In early-onset disease, *L. monocytogenes* can be isolated from the conjunctivae, external ear, nose, throat, meconium, amniotic fluid, placenta, blood, and, sometimes, CSF; Gram stain of meconium may show gram-positive rods and provide early diagnosis. The highest concentrations of bacteria are found in the neonatal lung and gut, which suggests that infection is acquired in utero from infected amniotic fluid rather than via a hematogenous route. Purulent conjunctivitis and a disseminated papular rash have rarely been described in neonates with early-onset disease, but clinical infection is otherwise similar to that due to other bacterial pathogens.

Bacteremia

Bacteremia without an evident focus is the most common manifestation of listeriosis after the neonatal period. Clinical manifestations typically include fever and myalgias; a prodromal illness with nausea and diarrhea may occur. Because immunocompromised patients are more likely than healthy persons to have blood cultures during febrile illnesses, transient bacteremias in healthy persons may go undetected.

Central nervous system infection

Organisms that cause bacterial meningitis most frequently (*Streptococcus pneumoniae, Neisseria meningitidis*, and *Haemophilus influenzae*) rarely cause parenchymal brain infections such as cerebritis and brain abscess. By contrast, *L. monocytogenes* has tropism for the brain itself (particularly the brainstem), as well as for the meninges. Many patients with listerial meningitis experience altered consciousness, seizures, or movement disorders and truly have meningoencephalitis. Ventriculoperitoneal shunt infection has been reported.

Meningitis

Active surveillance studies of bacterial meningitis conducted by the CDC indicate that *L. monocytogenes* accounts for 20% of bacterial meningitis cases in neonates as well as in those older than 60 years and carries a mortality of 22%. Worldwide, *L. monocytogenes* is one of the three major causes of neonatal meningitis, is second only to pneumococcus as a cause of bacterial meningitis in adults older than 50 years, and is the most common cause of bacterial meningitis in patients with lymphoma, patients with organ transplants, or those receiving corticosteroid immunosuppression for any reason. Twenty percent of bacterial meningitis in those older than 50 years is caused by *L. monocytogenes*; therefore, empiric therapy for bacterial meningitis in all adults older than 50 years with a negative CSF Gram stain should include an antilisterial agent (either ampicillin or TMP–SMX), especially in the absence of associated pneumonia, otitis, sinusitis, or endocarditis, which would suggest an alternative etiology.

Clinically, meningitis due to *L. monocytogenes* is usually similar to that due to more common causes; features particular to listerial meningitis are summarized in Table 142.1.

TABLE 142.1 **DISTINCTIVE FEATURES OF LISTERIAL MENINGITIS COMPARED WITH MORE COMMON BACTERIAL ETIOLOGIES**

Feature	Frequency (%)
Presentation can be subacute (>24 hours)	~60
Stiff neck is less common	15–20
Movement disorders (ataxia, tremors, myoclonus) are more common	15–20
Seizures are more common	~25
Fluctuating mental status is common	~75
Positive blood culture is more common	50–75
Cerebrospinal fluid (CSF)	
Positive Gram stain is less common	30–40
Normal CSF glucose is more common	>60
Mononuclear cell predominance is more common	~30

Brainstem encephalitis (rhombencephalitis)

An unusual form of listerial encephalitis involves the brainstem. In contrast to other listerial CNS infections, this illness usually occurs in healthy older children and adults; neonatal cases have not been reported. The typical clinical picture is one of a biphasic illness with a prodrome of fever, headache, nausea, and vomiting lasting about 4 days, followed by the abrupt onset of asymmetrical cranial nerve deficits, cerebellar signs, and hemiparesis or hemisensory deficits or both. Nuchal rigidity is present in about 50%, CSF is only mildly abnormal, and CSF culture is positive in about 40%; almost two-thirds are bacteremic. Respiratory failure develops in about 4% of cases. Magnetic resonance imaging is superior to computed tomography for demonstrating rhombencephalitis. Mortality is high, and serious sequelae are common in survivors.

Cerebritis and brain abscess

Parenchymal brain infection may occur without true abscess formation and is referred to as cerebritis; concomitant meningitis may or may not be present. Macroscopic brain abscesses account for about 10% of CNS listerial infections (Figure 142.1). Bacteremia is almost always present, and concomitant meningitis with isolation of *L. monocytogenes* from the CSF is found in 25%; both of these features are rare in other forms of bacterial brain abscess. About 50% of cases occur in known risk groups for listerial infection. Subcortical abscesses located in the thalamus, pons, and medulla are common; these sites are exceedingly rare when abscesses are due to other bacteria. Mortality is high, and survivors usually have serious sequelae.

Endocarditis

Listerial endocarditis may account for as much as 7.5% of adult listerial infections, produces both native valve and prosthetic valve disease, and has a high rate of septic complications and a mortality of 48%. Listerial endocarditis, but not bacteremia per se, may be an indicator of underlying gastrointestinal tract pathology, including cancer.

Localized infection

Focal infections from which *L. monocytogenes* has been isolated include direct inoculation resulting in conjunctivitis, skin infection, and lymphadenitis. Bacteremia can lead to hepatic infection, cholecystitis, peritonitis, splenic abscess, pleuropulmonary infection, septic arthritis, osteomyelitis, pericarditis, myocarditis, arteritis,

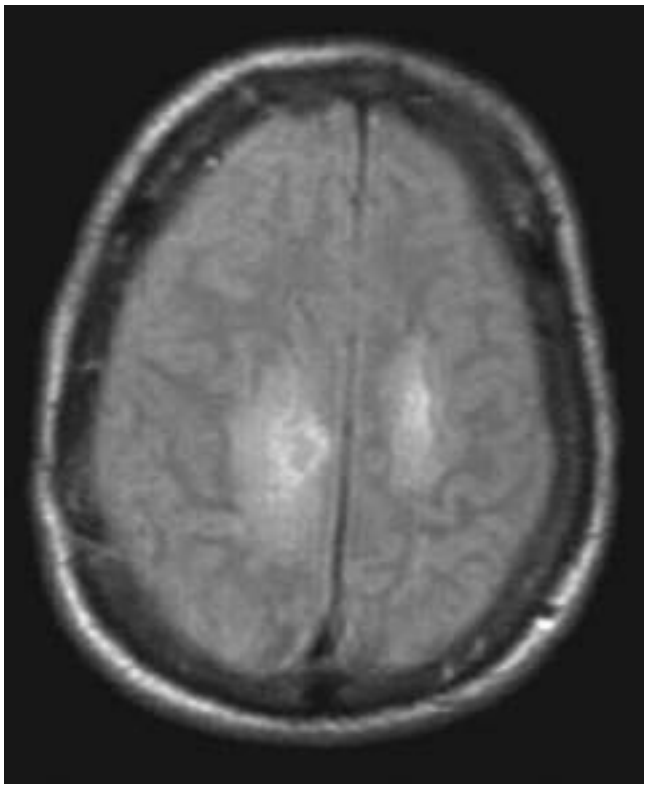

FIGURE 142.1 MRI of the brain showing bilateral frontoparietal lesions with ring enhancement (abscess) on the right. The patient was a 70-year-old man with multiple myeloma who presented with difficulty walking followed by inability to stand and progressive quadriparesis. An aspirate of the abscess grew *Listeria monocytogenes*.

necrotizing fasciitis, and endophthalmitis. Complications, including disseminated intravascular coagulation, adult respiratory distress syndrome, and rhabdomyolysis with acute renal failure, have been documented. There is nothing clinically unique about these localized infections; many, but not all, have occurred in those known to be at risk for listeriosis. Joint infection typically involves prosthetic joints in compromised hosts and requires prosthesis removal for cure.

Febrile gastroenteritis

Many patients with invasive listeriosis give a history of antecedent gastrointestinal illness, often accompanied by fever. Although isolated cases of gastrointestinal illness due to *L. monocytogenes* appear to be quite rare, at least seven outbreaks of foodborne gastroenteritis due to *L. monocytogenes* have been documented. In the largest outbreak to date 1566 individuals, most of them children between the ages of 6 and 10, became ill after eating caterer-provided cafeteria food at two schools, and 19% were hospitalized. Illness typically occurs 24 hours after ingestion of a large inoculum of bacteria (range 6 hours to 10 days) and usually lasts 1 to 3 days (range 1–7 days); attack rates have been quite high (52%–100%). Common symptoms include fever, watery diarrhea, nausea, headache, and pains in joints and muscles. Vehicles of infection have included chocolate milk, cold corn and tuna salad, cold smoked trout, and delicatessen meat. *Listeria monocytogenes* should be considered to be a possible etiology in outbreaks of febrile gastroenteritis when routine cultures fail to yield a pathogen.

Diagnosis

Listeriosis should be a major consideration as part of the differential diagnosis in any of the following clinical settings:

1. Septicemia or meningitis in infants younger than 2 months.
2. Meningitis or parenchymal brain infection in: (a) patients with hematologic cancer, AIDS, organ transplantation, corticosteroid immunosuppression, or those receiving anti-TNF agents; (b) patients with subacute presentation; (c) adults >50 years; and (d) those in whom CSF shows gram-positive bacilli.
3. Simultaneous infection of the meninges and brain parenchyma.
4. Subcortical brain abscess.
5. Fever during pregnancy.
6. Blood, CSF, or other normally sterile specimen reported to have "diphtheroids" on Gram stain or culture.
7. Foodborne outbreak of febrile gastroenteritis when routine cultures fail to identify a pathogen.

Diagnosis requires isolation of *L. monocytogenes* from clinical specimens (e.g., CSF, blood) and identification through standard microbiologic techniques. Antibodies to listeriolysin O have not proved useful in invasive disease, nor have polymerase chain reaction (PCR) probes. Antibodies to listeriolysin O may be useful during investigation of outbreaks of febrile gastroenteritis. *Listeria monocytogenes* DNA in CSF and tissue has been specifically detected by PCR assays. Real-time PCR of CSF for the *hly* gene, which encodes listeriolysin O, has been useful in diagnosing CNS listeriosis, including cases in which routine bacterial cultures were negative, but this test is not yet commercially available.

Magnetic resonance imaging is superior to computed tomography for demonstrating parenchymal brain involvement, especially in the brainstem.

Treatment

No controlled trials have established a drug of choice or duration of therapy for listerial infection. Recommendations for treatment of invasive infections are presented in Table 142.2.

Ampicillin is generally considered the preferred agent. Based on synergy in vitro and in animal models, most authorities suggest adding gentamicin to ampicillin for treatment of bacteremia in those with severely impaired cell-mediated immunity and in all cases of meningitis and endocarditis. In one uncontrolled study, the combination of TMP–SMX plus ampicillin was associated with a lower

TABLE 142.2 **INTRAVENOUS THERAPY FOR INVASIVE LISTERIOSIS**

Syndrome	Antibiotic[a]	Dosage[b]	Interval	Minimum duration
Meningitis	Ampicillin	200 mg/kg	q4h	3 wk
	plus gentamicin	5 mg/kg	q8h	
Brain abscess or rhombencephalitis	Ampicillin	200 mg/kg	q4h	6 wk
	plus gentamicin	5 mg/kg	q8h	
Endocarditis	Ampicillin	200 mg/kg	q6h	6 wk
	plus gentamicin	5 mg/kg	q8h	
Bacteremia	Ampicillin	200 mg/kg	q6h	2 wk

[a] Penicillin-allergic patients without endocarditis can be treated with trimethoprim–sulfamethoxazole alone, using 15 mg/kg of trimethoprim daily at 6- to 8-hour intervals. Patients with endocarditis should be desensitized to ampicillin and treated as above.
[b] Maximum daily dose of ampicillin should not exceed 15 g.

failure rate and fewer neurologic sequelae than ampicillin combined with an aminoglycoside.

For those intolerant of penicillins, TMP–SMX is believed to be the best alternative. Early transition to oral TMP–SMX has been used effectively and may be considered in selected patients with likely good adherence. No currently available cephalosporin should be used; none has adequate activity, and meningitis has developed in patients receiving cephalosporins. For this reason, ampicillin is always included in empirical therapy for septicemia or meningitis in infants ≤2 months of age.

Vancomycin has been used successfully in a few patients with penicillin allergy, but other patients have developed listerial meningitis while receiving the drug. Rifampin is active in vitro and is known to penetrate phagocytic cells; clinical experience is minimal, however, and in animal models the addition of rifampin to ampicillin was not more effective than ampicillin used alone. Both imipenem and meropenem have been used successfully to treat listeriosis, but caution is advised because both drugs lower the seizure threshold, treatment failures have been reported, and imipenem was less effective than ampicillin in a mouse model.

Initial dosing of antibiotics as for meningitis is prudent for all patients, even in the absence of CNS or CSF abnormalities, because of the high affinity of this organism for the CNS. Patients with meningitis should be treated for no fewer than 3 weeks; bacteremic patients without CSF abnormalities can be treated for 2 weeks.

No data exist concerning antimicrobial efficacy in listerial gastroenteritis; the illness is self-limited, and treatment is not warranted. Clinically significant antimicrobial resistance has not been encountered, but vigilance is warranted because transfer of resistance from enterococci to *L. monocytogenes* has been reported, tetracycline and quinolone resistance has emerged, and minimal inhibitory concentrations for penicillin have risen slightly. Because iron is a virulence factor for *L. monocytogenes*, it seems prudent to withhold iron replacement in patients with iron deficiency until the listerial infection is resolved.

Prevention

Food industry regulations were instituted in the United States over 20 years ago to minimize the risk of foodborne listeriosis and cut foodborne infection rates by more than one-half; rates have been relatively stable for several years. In contrast, rates of listerial infection appear to be rising in Europe.

Box 142.1 contains recommendations developed by the CDC for prevention of foodborne listeriosis.

Except from infected mother to fetus, human-to-human transmission of listeriosis does not occur; therefore, patients do not require isolation. Neonatal listerial infection complicating successive pregnancies is virtually unheard of, and intrapartum antibiotics are not recommended for mothers with a history of perinatal listeriosis.

BOX 142.1

Dietary recommendations for preventing foodborne listeriosis

For all persons

1. Cook raw food from animal sources (e.g., beef, pork, and poultry) thoroughly
2. Wash raw vegetables thoroughly before eating
3. Keep uncooked meats separate from vegetables, cooked foods, and ready-to-eat foods
4. Avoid consumption of raw (unpasteurized) milk or foods made from raw milk
5. Wash hands, knives, and cutting boards after handling uncooked foods

Additional recommendations for persons at high risk[a]

1. Avoid soft cheeses (e.g., Mexican-style, feta, Brie, Camembert) and blue-veined cheese; there is no need to avoid hard cheeses, cream cheese, cottage cheese, or yogurt
2. Leftover foods or ready-to-eat foods (e.g., hot dogs) should be reheated until steaming hot before eating
3. Consider avoidance of foods in delicatessen counters[b]

[a] Those immunocompromised by illness or medications, pregnant women, and the elderly.
[b] Although the risk for listeriosis associated with foods from delicatessen counters is relatively low, pregnant women and immunosuppressed persons may choose to avoid these foods or to thoroughly reheat cold cuts before consumption.

There is no vaccine. Listerial infections are effectively prevented by TMP–SMX given as prophylaxis against *P. jirovecii* to recipients of organ transplants or to individuals with the human immunodeficiency virus. The utility, or even the feasibility, of eradicating gastrointestinal colonization as a means to prevent invasive listeriosis is unknown. However, asymptomatic persons at high risk for listeriosis, known to have ingested a food implicated in an outbreak, could reasonably be given several days of oral ampicillin or TMP–SMX.

Nocardia

Lisa Haglund

Nocardia spp. are soilborne bacteria that are aerobic and slow-growing. In culture, they may require days to weeks before colonies appear. *Nocardia* are thin, filamentous, beaded gram-positive rods, and are variably acid-fast, 0.5 to 1.0 μm in diameter, with branching at right angles (Figure 143.1). Taxonomy of the genus has evolved considerably, and, through the use of molecular identification techniques, there are now 92 named *Nocardia* species, about half of which have been implicated in human infections. The most frequent nocardial species pathogenic for humans are *N. nova* complex, *N. brasiliensis, N. farcinica, N. cyriageorgica*, *N. abscessus* complex, and *N. transvalensis* complex. Less common human pathogens include *N. otitidiscaviarum*, *N. brevicatena-N. paucivorans* complex, and *N. pseudobrasiliensis*. *N. asteroides sensu stricto* is not currently defined in molecular terms, having been resolved into several other species. *Nocardia* are opportunistic pathogens; *N. brasiliensis* is more virulent, affecting normal hosts, and has a range geographically restricted to areas with warmer climates.

Nocardiosis is typically a suppurative infection with multiple abscesses. It is rarely granulomatous and not fibrotic. Acquisition of infection is by inhalation or by traumatic inoculation. Although nocardia are ubiquitous, they rarely colonize the human respiratory tract. Accordingly, treatment should be initiated when nocardia are isolated repeatedly from pulmonary specimens, particularly in an immunocompromised host. Antimicrobial therapy (alone or in combination with surgical drainage) is recommended, and the duration of therapy must be prolonged to prevent relapse.

Most patients with systemic nocardiosis possess underlying risk factors. Predisposing conditions are listed in Table 143.1. As the number of solid organ and hematopoietic stem cell transplantations has increased, the incidence of nocardiosis has risen. There is a correlation with the level of immunosuppression following transplantation, with most cases of nocardiosis occurring >1 but <12 months after transplantation (longer for renal transplant recipients) and at any time following intensified immunosuppression. There is also a correlation with cytomegalovirus (CMV) infection. Among HIV-infected persons, there is also a correlation with level of immunosuppression, as almost all cases of nocardiosis occur in individuals with CD4 lymphocyte counts of ≤100 cells/mm^3. In severely immunocompromised patients, co-occurrence of other opportunistic infections, including aspergillosis, mucormycosis, pneumocystosis, non-tuberculous mycobacteria, and other infections, may be found and should be sought if expected clinical improvement does not occur with appropriate therapy. Adjunctive immunotherapy with interferon-γ (IFN-γ) has been tried in cases that failed to respond to appropriate antibiotics.

Nocardiosis remains an uncommon opportunistic complication of HIV infection and transplant recipients. One possible explanation is that the prophylactic use of trimethoprim-sulfamethoxazole (TMP-SMX), pyrimethamine, or dapsone for *Pneumocystis jirovecii* (*carinii*) may also prevent nocardiosis. Nocardiosis can develop concurrently with receipt of TMP-SMZ prophylactically, especially when given at lower dosages, with preserved susceptibility to sulfa drugs in vitro.

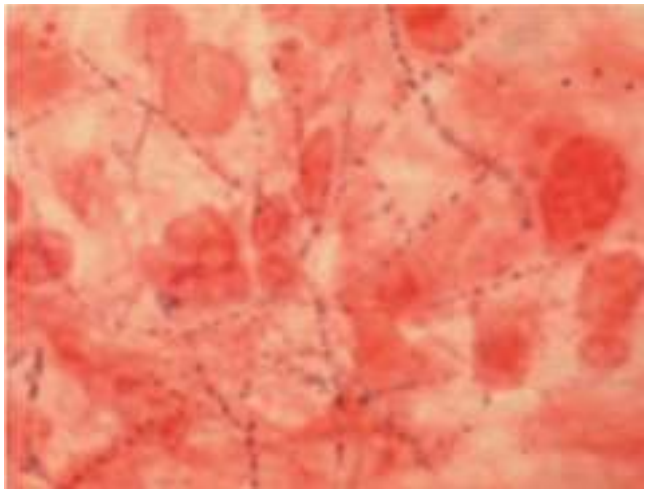

FIGURE 143.1 *Nocardia*, Gram stain.

Pathogenesis of systemic nocardiosis

Neutrophils inhibit the growth of nocardia, but eradication of organisms requires cell-mediated immunity. If cellular immunity is impaired, *Nocardia* can cause indolent abscesses with slow spread to distant sites, such as the brain or cerebrospinal fluid. Illness is usually subacute to chronic but may be fulminant in an immunocompromised host. Weight loss, anorexia, and fatigue are common in systemic nocardiosis. Bacteremia is unusual, including central line–associated bloodstream infections (CLABSIs), which require removal of the implicated catheter for cure.

Mycetoma, cutaneous nocardiosis, traumatic nocardiosis

Nocardial species can cause mycetoma, which typically manifests as a swollen area with sinuses draining purulent material. Primary cutaneous nocardiosis manifests as nontender, red, irregularly shaped raised lesions which may form sinus tracts and drain purulent material. Regional lymphadenopathy is uncommon. *Nocardia* arthritis usually presents as a monoarthritis, commonly involving the knee. Disease is often inoculated through a puncture wound and may follow a contaminated intramuscular injection. Other inoculation nocardial infections described include postoperative wound infections, osteomyelitis, and keratitis.

Pulmonary nocardiosis

Pulmonary disease is apparent in 65% to 85% of systemic nocardial infections. The roentgenographic features include infiltrates that may cavitate, sometimes accompanied by empyema, pericarditis, or mediastinitis. There is no specific radiographic appearance, thus a high degree of suspicion must be maintained to make the diagnosis. Sputum cultures may be overgrown with other organisms before *Nocardia* colonies appear. Therefore, it may be helpful to notify the microbiology lab to use selective media and hold cultures for *Nocardia* if it is a suspected pathogen. Respiratory samples submitted for fungal culture are more likely to grow *Nocardia* than those submitted for mycobacterial (acid-fast bacillus [AFB]) culture.

TABLE 143.1 **RISK FACTORS FOR SYSTEMIC NOCARDIOSIS**

Chronic pulmonary disease	Solid organ transplantation	Systemic lupus erythematosus	Renal failure
	Hematopoietic stem cell transplantation	Systemic vasculitis	Whipple's disease
Alcoholism	Chronic corticosteroid use	Ulcerative colitis	Hypogammaglobulinemia
Cirrhosis	Other drug-induced immunosuppression	Sarcoidosis	Chronic granulomatous disease
		Bronchiectasis	
Lymphoreticular malignancy	Cushing syndrome	Cystic fibrosis	Human immunodeficiency virus infection
	Graft vs. host disease	Tumor necrosis factor (TNF-α) inhibition	Pulmonary alveolar proteinosis
Diabetes			Anti-granulocyte-macrophage colony-stimulating factor (GM-CSF) autoantibodies

Nocardia meningitis and brain abscess

Central nervous system (CNS) nocardiosis is detected in 20% to 40% of systemic nocardial infections. Two-thirds have clinical findings such as fever, headache, stiff neck, or altered mental status. Hypoglycorrhachia is found in two-thirds of patients. Mildly elevated cerebrospinal fluid protein and a neutrophilic pleocytosis of approximately 1,000 white blood cells per μL are usually found. Nocardial brain abscess can be a complication of nocardial meningitis or can present in the absence of meningitis. Although meningitis without underlying brain abscess has been described, this is quite unusual, and an underlying abscess should always be suspected. Because of the high incidence of CNS infection, an imaging study of the brain should be performed if any personality or neurologic changes are found during workup of systemic nocardiosis.

Therapy of nocardiosis: Sulfonamide therapy

Sulfonamides remain the first-line agents for nocardiosis, and sulfadiazine, 6 to 8 g intravenously (IV) or orally daily, is a typical adult regimen. TMP-SMX is an alternative first-line treatment for nocardiosis. Disparity in sulfonamide susceptibility has been reported for *Nocardia*; however, several recent studies found overall 2% sulfonamide resistance in *Nocardia* spp., with less resistance to TMP-SMX, and it appears that some of the disparate observations were methodologic due to inherent difficulties in performing *Nocardia* susceptibilities for some antimicrobial agents. Table 143.2 summarizes typical dosages and durations of therapy for sulfonamide therapy of nocardiosis.

Sulfadiazine is a short-acting sulfonamide with low urinary solubility. TMP-SMX is a well-absorbed combination agent with a long plasma half-life of 11 and 9 hours for TMP and SMX, respectively. It is available orally as single- or double-strength tablets (80 mg TMP plus 400 mg SMX and 160 mg TMP plus 800 mg SMX, respectively) and as a liquid suspension containing 40 mg TMP plus 200 mg SMX per 5 mL. It is also available IV (5 mL = 80 mg TMP plus 400 mg SMX).

The most frequent side effects of TMP-SMX are upper gastrointestinal symptoms and skin rashes (3–4% each). Leukopenia, thrombocytopenia, and megaloblastic changes can develop rarely. Adverse effects of sulfonamide therapy include acute renal failure as a result of tubular damage from sulfa crystalluria. This effect may be prevented by adequate hydration and by alkalinizing the urine. Organ transplant recipients may be at increased risk of both bone marrow and renal toxicity due to overlapping toxicities with immunosuppressive medications. Hepatitis, intrahepatic cholestasis, pancreatitis, and aseptic meningitis have been reported with TMP-SMX. Serious adverse reactions are rare and include anaphylaxis, Stevens–Johnson syndrome, and hematologic effects, including thrombocytopenia, leukopenia, and hemolytic anemia.

TMP-SMX and other sulfonamides should not be given to patients with a demonstrated deficiency of folic acid or glucose-6-phosphate dehydrogenase. In HIV-infected patients, there is an increased incidence of adverse reactions to TMP-SMX, including reversible hyperkalemia and a severe hypersensitivity reaction with fever, hypotension, and multiorgan involvement on rechallenge with the drug.

Other agents with anti-nocardial activity

N. farcinica, N. pseudobrasiliensis, and other *Nocardia* spp. have been reported to have resistance to sulfonamides. The Clinical and Laboratory Standards Institute (CLSI) recommends use of the broth microdilution method for determining nocardial susceptibilities while acknowledging that consistent interpretation of sulfonamide susceptibilities, in particular, is difficult with this method. Susceptibility results are most reliable from an experienced laboratory. In vitro susceptibility does not uniformly correlate with clinical outcome in humans; therefore, clinical response should also guide selection of definitive antimicrobial therapy. The parenteral agents with greatest in vitro activity include imipenem-cilastatin (500 mg IV q6h), and amikacin (5–7.5 mg/kg IV q12h) (Table 143.3). With susceptible organisms, these agents have been as efficacious as sulfonamides in animal models; in fact, they may be more rapidly bactericidal than sulfonamides. Clinical experience

TABLE 143.2 **SULFONAMIDE DOSAGE AND DURATION OF THERAPY FOR TREATMENT OF NOCARDIA**

Type of nocardiosis	Dosage (divided BID-QID)	Duration	Comments
Cutaneous	5–10 mg/kg/d TMP-SMX[a]	2–4 mo	Longer for extensive disease or bony involvement as seen in mycetoma. Debridement helpful.
Pulmonary	10 mg/kg/d TMP-SMX	6–12 mo	12-mo minimum duration for immunocompromised host
Central nervous system	15 mg/kg/d TMP-SMX 50–100 mg/kg/d sulfadiazine	12 mo	

[a] TMP-SMX dosage based on mg/kg of the trimethoprim (TMP) component.

TABLE 143.3 **OTHER REGIMENS FOR TREATMENT OF NOCARDIA**

Drug	Dosage	Duration	Comments
Minocycline	100–200 mg PO BID	3–6 mo	Useful for pulmonary disease; poor CNS penetration
Imipenem–cilastatin	500 mg IV q6h	Until oral agent can be given	Dose must be adjusted for renal failure
Amikacin	5–7.5 mg/kg IV q12h	Until oral agent can be given	Nephrotoxic; dosage must be adjusted for renal failure
Ceftriaxone	2 g IV q12h	Until oral agent can be given	
Linezolid	600 mg PO or IV q12h		Bone marrow suppression and peripheral neuropathy

with alternative parenteral regimens is being assimilated, and treatment courses often include sulfonamide therapy. In the immunocompromised patient or in those with disseminated disease or CNS involvement, strong consideration should be given to initial empiric use of amikacin and imipenem-cilastatin while awaiting results of in vitro susceptibilities. For CNS nocardiosis, meropenem may be a useful alternative to imipenem-cilastatin, which may cause seizures; meropenem, doripenem, and ertapenem should have appropriate susceptibility testing done before being given.

Tetracyclines have good in vitro activity against some nocardial species. Minocycline has the best in vitro activity among the tetracyclines and is given 100–200 mg orally twice a day for 3 to 6 months (Table 143.3). Its drawbacks include poor cerebrospinal fluid penetration and side effects of vertigo, making it unsuitable for CNS nocardial disease.

Amoxicillin-clavulanate is an alternative to TMP-SMX or minocycline for treatment of cutaneous and lymphocutaneous disease caused by *N. brasiliensis*. Macrolides and the respiratory quinolones show some in vitro activity. Linezolid 400 to 600 mg orally twice daily has been used with success, but the long treatment course needed for nocardiosis may be complicated by drug toxicities, especially with twice-daily dosing. Tedizolid appears to be more active in vitro than linezolid, although tolerability with long-term usage has not been studied. Table 143.4 summarizes antimicrobial susceptibilities of selected *Nocardia* spp.

Pasteurella multocida

Andrew S. Webster, Paulina A. Rebolledo, Naasha J. Talati, and David S. Stephens

Pasteurella multocida ("killer of many species") is a nonmotile, gram-negative, facultative coccobacillus best known for its association with soft tissue infections after animal bites. However, *P. multocida* is also an opportunistic pathogen capable of causing invasive and life-threatening infections.

P. multocida is named in honor of Louis Pasteur, who first isolated it as the causative agent of fowl cholera in 1880. *P. multocida* is found worldwide. It commonly colonizes the upper respiratory tract of cats (70–90%), dogs (50–66%), and has been isolated from numerous other domestic pets and wild animals. Human infection is usually associated with animal exposure. Direct traumatic inoculation by a bite or scratch is the most common route of transmission; however, infection after contact with animal respiratory secretions through licks, nuzzling, or grooming is also described. Respiratory infections are uncommon but well described, and colonization of the human respiratory tract can also occur. *P. multocida* has been cultured from the respiratory tract of healthy veterinary workers and animal handlers. Antibodies against *P. multocida* are found twice as often in those who own pets or have occupational exposure to animals. Nevertheless, infections can occur in the absence of animal contact.

There are several species and subspecies of *Pasteurella* which have been shown to cause human disease, most commonly *P. multocida* subsp. *multocida, P. multocida* subsp. *septica, P. dagmatis, P. canis*, and *P. stomatis*. These organisms can resemble *Haemophilus* and *Neisseria* species when visualized on Gram stain, grow well on sheep and chocolate agar, and do not grow on MacConkey agar. Isolates from humans are typically oxidase-, catalase-, and indole-positive. Identification can be achieved by biochemical testing or molecular techniques, such as real-time polymerase chain reaction (PCR) or 16S rRNA gene sequencing. In a study of 65 clinical isolates, matrix-assisted laser desorption ionization–time of flight (MALDI-TOF) correctly identified *Pasteurella* at the species level 89% of the time.

Pasteurella multocida has five serotypes (A, B, D, E, F) based on capsular antigens. In human studies that examined serotypes, disease is usually caused by serotypes A (respiratory) and D (bite wounds). Further classification is possible based on 16 variants of lipopolysaccharide (LPS). Most studies examining potential virulence factors have been carried out in animals, and relevance to human infection is unknown. *P. multocida* has multiple methods of iron acquisition, some of which are host-specific. Outer membrane proteins (OMP) are thought to play a role not only in iron acquisition, but also in adherence. The unique LPS may help resist actions of complement, and immune responses generated are specific to the LPS serovariant. *P. multocida* capsule can possess antiphagocytic properties and may help promote colonization. A protein toxin, *P. multocida* toxin (PMT), has been isolated from some serotype A and D strains. PMT alters cell signaling pathways with effects on host immune response, cellular differentiation, and proliferation. A summary of virulence factors is provided in Table 144.1.

TABLE 144.1 **VIRULENCE FACTORS OF *PASTEURELLA MULTOCIDA***

Virulence factor	Effect
Multiple iron acquisition methods	Ensures iron acquisition across hosts
Unique and variable lipopolysaccharide (LPS)	Resists complement, lack of universal immune response
Capsule	Antiphagocytic, may mediate colonization
Outer membrane proteins (OMP)	Adherence, iron acquisition
Pasteurella multocida toxin (PMT)	Alters host cell signaling

Clinical presentation

Infections caused by *P. multocida* can be divided into three groups: bite wound infections, infections of the respiratory tract, and invasive disease.

Bite wound infection

Infections of the skin and soft tissue most commonly follow bites or scratches but can occur after an animal licks an open wound. Bite wounds account for 60% to 86% of *P. multocida* infections. While most bite wounds are polymicrobial, *P. multocida* is found as a pathogen in 75% of infected cat bites and up to 50% of infected dog bites. Skin infection with *P. multocida* is characterized by an extremely rapid onset; local pain and inflammation often occur within 4 to 6 hours of the injury and almost always within 24 hours. Purulent drainage and lymphangitis occur in 40% of cases, but fever and systemic symptoms are often absent.

Bite wound infections with *P. multocida* can lead to serious sequelae, even with appropriate antibiotic and aggressive surgical management. Tenosynovitis, abscess formation, and osteomyelitis can result, but bacteremia is rare. Necrotizing infections have been reported. Cat bites are more commonly associated with osteomyelitis because of the deep puncture wounds that penetrate the periosteum. Poor functional outcome is common with these infections, especially when involving the extremities. In patients with risk factors for invasive infections, an apparently insignificant and uninfected wound may lead to serious sequelae weeks later.

Respiratory tract infection

Respiratory infections are the second most common infection site and tend to occur in those with underlying lung disease such as chronic obstructive pulmonary disease (COPD) or bronchiectasis. Infection can occur after inhalation of contaminated aerosols or direct inoculation of the oral cavity with animal secretions and subsequent aspiration. Acute infection can be clinically indistinguishable from other forms of bacterial pneumonia. Chronic infection has been described in a patient with bronchiectasis. *P. multocida* has been isolated as a causative agent of sinusitis, otitis, epiglottitis, supraglottitis, bronchitis, lung abscess, and empyema. Bacteremia is seen in 15% to 50% of cases of respiratory infection.

Invasive or disseminated infection

Invasive or disseminated infections generally occur in the extremes of age or in those with some form of immunocompromise: pregnancy, diabetes mellitus, cirrhosis, chronic steroid use, malignancy, HIV infection, or organ transplantation. Most cases are associated with animal bites or scratches, some are associated with animal exposure without injury, and a small percentage of cases have no history of exposure to animals. In a single-center study of 44 patients with *P. multocida* infection, immunocompromised patients were more likely to present with a non-bite, non-skin, invasive infection. These patients were more likely to require hospitalization or ICU level of care and had a higher mortality rate.

Infectious arthritis is a rare complication of *P. multocida* infection and usually occurs in patients with underlying joint disease or steroid use. Infections are usually monoarticular and primarily affect the knee. Patients with bacteremia are more likely to have polyarticular infection. Osteomyelitis is usually seen following animal bite and tends to involve the upper extremity. Prosthetic joint infection (PJI) due to *P. multocida* has been increasingly reported. In a review of 32 cases, the authors found that almost all cases had known animal contact, the knee was most commonly infected, and 42% of cases had an underlying immunosuppressing condition.

Meningitis is usually seen among infants or in adults >55 years. A 2010 review noted 36 adult cases reported in the literature; additional cases have been reported since that time. There are four mechanisms by which *P. multocida* can cause meningitis: (1) direct inoculation following animal bite, (2) contamination from colonized site after trauma or neurosurgery, (3) bacteremic seeding of meninges, and (4) local spread from an infected site, such as otitis. The clinical presentation and cerebrospinal fluid (CSF) findings are typical of bacterial meningitis. Animal contact is reported in almost all cases. Neurologic complication rates are similar to other causes of bacterial meningitis and occur in approximately 22% of adult patients. In a case series of 29 adult patients in 2002, bacteremia was reported in 60% of patients, CSF Gram stain was positive in 50%, and mortality rate approached 30%. In a 2009 review of 38 pediatric cases, bacteremia occurred in 50% of cases with seizures complicating 29% of cases. Death was observed in only 2/38 cases.

Bacteremia can occur with any primary site of *P. multocida* infection but is documented in 20% to 30% of invasive infections. The most common comorbidities observed in cases of bacteremia are cirrhosis, diabetes, and malignancy. However, up to 38% of patients have no underlying comorbidities, 17% have no animal exposure, and 13% have no localized site of infection. A review of

156 cases of *P. multocida* bacteremia found a mortality rate of 23%. Endocarditis due to multiple *Pasteurella* species has been reported, including cases of prosthetic valve disease. Left-sided endocarditis is most common, although there are reports of pulmonic valve and tricuspid valve endocarditis. Presentation is typically acute, and mortality is approximately 50%, with higher mortality rates in those with immunosuppressing conditions.

P. multocida is also known to cause intra-abdominal infections. Cases of spontaneous bacterial peritonitis have been reported, mostly in the setting of alcoholic cirrhosis. Cases of peritoneal dialysis-associated infection have also been frequently reported. A 2015 review of 37 cases revealed that 87% of patients had cat exposure, with 25 cases confirming direct contact with dialysis equipment. In 10 cases, there was visible puncture of dialysis equipment. Cases of appendicitis-associated peritonitis have also been reported.

Other serious infections caused by *P. multocida* for which there are case reports in the literature include pyelonephritis, thyroiditis, mycotic aneurysm, vascular graft infection, endophthalmitis, uvulitis, liver abscess, cholecystitis, breast expander infection, chorioamnionitis, neonatal sepsis, and chronic ulceration of the penis.

TABLE 144.2 **ANTIBIOTIC SUSCEPTIBILITIES OF *PASTEURELLA MULTOCIDA***

Usually susceptible	Variable	Usually resistant
Penicillin and derivatives	Semisynthetic penicillins	Vancomycin
Ampicillin (± sulbactam)	Oxacillin	Clindamycin
Amoxicillin (± clavulanate)	Dicloxacillin	Erythromycin (oral)
Ticarcillin (± clavulanate)	Cloxacillin	
Piperacillin (± tazobactam)	Nafcillin	
Second- and third-generation cephalosporins[a]	Cefaclor	
Cefuroxime	First-generation cephalosporins	
Cefotetan	Cephalexin	
Cefoxitin	Cefazolin	
Cefixime[b]	Cephradine	
Cefprozil[b]	Cefadroxil	
Loracarbef[b]	Erythromycin (IV)	
Cefpodoxime[b]	Aminoglycosides	
Ceftriaxone	Gentamicin	
Ceftizoxime	Tobramycin	
Cefotaxime	Amikacin	
Ceftazidime		
Advanced-generation Cephalosporins		
Ceftaroline[b]		
Ciprofloxacin[b]		
Chloramphenicol		
Trimethoprim–sulfamethoxazole[b]		
Aztreonam		
Imipenem		
Tetracycline		
Doxycycline		

[a] Cefaclor, an oral second-generation cephalosporin, is often not effective.
[b] There are few clinical data on the use of these agents but by in vitro testing they should be effective.

Therapy

Antibiotics

The antibiotic of choice for treatment of susceptible *P. multocida* infections is penicillin. Ampicillin and amoxicillin are effective, but antistaphylococcal penicillins such as oxacillin and nafcillin are not recommended. The second- and third-generation cephalosporins have good activity against *P. multocida*, but first-generation cephalosporins and cefaclor are not reliable. There are few cases of β-lactamase-producing *P. multocida* in humans reported, mostly from respiratory samples. However, rates of β-lactamase production may be increasing. A 2006 French study of 192 consecutive clinical isolates found only one β-lactamase-producing *Pasteurella* strain in a respiratory sample, but a 2015 US single-center review noted β-lactamase production in 5/32 isolates tested, including nonrespiratory sites. The authors found no difference in severity or type of infection based on β-lactamase production. Antibiotic susceptibility testing should be routinely performed.

