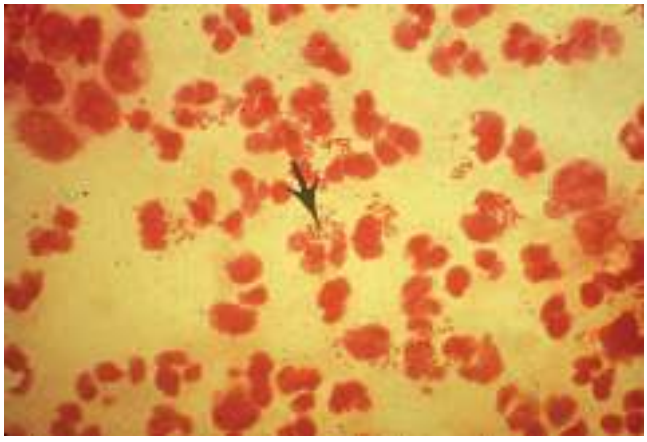

FIGURE 137.1 Gram stain of urethral discharge, showing gram-negative intracellular diplococci diagnostic of gonorrhea. Coincident nongonococcal urethritis cannot be ruled out.
Courtesy of Centers for Disease Control and Prevention.

The rapid rise of penicillin and tetracycline resistance was first identified in the 1970s. Resistance to both classes has been driven by chromosomal mutations and dissemination of plasmids carrying genes that encode for a β-lactamase and a protein that modifies the ribosomal target of tetracycline. By 2014, the Gonococcal Isolate Surveillance Project, which performed sensitivity testing on about 3% of male urethral isolates from around the United States (n = 5,093), found resistance rates of 25% for tetracycline and 16% for penicillin.

In the mid-1980s a single oral dose of a FQ successfully treated gonococcal urethritis in men. However, as early as 1990, resistance to ciprofloxacin was detected in *N. gonorrhoeae*. The prevalence of FQ resistance and the incidence of treatment failures continued to rise throughout the 1990s, and, in 2018, 31.2% of isolates from the CDC surveillance program harbored FQ resistance. *N. gonorrhoeae* has many mechanisms which may contribute to FQ resistance, but the primary mechanism is mutation in one or both genes (*parC* or *gyrA*) encoding differing topoisomerases. Fluoroquinolones are no longer recommended for the treatment of gonorrhea in the United States.

Due to increasing resistance to other drug classes, late-generation cephalosporins have become the mainstay of first-line treatment for gonococcal infection. Cephalosporin resistance is mediated through accumulation of chromosomal mutations that alter binding to the drug's target. Although cephalosporin resistance remains at a relativity low level, the steep rise in the rate of decreased cefixime susceptibility, which peaked in 2011 at 1.4%, does cause concern, as this class is the last reliable group of agents. During 2009–2018, the percentage of isolates with reduced ceftriaxone susceptibility (defined as an MIC of ≥0.125 μg/mL) fluctuated between 0.1% and 0.4% and was 0.2% in 2018. Because of the dramatic difference in bioavailability between oral and intramuscular dosing, the only recommended therapy is intramuscular ceftriaxone (Table 137.1). When coinfection with *C. trachomatis* is present or has not been ruled out, doxycycline should be added. Doxycycline (see Chapter 59, "Urethritis") is superior to azithromycin, especially in extragenital (e.g. rectal) sites. Azithromycin is preferred over doxycycline as a second agent only if coinfection with *Mycoplasma genitalium* (see Chapter 165, Mycoplasmas) has been diagnosed.

TABLE 137.1 **REGIMENS FOR UNCOMPLICATED GONORRHEA (URETHRITIS, CERVICITIS, PROCTITIS)**

Drug	Dose	CDC recommended	Safe in pregnancy	Effective in pharynx	Comments
Ceftriaxone	500 mg IM	Yes	Yes	Yes	Most effective
Plus Doxycycline	100 mg po, bid x 7 days	Yes	No	Yes	If coincident chlamydial infection is present or cannot be ruled out
Cefixime	400 mg PO	Secondary	Yes	Uncertain	Resistance developing and needs to be combined with azithromycin 1 g
Ciprofloxacin	500 mg PO	No	No	Uncertain	Significant resistance, not recommended, see text
Other fluoroquinolones	Various	No	No	Uncertain	Significant resistance, not recommended, see text
Spectinomycin	2 g IM	No	Yes	No	Unavailable in USA
Gentamicin	240 mg IM	No	Yes	No	Second-line and use with 2 g azithromycin. Severe penicillin allergy

In the face of rapidly increasing resistance, the recommended dose of ceftriaxone have been increased to 500 mg i.m., and further increases may be required in the future. Several new drugs are undergoing evaluation. Most are variants on fluoroquinolones (e.g., zoliflodaxin, delafloxacin, spiropyrimidinetriones, geptodidacin) or macrolides (e.g., solithromycin). The clinician should remain alert for such possible future developments.

Management of sexual partners should probably extend back for 60 days prior to the onset of symptoms or date of diagnosis. All patients with gonorrhea should be advised to undergo testing for infection with HIV. The recommended antigonococcal regimen is sufficiently effective that test of cure is not necessary, but retesting at 3 months should be encouraged to detect reinfection.

In some settings, expedited patient therapy—medication or prescriptions provided for patients to deliver to their sexual partners—is allowable. Since such therapies must be oral, they can no longer be considered first-line, and partners so treated should be advised to present for test of cure. Many medicolegal restrictions (e.g., CDC-recommended regimens, the need to call sexual partners) vary from state to state, and the clinician is advised to consult the local health department to receive current information.

Standard therapy

Intramuscular ceftriaxone is highly effective, and a 500 mg i.m. regimen is currently recommended by the CDC for the treatment of uncomplicated gonorrhea. Ceftriaxone is often diluted in 1% lidocaine to reduce discomfort. Other single-dose parenteral regimens (ceftizoxime or cefotaxime, 500 mg IM) offer no advantage over ceftriaxone. Resistance to cefoxitin, often in association with high-level tetracycline resistance, mandates that this drug should no longer be used in the treatment of uncomplicated gonorrhea.

Oral cephalosporins are less effective, and failure is associated with relative increases in *in vitro* resistance. Due to this increase in resistance, any oral cephalosporin should not be used unless ceftriaxone is unavailable. If an oral cephalosporin must be used, a single oral dose of cefixime 400 mg in combination with doxycycline 100 mg orally, twice daily for seven days seems reasonable. Fluoroquinolones should no longer be used to treat uncomplicated gonorrhea (see earlier discussion). However, for penicillin-allergic patients with severe (IgE-medicated) β-lactam allergy dual treatment with single doses of intramuscular gentamicin 240 mg plus a single dose of oral azithromycin 2 g is the only recommended therapy which is widely available in the United States. Earlier data supported the use of gentamicin (see Table 137.1), which may be effective in the same settings, but a meta-analysis found a 92% cure rate with this drug alone, which does not meet the criterion for cure rate of ≥95% required for CDC approval. Spectinomycin is no longer available in the United States. The use of any of these alternative agents mandates a test of cure 1 week after treatment.

Nonstandard therapy

The monobactam aztreonam and the carbapenems imipenem-cilastatin, meropenem, and ertapenem are uniformly effective against *N. gonorrhoeae* but are costly and available only in intravenous form. These drugs are never primary therapy for gonorrhea. Gentamicin 240 mg IM plus azithromycin 2 g PO or gemifloxacin 320 mg PO plus azithromycin 2 g PO demonstrated excellent efficacy against uncomplicated anogenital and pharyngeal gonorrhea. These regimens might be useful in the salvage treatment of infection with cephalosporin-resistant infections or in β-lactam-allergic patients.

Extragenital disease

A single dose of ceftriaxone, 1 g IM, in adults apparently cures gonococcal conjunctivitis, but clinical data are extremely limited. A single saline flush of the conjunctiva should be considered, but topical antibiotics have no proven additional benefit.

TABLE 137.2 **INITIAL REGIMENS FOR DISSEMINATED GONOCOCCAL INFECTION**[a]

Drug	Dose	CDC recommended	Safe in pregnancy	Comments
Ceftriaxone	1 g IV q24h	Yes	Yes	Most effective
Plus Doxycycline	100 mg po, bid x 7 days	Yes	No	If coincident chlamydial infection is present or cannot be ruled out
Ceftizoxime	1 g IV q8h	Secondary	Yes	No advantage over ceftriaxone
Plus Doxycycline	100 mg po, bid x 7 days		Yes	If coincident chlamydial infection is present or cannot be ruled out

[a] Intravenous therapy should be continued for 24 to 48 hours after improvement begins. Thereafter, the patient can be switched to an oral regimen based on susceptibility testing.

Elimination of *N. gonorrhoeae* from the oropharynx is particularly challenging. Some regimens successfully treating uncomplicated genital infection are not reliably effective for pharyngeal disease. The oropharynx is often where treatment failures from resistance will first be described.

No prospective studies on the treatment of disseminated gonococcal infection have been performed since 1976; hence, recommendations are empiric because the worldwide spread of resistant gonococci occurred after that time. The gonococcal arthritis–dermatitis syndrome should be treated with ceftriaxone (Table 137.2). Regimens employing other third-generation cephalosporins were equally effective in the past; however, this has not been examined in the more recent era of increasing cephalosporin resistance. If frank septic arthritis is not present, the patient can be switched to an oral regimen (Table 137.3), preferably with a cephalosporin, to complete 7 to 10 days of therapy. Prior to transition to oral therapy susceptibility testing of isolates is strongly recommended. The optimal duration of therapy is unknown. Gonococcal endocarditis should be treated with 4 weeks and meningitis with 2 weeks of an appropriate parenteral regimen, preferably ceftriaxone or another third-generation cephalosporin. There are no current studies of extended courses of FQ as treatment for extragenital disease, and, in the face of recent increases in resistance, these drugs should not be used.

TABLE 137.3 **FOLLOW-UP REGIMENS FOR DISSEMINATED GONOCOCCAL INFECTION**

Drug	Dosage	CDC recommended	Comments
Cefixime	400 mg PO, 2× daily	Yes	No data

Haemophilus

Amy Spallone and Daniel Musher

Haemophilus influenzae

General description and microbiology

Haemophilus influenzae is an extracellular, fastidious, small (1 × 0.3 μ), nonmotile, gram-negative bacterium, typically described as a coccobacillus; it is a pathogen of humans found primarily in the upper respiratory tract. Variable morphologic appearance and inconsistent retention of dyes may result in describer variability on stained smears. Colonies typically appear translucent, and encapsulated strains are mucoid and appear iridescent when grown on transparent media.

This organism was first isolated by Pfeiffer from the lungs of persons who died in 1892 during an influenza pandemic. Because it only grew on agar that contained blood cells and it was thought to be the causative agent of influenza, it was named *Haemophilus influenzae* (blood-loving [cause] of influenza). *H. influenzae* is a common cause of respiratory tract infections, including otitis media, sinusitis, bronchitis, and pneumonia.

Haemophilus requires growth factors supplied by erythrocytes. *H. influenzae* requires two supplements known as X factor and V factor. X factor comes from heat-stable iron-containing pigments that must be released from broken-up red blood cells to provide protoporphyrins; thus, porphyrin-based assays represent the most reliable method for identifying *Haemophilus influenzae* spp. V factor (nicotinamide adenine dinucleotide) diffuses from intact erythrocytes. The requirement for X factor renders blood agar unsuitable for culturing *H. influenzae,* although colonies may appear on blood agar around colonies that hemolyze blood, such as *Staphylococcus aureus*. Enriched CO_2 greatly facilitates its growth and sometimes is necessary to grow *H. influenzae. H. parainfluenzae* requires only V factor and therefore grows readily on blood agar plates. Inoculation onto appropriate media must be done without delay as *H. influenzae* rapidly degrades in clinical specimens.

Serotypes

H. influenzae species can be typeable (i.e., encapsulated) or n*ontypeable* (i.e., unencapsulated). Typeable *H. influenzae* has six serotypes (a to f) that contain antigenically distinct capsular polysaccharides. Nontypeable *H. influenzae* are genetically distinct from encapsulated strains and lack this polysaccharide capsule, but they exhibit substantial genetic diversity within their population structure. They are genetically distinct from encapsulated strains.

Nontypeable *H. influenzae* is most frequently implicated in inflammatory diseases of mucosal surfaces, such as otitis media, sinusitis, and exacerbation of inflammation or infection in patients who have structural lung disease. These strains are usually noninvasive (i.e., does not enter the bloodstream), but may, on occasion, cause invasive disease.

Serotype b strains of encapsulated *H. influenzae* represent the most medically significant strain because they represent an invasive pathogen in humans. Other serotypes of *H. influenzae* have invasive capacity that is intermediate, between nontypeable and type b isolates

Colonization

With no other known natural host, *H. influenzae* is recovered exclusively from humans, nearly always from the respiratory tract. Organisms bind to mucin or directly to epithelial cells, and person-to-person spread occurs via airborne respiratory droplets or direct contact. Colonization with *H. influenzae* begins after birth with frequent acquisition and clearance of new nontypeable strains in the respiratory tract, and recurrent otitis media has been associated with this course of nasopharyngeal colonization during the first years of life.

Depending on how frequently and carefully one attempts to detect it, *H. influenzae* can be found in the upper airways of about 25% of healthy adults, 50% of adults with chronic lung disease, and 50% to 75% of toddlers.

Colonization has important medical implications in patients with structural lung diseases, such as chronic obstructive pulmonary disease (COPD) and cystic fibrosis (CF). Multiple nontypeable strains of *H. influenzae* are often found in the lower respiratory tract in CF or in exacerbations of chronic obstructive lung disease. Clinically recognizable infections are often associated with acquisition of a new strains.

Type b strains of *H. influenzae* colonized the nasopharynx of 2–3% of healthy children, prior to the widespread use of conjugate vaccine. This colonization is regularly followed by clinically significant infection.

Disease/Immunity

Pathogenesis begins with colonization of the respiratory tract by expression of adhesin molecules on *H. influenzae*. These adhesin molecules vary in prevalence and distribution among nontypeable strains and have their own specificities for host mucosal cell receptors. Nontypeable strains cause disease by local invasion of mucosal surfaces inducing host inflammation, and nontypeable strains have different genetically based pathogenic potential. For example, strains capable of causing otitis media have different genes capable of producing the disease state compared to strains that are found in asymptomatic colonizers. This is also true in the setting of structural lung disease.

Immunity to infection by nontypeable *H. influenzae* is not completely understood, but a well observed trait of noninvasive infections with these strains is their tendency toward recurrence (i.e., chronic otitis media, COPD exacerbations). This suggests that strain-specific immune response still leaves susceptibility to infection by other strains. Because nontypeable strains cause mucosal infections, mucosal immunity likely plays an important role in host defense, but this remains an area of active research.

Type b strains of *H. influenzae* can gain access to the bloodstream and cause invasive disease. Antibody directed at the type b capsular polysaccharide protects against invasive infections via complement-mediated bactericidal and opsonic activity. Studies from the pre-vaccine era showed that systemic disease in the human population most commonly occurred before 4 years of age, by which time most children had acquired lifelong immunity due to naturally acquired antibodies.

Clinical manifestations of nontypeable *H. influenzae* infection

Otitis media

Approximately 25% to 35% of all acute otitis media cases are caused by nontypeable *H. influenzae* although definitive diagnosis with tympanocentesis is not routinely performed due to its invasive nature. Acute otitis media is most common among children and infants. The classic clinical presentation of acute otitis media includes fever, ear pain, and irritability. Antecedent viral respiratory infection is very common. Since 2000, most infants in developed countries have received pneumococcal protein-conjugate vaccine, which coincides with an increased proportion of acute otitis media being attributed to nontypeable *H. influenzae*.

Features specific to nontypeable *H. influenzae* as the cause of acute otitis media demonstrate less virulence when compared to pneumococcal otitis media, such as a lower frequency of fevers and otorrhea. However, a history of recurrent episodes, treatment failure, conjunctivitis, and bilateral otitis media typically indicates nontypeable *H. influenzae* as the causative agent.

Recurrent, chronic otitis media has been associated with nontypeable *H. influenzae* forming biofilms, which represents a community of bacteria intertwined in a matrix attached to a surface. Biofilms are more resistant to clearance either by host mechanisms of defense or antibiotics.

Chronic obstructive pulmonary disease and exacerbation

H. influenzae is the most commonly implicated bacterial cause of exacerbations in COPD, as demonstrated through bronchoscopic sampling of the lower respiratory tract, analysis of immune response to *H. influenzae* insolated in cases of exacerbations, and correlation of airway inflammation with sputum bacteriology analysis. COPD exacerbations are often the result of newly acquired strains of nontypeable *H. influenzae* which reach the lower airways by aspiration, causing a vigorous inflammatory response. This interaction includes factors such as the virulence of the new strain, degree of host inflammatory response, and pulmonary function.

Community-acquired pneumonia

In older adults, especially those with structural lung disease or immunodeficiencies, nontypeable *H. influenzae* is an important cause of community-acquired pneumonia. With the high rate of vaccination against pneumococcal infection in both children and adults, *H. influenzae* may now appear in some settings to be the most commonly identified cause of bacterial pneumonia. Clinical features of *H. influenzae* pneumonia are indistinguishable from

other bacterial causes of pneumonia. Chest x-ray often reveals patchy or lobar infiltrates and sputum Gram stains typically show a predominance of small gram-negative coccobacilli.

Sinusitis

Previous studies have used sinus aspirate cultures to show that nontypeable *H. influenzae* is a common cause of maxillary sinusitis. Clinical features include fever, purulent nasal discharge, headache, and facial pain (or tooth pain in the upper molars in the case of maxillary sinusitis).

Neonatal and postpartum sepsis

Invasive biotype IV, nontypeable (unencapsulated) strains have been identified as a common cause of neonatal sepsis, postpartum sepsis, or both. These organisms are genetically similar to *H. haemolyticus,* and some authorities believe that they should be removed from the group of nontypeable *H. influenzae* and placed in their own species. Biotype IV, nontypeable strains have also been implicated in causing postpartum endometritis and tubo-ovarian abscesses.

Bacteremia (invasive disease)

The incidence of *H. influenzae* type b bacteremia has declined dramatically since the introduction of the protein conjugate *H. influenzae* type b vaccine, but the incidence of invasive disease with other serotypes of *H. influenzae* and nontypeable *H. influenzae* has increased. Nontypeable *H. influenzae* has occasionally been implicated in invasive disease, primarily in older adults with underlying conditions such as alcohol use disorder, cardiac disease, structural lung disease, HIV infection, and cancers. In such cases, morbidity and mortality are substantial. The source of infection in *H. influenzae* bacteremia is typically the respiratory tract.

Conjunctivitis

The most common bacterial cause of conjunctivitis in children is nontypeable *H. influenzae*, which can occur in outbreaks at schools and daycare centers. *H. influenzae* conjunctivitis is marked by purulent discharge and conjunctival hyperemia, which can occasionally become severe with copious purulent discharge, lid edema, chemosis, and keratitis.

Clinical manifestations of type b *H. influenzae* infection

Meningitis

Often preceded by an upper respiratory infection, meningitis represents the most serious manifestation of invasive infection with *H. influenzae* type b. Clinically, its presentation resembles other common causes of bacterial meningitis with fever and nuchal rigidity that, if untreated, rapidly progresses to encephalopathy, seizures, and coma. Infection occurs in children who have not been vaccinated or who cannot make IgG. Adult cases have always been rare because antibody to other bacteria, for example, encapsulated Enterobactereaceae, cross reacts with type b polysaccharide and are even more rare now because the organism is no longer commonly found in the population. But meningitis with non-typable *H. influenzae* serotypes can occur in adults with a history of head trauma, cerebrospinal fluid leak, neurosurgery, paranasal sinusitis, and otitis.

Meningitis in neonates has always been uncommon because maternal antibody is still present. When it occurs, it resembles group B streptococcal infection. Nuchal rigidity is often absent. The developemtn of a subdural effusion is a common complication that is often marked by a tense anterior fontanelle, seizures, hemiparesis, and neurologic deterioration. These symptoms typically develop despite adequate antibiotic therapy. In older children, papilledema and encephalopathy occur.

Even with appropriate management, permanent neurologic sequelae, especially deafness, occur in many survivors of *H. influenzae* meningitis.

Epiglottitis

Rapidly progressive cellulitis of the epiglottis with *H. influenzae* and subsequent acute respiratory obstruction of the supraglottic tissue is a medical emergency and a potentially lethal disease. Clinical features include sore throat, fever, dyspnea, dysphagia, pooling of oral secretions, and drooling from the mouth. A classic presentation is based on the patient's posturing with an upright position, extended neck, and chin protrusion in an attempt to reduce airway obstruction. Examination of the larynx should only be performed in a setting in which a secure airway can be achieved as examination maneuvers can lead to fatal respiratory obstruction.

Pneumonia/Empyema

Primary lung infection with *H. influenzae* type b occurs most frequently in children between ages 4 months and 4 years in either the winter or spring months. They often present with a consolidative pneumonia with occasional pleural involvement. A rare but important complication of *H. influenzae* type b pneumonia is the development of pericarditis, which can present as severe dyspnea, tachycardia, and cardiovascular failure.

Cellulitis

Cellulitis due to *H. influenzae* type b is most common among young children and is seen often in the periorbital region or on the cheek. Clinically, it is distinguished by fever, signs of inflammation, and a distinctive red-blue coloration with rapid progression over hours. Accompanying bacteremia is very common and secondary septic foci can develop.

Septic arthritis

Septic arthritis in children <2 years old can occur with *H. influenzae* type b and is seen most often in a single, large, weight-bearing joint. Decreased mobility, pain, and swelling are typical symptoms, and

positive blood and synovial cultures are common. Typically, response to antibiotics is rapid and curative, but residual joint dysfunction has been documented to occur in a subset of children.

Septic arthritis due to *H. influenzae* type b also occurs in adults and can occur in the setting of extra-articular infection, such as meningitis, pneumonia, sinusitis, and cellulitis. Alcohol abuse, underlying joint disease, lupus, diabetes mellitus, splenectomy, multiple myeloma, lymphoma, and common variable hypogammaglobulinemia have been identified as predisposing factors for the development of *H. influenzae* septic arthritis in adults.

It must be noted that all these diseases are now rare in developed countries because of the widespread adoption of conjugate vaccine in infants and toddlers.

Clinical manifestations of other typeable *H. influenzae*

Although type b *H. influenzae* has always been the best recognized and the most virulent of the *H. influenzae* isolates, non-b types a through f occasionally infect children and adults. Types a, e and f have been most commonly implicated. These non-b typeable strains cause the same range of infections as caused by *H. influenzae* type b. Disease affects seemingly immunologically normal hosts and, when it occurs, is of severity similar to that caused by *H. influenzae* type b.

Diagnosis

Nontypeable *H. influenzae*

Since nontypeable *H. influenzae* is a common colonizer of the human upper respiratory tract, determining its role as a pathogen can be challenging. Means of diagnosing otitis media, for example, typically involves invasive diagnostic measures with tympanocentesis. Because this procedure is reserved for difficult or treatment-refractory cases, treatment of otitis media is empiric, based on research studies that have implicated *Streptococcus pneumoniae*, nontypeable *H. influenzae*, and *Moraxella catarrhalis* as the most common pathogens isolated in middle ear fluid cultures.

In cases of COPD exacerbations and community-acquired pneumonia, the presence of numerous small Gram negative coccobacilli on microscopic examination of Gram-stained sputum, supported by isolation of *H. influenzae* by culture suggests the diagnosis.

Isolation of nontypeable *H. influenzae* in blood cultures indisputably signifies its presence as a pathogen and agent of invasive disease, but bacteremia is uncommon in patients with these infections.

Type b *H. influenzae*

Cultures from blood, cerebrospinal fluid, and other sterile fluids are typically diagnostic for invasive disease with *H. influenzae* type b and are confirmatory in a number of conditions, including meningitis, epiglottitis, cellulitis, and septic arthritis.

Detection of *H. influenzae* type b capsular antigen by immunoelectrophoresis, latex agglutination, or enzyme-linked immunosorbent assay can be diagnostic in serum, CSF, and urine. Antigen can also be found in pleural, pericardial, and joint fluid in the setting of infection with *H. influenzae* and can assist in diagnosis as it often persists even after antibiotic therapy has been initiated.

Treatment

Nontypeable *H. influenzae*

An important consideration in the treatment of suspected *H. influenzae* infections is that about 30% of nontypeable strains are β-lactamase producers. A recently recognized mechanism of resistance in *H. influenzae* is a mutation in the gene (fts 1 gene) coding for penicillin-binding protein 3. β-lactam penicillins, such as amoxicillin and ampicillin, should only be used in cases of confirmed susceptible isolates. Clinicians starting empiric treatment for conditions such as otitis media and exacerbation of COPD should select antimicrobial agents with activity against β-lactamase producing nontypeable *H. influenzae*, *Streptococcus pneumoniae,* and *Moraxella catarrhalis*. These include amoxicillin-clavulanate, third-generation cephalosporins, fluoroquinolones, macrolides (e.g., azithromycin), and tetracyclines.

Type b *H. influenzae*

Infection with *H. influenzae* type b can be rapidly fatal, and it requires swift diagnosis and treatment initiation. The favored regimen for *H. influenzae* type b infections in children and adults is cefotaxime or ceftriaxone. Treatment should be continued until the patient is afebrile and has resolution of signs and symptoms for 3 to 5 days with a total duration of treatment not exceeding 7 to 10 days. Complications of metastatic infection (e.g., pericarditis, endocarditis, osteomyelitis) will require more prolonged therapy.

In addition to antimicrobials and supportive care, corticosteroids are administered to patients diagnosed with *H. influenzae* type b meningitis for the first four days of treatment to reduce inflammation and subsequent neurologic sequelae resulting from the release of bacterial cell wall components during microbial killing.

Chemoprophylaxis for type b H. influenzae

Secondary cases (illness occurring within 60 days of contact with an infected patients) of *H. influenzae* type b disease are uncommon, but rates are highest among household contacts aged <12 months (6%), <24 months (3%), and <48 months (2.1%). Chemoprophylaxis with rifampin is recommended for index patients who did not receive cefotaxime or ceftriaxone as part of the treatment and all household contacts (except pregnant women) of an invasive *H. influenzae* type b case who live in a household with a child <4 years of age who has not received their age-appropriate number of *H. influenzae* type b vaccines or a child <18 years of age, regardless of their immunization status, who is immunocompromised.

Rifampin prophylaxis, given for 4 days, has been shown to eradicate the carrier state and significantly reduce secondary

cases in household members and close contacts. Sufficient exposure to warrant prophylaxis is defined as a susceptible host who is a household member or who has spent at least 4 hours each day with the index patient for at least 5 days within the week preceding hospitalization.

In a daycare or classroom setting, chemoprophylaxis is recommended when unimmunized or incompletely immunized children attend the facility and two or more cases of invasive *H. influenzae* type b have occurred within 60 days.

Chemoprophylaxis can be given in conjunction with treatment barring any drug–drug interactions. Chemoprophylaxis is not generally indicated for contacts of patients with invasive disease caused by nontypeable *H. influenzae*.