Pasteurella is uniformly sensitive to tetracycline and chloramphenicol. Fluoroquinolones, azithromycin, clarithromycin, and trimethoprim-sulfamethoxazole (TMP-SMX) have good in vitro activity. Clinical experience with these agents is limited, but they are an option for patients allergic to penicillin and cephalosporins who cannot tolerate tetracyclines. While *Pasteurella* is universally resistant to clindamycin and vancomycin, most strains are resistant to erythromycin and only moderately sensitive to aminoglycosides. Table 144.2 shows appropriate antibiotic choices based on available data.

Prophylactic antibiotic therapy for bite wounds

Although antimicrobial therapy is indicated for infected bite wounds, its value in prophylaxis following bite injury is controversial. This is largely due to the small number of patients enrolled in such studies. The decision to prescribe antibiotics at the time of injury depends on the risk of infection, which can be assessed by the criteria in Table 144.3. In addition, specific risk factors for *P. multocida* are listed in Table 144.4. If a wound generally shows no sign of infection after 24 hours, *P. multocida* infection is unlikely to develop. However, for individuals with underlying risk factors and for bites at risk for *P. multocida* infection, prophylaxis is reasonable even if they present late. Because bite wounds usually contain multiple organisms, including anaerobes, prophylaxis is usually with amoxicillin-clavulanate for 3 to 5 days. Alternatives include

TABLE 144.3 **RISK FACTORS FOR WOUND INFECTION**

	High	Low
Type of wound	Puncture	Laceration
	Crush injury	No crushing of tissues
	Foreign material introduced	No contamination
	Extends to bone or joint	Superficial
	Requires surgical repair	No surgical repair
Site of wound	Extremity, especially hand	Trunk, buttocks, head, minor facial wounds
Species of animal	Cat, pig, bovine	Dog, rodent
Delay before presentation	>8 h	≤6 h, or >48–72 h without signs of infection
Management prior to presentation	Poor cleaning	Good cleaning
Patient characteristics	>55 yr or ≤1 yr of age	No underlying disease

TMP-SMX or quinolones, in addition to clindamycin or metronidazole to cover anaerobes. For further discussion of the management of bite wounds, see Chapter 23, "Human and animal bites."

Treatment of infected wounds

Infected wounds should be thoroughly cleaned and have deep cultures performed before the initiation of antibiotics. Surgical evaluation should be performed especially when joints or extremities are involved or when there is extensive tissue damage. If infection with intense local inflammation develops within 24 hours, *Pasteurella* should be strongly suspected. Because the rate of serious sequelae is high, the clinician should have a low threshold for admission and surgical consultation. If infection develops after 24 to 48 hours, gram-positive organisms are more likely to be the cause, and therapy should be directed toward *Staphylococcus, Streptococcus* spp., and anaerobes. However, if the patient has underlying risk factors for *P. multocida* infection, coverage for this organism should be included in the regimen. Table 144.1 shows the antibiotics of choice for *P. multocida*. Uncomplicated cellulitis should be treated for 7 to 10 days, but more complicated wound infections may require longer treatment.

TABLE 144.4 **RISK FACTORS FOR *PASTEURELLA MULTOCIDA* INFECTION**

Wound	Patient
Deep puncture	≤1 yr or >55 yr of age
Feline, porcine	Liver disease, especially cirrhosis HIV
Deep feline scratch	Solid tumors, leukemias
	Immune-modulating medications
	Chronic respiratory disease
	Collagen vascular disease
	Pregnancy
	Artificial heart valve
	History of cranial trauma or surgery

Therapy for other *P. multocida* infections

A key factor in successful treatment of *P. multocida* infections is suspicion of the organism. A history of animal contact should always be obtained, and the patient examined carefully for signs of even minor trauma. Gram stains of wounds or purulent collections are positive in up to 50% of cases. If *P. multocida* infection is a possibility, therapy should include penicillin or a second- or third-generation cephalosporin. Tetracycline, fluoroquinolones, and TMP-SMX are alternatives if β-lactam allergy is present.

In β-lactam-allergic patients presenting with meningitis, chloramphenicol can be used. Cases of successful treatment with aztreonam and meropenem have been reported. The optimal duration of treatment for meningitis and respiratory infections is unknown, but most series suggest 2 weeks and 7 to 10 days, respectively. Joint infections, osteomyelitis, and abscesses require drainage and debridement in addition to antibiotic therapy. In the review of prosthetic joint infection, prosthesis removal was required in 54% of cases. Patients with endocarditis should be treated with medical and surgical therapy, and duration of antibiotics is generally 6 weeks. Limited experience with peritoneal dialysis catheter infections shows that 2 weeks of antibiotics is typically sufficient, with 65% of cases receiving intraperitoneal antibiotics. Peritoneal dialysis catheter retention was possible in 89% of patients.

Pneumococcus

Maurice A. Mufson and Nancy B. Norton

Introduction

An enduring pathogen since its discovery in 1881, *Streptococcus pneumoniae* (pneumococcus) ranks first among all causes of community-acquired pneumonia (CAP), second as a cause of bacterial meningitis among adults, and is a frequent cause of sepsis and meningitis among children. The high case-fatality rates from invasive (bacteremic) pneumococcal disease (IPD) attest to its importance as a pervasive pathogen. Case-fatality rates in IPD approach about one in six cases of pneumonia among elderly and about one in ten among middle-aged adults, about one in three cases of meningitis among adults and one in 20 cases of meningitis in children, and nearly nil in cases of bacteremia without localization among children 4 years of age or younger. Persistent high case-fatality rates from IPD during the second half of the twentieth century, despite effective antibiotic treatment regimens, drove the development and licensure of polysaccharide vaccines for adults and children.

Diagnostic procedures

Pneumonia

The antibiotic treatment of CAP among patients admitted to hospital must be initiated without delay and should be started before the patient leaves the emergency department, based on expert empiric treatment guidelines, even before the causative organism is established by diagnostic laboratory procedures. The diagnosis of *S. pneumoniae* pneumonia initially represents a presumptive clinical judgment taking into account its common occurrence, symptoms and signs, age of the patient, and the results of rapid laboratory tests, when available. Unequivocal evidence of the specific etiologic diagnosis of *S. pneumoniae* pneumonia requires isolation of the organism from blood or another otherwise sterile site, such as pleural fluid, with results not available usually until the next day. Blood cultures should be done to assess the invasive nature of the infection and to test the isolated strain for antibiotic sensitivity, because of the increasing emergence of intermediate and high resistant strains worldwide. A single set of cultures obtained before the start of antibiotic treatment is adequate for recovery of the organism. All *S. pneumoniae* strains recovered from sputum and blood, cerebrospinal fluid (CSF), and pleural fluid must be tested for susceptibility to penicillin and other antibiotics commonly used in the treatment of pneumococcal disease. *S. pneumoniae* can be recovered also from respiratory tract secretions. The finding of pneumococci in sputum or a nasal swab should be interpreted in light of their frequent carriage in the upper respiratory tract. Their recovery from the respiratory secretions adds only modest confidence for establishing a specific etiologic diagnosis. To monitor in a community the occurrence of pneumococcal vaccine serotypes or the emergence of replacement serotypes, specific serotypes can be determined by capsular swelling procedures (quelling reaction) employing serotype-specific antisera (Statens Serum Institut, Copenhagen, Denmark).

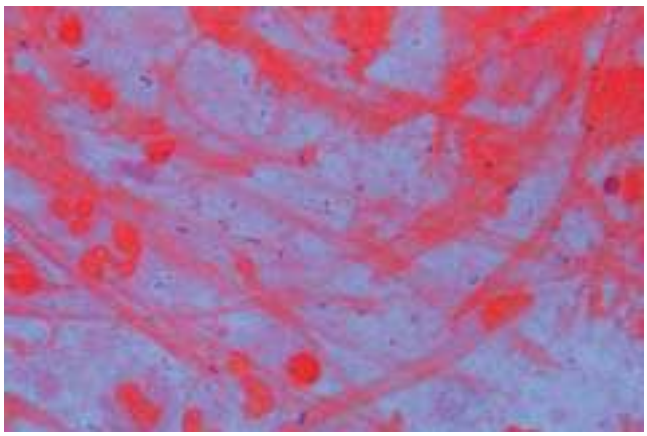

FIGURE 145.1 Gram-stained sputum specimen positive for *Streptococcus pneumoniae* demonstrates lancet-shaped gram-positive diplococci.

Although recovery of *S. pneumoniae* from blood or pleural fluid represents the "gold standard" of etiologic diagnosis in CAP, rapid laboratory procedures can provide early evidence of this infection. Such tests include recognition of the organism on a Gram-stained smear of respiratory secretions by the presence of characteristic gram-positive, lancet-shaped diplococci (Figure 145.1) and detection of pneumococcal antigen in urine. The detection of pneumococcal C-polysaccharide cell wall antigen in a urine specimen by a commercial immunochromatographic membrane assay (BinaxNOW® *Streptococcus pneumoniae* Test) provides a quick (about 15 minutes), reasonably sensitive, and highly specific test for establishing the diagnosis in adults who become blood culture positive. In IPD, the immunochromatographic membrane assay of urine is about 77% to 87% sensitive and about 97% to 100% specific. In children with IPD, it is somewhat less specific. The immunochromatographic membrane assay applied to pleural fluid also provides a sensitive and highly specific means of identifying pneumococcal antigen.

The BinaxNOW® test involves dipping a special swab into a urine specimen, or a pleural fluid specimen, at room temperature and applying the swab to an immunochromatographic membrane in a booklet-like device that is closed after the swab is set up. A positive test result, which must be read 15 minutes later, appears as a pink-to-purple colored line in a window on the cover of the booklet. Importantly, isolation of the pneumococcal organism is still necessary to assess susceptibility to penicillin and other antibiotics.

Meningitis

A specific diagnosis of pneumococcal meningitis can be confirmed quickly during the initial examination of the patient by identification of the organism on a Gram stain of CSF or by detection of pneumococcal C-polysaccharide cell wall antigen in a CSF specimen using the immunochromatographic membrane assay. The test is performed and read in the same manner as described above for testing a urine specimen. However, in patients with pneumococcal meningitis, the test shows a very high sensitivity (100% or nearly so) and very high specificity (100% or nearly so) in both children and adults. The availability of rapid diagnostic tests for the diagnosis of *S. pneumoniae* meningitis facilitates prompt initiation of appropriate antibiotic therapy while waiting for the results of the culture of CSF.

Antibiotic susceptibility testing

The spectrum of antibiotic minimum inhibitory concentrations (MICs) of *S. pneumoniae* strains is routinely determined employing automated procedures against a panel of antibiotics specified by the Clinical and Laboratory Standards Institute (CLSI, Wayne, PA). The panel of antibiotics includes penicillin, cefaclor, cefuroxime, cefotaxime, ceftriaxone, cefepime, meropenem, levofloxacin, azithromycin, erythromycin, tetracycline, chloramphenicol, clindamycin, amoxicillin-clavulanate, trimethoprim–sulfamethoxazole, and vancomycin. MIC breakpoints for non-meningitis and meningitis isolates to selected antibiotics are included in the footnotes of Tables 145.1 and 145.2, respectively.

Although automated procedures have eclipsed other means of MIC determination, the MIC of an individual isolate of *S. pneumoniae* can be determined employing the E-test (AB Biodisk, Solna, Sweden). In this test, a penicillin-impregnated plastic-coated paper strip is placed on a blood agar plate inoculated with the isolate to produce a semiconfluent growth and incubated for 24 hours in a 5% CO_2 atmosphere. The MIC represents the point of intersection of the strip by the ellipsoid zone of inhibition.

Infections due to the pneumococcus

Pneumonia

Importance

Pneumonia is the most common clinical presentation of *S. pneumoniae* infection and accounts for about 40% to 60% of CAP. *S. pneumoniae* remains the most common cause of CAP; *Mycoplasma pneumoniae* and *Haemophilus influenzae* are the second and third most common causes, respectively. Only about 20% of pneumococcal pneumonias are invasive infections. The burden of pneumococcal pneumonia represents the number of invasive and noninvasive cases. By one estimate, almost one million cases of pneumococcal pneumonia occur each year in the United States, resulting in between 100 000 and 400 000 hospitalizations. Pneumococcal pneumonia affects every age group, but it is most prevalent in children under 5 and adults greater than 65 years of age. Case-fatality rates vary widely, from about 2% in children to as high as 40% in elderly persons.

Certain underlying morbidities increase the risk of acquiring pneumococcal pneumonia. In children, these include age less than 5 years, especially less than 2 years, absence of breastfeeding, day-care attendance, exposure to cigarette smoke, and lack of immunization with PCV7 or PCV13. In adults, these include age 55 years or older, immunodeficiencies due to human immunodeficiency virus (HIV), diabetes mellitus, functional or actual asplenia, humoral immunity defects, complement deficiencies, and neutrophil dysfunction. Additional risk factors include asthma; chronic obstructive

TABLE 145.1 RECOMMENDED EMPIRIC ANTIBIOTIC TREATMENT REGIMENS FOR S. PNEUMONIAE PNEUMONIA WHEN THE DIAGNOSIS IS SUSPECTED ON CLINICAL FINDINGS OR CONFIRMED BY LABORATORY PROCEDURES OR A POSITIVE BLOOD CULTURE

Clinical assessment of pneumonia	Recommended antibiotics[a]	Recommended antibiotic dosages[a]
Ambulatory adult without any comorbidity or recent antibiotic treatment	First choice: a macrolide, either azithromycin or clarithromycin or erythromycin	Azithromycin 500 mg on d 1 and then 250 mg PO for 4 d; or clarithromycin 500 mg PO q12h for 7–14 days; or erythromycin 500 mg PO q12h for 7–14 d
	Alternate choice: doxycycline	Doxycycline 100 mg PO q12h for 7–14 d
Ambulatory adult 50 years of age and older with one or more comorbid condition and/or recent antibiotic treatment	First choice: a fluoroquinolone with antipneumococcal activity.	Levofloxacin, 750 mg PO q24h for 5 d; gatifloxacin, 400 mg PO q24h for 7–14 d; moxifloxacin, 400 mg PO q24h for 7–14 d; or gemifloxacin, 320 mg PO q24h for 7 d
	Alternate choice: amoxicillin–clavulanate or amoxicillin or cefuroxime plus a macrolide	Amoxicillin–clavulanate 875 mg/125 mg PO q12h for 7–14 d; amoxicillin 875 mg PO q12h for 7–14 d; or cefuroxime axetil 500 mg PO q12h for 7–14 d, plus azithromycin or clarithromycin as described above
Hospitalized adult with or without either comorbid conditions or recent antibiotic treatment	First choice: a fluoroquinolone with antipneumococcal activity	Levofloxacin, 750 mg PO q24h for 5 d; gatifloxacin, 400 mg PO q24h for 7–14 d; moxifloxacin, 400 mg PO q24h for 7–14 d; or gemifloxacin, 320 mg PO q24h for 7 d
	Alternate choice: ceftriaxone or cefotaxime plus a macrolide	Ceftriaxone, 1–2 g IV/IM q24h for 7–14 d; or cefotaxime, 1–2 g IV q8h for 7–14 d; plus Azithromycin, 500 mg IV, then PO, q24h for 7–10 d; or clarithromycin 500 mg PO q12h for 7–14 d

[a] *Streptococcus pneumoniae* isolated from blood or pleural fluid must be tested for antibiotic susceptibility and choice of antibiotic treatment should be based on these results. For these *S. pneumoniae* isolates (non-meningitis isolates), the MIC breakpoints in μg/mL of penicillin parenterally administered susceptible ≤2, intermediate = 4, and resistant ≥8; ceftriaxone susceptible ≤1, intermediate = 2, and resistant ≥4; cefotaxime susceptible ≤1, intermediate = 2, and resistant ≥4; azithromycin susceptible ≤0.5, intermediate = 1, and resistant ≥2; levofloxacin susceptible ≤2, intermediate = 4, and resistant ≥8. The antibiotic regimen selected should exceed these MICs.

TABLE 145.2 RECOMMENDED EMPIRIC ANTIBIOTIC TREATMENT REGIMENS FOR *S. PNEUMONIAE* MENINGITIS

Penicillin allergy	Age group	Recommendations for antibiotics	Recommendations for dosage of antibiotics[a]
No	Child	Ceftriaxone or cefotaxime	Ceftriaxone, 50 mg/kg IV q12h, or cefotaxime[a], 50 mg/kg IV q6h
		plus vancomycin	plus vancomycin, 10–15 mg/kg IV q6h (or q12h if 12–16 yr), 10–14 d
			plus dexamethasone 0.15 mg/kg IV q6h for 2–4 d, starting 10–20 minutes before first dose of antibiotics[b]
	Adult	Ceftriaxone or cefotaxime	Ceftriaxone, 2 g IV q12h, or cefotaxime, 2 g IV q4h
		plus vancomycin	plus vancomycin, 1 g IV q12h, 10–14 d
		plus dexamethasone, maybe plus rifampin	plus dexamethasone 0.15 mg/kg IV q6h for 2–4 d, 10–20 minutes before antibiotics, maybe plus rifampin, 300 mg PO q12h for 10–14 d
Yes	Child	Chloramphenicol	Chloramphenicol, 75–100 mg/kg IV q6h
		plus vancomycin	plus vancomycin 10–15 mg/kg IV q6h (or q12h if 12–16 yr), 10–14 d
		plus dexamethasone	plus dexamethasone 0.15 mg/kg IV q6h for 2–4 d, starting 10–20 minutes before first dose of antibiotics[b]
	Adult	Chloramphenicol	Chloramphenicol, 1500 mg IV q6h
		plus vancomycin	plus vancomycin, 1 g IV q12h, 10–14 d
		plus dexamethasone, maybe plus rifampin	plus dexamethasone 0.15 mg/kg IV q6h for 2–4 d, 10–20 minutes before antibiotics, maybe plus rifampin, 300 mg PO q12h for 10–14 d

[a] *Streptococcus pneumoniae* isolates recovered from cerebrospinal fluid (CSF) must be tested for antibiotic susceptibility and an antibiotic treatment regimen should be selected based on these results. For these CSF *S. pneumoniae* isolates, the MIC breakpoints in μg/mL of penicillin parenterally administered susceptible ≤0.06 and resistant ≥0.12; ceftriaxone susceptible ≤1, intermediate = 2, and resistant ≥4; cefotaxime susceptible ≤1, intermediate = 2, and resistant ≥4; vancomycin susceptible ≤1; chloramphenicol susceptible ≤4 and resistant ≥8. The antibiotic regimen selected should exceed these MICs. *S. pneumoniae* CSF isolates respond to ceftriaxone and cefotaxime because these third-generation cephalosporins achieve levels in the CSF above the MIC of most of these strains.

[b] Adjunctive dexamethasone, 0.15 mg/kg, every 6 hours for 2–4 days, in children residing in high-income countries (not low-income countries), preferably started 10–20 minutes before antibiotic therapy is begun, shows a decrease in any hearing loss and short-term neurologic sequelae, modest diminution of severity of illness, and slightly lowered case-fatality rate.

pulmonary disease; viral infections (especially influenza infection); chronic cardiac, hepatic, or renal conditions; alcoholism; and active and passive exposure to cigarette smoke.

Clinical and laboratory findings

The incubation period of pneumococcal pneumonia is 1 to 3 days. The onset of symptoms may be sudden, starting with rigors or a single shaking chill followed by high fever (102°F to 105°F), cough productive of rusty or blood-streaked sputum, dyspnea, tachypnea, hypoxia, pleuritic chest pain, and malaise. Because of pleuritic pain, patients may be observed to splint the affected lung. Other less specific symptoms include nausea, vomiting, headache, fatigue, and muscle aches. Some of the more serious complications that may develop and contribute to fatality rates are empyema, pericarditis, and respiratory failure.

Physical examination of the lungs may reveal rales over the affected lobe or segment. An increase in tactile fremitus and the presence of egophony indicates consolidation. Larger pleural effusions or empyema are demonstrated by dullness on chest percussion.

Neutrophilic leukocytosis occurs in about 80% of patients at presentation with most other patients developing leukocytosis within a few days. Some elderly and immunocompromised patients may never develop leukocytosis, so the absence of leukocytosis either at presentation or throughout the illness does not rule out pneumonia or invasive disease.

A chest radiograph should be obtained on each adult suspected of CAP. Pneumococcal pneumonia typically shows a lobar pattern of infiltration, but may demonstrate a focal segmental infiltrate. Chest radiographs may be clear early in the disease or in a dehydrated patient so a negative chest radiograph should be repeated after 24 hours. A negative chest radiograph may persist in some elderly or immunocompromised patients even in the presence of pneumonia.

Course and treatment

With appropriate antibiotic treatment the earliest response usually occurs within 12 to 36 hours, but sometimes as late as 96 hours. Fever defervesces first followed by amelioration of the respiratory rate, cough, and chest pain. Radiographic findings should not be used to assess early response to treatment because infiltrates usually clear slowly, over the next 2 to 3 weeks.

As *S. pneumoniae* is the dominant pathogen of CAP, deciding on a treatment regimen for CAP involves two key points: (1) judging the likelihood that *S. pneumoniae* is the pathogen and whether it is resistant to penicillin or other antibiotics, because as many as one-third of the *S. pneumoniae* strains exhibit intermediate or high resistance to penicillin, depending on the individual community, and (2) applying a validated quantitative severity score for assessing the severity of the pneumonia, as an adjunct to clinical judgment.

S. pneumoniae is frequently suspected as the pathogen of CAP on clinical grounds, sometimes aided by the results of rapid diagnostic procedures; however, the physician will not know whether the strain is penicillin susceptible or resistant unless cultures become positive. Consequently, appropriate antibiotic treatment must be started based on guidelines for the empiric antibiotic treatment of CAP (Table 145.1). Importantly, invasive pneumococcal pneumonia caused by intermediate resistant strains (MICs 4 μg/mL) can be successfully treated with antibiotic regimens that are employed to treat penicillin-susceptible strains.

A scoring method commonly used for stratifying risk in patients presenting with pneumonia is the CURB-65 score, which is a straightforward evaluation that divides patients into low- and high-risk categories. The patient receives one point for the presence of each of the following characteristics: *C*onfusion (acute) (≤8 on an abbreviated Mental Test), *U*rea (blood urea nitrogen > 19 mg/dL or 7 mmol/L), *R*espiratory rate > 30/minute, *B*lood pressure: diastolic < 60 or systolic < 90mm Hg, and age ≥65 years. A score of 3, 4, or 5 represents severe pneumonia with a high risk of death that must be managed in the hospital; a score of 2 represents less severe pneumonia, but one that carries an increased risk of death and should also be managed in the hospital; and a score of 0 or 1 represents mild pneumonia that can be managed on an ambulatory basis.

For an ambulatory adult without comorbid conditions or recent antibiotic treatment (within 3 months) and a CURB-65 of 0 or 1, the recommended treatment is a macrolide, either azithromycin, clarithromycin, or erythromycin, or alternatively, doxycycline (Table 145.1). For an adult older than 50 years with a score of 0 or 1, who has one or more comorbid conditions and/or recent antibiotic treatment, the recommendation is for a fluoroquinolone with antipneumococcal activity such as levofloxacin, gatifloxacin, moxifloxacin, or gemifloxacin. If *S. pneumoniae* is recovered from the patient and determined to be penicillin susceptible then amoxicillin-clavulanate or amoxicillin or cefuroxime plus either a macrolide or doxycycline is an alternative treatment.

A hospitalized (non-ICU) adult (CURB-65 score of 2 or greater) with or without comorbid conditions or recent antibiotic therapy should be treated with a fluoroquinolone with antipneumococcal activity or ceftriaxone or cefotaxime plus a macrolide (Table 145.1).

Meningitis

Importance and clinical findings

Pneumococcal meningitis, the most common bacterial meningitis, affects mainly older adults. Fatalities occur in about 20% to 30% of cases, with adults older than 50 years suffering the highest case-fatality rates. Among children, the case-fatality rate varies between 5% and 15%, substantially higher than the rate in invasive pneumococcal pneumonia. Between one-fourth and one-half of children who survive meningitis develop neurologic sequelae. The disease can develop as a complication of invasive *S. pneumoniae* pneumonia, purulent mastoiditis and sinusitis, endocarditis, asplenia, sickle cell disease, alcoholism, or a skull fracture with communication between the nasopharynx and the subarachnoid space. Patients with meningitis need to be tested for extra-meningeal sources of infection.

The clinical symptoms of meningeal inflammation include fever, headache, and stiff neck and the presence of a Kernig or Brudzinski sign or both; elevated CSF pressure; and CSF findings of frequent neutrophils, glucose level <40 mg/mL, and total protein about 100 mg/mL. Among elderly persons, the symptoms of meningitis may be confounded by changes of age, such as a stiff-feeling neck because

of arthritic changes in the cervical vertebrae or the confusion of dementia. Common neurologic complications include seizures and cranial nerve abnormalities.

Pneumococcal meningitis is a medical emergency and patients suspected of having meningitis require immediate diagnosis and treatment. A clinical diagnosis of meningitis almost always seems apparent based on clinical findings alone. A specific etiologic diagnosis of pneumococcal meningitis requires confirmatory laboratory procedures. Initially, this can be accomplished by recognition of the typical morphology of *S. pneumoniae* on a Gram smear of CSF or by testing the CSF using the rapid immunochromatographic membrane assay or both. Ultimately, the infecting strain needs to be isolated so that its MIC to the panel of antibiotics (see above, Antibiotic susceptibility testing) can be determined.

During the years 2000–2010 of routine immunization of children with PCV7, pneumococcal meningitis caused by vaccine serotypes decreased by almost two-thirds in children 2 years of age or younger and by about one-half among adults 65 years and older, but nonvaccine serotypes accounted for almost two-thirds of cases.

Treatment (Table 145.2)

Both adults and children should be treated with combination therapy, including a third-generation cephalosporin and vancomycin. Adjunctive dexamethasone, in children residing in high-income countries (not low-income countries), preferably started 10 to 20 minutes before antibiotic therapy is begun, shows a decrease in any hearing loss and short-term neurologic sequelae, modest diminution of severity of illness, and slightly lowered case-fatality rate. Adjunctive dexamethasone in adults, given 10 to 20 minutes before antibiotics, can provide some benefit, mainly by reduction of neurologic and auditory sequelae among survivors, although it does not significantly reduce case-fatality rates and questions remain of its ultimate benefit.

Otitis media

Importance and treatment

S. pneumoniae ranks among the three most common pathogens of acute otitis media (AOM) in children (*Haemophilus influenzae* and *Moraxella catarrhalis* are the other two pathogens) and penicillin-resistant *S. pneumoniae* represents a continuing problem in the treatment of this common infection. PCV7 was developed, in part, for prevention of AOM and its routine administration has substantially decreased AOM and long-term recurrent episodes due to vaccine serotypes.

Among children infected with a penicillin-susceptible strain, amoxicillin remains the preferred antibiotic (80–90 mg/kg/day PO, q12h for 5 to 7 days, limited to 1000 mg/dose) or amoxicillin–clavulanate (90 mg/kg/day PO, q12h for 10 days, preparation 600 mg/42.9 mg/5 mL suspension, given with milk or food). Treat children allergic to penicillin with erythromycin–sulfisoxazole (40–50 mg/kg/day PO, divided q6–8h, limited to 2 g/day). When penicillin-resistant strains are suspected, treat with amoxicillin–clavulanate (90 mg/kg/day PO, q12h for 10 days) or ceftriaxone (50 mg/kg IM/IV, once, limited to 1 g/dose).

AOM in adults can be treated with amoxicillin (500 mg q12h PO for 5–7 days or with more serious disease 500 mg q8h PO for 5–7 days), amoxicillin–clavulanate (500 mg/125 mg or 875 mg/125 mg PO, q12h, with food or milk), azithromycin (500 mg PO q24h × 1 day and 250 mg PO q24h × 4 days), erythromycin, clarithromycin, or trimethoprim–sulfamethoxazole. When penicillin-resistant strains are the likely pathogen, treat with azithromycin or clarithromycin.

Pneumococcal polysaccharide vaccine

Two pneumococcal vaccines of differing production are licensed (as of June 2013) for immunoprophylaxis of adults and children in the United States (see above, Introduction). The first PPSV23 received approval by the Food and Drug Administration (FDA) in 1983 and the second vaccine PCV13 received approval in February 2010.

PPSV23 is safe, cost-effective, and efficacious, with an overall efficacy rate of about 65% to 70% in immunocompetent adults for the serotypes contained in the vaccine. The 23 serotypes included in PPSV23 represent the most common serotypes that infect children and adults (namely 1, 2, 3, 4, 5, 6B, 7F, 8, 9N, 9V, 10A, 11A, 12F, 14, 15B, 17F, 18C, 19F, 19A, 20, 22F, 23F, and 33F) and cover between 70% and 80% of IPD, depending upon the locality in the United States. Serotype 6A is not included in PPSV23, but is included in PCV13.

PPSV23 is recommended for adults at increased risk of serious IPD, including all adults 65 years and older and adults younger than 65 years of age who suffer certain underlying diseases including chronic heart and lung diseases, diabetes mellitus, CSF leak, cochlear implant, alcoholism, chronic liver disease and cirrhosis, functional and anatomic asplenia, lymphoma, leukemia, Hodgkin's disease, HIV infection, chronic renal failure, nephrotic syndrome, generalized malignancy, solid organ transplant, multiple myeloma, iatrogenic immunosuppression and who smoke cigarettes. However, adults 19 years of age and older who suffer immunocompromising diseases, CSF leaks, cochlear implants, and functional or anatomic asplenia, and who never previously received PPSV23 should, when these underlying diseases are recognized, receive one dose of PCV13 first and then receive one dose of PPSV23 about 8 weeks subsequently. If they previously received one or more doses of PPSV23, they should receive one dose of PCV13 one year after the last dose of PPSV23.

Routine revaccination with PPSV23 is not recommended. Adults who received their first dose of vaccine before 65 years of age should receive a second dose of PPSV23 after 65 years of age and at least 5 years after the first dose. Also a second dose of vaccine is recommended 5 years after the first dose for adults 19 years and older with immunocompromising diseases, CSF leaks, cochlear implants, and functional or anatomic asplenia. Antibodies wane over time in all adults; second doses of vaccine provide satisfactory booster responses. Injection site reactions occur somewhat more frequently after revaccination than after primary vaccination.

Recently, PCV13 was recommended for all adults age 65 years and older. If they have never received a pneumococcal vaccine the recommendation is for a single dose of PCV13 followed in 6 to 12 months by a single dose of PPSV23. However, if they have received a single dose of PPVS23 after age 65, they should receive also a single dose of PCV13 at least 1 year later. If they had received a single dose of PPVS23 before 65 years of age, then after age 65 years they should receive first a single dose of PCV13 and 6 to 12 months later a single dose of PPVS23. The two doses of PPVS23 should be given at least 5 years apart.

Routine immunization of children with PCV7 (which included serotypes 4, 6B, 9V, 14, 18C, 19F, and 23F) for prevention of otitis media and IPD cases began in 2000 and ended in 2010. In assessments conducted during the ensuing 10 years, PCV7 proved highly efficacious in children, reducing substantially IPD cases due to vaccine serotypes, as much as 80% to 90%, or near elimination of some vaccine serotypes, and a reduction by at least one-half of total cases of IPD. Unexpectedly, an additional benefit of its usage in children was a substantial decrease among adults of IPD cases caused by PCV7 serotypes, likely due to diminished shedding of these serotypes by children, and consequently, less spread of these serotypes from children to adults, especially grandparents. As the number of cases of IPD due to vaccine serotypes declined both in children and adults, several other serotypes emerged worldwide to occupy this void, designated replacement serotypes, which were not included in PCV7 vaccine. The need to cover these replacement serotypes led to the development and approval of PCV13.

In 2010, PCV13 (which includes serotypes 1, 3, 4, 5, 6A, 6B, 7F, 9V, 14, 18C, 19A, 19F, and 23F) replaced PCV7 for routine childhood immunization against pneumococcal otitis media and IPD. It is recommended for routine immunization of children 6 weeks to 5 years of age, starting at 2 months of age. The dose is 0.5 mL intramuscularly administered at 2, 4, 6, and 12 to 15 months of age. A catch-up schedule for children with an incomplete schedule of PCV13 or only PCV7 is available at the ACIP website (http://www.cdc.gov/vaccines/acip/index.html). A single dose of PCV13 is recommended for children 6 to 18 years of age. Children 2 years of age and older who are immunocompromised or have sickle cell disease or functional or anatomic asplenia should receive one dose of PPSV23 eight weeks or later after their last dose of PCV13 and a second dose of PPSV23 five years later, whereas immunocompetent children 2 years of age and older with chronic illness (chronic heart or lung diseases, cochlear implants, CSF leaks, or diabetes mellitus) should receive only a single dose of PPSV23 eight weeks or later after their last dose of PCV13.

Currently, pneumococcal vaccine coverage among at-risk adults falls short of Healthy People 2020 goals. Wider vaccine usage in children and adults can be expected to alter the prevalence of *S. pneumoniae* as an etiologic agent of AOM, pneumonia, and meningitis.

Pseudomonas, stenotrophomonas, and burkholderia

Titus L. Daniels

Pseudomonas aeruginosa is an aerobic, gram-negative bacillus with a diversified ecologic niche. *P. aeruginosa* is highly pathogenic among immunocompromised patients and is responsible for substantial morbidity and mortality. *P. aeruginosa* is principally a healthcare-associated pathogen, although community-onset infection has been described among immunocompetent and immunocompromised patients (i.e., neutropenia, HIV, AIDS). Such patients may be encountered by primary care and subspecialty physicians alike, and diagnosis requires a high index of suspicion. Infections commonly associated with *P. aeruginosa* include pneumonias, bloodstream infections (BSI), urinary tract infections, and surgical site infections (Table 146.1). Two related species, *Stenotrophomonas maltophilia* and *Burkholderia cepacia*, are briefly discussed.

Epidemiology

The epidemiology of *P. aeruginosa* infections reflects its predilection for moist environments. In hospitals, *P. aeruginosa* has been isolated from respiratory devices, disinfectants, distilled and tap water, and sinks. *P. aeruginosa* can readily colonize the upper respiratory tract of mechanically ventilated patients, the gastrointestinal tract of patients receiving chemotherapy or broad-spectrum antibiotics, and the wounds of burn patients. Colonization usually precedes invasive infection.

Among healthcare-associated infections occurring in intensive care units, *P. aeruginosa* is among the most commonly identified pathogens. Emergence and spread of antimicrobial resistance, especially multidrug resistance (MDR), among *P. aeruginosa* is frequent. The National Healthcare Surveillance Network 2020 report revealed that 26.2% of device-associated isolates are resistant to quinolones and 20.3% are resistant to extended-spectrum cephalosporins. Furthermore, 20.7% of the isolates are resistant to carbapenems, an agent once considered universally active against *P. aeruginosa*. The emergence and spread of MDR *P. aeruginosa* challenges the clinician when selecting appropriate antimicrobial therapy and underscores the importance of obtaining cultures with susceptibility testing in patients suspected of having bacterial infections. Knowledge of local antimicrobial resistance trends is essential to ensure optimal patient outcomes.

Diagnosis

The clinical features of *P. aeruginosa* infections are indistinguishable from those of other bacterial organisms, and a definitive diagnosis requires specimen cultures from the suspected site of infection (i.e., blood, sputum, urine) to identify the organism. Other clinically important gram-negative organisms that resemble *P. aeruginosa* come from the genera *Stenotrophomonas*, *Burkholderia*, and *Ralstonia*.

TABLE 146.1 **RISK FACTORS FOR *P. AERUGINOSA* INFECTIONS**

Type of infection	Setting
Bacteremia	Neutropenia, pulmonary or urinary tract focus, burns
Pneumonia	Mechanical ventilation, neutropenia, chronic lung disease
Endocarditis	Injection drug use, prosthetic heart valve
Meningitis, brain abscess	Hematogenous or contiguous spread, neurosurgery, penetrating head trauma
Urinary tract infection	Bladder instrumentation
Osteomyelitis, septic arthritis (e.g., sternoclavicular joint)	Contiguous or hematogenous spread, injection drug use
Osteochondritis	Puncture wounds of the feet
Malignant external otitis	Diabetes, advanced age
Green nail syndrome	Water immersion, wet skin

Antimicrobial therapy

Initial selection of an agent should be guided by the site of infection, the patient's allergy history, and the institutional antibiogram. Early, aggressive antimicrobial therapy, with modification when susceptibility results become available, imparts a survival advantage and minimizes the emergence of antimicrobial resistance. Although several antipseudomonal antibiotics exist (Table 146.2), intrinsic or acquired resistance and bacterial persistence at sites of infection complicate management and eradication.

β-lactam antibiotics active against *P. aeruginosa* include the extended-spectrum penicillins, some extended-spectrum cephalosporins, the carbapenems (except ertapenem), and the monobactam aztreonam. Newer generation combination β-lactam β-lactamase inhibitors have become available for the treatment of resistant gram-negative bacteria, including *P. aeruginosa.* These agents form the basis for treatment of most *Pseudomonas* infections due to extensive clinical experience and patient tolerability. The high prevalence of reported penicillin allergy is the primary limitation.

The aminoglycosides tobramycin, amikacin, and gentamicin have excellent in vitro activity against *P. aeruginosa*. The concentration-dependent bactericidal activity and the post-antibiotic effect of aminoglycosides provide the rationale for once-daily dosing. Aminoglycoside monotherapy should be avoided due to selection of resistant mutants and increased risk of clinical failure. Renal function and serum aminoglycoside levels should be monitored closely.

The quinolones have been frequently used for the treatment of infections caused by *P. aeruginosa* and other bacteria. They possess excellent tissue penetration, good oral bioavailability, and a favorable safety profile. Ciprofloxacin is considered the more active fluoroquinolone. Increasing resistance to the quinolones, however, should temper reliance on their use as the basis for empiric therapy against *P. aeruginosa*, especially among hospitalized patients.

Use of polymyxin antibiotics has reemerged due to MDR and pandrug-resistant gram-negative infections, including *P. aeruginosa*. The polymyxins possess activity against a variety of gram-negative organisms but have been limited in use due to their adverse effects, namely nephrotoxicity and neurotoxicity. Polymyxins are currently recommended only for isolates resistant to other antibiotics. Susceptibility testing should be performed as resistance to the polymyxins has been reported.

Much controversy exists over the use of combination therapy ("double-coverage") for the treatment of infections due to *P. aeruginosa*. Data from a Cochrane review of sepsis comparing β-lactam and aminoglycoside combination therapy versus β-lactam monotherapy found no advantage to combination therapy for all-cause mortality (relative risk [RR] 1.01; 95% confidence interval [CI] [0.75, 1.35]) or clinical failure (RR 1.11; 95% CI [0.95, 1.29]). Empiric combination therapy for most serious infections may still be warranted when considering local resistance data and to ensure appropriate treatment of other possible infecting organisms. The guiding principle for selecting combination therapy should be that each agent has a unique mechanism of action; this will avoid a possible antagonistic effect and increase the likelihood that at least one administered agent is active against the offending organism; β-lactam and aminoglycoside combination therapies are the most studied and continue to be primarily recommended.

Infections caused by *P. aeruginosa*

Respiratory infections

P. aeruginosa pneumonia may follow colonization of patients in the setting of mechanical ventilation, antibiotic administration, neutropenia, AIDS, and chronic pulmonary disease, particularly in patients with cystic fibrosis (Table 146.3). Lower respiratory tract infection may be distinguished from airway colonization by an increase in quantity and purulence of respiratory secretions. Clinical manifestations may be fulminant, with fever, chills, dyspnea, productive cough, and systemic toxicity. Diffuse bronchopneumonia with nodular infiltrates is commonly seen on chest radiograph. Cavitary lesions may occasionally be seen. Pneumonia may be accompanied by bacteremia, particularly in neutropenic patients. Empiric antimicrobial treatment in the hospitalized or neutropenic patient with fever and lung infiltrate should include coverage for *P. aeruginosa*. Conventional antimicrobial therapy for *P. aeruginosa* pneumonia includes an antipseudomonal β-lactam combined with an aminoglycoside or a quinolone. Inhaled tobramycin (300 mg q12h) may be considered as adjunctive therapy.