Vaccine

The primary strategy for preventing disease with type b *H. influenzae* is immunization. The vaccine is composed of type b capsular polysaccharide conjugated to a carrier protein, which induces serum antibody production against the capsule, provoking bactericidal activity against the organism. This vaccine is widely available and considered highly effective in reducing the circulation of type b strains and preventing nasopharyngeal colonization and invasive disease in infants and children. The widespread use of the conjugated vaccine has almost eradicated invasive *H. influenzae* type b disease among children <5 years of age in the United States.

Two conjugated vaccines are currently available in the United States, and all children should be immunized with a conjugated vaccine beginning at 2 months of age. After the series is completed, an additional booster dose is indicated between 12 and 15 months of age due to declining antibody titers. The most common adverse reactions are pain and swelling at the injection site. Serious adverse reaction to the vaccines are rare.

Localized populations with low vaccination rates facilitate the continued circulation of *H. influenzae* type b strains and thus careful surveillance in these populations remains important.

At this time, there are no available vaccines for nontypeable *H. influenzae* in the United States. However, studies in Europe are under way and a vaccine containing a conserved surface protein has shown partial efficacy in prevention of otitis media.

There are no vaccines available or under study for typeable strains other than type b due to the rarity of infection caused by these organisms.

Legionellosis

Thomas J. Marrie, Shelly McNeil, and Mark Robbins

Etiologic agents

The Order Legionellales includes the family *Legionellaceae* which, in turn, includes the genera *Legionella, Berkiella, Occultobacter*, and *Nucleophilum*, among others. Of these, members of the genus *Legionella* are the predominant human pathogens. The genus name *Legionella* ("body of soldiers") was derived from the fact that the first recognized outbreak of infection due to these microorganisms affected members of the American Legion in 1976. *Pneumophila* ("lung loving") was the species designation for the first isolate, given its predilection for pulmonary infection. There are now >60 species and >70 serogroups in the family *Legionellaceae*, and about half of these are known to be pathogenic in humans. The predominant pathogen in this family is *L. pneumophila serogroup 1* which accounts for 80% to 90% of cases of Legionnaires' disease (LD) worldwide (Box 139.1). However, *L. pneumophila* includes 16 serogroups in total, and a degree of regional variation is observed. Additionally, in Australia and New Zealand, *L. longbeachae* accounts for 30% of the cases. Legionellaceae are gram-negative, aerobic, non–spore-forming bacilli that measure 0.3 to 0.9 μm wide and 2 to 20 μm long. These organisms require special media for growth. Charcoal yeast extract agar buffered to pH 6.9 and containing α-ketoglutarate along with cefamandole, polymyxin B, and anisomycin to prevent growth of other microorganisms is the primary medium used for isolation of these organisms. Addition of α-ketoglutaric acid to the medium promotes growth of *Legionella* likely by stimulation of oxygen-scavenging enzymes.

These organisms are visualized poorly, if at all, by Gram stain. In tissue, silver impregnation stains such as the Dieterle or Warthin–Starry method allow visualization of the organisms.

The genome of *L. pneumophila* ranges in size from 3.34 to 2.52 MB. The GC content ranges from 86% to 88%, and 86% to 87% of the genes are coding genes. Three hundred virulence proteins, termed "effectors" are active in infection with this microorganism. Currently, the genomes of 38 *Legionella* spp. have been sequenced.

Epidemiology and pathogenesis

Legionellae are aquatic microorganisms and thus the epidemiology of infections due to these microorganisms is linked to water systems that are contaminated with these bacteria, with optimal water temperature for growth being 25°C/77°F to 42°C/107°F. Growth is supported by biofilm formation as well as symbiotic relationships with water-dwelling amoebae and other organisms. The earliest known outbreak of LD occurred in 1965, at St. Elizabeth's Hospital in Washington, DC. The outbreak that gave this illness its name and led to the isolation of the causative microorganism was associated with the 58th Annual Convention of the American Legion held at a hotel in Philadelphia from July 21 to July 24, 1976. One hundred and eighty-two of the attendees at the convention developed pneumonia. One hundred and forty-seven (81%) were hospitalized, and 29 (16%) died. This outbreak of pneumonia of apparent unknown cause triggered an

extensive epidemiologic and microbiologic investigation by the US Centers for Disease Control and Prevention (CDC), culminating in the isolation of a new microorganism, *L. pneumophila*, about 6 months later.

Legionellosis can occur as sporadic (endemic) cases or as outbreaks in the community or in healthcare facilities, and much has been learned about legionellosis through outbreak investigations. Outbreaks have varied in size from a few cases to the largest outbreak yet reported of 800 suspected and 449 confirmed cases in Murcia, Spain, in July 2001.

A study from Europe, from 2011 to 2015, indicated that there were 30,532 cases of LD there, with the majority of cases arising from France, Germany, Italy, and Spain. For cases with a reported probable setting of acquisition, 70.7% were reported as community-acquired, 19.9% as travel-related, and 7.3% as healthcare-related. The vast majority (90.1%) were reported as sporadic cases while 9.9% were cluster-related, with the largest clusters occurring in Portugal (433 cases), Spain (57 cases), and the United Kingdom (23 cases). The case fatality ratio decreased from 10.5% in 2011 to 8.1% in 2015, while the annual incidence increased from 0.97 cases/100,000 population in 2011 to 1.3 cases/100,000 population in 2015.

With the use of geographic information systems it has been shown that the dispersion distance of *Legionella* from a contaminated cooling tower is about 11.6 km. When data on 3,254 patients with LD reported to the CDC in the United States from 1980 through 1989 were analyzed, investigators found that disease rates were higher in northern states and during the summer. The mean age of patients with LD was 52.7 years compared with 34.7 years for the US population. In contrast to earlier reports, persons with LD were now more likely to be black. They were also more likely to be smokers, or have diabetes, cancer, AIDS, or end-stage renal disease. Indeed, the observed number of cases among patients with AIDS was 42-fold higher than expected. Twenty-three percent of the cases were nosocomially acquired. However the number of reported cases of LD in the United States increased 4.5-fold from 2000 to 2016. The reasons for this increase are multifactorial including increased testing and reporting. Climate change and an aging population likely play a role as well. The highest rates continue to be in Mid-Atlantic States, lowest in the western and south-central states. The rate of LD is higher in males than in females and higher in African Americans. The highest rates were in those ≥80 years of age at 4.7/100 000 compared with 0.4/100 000 for those <50 years of age.

Other risk factors for LD in the setting of an outbreak are cigarette smoking (relative risk 1.7 to 3.4) (smoking cannabis and tobacco may be a risk factor for severe LD) and consumption of three or more drinks of alcohol per day (confers a relative risk of 3.5). More recently investigators have begun to combine studies of traditional risk factors with a dissection of host susceptibility using molecular biology tools. A mutation leading to a stop codon at position 392 results in a dysfunctional Toll-like receptor (TLR) 5 protein unable to recognize flagellin and is a risk factor for *L. pneumophila* infection in nonsmokers. Reduced interferon-γ release has been noted in patients who have recovered from LD. A number of biological modifying agents used to treat cancer, autoimmune disease, and multiple sclerosis seem to increase the risk of LD. For example, treatment with infliximab results in a 15-fold increase in risk and adalimumab a 38-fold increase.

It is interesting in light of the preceding information about the role of cell-mediated immunity in LD that patients with HIV infection who have a defect in cell-mediated immunity are relatively infrequently infected with *Legionella* spp. This may be partially related to the efficacy of trimethoprim-sulfamethoxazole prophylaxis administered for *Pneumocystis* prophylaxis in the subset of patients with CD4 counts <200/mm^3 providing protection against *Legionella* as well. Recent prospective case-control studies have shown no differences in disease severity or outcome of LD in those with HIV infection compared to control populations.

Outbreaks provide an opportunity to learn about the mechanisms of transmission of LD. In most instances, *Legionella* is transmitted to humans by inhalation of aerosols containing the bacteria. Outbreaks have been associated with exposure to a variety of aerosol-producing devices, including showers, a grocery store mist machine, cooling towers, whirlpool spas, decorative fountains, and evaporative condensers. Other water sources implicated in transmission of LD include showers and spas in wellness centers, water on trains, birthing pools, dental units, asphalt paving machines, and windscreen wiper fluid without added screen wash. New reservoirs for *Legionella* continue to be identified, such as compost facilities. It is also likely that aspiration of contaminated potable water by immunosuppressed patients is a mechanism whereby infection with *Legionella* is acquired. Legionellosis is believed to occur worldwide, but data are limited or nonexistent for many countries. Legionellosis is uncommon in areas without hot water heaters and complex water distribution systems. However, even in these areas, aspiration of contaminated natural water, as, for example, following boating accidents, can result in LD. Contrary to popular belief

that person-to-person transmission does not represent a route of transmission for *Legionella*, a recent case report involving such a mechanism has been presented.

Pathogenesis

Our knowledge of the pathogenesis of *Legionella* infections in humans is still incomplete. The alveolar macrophage is the target cell for *Legionella* in the lower airways. Both E-cadherin and b_1 integrin receptors mediate filamentous *L. pneumophila* attachment to lung epithelial cells. Only virulent strains of *Legionella* are capable of initiating parasite-directed endocytosis. Following phagocytosis or endocytosis, there is abrogation of phagosome–lysosome fusion, which is essential for the intracellular growth of this microorganism. The replicative phagosome becomes associated with the endoplasmic reticulum.

Following a latent period of about 12 hours, the bacteria start dividing. During this latent period, there is synthesis of up to 35 proteins and repression of 32 proteins. Iron must be available in the phagosome for growth. Virulent *L. pneumophila* strains are sensitive to sodium chloride.

Once the replicative phagosome has been established, the bacteria begin to multiply with a doubling time of 2 hours. Heat shock protein 60 (Hsp 60), a chaperone protein, is a dominant protein during this intracellular phase, suggesting that it has an essential role in the viability of the microorganism. Several morphologic changes occur as the number of bacteria increase: they become shorter and accumulate intracytoplasmic membranes and vesicles.

It is likely that *Legionella* behave differently while multiplying in macrophages than they do while multiplying in amebae, their natural hosts. Because airborne amebae have been found in water aerosols, this finding may have implications for LD in humans.

Infectious syndromes

Pneumonia is the most common manifestation of infection with *Legionella* spp. It may occur in the community as sporadic cases or as outbreaks. Epidemiological studies have estimated that Legionella accounts for <10% of cases of community-acquired pneumonia. In addition, *Legionella* is one of the agents of healthcare-associated pneumonia, particularly in hospitals with known water colonization and in patients with various medical and surgical risk factors for microaspiration. There may be a variety of extrapulmonary manifestations, and sometimes the clinical picture is dominated by these.

In the Philadelphia outbreak, fever was present in 97% of the patients, malaise in 89%, cough in 86%, chills in 74%, dyspnea in 59%, myalgias in 55%, headache in 53%, chest pain in 52%, sputum production in 50%, and diarrhea in 41% at presentation. Sixty percent had a white blood cell count >10,000/mm^3, and 34% had bilateral pulmonary opacities on chest radiograph.

When patients with LD are compared with those with community-acquired pneumonia due to other agents, the patients with LD are more likely to have myalgias, headache, diarrhea, and a higher mean oral temperature at the time of presentation. They also present to hospital sooner after the onset of symptoms—4.7 days vs. 7.7 days (P = 0.02). When patients with LD were compared with patients with bacteremic pneumococcal pneumonia, the following features were associated with *Legionella* pneumonia: male sex (odds ratio [OR] 4.6; 95% confidence interval [CI] [1.48, 14.5]); heavy alcohol consumption (OR 4.8; 95% CI [1.39, 16.42]); previous β-lactam therapy (OR 19.9; 95% CI [3.47, 114.2]); axillary temperature >39°C (OR 10.3; 95% CI [2.71, 38.84]); myalgias (OR 8.5; 95% CI [2.35, 30.74]); gastrointestinal symptoms (OR 3.5; 95% CI [1.01–12.18]). Negative associations included pleuritic chest pain, previous upper respiratory tract infection, and purulent sputum.

In a study comparing the radiographic features of LD, pneumococcal pneumonia, mycoplasma pneumonia, and psittacosis, it was noted that radiographic deterioration following diagnosis was a particular feature of LD, occurring in 30/46 (65%) compared with 14/27 (52%) patients with bacteremic pneumococcal pneumonia. It should be pointed out that this study was done at a time when erythromycin was the standard therapy for LD. In general, several days were required before a therapeutic effect was evident with this agent. With current therapies the same degree of radiographic deterioration is unlikely. About half the patients with LD have unilateral pneumonic involvement throughout the course of their illness. The lower lobes are involved most commonly, and pleural effusions are seen in about 35% of cases. The severity of the radiographic findings correlated significantly with the presence of *L. pneumophila* in sputum by direct fluorescent antibody. Lung abscess, empyema, and bulging fissure sign are other radiographic features that are occasionally seen in patients with LD.

Relative bradycardia is seen in about two-thirds of patients with LD. Most patients appear acutely ill. Crackles are generally present on auscultation of the chest. Many experts feel that LD cannot be distinguished from other causes of pneumonia on the basis of clinical features. However, recent attempts at creating diagnostic scoring systems have shown promising results, although prospective validation is required prior to widespread clinical application

One of the remarkable things about LD is the range of extrapulmonary manifestations, which primarily reflect metastatic spread although cases of primary extrapulmonary infection have been reported. Although they occur in about 30% of patients, they can dominate the clinical picture and determine the outcome: there can be a variety of central nervous system manifestations. These include lethargy, confusion, delirium, stupor, coma, seizures, hallucinations, slurred speech, fine or coarse tremors, hyperactive reflexes, absence of deep tendon reflexes, and signs of cerebellar dysfunction, including nystagmus and gait disturbance. There is some evidence that the central nervous system manifestations of legionellosis are due to an autoimmune mechanism, and case reports indicate that treatment with high-dosage intravenous immunoglobulin is of benefit. Peripheral neuropathy and cranial nerve palsies, incontinence, or urinary retention are other manifestations. Myocarditis, pericarditis, and endocarditis have all been reported, albeit uncommonly, as extrapulmonary manifestations of LD. Acute

renal failure, tubulointerstitial nephritis, tubular necrosis, and rapidly progressive glomerulonephritis are renal manifestations of LD. Gastrointestinal manifestations include peritonitis, hepatitis, and pancreatitis. Rhabdomyolysis, reactive arthritis, septic arthritis, and osteomyelitis are uncommon musculoskeletal manifestations.