Patients with cystic fibrosis are prone to chronic lower respiratory infections with mucoid strains of *P. aeruginosa*. These infections usually persist for a lifetime, with frequent acute exacerbations manifested by decreased exercise tolerance, increased cough and sputum, and weight loss. Therapy consists of an antipseudomonal penicillin containing ticarcillin or piperacillin plus an aminoglycoside. These patients may require large doses because of altered pharmacokinetics. Aggressive physiotherapy, nutrition, and hydration are essential.

TABLE 146.2 **ANTIMICROBIAL AGENTS FOR *P. AERUGINOSA***

Antimicrobial agent	Dose[a]/route /interval	Comment
β-Lactams		
Piperacillin–tazobactam	3.375 g IV q6h or 4.5 g IV q6h 4.5 g IV bolus, followed by 3.375 g IV q8h infused over 4 hours	Recommended interval dosing Recommended extending infusion dosing
Ceftazidime	2 g IV q8h	Preferred agent for CNS infections
Cefepime	2 g IV q12h	
Ceftazidime-avibactam	2.5 g IV q8h	
Ceftoloazone-tazobactam	1.5 g IV q8h	Recommended dose for cUTI and cIAI Recommended dose for HABP/VABP
Cefiderocol	2 g IV q8h infused over 3 hours	No gram positive or anaerobic activity
Meropenem	1 g IV q8h	
Meropenem-vaborbactam	4 g IV q8h infused over 3 hours	Addition of vaborbactam to meropenem does not increase activity against *Pseudomonas aeruginosa or Stenotrophomonas maltophilia*
Imipenem-cilastatin	0.5 g IV q6h	
Aztreonam	2 g IV q8h	Frequently reserved for penicillin-allergic patients
Quinolones		
Ciprofloxacin	400 mg IV q12h 500–750 mg PO q12h	Most active antipseudomonal quinolone in vivo
Delafloxacin	300 mg IV q12h 450 mg PO q12h	
Levofloxacin	750 mg IV/PO daily	
Prulifloxacin	600 mg PO daily	Not available in the United States
Aminoglycosides[b,c,d]		
Amikacin	15mg/kg IV once daily or 7.5 mg/kg IV q12h	
Gentamicin	5 mg/kg IV once daily or 2 mg/kg loading dose, then 1.7 mg/kg IV q8h	
Tobramycin	5 mg/kg IV once daily or 2 mg/kg loading dose, then 1.7 mg/kg IV q8h	
Polymyxins		
Polymyxin E (colistin)	1.5 mg/kg IV q8h	
Polymyxin B	0.75–1.25 mg/kg IV q12h	

[a] Suggested dosing is for adult patients with normal renal and hepatic function.
[b] Aminoglycosides are not recommended for monotherapy against *P. aeruginosa*.
[c] Once-daily aminoglycoside dosing has been shown to be effective, less nephrotoxic, and less ototoxic, and is the preferred dosing method.
[d] Aminoglycoside levels and renal function should also be closely monitored during therapy.
cIAI, complicated intra-abdominal infection; CNS, central nervous system; cUTI, complicated urinary tract infection; HABP/VABP, hospital acquired bacterial pneumonia/ventilator acquired bacterial pneumonia.

Bloodstream infections

BSI may complicate *P. aeruginosa* infections at other sites. Predisposing factors include neutropenia, hematologic malignancy, organ transplantation, vascular and urinary tract catheterization, and antibiotic use. The lower respiratory tract is the most common source of *Pseudomonas* bacteremia, followed by skin, soft tissues, and the urinary tract. Evaluation should include an aggressive search for the source of the bacteremia.

No distinct clinical characteristics differentiate *P. aeruginosa* BSI from other gram-negative bacteremias. Most patients have fever, tachycardia, and tachypnea. Many have signs of systemic toxicity with hypotension, shock, disseminated intravascular coagulopathy, and altered mental status. Skin manifestations include papules,

TABLE 146.3 **MANAGEMENT OF *P. AERUGINOSA* INFECTIONS**

Infection	Antibiotics[a]	Adjunctive
Meningitis	Ceftazidime[b] + AG	Intrathecal AG
Bacteremia	AP-BL + AG or FQ	Identify source
Endocarditis	AP-BL + AG or FQ	Valvulectomy for persistent bacteremia
Pneumonia	AP-BL + AG or FQ	Aggressive respiratory care
Malignant external otitis	AP-BL + AG or FQ	Surgical debridement may be necessary
Osteomyelitis	AP-BL + AG or FQ	Surgical debridement
Urinary tract	FQ alone or AP-BL ± AG	Remove catheter

[a] Recommended antibiotics for empiric coverage against *P. aeruginosa*. Therapy should be refined once susceptibility data are available.
[b] Aztreonam may be used for patients with penicillin or cephalosporin allergy. Other AP-BL do not achieve reliable cerebrospinal fluid concentrations.
AG, aminoglycoside; AP-BL, antipseudomonal β-lactam; FQ, fluoroquinolone (i.e., ciprofloxacin or levofloxacin).

bullae, and, rarely, ecthyma gangrenosum (Figure 146.1), a focal skin lesion characterized by hemorrhage, necrosis, and vascular invasion by bacteria. Prompt initiation of combination antimicrobial therapy is crucial because there is a high mortality. Therapy should continue for 2 to 3 weeks in seriously ill patients.

Infective endocarditis

Infective endocarditis caused by *P. aeruginosa* is rare and occurs primarily in the setting of injection drug use and occasionally with prosthetic heart valves. Injection drug users acquire this organism from nonsterile diluents such as tap water or nonsterile paraphernalia. Bacteremia with fever is invariably present. Tricuspid valve infection, which is typical, commonly presents with signs of septic pulmonary embolism. If treatment is early and aggressive with effective antibiotics, cure may be achieved without surgery. Tricuspid valvulectomy may be necessary in the event of bacteriologic failure or recurrence. Involvement of the aortic and mitral valves may manifest as a severe acute illness with sepsis and large arterial emboli necessitating early surgical valve replacement in addition to antimicrobial treatment. Combination

FIGURE 146.1 Ecthyma gangrenosum. (A) Lesions with ulceration and surrounding erythema. (B) A more classic lesion with necrosis and surrounding erythema.

therapy with a β-lactam agent and an aminoglycoside in high doses (e.g., tobramycin, 8 mg/kg/d) is recommended. Antibiotic therapy should be continued for at least 6 weeks.

Urinary tract infections

P. aeruginosa is a common nosocomial urinary pathogen. These infections are commonly associated with indwelling urinary catheters. Bacteremia, a common complication, may lead to metastatic infection (e.g., vertebral osteomyelitis). Symptomatic urinary tract infections should be treated by removing the catheter when possible and by administering an antibiotic. Monotherapy with an antipseudomonal β-lactam or a quinolone suffices unless there is secondary bacteremia or upper urinary tract infection. Oral quinolones may be used successfully even in complicated urinary tract infections. A 7- to 10-day course of treatment is adequate for uncomplicated cases. Longer courses of 2 to 3 weeks may be necessary for pyelonephritis, renal abscess, or complicating bacteremia. Asymptomatic bacteriuria does not typically require treatment. Eradication of the bacteriuria is often impossible if the patient has an anatomic abnormality or a foreign body, and antibiotics in this setting may select only for resistant organisms.

Meningitis

P. aeruginosa is a rare cause of meningitis and brain abscess in the general population, although it is a well-described complication of neurosurgery-related meningitis. Infection may occur by (1) extension from a contiguous structure such as mastoid or sinuses, (2) direct inoculation from penetrating trauma or neurosurgical procedures, or (3) metastatic spread from a distant site. Ceftazidime is the antimicrobial of choice because of its excellent in vitro activity and its ability to penetrate cerebrospinal fluid (CSF). Aztreonam and the carbapenems have good in vitro activity, but experience with these agents is limited. The extended-spectrum cephalosporins are not indicated for the treatment of meningitis. Addition of an aminoglycoside may be justified on the basis of possibly conferring synergy and preventing emergence of antibiotic resistance. Because of poor penetration of aminoglycosides into CSF, intrathecal or intraventricular doses may be required. There are anecdotal reports of successful therapy with parenteral ciprofloxacin, but quinolones should be used only when other antibiotics have failed or when organisms are resistant to β-lactam agents. Cure of *Pseudomonas* central nervous system infections may require surgical drainage of brain abscesses, debridement of infected tissues, and removal of prosthetic materials. A minimum of 2 weeks and as many as 6 weeks of antimicrobial therapy may be necessary.

Ear infections

Otitis externa is most commonly caused by *P. aeruginosa* and is usually associated with immersion (swimmer's ear). Patients complain of pain and pruritus. Examination reveals edema, exudate, and erythema of the pinna and external canal. This infection is treated with topical agents such as antibiotic drops (polymyxin, neomycin, or a quinolone) plus hydrocortisone or dilute acetic acid (see Chapter 6, "Otitis").

A more invasive and necrotizing process involving the bone and soft tissues of the external auditory canal and with potential to extend to the temporal bone and base of the skull is referred to as *malignant otitis externa* (Figure 146.2). This principally affects elderly persons and diabetics. Otalgia and purulent drainage from the external ear canal are present. Neurologic complications such as cranial nerve palsies may become manifest. CT or MRI is useful to delineate the extent of bone and soft tissue destruction and to monitor treatment. Because debridement may be necessary, surgical consultation is advised. Combination antimicrobial treatment is recommended for a minimum of 4 weeks. The course of treatment should be extended to 6 to 8 weeks for more extensive disease.

Bone and joint infections

P. aeruginosa causes osteomyelitis and septic arthritis as a result of hematogenous dissemination or contiguous spread. Vertebral osteomyelitis usually occurs in elderly patients with urinary tract infections associated with bladder instrumentation and in intravenous drug users. Neck or back pain with paraspinal tenderness is a

FIGURE 146.2 Malignant otitis externa. Edema and erythema of the helix, antihelix, and scapha of the ear are seen here. As infection progresses, the tragus often becomes involved. Visualization of the canal is frequently limited due to edema and pain.

FIGURE 146.3 Osteochondritis following a nail puncture wound of the sole. Cellulitis is often a prominent feature in patients with acute osteochondritis due to *P. aeruginosa*, as evidenced in this photo. Edema is also a common finding.

common presentation. CT and MRI are sensitive diagnostic means of defining the extent of disease. The pathogen can be isolated by needle aspiration or biopsy under fluoroscopic or CT guidance. Occasionally, surgical exploration for biopsy, culture, and decompression is necessary. Removal of prosthetic material is usually necessary. Combination antibiotic therapy with an antipseudomonal β-lactam and either an aminoglycoside or quinolone should be used for a minimum of 4 to 6 weeks. Monotherapy has been used successfully, but treatment failures have occurred.

Contiguous osteomyelitis arises from direct extension of infected overlying skin and soft tissues or penetrating trauma. *P. aeruginosa* may be implicated in this setting in patients with infected diabetic foot ulcers. Vascular insufficiency and the polymicrobial nature of this infection may complicate management. The goal of therapy is to achieve effective levels of antimicrobials in bone and soft tissues. Prolonged antimicrobial treatment (up to 6 weeks), including a β-lactam antipseudomonal agent and an aminoglycoside, has been the current standard, but quinolones used either alone or in combination with a β-lactam have proved efficacious in open-label trials.

Osteochondritis of the foot involving bone and fibrocartilaginous joints is frequently seen following puncture wounds through the soles of footwear colonized by *P. aeruginosa* (Figure 146.3). Treatment consists of surgical debridement combined with an antimicrobial agent such as ceftazidime or ciprofloxacin for a minimum of 4 weeks.

Skin infections

Exposure to contaminated whirlpools, hot tubs, and swimming pools may produce *P. aeruginosa* folliculitis, a diffuse red maculopapular or vesicopustular rash (Figure 146.4). The eruption is self-limited and does not require specific antimicrobial treatment.

FIGURE 146.4 Folliculitis. The folliculitis of *P. aeruginosa* may appear similar to other common dermatologic conditions. The appearance of the lesions in Panel A raises the possibility of shingles. The patient in Panel B has a widespread infection that may be confused with staphylococcal infection or steroid-induced folliculitis. Culturing the contents of the lesions will aid in obtaining an accurate diagnosis.

Burn wounds may become colonized and subsequently infected with *P. aeruginosa*. Bloodstream invasion may thus occur, resulting in septicemia. Systemic antibiotic combinations should be administered. A topical agent such as mafenide acetate or silver sulfadiazine may be considered to reduce burn wound colonization. Avoidance of hydrotherapy also reduces the risk of *Pseudomonas* infections in burn patients.

Persons with a history of submersion of the hands may develop greenish discoloration of the nail plates and *Pseudomonas* nail bed infection. This condition has been called *green nail syndrome* (Figure 146.5). Treatment requires elimination of the exposure; orally administered ciprofloxacin is a useful adjunct.

The warm, moist toe webs of the feet may become infected with *P. aeruginosa*. The spaces between the third, fourth, and fifth toes are the most common sites. Toe web infections have been most commonly associated with military recruits, athletes, and laborers. Tinea pedis is a common antecedent. The infected tissue is damp, boggy, macerated, and white. Adjacent skin and subcutaneous tissue may become inflamed. More severe infection can progress to ulceration (Figure 146.6).

Pseudomonas toe web infection may resemble tinea pedis but does not improve with topical antifungal agents. *Pseudomonas* should be suspected when green pigment is visible on the patient's socks, bandages, or on dried exudate. Green toenails strongly suggest the diagnosis, and further evidence is obtained if Wood's light shows green-white fluorescence (Figure 146.7).

Treatment of toe web infections includes an antipseudomonal antimicrobial and soaking with 2% acetic acid solution. Prevention of infection is best achieved by keeping feet and toes clean and dry and by wearing work boots or athletic shoes on alternate days to allow for the lining to fully dry.

FIGURE 146.6 Toe web infection. As toe web infections progress, a characteristic macerated appearance is seen.

FIGURE 146.5 Green nail syndrome. Note the characteristic green appearance of the nail.

Infections caused by related species

Stenotrophomonas maltophilia is a healthcare-associated, gram-negative pathogen that may cause bacteremia, pneumonia, and wound infection. *S. maltophilia* healthcare-associated pneumonia

FIGURE 146.7 Use of a Wood's light reveals the typical luminescence classically described with *P. aeruginosa*.

is associated with mechanical ventilation, tracheostomy, use of nebulizers, and previous exposure to broad-spectrum antibiotics. Patients usually have preexisting lung conditions such as chronic obstructive pulmonary disease. Isolation of *S. maltophilia* from the respiratory tract in ventilator-associated pneumonia is an important predictor of mortality. Management of *S. maltophilia* pneumonia and other infections is often difficult because the organism is usually resistant to most antipseudomonal β-lactams, carbapenems, and aminoglycosides. Trimethoprim-sulfamethoxazole (TMP-SMX) is the antibiotic of choice for therapy. Ceftazidime, ticarcillin-clavulanate, and the quinolones have variable activity among strains. Combination therapy with TMP-SMX and a β-lactam such as ticarcillin-clavulanate or ceftazidime (if susceptibility is documented) has been proposed based on in vitro synergy and anecdotal reports of clinical efficacy. The polymyxins retain activity against selected highly resistant isolates.

Burkholderia cepacia is an opportunistic pathogen that may colonize the respiratory tract of a patient with cystic fibrosis and lead to persistent disease with progressive respiratory failure. Therapy is thwarted by antibiotic resistance to many β-lactam agents and aminoglycosides. The extended-spectrum cephalosporin agents (ceftolazone/tazobactam, ceftazidime/avibactam, cefiderocol) appear to have promise, with early in vitro data showing activity. Susceptibility testing is essential as resistance is variable to quinolones, TMP-SMX, and the carbapenems is common and variable. Chloramphenicol may retain activity, whereas the polymyxins are generally ineffective.

Rat-bite fevers

Neil S. Lipman

For 2,300 years, illness associated with rat bites has been recognized in India, which is believed to be the country of origin for the disease. The first recorded description of rat-bite fever was in lectures by a physician at Yale in the early nineteenth century. It was not until 1902 that Japanese workers describing the clinical entity in a European journal coined the term "*Rattenbisskrankheit*," or rat-bite fever. Rat-bite fever comprises two clinically similar but distinct bacterial diseases caused by unrelated agents, *Streptobacillus moniliformis, Streptobacillus notomytis*, and *Spirillum minus*. The organisms are distributed worldwide. Historically streptobacillary disease was reported to be more common in the United States and Europe, and spirillary disease more common in the Far East; however, almost all recently reported cases of rat-bite fever, which have been increasing in number, are predominantly streptobacillary. Genetic analysis of several recent disease-associated isolates has revealed that *S. notomytis*, not *S. moniliformis*, was the cause of rat-bite fever cases when exposure was to the black rat, *Rattus rattus*, and not the Norway or brown rat, *Rattus norvegicus.* The Norway rat is sold as pets, used as laboratory animal models, and is more common in many urban centers. It is likely that some of the previously reported cases of *S. moniliformis*-associated disease were cause by *S. notomytis,* as identification of the latter is challenging by conventional methods.

Rat-bite fevers are most frequently associated with the bite or, less frequently, a scratch or direct contact (e.g., kissing pet rat) with principally pet, but also wild or laboratory rats. A number of reported cases were not associated with rat bites or contact, although all patients had a history of occupational exposure to rat-infested areas or contaminated materials. Disease caused by these agents has also followed contact with a variety of other species, including mice, gerbils, guinea pigs, squirrels, dogs, cats, ferrets, turkeys, and weasels, all of which presumably had contact with rats or contaminated materials. Estimates are that 3 to 6 million animal bites occur annually in the United States of which 2% to 5% are caused by rodents. Many cases of rat-bite fever occur in individuals of low socioeconomic status in cities or, with increasing frequency, in association with pet rats, whose popularity is increasing. In 2011, it was estimated that 0.1% of US households owned one or more pet rats. Rats are also often fed to pet snakes and other reptilians with cases of rat-bite fever described in their owners. Asymptomatic rats are the principal reservoirs for the organisms that reside as commensals in the nasopharynx, middle ear, and proximal trachea.

Diagnosis is rare, likely the result of a low incidence of disease despite substantial potential exposure, a low index of suspicion of attending physicians, the routine postexposure use of effective antimicrobials, and the difficulty of isolating the organism in the laboratory. The true incidence in the United States is unknown since the disease is not reportable. Many of the reported cases in the United States are associated with children under the age of 12.

The rat is the natural reservoir and primary host of *S. moniliformis, S. notomytis*, and *S. minus*, none of which is routinely associated with natural disease in the species. Rarely, otitis media has been described with *S. moniliformis* in the Norway rat and *S. notomytis* in the black rat. The organisms are nasopharyngeal commensals and may be found in other tissues including the urine and blood. It is estimated that 10% to 100% of domestic and 50% to 100% of wild rats are colonized with *S. moniliformis*. Estimates of infection rates in laboratory rats during the first half of the previous century were similar to those reported for wild populations, but modern production techniques and maintenance, in concert with frequent monitoring of commercial suppliers, has reduced this rate dramatically. Almost all contemporary laboratory rat colonies

in developed countries are free of *S. moniliformis*. Although disease in humans has occasionally been associated with other species, these species are not believed to be commensal carriers.

Presentation

Rat-bite fevers are acute, systemic illnesses with relapsing fever. Streptobacillary rat-bite fever, streptobacillary fever, or streptobacillosis follows infection with *S. moniliformis* or *S. notomytis*. *Haverhill fever* and *epidemic arthritic erythema* are diseases caused by *S. moniliformis* acquired through ingestion of contaminated water, raw milk, or food. *Sodoku*, which derives from the Japanese word for rat (*so*) and poison (*doku*), spirillary rat-bite fever, and spirillosis are diseases resulting from *S. minus* infection. Although similar, these diseases can be differentiated clinically (Table 147.1). Streptobacillary rat-bite fever has a shorter incubation period than the spirillary form and is often accompanied by rash and arthralgia. Haverhill fever is more frequently associated with vomiting, diarrhea, and sore throat. An indurating chancre develops at the site of inoculation and accompanies clinical signs in the spirillary form. Dual infections, albeit extremely rare, may occur. Most cases of streptobacillary disease spontaneously resolve within 2 weeks. If the patient goes untreated, 13% of cases are fatal. Mortality is >50% in untreated patients with endocarditis. The clinical course of disease in infants may be particularly rapid and fatal. Mortality has been reported in adults following a short (<12 hour) presentation.

The incubation period of streptobacillary rat-bite fever is 2 to 10 days; however, onset usually occurs within 3 days of exposure. Clinical signs develop despite rapid healing of the bite wound, presumably as a result of bacteremia and septicemia. Illness of sudden onset is characterized by remittent chills, fever, headache, and myalgia and results from direct infectious as well as immune-mediated mechanisms. A morbilliform or petechial rash, which may be a result of leukocytoclastic vasculitis, develops in 75% of patients, frequently within days of onset, on either the lateral or the extensor surfaces of the extremities, sometimes involving the palms and soles. Infrequently, the rash may be generalized and/or present with pustules, desquamation, and purpura. Simultaneous with rash development, approximately 50% of patients have severe arthralgia or frank arthritis of at least one, but frequently more than one, large joint. The arthritis may be suppurative or nonsuppurative; monoarticular or migrating and polyarticular; and, rarely, occurs without other manifestations. Untreated, the course is biphasic, with fever and symptoms diminishing 2 to 5 days after onset and recurring several days later. Arthritis, endocarditis, myocarditis, pericarditis, hepatitis, pancreatitis, parotiditis, prostatitis, pneumonia, nephritis, meningitis, osteomyelitis, discitis, soft tissue abscesses, septicemia, and chorioamnionitis are reported complications. Relapsing fever with return of constitutional symptoms of 1 to 6 days' duration is not uncommon. Afebrile cases have been described.

In the United States, the spirillary form is considerably less common than streptobacillary disease. Illness follows an incubation period, usually 7 to 21 days but sometimes as short as 2 days or as long as months. There is initial healing of the bite wound. Subsequently, an indurated chancre or eschar develops at the wound site and is accompanied by a regional lymphadenitis and lymphangitis, fever, rigors, myalgia, and, in about 50% of the cases, an erythematous maculopapular rash originating from the wound. Arthritis is uncommon. Untreated, fevers and other symptoms resolve but then recur regularly, and mortality is estimated at between 7% and 13%.

Diagnosis

Diagnosis is suggested by a rat bite or rat contact, or exposure to rat-infested areas or contaminated materials, and clinical presentation. Patients may present without a history of rat bite or after a prolonged disease course. For infections caused by *S. moniliformis* or *S. notomytis*, definitive diagnosis depends on isolation of the organism by microbiologic culture and/or identification of the bacterium in culture or blood, fluid, or tissue samples by amplifying part of the 16S RNA gene using a generic primer set, followed by sequencing,

TABLE 147.1 **CLINICAL FEATURES OF RAT-BITE FEVERS**

Indurated bite wound	–	+++
Recurrent fever/constitutional signs (untreated)	Irregular periodicity	Regular periodicity

using polymerase chain reaction (PCR). A *S. moniliformis*-specific PCR, which likely also detects *S. notomytis* because of its >99.9% genetic similarity to *S. moniliformis,* has also been described using primers based on human and rodent strains. Detection by PCR in blood is more difficult than tissues because the copy number is lower, hemoglobin is inhibitory, and clearance of dead organisms is quicker after antibiotic treatment is initiated. Use of MALDI-TOF for identification has been inconsistently rewarding. There are no reliable serologic tests currently available in humans for either organism. A high index of suspicion in the laboratory is frequently necessary as these organisms are extremely difficult to isolate.

S. moniliformis and *S. notomytis* are fastidious, facultatively anaerobic, highly pleomorphic, asporogenous, gram-negative rods, measuring less than 1 × 1 to 5 μm long. Curved and looping, nonbranching filaments as long as 150 μm may be formed. Characteristic bulbous swellings have been described in older cultures or in cytologic specimens of *S. moniliformis*, resulting in dismissal of the organism as proteinaceous debris. *S. moniliformis* has two variants, the bacillary and the cell-wall–deficient, penicillin-resistant, apathogenic L-phase variant. Spontaneous conversion from one form to another, which alters the organism's sensitivity to antimicrobial agents, may be responsible for clinical relapses and resistance to therapy. *S. moniliformis* and *S. notomytis* are difficult to identify in most hospital laboratories because of their fastidious growth requirements and slow growth. The organisms may be demonstrated by Giemsa, Gram, Wright, or silver stain in blood, synovial fluid, or other body fluids; samples should be mixed with 2.5% sodium citrate to prevent clotting before examination. Blood and joint fluid should be cultured in media enriched with 15% blood; 20% horse, calf, or rabbit serum; or 10% to 30% ascitic fluid. Media employed successfully include blood agar bases, chocolate agar, Schaedler agar, thioglycollate broth, meat-infusion broth, and tryptose-based media. Nalidixic acid can be added to the media to prevent overgrowth by gram-negative bacteria. Brain–heart infusion cysteine broth supplemented with Panmede, a papain digest of ox liver, has been advocated. The medium should not contain sodium polyanethol sulfonate (SPS), an anticoagulant and bacterial growth promoter used in blood culture media, as it inhibits the growth of the organism. Inoculated media are incubated at 37°C/98.6°F in humidified 5% to 10% carbon dioxide atmosphere. Characteristic "puffballs" appear after 2 to 6 days in broth; on agar 1 to 2 mm round, gray, smooth, glistening colonies are observed. L-forms produce colonies with a typical fried-egg appearance. Identification is made by biochemical profile. The API ZYM system and fatty acid profiles may be valuable in rapid identification. In the United States the Centers for Disease Control and Prevention's Meningitis and Special Pathogens Branch or a state public health laboratory can be contacted for assistance with culture and/or diagnosis. The shell vial cell culture technique has been described to isolate *S. moniliformis* when growth in culture media was unsuccessful.

S. minus is a gram-negative aerobic, motile, rigid spiral bacterium. It is 0.2 to 0.5 × 3 to 5 μm long and has two to six wide angular windings and pointed ends with one flagellum at each pole. *S. minus* cannot be grown on any artificial medium. It may be demonstrated in dark-field microscopy in wet mounts of blood, exudate from the bite wound, cutaneous lesions, and lymph nodes or in Giemsa- or Wright-stained specimens from these sites. Isolation requires intraperitoneal inoculation of infected materials into guinea pigs or mice followed by dark-field examination of the animal's blood or peritoneal exudate 1 to 3 weeks later.

Differential diagnosis of rat-bite fevers can be broad and can include septic arthritides such as Lyme disease, gonococcal arthritis, and brucellosis and noninfectious inflammatory polyarthropathies such as rheumatoid arthritis. Presentation with fever and rash mimic systemic lupus erythematosus, viral exanthems, rickettsial infections, secondary syphilis, and drug reactions. A biologic false positive for syphilis occurs in up to 25% of patients with streptobacillary disease and in up to 50% of cases with the spirillary form.

Therapy

Both streptobacillary and spirillary forms of rat-bite fever respond well to appropriate antimicrobial therapy. *S. minus* is more sensitive to therapy. Penicillin is the drug of choice for both organisms, and a dramatic response to therapy may be expected. Dosage of 600,000 U of procaine penicillin G, administered intramuscularly, twice daily for at least 7 days, is recommended for uncomplicated forms of the disease. Intravenous penicillin therapy should be initiated until antimicrobial sensitivity is determined in cases of severe disease. Adults should receive 400,000 to 600,000 U/day, increasing dosage to 1.2 million U/d if no response is observed within 48 hours. Children are treated with 20,000 to 50,000 U/kg/d for 7 days followed by 7 days of oral penicillin V therapy. Endocarditis, if present, should be treated with high-dose penicillin G (susceptible isolates: 4.8 million U/d procaine penicillin intramuscularly; resistant isolates: 20 million U/d intravenously) in combination with gentamicin or streptomycin daily for 4 to 6 weeks. Streptomycin enhances activity against the L forms of *S. moniliformis*. Children with endocarditis should be treated with 160,000 to 240,000 U/d penicillin G up to the maximum adult dose. Tetracycline (500 mg/kg q6h by mouth) or streptomycin (7.5 mg/kg BID intramuscularly) are effective alternatives in penicillin-allergic patients. Amoxicillin-clavulanate, doxycycline, second- and third-generation cephalosporins, ciprofloxacin, chloramphenicol, clindamycin, the macrolides erythromycin and clarithromycin, and vancomycin have been successfully employed. Treatment failures have been reported with erythromycin. Prophylactic administration of penicillin may be considered following a rat bite, although the risk of nascent infection is low. However, prophylaxis should be a high consideration in infants because of the possibility of rapid progression and severe outcomes.

Salmonella

Bruce S. Ribner

The salmonellae are gram-negative, non–spore-forming, facultatively anaerobic bacteria in the family Enterobacteriaceae. More than 2,500 different serotypes of *Salmonella* have been identified.

Salmonellae are widely distributed in nature. They are generally found in the gastrointestinal (GI) tracts of the hosts with which they are associated. Some salmonellae, such as *S. typhi* and *S. paratyphi*, are found to colonize only the human GI tract. Other *Salmonella* serotypes, such as *S. typhimurium*, have a wide range of hosts, including humans. Finally, some organisms, such as *S. dublin* and *S. arizona*, are rarely found in the GI tracts of humans. The specificity and range of the different serotypes helps to determine the epidemiology of infections caused by these bacteria.

Infections caused by the salmonellae are grouped into three major syndromes: gastroenteritis, typhoid or enteric fever, and localized infection outside of the GI tract. Although there is considerable overlap between these syndromes, their epidemiology and clinical presentations are distinct enough to make discussion by syndrome useful.

Gastroenteritis

Gastroenteritis accounts for most *Salmonella* infections in humans. The incidence of *Salmonella* gastroenteritis in the United States doubled during the 1980s and 1990s. Much of this increase was attributed to the widespread contamination of chickens and eggs as the industry became increasingly centralized. While the rate of *Salmonella* gastroenteritis stabilized in the late 1990s due to increased public awareness and improved sanitation during commercial processing, since then this rate has increased by 44%. It is estimated that there are 1.35 million episodes of *Salmonella* gastroenteritis annually in the United States, resulting in 26,500 hospitalizations and 420 deaths. Most cases of *Salmonella* gastroenteritis are traced to the ingestion of inadequately cooked poultry or eggs, either directly or through the consumption of such foods as Caesar salad, sauces containing raw eggs, and inadequately cooked stuffing contaminated by salmonellae from raw poultry. A recent study detected salmonellae contamination in 14% of the chickens sold in the United States: 68% of these isolates were resistant to at least one antibiotic. Beef, milk, and, rarely, fruits and vegetables have also been responsible for salmonellae infections. Pet reptiles, such as turtles, snakes, and lizards, frogs, and baby ducklings and chicks often have asymptomatic colonization of the GI tract. Young children who play with these animals may forget to wash their hands before eating, resulting in *Salmonella* gastroenteritis. Individuals at greatest risk for acquiring symptomatic disease are neonates under the age of 3 months; those with achlorhydria, either naturally or secondary to medication, or who are taking antacids; transplant recipients; individuals with lymphoma; patients with AIDS; and those aged >50 years. Children <5 years of age represent 27% of all patients with *Salmonella* gastroenteritis.

Salmonella gastroenteritis

Salmonella gastroenteritis has an incubation period of 8 to 72 hours, with shorter incubation periods being associated with higher amounts of ingested bacteria. The typical illness is accompanied by fever,

nausea, vomiting, abdominal cramping, and watery diarrhea; it lasts 4 to 7 days. The stool usually contains neutrophils, but dysentery, with gross blood and pus in the stool, is uncommon. Patients with *Salmonella* gastroenteritis occasionally have headaches and myalgias. Bacteremia, seen in approximately 8% of patients, is most common in those with impaired immunity (children <3 months and adults >65 years of age, those on corticosteroids or other immune suppressants, individuals with AIDS, those with inflammatory bowel disease, and those with hemoglobinopathies) or who are on hemodialysis. Bacteremia tends to occur early during the course of the illness. *Salmonella* gastroenteritis is typically a mild disease; it rarely leads to severe dehydration and cardiovascular collapse, although it is estimated that there are 26,500 hospitalizations and 420 fatalities a year in the United States from *Salmonella* gastroenteritis.

Approximately 50% of newborns with *Salmonella* gastroenteritis have GI carriage of the organism for >6 months. This rate decreases with age; <10% of adults remain colonized at 3 months. The administration of antibiotics during the early phase of illness is felt to increase the likelihood of carriage.

Typhoid or enteric fever

Typhoid fever is caused by salmonellae serotypes such as *S. typhi* and *S. paratyphi*, which are almost exclusively associated with humans. Transmission is by ingestion of contaminated food and water; although person-to-person transmission is possible, it is uncommon because of the large inoculum size required to cause illness in most individuals. In contrast to *Salmonella* gastroenteritis, the incidence of typhoid fever in developed countries has markedly decreased over the past few decades as sanitation and the quality of the water supply have improved. Most typhoid fever in the United States is acquired during foreign travel. A high percentage of infections acquired in the United States results from the ingestion of food prepared by chronic carriers, many of whom initially became colonized in another country.

Typhoid fever has an incubation period that is usually 7 to 21 days (range 3–60 days), depending on the size of the inoculum and the health of the host. Symptoms consist of fever, abdominal pain, hepatosplenomegaly, headache, and myalgias. Diarrhea is rare after the first few days. Although typhoid fever has classically been characterized as having a temperature–pulse dissociation with bradycardia in the face of a high fever, this phenomenon is uncommon. Rose spots, which are faint, maculopapular, salmon-colored blanching lesions found predominantly on the trunk, are seen in approximately one-third of patients. Biopsy of these lesions reveals perivascular, mononuclear cell infiltration, and culture frequently yields the organism.

Ninety percent of patients with typhoid fever have bacteremia during the first week of illness. This percentage decreases as the illness progresses. Positive stool cultures do not appear before the second week of illness, and the rate increases until, by the third week, 75% of patients have positive stool cultures. The white blood cell count is usually low in relation to the degree of illness. Occasionally an absolute leukopenia is seen.

The patient with untreated typhoid fever will have 4 to 8 weeks of sustained fever. Mortality of those with untreated disease is estimated to be 12% to 30% worldwide but only 1% in the United States. Mortality is highest in the immunocompromised, especially those with hemoglobinopathies, malaria, schistosomiasis, and infection with HIV. The major complication of untreated disease is hemorrhage from intestinal perforation secondary to ulceration and necrosis of the Peyer's patches in the ileum. Such hemorrhage may be seen during the third or fourth week of illness, often when the patient seems to be clinically improving. Other complications include pericarditis, endocarditis, splenic and hepatic abscesses, cholangitis, meningitis, and pneumonia. Ten percent of untreated patients relapse. Although one-fourth of patients with typhoid fever will have positive urine cultures, actual infection of the urinary tract with *S. typhi* and *S. paratyphi* is rare.

The differential diagnosis in a patient presenting with enteric fever may include malaria, amebiasis, and viral illnesses such as dengue or Epstein–Barr virus infection, and infection with non-*Salmonella* bacterial pathogens such as *Yersinia, Campylobacter*, and *Pseudomonas*.

Localized infections outside of the gastrointestinal tract

On rare occasions, *Salmonella* infection may present as a localized infection at a site other than the GI tract. This is most likely in patients with underlying illnesses. Sustained bacteremia with *S. choleraesuis*, *S. dublin* or *S. heidelberg* suggests an intravascular focus such as seeding of an atherosclerotic plaque or of the clot within a preexisting aneurysm, especially if the patient is elderly. If infection is localized to the abdominal aorta, surgery is generally necessary, as medical management alone is associated with a high mortality rate. Rarely, sustained bacteremia may result from endocarditis with a valve ring or septal abscess. Localized infection may also present as a hepatic or splenic abscess, especially if the patient has biliary tract stones, cirrhosis, or cholangitis.

Salmonellae are the second most common cause of gram-negative meningitis in neonates. They are also a common cause of osteomyelitis in children with hemoglobinopathies such as sickle cell disease.

Historically, *Salmonella* infection of the urinary tract was rare in the absence of nephrolithiasis, renal schistosomiasis, or renal tuberculosis. However, recent studies have documented an increase in *Salmonella* cystitis in elderly women, most of whom lacked structural abnormalities. It is felt that *Salmonella* cystitis most likely represents ascending infection of strains with greater pathogenicity for the urinary tract.

Approximately 2% of individuals who have *Salmonella* gastroenteritis will develop Reiter's syndrome. This occurs within 2 weeks of the onset of diarrhea and is associated with human leukocyte antigen (HLA) B27.

Chronic carriage

Because *Salmonella* is excreted in the stool of a high percentage of those recovering from acute infection for several months, the chronic carrier state is not considered to be present unless the

organism persists in the stool for >1 year. This occurs in approximately 1% to 4% of those with *S. typhi* infection and in fewer than 1% of those infected with other serotypes. Biliary tract carriage is most likely to occur in the elderly and those with cholelithiasis. Urinary tract carriage is most likely in those with bladder schistosomiasis and nephrolithiasis. Many chronic carriers have no clear history of a preceding acute *Salmonella* infection.

Diagnosis

Many clinical laboratories have changed to culture-independent diagnostic testing (CIDT) over the past decade. While such testing is potentially more rapid and detects pathogens that were frequently missed by culture alone in the past, they often do not identify organisms to the species level or identify the serotype of the organism. This negatively impacts the ability to detect foodborne outbreaks. They also do not provide antibiotic susceptibility information to guide treatment in those patients who require antibiotics. For these reasons, the US Centers for Disease Control and Prevention (CDC) encourages laboratories to culture specimens after a CIDT is positive (a practice called *reflex culturing*), and CIDT manufacturers have been encouraged to develop new tests to provide information that is now available only from cultured specimens.

Gastroenteritis

Although certain features may suggest *Salmonella* gastroenteritis in a patient, many other pathogens may produce an illness that is clinically indistinguishable. The diagnosis of *Salmonella* gastroenteritis depends on the isolation of the organism from a stool or blood specimen. As many clinical laboratories report that only 1% to 3% of stool specimens submitted for culture yield an enteric pathogen, and as mild gastroenteritis caused by *Salmonella* should not be treated with antibiotics (see "Therapy" section), many authorities have devised algorithms for selecting patients with gastroenteritis who should have stool cultures. Epidemiologic factors that should be sought as indicators of possible infectious diarrhea include the following: (1) travel to a developing area; (2) daycare center attendance or employment; (3) consumption of unsafe foods (e.g., raw meats, eggs, or shellfish; unpasteurized milk or juices) or swimming in or drinking untreated fresh surface water from, for example, a lake or stream; (4) visiting a farm or petting zoo or having contact with reptiles or with pets with diarrhea; (5) knowledge of other ill persons (such as in a dormitory or office or at a social function); (6) certain recent or regular medications (antibiotics, antacids, antimotility agents); (7) underlying medical conditions predisposing to infectious diarrhea (AIDS, immunosuppressive medications, prior gastrectomy, extremes of age); (8) receptive anal intercourse or oral–anal sexual contact; and (9) occupation as a food handler or caregiver. Signs and symptoms that suggest a bacterial etiology for gastroenteritis include fever, abdominal pain, and bloody stools. Some laboratories have also included a screen for the presence of fecal leukocytes or lactoferrin to select those stools that warrant further culture for enteric pathogens.

As mentioned previously, only 8% of patients with *Salmonella* gastroenteritis will have an accompanying bacteremia. This is most common in those with underlying diseases and tends to occur early during the course of the illness.

Typhoid or enteric fever

The patient with typhoid or enteric fever most commonly will present with symptoms of fever, abdominal pain, hepatosplenomegaly, headache, and myalgias. In endemic areas, the differential diagnosis is frequently between typhoid fever and malaria. Less commonly, rickettsial infection, dengue fever, plague, and tularemia may present with a similar syndrome. Systemic vasculitis may also present with a clinical picture similar to enteric fever. The definitive diagnosis of typhoid requires isolation of *S. typhi* or *S. paratyphi* or demonstration of the presence of antigens of these bacteria in body fluids. The body sites most likely to yield positive assays depend on the stage of illness. During the first week, blood cultures are most likely to be positive, whereas during the second and third week of illness stool cultures are usually positive. Cultures of rose spots, if present, and of a bone marrow aspirate are also frequently positive.

Serology for antibody to *S. typhi* antigens has been used widely in the past for the diagnosis of typhoid fever. Such assays must be used with caution as the antibodies persist for years after infection and may be elevated from vaccination. Although a fourfold rise in antibody titers in the context of an appropriate clinical illness is strong support for the diagnosis of enteric fever, a very elevated single assay can also be highly suggestive.

Localized infections outside of the gastrointestinal tract

The diagnosis of localized *Salmonella* infection outside of the GI tract depends on the isolation of the organism. This is especially true of localized infections such as visceral abscesses or endothelial infections, as there are no features that distinguish localized infection by the salmonellae as compared with the more common bacterial pathogens.

Chronic carriage

As mentioned previously, the chronic carrier state is not considered to be present unless the organism persists in the stool for >1 year. Although colonic colonization in the absence of biliary involvement has been reported, the overwhelming majority of patients with GI colonization have the gallbladder as the focus. To determine the site of colonization, a colonoscopy to detect colonic mucosal abnormalities and a culture of common bile duct drainage have been used. Imaging of the gallbladder can also be useful in determining underlying causes for colonization of the gallbladder such as cholelithiasis.

Patients with urinary tract chronic colonization can be evaluated with imaging studies to determine whether anatomic abnormalities, such as strictures or stones, are present. Such abnormalities make medical management alone less likely to be successful.

Therapy

People with diarrhea who attend or work in childcare centers, long-term care facilities, patient care, food service, or recreational water venues (e.g., pools and lakes) should follow jurisdictional recommendations for outbreak reporting and infection control.

Gastroenteritis

Salmonella gastroenteritis is usually a self-limited disease, and therapy should be primarily directed to the replacement of fluid and electrolyte losses. Antimotility agents such as loperamide are to be discouraged, especially if there is blood or mucus in the stool. Widespread resistance to chloramphenicol, ampicillin, and trimethoprim-sulfamethoxazole (TMP-SMX) now exists among the salmonellae, and multidrug-resistant salmonellae have been reported. Recent studies have shown that 5% of non-typhoidal *Salmonella* in the United States are resistant to five or more antimicrobial agents. Antimicrobial therapy for uncomplicated nontyphoidal *Salmonella* gastroenteritis, including short-course or single-dose regimens with oral fluoroquinolones, amoxicillin, or TMP-SMX, does not significantly decrease the length of illness, including duration of fever or diarrhea, and is associated with an increased risk of relapse, positive cultures after 3 weeks, antimicrobial resistance, and adverse drug reactions. However, certain patients are at increased risk for invasive infection and may benefit from preemptive antimicrobial therapy. Such patients would include neonates less than 3 months of age, those >50 years of age with cardiac, valvular, or endovascular abnormalities, or substantial joint disease, those on corticosteroids, persons with HIV infection, and persons with immunosuppression, inflammatory bowel disease, or hemoglobinopathies. Antibiotic therapy is also appropriate in those with severe disease (e.g., those with severe diarrhea, high fever, bloodstream infection, or who need hospitalization). Treatment in these patients should consist of an oral or intravenous antimicrobial administered for 7 days if immunocompetent and 14 days if immune compromised. Specific recommendations are listed in Table 148.1.

Typhoid fever

Fluoroquinolones have traditionally been the agents of choice for the treatment of typhoid fever. However, the recent emergence of nalidixic acid-resistant *S. enterica Typhi* (NARST), especially in strains acquired in southern and southeastern Asia, has led to the recommendation that other agents be preferentially used for the empiric treatment of typhoid fever. For patients who can tolerate oral therapy, azithromycin should be used for the treatment of typhoid fever. For hospitalized patients, ceftriaxone is the preferred empiric

TABLE 148.1 **THERAPY OF *SALMONELLA* INFECTIONS**

Syndrome	Suggested therapy
Gastroenteritis	
Normal host	Rehydration
Normal host with severe disease or risk factors	Levofloxacin, 500 mg (or other fluoroquinolone) once a day for 7 d; or azithromycin, 500 mg once a day for 7 d
Immunocompromised adult	Levofloxacin, 500 mg (or other fluoroquinolone) once a day for 14 days; or azithromycin, 500 mg once a day for 14 d
Neonate or immunocompromised child	None or ceftriaxone, 100 mg/kg/d in two equally divided daily doses for 7 d; or azithromycin, 20 mg/kg/d once a day for 7 d
Typhoid fever	
Adult	Ceftriaxone, 2 g IV qd for 10–14 d; or azithromycin, 500 mg PO or IV qd for 7 d
Children, pregnant women	Ceftriaxone, 100 mg/kg/d in two equally divided daily doses for 10–14 d; or azithromycin, 20 mg/kg/d IV or PO once a day for 7 d
Severe disease in those with history of travel to Pakistan, Iraq, or acquired in US	Adult: Meropenem 1 gm q8h (or other carbapenem) for 10-14 days Children: Meropenem 40mg/kg q8h (max 6000 mg/d)(or other carbapenem) for 10-14 days
All patients with severe typhoid fever (delirium, obtundation, stupor, coma, or shock)	dexamethasone, 3 mg/kg initially, followed by 1 mg/kg q6h for 48 h
Chronic carrier	
Adult	Ciprofloxacin, 500 mg PO BID for 4 wk; or amoxicillin, 1 g PO TID for 3 mo; or TMP-SMX, 160/800 mg PO BID for 3 mo
Children	Amoxicillin, 40 mg/kg PO up to 1 g TID for 3 mo; or TMP-SMX, 5 mg/kg TMP BID for 3 mo

Due to the emergence of antimicrobial resistance, therapy should be guided by resistance testing whenever possible.
Abbreviations: TMP-SMX = trimethoprim–sulfamethoxazole

agent. However, for patients with a travel history to Pakistan or Iraq, or for those who acquire disease in the United States, the CDC currently recommends that a carbapenem be used for those who cannot tolerate oral therapy. (see Table 148.1).

Most authorities recommend a short course of dexamethasone for severe disease with altered mental status or shock (see Table 148.1).

Chronic carrier

Patients with positive stool or urine cultures for salmonellae >12 months after resolving their acute infection are considered carriers. More than 80% of these patients can have the carrier state eradicated with the administration of ciprofloxacin for 1 month, oral amoxicillin for 3 months, or TMP-SMX for 3 months. The presence of anatomic abnormalities, such as biliary or kidney stones, makes eradication much more difficult and should be evaluated prior to initiating long-term therapy. In the presence of such abnormalities, surgery combined with antimicrobial therapy is often required for eradication. Patients with urinary carriage associated with *Schistosoma haematobium* should be treated with praziquantel before attempting eradication of *S. typhi*.

Prevention

The prevention of *Salmonella* infection relies on proper food handling and sanitation. In developed countries, this involves careful attention to the separation of raw and cooked foods and an awareness of the multiple ways in which cross-contamination can occur in food preparation areas. Parents should also monitor their children to ensure careful hand hygiene after contact with reptiles and fowl.

For travel to developing countries, there are currently two commercially available vaccines for the prevention of *S. typhi* infection. One is an oral live attenuated vaccine, while the second is a parenteral capsular polysaccharide vaccine. These vaccines achieve approximately 50% to 80% efficacy, starting roughly 2 weeks after vaccination, and confer protection that lasts for several years. They are recommended for travelers to parts of the world where typhoid fever is endemic. However, as none of the available vaccines is completely protective, the first line of prevention for travelers to areas where typhoid is endemic is care in consumption of food and water. Travelers should avoid tap water, ice produced from local tap water, salads, uncooked vegetables, and unpasteurized milk and milk products such as cheese, and should eat only food that has been cooked and is still hot or fruit that has been washed in clean water and then peeled by the traveler personally.

Staphylococcus

Suzanne F. Bradley

Treatment of staphylococcal infection depends on the site involved, severity of infection, and antibiotic susceptibility pattern of the organism causing the infection. Although most serious staphylococcal infections are due to coagulase-positive staphylococci (*Staphylococcus aureus*), infections due to coagulase-negative staphylococci (e.g., *S. epidermidis*) are increasing and may also be life-threatening. *S. aureus* is a highly invasive pathogen, able to spread hematogenously to many organs, thus leading to metastatic foci of infection. Coagulase-negative staphylococci are generally healthcare-associated (HA) infections that require the presence of prosthetic material to gain a foothold and cause infection.

Susceptibility to antibiotics

Staphylococci have a propensity to develop resistance to antibiotics relatively quickly. Most staphylococci are no longer susceptible to the effects of penicillins alone because the bacteria produce enzymes or beta-lactamases that inactivate many of those drugs. One approach to the problem of antibiotic resistance in staphylococci has been the use of penicillinase-resistant penicillins (e.g., nafcillin, oxacillin, and methicillin). Alternatively, penicillins have been combined with inhibitors of beta-lactamases. Examples of penicillin–beta-lactamase -inhibitor combinations include amoxicillin-clavulanate (Augmentin), ampicillin-sulbactam (Unasyn), piperacillin-tazobactam (Zosyn), and ticarcillin-clavulanate (Timentin). The penicillin and penicillin–beta-lactamase-inhibitor combinations are effective for the treatment of penicillin-resistant, but methicillin-susceptible, staphylococci.

Other β-lactam antibiotics are also useful for the treatment of methicillin-susceptible staphylococci (MSSA). First-generation cephalosporins (cefazolin, cephalexin) are the most active, followed by second-generation agents (cefuroxime, cefotetan, cefoxitin). Third-generation (ceftriaxone, cefotaxime) and fourth-generation (cefepime) cephalosporins have less activity. First-generation cephalosporins are still considered the first-line agents in this class for most serious methicillin-susceptible staphylococcal infections.

Since the 1970s, both *S. aureus* and coagulase-negative staphylococci have become increasingly resistant to β-lactam antibiotics, including penicillinase-resistant penicillins, penicillin–beta-lactamase-inhibitor combinations, cephalosporins, and carbapenems. These so-called *methicillin-resistant* strains bind most β-lactam antibiotics poorly due to the alterations in penicillin-binding proteins (PBP2a) present on their cell walls. Methicillin-resistant *S. aureus* (MRSA) and methicillin-resistant *S. epidermidis* (MRSE) are common in healthcare settings worldwide. MRSA and MRSE account for more than 50% and 90% of all staphylococcal isolates causing nosocomial infection in some medical centers. These HA strains are usually resistant to many other classes of antibiotics, including macrolides, lincosamines (clindamycin), quinolones, and aminoglycosides, but some remain susceptible to sulfonamides and tetracyclines.

Newer community-associated MRSA (CA-MRSA) strains have emerged that are not related to HA-MRSA strains and are now prevalent in healthcare settings. These CA-MRSA strains are resistant to β-lactam antibiotics, but, in contrast with HA-MRSA strains, are more frequently susceptible to many classes

of antibiotics including clindamycin and sulfonamides. Strains of CA-MRSA that are resistant to erythromycin but appear to be susceptible to clindamycin on initial screening should be further tested for inducible cross-resistance to clindamycin using a double-disk diffusion test (D test). If inducible resistance is shown, the laboratory will report resistance to both erythromycin and clindamycin.

Until recently, the glycopeptide vancomycin has been the primary treatment for serious MRSA infections. However, vancomycin treatment can be slow or ineffective in clearing MRSA infection, and vancomycin-resistant *S. aureus* (VRSA) has emerged with prolonged use. Minimum inhibitory concentrations (MICs) of vancomycin appear to be increasing for MRSA. Some experts now recommend using higher dosages of vancomycin to achieve a trough serum concentration of 15 to 20 μg/mL when treating serious MRSA infections. These higher serum vancomycin concentrations may be associated with more toxicity, however. Newer semi-synthetic glycopeptides, such as telavancin, dalbavancin, and oritavancin, have been approved for treatment of skin and soft tissue infection (SSTI); their toxicity profiles are similar to vancomycin.

Other antibiotics with activity against MRSA, oxazolidinones (linezolid and tedizolid), quinupristin-dalfopristin, daptomycin, and tigecycline, have been developed. These drugs have been used primarily for serious infections when patients have side effects from vancomycin or when treatment with vancomycin fails. Currently, the greatest experience in the treatment of serious MRSA infections in patients intolerant or refractory to vancomycin has been with linezolid and daptomycin. Side effects have limited the use of quinupristin-dalfopristin. Tigecycline is bacteriostatic, and increases in all-cause mortality have been described during treatment of serious infection with this drug. The cephalosporin ceftaroline has potent activity against *S. aureus* and MRSA due to its increased ability to bind to PBP2a. The fluoroquinolone, delafloxacin, is currently approved only for the treatment of SSTI; whether it will retain its activity against MRSA or become resistant like ciprofloxacin is not known.

Although it may be tempting to treat both MSSA and MRSA infections with vancomycin or one of the newer agents, there are several reasons why this practice should be discouraged. One is that MSSA infections clear more slowly when treated with vancomycin than with a β-lactam antibiotic. The second is that the overuse of vancomycin has contributed to the increase in vancomycin resistance among enterococci (VRE) as well as *S. aureus*. Finally, resistance to newer agents has already been reported in *S. aureus*. Thus, organisms that are identified as MSSA should be treated with a penicillinase-resistant β-lactam antibiotic; only if the infecting organism is MRSA should vancomycin or newer agents be used.

The situation with coagulase-negative staphylococci is more difficult because the routine assays used by most laboratories to determine methicillin resistance are not as well established for coagulase-negative staphylococci as for *S. aureus*. Thus, some authorities recommend the use of vancomycin for serious coagulase-negative staphylococcal infections in spite of routine antimicrobial susceptibility testing that suggests methicillin susceptibility. A polymerase chain reaction test for methicillin resistance that detects the presence of the *mec*A gene that encodes for PBP2a is used in some laboratories for both *S. aureus* and coagulase-negative staphylococci; however, this test is costly, labor intensive, and not readily available at most hospitals. Detection of methicillin resistance by latex agglutination testing for the presence of PBP2a is also available.

For patients allergic to β-lactam antibiotics, other antimicrobial agents for staphylococcal infections include (depending on susceptibility results) trimethoprim-sulfamethoxazole (TMP-SMX); quinolones, such as levofloxacin or moxifloxacin; clindamycin; and erythromycin. The use of these antistaphylococcal agents should generally be restricted to the treatment of localized, uncomplicated infections. Vancomycin, daptomycin, linezolid, quinupristin-dalfopristin, and tigecycline are alternatives for serious staphylococcal infections in allergic patients.

Infection control issues

Because of the difficulty in treating MRSA infections and the propensity for *S. aureus* to spread among patients from the hands of healthcare providers, guidelines for the control of MRSA within acute care hospitals have been issued. Patients who have MRSA should be isolated in a private room under Contact Precautions, ensuring that healthcare providers wear gloves for general care of the patient, don gowns when performing tasks likely to result in contamination of clothing by secretions, and assiduously wash their hands before and after patient care. Special care should be taken with wounds from which MRSA has been isolated and with sputum in a patient with pneumonia due to MRSA.

Routine decolonization of patients who are infected or colonized with MRSA is generally not done, in part because the effect is transient and recolonization within 90 days is common. However, for some acutely ill patients, colonization with *S. aureus* can increase the risk of infection. Recent randomized trials suggest that transient decolonization of skin with daily chlorhexidine baths and a brief course of mupirocin ointment applied to the nares can decrease the risk of MRSA infection in intensive care unit patients and *S. aureus* surgical site infections in patients undergoing cardiothoracic and orthopedic procedures. Intra-nasal povidone-iodine has been used in some settings as an alternative to mupirocin. Treatment of all patients should be discouraged as resistance to mupirocin may develop rapidly when use is chronic and widespread. Chlorhexidine resistance may also be emerging with increasing use.

Infections due to *S. aureus*

Skin and soft tissue infections

S. aureus is the most common cause of SSTI, and many SSTIs are now caused by CA-MRSA strains. Cellulitis associated with purulent drainage or exudate is most commonly due to *S. aureus*. Folliculitis, furuncles, abscesses, and wound infections are also common (Table 149.1).

Superficial infections such as impetigo may be treated with topical agents such as mupirocin. Incision and drainage alone is

TABLE 149.1 TREATMENT OF NON-CARDIAC INFECTIONS DUE TO *STAPHYLOCOCCUS AUREUS*

Infection	First-line treatment[a]	Second-line treatment[a,b]	Comments
Folliculitis Impetigo	Mupirocin		
Small abscesses	Incision & drainage		
Purulent Infections – Outpatient management

Abbreviations: MSSA = methicillin-susceptible *Staphylococcus aureus*; MRSA = methicillin-resistant *S. aureus*; TMP-SMX = trimethoprim-sulfamethoxazole, SIRS = systemic inflammatory response

[a] Usual adult doses. Doses of cefazolin and vancomycin dependent on renal function. For linezolid, monitor CBC weekly. Daptomycin, monitor creatine phosphokinase once or twice weekly.

[b] Second-line drugs used mostly for patients allergic or intolerant to β-lactam antibiotics.

generally reserved for small, localized abscesses in healthy patients; it is not clear that antibiotic use improves the outcome from infection. Initial empiric treatment with systemic antibiotics is recommended when the infection is more extensive, involves multiple sites, is in an area that is difficult to drain, is rapidly progressive, or systemic symptoms and signs of inflammation are present. Antibiotic therapy should be considered in older adults, diabetics, and in patients with HIV or neoplasms. In most instances where antibiotic therapy is warranted, empiric treatment should initially be directed against MRSA until culture results obtained from abscesses or purulent are known. Culture results can be particularly helpful if patients do not respond to initial therapy and in outbreak settings. For patients with less severe purulent infection who can take and tolerate oral medications, empiric therapy with TMP-SMX, doxycycline, or minocycline can be considered. In patients with systemic illness and rapidly progressive or worsening infection who warrant inpatient treatment, empiric IV vancomycin, daptomycin, telavancin, ceftaroline, and oxazolidinones can be given.

Once culture and susceptibility results are known, then antibiotic therapy can be modified appropriately. Many patients will require intravenous (IV) administration of antibiotics until the acute illness has improved, then therapy can be switched to oral agents. If MSSA is identified, nafcillin or cefazolin followed by dicloxacillin, cephalexin, or clindamycin is recommended.

Osteoarticular infections

Staphylococcus aureus is the leading cause of osteoarticular infections. These infections are difficult to treat and frequently require long-term therapy with IV antibiotics.

In general, IV therapy directed against MRSA should be used until results of culture and antibiotic susceptibilities are available from deep tissue or joint aspirates. In the case of native joint septic arthritis, drainage of infected synovial fluid is essential to preserve joint function and eradicate infection. IV therapy should continue for at least 3 to 4 weeks.

For treatment of acute osteomyelitis, IV antibiotics are generally recommended with prolonged treatment (6–8 weeks). Patients with vertebral osteomyelitis, paraspinous abscess, and/or epidural abscess often require treatment for months beyond 6 to 8 weeks of IV therapy to assure healing and prevent relapse. Prolonged treatment can usually be accomplished by giving an oral agent for MRSA (TMP-SMX, doxycycline, or clindamycin) or MSSA (cephalexin, dicloxacillin, clindamycin, or amoxicillin-clavulanate) based on antimicrobial susceptibility patterns.

Treatment of staphylococcal infections in patients with prosthetic joints or spinal hardware in place can be particularly difficult without removal of the device. For prostheses present <30 days or when symptoms have been present <3 weeks, a strategy to debride and retain the prosthesis may be tried. Two weeks of therapy consisting of oral rifampin in combination with vancomycin or daptomycin for methicillin-resistant staphylococci and rifampin plus nafcillin or cefazolin for methicillin-susceptible staphylococci is given followed by 3 months of rifampin in combination with a susceptible oral agent.

For late prosthetic infections and those with more prolonged symptoms, resection of the device is generally advised followed by 4 to 6 weeks of IV therapy with the goal of reimplantation. For patients who cannot tolerate surgical resection, IV antibiotics may be followed by chronic suppression of the infection with a susceptible and single oral agent. In no instance may rifampin be given as treatment alone due to the prompt emergence of resistance.

Pulmonary infections

In the past, *S. aureus* pneumonia was seen primarily in elderly patients with underlying illnesses. Recently, severe CA-MRSA pneumonia has been seen in children and young adults, sometimes following influenza infection or in the setting of HIV infection. Patients with severe community-acquired pneumonia requiring admission to the intensive care unit or who have necrotizing pneumonia, cavitating infiltrates, or empyema should be treated empirically for MRSA until sputum and blood culture results are known. Vancomycin or linezolid may be given empirically until culture and susceptibility results are known. Vancomycin, linezolid, or clindamycin may be given for 7 to 21 days depending on the extent of the infection and the patient response. Daptomycin should not be used because the drug does not achieve adequate lung tissue levels. Drainage of loculated fluid in the pleural space is essential for resolution of infection.

Bacteremia

S. aureus bacteremia may reflect an uncomplicated or transient event often associated with a removable focus, most often an intravascular catheter, or it may be the first indication of deep-seated visceral infection, including endocarditis. *S. aureus* bacteremia is considered uncomplicated if there is no evidence for endocarditis, there are no implanted prosthetic devices, and catheters have been removed and foci promptly drained. In addition, the patient must have resolution of fever within 72 hours of treatment, documented clearance of blood cultures drawn within 2 to 4 days of the initial positive culture, and no evidence for metastatic sites of infection.

Recent guidelines recommend that all patients with *S. aureus* bacteremia have echocardiography, and preferably a transesophageal echocardiogram (TEE). However, some studies have questioned that recommendation for uncomplicated bacteremia. Others have found that if none of the following risk factors (bacteremia >4 days' duration, presence of a permanent intracardiac device, hemodialysis dependency, spinal infection, and presence of non-vertebral osteomyelitis) is present, then the likelihood of *S. aureus* endocarditis is <1% and echocardiography is not warranted. One suggested approach is to perform a transthoracic echocardiogram (TTE) only in patients with *S. aureus* bacteremia who have one or more risk factors, complicated bacteremia, or clinical suspicion for endocarditis. If a good-quality TTE cannot exclude endocarditis, then a TEE should be performed in those patients.

For patients who have uncomplicated *S. aureus* bacteremia or complicated bacteremia without echocardiographic or deep visceral evidence of infection, 14 days of treatment with nafcillin or cefazolin for MSSA and vancomycin or daptomycin for MRSA is

recommended. For patients in whom deep-seated infections are documented and for those in whom the clinical suspicion of endocarditis remains high, longer courses of therapy (4–6 weeks) are required. Relapse of infection is common following *S. aureus* bacteremia, so patients should be carefully watched for recurrence of symptoms and signs following the discontinuation of treatment.

In contrast with *S. aureus*, metastatic complications from coagulase-negative bacteremia are uncommon. Temporary IV devices, such as central venous catheters, peripherally inserted central catheters, and midline catheters, should be removed and 7 to 10 days of antimicrobial therapy given. For semi-permanent IV devices, such as Hickman or Groshong catheters and subcutaneous ports, which are more difficult to remove, a 2-week trial of vancomycin or nafcillin with or without rifampin may be adequate to cure the infection. However, if bacteremia relapses, or if tunnel infection or septic phlebitis is present, then the catheter or port should be removed (see Chapter 105, "Intravascular catheter-related infections").

Endocarditis

S. aureus is the most common cause of native valve endocarditis; the presentation can be acute with frequent complications and high mortality. Patients with left-sided cardiac lesions may have metastatic abscesses in spleen, brain, kidney, and myocardium. Right-sided *S. aureus* endocarditis is frequently found in IV drug users. In that population, pulmonary emboli are a common presenting symptom, the mortality rate is significantly lower, and shorter courses of therapy may be indicated.

Coagulase-negative staphylococci are the most common cause of endocarditis in patients with prosthetic valves and intracardiac devices, and the presentation may be more subacute. TEE is particularly useful for detection of prosthetic valvular dehiscence and paravalvular abscesses that typically require surgical intervention. For details of specific antibiotic regimens for endocarditis, see Chapter 37, "Endocarditis."

Toxic shock syndrome

Under certain conditions, such as those brought about by the use of tampons during menstruation and by the packing of surgical wounds, *S. aureus* elaborates toxins that lead to multiorgan system disease in the absence of bacteremia. Treatment of shock and the removal of tampons or surgical packing are the primary goals of therapy. Anti-staphylococcal therapy is secondary, initiated primarily to eradicate the carriage of toxin-producing *S. aureus* strains (see Chapter 18, "Toxic shock and Kawasaki's disease").

Streptococcus groups A, B, C, D, and G

Dennis L. Stevens, J. Anthony Mebane, and Karl Madaras-Kelly

Classification

In the early 1950s, Lancefield divided streptococci into groups based on carbohydrates present in the cell wall and designated the groups A through H and K through T. In addition, streptococci may be classified by their characteristics on culture on sheep blood agar. β-Hemolytic streptococci produce zones of clear hemolysis around each colony, α-hemolytic streptococci (*Streptococcus viridans*) produce a green discoloration characteristic of incomplete hemolysis, and absence of hemolysis is characteristic of γ-streptococci.

Group A

Pharyngitis

The sole member of Lancefield group A is *Streptococcus pyogenes*. Group A streptococcus is ubiquitous in the environment but with rare exceptions is exclusively found in or on the human host. About 5% to 20% of the population harbor group A streptococcus in their pharynx, and some are colonized on their skin. This organism produces a variety of suppurative infections; however, streptococcal pharyngitis, the most common, is characterized by the onset of sore throat, fever, painful swallowing, and chilliness. These symptoms combined with submandibular adenopathy, pharyngeal erythema, and exudates correlate with positive throat cultures in 85% to 90% of cases. Sore throat without fever or any of the other signs and symptoms has a low predictive value for pharyngitis caused by group A streptococcus. Rapid strep tests correlate with positive cultures in 68% to 99% of cases, but results depend greatly on the individual performing the test as well as the bacterial colony count. Colony counts >100 per plate correlated with positive rapid strep tests in 95% of patients, and counts of <100 per plate correlated with positive rapid strep tests for only 68% of patients.

Therapy

Penicillin remains the drug of choice for group A streptococcal pharyngitis and tonsillitis (Table 150.1). In the past, the purpose of treatment of streptococcal pharyngitis was largely to prevent postinfectious immunologic sequelae. However, because some patients with pharyngitis have subsequently developed streptococcal toxic shock syndrome with or without necrotizing fasciitis, it seems prudent to diagnose and treat streptococcal pharyngitis aggressively in an attempt to prevent this complication as well. Antibiotic treatment of streptococcal pharyngitis reduces pharyngeal pain and fever by approximately 24 hours in children. Penicillin treatment within 10 days of the onset of pharyngitis is extremely effective in the prevention of rheumatic fever, although it is unclear whether it prevents poststreptococcal glomerulonephritis. Penicillin fails to eradicate group A streptococcus from the pharynx in 5% to 25% of patients with pharyngitis or tonsillitis, although penicillin resistance has never been documented. The most likely explanation for such failure, particularly in patients with tonsillitis, is the inactivation of penicillin by β-lactamases produced by co-colonizing organisms such as *Staphylococcus aureus, Haemophilus influenzae, Moraxella catarrhalis*, and

TABLE 150.1 **STREPTOCOCCAL INFECTIONS**

Organism	Lancefield group	Type of infection	Therapy
Streptococcus pyogenes	A	Pharyngitis and impetigo	Benzathine penicillin IM, 1.2 million U for adults; 600,000 U for children ≤27 kg
			Penicillin G or V, 400,000 U PO QID for 10 d for adults; 200,000 U QID for children ≤27 kg
			Erythromycin ethyl succinate, PO 40 mg/kg/d
		Recurrent streptococcal pharyngitis, tonsillitis	Same as above or ampicillin + clavulanic acid, PO 20–40 mg/kg/d cephalosporin
			Dicloxacillin, 500 mg PO QID for 10 d for adults
			Clindamycin, 10 mg/kg/d PO in 4 doses for 10 d
		Cellulitis and erysipelas	Nafcillin, 8–12 g/d IV for 7–10 d or penicillin or ceftriaxone in appropriate doses
		Necrotizing fasciitis, myositis, and streptococcal toxic shock syndrome	Clindamycin, 900 mg IV q8h and penicillin G, 4 million U IV q4h for adults Duration until resolution of infection
		Prophylaxis of rheumatic fever	Benzathine penicillin, 1.2 million U IM q28d Penicillin G, 200,000 U PO BID for children ≤27 kg
			Sulfadiazine, 1 g/d for patients >27 kg; 500 mg/d for patients ≤27 kg Erythromycin, 250 mg PO BID
Streptococcus agalactiae	B	Neonatal sepsis	Penicillin, IV 100,000–150,000 U/kg/d in 2–3 divided doses for infants ≤7 d of age
		Postpartum sepsis Septic arthritis Soft-tissue infection Osteomyelitis Intrapartum prophylaxis	Penicillin, 200,000–250,000 U/kg/d IV in 4 divided doses for infants >7 d of age Ampicillin, 100 mg/kg/d IV in 2–3 divided doses for infants ≤7 d of age Ampicillin, 150–200 mg/kg/d IV in 4 divided doses for infants >7 d of age
			Ampicillin, 8–12 g IV in 4–6 divided doses or penicillin 12–24 million U/d for adults
			Penicillin or ampicillin as for neonatal sepsis or postpartum sepsis above
			Penicillin or ampicillin as for postpartum sepsis above
			1. Aqueous penicillin G 5 million U IV loading dose followed by 2.5 million U q4h for 4 doses
			2. Ampicillin 2 g IV loading dose followed by 1 g q4h for 4 doses
Streptococcus equi	C	Bacteremia Cellulitis	Penicillin as for streptococcal toxic shock syndrome above
Enterococcus faecalis[a]	D	Endocarditis Bacteremia	Ampicillin + gentamicin
		Urinary tract infection	
		Gastrointestinal abscess	
Streptococcus bovis	D	Bacteremia Abscesses	Penicillin as for *Streptococcus equi* above
Streptococcus canis	G	Bacteremia Cellulitis	Penicillin as for *Streptococcus equi* above
		Pharyngitis	

[a] Linezolid has activity against vancomycin-resistant enterococci (VRE). See Chapter 133, "Enterococcus," for more details.

Bacteroides fragilis. A second course of penicillin fails in >50% of patients, and treatment with dicloxacillin, a cephalosporin, amoxicillin/clavulanate, erythromycin, or clindamycin will subsequently cure 90% to 95% of patients. Recent studies demonstrate that outer membrane vesicles from *M. catarrhalis* and *H. influenzae* that are β-lactamase positive hydrolyze penicillin. Preparations containing procaine penicillin G plus benzathine penicillin are no more effective than benzathine alone but are less painful on injection. Ceftriaxone is under study for this indication. Resistance to erythromycin is about 5% in the United States, but in 1970, it reached a prevalence of 70% in Japan during a period of extensive erythromycin use in that country. In Finland and Sweden, emergence of erythromycin resistance has also paralleled erythromycin use. Recent studies from China document erythromycin and clindamycin resistance in a recent epidemic of scarlet fever following streptococcal pharyngitis. This could be a game changer if this strain spreads to other parts of the world.

Prophylactic treatment for populations at risk (e.g., schools, military) is indicated during epidemics of streptococcal pharyngitis when rheumatic fever is prevalent. The incidence of rheumatic fever has declined in developed nations but flourishes in developing countries. Antistreptococcal prophylaxis should be continuous in individuals with a history of rheumatic fever. Benzathine penicillin given intramuscularly once each month has the greatest efficacy, although oral agents such as phenoxymethyl penicillin are also effective. In recent years, the US military has demonstrated that such prophylaxis, particularly benzathine penicillin, prevents epidemics of streptococcal infections among young soldiers living in crowded conditions. Routine follow-up culture to verify eradication is not recommended except in patients with a history of rheumatic fever. Following appropriate treatment for symptomatic pharyngitis, treatment is not needed for continued positive cultures unless symptoms recur.

Scarlet fever

Severe cases of scarlet fever were prevalent in the United States, western Europe, and Scandinavia during the nineteenth century, and mortality rates of 25% to 35% were not uncommon. In contrast, scarlet fever today is rare and, when it occurs, is very mild. The primary site of infection is usually the pharynx, although surgical site infections have also been described. Classically, a diffuse, erythematous rash with sandpaper consistency appears 2 days after the onset of pharyngitis. Circumoral pallor and "strawberry" tongue are common findings, and desquamation occurs approximately 6 to 10 days later. The cause of the rash is uncertain, although most agree that extracellular toxins, likely the pyrogenic exotoxins formerly called "scarlatina toxins," are responsible. Treatment of the underlying infection with penicillin (see "Pharyngitis") and general supportive measures are indicated. Specifically, severe hyperpyrexia (fevers of 41.7°C/107°F to 43.3°C/110°F) has been described, and antipyretics may be necessary to prevent febrile seizures, particularly in children.

Pyoderma (impetigo contagiosa)

Impetigo is a superficial vesiculopustular skin infection. Although *S. aureus* is the most common organism isolated in modern times, group A streptococcus is likely the most significant pathogen. Impetigo is most common in patients with poor hygiene or malnutrition. Colonization of the unbroken skin occurs first; then minor abrasions, insect bites, and so on initiate intradermal inoculation. Single or multiple thick, crusted, golden-yellow lesions develop within 10 to 14 days. Penicillin orally or parenterally, or bacitracin or mupirocin topically, is effective treatment and will reduce transmission of streptococci to susceptible individuals. None of these treatments, including penicillin, prevents poststreptococcal glomerulonephritis. Although *S. aureus* may cause impetigo, it has never been implicated as a cause of glomerulonephritis.

Erysipelas

Erysipelas occurs most commonly in the elderly and very young. It is caused almost exclusively by group A streptococcus and is characterized by an abrupt onset of fiery red skin localized on the face or extremities (Figure 150.1). Distinctive features are well-defined margins, particularly along the nasolabial fold, scarlet or salmon red rash, rapid progression, and intense pain. Flaccid bullae may develop during the second to third day of illness, and desquamation of the involved skin occurs 5 to 10 days into the illness. In contrast, the rash of scarlet fever is generalized, has a diffuse pink or red hue that blanches on pressure, and has a sandpaper consistency. The organism is present in the lesion, although it is difficult to culture. Treatment with penicillin, a cephalosporin, or nafcillin is effective. Swelling may progress despite treatment, although fever, pain, and the intense redness usually diminish with 24 hours of treatment.

Cellulitis

S. pyogenes (group A streptococcus) is the most common cause of cellulitis, and although group A is the most common, β-hemolytic streptococci of groups B, C, and G also cause cellulitis in specific clinical settings. Patients with chronic venous stasis or lymphedema

FIGURE 150.1 Erysipelas in a middle-aged woman. Note the brilliant red (salmon color) and the distinct demarcation along the nasolabial fold. The patient had a temperature of 39°C/102°F, tachycardia, normal blood pressure, and negative blood cultures. She responded well to intravenous penicillin G but developed superficial desquamation over the cheeks 10 days after admission.

are predisposed to recurrent cellulitis caused by groups A, C, and G streptococci. Cellulitis in diabetic and elderly patients, particularly those with peripheral vascular disease, may also be caused by group B streptococci. Clinical clues to the category of cellulitis such as dog bite (*Capnocytophaga*), cat bite (*Pasteurella multocida*), human bite (mouth anaerobes and *Eikenella corrodens*), freshwater injury (*Aeromonas hydrophila*), seawater (*Vibrio vulnificus*), and furuncles (*S. aureus*) are extremely important. Definitive diagnosis in the absence of such factors rests on aspiration of the leading edge of the cellulitic lesion. At best, a bacterial cause is established in only 15% of cases. Cellulitis caused by groups A, B, C, and G streptococci responds to penicillin, nafcillin, erythromycin, clindamycin, and a variety of cephalosporins. Ceftriaxone, cefpodoxime proxetil, and cefuroxime axetil have the greatest in vitro activity, and all have US Food and Drug Administration (FDA)-approved indications for the treatment of streptococcal cellulitis. Although most quinolones have efficacy in the treatment of cellulitis, older quinolones such as ciprofloxacin should be avoided because of their poor in vitro activity against streptococci. Newer quinolones may be considered as second-line therapy.

Invasive group A

In the past 20 years, there has been an increase in the number of severe group A streptococcal soft tissue infections and bacteremia associated with shock and death in 30% to 70% of cases. Shock and organ failure early in the course of infection define streptococcal toxic shock syndrome, and the inciting infection may be necrotizing fasciitis, myositis, pneumonia, peritonitis, septic arthritis, uterine infection, and others. Predisposing factors include varicella virus infections, penetrating or blunt trauma, and nonsteroidal anti-inflammatory agents.

Therapy

When large numbers of streptococci accumulate, more organisms are in the stationary phase and are less affected by β-lactam antibiotics (the Eagle phenomenon). The decreased expression of critical penicillin-binding proteins in such slow-growing bacteria presumably explains the lack of efficacy of penicillin. In vitro, clindamycin—but not penicillin—prevents synthesis of toxins. Interestingly, in experimental necrotizing fasciitis and myositis, clindamycin has markedly better efficacy than penicillin. Thus some authorities recommend treatment with both penicillin and clindamycin (and debridement when appropriate). Uncontrolled observations suggest that intravenous immunoglobulin may be helpful as well.

Group B

S. agalactiae (the only species in Lance-field group B) colonizes the vagina, gastrointestinal tract, and occasionally the upper respiratory tract of normal humans. Group B streptococci are the most common cause of neonatal pneumonia, sepsis, and meningitis in the United States and western Europe, with an incidence of 1.8 to 3.2 cases per 1,000 live births. Preterm infants born to mothers who are colonized with group B streptococci in the third trimester and have premature rupture of the membranes are at highest risk for early-onset pneumonia and sepsis. The mean time of onset is 20 hours postpartum, and symptoms are respiratory distress, apnea, and fever or hypothermia. Ascent of the streptococcus from the vagina to the amniotic cavity causes amnionitis. Infants may aspirate streptococci either from the birth canal during parturition or from amniotic fluid in utero. Radiographic evidence of pneumonia and/or hyaline membrane disease is present in 40% of cases. Type III strains account for most cases of group B streptococcal meningitis in neonates.

Late-onset neonatal sepsis occurs 7 to 90 days postpartum. Symptoms are fever, poor feeding, lethargy, and irritability. Bacteremia is common, and meningitis occurs in 80% of cases.

The standards of modern-day prenatal care include swab culture of the lower vagina and anorectum for these organisms at 35 to 37 weeks of pregnancy. Women presenting in labor without such cultures can be screened with a rapid antigen-detecting kit, although the false-negative rate may be 10% to 30%. Both passive immunization with intravenous immunoglobulin and active immunization with multivalent polysaccharide vaccine show promise and in the future may become the best approach to prevention of neonatal sepsis as well as postpartum infection in the mother. Women colonized with group B streptococcus in the third trimester should receive penicillin or ampicillin during delivery (see later discussion).

Adults with group B infections include postpartum women and patients with peripheral vascular disease, diabetes, or malignancy. Soft tissue infection, septic arthritis, and osteomyelitis are the most common presentations.