The clinical course of LD with currently available treatments seems to be different now than when erythromycin was the treatment of choice. This is exemplified by a study of 25 patients with LD who were treated with azithromycin. These patients were all diagnosed using an assay for *Legionella* urinary antigen, and thus early diagnosis (results are available in a few hours in contrast to several days for culture of the microorganism or weeks for a serologic diagnosis) may have accounted for the very favorable outcomes. Twenty-two of twenty-three evaluable patients were cured. At the 10-day follow-up, 45% had signs and symptoms, whereas at the 4- to 6-week follow-up period 35% had signs and symptoms. It is also apparent that different strains of *Legionella* may vary in virulence. Thus in the Murcia, Spain, outbreak involving 800 suspect and definite cases, the mortality was 1.1% for definite and 0.9% for suspect cases.

Pontiac fever

In July 1968, an explosive epidemic of acute febrile illness occurred at a county health department facility in Pontiac, Michigan. This self-limiting illness of 2 to 5 days' duration was characterized by fever, headache, myalgia, and malaise. It affected 144 persons. The mean incubation period was approximately 36 hours. Later it was shown that Pontiac fever was due to *L. pneumophila* endotoxin. There has been speculation that Pontiac fever is due to inhalation of free-living amebae that are commonly present in environmental sites containing *Legionella*. Subsequently many outbreaks of Pontiac fever have occurred. It has been associated with exposure to *L. pneumophila* serogroups 1, 6, and 7; *L. feelei*; *L. micdadei*; and *L. anisa*. Most commonly, exposure to contaminated whirlpools, cleaning evaporative condensers, and water fountains has resulted in Pontiac fever. The pathogenesis is still incompletely understood, although some investigators feel it is exposure to *Legionella* endotoxin that results in the symptoms. In support of this is the finding of high concentrations of *Legionella* endotoxin in contaminated water associated with Pontiac fever. One hundred and seventy people who had visited a hotel and leisure complex in Lochgoilhead, a village on the west coast of Scotland, became ill with headache, fever, arthralgia, myalgia, cough, and breathlessness. This illness was initially labeled "Lochgoilhead fever" but because *L. micdadei* was isolated from the whirlpool spa and 60 of 72 persons with symptoms seroconverted to *L. micdadei*, this likely represented Pontiac fever. An outbreak of Pontiac fever and legionellosis at a hotel in Oklahoma from March 15 to March 21, 2004, is instructive because the sensitivity and specificity of the *Legionella* urinary antigen test were 35.7% and 100%, respectively, and for serology 46.4% and 90%. Because the urinary antigen test detects *L. pneumophila* serogroup 1 lipopolysaccharide (endotoxin), this outbreak adds to the evidence that *Legionella* endotoxin is the cause of Pontiac fever. In the Oklahoma outbreak, 3 of 101 (2.9%) persons with Pontiac fever were hospitalized.

Nosocomial (healthcare-associated) Legionnaires' disease

Nosocomial LD continues to occur. In a 20 US state and large metropolitan area surveillance study there were 2,809 cases of LD, 553 (20%), of which were nosocomial. Sixteen of the 21 (76%) jurisdictions reported nosocomial cases which occurred at 72 facilities (15 hospitals and 58 long-term care facilities). The case fatality rate was 25% for definite cases and 10% for possible cases.

The clinical features of nosocomial LD are not different from those of nosocomial pneumonia due to any bacterium. Immunocompromised patients, especially those receiving corticosteroid therapy, are most susceptible to *Legionella* if it is contaminating the hospital water supply. Indeed, nosocomial LD is all about contamination of the hospital's potable water: if there is no *Legionella* in the potable water there are usually no cases of nosocomial LD. This has led to a debate about whether to conduct routine surveillance for *Legionella* in the potable water and, if it is found, eradicate it. However, there are those who maintain that if you do not have a problem with nosocomial LD you should not do routine surveillance. Having battled nosocomial LD for many years, my opinion (TM) is that all hospitals should carry out routine surveillance of their water for *Legionella*. If it is present, all cases of nosocomial pneumonia should be investigated for *Legionella*, and, if found, measures to control or eradicate *Legionella* from the hospital water supply should be taken (Box 139.2).

More recently some investigators have proposed that there is a risk of nosocomial LD if ≥30% of water samples are positive for *Legionella* spp. A review of available data suggests that this number has sensitivity of 59% and a specificity of 74%.

Immunocompromised patients should not drink the hospital water (if it is contaminated with *Legionella*) nor should they shower in it. Only sterile water should be used to flush nasogastric tubes. Occasionally unusual sources of nosocomial LD such as

BOX 139.2

Control of *Legionella* in hot water systems

1. **Physical measures**
   Maintain water temperature above 55°C
   Ultraviolet irradiation
   Sonication
   Terminal tap water filters
2. **Chemical measures**
   Prevent scale formation in the pipes
   Biocides: sodium hypochlorite, ozone
   Charcoal filters
   Copper–silver ionization
3. **Maintain good plumbing practices**
   Dead spaces in calorifiers should be removed
   Dead legs should be removed
   Regular flushing of outlets
   Pumps and calorifiers should be in series not in parallel

contaminated esophageal probes are found. The CDC has issued guidelines for the prevention of healthcare-associated pneumonia but has not made any firm recommendations on the measures outlined in Box 139.2 for eradication or control of *Legionella* in potable water. Copper–silver disinfection and point-of-use filters have proved effective in control of nosocomial LD in some institutions.

Diagnosis

A high index of suspicion is necessary for the diagnosis of sporadic cases of LD. Outbreaks of pneumonia usually trigger a workup for *Legionella* so these are easier to diagnose.

Isolation of the organism from respiratory secretions or other specimens is the definitive diagnostic test. Detection of *Legionella* antigen in urine by enzyme-linked immunosorbent assay is about 80% sensitive and >95% specific. This test is readily available for *L. pneumophila* serogroup 1. Diagnostic kits are also available for detection of antigens of *L. pneumophila* 1 to 6. Legionella antigen is excreted in the urine for days to weeks (rarely up to 1 year) after the onset of pneumonia. It should be noted that the antigen test positivity rate varies with the severity of the disease, being positive in 40% to 53% of mild cases and in 88% to 100% of severe cases. Despite these performance characteristics, diagnosis remains difficult as appropriate testing indications remain poorly established despite guidance being provided in the most recent Infectious Diseases Society of America (IDSA) community-acquired pneumonia guidelines. In fact, studies using the IDSA recommended testing indications showed that only 1.6% of indicated samples were positive for an overall sensitivity of 63% (95% CI [44%, 79%]) and specificity of 35% (95% CI [33%, 37%]), thus a high degree of clinical suspicion is needed for accurate diagnosis.

Demonstration of a fourfold rise in antibody titer between acute and convalescent serum samples using an indirect immunofluorescence whole-cell assay can also be used to diagnose LD. Up to 12 weeks may be required to demonstrate a fourfold rise in antibody, so serology is not useful for the acute management of this disease. A single or static titer of ≥1:256 is no longer considered satisfactory for the diagnosis of LD. Polymerase chain reaction (PCR) applied to respiratory secretions, pulmonary tissue, or pleural fluid is also useful and has a sensitivity of 83% (95% CI [79%, 87%]) and a specificity of 90% (95% CI [88%, 92%]). Culture has a sensitivity of 60%, and the direct fluorescent antibody test on a sputum specimen has a sensitivity of 67% (95% CI [30%, 91%]) and a specificity of 100% (95% CI [91%, 100%]). Loop-mediated isothermal amplification (LAMP) is a process similar to PCR but requires less equipment and shorter time for processing specimens. To date its use has been confined to environmental samples

Treatment

In the original outbreak of LD, it was observed that those who were treated with the macrolide erythromycin had a lower mortality rate than individuals who were treated with other antibiotics. Subsequently a newer macrolide, azithromycin, was shown to have a bactericidal effect in the guinea pig alveolar macrophage model, and it had a 5-day post-antibacterial effect when it was removed from the system, whereas erythromycin in the same model was bacteriostatic and had no post-antibacterial effect. These observations have been confirmed in clinical trials wherein 20 of 21 patients treated with azithromycin were cured (see Box 139.3).

It is noteworthy that because β-lactam antibiotics do not penetrate host cells they are ineffective in LD even though they show activity in vitro. Data from a prospective, nonrandomized study indicate that levofloxacin is superior to older generation macrolides for the treatment of severe LD. In this study carried out in Murcia, Spain, 3.4% of the patients receiving levofloxacin had complications compared with 27.2% of those receiving macrolides; the levofloxacin patients had a shorter length of stay (5.5 vs. 11.3 days). Addition of rifampin to levofloxacin provided no additional benefit. However,

BOX 139.3

Antibiotic treatment of Legionnaires' disease

1. Fluoroquinolones
   - Levofloxacin, 750 mg IV (PO for mild cases) once daily
   - Moxifloxacin, 400 mg IV or PO once daily (only available PO in most countries)
   - Ciprofloxacin, 750 mg IV or PO q12h
2. Macrolides
   - Azithromycin, 1 g IV or PO, as a loading dose and then 500 mg IV or
   - PO (due to the long half-life) of azithromycin; only 5 days necessary for treatment of mild cases; 7–10 days for more severe cases
   - Erythromycin, 1 g q6h IV; phlebitis is problematic at this dosage (unless infused through a central line); transient deafness, especially in patients who are receiving treatment with diuretics, also occurs at this dosage level
   - Clarithromycin, 500 mg q12h IV or PO (IV formulation not available in all countries)
3. Doxycycline, 200 mg loading dose, and then 100 mg q12h IV or PO
4. Rifampin, 300–600 mg q12h PO (IV formulation available in some countries). Rifampin should only be used in combination with a macrolide. There are no data supporting a synergistic role when it is used with other classes of antimicrobials. Recent data indicate that treatment with rifampin is associated with longer length of stay and higher bilirubin levels

For cases of mild to moderately severe disease in immunocompetent patients treatment for 7 days is usually sufficient. For immunocompromised patients, treatment for 21 days or longer may be necessary. In these instances individual decisions are necessary and are based on the underlying process that requires the immunosuppression, degree of immunosuppression, and response to therapy. Close follow-up is necessary once treatment is discontinued because relapse is not infrequent.

it should be noted that 33/76 of patients receiving a macrolide were treated with erythromycin; the remaining 43/76 were treated with clarithromycin, and none was treated with azithromycin. In a study of 139 cases of *L. pneumophila* pneumonia from a prospective series of 1,934 consecutive cases of community-acquired pneumonia, the overall mortality rate was 5%. Eighty patients received initial therapy with a macrolide and 40 with levofloxacin. Patients who received levofloxacin had a shorter time to defervescence (2 vs. 4.5 days) and to clinical stability (3 vs. 5 days). The complication rates were the same in both groups at 25%. The case fatality rate for those treated with levofloxacin was 2.5% versus 5% for those treated with macrolides ($p = 0.906$). The median length of stay was 8 days for the levofloxacin-treated group and 10 days for those who received macrolides ($p = 0.014$). Alternatively, two more recent retrospective cohort analyses which excluded patients receiving erythromycin, one with 410 and one with 3,152 adult patients with LD, found no differences between fluoroquinolones and azithromycin or clarithromycin in terms of mortality, length of stay, rates of *Clostridium difficile* infection, or total hospitalization cost. In a study of 33 patients admitted to an intensive care unit with LD, fluoroquinolone administration within 8 hours of intensive care unit arrival was associated with decreased mortality.

In a recent study from Spain, the authors compared monotherapy (11 patients treated with clarithromycin) to combination therapy with clarithromycin and rifampin (21 patients). All patients were cured; however, the patients who received rifampin had a 50% longer length of stay and a trend toward higher bilirubin levels. A review of the data on rifampin in LD led to the conclusion that it should be considered only for patients with severe disease or significant comorbid conditions including immunocompromised hosts and those refractory to conventional monotherapy regimens.

Many factors should be considered when deciding on the duration of therapy. Immune status and severity of the infection are probably the two most important factors. In mild to moderate cases of LD in immunocompetent subjects with a rapid response to therapy, a duration of 7 days is sufficient. Indeed in this setting a 5-day course of azithromycin, given its long half-life, is probably sufficient. In patients with severe disease and/or immunocompromised state, a 3-week course of treatment with either fluoroquinolones or macrolides (other than azithromycin) is necessary to avoid relapse. Careful follow-up of immunocompromised patients to identify relapse of infection early is necessary. One should also remember that in some patients with legionellosis polymicrobial infection may be present.