Therapy

Penicillin is the treatment of choice, although in practice many neonates are empirically treated with ampicillin, 100 to 200 mg/kg/d, plus gentamicin. Once the diagnosis is established, penicillin or ampicillin should be given (Table 150.1). Adults should receive 12 million to 24 million units of penicillin per day for bacteremia, soft tissue infection, or osteomyelitis; the dosage should be 8 to 12 g of ampicillin or 24 million units per day of penicillin for meningitis. Vancomycin or a first-generation cephalosporin is the alternative for patients allergic to penicillin. Intrapartum administration of ampicillin or aqueous penicillin G to women colonized with group B streptococcus during the third trimester, who had group B strep bacteriuria during the pregnancy, or who have premature labor or prolonged rupture of the membranes prevents group B neonatal sepsis. Infants should continue to receive ampicillin for 36 hours postpartum.

Groups C and G

Groups C and G streptococci may be isolated from the throats of both humans and dogs, produce streptolysin O, and resemble group A in colony morphology and spectrum of clinical disease. Before rapid identification tests were developed, many infections caused by groups C and G, such as pharyngitis, cellulitis, skin and wound infections, endocarditis, meningitis, osteomyelitis, and arthritis, were mistakenly attributed

to group A. Rheumatic fever following group C or G streptococcal infection has not been described. These strains also cause recurrent cellulitis at the saphenous vein donor site in patients who have undergone coronary artery bypass surgery. Both organisms are susceptible to penicillin, erythromycin, vancomycin, and clindamycin, though recent studies document clindamycin resistance in 17% of strains of group G.

Group D

Group D consists of gram-positive, facultatively anaerobic bacteria that are usually nonhemolytic but may demonstrate α- or β-hemolysis. *S. faecalis*, renamed *Enterococcus faecalis*, was previously classified as group D because it hydrolyzes bile esculin and possesses the group D antigen. *S. bovis* is also a cause of subacute bacterial endocarditis and bacteremia often in patients with underlying gastrointestinal malignancy. Enterococci are commonly isolated from stool, urine, and sites of intra-abdominal and lower extremity infection. Enterococci cause subacute bacterial endocarditis and have become an important cause of nosocomial infection, not because of increased virulence, but because of antibiotic resistance. First, person-to-person transfer of multidrug-resistant enterococci is a major concern to hospital epidemiologists. Second, superinfections and spontaneous bacteremia from endogenous sites of enterococcal colonization are described in patients receiving quinolone or moxalactam antibiotics. Last, conjugational transfer of plasmids and transposons between enterococci in the face of intense antibiotic pressure within the hospital milieu have created multidrug-resistant strains, including some with vancomycin and teicoplanin resistance.

Therapy

Serious infections with enterococci, such as endocarditis or bacteremia, require a synergistic combination of antimicrobials; that is, ampicillin or vancomycin together with an aminoglycoside (see Chapter 133, "Enterococcus"). Unlike enterococci, *S. bovis* remains highly sensitive to penicillin. Vancomycin-resistant enterococci (VRE) are being described with increasing frequency. Linezolid, an oxazolidinone antibiotic, has excellent activity against VRE, although antibiotic resistance can develop during therapy.

Viridans streptococci

John L. Brusch

Viridans streptococci are a heterogeneous group of non-motile, catalase negative, gram-positive cocci. The initially identified isolates produced green hemolysis (α-hemolysis) when grown on sheep blood agar, hence the name *viridans* (green). They are subdivided on the basis of hemolysis types, Lancefield type, growth properties, and physiologic biochemical reactions into five major groups: *Streptococcus mutans*, *S. salivarius*, *S. anginosus*, *S. sanguinis,* and *S. mitis.* Various species can be distinguished on the basis of their physiologic and biochemical profiles Clinical laboratories often do not speciate isolates even if they are recovered from blood or other usually sterile sites. Isolates recovered in mixed culture or from mucosal surfaces are normally reported only as nonhemolytic or α-hemolytic streptococci. Box 151.1 lists the most common species of viridans streptococci isolated from blood cultures.

Viridans streptococci are an important part of the normal microbial flora in humans. They are indigenous to the oral cavity, upper respiratory tract, female genital tract, and gastrointestinal tract. These lack traditional virulence factors, such as endo- and exotoxins, and they are considered to be of low virulence. The sole pathogenic factor of members of the non-*S. anginosus* groups is production of an extracellular dextran, glucan, that facilitates their adherence to a preformed fibrin/platelet thrombus as well as to dental enamel. The *S. anginosus* group (*S. intermedius, S. constellatus*, and *S. anginosus*) are variably hemolytic. Their colonies are quite small on blood agar. Growth may be enhanced in the presence of carbon dioxide (CO_2). Many isolates are facultative anaerobes. Unlike other groups, *S. anginosus* possesses many pathogenic components. Surface adhesions facilitate binding the group to fibronectin, platelets and fibrin thrombi. A polysaccharide capsule can inhibit phagocytosis. Some strains possess the same genes as does *S. pyogenes* for productions of superantigens and DNAse. Many actually invade myocardial cells, valvular structures, pericardium, and extra-cardiac sites, which results in abscess formation. They do so by producing superantigens that are able to quickly trigger a massive outpouring of inflammatory cytokines. The resulting clinical picture appears much more like that of *S. aureus* than that of streptococci.

Infections

Viridans streptococci are important causes of infective endocarditis (IE). In addition, they are increasingly identified as causes of septicemia in immunocompromised individuals. Among immunocompetent individuals, these bacteria may lead to brain abscesses and a wide range of infections of the lower respiratory tract. Viridans streptococci may occur as a sole pathogen but are more typically found as part of a mixed aerobic-anaerobic infection.

Infective endocarditis

Viridans streptococci account for approximately 25% of cases of IE. Essentially, all of them represent subacute disease. The incidence of viridans streptococcal endocarditis has not changed appreciably since the American Heart Association recommended, in 2007, the cessation of routine antibiotic prophylaxis of

BOX 151.1

dental procedures for all but those at greatest risk of developing IE. Those who develop *S. viridans* IE have underlying cardiac valve abnormalities, such as degenerative valve disease or rheumatic heart disease. Such valvular configurations lead to turbulence in blood flow with resultant deposition of non-infected platelets/fibrin thrombi (NBTE). (Refer to Chapter 37 for a more in-depth discussion of this process.) Viridans streptococcal IE follows an indolent course. Low-grade fever, fatigue, and malaise are characteristic early clinical manifestations. Almost inevitably there is a preexisting murmur which usually does not change in nature until far later in the clinical course. Initial presentations may be renal failure, the various cutaneous manifestations of subacute bacterial endocarditis (SBE), and back pain; all of these represent immune complex disease or embolization from the valvular vegetation. Congestive heart failure occurs far later into the illness.

The critical element for diagnosis of IE is demonstration of continuous bacteremia. In the absence of recent antimicrobial therapy, two blood cultures will retrieve this type of streptococci in 95% of cases. Echocardiography, either transthoracic or transesophageal, may provide additional diagnostic and prognostic information in those cases.

Bacteremia and septicemia

Transient bacteremia due to viridans streptococci may occur in association with dental procedures but also with routine daily activities. It is rarely of clinical significance. In contrast, prolonged bacteremia has emerged as a genuine problem among patients undergoing cancer chemotherapy, especially among children. Viridans streptococci are now a leading cause of bacteremia in febrile, neutropenic patients. Infection occurs in association with aggressive cytoreductive therapy for acute leukemia or bone marrow transplantation. These agents damage the normal mucosal barriers of the mouth and intestinal tract. Other predisposing factors include prophylactic administration of trimethoprim-sulfamethoxazole (TMP-SMX) or quinolone, presence of an indwelling central venous catheter, and use of antacids or histamine type 2 (H_2) antagonists. Physical findings are mainly cutaneous, including erythema multiforme, petechiae, desquamation of palms and soles, and maculopapular rashes A fulminant shock syndrome characterized by hypotension, rash with palmar desquamation, acute renal failure, adult respiratory distress syndrome, and death has also been described. The viridans streptococcal shock syndrome occurs in up to 25% of pediatric patients with bacteremia, with mortality rates of 40% to 100%.

Meningitis and brain abscess

Viridans streptococci are an uncommon cause of meningitis, accounting for fewer than 5% of culture-proven cases. Infections occur in patients of all ages, including neonates. The source of infection usually is underlying ear, nose, or throat pathology; endocarditis; extracranial infection; or head trauma. Clinical manifestations are typical of acute pyogenic meningitis with signs of meningeal irritation, neurologic deficits, seizures, and altered sensorium. Although cerebrospinal fluid (CSF) pleocytosis is characteristically present with viridans streptococcal meningitis, the Gram stain of CSF is positive less than half of the time.

S. angiosus and *S. aureus* are the primary causes of brain abscess, often in association with anaerobic bacteria. Predisposing conditions include head and neck infection, lung abscess, and endocarditis. Clinical manifestations of brain abscess are primarily related to the size and location of the intracranial lesion, with headache being the most common presenting complaint. Fever is present in less than half of cases. CT or MRI is useful both for diagnosis and to follow the course of antimicrobial therapy. Definitive microbiologic diagnosis can be established from culture of brain abscess material obtained by excision or through stereotactic aspiration.

Pneumonia

Viridans streptococci are frequently identified in cultures of respiratory tract secretions. When recovered from expectorated sputum, viridans streptococci should rarely be considered significant because of their presence as normal oral flora. However, they may also be found in lower respiratory tract specimens obtained from patients with pneumonia by transtracheal aspiration or protected bronchial brush. *S. viridans* may cause lower respiratory tract infection in association with other oral organisms, especially anaerobes, following aspiration of oropharyngeal material. Predisposing conditions include periodontal disease, gingivitis, depressed cough and gag reflexes, dysphagia from esophageal disease, depressed consciousness, seizures, and ethanol abuse. Pneumonia usually develops in dependent lung segments and may lead to necrosis with abscess formation and/or empyema. The diagnosis of aspiration pneumonia should be suspected by the presence of purulent sputum and an abnormal radiograph in a patient at high risk of aspiration. Viridans streptococci are also occasionally identified as sole pathogens in patients with lower respiratory tract infection.

Odontogenic infections

S. viridans, especially *S. angiosus*, may produce a wide variety of oral and endodontic infections ranging from dental caries to peritonsillar abscesses. These can spread to the sinuses, lung (empyema and lung abscess), brain, and deep space infections of the head and neck (jugular vein septic thrombophlebitis, necrotizing fasciitis of the neck).

There is also growing evidence linking chronic dental disease with coronary artery and cerebrovascular disease. Promotion of

TABLE 151.1 **ANTIBIOTIC TREATMENT OF SPECIFIED INFECTION DUE TO *STREPTOCOCCUS VIRIDANS***

Infection type	Antibiotic regimen[a]	Duration
Septicemia	Penicillin G, 12–18 million units IV qd, in divided doses, or vancomycin,[b] 15 mg/kg (not to exceed 1 g) IV q12h	2 wk
Meningitis	Ceftriaxone, 2 g IV qd, or vancomycin,[b] 15 mg/kg (not to exceed 1 g) IV q12h	2 wk
Brain abscess	Ceftriaxone, 2 g IV qd, or vancomycin,[b] 15 mg/kg (not to exceed 1 g) IV q12h, plus metronidazole, 500 mg IV or PO q6h	≥6 wk
Pneumonia[c] (aspiration)	Penicillin G, 8–12 million units IV qd, in divided doses, plus metronidazole, 500 mg P0 IV or PO q6h or β-lactam/β-lactamase inhibitor combination	2–3 wk
Endocarditis	See Chapter 37, "Endocarditis."	

[a] Doses should be adjusted according to age, weight, and renal function.
[b] For suspected or confirmed infections due to β-lactam–resistant viridans streptococci. Selection of empiric treatment for viridans streptococcal infections should take into account local patterns of antimicrobial susceptibility.
[c] Presence of enteric gram-negative bacilli might require additional antimicrobial agents.

good oral health needs to be part of an effective approach to prevention and treatment of cardiovascular disease.

Other bacteremic infections

Among other bacteremic infections are liver, spleen, or kidney abscesses and osteomyelitis. Successful therapy requires antibiotics along with appropriate drainage procedures.

Therapy

The β-lactam antibiotics have long been considered the drugs of choice for therapy for *S. viridans* infections because of previously uniform susceptibility to these agents. Resistance is now emerging as a significant problem in immunocompromised patients. Using a minimum inhibitory concentration (MIC) breakpoint criterion of ≤0.125 μg/mL for determining susceptibility, penicillin resistance has been reported in 25% to 50% of isolates recovered in some centers, with 5% to 10% of isolates resistant to high concentrations of penicillin (MIC ≥4 μg/mL). In contrast, most community isolates of viridans group streptococci, including those associated with infective endocarditis, remain susceptible to penicillin. Other β-lactam antibiotics have in vitro activity similar to that of penicillin. Vancomycin, daptomycin, and linezolid have consistently excellent activity against viridans streptococci, whereas tetracycline, clindamycin, and erythromycin have variable activity, often with 25% to 50% of isolates reported resistant. Most strains of *S. viridans* are resistant to TMP-SMX.

Because of the unpredictable antibiotic susceptibility of viridans streptococci, in vitro testing should be performed on all clinically significant isolates recovered from normally sterile body sites, such as blood or CSF. Often these cannot be performed in local clinical labs. In that case, the prescriber should consider regarding the isolate to be resistant.

Antibiotic regimens that are currently recommended for treatment of IE are summarized in Chapter 37, For streptococcal isolates that are moderately or highly resistant to β-lactam agents, penicillin should be given in combination with low doses of aminoglycoside. Table 151.1 lists recommended antibiotic regimens for the treatment of septicemia, central nervous system infections, and lower respiratory tract infections due to viridans streptococci.

In cases complicated by abscesses secondary to *S. anginosus* infection, surgical drainage is often required for cure.

Poststreptococcal immunologic complications

Barbara W. Stechenberg

Infections caused by group A β-hemolytic *Streptococcus (Streptococcus pyogenes)* are unusual in that they have been associated with nonsuppurative complications, acute rheumatic fever (ARF), and acute glomerulonephritis. These distinct clinical entities are not related to toxic effects of the organism and follow the infections by an interval during which immunologic mechanisms are triggered. Table 152.1 compares some features of two clinical syndromes.

Acute rheumatic fever

ARF is a multisystem collagen vascular disease that follows untreated or undetected group A streptococcal pharyngitis in <1% of persons. It is seen most commonly in children ages 5 to 15 and is associated with a genetic predisposition. It is more common in developing countries. There also appear to be strains of *S. pyogenes* more likely to be implicated in this condition (see Table 152.1).

The diagnosis of ARF is made clinically and is based on the modified Jones criteria (Table 152.2). The presence of two major or one major and at least two minor criteria suggests the diagnosis. Recent infection with *S. pyogenes* also must be suggested by either isolation of the organism from the throat or serologic evidence in the form of elevation of antistreptolysin O, antihyaluronidase, or antideoxyribonuclease B titers. The exception to this rule is chorea, which becomes manifest 2 to 6 months after infection, by which time evidence of a recent streptococcal infection may be lacking.

The most common clinical manifestations of ARF are carditis and arthritis. The former usually presents as a significant murmur, most commonly mitral insufficiency. Both myocarditis and pericarditis may accompany this valvulitis. It is the only manifestation that may result in residual disease. The arthritis is a migratory polyarthritis that generally involves the medium-size joints (elbows, wrists, ankles, and knees). Pain is often striking. Another characteristic finding is the dramatic response of the arthritis to salicylate therapy. Chorea known as Sydenham chorea or St. Vitus' dance usually occurs as an isolated, often subtle, neurologic disorder with behavioral aspects, particularly emotional lability. Erythema marginatum and subcutaneous nodules are rarely seen. The strongest diagnoses of ARF are based on carditis or chorea. The weakest is based on arthritis as a single major manifestation with two minor criteria.

The term *PANDAS* (pediatric autoimmune neuropsychiatric disorder associated with group *A Streptococcus*) has been used to refer to a group of neuropsychiatric or behavioral disorders, particularly obsessive-compulsive disorder (OCD), Tourette's syndrome, and tic disorder, with a possible relationship to group A streptococcal infections, and, perhaps, related pathologically to Sydenham chorea. Swedo and colleagues have proposed an autoimmune pathogenesis for these disorders, although this is controversial. Suggested diagnostic criteria include the presence of OCD or a tic disorder; pediatric onset; abrupt onset of symptoms or a course characterized by dramatic exacerbations of symptoms; a temporal association with group A streptococcal infection; and abnormal results of neurologic examination, such as choreiform movements, motor hyperactivity, and tics. Extensive investigation of its epidemiology, diagnosis, and treatment as well as its relationship to ARF are still underway.

TABLE 152.1 **COMPARISON OF ACUTE RHEUMATIC FEVER (ARF) AND ACUTE POSTSTREPTOCOCCAL GLOMERULONEPHRITIS (AGN)**

Feature	ARF	AGN
Prior infection	Pharyngitis	Pharyngitis or pyoderma
M-types	3, 5, 6, 14, 18, 19, 24	Pharynx: 1, 2, 3, 4, 12, 15 Skin: 4, 9, 52, 55, 59, 60, 61
Latency	2–4 wk	Throat: 10 d Skin: 3 wk
Recurrences	Common	Rare
Antibiotic prophylaxis	Useful	Not useful
Sequelae	Common (heart)	Rare

Prevention

Primary prevention of ARF requires the proper diagnosis and treatment of *S. pyogenes* pharyngitis. The accepted standard of care is the performance of a throat culture or rapid streptococcal antigen detection test. If the latter is negative in a child, a throat culture should be done because of the variable sensitivity of that test. Treatment of streptococcal pharyngitis should be undertaken, generally with oral phenoxymethyl penicillin (penicillin V) at 250 to 500 mg two or three times a day for 10 days; if compliance is an issue, benzathine penicillin G, 1.2 million units intramuscularly (IM) (if ≥27 kg or 600 000 U if ≤27 kg), is acceptable. For patients allergic to penicillin (without anaphylaxis), a first-generation cephalosporin (e.g., cephalexin 20 mg/kg/dose twice daily, max dose = 500 mg) for 10 days is the antibiotic of choice. Alternatives are clindamycin (7 mg/kg/dose three times daily, max dose = 300 mg) or clarithromycin (7.5 mg/kg/dose twice daily, max dose = 250 mg) for 10 days or azithromycin (12 mg/kg once daily, max dose = 500 mg) for 5 days, although resistance to the latter two agents is well known. Prompt treatment should prevent most cases of ARF after symptomatic pharyngitis. Initiation of therapy up to 8 days after infection begins is probably beneficial.

TABLE 152.2 **MODIFIED JONES CRITERIA FOR ACUTE RHEUMATIC FEVER**[a]

Major criteria	Minor criteria
Carditis	Previous rheumatic fever
Arthritis	Clinical
Chorea	Fever
Erythema marginatum	Arthralgia
Subcutaneous nodules	Laboratory
	Prolonged PR interval
	Elevated acute-phase
	reactants: erythrocyte sedimentation rate, C-reactive protein, white blood cell count

[a] Requirements: (1) evidence of antecedent group A streptococcal infection and (2) two major criteria or one major and at least two minor criteria.

Therapy

Treatment of ARF involves three important areas: eradication of *S. pyogenes*, treatment of the acute manifestations, and prevention of both recurrences and infective endocarditis in those with residual carditis. The first is accomplished with the regimens for primary prevention. These regimens should be used even if the throat culture is negative at the time of diagnosis of ARF. The mainstay of treatment of ARF is salicylates, both for arthritis and mild to moderate carditis. A dosage of 70 to 80 mg/kg/day should be initiated to produce a therapeutic blood level of 20 to 25 mg/dL. This is continued for at least 2 weeks, until acute inflammation has subsided, and then decreased gradually over the next 2 to 4 weeks. Patients with arthritis should be repeatedly evaluated for carditis during the initial 2 weeks. Persons with severe carditis and/or congestive heart failure may be treated with steroids, usually prednisone, at 2 mg/kg/day acutely for at least 2 weeks, with a gradual withdrawal over 4 to 6 weeks, with the introduction of salicylates to prevent rebound. Supportive care of carditis is important; digitalization should be done slowly starting with one-quarter of the usual initial dose.

Sydenham chorea is usually self-limited over several weeks. If symptoms are debilitating, phenobarbital may be started at 15 to 30 mg every 6 to 8 hours. Haloperidol is an alternative. A short course of corticosteroids over 2 weeks with a 2- to 3-week taper may be beneficial.

Secondary prevention

Secondary prevention of infection with *S. pyogenes* is based on the fact that persons with ARF have at least 10% to 30% chance of recurrence of ARF when reinfected with this organism. Because of concerns about compliance, benzathine penicillin G, 1.2 million units IM every 4 weeks, is recommended, particularly in the first 5 years after clinical presentation and in persons with carditis. In areas of high prevalence of ARF, this regimen should be given every 3 weeks. Oral penicillin, 250 mg twice a day, is an acceptable alternative. Patients allergic to penicillin are treated with sulfadiazine, 500 mg twice a day. Erythromycin, 250 mg twice daily, should be reserved for persons allergic to both penicillin and sulfa. The duration of secondary prevention is controversial; many believe it should be lifelong, but there is evidence for discontinuing at age 21 or after 5 years (whichever is longer). Persons with residual carditis should

be educated about the importance of oral hygiene. They should receive antibiotics for prophylaxis against infective endocarditis (see Chapter 37, Endocarditis of natural and prosthetic valves: treatment and prophylaxis).

For patients with PANDAS, prompt recognition and treatment of group A streptococcal infections is important. The role of prophylactic antibiotics to prevent recurrences is unknown.

Acute poststreptococcal glomerulonephritis

Poststreptococcal acute glomerulonephritis (AGN) is an inflammatory disorder of the glomeruli. It occurs when soluble immunoglobulin G immune complexes are deposited at the glomerular basement membrane, causing complement activation and release of cytokines. This leads to infiltration of inflammatory cells. The streptococcal antigen involved has not been completely elucidated. It can follow either throat or skin infection with *S. pyogenes*. Table 152.1 lists the major strains associated with AGN and designated nephritogenic; since the early 1980s, the incidence of AGN has decreased remarkably, perhaps with a decrease in these M-types. AGN has rarely been associated with infection with group C streptococci.

The epidemiology of AGN reflects that of streptococcal pharyngitis (age 5 to 15 years; winter to spring) and pyoderma (younger age; summer months). Prompt therapy does not prevent AGN. The incubation period is about 10 days with pharyngeal strains and about 3 weeks following pyoderma.

Clinical manifestations include edema (85%), gross hematuria (25%), and hypertension (60% to 80%). A consequence of volume overload, the hypertension may lead to encephalopathic changes in a small number of patients. Symptoms referable to the cardiovascular system (cardiomegaly, congestive heart failure, pulmonary edema) are sometimes present. Fever is uncommon. Some patients have a mixed acute nephritis/nephrotic syndrome with ascites and anasarca. AGN is typically self-limited, with spontaneous diuresis and improvement in hypertension within 1 week. In fact, up to 50% have been asymptomatic during outbreaks. In children, fewer than 2% of cases are complicated by acute renal failure. This number may be higher in adults. Progression to chronic renal failure is also very unlikely.

Freshly voided urine typically demonstrates mild proteinuria, red and white blood cells, and red and white blood cell casts. Gross hematuria (usually brown) disappears rapidly, although microscopic hematuria persists for months as does the proteinuria. Striking hypocomplementemia is seen in 90% of patients, primarily C3 and CH50 with a normal C4. Diagnosis is supported by the latter finding in association with evidence of preceding *S. pyogenes* infection. Following pharyngeal infection, antistreptolysin O elevations are common. However, it is less useful following skin infections, after which anti-DNAase B or antihyaluronidase are more likely to be high. Attempts to culture the organism also should be undertaken.

Therapy

Therapy is supportive. Antibiotics should be given to eradicate any streptococcal carriage, using the same agents as described for ARF. Oral therapy should be continued for 10 days However, no data have demonstrated that this therapy either prevents AGN or alters its natural history. Patients with obvious edema, hypertension, or azotemia may require hospitalization, although most patients respond to careful restriction of fluid and salt intake. Diuretic therapy is usually successful in controlling hypertension. Prognosis is generally excellent. Relapses are rare.

There is no need for antibiotic prophylaxis to prevent future attacks because repeated episodes are rare.

Shigella

Eduardo Rodríguez-Noriega

Introduction

Shigellosis is an inflammatory, infectious diarrheal disease that is endemic in children living in high-risk countries. The disease can be acquired by travelers to those regions, and the risk of the disease is generally higher among men who have sex with men (MSM).

Microbiology

Shigella spp. is a gram-negative rod that belongs to the Enterobacteriaceae family of bacteria. There are four species of *Shigella*: 15 types of *S. dysenteriae*, including *S. dysenteriae* serotype 1; 15 types of *S. flexneri*, 19 types of *S. boydii*, and one serotype of *S. sonnei*. Humans are the only known natural host of *Shigella*, and the infection of shigellosis is transmitted via the fecal-oral route from person to person.

Pathogenesis

Intestinal infections of *Shigella* produce damage to the terminal ileum, colon, and rectum. The pathogen possesses multiple virulence factors, including enterotoxins, siderophores, effectors, proteases, and lipopolysaccharides. After the oral ingestion of small amounts of the bacteria, the production of enterotoxins is responsible for the initial onset of watery diarrhea.

During translocation, *Shigella* is ingested by macrophages once it invades the mucous intestinal layer. In this site, the replication and dissemination of *Shigella* spp. occurs, together with the activation of neutrophils, the production of inflammatory cytokines, epithelial abscesses and ulcerations, and the destruction of tissue, which leads to further disruption of the epithelial barrier. During this stage of infection, patients develop dysentery that is accompanied by the symptoms of bloody stool, fever, and abdominal cramps.

The further development of *Shigella*'s invasion of the intestinal layer causes the downregulation of the inflammatory response and innate immune response, the latter of which leads to diminished immune response and reinfections.

Epidemiology

In 2015, infectious diarrhea was responsible for >1,310,00 deaths worldwide in children <5 years of age. In that same age group, infectious diarrhea caused >499,000 deaths. *Shigella* and rotavirus were the two

leading causes of diarrhea-related death, contributing to the death of 164,300 and 199,000 children, respectively.

However, in a recent reassessment of the causes of diarrhea conducted within the Global Enteric Multicenter Study (GEMS), it was revealed that among 11,400 specimens collected from 5,700 cases, *Shigella* spp. was the pathogen most often encountered out of the six that were found, surpassing rotavirus, adenovirus, Shiga toxin enterotoxigenic *Escherichia coli*, *Cryptosporidium* spp., and *Campylobacter* spp. *Shigella* spp. and rotavirus, meanwhile, were found to be the most frequently found pathogens in mixed infections.

Shigellosis is known to occur regularly among travelers to regions that are considered at high risk for shigellosis. Shigellosis can be sexually transmitted by MSM who engage in oro-anal contact, have multiple sexual partners, and engage in unprotected sex. Among this group of at-risk individuals, *S. flexneri* serotype 3a in particular can cause shigellosis outbreaks in middle-aged men with no travel history to high-risk regions. A relatively new strain of *Shigella*, *S. flexneri* type 3a, has spread around the world and acquired multiple antimicrobial resistant determinants, including resistance to azithromycin.

Outbreaks can occur, particularly in cases involving MSM, through *Shigella* clusters, where resistance to more than one antibiotic can be detected, including resistance to ciprofloxacin and azithromycin. Meanwhile, *S. flexneri* may cause annual epidemics in the months of June to September in some countries; these outbreaks are usually waterborne and are frequently associated with recreational water activities involving untreated water. These epidemics are cyclic in some areas that are characterized by overcrowding and the presence of children >5 years old in families.

When outbreaks occur involving school-aged children, decisions regarding children's exclusion from school activities are another problem that must be dealt with. Exclusion policies should specify the type of treatment child patients should receive before reintegration is considered.

Clinical manifestations

The incubation period of the disease is calculated to be 1 to 4 days from the ingestion of the bacteria, although it sometimes lasts up to 8 days. Risk groups include children between the ages of 1 and 4 years, travelers to endemic areas, MSM, children in daycare, and those children's household contacts.

Asymptomatic infections can occur; most patients with the disease become symptomatic, however, with the presence of fever, headache, anorexia, vomiting, and, initially, watery diarrhea. After this initial stage, patients can develop dysentery accompanied by blood in their stool, abdominal cramps, and tenesmus.

In children, manifestations of the disease are more severe when they are infected with *S. dysenteriae* type 1. More often than other infected groups, this group of patients often exhibits leukemoid reactions, develops systemic complications associated with hemolytic uremic syndrome (HUS), experiences more frequent and more severe hyponatremia, and develops neurologic abnormalities.

In the controlled human infection model for *Shigella*, abdominal pain or cramps are found to develop in 81% of cases, followed by diarrhea in 76%, fever in 50%, nausea in 46%, dysentery in 27%, and vomiting in 24%. The presence of significant blood in stools, fevers of >38°C/101.1°F, and vomiting are important risk factors, as are subjective observations of loose stool output for a period of 24 hours.

Laboratory manifestations

Patients suffering from diarrhea caused by *Shigella*, especially in the severe dysenteric form, will have polymorphonuclear leukocytes in their stool. The presence of inflammatory cells in a patient's stool indicates the presence of an inflammatory etiology. Other diarrheal infections, such as those resulting from vibrios or viruses, do not cause inflammatory cells to appear in the feces of patients.

In >85% of patients with shigellosis, >50 fecal leukocytes can be found per high-power field. The testing of stool culture for *Shigella* requires particular selective media, is difficult to process, and requires >48 hours for a preliminary diagnosis; nevertheless, it is an essential recourse for epidemiological studies and for detecting antibiotic resistance.

Shigella dysentery is one cause of leukemoid reactions in which peripheral leukocytes counts are often >40,000. In patients with *Shigella* bacteremia, other laboratory abnormalities may occur, including elevated creatinine levels and thrombocytopenia.

In the presence of acute kidney injury, hemolytic anemia, thrombocytopenia, and proteinuria during or after an episode of infection, inflammatory diarrhea is an indication of HUS.

Recently, the use of a multiples molecular assay has been compared to conventional methods of detecting Shigella. In 1,716 stool samples, the molecular test detected 59% of the etiological agents present, compared with 39% detected using a traditional methodology. Of the episodes the molecular assay detected, 67.5% were caused by a single agent and 32.5% by multiple agents.

Intestinal complications

In patients with severe *Shigella* dysentery, critical intestinal complications can develop, including rectal prolapse, toxic megacolon, intestinal perforation, intestinal obstruction, appendicitis, and persistent diarrhea.

Systemic complications

Systemic complications, also referred to as extraintestinal complications, may include dehydration, hyponatremia, hypoglycemia, leukemoid reactions, bacteremia, metastatic infections

such as meningitis, osteomyelitis, arthritis, splenic abscess, and seizures. During or after acute infections, other complications can develop, including HUS, reactive arthritis, and irritable bowel syndrome.

The association between shigellosis and HUS is one of multiple etiologies of severe complications involving shigellosis, including *Shigella* infection with Shiga toxin *E. coli*, with a pneumococcus-induced syndrome and differential diagnoses with other causes, including atypical HUS, which develops in the presence of cobalamin C defects, and diseases that coexist with shigellosis, such as malignancy and immunosuppression.

Incidences of HUS secondary to infection with Shiga-toxin producing bacteria account for 85% to 90% of all cases of HUS as a complication of shigellosis; 5% to 10% are due to mechanisms related to the atypical HUS, and 5% are secondary to pneumococcal infections.

The development of bacteremia in cases of shigellosis occurs in children <1 year old in more than 4% of cases. Risk factors for the development of bacteremia include severe dehydration, abdominal tenderness or ileus, agitation, lethargy, and leukocytosis. Children who develop bacteremia are at elevated risk of experiencing leukemoid reactions and developing renal failure, thrombocytopenia, and HUS.

Bacteremia can also develop in adults >65 years of age who are immunocompromised or in HIV-infected women who are at risk for shigellosis while tending to sick children in their home.

Antimicrobial resistance

In a manner similar to that of other Enterobacteriaceae, *Shigella* are able to develop antimicrobial-resistant determinants that include extended-spectrum β-lactamases such as those of the CTX-M groups, TEM, and SHV. The resistance can be disseminated through plasmids and integrins, and the organism can then develop mutations and quinolone-resistant genes.

Shigella can thus develop resistance to three or more first- and second-line recommended antimicrobials. Some *S. sonnei* are occasionally found carrying the polymyxin-resistant gene MCR-1. Meanwhile, resistance to azithromycin is frequently found in isolates from older HIV-infected males, with 90% of such cases occurring in MSM. The resistance to azithromycin has recently been increasing in Southeast Asia, and has been noted especially in *S. sonnei* isolates from patients in Vietnam and Laos.

The continuing evolution of *Shigella* and its increasing resistance to antimicrobials has prompted calls for modifications to current treatment guidelines and the establishment of species-specific breakpoints for resistance and susceptibility in the future.

Treatment

Taking into consideration current local trends of resistance in *Shigella*, the recommended treatment for patients <10 years old includes the use of a quinolone as first-line therapy and the use of a β-lactam or cephalosporin as second-line therapy. In areas where resistance to quinolones is elevated, azithromycin is an alternative choice, and, in the absence of extended-spectrum β-lactamases production, cefixime can also be used.

Prevention

There is currently no vaccine available, though multiple efforts are currently under way to find the most suitable candidate.

Tularemia

Kari Neeman and Jessica N. Snowden

Microbiology

Francisella are small, aerobic, catalase-positive, pleomorphic, gram-negative intra- and extracellular coccobacilli. There are four recognized subspecies of *F. tularensis* (*tularensis* [type A], *F. holarctica* [type B], *F. mediasiatica*, and *F. novicida*).

Epidemiology

F. tularensis type A, which has been described as the more virulent of the subspecies, is found predominantly in North America. *F. tularensis* type B exists throughout the northern hemisphere. Tularemia is a zoonotic infection that can infect a wide variety of invertebrates such as the dog tick (*Dermacentor variabilis*), the wood tick (*Dermacentor andersoni*), the lone star tick (*Amblyomma americanum*), and deer flies (*Chrysops* spp.), and vertebrates (rabbits, muskrats, prairie dogs, other rodents, and occasionally cats). Transmission to humans is accomplished by bites of the arthropod vectors or contact with tissues or fluids from infectious animals. In addition, *F. tularensis* can be acquired by contact with or ingestion of contaminated material, including food and water, and by inhalation of infectious particles.[2] Water-associated outbreaks are predominantly associated with *F. tularensis* type B.[3] The infectious inoculum is estimated to be from 1 to 10 organisms.[4]

Tularemia occurs in all age groups, with the incidence in children the highest. Males have a higher incidence in all age categories, thought to be secondary to their occupational and leisure activities.[5] In areas where tularemia is endemic, the disease is seasonal, with the highest incidence in late spring extending throughout the summer months into early autumn.[6] In the United States, approximately 100 to 300 cases of tularemia are reported to the Centers for Disease Control and Prevention (CDC) annually, with most cases being reported from Missouri, Kansas, Arkansas, and Oklahoma over the past decade.[7]

Clinical manifestations

The clinical presentation, with severity ranging from mild to fatal disease, depends on patient characteristics, bacterial subspecies, inoculum dose, and route of transmission. The mean incubation period of tularemia is 3 to 5 days but may range from 1 to 21 days.[8] Six classical clinical presentations of tularemia have described based on the route of acquisition of the organism.(Table 154.1) Despite the route of acquisition though, generally symptom onset is abrupt with fever, chills, myalgia, vomiting, fatigue, and headache. Fever may be continuous or biphasic, with an intermittent period of defervescence. Pulse–temperature dissociation is also a classic finding.[9,10] Ulceroglandular and

TABLE 154.1 **CLINICAL FORMS OF TULAREMIA**

Form	Route of acquisition
Ulceroglandular or glandular	Vector-borne and direct contact (touching infected animals or material contaminated with *F. tularensis*)
Oculoglandular	Touching the eye with contaminated fingers or possibly from infective dust
Oropharyngeal	Ingesting contaminated food or water
Pneumonic	Inhaling contaminated dust or laboratory-acquired infection
Typhoidal	Unknown (probably oral or respiratory)

glandular tularemia are by far the most frequent forms of the disease, usually acquired by vector-borne transmission, direct or indirect contact with an infected animal. Ulceroglandular tularemia, the most common form (75% of cases), presents as a skin ulceration at the inoculation site with associated regional lymphadenopathy. The site of inoculation may become evident within the first 24 hours, with a swollen papule that progresses to rupturing, leaving a punched-out ulcer with raised edges. The skin overlying the regional lymph nodes may be inflamed, and, if untreated, approximately 50% of the lymph nodes suppurate and drain. The glandular form, the second most common form (15% of cases), lacks the more peripheral ulceration but otherwise presents similarly.[11] The oculoglandular form (1% of cases) presents with irritation and inflammation of eye and preauricular lymphadenopathy.[11] Typhoidal tularemia presents as fever of unknown origin and lacks the classic skin and lymph node involvement. The hallmark clinical findings are high fever, splenomegaly, and hepatomegaly.[12] Pneumonic tularemia occurs either after exposure to aerosolized particles of *F. tularensis* or from hematogenous spread from a distal site that can occur secondary to any other untreated form of tularemia but is more commonly seen with the typhoidal form.[13] Pulmonary infection remains the most lethal form of tularemia with a case fatality rate of 30% to 60% of those untreated.[11] In pneumonic tularemia, the course of disease differs markedly between type A and type B, with type A resulting in a more fulminant presentation.[14]

Diagnosis

Diagnosis of tularemia is based on recovery of an isolate, antigen or molecular detection, and serology. Growth of *F. tularensis* in culture is the definitive means of confirming the diagnosis of tularemia. Because *F. tularensis* has been associated with laboratory-acquired infections, laboratory personnel should be notified of the diagnostic possibility to enhance the diagnostic yield and to ensure that safety procedures are followed.[15] Culture of the organism should only be attempted in a biosafety level 2 laboratories. Since the organism grows poorly on standard media, it must be grown on media enriched with cysteine (e.g., modified Thayer-Martin media, chocolate agar) and may take upward of 10 days of incubation for growth.[16]

The diagnosis of tularemia is usually established by serologic testing; a fourfold or greater change in *F. tularensis* agglutinin titer between acute and convalescent sera confirms the diagnosis, whereas a single convalescent titer of ≥1:160 by tube agglutination or 1:128 by microagglutination is consistent with recent or past infection.[8,10] In patients with tularemia, antibodies appear approximately 2 to 3 weeks after infection and may be detected several years after recovery.

Treatment

Because tularemia is overall a fairly rare entity there have been no randomized controlled trials to determine the efficacy of antimicrobial therapy (Table 154.2). In the past, streptomycin has been the drug of choice in treating this infection. In one meta-analysis the use of streptomycin was associated with a 97% clinical cure rate compared to only 86% with gentamicin.[17] In one series involving only children, gentamicin was associated with a 93% success rate.[6] Given streptomycin's known vestibular toxicity and reports of hypersensitivity reactions among personnel involved in its administration, gentamicin has now primarily replaced streptomycin. Of note, in tularemic meningitis, streptomycin or chloramphenicol still may be the drug of choice.[18,19] Chloramphenicol and tetracyclines have been second-line therapy in the past but with their bacteriostatic activity are associated with higher relapse rates, especially with *F. tularensis* type A.[17,20] Fluoroquinolones, which have intracellular bactericidal activity, have had good in vitro activity

TABLE 154.2 **TREATMENT**

	Adults	Children
First-Line Therapy	Gentamicin 5 mg/kg IM or IV once daily × 10 days *Drug of choice in pregnancy*	Gentamicin 2.5 mg/kg IM or IV TID × 10 days
Second-Line Therapy	Doxycycline 100 mg PO/IV BID × 14 days *Not in pregnancy* Chloramphenicol 15 mg/kg IV q6h × 14 days *Not in pregnancy* Ciprofloxacin 500 mg PO BID × 10 days	Doxycycline (*Children ≥8 years old*) Weight <45 kg: 2.2 mg/kg PO/IV BID × 14 days Weight ≥45 kg: 100 mg PO/IV BID × 14 days Chloramphenicol 15 mg/kg IV q6h × 14 days Ciprofloxacin 15 mg/kg PO/IV BID × 10 days

against *F. tularensis*.[21,22] The use of ciprofloxacin for the treatment of *F. tularensis* type B has shown low relapse rates in both adult and pediatric series.[23,24] Observational studies in the United States, where *F. tularensis* type A is more prevalent, have shown greater success when fluoroquinolones (ciprofloxacin, levofloxacin) were started earlier in the disease course and given for at least 10 days or in combination with aminoglycoside initially.[7,12,25] The use of fluoroquinolones in juvenile animals has been associated with arthropathy, but a recent meta-analysis has shown that while musculoskeletal complaints are more common on therapy, they resolve with completion of therapy and therefore can be used with reassurance in pediatric patients.[26,27] In cases of *F. tularensis* as a biological weapon, post-exposure prophylaxis is recommended for all individuals within 24 hours of known exposure. Doxycycline and ciprofloxacin given orally are the preferred agents for a total of 14 days.[28]

Prevention

Prevention of human tularemia relies on avoidance of known vectors and careful handling of potentially contaminated animal tissue. Children in endemic areas should have hair and skin checked regularly for ticks. Hunters handling animal carcasses, especially rabbits, should utilize gloves and cook meat thoroughly. Previously in the United States, a live attenuated vaccine *F. tularensis* LVS was used to vaccinate at-risk laboratory workers, but currently this is under review by the US Food and Drug Administration (FDA) and is not available.

Tuberculosis

Jay B. Mehta and Asim K. Dutt

In the United States, the epidemiology of tuberculosis (TB) has changed in recent years and since 1992 the incidence of TB has resumed a downward trend; from 10.4 in 1992 to 3.0 in 2013. However, infection by human immunodeficiency virus (HIV) and the increase in homelessness, poverty, and drug abuse continue to remain the major risk factors for active TB. Tuberculosis occurs most commonly among ethnic minorities, African Americans, and Hispanics 25 to 44 years of age. Immigrants from developing countries with a high prevalence of TB and drug resistance and other foreign born have contributed more than one-half of the total new cases in last few years. Drug-resistant disease is a major concern.

Diagnosis

After history and physical examination, the chest x-ray is required to support the diagnosis of TB (Figure 155.1). Whenever there is a suspicion of pulmonary TB, three spontaneously produced sputum specimens should be examined by microscopy and culture. If necessary, sputum production may be induced by inhalation of aerosol of warm saline (Figure 155.2). When suspicion of TB is high and microscopy is negative, a bronchial washing, transbronchial biopsy, or postbronchoscopy sputum may be productive. On rare occasions diagnosis must be made by open lung biopsy. Positive sputum microscopy suggests TB, but the only positive identification of *Mycobacterium tuberculosis* is by culture or DNA probe to distinguish it from less virulent nontuberculous mycobacteria (NTB). Drug susceptibility testing should be performed. For early detection of drug resistance DNA analysis might be very useful but this technology is still under investigation.

Latent TB infection

The goal of testing for latent TB infection is to identify the individuals who are at a higher risk for developing TB, and hence who would benefit from preventive therapy. Tuberculosis skin test (TST) has been in use for many decades, but the results are flawed and unreliable in detecting TB infection. With advancement in immunology and genomics, T-cell–based in vitro assays of interferon (IFN) released by T cells after stimulation with *M. tuberculosis* antigens are developed to identify TB infection. Two interferon-gamma release assays (IGRAs) are available as commercial kits: the Quanti FERON-TB gold assay (QFT-GIT) and the T-SPOT.TB (Oxford Immunotec).

Studies indicate that IFN-γ detection has higher specificity for *M. tuberculosis* and less cross-reactivity with bacille Calmette–Guérin (BCG) vaccination than TST. The sensitivity of T-SPOT.TB appears to be higher than for QFT-GIT or TST, likely because the testing platform ensures that an adequate number of mononuclear cells are available even if the lymphocyte count is low. The Centers for Disease Control and Prevention (CDC) recommends the QFT-GIT test for detection of latent infection, which has the advantage of a single test for patients. IGRAs should not be used for diagnosis of active TB. The guidelines suggest that this test can be used in place of, but not in addition to TST in situations in which CDC recommends

FIGURE 155.1 Pulmonary tuberculosis. Characteristic findings on chest x-ray (CXR) include upper lobe infiltrates, involvement of apical or posterior segments, and cavities with thick walls, smooth inner contours, and no air–fluid levels. Pleural reaction and distal infiltrates from endobronchial spread may be seen. Disease activity cannot be determined from the CXR alone and must be proved or excluded by sputum smear and culture.
Courtesy of Dr. David Schlossberg.

use of TST. Although the evidence is limited, IGRAs appear to be unaffected by NTB infection. *Mycobacterium marinum* and *Mycobacterium kansasii* infection are exceptions.

Diagnosis of tuberculosis

Nucleic acid amplification (NAA) tests amplify nucleic acid regions and identify the *M. tuberculosis* complex. The NAA test can be directly used in clinical specimens (such as sputum) as "direct amplification tests." The Amplicor MTB test (Roche Diagnostic System), the Amplified Mycobacterium Direct test (MTD) (Gene-Probe, Inc.), and the BD Probe-Tec ET assay (Becton Dickinson Biosciences) are commercially available. However, NAA tests cannot replace conventional tests (microscopy and culture) and should be interpreted along with conventional tests and clinical data.

Rapid detection drug resistance

Line probe assays are novel DNA strip tests that use the polymerase chain reaction (PCR). Commercially available kits include the INNO-LiPA RIF TB kit (Immunogenetics) and Geno Type MTBDR assays (Hain Lifescience). These kits are not US Food and Drug Administration (FDA) approved. Although sensitivity

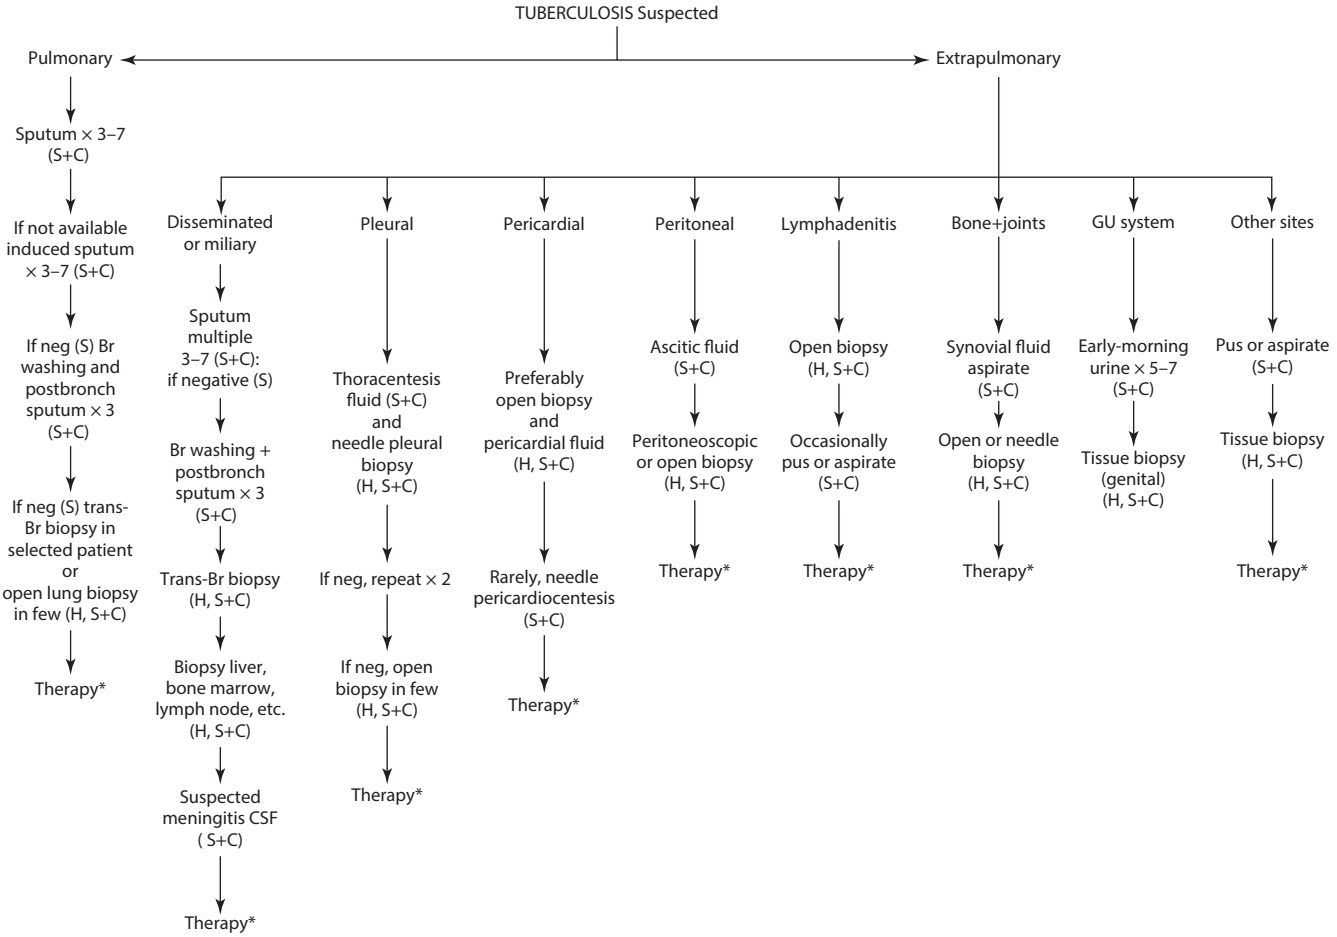

FIGURE 155.2 Diagnosis of suspected tuberculosis. S, smear; C, culture for mycobacteria; H, histology; Br, bronchial; Bronch, bronchoscopy; CSF, cerebrospinal fluid; neg, negative; GU, genitourinary. *Therapy started in suspected cases, awaiting culture results and/or clinical response.

on culture isolates may be over 95% in detecting rifampin resistance, the tests are expensive and require sophisticated laboratory support.

Also, phage-based assays are available as commercial kits but are not approved by the FDA. The test is performed in culture isolates and has high sensitivity but low specificity. This may be used for rifampin resistance in culture isolates, which increases turnaround time. The tests show promise but are not routinely used.

Extrapulmonary tuberculosis

Extrapulmonary TB cases represent 15% to 20% of the total cases but this percentage could be higher in those with HIV coinfection. TB can involve any organ of the body but the lymphatic system and bone are common sites. Miliary and central nervous system TB are rare but carry high morbidity and mortality. In most extrapulmonary TB cases plain radiograph is frequently not adequate to prove the diagnosis. CT scan or MRI is required.

Signs and symptoms of extrapulmonary TB depend upon the site involved. Atypical presentation such as chronic pain, fatigue, and failure to thrive are not uncommon in elderly patients. Clinical presentation of miliary TB can be acute or subacute. Multiorgan failure including acute respiratory distress syndrome can be life threatening. Tissue diagnosis by microscopy and culture or DNA probe confirmation is required if secretions are negative for acid-fast bacilli smear and culture. Frequently treatment has to be started while the final bacteriologic confirmation is pending.

Patients with lymphatic TB generally present with pain and swelling in the area of involvement. In children cervical lymph nodes are frequently involved.

Bone and joint disease may present with joint pain or back ache (Pott's disease). With chronic disease, destruction of bone with local sclerosis and spinal deformity is noted. Disease is most common in the lower thoracic and lumbar vertebrae. Involvement of the surrounding soft tissue may lead to cold abscess.

For the diagnosis of extrapulmonary TB, secretions and/or biopsy material must be obtained from the site (Figure 155.2). In the case of tuberculous meningitis it may be necessary to initiate therapy empirically because the disease may become irreversible before the diagnosis can be made. Low glucose, high protein, and lymphocytosis is frequently noted in cerebrospinal examination.

Therapy

Principles of chemotherapy

Initial treatment of TB should include four drugs: generally isoniazid (INH), rifampin (RIF), ethambutol (EMB), and pyrazinamide (PZA). Directly observed therapy (DOT) is the preferred strategy. After daily treatment for the first 4 to 6 weeks, a twice or three time weekly regimen can be selected. Table 155.1 lists drugs, dosages, and major side effects. Several first-line bactericidal drugs are commonly combined initially because they reduce the bacterial population rapidly without the risk of resistance. Second-line drugs are most useful when resistance to two or more first-line drugs is found or they cannot be used because of life-threatening side effects or intolerance (Figure 155.3). Currently 11 drugs are approved by the FDA. Of the approved drugs, INH, RIF, EMB, and PZA are considered first-line drugs. While fluoroquinolones are not FDA approved for TB, they are commonly used for drug-resistant TB cases. Rifabutin (RBT) and rifapentine (RPT) can be considered as important drugs in certain circumstances. Streptomycin (SM) is no longer included in the list of first-line drugs.

The bactericidal drugs in suitable combinations actually kill actively multiplying extracellular bacilli in TB lesions. Rapid elimination of these bacilli renders the sputum bacteriologically negative, leading to cure. No bactericidal drug should be used alone to treat active TB because this inevitably leads to resistance to that drug. When initial therapy fails at this stage, the sputum bacteriology does not become negative, as shown by persistence of positive sputum smears beyond 2 months. Failure of therapy is usually due to emergence of drug-resistant organisms, most often due to poor compliance, prescription of an inadequate regimen, or inadequate dosage of individual drugs.

In the continuation phase of therapy, the drugs slowly eliminate small populations of intermittently metabolizing bacteria in the closed caseous lesion or within macrophages. Incomplete therapy may lead to relapse after discontinuation of treatment, often with drug-sensitive organisms.

Drug-resistant organisms

The inclusion of a number of drugs in a regimen should be based on the awareness of the circumstances under which drug-resistant bacilli are likely to be present (Box 155.1).

At the minimum, a four-drug regimen should be initiated when drug resistance is likely, until susceptibility results are available. The number of drugs in the initial regimen may have to be increased to five to seven if the organisms are resistant to three or more drugs and HIV infection is present, as often occurs in large cities in the United States and in many developing countries.

Management of tuberculosis

Newer approaches are advocated for a better outcome. For the care of patients with TB, responsibility for completion and success now lies with the healthcare providers and not the patients. The duration of treatment in the continuation phase should be extended in specific situations. New anti-TB medications show promise; these are used when necessary. DOT is strongly recommended; the patient is observed ingesting each dose of medication, for improving completion of therapy with a good outcome.

Drug regimens

There are four basic regimens recommended by the CDC for treatment of adult TB disease caused by susceptible organisms

TABLE 155.1 **ANTITUBERCULOSIS DRUGS**

Drug	Daily dosage	Twice-weekly dosage	Side effects	Mode of action
FIRST-LINE DRUGS				
Isoniazid (INH)	5 mg/kg (usually 300 mg) PO or IM	15 mg/kg (usually 900 mg) PO	Peripheral neuritis, hepatotoxicity, allergic fever and rash, lupus erythematosus phenomenon	Acts strongly on rapidly dividing extracellular bacilli; acts weakly on slowly multiplying intracellular bacilli
Rifampin (RIF)	10 mg/kg (usually 450–600 mg) PO	10 mg/kg (usually 450–600 mg) PO	Hepatotoxicity, nausea, vomiting, allergic fever and rash, flu-like syndrome, petechiae with thrombocytopenia or acute renal failure during intermittent therapy	Acts on both rapidly and slowly multiplying extracellular and intracellular bacilli, particularly on slowly multiplying persisters
Rifabutin (Ansamycin)	300 mg PO daily, twice or thrice weekly	Used as RIF substitute	Same as rifampin; uveitis, arthralgia, leukopenia	Same as above
Rifapentine	300–600 mg PO once weekly in continuation phase	Seronegative HIV, noncavitary TB	Same as rifampin; not used in HIV	
Rifamate (INH 150 mg plus RIF 300 mg)	2 capsules PO qd	2 capsules plus 2 tablets of INH (300 mg)	Same as INH/RIF	Same as INH/RIF
Rifater (INH 50 mg plus RIF 120 mg plus PZA 300 mg)	5–6 capsules PO qd		Same as INH/RIF/PZA	Same as INH/RIF/PZA
Pyrazinamide (PZA)	25–30 mg/kg PO (usually 1.5–2 g)	45–50 mg/kg PO (usually 3–3.5 mg)	Hyperuricemia, hepatotoxicity, allergic fever and rash	Active in acid pH (2.5 g) on intracellular bacilli
Ethambutol (EMB)	15–25 mg/kg/d initially, followed after 2 months with 15 mg/kg/d	50 mg/kg PO	Optic neuritis, skin rash, hyperuricemia	Weakly active against both extracellular and intracellular bacilli to inhibit the development of resistance
SECOND-LINE DRUGS				
Streptomycin	10–15 mg/kg (usually 0.5–1 g) 5 days/week; IM or IV	20–25 mg/kg (usually 1–1.5 g)	Cranial nerve VIII damage (vestibular and auditory), nephrotoxicity, allergic fever, rash	Active against rapidly multiplying bacilli in neutral or slightly alkaline extracellular medium
Kanamycin	15–30 mg/kg qd IM or IV	15–30 mg/kg	Same as streptomycin	Same as streptomycin

(*continued*)

TABLE 155.1 CONTINUED

Drug		Daily dosage	Twice-weekly dosage	Side effects	Mode of action
Amikacin		15–30 mg/kg qd IM or IV	15–30 mg/kg	Same as streptomycin	Same as streptomycin
Capreomycin		15–30 mg/kg/d IM or IV	15–30 mg/kg	Same as streptomycin	Same as streptomycin
Ethionamide		10–15 mg/kg (usually 500–750 mg) in divided doses PO with 100 mg pyridoxine	Not used	Nausea, vomiting, anorexia, allergic fever and rash, hepatotoxicity, neurotoxicity, hypothyroidism	Same as streptomycin
Cycloserine		15–20 mg/kg (usually 0.75–1 g) in divided doses with 200 mg pyridoxine PO	Not used	Personality changes, psychosis, convulsions, rash	Same as ethambutol
Para-aminosalicylic acid Thiocetazone[a]		150 mg/kg (usually 12 g) in divided doses PO 150 mg PO	Not used Used rarely	Nausea, vomiting, diarrhea, hepatotoxicity, allergic rash and fever, hypothyroidism Allergic rash and fever, Stevens–Johnson syndrome, blood disorders, nausea, vomiting	Weak action on extracellular bacilli; inhibits development of drug-resistant organisms Same as para-aminosalicylic acid
Clofazimine		200–300 mg PO qd	Not used	Pigmentation of skin, abdominal pain	Not fully known
NEWER AGENTS					
Ofloxacin	400 mg q12h	Not used	Gastrointestinal: diarrhea, nausea, abdominal pain, anorexia; central nervous system: dizziness, restlessness, nightmares, ataxia, seizures	Rapidly multiplying bacilli at neutral or alkaline pH	
Gatifloxacin	400 mg PO qd	Not used	Same as ofloxacin	Same as ofloxacin	
Levofloxacin	500 mg PO qd	Not used	Same as ofloxacin	Same as ofloxacin	
Moxifloxacin	400 mg PO qd	Not used	Same as ofloxacin	Same as ofloxacin	
Azithromycin	500 mg/d	Not used	Diarrhea, nausea, abdominal pain, elevation of liver enzymes	Rapidly multiplying bacilli in macrophages	
Clarithromycin	1 g q12h	Not used	Same as azithromycin	Same as azithromycin	

[a] Not available in the United States.

(Table 155.2). Each treatment regimen consists of an initial 2-month therapy of INH, RIF, EMB, and PZA followed by a continuation phase of 4 to 7 months.

It is recommended that the duration of treatment of any of the regimens should be extended in drug-susceptible pulmonary TB patients who show cavitations in the initial chest x-ray or whose sputum culture had not converted to negative during the intensive phase of therapy (2 months). These clinical indicators may predict adverse outcome with regard to failure and relapse. The continuation phase of therapy should be extended for another 3 months.

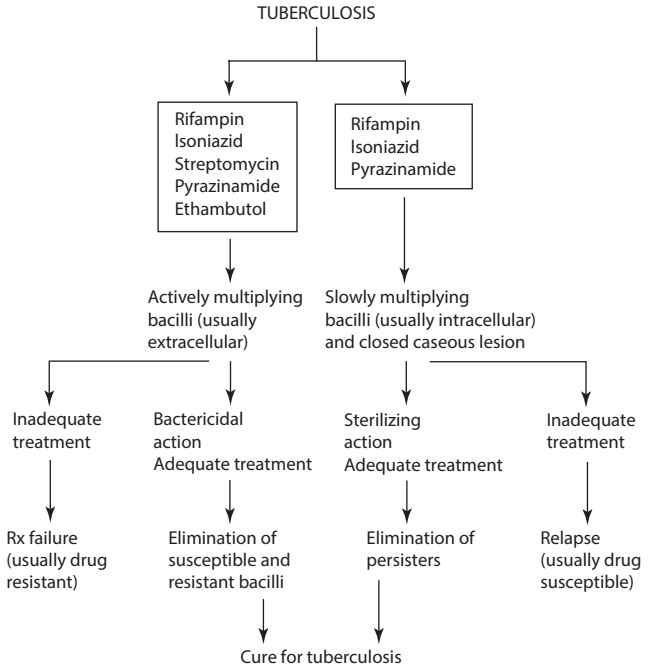

FIGURE 155.3 Principles of chemotherapy of tuberculosis.

Sputum smears and cultures must be obtained at the end of the intensive phase of treatment.

Six-month regimen

The addition of PZA to INH, RIF, and EMB daily for the initial 2 months, followed by INH and RIF daily or twice weekly for another 4 months (a total of 6 months), has proved to be highly successful. Addition of PZA accelerates reduction of the bacterial population and shortens the regimen to 6 months, although its cost is greater.

BOX 155.1

Conditions and patients with increased risk of drug-resistant TB

- History of treatment with anti-TB drugs, including preventive therapy
- Patients from areas with high prevalence of initial or primary drug resistance (>4%), e.g., urban population in the northeastern United States, Florida, California, US–Mexican border
- Foreign-born persons from areas with high prevalence of drug-resistant TB, e.g., Southeast Asia, Mexico, South America, Africa
- Contacts of persons with drug-resistant disease
- Disease in persons who are homeless, drug abusers, and HIV infected
- Persons with positive sputum smears and cultures after 2 months of chemotherapy

After drug susceptibility results are available, usually in 2 months, the regimen is modified accordingly. If the organisms are found to be susceptible to both drugs, therapy is completed with INH–RIF daily or twice weekly for another 4 months. In cases of INH resistance, therapy may consist of RIF, PZA, and EMB for a total of 6 or 9 months; INH may be included in the regimen because of its action on persisters, which generally remain INH sensitive. In RIF-resistant cases other bactericidal drugs should be continued for at least 10 to 12 months to prevent relapse. If the isolate is resistant to PZA, INH and RIF should be continued for a total of 9 months.

Treatment of multidrug-resistant disease

Where the prevalence of multidrug resistance (MDR) and HIV infection is very high, it is necessary to initiate a five- to seven-drug regimen, including second-line drugs. This is applicable to large urban populations such as in New York City, Miami, parts of New Jersey, and San Francisco, as well as for persons from developing countries.

In the treatment of MDR disease, i.e., resistance to INH and RIF, some basic principles must be followed: (1) a single drug must not be added to a failing regimen, (2) at least three new drugs that the patient has not yet taken should replace the existing drug regimen until the susceptibility results are available, (3) the total duration of therapy must be prolonged to 24 months or more, (4) the regimen should include an injectable drug for at least 4 months after the culture is converted to negative, and (5) DOT should be used to ensure compliance, because it is the patient's last chance at a cure.

Extensively drug-resistant TB (XDR-TB) has been reported recently from different parts of the world, first from South Africa. XDR-TB is defined as resistance to at least RIF and INH among the first line of anti-TB drugs (MDR-TB), in addition to resistance to any fluoroquinolone and to at least one of three injectable second-line anti-TB drugs used in TB treatment (capreomycin, kanamycin, amikacin). This development is a serious concern globally.

Most drugs used for MDR disease are second-line drugs (see Table 155.1): ethionamide, cycloserine, para-aminosalicylic acid (PAS), capreomycin, and kanamycin. Newer drugs, fluoroquinolones (gatifloxacin and moxifloxacin) and amikacin, are available but unproven. Finally, clofazimine and thiocetazone (not available in the United States) may be used but also are unproven. FDA has recently approved bedaquiline for MDR-TB but cardiac toxicity remains a concern. These second-line drugs are often rather toxic, and close monitoring is necessary. Monthly bacteriologic studies are necessary to monitor response to treatment.

Because of high failure and relapse rates in MDR-TB, surgical resection of the major diseased area of the lung is again becoming necessary after reasonable medical treatment has been given to reduce the bacterial load.

Preventive therapy for recent contacts with MDR-TB is controversial. However, possible regimens are PZA plus EMB, and PZA plus a fluoroquinolone, or EMB plus a fluoroquinolone for 12 to 24 months, during which periodic clinical, bacteriologic, and radiologic monitoring must be maintained.

The combination of RIF and PZA or rifabutin and PZA were suggested for shorter periods of time, but the regimens are highly toxic. Experts should be consulted prior to the use of the regimen.

TABLE 155.2 **DRUG REGIMENS FOR PULMONARY TB IN ADULTS CAUSED BY DRUG-SUSCEPTIBLE ORGANISMS**

Initial phase			Continuation phase			
Regimen	**Drugs**	**Interval and doses±§**	**Regimen**	**Drugs**	**Interval and doses±§**	**Range of total doses**
1	**INH**	7 days/week for 56 doses (8 weeks)	**1a**	**INH**	7 days/week for 126	182–130
	RIF	**or**		**RIF**	doses (18 weeks)	(26 weeks)
	PZA	5 days/week for 40 doses (8 weeks)			**or**	
	EMB				5 days/week for 90 doses (18 weeks)	
			1b#	**INH**	2 days/week for 36	92–76
				RIF	doses (18 weeks)	(26 weeks)
			1c	**INH**	1 day/week for	74–58
				RPT	18 doses (18 weeks)	(26 weeks)
2	**INH**	7 days/week for 14 doses	**2a**	**INH**	2 days/week for 36	62–58
	RIF	(2 weeks), then 2 days/week for 12 doses	**2b**	**RIF**	doses (18 weeks)	(26 weeks)
	PZA	(6 weeks)		**INH**	1 day/week for	44–40
	EMB	**or**		**RPT**	18 doses	(26 weeks)
		5 days/week for 10 doses			(18 weeks)	
		(2 weeks), then 2 days/week for 12 doses (6 weeks)				
3	**INH**	3 times weekly for 24	**3a**	**INH**	3 times weekly for 54	78
	RIF	doses (8 weeks)		**RIF**	doses (18 weeks)	(26 weeks)
	PZA					
	EMB					
4	**INH**	7 days/week for 56 doses	**4a**	**INH**	7 days/week for 217	273–195
	RIF	(8 weeks)	**4b**	**RPT**	doses (31 weeks)	(39 weeks)
	EMB	**or**		**INH**	**or**	118–102
		5 days/week for 40 doses (8 weeks)		**RIF**	5 days/week for 155 doses (31 weeks)	(39 weeks)
					Twice weekly for 62 doses (31 weeks)	

Abbreviations: INH = isoniazid; RIF = rifampin; PZA = pyrazinamide; EMB = ethambutol; RPT = rifapentine.
± When DOT is used, drugs may be given 5 days/week and the necessary doses adjusted accordingly.
§ Patients with cavitation in initial chest x-ray and positive cultures at completion of 2 months of therapy should receive a 7-month continuation phase.
Adapted from CDC: Core Curriculum for Tuberculosis Fifth Edition 2011.

Treatment regimens for HIV-infected persons

In the United States the current 6-month treatment consisting of INH, RIF, PZA, and EMB or SM daily for 2 months, followed by INH and RIF daily or twice weekly for another 4 months, is not adequate in HIV-infected patients. However treatment of TB in HIV-infected patients is complex and requires due attention to the patient's need for antiretroviral therapy (ART), potential drug reactions, and complication secondary to the immune reconstitution inflammatory syndrome (IRIS). Rifamycins are known to induce liver CYP3A4 enzymes that can increase metabolism of protease inhibitor (PI) and non-nucleoside reverse transcriptase inhibitors (NNRTIs). Rifampin is more potent an inducer than rifabutin hence rifabutin is preferred over rifampin if certain antiviral drugs are used to treat HIV infection; however, adjustment of the rifabutin dosage is still necessary with some of the antiretroviral medications. Clinically significant interactions between rifampin and nucleoside analogs are rare. Therefore, nucleoside analogs can be used within ART regimens along with a third antiretroviral agent (e.g., efavirenz).

The CDC recommends that therapy for patients with HIV infection be prolonged to 9 months or for at least 6 months following conversion of sputum cultures to negative (Table 155.2).

Treatment-limiting side effects are frequent in HIV-infected patients, and they require innovative measures. Rifabutin has fewer drug–drug interactions due to its decreased induction of the cytochrome P450 system. It works better with those HIV-positive patients who are on certain PI and NNRTI antiviral drugs. Therefore, rifabutin may be used in place of RIF. The current recommendation is that HIV-infected patients with CD4 cell counts $<100/mm^3$ should receive therapy daily during the intensive phase and daily or thrice weekly during the continuation phase. If adverse affects such as uveitis and cytopenia occur, medication must be discontinued at once and appropriate consultation should be obtained.

Smear-negative tuberculosis

Positive sputum smears indicate a large bacterial population and advanced disease, whereas negative smears generally suggest less advanced disease. Occasionally a patient who is smear negative is also culture negative but is treated for TB on the basis of clinical and x-ray findings and response to therapy. A suggested regimen for such patients is INH, RIF, PZA, and EMB for 2 months, followed by INH and RIF for an additional 2 months (4 months total). However, HIV-infected patients should be treated for a minimum of 6 months.

Extrapulmonary tuberculosis

The bacterial load in extrapulmonary TB usually is much smaller than in cavitary pulmonary TB. Thus, 6- to 9-month regimens (see Table 155.2) are adequate for treatment of extrapulmonary TB. Figure 155.2 indicates the steps in the diagnosis of pulmonary and extrapulmonary TB. It is generally recommended that the duration of therapy be prolonged in TB spondylitis (Pott's disease) and meningitis to 9 to 12 months, respectively. Corticosteroids may be added for patients with tuberculous pericarditis and tuberculous meningitis.

Directly observed therapy

The fact that most of the 6-month regimens may be given intermittently two or three times per week has led to the development of some innovative regimens. The Denver regimen consists of DOT administration of daily INH, RIF, PZA, and SM or EMB for 2 weeks, followed by twice-weekly doses for 6 weeks and then twice-weekly administration of INH or RIF for another 16 weeks. Another DOT regimen is INH, RIF, PZA, and EMB or SM three times a week for 6 months (Table 155.2, options 2 and 3).

To ensure completion of therapy, DOT is the preferred initial strategy and deserves special emphasis. DOT can be provided daily or intermittently in the office, clinic, or in the field by trained personnel. Using DOT can only improve the outcome. Aggressive interventions may be initiated when the patient misses doses.

Therapy in special situations

Pregnancy

Treatment with INH, RIF, and EMB is safe in pregnancy. SM should not be used because of toxicity to the eighth nerve of the fetus. Experience with PZA is limited in pregnancy, and at present it should be avoided if possible. If PZA is not included in the treatment regimen, the minimum duration of therapy is 9 months. Pregnancy alters the distribution and metabolism of several drugs, particularly the serum concentration of PIs are decreased. Therefore, treatment of TB in an HIV-infected pregnant woman requires special attention.

Renal failure

INH and RIF dosages need not be altered in renal failure because these drugs are excreted by the liver. Renal dialysis patients should receive the drugs after dialysis. EMB dosage must be reduced to 8 to 10 mg/kg in advanced renal failure, and the serum level should be assayed. Aminoglycoside dosage must also be adjusted, and the level should be monitored if they must be used in very unusual circumstances. PZA dosage should be reduced to 15 to 20 mg/kg.

Liver disease

Alcoholic liver disease does not preclude use of anti-TB drugs. However, monitoring for side effects must be careful and regular. In overt liver failure, one suggested regimen is amikacin plus EMB plus a fluoroquinolone.

Combined preparations

In the United States, two commercial preparations of combination drugs are available. It is advantageous to use combination preparations because they preclude the taking of only one bactericidal drug, which encourages drug resistance. Rifamate is a combination capsule of INH, 150 mg, and RIF, 300 mg, and two capsules are the recommended daily dose. Another preparation, Rifater, contains INH, 50 mg, RIF, 120 mg, and PZA, 300 mg, in each tablet; the recommended dose is five tablets daily. We strongly recommend the use of combination preparations for therapy as a safeguard against development of drug resistance and medication errors, particularly for patients not on DOT.

Corticosteroid therapy

Corticosteroids are not routinely used in the treatment of TB. Prednisone, 20 to 30 mg/day, may improve the general sense of well-being, reduce fever, increase appetite, and improve nutrition of markedly toxic or severely debilitated patients. The drug should be tapered off gradually after 4 to 8 weeks. In disseminated TB associated with hypoxemia and respiratory failure, prednisone, 40 to 60 mg/day, may improve oxygenation. Steroids have been successfully used in AIDS patients with TB, but they may promote opportunistic infections. Most authorities believe that complicated tuberculous meningitis should be treated with prednisone, 60 to 80 mg/day, slowly tapered after 8 to 12 weeks. Some advise corticosteroid therapy for all cases of tuberculous pericarditis to prevent constrictive pericarditis.

Monitoring and follow-up of patients

Intense bacteriologic monitoring is necessary during therapy of pulmonary TB. We recommend that three to five specimens of bronchial secretions (sputum) be examined initially by smear and culture, followed by drug susceptibility testing. During therapy, at least one specimen of sputum should be examined every 2 weeks until conversion to negative occurs. This permits early detection of noncompliance and impending failure. After completion of treatment, to detect early relapse, one specimen every 3 months three times should be examined before discharging the patient from the clinic.

Monitoring for side effects should be done monthly after explaining to the patient the symptoms of side effects for which to be alert (e.g., nausea, vomiting, anorexia, dark urine, jaundice). Blood should be collected for baseline complete blood count and renal and hepatic function tests. We do not recommend routine monthly blood studies. Rather, the patients are advised to discontinue medication when symptomatic and to report for repeat hepatic function studies at that time. The drugs are then adjusted to the laboratory findings. Some clinicians, however, do recommend routine blood studies, either of all patients or only of those at risk for hepatotoxicity due to underlying liver disease or with other risks for hepatotoxicity. For EMB, vision and color studies are performed monthly, and for SM or other aminoglycosides or capreomycin monthly examination for balance and hearing loss are performed.

Prophylaxis

For prophylaxis, see Chapter 113, Nonsurgical antimicrobial prophylaxis.

Nontuberculous mycobacteria

Timothy Aksamit and David E. Griffith

Introduction

The nontuberculous mycobacteria (NTM) are ubiquitous in the environment; so much so that some experts feel they should be referred to as "environmental mycobacteria." While there are almost 150 identified NTM species, the most common NTM associated with human disease in the United States are *Mycobacterium avium* complex (MAC), *Mycobacterium kansasii*, *Mycobacterium fortuitum* and *Mycobacterium abscessus*. Many other NTM species can cause human disease but are generally rarely encountered clinically, while a few NTM species, most notably *Mycobacterium gordonae*, are frequently isolated as specimen contaminants and almost never cause disease.

Infection is thought to occur from environmental exposure to the NTM with three potential portals of entry; the respiratory tract, the gastrointestinal tract, and direct inoculation of the skin and soft tissues. There had been no documented occurrences of either human-to-human or animal-to-human transmission until recent reports of the transmissibility between patients in several cystic fibrosis (CF) clinics.

The most common clinical manifestation of NTM infection in the immunocompetent host is chronic pulmonary disease. Symptoms are usually insidious in onset and variably include cough, sputum production, fatigue, weight loss, weakness, hemoptysis, and night sweats. MAC is the most common respiratory pathogen. Patients with MAC lung disease are divided between two groups. The first are primarily female patients without a history of smoking or pre-existing lung disease who have noncavitary disease characterized by nodular densities and bronchiectasis, usually in the right middle lobe and lingula. The second group are primarily male patients with pre-existing lung disease, most often chronic obstructive lung disease, and cavitary abnormalities radiographically, similar to tuberculosis.

Lymphadenitis is the most common NTM disease manifestation in children and is usually due to MAC or less commonly *Mycobacterium scrofulaceum*. The most important differential diagnosis is tuberculosis lymphadenitis, although NTM account for approximately 90% of mycobacterial lymphadenitis in children (but only 10% in adults). Symptoms are usually minimal with unilateral involvement of submandibular, submaxillary, preauricular, or cervical lymph nodes most common. Skin and soft-tissue infections are usually due to *Mycobacterium marinum* or the "rapidly growing mycobacteria" (RGM), *M. abscessus*, *M. fortuitum*, *Mycobacterium chelonae*, and are the result of direct inoculation either after trauma or surgery. Dissemination of NTM pathogens is most often associated with the severe immunosuppression of advanced acquired immunodeficiency syndrome (AIDS) and caused by MAC. Disseminated NTM infections can also occur in other immunocompromised states, sometimes associated with indwelling foreign bodies such as venous catheters, dialysis catheters, or other prosthetic devices.

Diagnostic criteria of nontuberculous mycobacterial (NTM) lung disease

The diagnostic criteria for NTM lung disease include a compilation of clinical, radiographic, and microbiologic criteria. Although a diagnosis of NTM lung disease may be suspected by one or more of these three

criteria, all must be present to establish a diagnosis. Clinical, radiographic, and microbiologic criteria are equally important. The minimum evaluation of a patient suspected of NTM lung disease should include (1) chest radiograph or, in the absence of cavitation, chest high-resolution computed tomography (HRCT) scan, (2) three or more sputum specimens for acid-fast bacilli (AFB) analysis, and (3) exclusion of other disorders such as tuberculosis and lung malignancy.

The following criteria apply to symptomatic patients with radiographic infiltrates, nodular or cavitary, or an HRCT scan that shows multifocal bronchiectasis with multiple small nodules. These criteria fit best with MAC, *M. kansasii*, and *M. abscessus*. There is not enough known about most other NTM to be certain that these diagnostic criteria are universally applicable for all NTM respiratory pathogens. Expert consultation should be obtained when NTM are recovered that are either infrequently encountered or that usually represent environmental contamination. Substantial variation in the epidemiology of NTM lung disease has been recognized between countries such that mindfulness of the epidemiologic data is imperative in making assessments of clinical likelihood of disease versus colonization dependent on specific NTM species.

Clinical criteria include respiratory or systemic symptoms attributed to NTM lung disease not attributable to other established diagnoses. Radiographic findings as noted above may vary, especially in the context of whether there is or is not pre-existing lung disease. In the absence of radiographic changes related to pre-existing lung disease or of cavitary change, the most common findings include nodular infiltrates, cylindrical bronchiectasis, and consolidation. Pleural disease, prominent mediastinal/hilar adenopathy, air–fluid levels, and ground-glass opacities on high-resolution chest computed tomography are not commonly seen in non-human immunodeficiency virus (HIV) patients with NTM lung disease. Microbiologic criteria also may vary. If three sputum results are available at least two AFB cultures should be positive, regardless of AFB smear results. In the absence of at least two positive cultures, consideration should be given to repeating three sputum specimens for AFB smear and culture or obtaining bronchoscopy with wash or lavage. If only one bronchial wash or lavage is available, one positive culture regardless of smear is necessary. If the sputum or bronchial wash results are nondiagnostic or another disease cannot be excluded, transbronchial or lung biopsy with mycobacterial histopathologic features (granulomatous inflammation or AFB) and yielding an NTM on culture, or biopsy showing mycobacterial histopathologic features (granulomatous inflammation or AFB) and one or more sputum or bronchial washing that is culture positive for an NTM are required.