It is likely, given the small numbers of patients with LD, that we will never get evidence from randomized trials to guide our therapeutic choices, and we will have to depend on evidence such as summarized here. There are conflicting results from systematic reviews and meta-analyses on the role for adjunctive corticosteroids in adults admitted with severe community-acquired pneumonia. One such recent study including 1,506 patients from six trials and demonstrated a 30-day mortality rate of 5.0% in the group assigned to corticosteroids, and a mortality rate of 5.9% was observed in the group assigned to placebo ($p = 0.24$). However, time to clinical stability and length of hospitalization were each reduced by approximately 1 day in the group treated with corticosteroids ($p < 0.001$) Alternatively, a separate systematic review and meta-analysis demonstrated a reduction in overall mortality among adult patients with severe community-acquired pneumonia treated with corticosteroids (relative risk [RR] 0.39; 95% CI [0.20, 0.77]) along with decreased need for mechanical ventilation (RR 0.54; 95% CI [0.50, 0.58]), decreased likelihood or acute respiratory distress syndrome development (RR 0.24; 95% CI [0.10, 0.56]), and shorter duration of hospitalization (mean difference −1.00 days (95% CI −1.79, 0.21]) Discrepancies may relate in part to definitions of severe community-acquired pneumonia used as inclusion criteria.

Leprosy

Bahir H. Chamseddin and Travis Vandergriff

Epidemiology

Leprosy is an ancient disease that has been the cause of great morbidity and mortality for centuries. A 4,000-year-old skeleton with evidence of lepromatous leprosy was found in India, and DNA from the causative agent, *Mycobacterium leprae*, has been isolated from a Byzantine skeleton from Israel dated to 300–600 AD. More recent evidence has demonstrated cases of leprosy in England dating to approximately 400–500 AD. *M. leprae* is an unculturable, obligate intracellular, gram-positive, acid-fast bacillus (AFB). It multiplies very slowly in the host and grows best at 33°C/91.4°F, which accounts for its predilection for cooler parts of the body such as the skin, testis, anterior segment of the eye, mucous membranes of nasal passages, ear lobes, and extremities. A second, less common cause of leprosy, *M. lepromatosis*, is found in both the North America and Asia and has a predilection to infecting internal organs, thus implying growth at 37°C/98.6°F.

The origin of leprosy is unknown. One theory proposes that leprosy originated in a single clone in East Africa and then spread to Asia, the Middle East, Europe, and, by way of the slave trade, into West Africa. Recent evidence shows highly diverse strains of *M. leprae* in medieval Europe, suggesting a possible European origin for the disease. By all accounts, the disease is now endemic in a number of regions, mainly in Asia, Africa, South America, and the Pacific. It is especially prevalent in India and Brazil. India alone accounts for >50% of the global leprosy burden of disease. Isolated pockets of disease are found in many parts of the world, and, as a consequence of international travel, affected individuals may be encountered in any location. In the United States, infected patients may be found in any state, but most are in California, Hawaii, Florida, Texas, and Louisiana. Most cases encountered in the United States are seen in immigrants born in endemic regions; however, one-third of all patients in the United States acquire their disease without ever leaving the country.

The primary mechanism of transmission is thought to be via nasal inhalation of aerosolized organisms. *M. leprae* cannot breach intact skin. Armadillos are known to harbor *M. leprae*, and a number of cases have been traced to exposure to these animals in North and South America likely by exposure to the wild animals during hunting, consumption, or processing of armadillo meats. Polymerase chain reaction (PCR) studies indicate that nasal carriage of *M. leprae* can occur in persons without clinical evidence of infection and is transient. Serologic studies suggest that most people in endemic areas have been exposed to the organism, resulting in development of mucosal immunity that prevents progressive infection. However, transmission of the organism is likely to occur during subclinical infection. Very few exposed persons ultimately go on to develop clinical disease. The incubation period ranges from 9 months to 20 years. Risk factors for the development of clinically apparent leprosy include high bacterial load of the index case and close (household) contact with, and genetic relatedness to, the index cases. Genetic studies have identified abnormalities in innate and acquired immunity, increasing our knowledge of the genetic predisposition of some individuals to the disease. A locus within the gene *PARK2/PACRG* located on chromosome 6q25–q27 has been associated with susceptibility to leprosy, but the exact mechanism by which it exerts this influence is unclear. Global risk markers for development of the disease include increased age, poor sanitary and socioeconomic conditions, lower level of education, and food insecurity.

Pathophysiology

Much like tuberculosis, leprosy is a chronic infectious disease that develops as a consequence of both the host's immune reaction to *M. leprae* as well as from direct effects of bacillary spread and multiplication. Schwann cells infected with bacilli have been shown in mouse models to undergo reprogramming and transformation into progenitor/stem-like cells (pSLC). These reprogrammed cells promote bacterial dissemination by differentiation into other cell types, such as muscle, and later become incorporated into other body tissues. Those susceptible to infection demonstrate an impaired cell-mediated immune response to the organism. This is thought to result from a genetic predisposition because cases cluster in families, and there is a high concordance rate in identical twins.

M. leprae has a tropism for nerves that are then damaged as a consequence of immune response to intraneural bacilli as well as physical effects induced by proliferation of bacilli within the nerves. As a result, many of the clinical manifestations are due to peripheral nerve damage with loss of motor and sensory function leading to ulcers, contractures, and loss of tissue substance. Other tissues, such as the skin, may harbor innumerable organisms in some forms of the disease, and deforming cutaneous nodules may develop. Immune response to organisms in skin leads to severe forms of vasculitis with extensive cutaneous necrosis.

M. lepromatosis has been shown to heavily infect internal organs with evidence of AFB in the skin, liver, spleen, lymph nodes, bone marrow, kidneys, adrenal glands, and tracheal mucosa in patients with diffuse lepromatous leprosy. Clinical affliction by this newly discovered species is seen in nerve invasion, vasculitis, and panniculitis leading to skin ulceration and the reversal reactions related to the high AFB burden.

Classification and clinical presentation

There may be a number of different clinical presentations in patients with leprosy, depending on the level of immunity and the duration of the disease. Individuals with the early indeterminate form present with one or more scaly hypopigmented anesthetic macules of the skin appearing initially on the face, although the limbs, trunk, or buttocks may be involved. If untreated, this may progress to any form of the disease. Others present only with sensorimotor neuropathy with enlargement of the peripheral nerves without skin lesions. Nerves affected most commonly include the ulnar and median nerves, the common peroneal nerve, the posterior tibial nerve, and the facial and great auricular nerves. Other areas of the body, such as the nasopharynx, eyes, and testicles, may also be involved.

Classically, patients present with symptoms that can range from one polar form of the disease (tuberculoid) to another (lepromatous) or anywhere in between (borderline tuberculoid, borderline, or borderline lepromatous). Tuberculoid leprosy presents with a small number of asymmetric skin lesions that are hypopigmented, have well-demarcated borders, and are associated with anesthesia. Commonly, cutaneous nerves are enlarged and few bacilli are detectable on biopsy (paucibacillary form). Lepromatous leprosy presents as widely distributed symmetric skin lesions that can manifest as macules, papules, plaques, or nodules, which are red to brown (Figure 140.1). Biopsy shows dense granulomatous infiltrates and many bacilli (multibacillary form). Borderline cases may present anywhere between these two extremes.

The World Health Organization (WHO) schema is the most commonly used classification system and is based on the number of skin lesions and number of bacilli present in smears. Patients with five or fewer skin lesions without evidence of bacilli on skin smears are considered paucibacillary, whereas those with six or more skin lesions with or without bacilli on skin smears are considered to be multibacillary. Classification of patients into multibacillary and paucibacillary groups determines the duration of their treatment. Last, classification of disease can be ordered by level of disability, with grade 1 disability involving impaired peripheral sensation without visible impairments while grade 2 disability encompasses disease that has any visible impairments or physical deformities.

Leprosy in reaction refers to clinical disease produced when there is a change in the host's immune response to *M. leprae*. There are two forms of reactional leprosy. Type 1 reactions are induced by cell-mediated immunity and are referred to as *upgrading* and *downgrading* reactions. Upgrading reactions are characteristically seen in patients with borderline lepromatous disease who undergo a shift toward more tuberculoid (paucibacillary) forms. These may develop after induction of therapy. Downgrading reactions occur with transformation from a tuberculoid to a more lepromatous (multibacillary) form and often develop in the absence of treatment. Both may appear similar clinically and are manifest by erythema and edema of existing skin lesions associated with painful neuropathy and ulceration.

Type 2 reactions are immune complex–mediated and include erythema nodosum leprosum (ENL) and Lucio's phenomenon. Both of these are manifestations of immune complex–mediated vasculitis that lead to prominent inflammation and often ulceration with acute damage to nerves. Patients present with fever, multiple erythematous tender nodules, and varying degrees of neuritis, edema,

FIGURE 140.1 Lepromatous leprosy on the ear.

arthralgias, leukocytosis, iridocyclitis, pretibial periostitis, orchitis, and nephritis.

Patients infected with HIV do not have an increased incidence of leprosy, and coinfection with *M. leprae* and HIV appears to have minimal effect on the course of either disease.

Diagnosis

The diagnosis is primarily clinical and is based on the presence of one of three cardinal findings: hypopigmented or reddish patches with definitive loss of sensation, thickened peripheral nerves, and demonstration of AFB.

Definitive diagnosis of *M. leprae* is difficult because the organism cannot be cultured in vitro. The gold standard for the diagnosis of leprosy is a skin biopsy specimen obtained from the advancing edge of an active lesion and detection of bacilli in tissue sections using the Fite–Faraco staining method. The slit skin smear has a high specificity but a low sensitivity (10–50% of all leprosy patients are smear negative). Slit skin smears may be useful as an adjunctive procedure to semiquantitate acid-fast organisms in infected skin for monitoring the response of patients during and after treatment.

Serologic tests have been developed to detect IgM antibodies to phenolic glycolipid I (PGL-I), a glycolipid unique to *M. leprae*. Although individuals positive for PGL-I have approximately an eightfold risk for developing clinically apparent leprosy, it is not a useful screening test in the general population because a positive test does not necessarily predict development of the disease. A currently available enzyme-linked immunosorbent assay (ELISA) based on the LID-1 and ND-O antigens (ND-O-LID) is positive for most patients with multibacillary leprosy and has high sensitivity (95.7%) and specificity (93.2%); it has been suggested that it replace the slit skin smear test in cases of multibacillary leprosy.

Another major recent advance in the laboratory diagnosis of leprosy is the development of PCR assays that have reported specificity of 100% and a sensitivity ranging from 34% to 80% in patients with paucibacillary forms of the disease to >90% in patients with multibacillary forms of the disease.

Although the lepromin test is not used to establish diagnosis of leprosy, it can provide an indication of the immune response expected of the patient, especially in tuberculoid forms. It is accomplished by intradermal injection of 0.1 mL standardized suspension of heat-killed mycobacteria and waiting 3 to 4 weeks for a violaceous-erythematous papule to signify a cell-mediated immune response.

Treatment

Treatment depends on whether the individual has paucibacillary or multibacillary disease. Virtually all patients are treated with multidrug therapy with monthly supervision, as first implemented by the WHO in 1981 (Table 140.1); this regimen has been modified several times since then. Dapsone and clofazimine are weakly bactericidal when used alone, although they are mycobactericidal and kill >99% of bacilli when used in combination. Rifampin is highly bactericidal alone. No antileprosy drugs should be prescribed in isolation because of the likelihood of developing resistance. Administration of antibiotics renders the patient noninfectious in a matter of weeks.

TABLE 140.1 **WORLD HEALTH ORGANIZATION-RECOMMENDED DRUG THERAPY**

	Paucibacillary	Multibacillary
Monthly, supervised	600 mg rifampin	600 mg rifampin and 300 mg clofazimine
Daily, unsupervised	100 mg dapsone	100 mg dapsone and 50 mg clofazimine
Duration of therapy	6 mo	12 mo (6 mo)
Follow-up	2 yr	5 yr

Paucibacillary adult (children) patients (fewer than five lesions) receive a supervised dose of rifampin, 600 mg (450 mg) orally once per month for 3 months, and a daily unsupervised dose of dapsone, 100 mg (50 mg) orally for 6 months. At the end of 6 months, therapy is discontinued. Multibacillary patients receive a supervised dose of rifampin, 600 mg orally once monthly; a 300 mg dose of clofazimine; an unsupervised daily dose of dapsone, 100 mg orally; and a 50 mg daily oral dose of clofazimine for 12 months. A recent open label randomized controlled clinical trial featuring 600 patients with multibacillary leprosy showed no significant difference in reaction or disability outcomes after 6 months of treatment versus 12 months. Relapses may occur at a rate of 2.9 to 4.5 per 1,000 people per year but should be treated in the same manner as the initial disease, providing there is no drug resistance.

Where only a single lesion is present, the WHO recommends treatment with a single oral dose combination of rifampin, 600 mg, ofloxacin, 400 mg, and minocycline, 100 mg. The cure rate at 18 months of follow-up in patients receiving a single dose is slightly less than in those who receive 6 months of treatment (47% vs. 55%), and relapse rates appear to be slightly higher in these patients. However, the simplicity of this regimen and the fact that the overwhelming majority of these patients show clinical improvement makes this a feasible treatment option in the appropriate clinical context.

All patients are evaluated for relapse at least monthly. Most programs continue inspections for 5 to 10 years in all patients. Relapse rates vary between 1% and 3% in both paucibacillary and multibacillary patients. Patients should be instructed to recognize the signs and symptoms of recurrent disease as well as adverse reactions to medications. It may take up to 5 years for bacilli to be completely cleared in patients with multibacillary disease. Although many of the neurologic problems may be permanent, skin lesions usually disappear within 1 year of treatment, and reappearance of skin lesions is highly suggestive of relapse.

Major drug side effects are relatively uncommon with present regimens. Clofazimine may cause gastrointestinal symptoms and a purplish skin discoloration, both of which clear with discontinuation

TABLE 140.2 **RECOMMENDED TREATMENT OF REVERSAL REACTIONS**

	Type 1 reaction	Type 2 reaction (erythema nodosum leprosum, Lucio's Phenomenon)
Mild	Symptomatic	NSAIDs, symptomatic
Severe	40–60 mg prednisone	40–60 mg prednisone or 300 mg clofazimine (chronic) or 300–400 mg thalidomide
Duration	Slowly taper as tolerated	Slowly taper prednisone as tolerated Taper clofazimine to 100 mg in 12 months Taper thalidomide as tolerated to 100 mg, discontinue as soon as indicated

All patients should receive prednisone in the presence of neuritis.
Abbreviation: NSAIDs = nonsteroidal anti-inflammatory drugs.

of the drug. Dapsone often causes mild anemia, although severe anemia may result in patients with glucose-6-phosphate dehydrogenase deficiency, so all patients should be tested for this enzyme before initiation of therapy. Other side effects include agranulocytosis, cutaneous eruptions, peripheral neuropathy, gastrointestinal distress, and nephrotic syndrome. Rifampin rarely causes adverse effects but may cause orange discoloration of the urine, stool, and other body fluids. Pregnant women have safely taken dapsone and clofazimine, but experience with rifampin is limited.

Goals for the WHO Global Leprosy Strategy 2016–2020 include strengthening government ownership over healthcare surveillance and disease eradication, protection of vulnerable populations including children and underserved populations through early detection of disease, and ending social discrimination.

Treatment of reversal reactions

Reversal reactions occur in up to 25% of patients, usually during therapy. Early diagnosis and prompt treatment of reversal reactions is of great importance to prevent many of the deforming complications of leprosy (Table 140.2).

Mild reactions can be treated symptomatically; however, severe type 1 reactions with neuritis or silent neuropathy require prompt initiation of systemic glucocorticoid therapy, starting at a minimum dose of 40 to 60 mg of prednisone, tapering once the reaction is controlled. In patients with nerve damage from reactional leprosy that is present for 3 to 6 months, the response to therapy is <67%. When present for >6 months, the response to therapy is even poorer.

Mild to moderate type 2 reactions can be treated with nonsteroidal anti-inflammatory drugs and other symptomatic modalities. Severe ENL or the presence of neuritis requires prednisone (as prescribed in type 1 reactions). Clofazimine is useful for chronic reactions, and its use has been credited with the overall decrease of ENL in leprosy. Thalidomide, 300 to 400 mg orally, will suppress ENL within 48 hours and is considered the drug of choice for young men with severe ENL. Its high teratogenic potential has prevented its widespread use. Lucio's phenomenon is treated with systemic corticosteroids in addition to standardized antibacterial treatment, which should be continued during all reversal reactions. Azathioprine, methotrexate, and cyclosporine have been used to treat type 2 reactions; results have been mixed.

Meningococcus and miscellaneous neisseriae

Chuen-Yen Lau and Edmund C. Tramont

Meningococcal infection, first recognized more than two centuries ago as epidemic cerebrospinal fever, occurs worldwide as endemic sporadic cases with the potential to spread and expand into an epidemic. Humans are the only natural host for the bacteria. Transmission of the organism occurs from person to person by direct contact with colonized respiratory secretions or airborne droplets with subsequent colonization of the nasopharynx as part of its microbiome. Nasopharyngeal carriage approximates 5% to 15% in non-epidemic periods but may approach 50% to 95% during epidemics. The carriage rate is increased when there is crowding or close personal contact, such as in military barracks, dormitories, prisons, convocations, and indoor sporting events. Spontaneous loss and acquisition of oropharyngeal and nasopharyngeal carriage typically occurs over weeks to months, though colonization may be persistent in some persons. Sexual or oral-genital transmission of meningococci may result in anogenital carriage.

Meningococcal disease (e.g., bacteremia, meningitis) rates are highest in children <1 year of age, followed by a second peak in adolescence associated primarily with exposure to persons from different locations, as is common in college dormitories (Figure 141.1). The highest case fatality rates are associated with serogroup W (21%) and serogroup C (14%), and the highest mortality occurs in patients >85 years of age (~28%). With rare exceptions, invasive meningococci have a polysaccharide capsule that forms the basis for serogrouping of strains, and, except for serogroup B, is the principal bacterial antigen to which protective immunity develops (see later discussion). Invasive disease occurs almost exclusively in persons who lack specific bactericidal anti-meningococcal antibody. However, there are four situations where antibodies may not be protective: (1) individuals with complement component or properdin deficiencies are at an increased risk for developing invasive meningococcal infections because their serum lacks the capacity for complement-antibody–mediated lysis (bactericidal activity) of the meningococcal organism; hence, complement deficiency, most often of the terminal components, or properdin deficiency should be considered in persons with recurrent episodes of invasive meningococcal infection; (2) asplenic individuals are also at increased risk for suffering invasive meningococcal disease because of decreased efficiency of clearing of the encapsulated invading microorganisms from the blood; (3) on rare occasions, persons may develop serum immunoglobulin A (IgA) antibodies that block the bactericidal action of immunoglobulin G (IgG) and immunoglobulin M (IgM) antibodies; or (4) in persons who possess genetic upper airway surfactant protein mutations that result in an impaired local first-line innate immune defense. All of these individuals should be periodically vaccinated to maintain as high a titer of anti-meningococcal antibodies as possible.

Clinical features

As with most other invasive gram-negative bacteria, the clinical consequences of meningococcal infection are primarily the result of meningococcal endotoxin (lipopolysaccharide) release and subsequent activation of the procoagulation, anticoagulation, fibrinolysis, complement, and kallikrein–kinin cascades resulting in the excessive release of various inflammatory mediators ("cytokine storm"). The clinical manifestations of meningococcal infection range from a clinically mild transient bacteremia to fulminant meningococcemia,

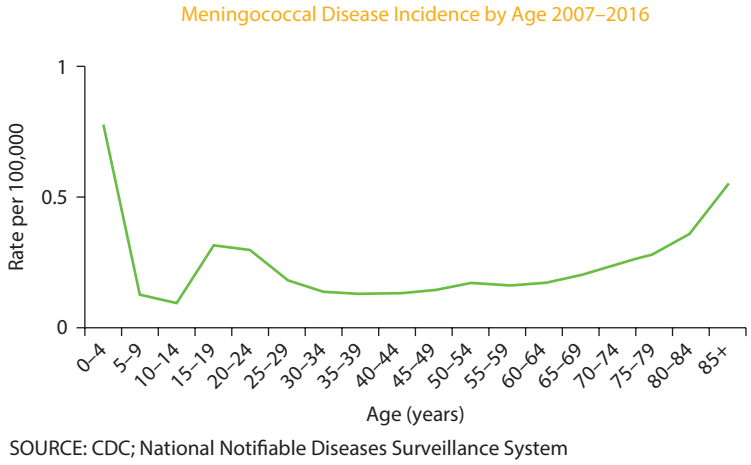

FIGURE 141.1 Rates of meningococcal disease by age group.

also referred to as *Waterhouse–Friderichsen syndrome* or *purpura fulminans* (Figure 141.2), with or without concurrent bacterial meningitis. Unless treated within hours of presentation, the mortality rate of the latter is high.

Most often, *Neisseria meningitidis* acquisition results in asymptomatic colonization of the nasopharynx and oropharynx as part of their respective microbiomes. The mildest form of invasive disease, a transient bacteremia, begins insidiously with fever, malaise, and symptoms of an upper respiratory tract infection. A few petechial skin lesions may appear, but neither signs nor symptoms of sepsis or meningitis develop. Signs and symptoms usually resolve spontaneously within 24 to 48 hours. However, the transient bacteremia may progress to acute meningococcemia heralded by fever, chills, malaise, weakness, headache, myalgias, nausea, and/or vomiting when the victim lacks functional bactericidal antibody for whatever reason.

Skin manifestations, especially a petechial rash (Figure 141.3), raise the index of suspicion for invasive meningococcal infection. The rash commonly appears in crops on the ankles, wrists, axilla, arms, legs, trunk, and mucous membranes, whereas the palms, soles, neck, and face are usually spared. The rash may also be urticarial, maculopapular, ecchymotic, or gangrenous depending on the degree of vascular pathology. In severe invasive meningococcal disease, the rash rarely fails to develop. Fulminant meningococcemia complicates acute meningococcemia in 5% to 15% of cases and is usually associated with the rash progressing into massive skin and mucosal hemorrhage, disseminated intravascular coagulopathy (DIC), and vascular collapse (Waterhouse–Friderichsen syndrome). Adrenal hemorrhage may occur despite appropriate antibiotic therapy.

Meningitis usually occurs along with the manifestations of meningococcemia but not always. Clinically, meningococcal meningitis resembles acute meningitis of any cause, presenting with fever, headache, altered sensorium/cognition, and nuchal rigidity. Painful myalgias may be a discriminating feature. *N. meningitidis* is now the most common cause of meningitis among children >6 months of age and young adults.

On rare occasions, a chronic meningococcemia develops. This is characterized by intermittent febrile episodes, lasting 2 to 10 or more days, accompanied by a variety of skin lesions (macular, maculopapular, petechial, ecchymotic, or pustular), arthralgias or arthritis, myalgias, and splenomegaly. This manifestation may last for months and is sometimes fatal, but it usually resolves spontaneously. Occasionally, *N. meningitidis* may cause oropharyngitis,

FIGURE 141.2 Purpura fulminans (Waterhouse–Friderichsen syndrome or severe ecchymotic rash).

FIGURE 141.3 Petechial rash lower extremity.

sinusitis, pneumonia, conjunctivitis, endophthalmitis, proctitis, urethritis, cervicitis, immune-mediated arthritis, endocarditis, myocarditis, pericarditis, or pelvic inflammatory disease (PID). As may develop with other infections, general nonspecific helpful laboratory abnormalities include an elevated white blood cell count, C-reactive protein, and/or procalcitonin levels.

Culture and laboratory findings

N. meningitidis is an aerobic, oxidase-positive, gram-negative diplococcus (coffee bean shape) that grows best at 35°C/95°F to 37°C/98.6°F in a moist environment of 5% to 7% carbon dioxide (candle jar). The gold standard for diagnosis of systemic meningococcal infection is the isolation of *N. meningitidis* by culture from a usually sterile body fluid such as blood and/or cerebrospinal fluid (CSF) (most common), or synovial, pleural, or pericardial fluid. For culture of a normally sterile site, nonselective culture media are standard but a selective antibiotic-containing culture medium, such as Thayer–Martin, Martin–Lewis, or New York City culture medium, is necessary to reduce the overgrowth of commensals when the culture specimen is obtained from a nonsterile site such as the oropharynx, urethra, vagina, or rectum.

In meningococcal meningitis, the frequency of positive blood cultures is 50% to 60%, and the frequency of positive CSF cultures is 80% to 90%. Isolation of the organism by culture not only confirms the etiology but also allows antibiotic susceptibility testing, which has become important in light of increased antibiotic resistance, especially to the penicillins. Gram stain and culture of a skin lesion can increase the diagnostic yield, although a negative result does not exclude *N. meningitidis*. A number of rapid point-of-care diagnostic tests (RDTs) are also available, ranging from PCR to simple dipstick and agglutination tests.

Chemistry and cytologic findings suggestive of bacterial meningitis include a CSF glucose concentration of <45 mg/dL (2.5 mmol/L), a protein concentration >500 mg/dL, and a white cell count >1,000/μL. The CSF is generally cloudy with a leukocytosis consisting predominantly of polymorphonuclear neutrophils associated with hypoglycorrhachia. However, one or more of the classic findings is often absent in meningococcal meningitis. The Gram stain of the CSF is positive in about 75% of cases (Figure 141.4). Although non-specific, elevated serum white blood cell count, C-reactive protein, and procalcitonin level may inform management.

N. meningitidis is serogrouped based on the distinct chemical composition of its polysaccharide capsule. The meningococcus has been classified as serogroups A, B, C, D, 29E, H, I, J, K, L, W (W-135), X, Y, Z, and nontypeable (indicates organism is nonencapsulated). Serogroups A, B, C, W, and Y are responsible for the vast majority of cases of invasive disease. With rare exceptions, invasive meningococci are encapsulated, attesting to the virulence conveyed by the polysaccharide capsule. In contrast, meningococci colonizing mucous membranes are usually not encapsulated.

Commercial latex agglutination kits, which can also be used on body fluids such as CSF and urine, utilize latex beads coated with antibodies to meningococcal capsular antigens to detect five capsular types: A, B, C, Y, and W, but the sensitivity for serogroup B is relatively low.

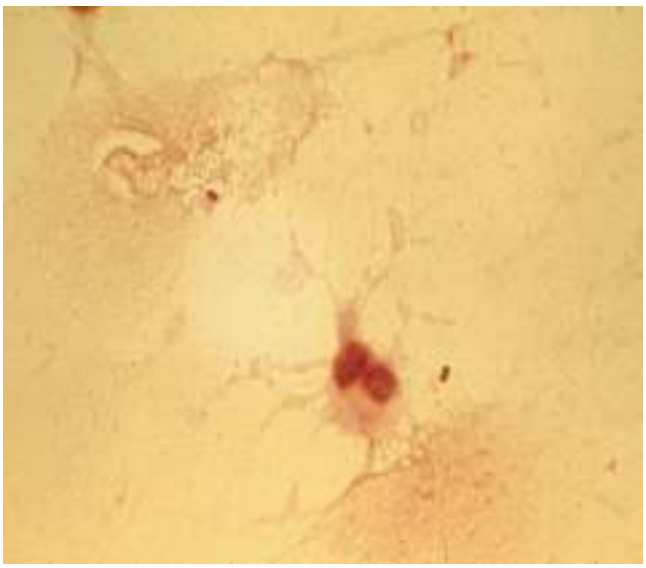

FIGURE 141.4 Gram stain of cerebrospinal fluid (CSF): note gram-negative diplococci and polymorphonuclear leukocyte.