The preferred staining procedure is the fluorochrome method. Specimens should be cultured on both liquid and solid media. Species that require special growth conditions and/or lower incubation temperatures include *Mycobacterium haemophilum*, *Mycobacterium genavense*, and *Mycobacterium conspicuum*. These species can cause cutaneous and lymph node disease. In general, NTM should be identified to the species level. Methods of rapid species identification include commercial DNA probes (MAC, *M. kansasii*, and *M. gordonae*) and high performance liquid chromatography (HPLC). Routine susceptibility testing of MAC isolates is recommended for clarithromycin only. Routine susceptibility testing of *M. kansasii* isolates is recommended for rifampin only. Routine susceptibility testing, for both taxonomic identification and treatment of RGM (*M. fortuitum*, *M. abscessus*, and *M. chelonae*) should be for amikacin, imipenem (*M. fortuitum* only), doxycycline, the fluorinated quinolones, a sulfonamide or trimethoprim–sulfamethoxazole, cefoxitin, clarithromycin, linezolid, and tobramycin (*M. chelonae* only).

Substantial changes have recently occurred in NTM taxonomy including for *M. abscessus* which underwent a taxonomic change with the identification of two new species, *Mycobacterium massiliense* and *Mycobacterium bolletii*, previously identified as *M. abscessus*. They had otherwise been identical based on the widely adopted mycobacterial speciating technique utilizing sequencing of the 16S ribosomal RNA gene. This gene is highly conserved in the mycobacterial genome such that very small sequence differences can define a new mycobacterial species. It has subsequently come to light that elsewhere in the mycobacterial genome, the organism identified as *M. massiliense* has a smaller, inactive erythromycin methylase or *erm* gene (an inducible gene that causes macrolide resistance and is discussed further below) than *M. abscessus* subsp. *abscessus*, but because the name *M. bolletii* had been applied to this species with the inactive *erm* gene first, the new "official" nomenclature for this organism is currently *M. abscessus* subsp. *bolletii* even though it is widely still referred to as *M. massiliense* in the medical literature. Molecular techniques for organism identification are becoming an increasingly necessary component for informed decision making by the clinician.

Diagnostic criteria of nontuberculous mycobacterial (NTM) extrapulmonary disease

The diagnosis of extrapulmonary NTM disease also requires a compilation of clinical, microbiologic, and histopathologic test results in the context of lack of other diagnoses to explain symptoms and findings. Microbiology and histopathology results are generally of most value. Specifically, AFB smear and culture of fluid or tissue is required. Specimens can be obtained by needle aspirate, core biopsy, or excisional biopsy. Tissue biopsy is generally the most sensitive means of obtaining a specimen for culture to establish extrapulmonary NTM disease. In some instances, histopathologic findings of granulomatous inflammation with or without AFB organisms present may be suggestive of NTM disease. However, prior to treatment for extrapulmonary NTM disease definitive identification by culture is recommended.

General principles of therapy for nontuberculous mycobacteria (Table 156.1)

The greatest misunderstanding about treatment regimens for NTM pathogens is the result of the expectation that all NTM infections should respond in a predictable manner to antimicrobial therapy, in a manner similar to *Mycobacterium tuberculosis*. That is, treatment

TABLE 156.1 **TREATMENT OF NONTUBERCULOUS MYCOBACTERIAL INFECTIONS (SEE TEXT FOR DETAILS)**

NTM species	Disease	Treatment	Comment
MAC	Pulmonary[a]	Clarithromycin 500 mg BID or azithromycin 250 mg/d plus ethambutol 15 mg/kg/d plus rifampin 600 mg/ d Consider streptomycin or amikacin 10–15 mg/kg IM or IV for severe disease	Treat for 1 year of negative AFB cultures Rifabutin 150–300 mg daily may be substituted for rifampin
MAC	Disseminated	Clarithromycin 500 mg BID or azithromycin 500 mg/d with ethambutol 15 mg/kg/d ± rifabutin 300 mg/d	Treatment lifetime or may be stopped with CD4+ T-cell count over 100 cells/mm^3 for 12 months
MAC	Lymph node Involvement	Complete surgical excision of involved nodes usually curative	If adjunctive chemo-therapy necessary, see drugs for pulmonary disease
M. kansasii	Pulmonary	Rifampin 600 mg/d Isoniazid 300 mg/d Ethambutol 15 mg/kg/d	Treat for 1 year of negative AFB cultures Clarithromycin and moxifloxacin also with excellent activity against *M. kansasii*
M. kansasii	Disseminated	Substitute rifabutin 150–300 mg/d for rifampin in HIV +	Treatment duration as for disseminated MAC
M. abscessus subsp. *bolletii*	Pulmonary	Clarithromycin 500 mg BID plus amikacin 10–15 mg/kg 3–5 times per week	Consider second parenteral drug such as cefoxitin or imipenem. Activity of linezolid, tigecycline, and clofazimine is variable
M. abscessus subsp. *bolletii*	Soft tissue	Clarithromycin 500mg BID plus amikacin 10–15 mg/kg 3–5 times per week for a minimum of 2 weeks, 4–6 months for severe infection	Consider second parenteral drug for severe disease. Removal of foreign body and surgical debridement also important. Other agent activity variable including linezolid, tigecycline, or clofazimine
M. abscessus subsp. *abscessus*	Pulmonary	Amikacin 10–15 mg/kg 3–5 times per week plus second parenteral drug such as cefoxitin or imipenem	Other agents with variable activity: linezolid, tigecycline, and clofazimine Role of azithromycin in presence of active *erm* gene is uncertain
M. abscessus subsp. abscessus	Soft tissue	Amikacin 10–15 mg/kg 3–5 times per week plus second parenteral drug such as cefoxitin or imipenem for a minimum of 2 weeks, 4–6 months for severe infection	Other agents with variable activity: linezolid, tigecycline, and clofazimine. Role of azithromycin in presence of active *erm* gene is uncertain. Removal of foreign body and surgical debridement also important
M. chelonae	Pulmonary	Clarithromycin 500 mg BID plus tobramycin 3–5 mg/kg 3–5 times per week	Consider third agent such as imipenem or linezolid. Clofazimine, doxycycline, and quinolone susceptibility varies
M. chelonae	Soft tissue	Clarithromycin 500 mg BID plus tobramycin 3–5 mg/kg 3–5 times per week for a minimum of 2 weeks, 4–6 months for severe infection	Consider third agent for severe disease. Susceptibility to imipenem, linezolid, clofazimine, doxycycline, and quinolone varies. Removal of foreign body and surgical debridement may be important
M. marinum	Soft tissue	Clarithromycin 500 mg BID plus ethambutol 15 mg/kg/d. Treat 1–2 months after resolution of symptoms (usually 3–4 months total)	Susceptible to multiple agents. Surgical debridement may also be important
M. fortuitum	Pulmonary	2 agents to which the organism is susceptible for 6 months. Consider parenteral medication for severe disease	Susceptible to multiple medications including quinolones, doxycycline, trimethoprim/sulfa, macrolides, amikacin
M. fortuitum	Soft tissue	As above. Treatment 3–6 months	
M. simiae, *M. xenopi* *M.malmoense* *M. szulgai*		Too little information to make standard or routine recommendation	Usually a macrolide-based regimen

[a] Consider three times weekly therapy (TIW) with clarithromycin 1000 mg, ethambutol 25 mg/kg/dose, and rifampin 600 mg for mild nodular/bronchiectatic (noncavitary) disease.

regimens should be based on in vitro susceptibility testing and the NTM pathogen should respond to antimicrobial agents based on in vitro susceptibility results. The most difficult and frustrating aspect of NTM therapy for most clinicians is the lack of a clear association between in vitro susceptibility results and clinical (in vivo) response for many NTM pathogens including the most common one, MAC. For many NTM, including MAC, laboratory cutoffs for "susceptible" and "resistant" do not have a demonstrable clinical correlate and have not been confirmed to be clinically meaningful. The situation is complicated further because there is a spectrum of response by NTM pathogens based on in vitro susceptibilities. For instance, diseases caused by *M. kansasii*, *M. fortuitum*, and *M. marinum* respond predictably to treatment regimens based on in vitro susceptibilities. Response of disease caused by MAC correlates with in vitro susceptibility to macrolides (clarithromycin and azithromycin), but not other agents. Lastly, there are a number of NTM species (*M. abscessus, Mycobacterium simiae, Mycobacterium malmoense*, *Mycobacterium xenopi*, etc.) for which there is no established correlation between in vitro susceptibilities and in vivo response for any antimicrobial agents. The explanation(s) for the dichotomy between in vitro susceptibility results and in vivo response (clinical outcome) for many NTM is (are) currently not known.

The presence of the *erm* gene noted above has recently provided a potential explanation for the discordance between in vitro testing and phenotypic response: erythromycin methylase (*erm*) genes encode a diverse collection of methylases that impair binding of macrolides to ribosomes, reducing the inhibitory activity of these agents. The primary mechanism of acquired clinically significant macrolide resistance for some mycobacteria, especially RGM, is the presence of an inducible *erm* gene. All isolates of *M. abscessus* subsp. *abscessus*, *M. fortuitum*, and several other RGM, but not *M. chelonae*, contain an inducible *erm* gene. The most interesting aspect of this inducible gene is that if an *M. fortuitum* or *M. abscessus* subsp. *abscessus* isolate is exposed to macrolide, the *erm* gene activity is induced with subsequent in vivo macrolide resistance which may not be reflected by the initial in vitro minimum inhibitory concentration (MIC) of the organism for the macrolide. It is only with incubation of NTM in the presence of a macrolide that the *erm* gene and the associated macrolide resistance will be identified.

The clinician must use in vitro susceptibility data for many NTM with the awareness that, unlike tuberculosis, NTM disease may not be eradicated in a given patient with therapy based on in vitro susceptibility results.

Lastly, the clinician may not uncommonly encounter different NTM isolates synchronously or metachronously, and should monitor microbiologic response during and microbiologic status after a treatment course.

Recommended drug treatment for MAC lung disease

As discussed in the general principles of NTM therapy, the macrolides (clarithromycin and azithromycin) are the only antimicrobial agents for which there is a demonstrated correlation between in vitro susceptibility and in vivo response for MAC lung disease. The cornerstones of MAC therapy, therefore, are the macrolides, clarithromycin and azithromycin, with the addition of ethambutol. These agents are then combined with companion drugs, usually a rifamycin and, possibly, an injectable aminoglycoside. It is necessary to include companion drugs with the macrolide to prevent the emergence of macrolide-resistant MAC isolates. The macrolides should *never* be used as monotherapy for treatment of MAC disease (pulmonary or disseminated). Likewise, the use of macrolide and fluoroquinolone may be associated with cardiac toxicity and puts the patient at risk for development of macrolide-resistant MAC disease.

An important illustration of how the dichotomy between in vitro susceptibility results and in vivo response in MAC disease can be detrimental is provided by the example of ethambutol. There has not been a demonstrated correlation between ethambutol in vitro susceptibility and clinical response in any previous study; however, the duration of ethambutol use is associated with improved microbiologic response for patients receiving an intermittent clarithromycin-containing regimen and the exclusion of ethambutol from treatment regimens is a major risk factor for the development of macrolide-resistant MAC. It would be potentially risky to the patient for a physician to exclude ethambutol from a multidrug MAC treatment regimen based on in vitro susceptibility results.

There is another difficult-to-explain phenomenon associated with MAC drug therapy. Patients who have failed prior MAC therapy, with or without a macrolide, have lower sputum conversion rates with macrolide-containing treatment regimens, even with macrolide-susceptible MAC isolates, than do patients with no prior therapy. Although the explanation for this observation is also not clear, it is evident that the best chance for treatment success in MAC lung disease is the first treatment effort.

The recommended treatment length for MAC pulmonary disease is a duration of therapy that includes 12 months of sputum culture negativity. This treatment goal dictates that patients should have sputum collected for AFB analysis on a regular basis throughout the course of treatment.

The intensity of MAC treatment should be proportionate to the disease burden; other considerations should be individualized patient factors including tolerance to medications, medication cost, and acceptance of necessary monitoring and risks for the multidrug regimens.

For most patients with nodular/bronchiectatic disease, or those with fibrocavitary disease who cannot tolerate daily therapy, or those patients for whom disease suppression is an appropriate goal, intermittent, three times weekly, therapy is recommended. Recommended intermittent drug dosages include: (1) clarithromycin, 1000 mg, or azithromycin, 500 to 600 mg, (2) ethambutol, 25 mg/kg, and (3) rifampin, 600 mg, given three times weekly. Intermittent therapy is not recommended for patients with cavitary disease or patients who have received previous therapy for MAC.

The recommended regimen for patients with fibrocavitary disease or severe nodular/bronchiectatic disease, includes (1) clarithromycin, 1000 mg/day (or 500 mg twice daily) or azithromycin, 250 mg/day, (2) ethambutol, 15 mg/kg/day, and (3) rifampin, 10 mg/kg/day (maximum 600 mg/day). For some

patients, the doses of clarithromycin may need to be split (e.g., 500 mg twice daily) because of gastrointestinal intolerance and for patients of small body mass (less than 50 kg) or age over 70 years, the clarithromycin dose may need to be reduced to 500 mg/day or 250 mg twice a day because of gastrointestinal intolerance.

A more aggressive and less well-tolerated treatment regimen for patients with severe and extensive (multilobar), especially fibrocavitary, disease consists of clarithromycin, 1000 mg/day (or 500 mg twice a day), or azithromycin, 250 mg/day, rifabutin, 150 to 300 mg/day, or rifampin, 10 mg/kg/day (maximum 600 mg/day), ethambutol (15 mg/kg/day), and consideration of inclusion of a parenteral agent, either amikacin or streptomycin, for the first 2 or 3 months of therapy (see dosage discussion below). Patients receiving clarithromycin and rifabutin should be carefully monitored for rifabutin-related toxicity, especially hematologic (leukopenia) and ocular (uveitis) toxicity. Active investigations are ongoing attempting to define the role of inhaled amikacin in the treatment of NTM lung disease. To date, although inhaled amikacin is often used there is very little published data supporting the indication, dose, and duration of the best use as a companion drug.

Macrolide-resistant MAC lung disease is associated with a very poor prognosis. The two major risk factors for macrolide-resistant MAC disease are macrolide monotherapy or treatment with macrolide and inadequate companion medications. The treatment strategy associated with the most success includes both the use of a multidrug regimen including a parenteral aminoglycoside (streptomycin or amikacin) and surgical resection ("debulking") of disease. The optimal drug regimen for treating macrolide-resistant strains is unknown but some experts recommend ethambutol, rifabutin, and an injectable agent. The role of other drugs, such as moxifloxacin or clofazimine, is still not known. Likewise, the future role of newer antimicrobials being developed and in early clinical usage trails for tuberculosis is equally unclear at this time.

Patients whose disease is predominantly localized to one lung and who can tolerate resectional surgery might also be considered for surgery if there is poor response to drug therapy, the development of macrolide-resistant MAC disease or the presence of significant disease-related complications such as hemoptysis. Whenever possible, this surgery should be performed at centers with thoracic surgeons who have considerable experience with lung resectional surgery for mycobacterial disease, which is potentially associated with significant morbidity and mortality.

Disseminated MAC disease

Successful treatment of disseminated MAC in persons with AIDS is based on treatment of both the mycobacterial infection and the HIV infection. Clinicians must, therefore, be aware of the drug–drug interactions between the antimycobacterial and antiretroviral medications. Current guidelines for the use of antimycobacterial drugs with HIV therapies can be found at www.cdc.gov/nchstp/tb/TB_HIV_DRUGS/TOC.htm.

All patients should be treated with clarithromycin, 1000 mg/day or 500 mg twice a day, or as an alternative, azithromycin at a dose of 500 mg daily, and ethambutol at the dose of 15 mg/kg daily. Rifabutin, if added, should be used at a dose of 300 mg daily, with adjustments for interactions with antiretroviral drugs. As with macrolide-resistant MAC lung disease, patients with macrolide-resistant strains are far less likely to be successfully treated. Other drugs that should be considered for inclusion are amikacin and moxifloxacin. Clofazimine has been associated with excess mortality in the treatment of disseminated MAC disease and should not be used. Treatment of MAC in patients with AIDS should be considered lifelong, unless immune restoration is achieved by antiretroviral therapy. MAC treatment may be stopped for patients who are asymptomatic, and have achieved a CD4+ T-cell count of over 100 cells/mm^3 for at least 12 months.

Preventive therapy for disseminated MAC is recommended for all HIV-infected patients with less than 50 CD4+ T-cells/mm^3. Based on efficacy and ease of use, azithromycin—given as 1200 mg once weekly—is the preferred agent. Clarithromycin is also effective; however, it is considered an alternative agent because it must be given twice daily and the risk of breakthrough with macrolide-resistant strains is higher with daily clarithromycin than with weekly azithromycin. Rifabutin is also effective but should only be used when a macrolide cannot be tolerated. Primary MAC prophylaxis should be discontinued among adult and adolescent patients who have responded to antiretroviral therapy with an increase in CD4+ T-lymphocyte counts to more than 100 cells/mm^3 for more than 3 months. Primary prophylaxis should be reintroduced if the CD4+ T-lymphocyte count decreases to less than 50 to 100 cells/mm^3.

MAC lymphadenopathy

The treatment of choice for MAC lymphadenopathy, as well as localized lymphadenopathy due to most NTM pathogens, is complete surgical resection of the involved lymph nodes. When complete surgical resection is not possible, due for instance to nerve impingement or encasement by the infected nodes, then chemotherapy with MAC treatment regimens similar to those for lung and disseminated disease would be necessary.

M. kansasii pulmonary disease

The recommended regimen for treating pulmonary *M. kansasii* disease includes daily rifampin (600 mg/day), isoniazid (300 mg/day), and ethambutol (15 mg/kg/day) for a duration that includes 12 months of negative sputum cultures. Limited data suggests that intermittent therapy with rifampin, ethambutol, and clarithromycin for *M. kansasii* disease can also be successful. The recommended treatment duration, as with MAC lung disease, is a duration that includes 12 months of sputum AFB culture negativity.

Patients whose *M. kansasii* isolates have become resistant to rifampin as a result of previous therapy have been treated successfully with a regimen that consists of high-dose daily isoniazid (900 mg), high-dose ethambutol (25 mg/kg/day), sulfamethoxazole (1 g three times per

day) combined with several months of streptomycin or amikacin. The excellent in vitro activity of clarithromycin and moxifloxacin against *M. kansasii* suggests that multidrug regimens containing these agents and at least one other agent based on in vitro susceptibilities, such as ethambutol or sulfamethoxazole, are likely to be even more effective for treatment of a patient with rifampin-resistant *M. kansasii* disease.

Disseminated *M. kansasii*

The treatment regimen for disseminated disease should be the same as for pulmonary disease. Because of the critically important role of rifamycins in the treatment of *M. kansasii* disease, it is important to construct *M. kansasii* and antiretroviral treatment regimens that are compatible (see website in disseminated MAC disease discussion above). An option for treating HIV-infected patients who receive an antiretroviral regimen not compatible with rifamycins is to substitute a macrolide or moxifloxacin for the rifamycin. There is no recommended prophylaxis regimen for disseminated *M. kansasii* disease.

M. abscessus disease

M. abscessus isolates are uniformly resistant to the standard antituberculous agents. *M. abscessus* isolates generally have low or intermediate MICs, compared to achievable drug levels, to clarithromycin, amikacin, and cefoxitin. Some isolates have low or intermediate MICs to linezolid, tigecycline, and imipenem.

For serious skin, soft-tissue, and bone infections caused by *M. abscessus*, clarithromycin 1000 mg/day or azithromycin 250 mg/day should be combined with one or more of the parenteral medications (amikacin, cefoxitin, or imipenem). Macrolide, especially clarithromycin, offers little additional benefit in the presence of an active *erm* gene, e.g., *M. abscessus* subsp. *abscessus*. Intravenous amikacin is given at a dose of 10 to 15 mg/kg daily to adult patients with normal renal function to provide peak serum levels in the low 20 μg/mL range. The lower dose (10 mg/kg) should be used in patients over the age of 50 and/or in patients in whom long-term therapy (greater than 3 weeks) is anticipated. The amikacin combined with high-dose cefoxitin (up to 12 g/day given intravenously in divided doses) is recommended for initial therapy (minimum 2 weeks) until clinical improvement is evident. Cefoxitin availability or intolerance may necessitate the choice of an alternative agent such as imipenem (500 mg two to four times daily), which is a reasonable alternative to cefoxitin. For serious disease, a minimum of 4 months of therapy is necessary to provide a high likelihood of cure. For bone infections, 6 months of therapy is recommended. Surgery is generally indicated with extensive disease, abscess formation, or where drug therapy is difficult. Removal of foreign bodies such as breast implants or percutaneous catheters is important and likely essential to recovery.

In contrast to the efficacy of medication regimens for nonpulmonary disease, no antibiotic regimens based on in vitro susceptibilities have been shown to produce long-term sputum conversion for patients with *M. abscessus* lung disease. The goal of 12 months of negative sputum cultures while on therapy may be optimal, but there is no medication strategy to reliably achieve this goal. Alternative goals of therapy such as symptomatic improvement, radiographic regression of infiltrates, or improvement in sputum culture positivity, short of conversion to negative cultures, are more realistic for *M. abscessus* lung disease. Combination therapy (as outlined above) with or without macrolide plus one or more parenteral agent (amikacin, cefoxitin, or imipenem for 2–4 months) usually produces clinical and microbiologic improvement, but the cost and morbidity are significant impediments to a curative course of therapy. Several recently published series of *M. abscessus* lung disease patients treated with a combination of parenteral and oral agents suggest improved clinical response rates in contrast to historical controls. Linezolid and tigecycline may also have variable activity but also carry costs that are high and tolerance which is limited. For some patients, symptoms can be controlled with intermittent periods of therapy with clarithromycin or azithromycin alone or in combination with one or more parenteral drugs. Curative therapy for *M. abscessus* lung disease is more likely to be obtained with limited disease and a combination of surgical resection of involved lung and chemotherapy (not dissimilar to the approach to macrolide-resistant MAC lung disease). Unfortunately, with current antibiotic options, *M. abscessus* is a chronic incurable infection for most patients and, if disease is present, represents a contraindication for lung transplantation in those with advanced lung disease.

M. chelonae pulmonary and extrapulmonary disease presents in a similar fashion to *M. abscessus* but should be differentiated from *M. abscessus*/*M. chelonae* in the laboratory given the better response to antibiotics for *M. chelonae* than *M. abscessus*. This improved response to antibiotics is, in part, related to the lack of an active *erm* gene in *M. chelonae*.

M. marinum disease

M. marinum isolates are susceptible to rifampin, rifabutin, ethambutol, clarithromycin, sulfonamides, and trimethoprim sulfamethoxazole, intermediately susceptible to streptomycin, doxycycline and minocycline, and resistant to isoniazid and pyrazinamide.

For skin and soft-tissue infections due to *M. marinum* a reasonable approach is to treat with two active agents for 1 to 2 months after resolution of symptoms, typically 3 to 4 months in total. Some experts believe that minimal disease can be treated with a single agent. Excellent outcomes have also been reported for the combinations of clarithromycin and rifampin, clarithromycin and ethambutol, and the combination of ethambutol and rifampin. Clarithromycin and ethambutol are likely to provide the optimal balance of efficacy and tolerability for most patients, with the addition of rifampin in cases of osteomyelitis or other deep structure infection. Surgical debridement may also be indicated, especially for disease involving the closed spaces of the hand and for disease that has failed to respond to standard therapy.

Emerging areas of NTM infections

Increased numbers of published reports have highlighted several emerging areas of NTM infections over the past decade. These

newer and somewhat less common infections are worth noting and have linked growing numbers of individuals developing NTM infections to specific underlying disease conditions or specific home, work, or nosocomial environmental exposures, including CF, hypersensitivity pneumonitis-like lung disease (hot tub lung), and healthcare-associated NTM infections, respectively.

Cystic fibrosis-associated NTM disease

A recent cross-sectional assessment from multiple CF centers across the United States found that approximately 13% of all surveyed CF patients, and 40% over the age of 40, had NTM isolated from sputum. Similar to non-CF NTM pulmonary disease most NTM isolated were MAC (76%) or *M. abscessus* (18%). The explanation for this high prevalence of NTM in CF patients remains uncertain. Ambient exposure to NTM organisms from ubiquitous environmental water and soil sources coupled with abnormal host pulmonary factors such as altered mucociliary clearance and structural abnormalities accompanying advancing bronchiectasis may contribute to the development and phenotypic expression of NTM pulmonary disease commonly encountered in this group of patients. The diagnosis of NTM pulmonary disease in CF patients is similar to that of patients with non-CF NTM disease with the recognition that underlying bronchiectasis and other pathogens are present and may account for respiratory symptoms and radiographic abnormalities. The decision to treat NTM pulmonary infection in CF patients is complicated by a paucity of information about the effect of NTM infection on the natural history of CF, although CF patients with heavy *M. abscessus* growth from sputum appear to be at particular risk for more rapidly progressive disease and, in some instances, respiratory failure. Overall, treatment decisions require consideration of benefits weighed against risks and medication side effects for individual patients. Treatment regimens for CF patients with NTM lung disease are also similar to those for non-CF NTM pulmonary disease. CF patients on azithromycin for noninfective purposes should have surveillance for NTM in sputum prior to and during treatment with macrolides to avoid macrolide monotherapy in a patient with occult or undiagnosed NTM disease. The presence of active or untreated *M. abscessus* lung disease is a contraindication to listing for lung transplantation at many transplant centers in the United States. Recent reports of the transmissibility of *M. abscessus* species in two outpatient CF clinics is worth noting given the previous lack of human-to-human transmissibility of NTM lung disease.

Hypersensitivity pneumonitis-like NTM pulmonary disease

Several series of patients developing hypersensitivity pneumonitis-like lung disease following NTM exposure have been reported over the past decade. Most reports describe development of a typical pattern of hypersensitivity pneumonitis-like lung disease in association with hot tub exposure. Some investigators have used the term "hot tub lung" to describe this presentation. In the cases of exposure to hot tubs, MAC has been the mycobacterial organism isolated from sputum, bronchoalveolar lavage, tissue, and hot tub water. Furthermore, comparison of MAC isolates from the hot tub water and lung specimens when assessed by genotyping methods has demonstrated identical matches. Controversy still exists, however, as to whether hot tub lung is an infectious process, inflammatory process, or a combination of processes.

Hypersensitivity pneumonitis-like lung disease patients tend to be young and without preexisting lung disease. The clinical presentation varies widely from mild respiratory symptoms to respiratory failure requiring mechanical ventilatory support. Key elements to the diagnosis of MAC hypersensitivity-like lung include a compatible clinical history (subacute onset of respiratory symptoms, hot tub exposure), characteristic radiographic findings, and MAC isolates in sputum, bronchoalveolar lavage, tissue, and hot tub water (and compatible histopathology when available).

Patient prognosis is generally excellent independent of severity on presentation. The most benefit is gained by simply removing the patient from antigen exposure. In the case of hot tub lung, removal from antigen exposure generally involves drainage of hot tub water and complete avoidance of hot tub use. Whether continued exposure to ambient environmental MAC organisms can propagate the hypersensitivity pulmonary reaction is uncertain. For select patients with hypersensitivity pneumonitis-like lung disease, use of systemic corticosteroids may be of benefit and hasten recovery of pulmonary symptoms, gas exchange abnormalities, and radiographic abnormalities. Likewise, antimycobacterial therapy with the same medications as standard pulmonary MAC lung disease may be required in some patients but with shorter durations of therapy, usually 3 to 6 months. Most patients can be expected to have complete or near complete resolution of respiratory symptoms as well as pulmonary function and radiographic abnormalities.

Healthcare-associated NTM disease

Transmission of NTM disease in the healthcare setting has most frequently been linked to tap (municipal) water exposure. While various NTM species (including MAC, *M. kansasii*, *M. xenopi*, and *M. simiae*) have been isolated from municipal water supplies, *M. fortuitum* and *M. abscessus* have most often been implicated in healthcare-associated NTM disease. Even with use of potent disinfectants, including organomercurials, chlorine, bromine, 2% formaldehyde, and glutaraldehyde, after tap water exposure, NTM organisms may persist on equipment or devices. The inability to eliminate these organisms underscores the importance of avoidance of tap water for preventing healthcare-associated NTM disease. Examples of healthcare-associated NTM infections include infections involving median sternotomy, plastic surgery procedures, liposuction, laser-assisted in situ keratomileusis (LASIK), dialysis-related outbreaks, long-term central intravenous catheters, tympanostomy tubes, and prosthetic devices such as heart valves, knee and hip joints, lens implants, and metal rod bone stabilizers. Pseudo-outbreaks have involved bronchoscopes contaminated with *M. abscessus* and *Mycobacterium immunogenum*. Documented outbreaks of hygiene-associated *M. fortuitum* and *Mycobacterium mageritense* furunculosis in association with use of contaminated whirlpool footbaths have been described in nail salons.

As a result of the increased understanding of environmental NTM reservoirs and reports linking the use of tap water to healthcare-associated NTM infections it is recommended that tap water not be used in preparation of surgical procedures, prosthetics, and intravascular catheters; not used in cleaning of fiberoptic endoscopes; and not be used to rinse the mouth out prior to collecting expectorated sputum samples. Moreover, recognition that alternative medicines or unapproved substances for injection may also be at risk of contamination by NTM warrants caution against use of these products as well. Reports of transmissibility of *M. abscessus* in CF clinics as referenced above underscores the need for respiratory isolation and adherence to standard infection control principles.

Vibrios

Duc J. Vugia

Vibrios are motile, rod-shaped, facultative-anaerobic, gram-negative bacteria that can cause gastroenteritis, wound infection, and septicemia in humans. They are naturally found in marine, estuarine, and brackish waters in the United States and in other parts of the world. In the United States, they are recovered from the environment most commonly in summer and fall, when the water is warmer. *Vibrio* has also been isolated from a variety of fish and shellfish, including oysters, clams, mussels, crabs, and shrimp. Human cases of illness associated with *Vibrio* infection occur mostly in summer and fall and usually follow ingestion of raw or undercooked shellfish, particularly oysters, or exposure of a wound to fish, shellfish, or seawater. In countries with endemic or epidemic cholera, infection may occur after ingestion of any contaminated food or water; in the United States, cholera is endemic along the Gulf Coast.

Of more than 100 *Vibrio* species identified, about a dozen have caused human illnesses or been isolated from clinical specimens. The major clinical presentations associated with more commonly reported species are shown in Table 157.1. *Vibrio* spp. have been isolated more frequently from stool, wound, or blood, and less frequently from bone, cerebrospinal fluid, gallbladder, sputum, and urine.

Gastroenteritis and cholera

Clinical presentation

Gastroenteritis is the most common clinical presentation of infection with most pathogenic vibrios. The disease ranges in severity from mild, self-limited diarrhea to frank, life-threatening cholera.

Cholera is a profuse, watery diarrhea mediated via an enterotoxin produced by epidemic strains of *V. cholerae* O1 and O139. After attachment of toxigenic vibrios to intestinal epithelial cells, the cholera toxin, consisting of one A (activation) subunit and five B (binding) subunits, is generated. It stimulates intracellular cyclic adenosine monophosphate (AMP), resulting in a secretory diarrhea. Other symptoms include nausea, vomiting, abdominal cramps, and muscle cramps of extremities; fever is typically not seen because the disease is toxin-mediated and there is no invasion of the intestinal epithelium. Illness develops 4 hours to 5 days after ingestion of the bacteria and can rapidly lead to severe dehydration, electrolyte imbalance, metabolic acidosis, and death. Cholera usually lasts <7 days even without antibiotic therapy.

Gastroenteritis due to *V. cholerae* non-O1, non-O139 and other *Vibrio* species may also be mediated via an enterotoxin, but the diarrhea is usually not so severe. However, bloody stool, low-grade fever, and elevated white blood cell count may be noted along with nausea, vomiting, and abdominal cramps. The median incubation period is 1 day, ranging from 4 hours to 5 days, and the duration of illness is typically less than 7 days, ranging from 1 to 15 days.

TABLE 157.1 **COMMONLY REPORTED *VIBRIO* SPECIES AND ASSOCIATED MAJOR CLINICAL PRESENTATIONS**

	Clinical presentations		
Species	**Gastroenteritis**	**Wound infection**	**Septicemia**
V. cholerae[a]			
O1	++	+	+
O139	++		+
non-O1, non-O139	++	+	+
V. parahaemolyticus	++	++	+
V. vulnificus	+	++	++
V. alginolyticus[b]	+	++	+
V. fluvialis	++	+	+
V. furnissii	+		+
V. mimicus	++	+	+

++, Common; +, rare.
[a] Only toxigenic *V. cholerae* O1 or O139 causes cholera.
[b] Ear infection is common with *V. alginolyticus*.

Therapy

For cholera, prompt replacement of fluid volume and electrolytes with an appropriate intravenous (IV) or oral solution is critical. If the patient has severe dehydration (loss of at least 10% of body weight) or cannot drink, IV fluid replacement with Ringer's lactate is recommended. Normal saline does not contain appropriate electrolytes to correct metabolic acidosis and is therefore not recommended. If the patient can drink, a solution containing glucose and adequate electrolyte replacement is recommended, such as those prepared with the oral rehydration salts (ORS) endorsed by the World Health Organization or commercially available ORS/electrolyte replacement solutions.

Treatment of cholera with antimicrobials is secondary to fluid and electrolyte replacement and recommended for patients with moderate to severe cholera. Appropriate antibiotics can decrease volume and duration of diarrhea and shedding of vibrios. Multidrug-resistant strains of *V. cholerae* O1 have been documented in Asia and Africa, and antibiotic susceptibility testing should be performed on isolates from cholera patients to inform drug choices. For most settings, a single dose of doxycycline, 300 mg orally for adults, including pregnant women, and children 12 years and older, or 2–4 mg/kg orally for children <12 years old, is the drug of choice. Alternatively, a single dose of azithromycin or ciprofloxacin, 1 g orally for adults, including pregnant women, or 20 mg/kg up to a maximum of 1 g orally for children can also be used. Of note, quinolone-resistant strains of *V. cholerae* have been reported in South Asia. As quinolones and macrolides are used more commonly, resistance to these classes of antibiotic may increase, and, therefore, cholera patients treated with any antibiotic should have their isolates tested for susceptibility and the patients should be closely followed for appropriate clinical response.

For severe or prolonged gastroenteritis due to other vibrios, fluid and electrolyte replacement along with quinolone or doxycycline treatment is in order. However, mild or moderate gastroenteritis is usually self-limited and may not need therapy other than oral rehydration.

Extraintestinal infections

Clinical presentations

For extraintestinal sites, wound infection and septicemia are the most common clinical presentations. Wound infection with vibrios occurs after exposure of a break in skin to seawater or after a skin injury from handling fish or shellfish. Wound infection may be mild and self-limited or severe and invasive. Septicemia, which may be primary following ingestion of raw shellfish or secondary following wound infection, indicates severe disease.

Among vibrios causing extraintestinal infections, *V. vulnificus* frequently causes two important clinical syndromes: primary septicemia and wound infections. Primary septicemia occurs predominantly in adults with liver disease, including cirrhosis and hemochromatosis; alcoholism; other chronic underlying diseases, including renal failure and diabetes; or with immune suppression, including cancer and HIV infection. In these susceptible persons, septicemia usually follows ingestion of raw shellfish, typically raw oysters. Between 7 and 48 hours after eating shellfish containing *V. vulnificus*, infected patients present with fever, chills, nausea, vomiting, abdominal pain, diarrhea, mental status changes, suggestive skin lesions (including bullae, cellulitis, and ecchymoses), and often hypotension or shock. Mortality for patients with *V. vulnificus* primary septicemia is >50%, and it increases with hypotension within 12 hours of hospitalization or when appropriate antibiotic therapy is delayed.

V. vulnificus wound infection, however, results from injury to the skin from handling fish or shellfish or exposure of a fresh wound to seawater. Any healthy person may acquire this infection, but persons with the underlying diseases listed previously are at higher risk for severe skin and soft tissue infection, secondary septicemia, and death. Infected persons develop inflammation of the wound, fever, and chills 4 hours to 4 days after exposure. Wound infections range from mild cellulitis to severe necrotizing fasciitis and myositis requiring extensive debridement or amputation. Secondary disseminated skin lesions such as bullae may be due to secondary septicemia (Figure 157.1). The case fatality rate for *V. vulnificus* necrotizing fasciitis increases when surgical intervention is later than 24 hours after admission or when effective antibiotics are not used.

Therapy

For invasive *Vibrio* diseases, prompt treatment with early antibiotic administration, aggressive wound management, and supportive care are crucial. For invasive *V. vulnificus*, doxycycline (100 mg IV q12h) combined with a third-generation cephalosporin (e.g., ceftazidime 2 g IV q8h) should be given without delay. Alternatively, a fluoroquinolone (e.g., ciprofloxacin) can also be used in combination with a third-generation cephalosporin. The duration of treatment should be individualized to the presentation and clinical course but should

FIGURE 157.1 (A) Characteristic skin lesions associated with *Vibrio vulnificus* infection on the leg of a 75-year-old patient with liver cirrhosis in whom septic shock and bacteremia developed. (B) *Vibrio vulnificus* bacteremia developed 1 day after a fish bone injury on the fourth finger of the left hand (*arrow*) in a 45-year-old patient with uremia. (C) Gram-negative curved bacilli isolated from a blood sample of the 45-year-old patient with uremia.
From Hsueh et al. *Vibrio vulnificus* in Taiwan. *Emerg Infect Dis*. 2004;10(8):1363–1368.

be considered for at least 7 to 14 days. Necrotic tissue should be surgically debrided within 24 hours of admission and, occasionally, amputation of an affected limb may be necessary.

Laboratory diagnosis

For a patient with a gastrointestinal or cholera-like illness thought to be caused by *Vibrio*, testing of stool specimens with a culture-independent diagnostic test (CIDT, e.g., polymerase chain reaction) or culture using thiosulfate-citrate-bile salts-sucrose agar should detect the causative pathogen. Ideally, stool specimens for culture should be collected before treatment with antimicrobials.

Selective culture media are not necessary for extra-intestinal infections because common media used to culture blood and wounds contain at least 0.5% sodium chloride, which is adequate to grow halophilic (salt-loving) *Vibrio* spp.

For cholera patients already treated with antimicrobials and whose stool culture was either negative or not processed for vibrios, *V. cholerae* vibriocidal or antitoxin antibodies can be detected by serologic assays.

Prevention

Most *Vibrio* gastroenteritis, cholera, and primary *V. vulnificus* septicemia can be prevented. For prevention of cholera, travelers should be informed on whether cholera is endemic in the country or region being visited and should take appropriate precautions with all foods and drinks. In general, well-cooked foods and hot or carbonated drinks are safe. Additionally, lyophilized CVD 103-HgR, a live attenuated oral cholera vaccine (Vaxchora, PaxVax, Redwood City, California), is recommended for adults aged 18 to 64 years who travel to an area with active cholera transmission. In the United States, *Vibrio* gastroenteritis can be prevented by avoiding consumption of raw or undercooked shellfish. Patients with underlying liver and other chronic diseases or with immunosuppression, which puts them at increased risk of *V. vulnificus* septicemia, should avoid raw unprocessed oysters and other raw shellfish.