A number of RDTs are available, ranging from PCR to simple dipstick and agglutination tests. Advantages of these tests over culture are rapidity, reliability in the setting of concomitant antibiotics, and, in the case of PCR, simultaneous testing for infection due to *N. meningitidis, Streptococcus pneumoniae, Haemophilus influenzae*, *Escherichia coli, Listeria monocytogenes, Streptococcus agalactiae*, cytomegalovirus (CMV), Enterovirus, herpes simplex (HSV-1, HSV-2), human herpesvirus (HHV-6), human parechovirus, varicella-zoster virus (VZV), or *Cryptococcus neoformans/gatii* (Biofire ME, Utah).

Therapy

Ceftriaxone is the drug of choice for meningococcal disease. Because of the potential for rapid progression, ceftriaxone therapy should be administered within 30 minutes of considering the diagnosis of meningococcal meningitis and is administered intravenously (IV), at least initially. Infected persons should receive 2 g IV every 12 hours for at least 7 days. Those who are β-lactam-allergic should receive chloramphenicol. Chloramphenicol- and ceftriaxone-resistant isolates have been encountered but are rare. Although use of penicillin G has been limited since reports of resistance in the late 1980s, meningococcal meningitis is very responsive with penicillin G once the isolate is proved to be penicillin susceptible (minimum inhibitory concentration [MIC] <0.1μg/mL). Seven days of therapy is usually sufficient but may be lengthened based on clinical judgment regarding the severity of illness, patient response, or if testing demonstrates reduced sensitivity to the selected regimen (Table 141.1).

Since exact etiology is typically unknown upon presentation, initial treatment must cover potential causes of meningitis beyond *N. meningitidis*. Empiric antimicrobial therapy is usually given for cases

TABLE 141.1 **TREATMENT OF MENINGOCOCCAL MENINGITIS**

Antibiotic	Scenario	Dosing	Comment[a]
Ceftriaxone	Preferred treatment	Adults: 2 g IV q12h Children: 100 mg/kg IV (up to 4 g) in 1–2 doses per day	Good CNS penetration
Chloramphenicol	ß-lactam allergy, preferred alternative	Adults: 12.5 mg/kg IV (up to 6 g/d) q6h Children: 75–100 mg/kg IV (up to 2–4 g/d) in 1–2 doses per day	Concentrates in CSF; potential to cause irreversible aplastic anemia; rare resistance
Meropenem[b]	Alternative	Adults: 2 g IV q8h	Limited data for use in children
Moxifloxacin[b,c]	Alternative	Adults and adolescents with skeletal maturity: 400 mg q24h	Resistant isolates have been encountered
Penicillin G	Penicillin MIC <0.1 μg/mL	Adults: 300 000 U/kg/d IV divided q4h Children: 250 000–300 000 U/kg/d IV divided q4h	Limit 24 million U/d; penicillin resistance has been reported since 1988

[a] Treatment is 7 days, but may be extended based on clinical scenario or if the organism is not fully sensitive to the selected regimen.
[b] Option for ceftriaxone-, penicillin-, and other β-lactam-allergic patients.
[c] Other quinolones have been successful.
Abbreviations: MIC = minimal inhibitory concentration; CNS = central nervous system; CSF = cerebrospinal fluid.

of presumed bacterial meningitis based on age and immune status. For immunocompetent infants <1 month of age, empiric treatment is chosen to cover group B streptococcus, *Escherichia coli* and *Listeria*. For immunocompetent patients between 1 month and 2 years of age, *Streptococcus pneumoniae, N. meningitidis, Streptococcus agalactiae, Haemophilus influenzae*, and *Escherichia coli* should be considered. From 2 to 50 years of age, *N. meningitidis* and *S. pneumoniae* are the predominant organisms. For patients older than 50 years, *S. pneumoniae*, *N. meningitidis*, *Listeria,* and aerobic gram-negative bacilli are covered. Of note, infections with *S. pneumoniae, N. meningitidis,* and *H. influenza* have significantly decreased with increased vaccine coverage.

Without a specific etiologic diagnosis, immunocompetent persons between 1 month and 50 years of age should receive initial empiric antimicrobial therapy with a broad-spectrum cephalosporin antibiotic, especially ceftriaxone or cefotaxime, plus vancomycin. Meropenem may be substituted for the cephalosporin if neither cefotaxime nor ceftriaxone can be administered. Dexamethasone may be added when neurologic deficits and sequelae of inflammation are of concern. Although dexamethasone has not been shown in prospective studies to be of benefit in meningococcal meningitis, it is often added during empiric therapy to reduce central nervous system inflammation, which is of particular concern with *S. pneumoniae*.

Supportive care is extremely important in all cases of meningitis. Potential complications such as purpura fulminans, DIC, acute respiratory distress syndrome (ARDS), neurocognitive sequelae, myocardial involvement, volume depletion, acidosis, and adrenal insufficiency should be anticipated. The mortality rate remains approximately 10% to 15%.

Long-term sequelae include hearing loss, other cranial palsies, and cognitive dysfunction. Treatment of myocardial failure can help to ameliorate pulmonary edema and poor peripheral perfusion. Adjunctive steroid therapy is indicated when acute adrenal insufficiency is a possibility, especially when the patient has progressed into the Waterhouse–Friderichsen syndrome or is obtunded. The primary treatment of DIC is aimed at the underlying cause, in this case *N. meningitidis*. Protein C concentrate has been investigated as a potential strategy to treat coagulopathy and purpura fulminans.

Prevention

Methods of prevention for meningococcal infection include respiratory droplet precautions, disease surveillance, antimicrobial chemoprophylaxis after identification of an index case, and vaccination prior to possible exposure and during outbreaks. Routine immunization is now recommended for young adults in addition to specific high-risk groups (see "Vaccine immunoprophylaxis"). Most often, *N. meningitidis* is harbored in the nasopharynx and/or oropharynx as a commensal in asymptomatic carriers. The organism is spread through direct contact, especially respiratory droplets. The risk of contracting a symptomatic *N. meningitidis* infection is approximately 4 cases per 1,000 among persons who have had "close contact" with a known carrier or patient with a virulent strain (defined as causing invasive disease). Close contacts are defined as persons living in the same household, dormitory, or barrack; attending a daycare center; handling clinical specimens or cultures; or anyone who has spent >4 hours with the index case from 10 days prior to the onset of illness through 24 hours after initiation of appropriate antibiotic therapy. This is to cover the 1- to 10-day incubation period for groups such as airline passengers, cruise shipmates, nursing home residents, and healthcare workers (Box 141.1).

Antimicrobial chemoprophylaxis

The risk of developing secondary invasive disease after exposure to a close contact is greatly diminished by chemoprophylaxis: administering prophylactic antibiotics to individuals who have had

BOX 141.1

Considered close contact of an index case

All household members
Daycare and preschool classmates, attendees, and workers
Healthcare workers with contact with oral and/or respiratory secretions from the index case
Workers and classmates in boarding schools or camps
Living in a common military barrack
Sharing an aircraft or boat cabin, especially if sitting next to the index case
Cruise shipmates with >4 hours contact with the index case
Laboratory workers handling culture from an index case

close contact to an index case (e.g., dormitory, barracks, living in the same house, prison, etc.). Antibiotics should be administered as early as possible, ideally within 24 hours of identification of the index case. Chemoprophylaxis >14 days after exposure is not necessary unless re-exposure occurs. Since pharyngeal cultures of the exposed individual are not helpful for determining the need for prophylaxis, obtaining cultures should not delay administration of prophylactic antibiotics.

Ceftriaxone, rifampin, and ciprofloxacin are used for chemoprophylaxis. Azithromycin may be used as an alternative. However, ciprofloxacin-resistant meningococcus has been reported. Furthermore, ciprofloxacin is not recommended for people <18 years or age or pregnant or lactating women due to risk of cartilage damage. Also rifampin is not recommended during pregnancy, and drug interactions must be considered (Table 141.2).

Vaccine immunoprophylaxis

Several meningococcal vaccines are now available. Menactra (MenACWY-DT) is a quadrivalent meningococcal polysaccharide vaccine conjugated to diphtheria toxoid. Another quadrivalent meningococcal polysaccharide vaccine conjugated to a mutant diphtheria toxin, Menveo (MenACWY-CRM), is also available. Nimenrix (MenACWY-TT), a quadrivalent meningococcal polysaccharide conjugated to a tetanus toxoid carrier, is available outside the United States. Two meningococcal serogroup B vaccines are now available in the United States; Trumemba (MenBFHbp) and Bexsero (MenB4C), respectively, for individuals 10 through 25 years of age. The major challenge in the development of the meningococcal serogroup B polysaccharide vaccine has been that the serogroup B polysaccharide is a poor immunogen because it is similar to human intracellular adhesion molecules. Hence, the sero-group B vaccines are based on non-capsular antigens, principally outer membrane proteins.

Meningococcal serogroup C vaccines Meningitec and NeisVacC are used in Canada, the United Kingdom, and other countries. Serogroup A vaccines MenAfriVac and PsA-TT are used in Africa. The MenHibrix/HibMenCY combination conjugate vaccine against meningococcus serogroups C and Y and *H. influenzae* type b was discontinued in 2017. The quadrivalent meningococcal polysaccharide vaccine Menomune was also discontinued in 2017.

In the United States, meningococcal vaccination against serogroups A, C, W, and Y is appropriate for persons 11 to 18 years old and 19 to 21 if starting college and living in a dormitory. Serogroup B vaccination should also be given to patients in these age groups, Vaccination against serogroups A, C, W, and Y is also indicated for patients with HIV and people traveling to or residing in endemic countries (Nepal, India [New Delhi], Mecca, and the "meningitis belt" of sub-Saharan Africa, which stretches from Senegal in the west to Ethiopia in the east). Those with prolonged increased exposure risk such as military recruits should be vaccinated against serogroups A, C, W, and Y as well as serogroup B. For patients with persistent complement component deficiencies, functional or anatomic asplenia, and individuals present during outbreaks, the following guidelines apply: children <10 should be vaccinated against serogroups A, C, W, and Y; those >10 years should be vaccinated against serogroups A, C, W, and Y as well as serogroup B. Specific schedules depend on age, host factors, geography, social circumstances, and prior history of vaccination. Select detailed recommendations are presented (Table 141.3).

TABLE 141.2 **ANTIBIOTICS USED FOR CHEMOPROPHYLAXIS OF *NEISSERIA MENINGITIDIS***

Antibiotic (route)	Age group	Dose	Duration	Comments
Ceftriaxone (IM)	Children <15 years	125 mg	Once	A regimen of choice
	Older children and adults	250 mg		
Rifampin (oral)	Children <1 month	5 mg/kg q12h	2 days	A regimen of choice
	Children ≥1 month	10 mg/kg q12h		Not recommended for pregnant women
				May reduce reliability of oral contraceptives
	Adults	600 mg q12h		Causes reddish-orange discoloration of bodily fluids
Ciprofloxacin (oral)	Adults	500 mg	Once	Not recommended for persons <18 years or pregnant/lactating women
				Can be used in children if no alternative available
Azithromycin (oral)	Children <15 years	10 mg/kg 500 mg	Once	Not routinely recommended
	Children >15 years			May be used in areas with ciprofloxacin resistance

TABLE 141.3 **VACCINATION RECOMMENDATIONS IN THE UNITED STATES FOR SELECT RISK GROUPS**

Risk group	Vaccine	Series/regimen
11–18 yo	• Menactra or Menveo (Quadrivalent ACWY vaccines) • Consider Trumemba or Bexsero (Serogroup B vaccines)	1 dose at age 11–12, booster at age 16. If 1st dose at age 13–15, booster at 16–18 years. Prefer administration from 16–18 years, but can be given up to 23 years.
19–21 yo and 1st year college in dormitory	• Menactra or Menveo (Quadrivalent ACWY vaccines) • Consider Trumemba or Bexsero (Serogroup B vaccines)	1 dose if has not yet received. Booster if prior dose given before age 16 Prefer administration from 16–18 years, but can be given up to 23 years.
HIV <2 years	• Menactra or Menveo (Quadrivalent ACWY vaccines)	4 doses of Menveo at 2, 4, 6, and 12 to 15 months 2 doses of Menactra at 9 to 23 months, 12 weeks apart Boost 3 years after primary series and then q5yrs
HIV >2 years	• Menactra or Menveo (Quadrivalent ACWY vaccines)	2 doses, 8–12 weeks apart If most recent dose before age 7, boost q3ys and then q5yrs. If ≥7, boost q5yrs
Prolonged exposure risk	• Menactra or Menveo (Quadrivalent ACWY vaccines) • Trumemba or Bexsero (Serogroup B vaccines)	1 dose, boost q5yrs 3 doses of Trumenba at 0, 1 to 2, and 6 months or 2 doses of Bexsero at least 1 month apart

Additional recommendations are available from the Advisory Committee on Immunization Practices (ACIP) for people visiting or residing in endemic regions, present during an outbreak, with persistent complement component deficiency, and functional or anatomic asplenia, including sickle cell disease.

As with the other polysaccharide-based vaccines, *H. influenzae* and *S. pneumoniae*, there is concern that vaccination could lead to an increased incidence of non-vaccine serotypes. Replacement by other serogroups has not yet materialized in the case of meningococcus.

Eculizumab

Treatment with eculizumab, a monoclonal antibody inhibitor of terminal complement used for complement-mediated hemolytic uremic syndrome and paroxysmal nocturnal hemoglobinuria, is associated with a 1,000- to 2,000-fold increased risk of meningococcal disease. Patients receiving eculizumab are candidates for both vaccination and chemoprophylaxis. They should undergo vaccination against serogroups A, C, W, and Y as well as serogroup B at least 2 weeks prior to starting eculizumab if possible. Daily chemoprophylaxis with penicillin may be used during eculizumab treatment. Penicillin-allergic patients may alternatively use azithromycin.

Infections with non-pathogenic *Neisseria* species

The nonpathogenic *Neisseria* species (*N. bacilliformis, N. lactamica, N. sicca, N. flava, N. subflava, N. mucosa, N. flavescens, N. cinerea, N. macacae, N. elongata*, and *N. polysaccharea*) are usually commensals of the oropharynx and nasopharynx. Infections caused by these organisms are extremely rare, occurring primarily in immunosuppressed hosts, especially those who are hypogammaglobulinemic or have defective antibody production (i.e., chronic lymphocytic leukemia). The relative lack of virulence of these organisms is attributed to the absence of encapsulation, and hence they have no predilection to resist bacterial lysis by nonspecific components of the blood or to invade the meninges. Thus they are easily controlled by normal innate host defense mechanisms.

Because these organisms are normally part of the microbiome, local extension occurs most often as part of a mixed infection, most commonly to the ear, sinuses, and lung. Conjunctivitis, meningitis, endophthalmitis, endocarditis, and urethritis have also been reported, attesting to the common tissue tropism that these sites share with the nasopharynx. These nonpathogenic *Neisseria* are easily treated with penicillin, cephalosporins, or quinolone antibiotics.

Listeria

Bennett Lorber

Introduction

Listeria monocytogenes is an infrequent cause of illness in the general population, but, in certain groups, including neonates, pregnant women, elderly persons, and those with impaired cell-mediated immunity, whether due to underlying disease or immunosuppressive therapy, it is an important cause of life-threatening bacteremia and meningoencephalitis. Increasing interest in this organism has arisen from concerns about food safety following lethal foodborne epidemics.

Microbiology

Listeria monocytogenes is a small, facultatively anaerobic, nonsporulating, catalase-positive, oxidase-negative, gram-positive rod that grows readily on blood agar, producing incomplete β-hemolysis. It possesses polar flagellae and exhibits a characteristic tumbling motility at room temperature (25°C). Optimal growth occurs at 30°C to 37°C, but, unlike most bacteria, *L. monocytogenes* also grows well at refrigerator temperature (4°C to 10°C), and, by so-called cold enrichment, it can be separated from other contaminating bacteria by long incubation in this temperature range. Selective media are available to isolate the organism from specimens containing multiple species (food, stool) and are superior to cold enrichment.

In clinical specimens, the organisms may be gram variable and may look like diphtheroids, cocci, or diplococci. Routine growth media are effective for growing *L. monocytogenes* from normally sterile specimens (cerebrospinal fluid [CSF], blood, joint fluid), but media typically used to isolate diarrhea-causing bacteria from stool cultures inhibit listerial growth. Laboratory misidentification as diphtheroids, streptococci, or enterococci occurs all too often, and the isolation of a "diphtheroid" from blood or CSF should always alert one to the possibility that the organism is really *L. monocytogenes*.

Seven listerial species are recognized (*Listeria monocytogenes*, *Listeria seeligeri*, *Listeria welshimeri*, *Listeria innocua*, *Listeria ivanovii*, *Listeria grayi*, and *Listeria marthii*), but *L. monocytogenes* is almost exlusively responsible for human infection. There are at least 13 serotypes of *L. monocytogenes*, based on cellular O and flagellar H antigens, but almost all disease is due to types 4b, 1/2a, and 1/2b, limiting the utility of serotyping for epidemiologic investigations. A number of newer molecular techniques, including pulsed-field gel electrophoresis, ribotyping, and multilocus enzyme electrophoresis, have been employed to separate isolates into distinct groups and have proved useful for investigating epidemics.

Epidemiology

Listeria monocytogenes is an important cause of zoonoses, especially in herd animals. It is widespread in nature, being found commonly in soil and decaying vegetation and as part of the fecal flora of many mammals. The organism has been isolated from the stool of approximately 5% of healthy adults with higher rates of recovery reported from household contacts of patients with clinical infection. Many foods are contaminated with *L. monocytogenes*, and recovery rates of 15% to 70% or more are common from raw vegetables, raw milk, fish, poultry, and meats, including fresh or processed chicken and beef available at supermarkets or deli counters. Ingestion of *L. monocytogenes* must be a very common occurrence.

Listeriosis was made a nationally reportable disease in 2000 in the United States. Two active surveillance studies performed by the Centers for Disease Control and Prevention (CDC) in the 1980s indicated annual infection rates of 7.4 per million population, accounting for approximately 1850 cases per year in the United States, with 425 deaths. By 1993, following food industry regulations instituted to minimize the risk of foodborne listeriosis, the annual incidence had declined to 4.4 cases per million. From 1996 through 2003 the crude incidence decreased 26%; estimated cases in the United States were 2228 and 1803 in 1996 and 2003, respectively, and deaths were 462 and 378.

The highest infection rates are seen in infants ≤1 month and in adults >60 years of age. Pregnant women account for about 30% of all cases and 60% of cases in the 10- to 40-year age group. Almost 70% of nonperinatal infections occur in those with hematologic malignancy, acquired immunodeficiency syndrome (AIDS), bone marrow or solid organ transplants, or in those receiving corticosteroid therapy, but seemingly healthy persons may develop invasive disease, particularly those older than 60 years.

Nonperinatal listeriosis is almost always the result of foodborne infection. Listeriosis is a relatively rare foodborne illness (~1% of US cases) but is associated with a case-fatality rate of 16% to 20% (second only to *Vibrio vulnificus* at 35% to 39%) and causes approximately 19% to 28% of all foodborne disease-related deaths. Mortality risk factors include nonhematologic cancers, steroid medication, and renal disease.

Numerous foodborne outbreaks resulting in invasive disease (e.g., bacteremia, meningitis) have been documented, with vehicles including milk, soft cheeses, butter, smoked fish, ready-to-eat pork products, hot dogs, deli-ready turkey, sprouts, taco or nacho salads, and cantaloupes. A 2002 outbreak due to contaminated turkey deli meat resulted in the recall of more than 30 million pounds of food products, one of the largest meat recalls in US history. In 2011, *L. monocytogenes*-contaminated cantaloupes were responsible for the deadliest foodborne outbreak in US history, with 28 states reporting illness in 146 persons and death in 30 (21% mortality). The importance of food as a source of sporadic listeriosis was illuminated by two CDC studies in which 11% of all refrigerator food samples were contaminated, 64% of patients had at least one contaminated food, and, in 33% of instances, the patient and food isolates had identical strains. Delicatessen-style ready-to-eat meats, especially chicken, had the highest rates of contamination. Cases were more likely than were controls to have eaten soft cheeses or deli-counter meats, and 32% of sporadic cases could be attributed to these foods.

Human listeriosis is typically acquired through ingestion of contaminated food, but other modes of transmission occur. These include transmission from mother to child transplacentally or through an infected birth canal and cross-infection in neonatal nurseries. Contaminated mineral oil used for bathing infants was the source of one outbreak. Localized cutaneous infections have occurred in veterinarians and farmers after direct contact with aborted calves.

The CDC has established PulseNet (http://www.cdc.gov/pulsenet/), a network of public health and food regulatory laboratories that use pulsed-field gel electrophoresis to subtype food-borne pathogens to detect promptly disease clusters that may have a common source. This system has proved effective in the early detection of listeriosis outbreaks.

Pathogenesis

Except for vertical transmission from mother to fetus and rare instances of cross-contamination in the delivery suite or neonatal nursery, human-to-human infection has not been documented.

Infection most often begins after ingestion of contaminated food. The oral inoculum required to produce clinical infection is unknown; experiments in healthy mammals indicate that $\geq 10^9$ organisms are required. Alkalinization of the stomach by antacids, H_2 blockers, proton pump inhibitors, or ulcer surgery may promote infection. The incubation period for invasive infection is not well established, but evidence from a few cases related to specific ingestions points to a mean incubation period of ~30 days, with a range from 11 to 70 days. In one report, two pregnant women, whose only common exposure was attendance at a party, developed listerial bacteremia with the same uncommon enzyme type; incubation periods for illness were 19 and 23 days.

Listeria monocytogenes can cause disease without promoter organisms, but, on occasion, intercurrent gastrointestinal infection with another pathogen may enhance invasion in individuals colonized with *L. monocytogenes*. Evidence for this is found in the common history of antecedent gastrointestinal symptoms in patients and household contacts, the long incubation period from ingestion to clinical illness, and two instances in which clinical listeriosis closely followed shigellosis. Both listerial meningitis and bacteremia have occurred shortly after colonoscopy, sigmoidoscopy, and upper endoscopy.

In the intestine, *L. monocytogenes* crosses the mucosal barrier aided by active endocytosis of organisms by endothelial cells. Once in the bloodstream, hematogenous dissemination may occur to any site; *L. monocytogenes* has a particular predilection for the central nervous system (CNS) and the placenta. It is generally believed that listeriae reach the CNS by a bacteremic route, but animal experiments suggest that brainstem infection may develop by intraaxonal spread of bacteria from peripheral sites to the CNS.

Several virulence factors have been identified that enable *L. monocytogenes* to function as an intracellular organism. The bacterium possesses the cell surface protein internalin, which interacts with E-cadherin, a receptor on macrophages and intestinal lining cells, to induce its own ingestion. A membrane lipoprotein appears to promote entry into nonmacrophage cells. The major virulence factor, listeriolysin O, along with phospholipases, enables listeriae to escape from the phagosome and avoid intracellular killing. Once free in the cytoplasm, the bacterium can divide and, by inducing host cell actin polymerization, propel itself to the cell membrane. Subsequently, by means of pseudopod-like projections, it can invade adjacent macrophages. The bacterial surface protein Act A is necessary for the induction of actin filament assembly and cell-to-cell spread and, therefore, is a major virulence factor. Through this novel life cycle, *L. monocytogenes* moves from cell to cell, evading exposure to antibodies, complement, or neutrophils.

Iron, which is essential for the life of virtually all bacteria, appears to be an important virulence factor of *L. monocytogenes*. Siderophores of the organism enable it to take iron from transferrin. In vitro, iron enhances organism growth, and, in animal models of listerial infection, iron overload is associated with enhanced susceptibility to infection and iron supplementation with enhanced lethality, whereas iron depletion results in prolonged survival. Attesting to the importance of iron acquisition as a virulence factor in humans are the clinical associations of sporadic listerial infection with hemochromatosis and of outbreaks with transfusion-induced iron overload in patients receiving hemodialysis.

Immunity

Resistance to infection with the intracellular bacterium *L. monocytogenes* is chiefly dependent on T-cell lymphokine activation of macrophages but involves both innate and adaptive immune responses. The adaptive response is predominantly cell mediated as evidenced by the overwhelming clinical association between listerial infection and conditions of impaired cell-mediated immunity, including lymphoma, pregnancy, AIDS, corticosteroid immunosuppression, and tumor necrosis factor-α (TNF-α) neutralizing agents. The production of nitric oxide by activated macrophages may play a role in natural immunity to listeriosis independent of T-cell function. The role of humoral immunity is unknown, although both immunoglobulin M (absent in neonates) and classical complement activity (low in neonates) have been shown to be necessary for efficient opsonization of *L. monocytogenes*.

Although listeriosis is 100 to 1000 times more common in patients with AIDS compared with the general population, it is somewhat surprising that it is not seen more commonly, given the ubiquity of the organism. The use of trimethoprim–sulfamethoxazole (TMP–SMX) for prophylaxis against *Pneumocystis jirovecii* (*carinii*) provides protection against listeriosis. Frequency of listeriosis is not increased in those with deficiencies in neutrophil numbers or function, splenectomy, complement deficiency, or immunoglobulin disorders.

Clinical manifestations

The species name derives from the fact that an extract of the *L. monocytogenes* cell membrane has potent monocytosis-producing activity in rabbits, but monocytosis is a very rare feature of human infection.

Infection in pregnancy

Mild impairment of cell-mediated immunity occurs during gestation, and pregnant women are prone to developing listerial bacteremia with an estimated 17- to 100-fold increase in risk. Listeriae proliferate in the placenta in areas that appear to be unreachable by usual defense mechanisms, and cell-to-cell spread facilitates maternal–fetal transmission. For unexplained reasons, CNS infection is extremely rare during pregnancy in the absence of other risk factors. Bacteremia manifests clinically as an acute febrile illness, often accompanied by myalgia, arthralgia, headache, and backache. Illness may occur at any time during pregnancy but usually occurs in the third trimester, probably related to the major decline in cell-mediated immunity seen at 26 to 30 weeks of gestation. Twenty-two percent of perinatal infections result in stillbirth or neonatal death; premature labor and spontaneous abortion are common. Untreated bacteremia is generally self-limited, although if there is a complicating amnionitis, fever may persist in the mother until the fetus is aborted. Early diagnosis and antimicrobial therapy can result in the birth of a healthy infant.

There is no convincing evidence that listeriosis is a cause of habitual abortion in humans.

Neonatal infection

When in utero infection occurs, it can precipitate spontaneous abortion. The fetus may be stillborn or die within hours of a disseminated form of listerial infection known as granulomatosis infantiseptica and characterized by widespread microabscesses and granulomas that are particularly prevalent in the liver and spleen. In this entity, abundant bacteria are often visible on Gram stain of meconium.

More commonly, neonatal infection manifests similar to group B streptococcal disease in one of two forms: (1) early-onset sepsis syndrome, usually associated with prematurity and probably acquired in utero, or (2) late-onset meningitis, occurring at about 2 weeks of age in term infants, who most likely acquired organisms from the maternal vagina at parturition. Cases have occurred after cesarean delivery, however, and nosocomial transmission has been suggested.