Wound infections may be difficult to prevent because vibrios exist naturally in the marine water environment. Persons with underlying conditions predisposing them to severe vibriosis should limit their exposure to seawater. For clinicians, a history of exposure to seawater, fish, or shellfish in a patient with an infected wound should raise clinical suspicion and prompt consideration of treatment for possible infection with a *Vibrio*.

Yersinia

Royce H. Johnson and Arash Heidari

Introduction

The genus *Yersinia* consists of 17 species, only 3 of which are consistently pathogenic for humans. These are *Y. pestis*, the agent of plague and *Y. enterocolitica* and *Y. pseudotuberculosis*, which are usually, but not entirely, gastrointestinal pathogens.

Yersinia pestis

An ongoing result of the unfortunate events of September 11, 2001, has been an increase in research on *Yersinia*, particularly, *Y. pestis*. This is an ancient organism, and, since its divergence from *Y. pseudotuberculosis* 1,500 to 20,000 years ago, it has largely existed as a rodent pathogen with only occasional human transmission. Three well-described pandemics of plague have occurred. The last of these began in the nineteenth century. Alexandre Yersin first isolated *Y. pestis* in 1894. The twentieth century saw major outbreaks in Vietnam and India. Between 2010 and 2015, 3,248 cases were reported with 584 deaths. The majority of cases currently are seen in sub-Saharan Africa, particularly Madagascar.

The majority of cases seen in the United States are from New Mexico, Arizona, Colorado, California, and Oregon. Climate change may well affect the bacteria, the vector, and the hosts, resulting in potential changes in the frequency and distribution of disease. In 2015, 16 cases were reported.

There has been remarkable progress in understanding the pathogenesis of *Yersinia* infections, particularly those caused by *Y. pestis*. A partial list of these advances include the effects of *Y. pestis* on flea behavior and its avoidance of both innate and adaptive (both humeral and cellular) immune response.

Natural infection occurs most commonly through the bite of an infected flea. The majority of these patients present with febrile lymphadenitis or bubonic plague. The incubation period is typically 2 to 6 days. Inguinal and femoral nodes are most frequently involved. Axillary and cervical presentations are less common. Inhalation of respiratory droplets from infected humans or animals, especially cats, may result in primary pneumonic plague. Pneumonic plague may also result from aerosols of bioterrorism agents. The ingestion of infected meat may result in pharyngitis and disseminated infection. Systemic disease without lymphadenitis may present as gram-negative sepsis, often with gastrointestinal symptoms. This usually results from an infected flea bite that does not produce a discernible bubo. A careful epidemiologic history is essential in the evaluation of patients with lymphadenitis, sepsis, or pneumonia.

All suspected *Y. pestis* infections must be reported to public health authorities. Specimens and cultures from suspected *Y. pestis* must be handled with *extreme caution* and in accordance with state and federal law. In the United States *Y. pestis* is a federal select category A agent.

Smear and culture of lymph node aspirate, sputum, cerebrospinal fluid, buffy coat, and blood should be undertaken expeditiously as dictated by clinical presentation. Gram stain and Wright Giemsa or the preferred Wayson stain should be prepared. The latter, if positive, will reveal the classic safety pin morphology that in the appropriate clinical setting is virtually diagnostic.

Y. pestis is easily propagated on normal laboratory media aerobically or anaerobically. Identification can be undertaken by the technology available in most modern hospital microbiology laboratories. Difficulty with identification has occurred. If cultures are negative, a passive hemagglutination serology performed at the US Centers for Disease Control and Prevention (CDC) can be utilized. All suspected specimens and isolates should be referred to an appropriate public health laboratory. The Insitut Pasteur developed a rapid diagnostic test using immunochromatography of specific F1 antigen in Madagascar.

Most isolates of *Y. pestis* have predictable sensitivity, and there is not a trend to increasing antimicrobial resistance. Naturally resistant isolates have been identified. There is also the likelihood that bioterrorism constructs of *Y. pestis* would be resistant to many antimicrobials. According to a recent publication by the CDC, Etest is equivalent to the reference broth dilution, and disk diffusion testing is not recommended. Rapid susceptibility methods are on the horizon.

Therapy

Streptomycin has been used as therapy since the 1940s. Its availability may be an issue. Gentamicin has been used successfully as an alternative (see Table 158.1).

TABLE 158.1 **THERAPY OF *YERSINIA PESTIS***

Preferred antibiotic	Classification for use
Streptomycin 1g q12h IM, may be given IV if necessary (some authorities would double the dose on the first day)	Availability an issue Call Pfizer Monitor renal, vestibular, and otic toxicity
Gentamicin 5–7 mg/kg/d Given as 2–3 doses IV	Monitor renal, vestibular, and otic toxicity Monitor blood levels and adjust for renal function
Ciprofloxacin 400 mg q8h IV 500 mg q12h PO	Not approved for pediatric use <16 yr
Levofloxacin 750 mg daily IV or PO	Not approved for pediatric use <16 yr
Moxifloxacin 400 mg daily IV or PO	Not approved for pediatric use <16 yr May be preferred in renal failure over other fluoroquinolones
Doxycycline 100 mg q12h IV or PO Some authorities would double the dose on the first day	Not approved for pediatrics ≤8 yr or in pregnancy
Chloramphenicol 25–30 mg/kg loading dose; reduction to 15 mg/kg q6h as patient improves	Predominantly for patients with meningitis and children. Meropenem may be an alternative in meningitis

There has been significant success with the use of tetracyclines in therapy of *Y. pestis*. In recent years doxycycline has been the tetracycline of choice. A randomized trial comparing gentamicin and doxycycline was conducted in Tanzania. The results were equivalent with <5% deaths.

A murine bubonic plague model demonstrated that ciprofloxacin was as effective as ciprofloxacin plus gentamicin and possibly more effective than gentamicin monotherapy. A recent in vitro pharmacodynamic model evaluated ciprofloxacin, moxifloxacin, gentamicin, ampicillin, and meropenem against streptomycin. All of the drugs out performed streptomycin. There are countervailing in vitro data that streptomycin and ciprofloxacin may be more active against both extracellular and intracellular organisms than either gentamicin or doxycycline. There are mouse data suggesting that levofloxacin-resistant organisms are significantly less fit than streptomycin-resistant organisms. Typical antibiotic courses are 7 to 10 days. Meningitis may require longer therapy.

Yersinia enterocolitica and *Y. pseudotuberculosis*

Y. enterocolitica and *Y. pseudotuberculosis* are most frequently associated with enterocolitis. Infection with *Y. enterocolitica* occurs much more often than with *Y. pseudotuberculosis*.

Y. enterocolitica is an important cause of enterocolitis worldwide, especially in colder climates and winter months. This is distinctly different from most enteropathogenic organisms. Most current data from the CDC estimate that *Y. enterocolitica* causes >117,000 illnesses with 35 deaths in the United States annually. Food, particularly pork, contaminated milk, and untreated water. have long been recognized as sources of infection. Serogroup O:3 is responsible for the majority of disease in the United States. The incubation period is 1 to 14 days, typically at the shorter end of this spectrum. Immunocompromised individuals, those with iron overload or treated with iron-chelating agents, and those with alkalinization of the stomach are at increased risk. Children have a greater risk when compared to adults.

The most common presentation is enteritis or enterocolitis, not unlike shigellosis. Typical symptoms include diarrhea, occasionally bloody, fever, abdominal pain, and vomiting. *Y. pseudotuberculosis* and *Y. enterocolitica* can present with abdominal pain that mimics appendicitis. Careful abdominal imaging with ultrasound or CT can usually distinguish *Yersinia*-induced mesenteric lymphadenitis from appendicitis. *Y. enterocolitica* can cause suppurative infection, including pharyngitis, pneumonia, empyema, hepatic abscess, lymphadenitis, and genitourinary and musculoskeletal infections. Sepsis, endocarditis, pericarditis, and myocarditis have all been reported. Rare cutaneous infections have also been reported.

Y. enterocolitica and *Y. pseudotuberculosis* have both been implicated in immunopathologic disease, including erythema nodosum, uveitis, and reactive arthritis. There may be a link to

TABLE 158.2 **THERAPY FOR *YERSINIA ENTEROCOLITICA***

Preferred antibiotic for serious infections	Classification of use
Ceftriaxone	
2 g in adults or 100 mg/kg/d for children	
Or	
Ciprofloxacin	Not approved for pediatrics ≤16 yr
400 mg q8h if susceptibility is shown	
Plus	
Gentamicin 5–7 mg/kg	
Given in 2–3 IV doses	
Other agents likely to be effective:	
Trimethoprim–sulfamethoxazole	
10 mg/50 mg/kg/d IV as 2 doses	
Doxycycline 100 mg q12h IV	Not approved for pediatrics ≤8 yr

inflammatory bowel disease. A role for *Y. pseudotuberculosis* in Kawasaki disease has been suggested.

Diagnosis of active infection is primarily by culture. Isolation from blood and sterile sites should not prove challenging in untreated patients. Culture of stool and other contaminated sites is more difficult. Cold enrichment and selective media may be helpful, but this usually requires specific discussion with the microbiology laboratory.

Therapy

Therapy is usually not required for *Y. enterocolitica* and *Y. pseudotuberculosis* gastroenteritis or mesenteric lymphadenitis in immunocompetent hosts (see Tables 158.2 and 158.3). Extraintestinal disease, particularly sepsis, requires antimicrobial therapy. Sepsis with either of the two species has a high mortality.

Y. enterocolitica often produce β-lactamases, thus precluding the use of penicillin and many cephalosporins. Most *Yersinia* strains are resistant to macrolides. Resistance to fluoroquinolones has been reported in Spain.

TABLE 158.3 **THERAPY FOR *YERSINIA PSEUDOTUBERCULOSIS***

Preferred antibiotic for serious infections (sepsis)	Classification of use
Ampicillin	
2 g q4h IV (200 mg/kg)	
Plus gentamicin	
5–7 mg/kg/d in 2–3 doses	
Alternative agent Doxycycline 100 mg q12h IV	Not approved for pediatric use ≤8 yr

Miscellaneous gram-positive organisms

Iqra Choudary, Steven K. Schmitt, and Roberto Baun Corales

Pediococcus species

Pediococci are gram-positive cocci that grow in pairs and tetrads and belong to the lactic acid bacteria group. Normal inhabitants of the gastrointestinal tract, they are used extensively in industry to ferment cheese and other dairy products, soy products, and alcoholic beverages. Thirteen species of pediococci are recognized today, but only *Pediococcus acidilactici* and *Pediococcus pentosaceus*, typically found in sugar-rich foods, have been identified as human pathogens. In recent years, these organisms have been increasingly recognized as a cause of bacteremia, endocarditis, and pneumonitis in the immunocompromised host. These organisms have also been isolated from intra-abdominal infections such as peritonitis and hepatic abscesses. Risk factors for *Pediococcus* infections include prior antibiotic therapy, abdominal surgery, and gastric feeding.

Diagnosis is made by isolation and identification of the organism from cultures of blood or other body fluids. *Pediococcus* species may be difficult to distinguish from enterococci and *Leuconostoc* species given its association with food. Approximately 95% of clinical isolates will cross-react with group D streptococcal antisera. Tests that aid in distinguishing pediococci from other organisms include a negative pyrrolidonyl arylamidase (PYRase) test and the absence of gas production from glucose. With newer application of molecular genetic techniques to determine relatedness of food-associated lactic acid bacteria, reorganization of the genus with novel morphologic or phenotypic differentiation of *Leuconostoc* species from *Pediococcus* species is being studied.

Pediococci are intrinsically highly resistant to vancomycin and other glycopeptides. Most strains are moderately susceptible to penicillin and ampicillin. Minimum inhibitory concentrations (MICs) are variable for cephalosporins. Imipenem appears active against all isolates, as does gentamicin. In vitro susceptibility to linezolid and daptomycin has been demonstrated. There have also been case reports of daptomycin being successfully used to treat pediococcocal endocarditis. Resistance to quinupristin–dalfopristin, erythromycin, clindamycin, tetracycline, tobramycin, and amikacin has been described. If a serious *Pediococcus* infection is suspected (e.g., on the basis of the characteristic tetrad morphology on Gram stain), intravenous penicillin at a dosage of 12 million or more units daily or imipenem may be used as empiric therapy. Susceptibility testing, preferably by MIC rather than disk diffusion, should be performed to determine appropriate therapy (Table 159.1).

Leuconostoc species

Leuconostoc species are catalase-negative, gram-positive coccobacilli that have been increasingly recognized as human pathogens over the last decade. These organisms are normally found in dairy products and vegetable matter and are used in the production of wine, dairy products, and dextrans. *Leuconostoc* species are not considered part of the normal human flora, but they have been isolated from the feces, vagina, and gastric fluid, primarily in hospitalized patients. Immunocompromised patients and those treated with vancomycin, to which leuconostocs are intrinsically resistant, may have gastrointestinal colonization with these organisms.

TABLE 159.1 **RECOMMENDED DRUG OF CHOICE FOR THE MISCELLANEOUS GRAM-POSITIVE ORGANISMS**

Organism	Antibiotic (Ab) (alternative Ab)	Route	Dosage	Duration
Pediococcus	Penicillin G Imipenem (Cephalosporins) (Linezolid)	IV	12 million U	(10–14 d)[a]
Leuconostoc	Penicillin G Ampicillin (Clindamycin) (Erythromycin) (Daptomycin)	IV	≥12 million U	(10–14 d)[a] 4 to 6 wk for endocarditis
Lactobacillus	Penicillin G Penicillin G and gentamicin (Clindamycin) (Erythromycin) (Linezolid)	IV IV IV	12million U daily 20–24 million U daily for endocarditis 1.0 mg/kg q8h	(10–14 d)[a] 6 wk
Oerskovia	Penicillin G, TMP–SMX (Vancomycin)	IV	(Moderate to high dosage)[a]	4–6 wk for endocarditis
Rothia	Penicillin G, (Vancomycin) (Cephalosporins) (Fluoroquinolones)	IV	20 million U daily for endocarditis	6 wk
Arcanobacterium	Erythromycin Penicillin V Penicillin G ± aminoglycosides (Clindamycin) (Tetracycline) (Linezolid)	PO/IV PO IV	40mg/kg (4 divided doses) 250–500 mg QID 2 million U q4h (for endocarditis)	10d Until clinical response 4–6 wk
Rhodococcus	Vancomycin (V) or imipenem plus rifampin (AIDS) or erythromycin (Sulfonamides) (Chloramphenicol) (Linezolid)	IV IV PO IV/PO	1 g q12h 500 mg q6h 600 mg/d 500 mg–1 g QID	2 wk 2–4 wk
Abiotrophia *Granulicatella* *Gemella*	Ampicillin or penicillin + gentamicin			

[a] Suggested by some authorities.
Abbreviations: TMP–SMX = trimethoprim–sulfamethoxazole; AIDS = acquired immunodeficiency syndrome.

Leuconostoc species may cause bacteremia in otherwise healthy neonates. At least four *Leuconostoc* species (including *Leuconostoc mesenteroides, Leuconostoc paramesenteroides, Leuconostoc cremoris*, and *Leuconostoc citreum*) may cause human infections. Risk factors for *Leuconostoc* infection include lengthy hospitalization requiring tracheostomy or parenteral nutrition, intravascular catheters, prior antibiotic therapy, prematurity, short gut syndrome, and serious underlying disease. *Leuconostoc* infections have been associated with pancreatitis, necrotizing enterocolitis, meningitis, and chylothorax to name a few.

Diagnosis is based on identification of the organism from cultures of blood or other sterile body fluids. On Gram stain the organisms appear as pairs or chains of slightly elongated gram-positive cocci that may appear rod-like. They may be difficult to distinguish from viridans streptococci, enterococci, lactobacilli, or pediococci. Helpful tests include the production of gas from glucose; a negative catalase, oxidase, and PYRase test; and the absence of arginine hydrolysis.

Leuconostoc isolates, like pediococci, are uniformly resistant to vancomycin and other glycopeptides. Most strains are susceptible

to penicillin, clindamycin, and gentamicin. Susceptibility to the cephalosporins, quinolones, and trimethoprim–sulfamethoxazole (TMP–SMX) is variable. Daptomycin and linezolid show activity against *Leuconostoc* spp. Resistance to quinupristin/dalfopristin has been demonstrated. Penicillin, the drug of choice, should be given at relatively high dosages (≥12 million units daily). In the case of penicillin allergy or resistance, therapy should be based on results of susceptibility testing. Appropriate therapy may also include removal of potentially infected devices such as indwelling intravascular catheters.

Lactobacillus species

Lactobacillus species are gram-positive rods that normally inhabit the human mouth, vagina, and gastrointestinal tract. More than 50 species of lactobacilli are recognized, many of which are used in the production of cheese, yogurt, pickles, and fermented beverages. Lactobacilli are widely considered to have low pathogenicity, and over the last decade have been used as probiotic factors (e.g., immunomodulation, microbe–microbe interactions, epithelial barrier protection), as part of prevention and treatment protocols for post-antibiotic enteric infections, vehicles for oral immunization, and as part of treatment policies called *ecoimmunonutrition*. Nevertheless, they have been reported to cause infections, including bacteremia, endocarditis, intra-abdominal and hepatic abscesses, meningitis, and pneumonia. Risk factors for serious infections caused by *Lactobacillus* species include underlying immunocompromised state (including human immunodeficiency virus [HIV] disease) and gastrointestinal surgery. Prior antibiotic therapy, particularly with vancomycin (to which most lactobacilli are resistant), has also been identified as a clinical risk factor. In patients with *Lactobacillus* bacteremia and endocarditis, cancer, recent surgery, and diabetes mellitus were identified as underlying risk factors. Additional history of dental infection or manipulation is common.

Diagnosis is based on identification of the organism from sterile body fluids. Lactobacilli are gram-positive rods, but they may appear coccoid if grown on solid media. Cultures grown in broth are more reliable for assessing morphology. Some *Lactobacillus* isolates may be difficult to distinguish from *Leuconostoc* species and streptococci. The combination of tests for gas production from glucose, arginine hydrolysis, PYRase, and carbohydrate fermentations should allow proper identification.

Intravenous penicillin (≥12 million units daily) is generally the drug of choice for serious infections. Endocarditis should be treated with penicillin 20 million to 24 million units daily plus gentamicin for 6 weeks. Lactobacilli are usually resistant to glycopeptides such as vancomycin. Susceptibility to cephalosporins and quinolones is variable, and most isolates are resistant to tetracycline and TMP–SMX. Most strains are susceptible in vitro to clindamycin, a possible alternative therapy in penicillin-allergic patients, but few clinical data are available. Lactobacilli are usually susceptible in vitro to linezolid but may be resistant to daptomycin and quinupristin–dalfopristin. Because of variable activity, susceptibility testing is critical in developing a treatment regimen. In the patient allergic to β-lactams who has endocarditis, penicillin desensitization should be considered.

Oerskovia and *cellulosimicrobium* species

Oerskovia species are yellow, gram-positive, non-acid-fast organisms with extensively branched filaments. They were first described by Orskov in 1938 as "motile *Nocardia*." Their usual habitat is soil, although they have also been isolated from decaying plant materials and grass cuttings. Two species of *Oerskovia* were originally recognized: *Oerskovia turbata* and *Oerskovia xanthineolytica*. Recently, *O. xanthineolytica* has been reclassified as *Cellulosimicrobium cellulans*, and *O. turbata* has been proposed for reclassification as a novel *Cellulosimicrobium* species. Both are rare causes of opportunistic infection in humans but should be considered as potential pathogens of low virulence, especially in the setting of indwelling devices. Reported infections caused by *Oerskovia* and *Cellulosimicrobium* species include native and prosthetic valve endocarditis, peritonitis, central venous catheter infections, bacteremia in immunocompromised hosts (including patients with acquired immunodeficiency syndrome [AIDS]), acalculus cholecystitis, prosthetic joint infection, keratitis, and endophthalmitis due to a penetrating eye injury. Several reported cases have been associated with exposure to soil, marine sediment, and bacterial contamination of hydrophilic contact lens solutions.

The diagnosis of *Oerskovia* and *Cellulosimicrobium* infections rests on laboratory identification from clinical specimens. Gram stain may reveal pleomorphic gram-positive nonmotile rods that can be mistaken for *Corynebacterium* spp. Culture reveals yellow colonies that are catalase positive when grown aerobically. They may be distinguished from other *Nocardia*-like organisms in that they are facultatively anaerobic and do not produce aerial mycelia. Identification is based on carbohydrate fermentation testing.

Successful treatment of *Oerskovia* infections requires removal of the contaminated foreign body in addition to appropriate antibiotic therapy, although some published cases report treatment without removal of infected vascular or peritoneal catheters. Antibiotics to which clinical isolates of *Oerskovia* and *Cellulosimicrobium* have been reported to be susceptible include penicillin (including extended-spectrum penicillins), vancomycin, TMP–SMX, cephalothin, and amikacin. Intermediate susceptibility or resistance has been described for ampicillin, ciprofloxacin, doxycycline, erythromycin, gentamicin, clindamycin, and the third-generation cephalosporins. Therapy should be based on susceptibility testing of the isolate. However, if culture results suggest *Oerskovia* infection, empiric parenteral penicillin or TMP–SMX therapy seems prudent while awaiting results of susceptibility testing.

Rothia species

Rothia dentocariosa is a small gram-positive pleomorphic rod belonging to the family Micrococcaceae. These organisms, common components of the normal oral microflora, were first isolated from carious dentine. The first description of human disease due to *Rothia* species was not reported until 1975, when the organism was recovered from a periappendiceal abscess. Over the last decade,

a number of case reports have described *Rothia* species as causing native and prosthetic valve endocarditis, aortic root abscess, neck abscess, peritonitis, septic arthritis, osteomyelitis, and pneumonia. The patient often has a history of recent dental infection or dental manipulation or is immunocompromised; however, a recent report includes identification in throat cultures of healthy individuals. *Rothia dentocariosa* has been isolated in lymph nodes of patients with cat scratch disease (CSD), suggesting a possible role, together with *Bartonella henselae*, in the pathogenesis of CSD. Another species of this genus (*Rothia mucilaginosa*, formerly known as *Stomatococcus mucilaginosus*) was found to be a member of the normal oral flora. This species has been described as opportunistic agents of infection in cases of endocarditis, meningitis, peritonitis, and other infections.

Diagnosis of *Rothia* infections depends on identification of the organism from the cultures of blood or other body fluids. *Rothia* species are catalase positive, nonmotile, urease negative, and indole negative. On Columbia chocolate horse blood agar, they appear to be gray and have a mucoid tendency after 48 hours of incubation. The organisms may appear branched, resembling *Actinomyces* or *Nocardia* species. They are distinguished from these genera by carbohydrate fermentation testing. *Rothia mucilaginosa* forms cocci in clusters and displays variable catalase reactions ranging from negative to weakly positive to strongly positive. The inability to grow in 5% NaCl distinguishes *R. mucilaginosa* from members of *Staphylococcus* and *Micrococcus* genera.

Penicillin is the drug of choice for treatment of infections due to *Rothia* spp. Because rare isolates may be resistant to penicillin, susceptibility testing should be performed. For endocarditis due to penicillin-susceptible strains, intravenous penicillin at dosages of 20 million units per day for 6 weeks is recommended. In the case of penicillin resistance or drug allergy, vancomycin, netilmicin, or teicoplanin therapy may be effective. *Rothia* species may also be susceptible in vitro to ciprofloxacin, rifampin, third-generation cephalosporins, vancomycin, chloramphenicol, and gentamicin. Resistance to amikacin, kanamycin, ciprofloxacin, and TMP–SMX has been described. In endocarditis cases due to *Rothia* spp., cardiac surgery may be beneficial when antimicrobial therapy alone is unsuccessful. Dental evaluation should also be considered in patients with infections due to *Rothia* species because carious or infected teeth may be a source of recurrent infection.

Arcanobacterium species

Arcanobacterium haemolyticum (formerly known as *Corynebacterium haemolyticum*) are facultatively anaerobic gram-positive to gram-variable pleomorphic rods (slender at first, sometimes clubbed, or in angular arrangements) that are nonmotile and nonsporulating. They are considered commensals of human nasopharynx and skin and are transmitted person to person by the droplet route. *Arcanobacterium* species have been recognized as causes of pharyngitis and cervical lymphadenopathy (indistinguishable from the pharyngitis caused by *Streptococcus pyogenes*) with additional symptoms of fever, pruritus, nonproductive cough, scarlatiniform skin rash with mild desquamation, and occasional formation of peritonsillar abscesses. Cutaneous infections, including ulcers, wound infection, cellulitis, and paronychia, are marked in some cases by the elaboration of lipid-hydrolyzing enzyme (sphingomyelinase D), producing dermonecrosis. Sepsis has been seen in immunocompromised states. Central nervous system (CNS) infections (brain abscess, cerebritis, meningitis), endocarditis, osteomyelitis, otitis media, sphenoidal sinusitis, empyema, and cavitary pneumonia have also been described.

Diagnosis is made by isolation and identification of the organism from cultures of blood, pharynx, skin lesions, or other clinical specimens (e.g., CNS abscess, cerebrospinal fluid [CSF], aortic valve, bone). Isolates of *Arcanobacterium* spp. are weakly acid fast, but this characteristic is typically not used for identification. On Loeffler's medium, the morphology closely resembles *Corynebacterium diphtheriae*. Tests that aid in diagnosis include fermentation of dextrose, lactose, and maltose but not mannitol or xylose. Colonies appear circular, discoid, opaque, and whitish, with a rough surface and friable consistency, a uniform feature at 48 hours of a black opaque dot at the center of each colony, and hemolysis at 24 to 48 hours incubation. Because *Arcanobacterium* species may present as part of polymicrobic infections with typical respiratory pathogens, they are often overlooked. Diagnosis often occurs only after repeated isolation. Increased awareness in microbiology laboratories of this organism may allow further elucidation of its pathogenicity in soft-tissue infections.

Most isolates of *A. haemolyticum* are susceptible to erythromycin, gentamicin, clindamycin, and third-generation cephalosporins. Newer studies report susceptibility to linezolid as well. They are resistant to sulfonamides and nalidixic acid in vitro. The drug of choice is erythromycin, 40 mg/kg orally or intravenously in four divided doses per day (2 g maximum). Although there have been reports of treatment failure with penicillin attributed to tolerance and failure to penetrate the intracellular location of the pathogen, penicillins with or without aminoglycosides are also widely used antibiotics, in most cases with success. In cases of abscess or tissue necrosis, surgical drainage or debridement may be a necesssary adjunct to antibiotic therapy.

Rhodococcus species

Rhodococcus equi (formerly known as *Corynebacterium equi*), zoonotic organisms readily found in soil contaminated with stool of grazing animals, particularly young horses, are nonfastidious, strict aerobic gram-positive bacteria displaying rod-to-coccus pleomorphism, with fragmenting and occasionally palisading forms. *Rhodococcus* are well-documented veterinary pathogens, causing granulomatous pneumonia in foals. They are opportunistic pathogens found in immunocompromised patients, including transplant patients and HIV-infected persons. Documented clinical presentations include slowly progressive granulomatous pneumonia with lobar infiltrates progressing to cavitating lesions on chest radiograph; abscesses of the central nervous system, pelvis, and subcutaneous tissue; and lymphadenitis. Vertebral osteomyelitis and pulmonary malakoplakia have also been reported. Recently, two cases of nosocomial *R. equi* infection have been associated with

ventriculoperitoneal shunts. Mortality exceeds 50% among AIDS patients with documented *R. equi* pneumonia, which is associated with a high rate of relapse despite adequate treatment. A newly described species of *Rhodococcus, Rhodococcus tsukamurella*, may cause multiple lung cavitary lesions in immunosuppressed patients and patients with indwelling foreign bodies.

Rhodococcus equi forms salmon pink colonies on blood agar from clinical specimens after 2 to 3 days of incubation. Colonies can be mucoid and coalescing; growth on Lowenstein–Jensen medium allows earlier detection of pigment. Synergistic hemolysis (resembling the CAMP test), displayed by cross-streaking on sheep blood agar with any of a number of other bacteria, including *A. haemolyticum, Staphylococcus aureus*, and *Corynebacterium pseudotuberculosis*, has been helpful in the diagnosis. In addition, *Rhodococcus* isolates are nonreactive to catalase, urease, and phosphatase and exhibit acid-fast staining. Some diagnostic laboratories use a commercial kit (API CORYNE strip; bioMerieux-Vitek, Hazelwood, MO) for identification. Prompt identification is necessary for optimal patient management.

Most strains are susceptible to inhibition by glycopeptide antibiotics, rifampin, and macrolides. Susceptibility to linezolid has been documented. Resistance to β-lactam antibiotics (except carbapenems) has been reported. The high relapse rate and attributable mortality rate, especially among AIDS patients, makes it difficult to recommend a standard treatment protocol. Repeat cultures are warranted during treatment to discover acquired resistance. A combination of at least two antibiotics parenterally (including a glycopeptide and rifampin) followed by oral maintenance therapy is recommended. Surgical wound resection has been performed in some cases, sometimes in combination with antimicrobial therapy. Antimicrobial prophylaxis may prove of benefit in AIDS patients. Recent data suggest treatment for *R. tsukamurella* infections to be a combination of β-lactam and aminoglycoside, along with removal of affected medical devices.

Abiotrophia and *granulicatella* species

First described in 1961 by Frenkel and Hirsch these were initially thought to be nutritionally variant streptococci (NVS). They are members of normal oral cavity flora and have been documented as agents of bacteremia and endocarditis in immunocompromised patients. They form gram-positive cocci in pairs and chains under optimal nutritional conditions (pyridoxal-supplemented media) but may display pleomorphic cellular morphology when growth conditions are suboptimal. Strains of these genera usually grow as small α-hemolytic colonies on chocolate agar but not on sheep blood agar unless the medium is supplemented or other bacteria are present to provide compounds needed for growth. Most strains exhibit positive PYR and LAP tests. They are susceptible to β-lactam agents, although elevated MICs for β-lactams have been observed for some strains. A combination of ampicillin and gentamicin is recommended for endovascular infections with these organisms.

Gemella species

This genus has recently grown to include a total of six species (*Gemella haemolysans, Gemella morbillorum, Gemella bergeriae*, *Gemella sanguinis, Gemella cuniculi*, and *Gemella palaticanis*). Most strains are PYR and LAP positive. They produce colonies on blood agar that resemble viridans streptococci. Although the cellular morphology of *G. morbillorum* resembles that of streptococci, *G. haemolysans* forms *Neisseria*-like diplococci that may also be arranged in tetrads and clusters and may appear to be gram variable. *Gemella haemolysans* is part of the normal flora of the oral cavity, *G. morbillorum* is part of the normal flora of the gastrointestinal tract, *G. cuniculi* has been reportedly isolated from rabbits, and *G. palaticanis* has been identified only in dogs but recently associated with a case of endocarditis in a child. *Gemella* strains have been isolated from cases of meningitis. It has been shown that these organisms are susceptible to vancomycin, penicillin G, and ampicillin. Synergy is seen between penicillin or vancomycin and gentamicin or streptomycin. Hence, penicillin and gentamicin are recommended for the treatment of *Gemella* endocarditis.

Helcococcus species

Helcococcus kunzii is currently the only species in this genus of PYR-positive, LAP-negative cluster-forming cocci that has been isolated from human clinical specimens. It forms small, nonhemolytic, slowly growing colonies on blood agar. This species has been described in recent reports as an agent of wound infection, bacteremia, and endocarditis. They are susceptible to vancomycin and β-lactam agents.

Lactococcus species

The genus *Lactococcus* was created to accommodate non-β-hemolytic Lancefield group N streptococci normally isolated from dairy products. Seven species have been currently recognized, with four subspecies. Members of this genus are homofermentators of lactic acid and resemble either streptococci or enterococci in terms of phenotypic traits and are infrequently isolated opportunistic pathogens. Though lactococci are commonly considered food-grade bacteria, they have been isolated from cases of endocarditis and a variety of other infections. They are susceptible to vancomycin and other β-lactam agents.

Globicatella species

The description of the species *Globicatella sanguinis* is α-hemolytic, PYR positive, LAP negative, and salt tolerant. They form cocci in chains. *Globicatella* spp. have been identified as a rare cause of shunt-associated meningitis and bacteremia. They are susceptible to vancomycin and β-lactam agents.

Aerococcus genus

This genus contains seven species. The most well-known species of this genus, *Aerococcus viridans*, forms clusters and though mostly associated with disease in lobsters, it has been noted as an infrequent cause of infection in compromised hosts. Another species, *Aerococcus urinae*, has been well documented as an agent of urinary tract infections and endocarditis in immunocompromised patients. Aerococci form α-hemolytic colonies on blood agar. *Aerococcus viridans* colonies are larger than those of *A. urinae*. These two species also differ in other phenotypic traits (*A. viridans* is PYR positive and LAP negative, whereas *A. urinae* is PYR negative and LAP positive). *Aerococcus urinae* is susceptible in vitro to a number of β-lactam agents and vancomycin; time-kill studies suggest a need for combination therapy, including an aminoglycoside for bactericidal therapy in endovascular infection.

Miscellaneous gram-negative organisms

Sampath Kumar and Kamaljit Singh

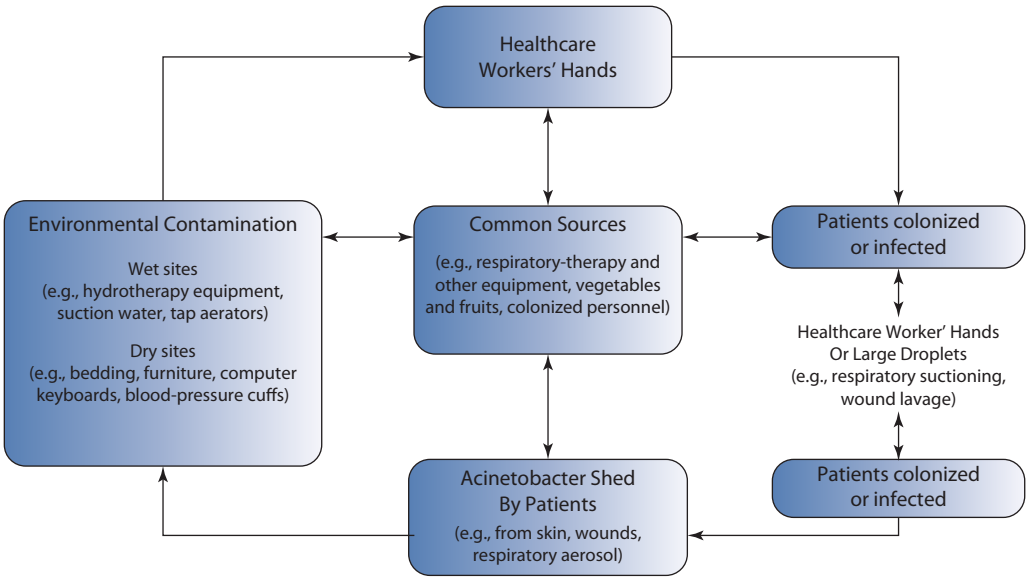
Most gram-negative infections are caused by organisms in the Enterobacteriaceae family or the *Pseudomonas* genus; however, a few are caused by a heterogeneous group of miscellaneous gram-negative organisms. These organisms do not fit conveniently into a single genera and have undergone frequent taxonomic changes, making understanding them even more difficult for clinicians. The clinical presentation varies widely, affecting different types of hosts and requiring a variety of antibiotics for therapy (Table 160.1). Varied predisposing environmental and host factors are outlined in Table 160.2.

Acinetobacter

Acinetobacter is a member of the family *Moraxellaceae*, with at least 25 genospecies. *A. calcoaceticus, A. lwoffii*, and *A. baumannii* are the species most commonly reported in the clinical literature. Because of problems with conventional methods for separating the *Acinetobacter* spp., the term "*A. calcoaceticus-baumannii* complex" is sometimes used. However, the use of matrix-assisted laser desorption ionization-time-of-flight mass spectrometry (MALDR-TOF MS) has allowed for rapid and accurate species identification that is superior to conventional methods. *Acinetobacter* spp. are nonmotile, oxidase-negative, gram-negative coccobacilli often appearing as diplococci and thus are easily confused with *Neisseria* or *Haemophilus* spp. They differ from the Enterobacteriaceae in that they do not grow anaerobically or reduce nitrates. They are distinguished from *Neisseria* and *Moraxella* by their negative oxidase reaction. Virulence factors include a polysaccharide capsule that may prevent phagocytosis and fimbriae that potentiate adherence to epithelial cells. Multidrug resistance among *Acinetobacter* spp has increased substantially over the past decade due in part to the organism's ability to accumulate multiple resistance genes carried on integrons or mobile genetic elements.

Epidemiology

Acinetobacter spp. are widely distributed in the environment, found in food, soil, water, and sewage. *Acinetobacter* spp. may be found on inanimate surfaces, including hospital equipment such as ventilator tubing, resuscitation bags, humidifiers, sinks, mist tents, dialysis baths, angiography catheters, pressure transducers, and plasma protein solutions. They are found on the skin of many animal species and humans, usually as commensal organisms. They are found as part of the normal oral flora and in the genitourinary and gastrointestinal tracts. The reservoirs, sources, and transmission patterns for *Acinetobacter* in healthcare facilities is outlined here.



Reservoirs, Sources, and Transmission Patterns for Acinetobacter in Healthcare Facilities

Weinstein RA, Silvia Munoz-Price, L Acinetobacter infection *N Eng J Med.* 2008;358:1271–81

Pathogenesis and clinical syndromes

A. baumannii is the most commonly found species in human clinical specimens followed by *A. lwoffii*. *Acinetobacter baumannii* is increasingly recognized as one of the most important causes of nosocomial infections and is of particular concern because of its propensity for multidrug resistance. Most infections due to *A. baumannii* are nosocomial, occurring in severely debilitated patients who have been exposed to broad-spectrum antibiotics in the intensive care unit, mechanical ventilators, and invasive devices (e.g., central venous catheters). In addition, *A. baumannii* is a cause of serious infections among military personnel returning from the Middle East, often with carbapenem-resistant strains of *A. baumannii,* and in victims of natural disasters. A wide variety of human infections due to *A. baumannii* have been reported, including ventilator-associated pneumonia, septicemia, endocarditis, meningitis, urinary tract infections, wound infections including necrotizing fasciitis, abscesses, peritonitis, osteomyelitis, and eye infections. Purulent pericarditis has been reported in

TABLE 160.1 **ANTIMICROBIAL THERAPY OF MISCELLANEOUS GRAM-NEGATIVE BACILLI**

Organism	First-line therapy	Alternative therapy
Acinetobacter	Ampicillin–sulbactam, piperacillin–tazobactam, imipenem–cilastatin, meropenem, ceftazidime, amikacin Minocycline Eravacycline	Fluoroquinolones, trimethoprim–sulfamethoxazole (TMP-SMX), tigecycline, colistin Phage therapy
Achromobacter	Imipenem-cilastatin, meropenem, tigecycline	Piperacillin–tazobactam, ceftazidime, TMP-SMX
Alcaligenes	Imipenem-cilastatin, meropenem, TMP-SMX	Amoxicillin–clavulanate, ceftazidime, piperacillin–tazobactam
Capnocytophaga canimorsus	Penicillin	Clindamycin, imipenem–cilastatin, ampicillin–sulbactam, amoxicillin–clavulanate
Pseudomonas oryzihabitans/luteola	Fluoroquinolones, ceftazidime, piperacillin-tazobactam	Imipenem–cilastin, meropenem, aztreonam, aminoglycosides, TMP-SMX
Chromobacterium	Imipenem-cilastin, ciprofloxacin, tigecycline	Tetracycline, TMP-SMX, gentamicin
Elizabethkingia meningoseptica	Vancomycin, rifampin, levofloxacin	Tigecycline, TMP-SMX
Ochrobactrum anthropi	Imipenem-cilastin	TMP-SMX, tetracyclines, aminoglycosides, fluoroquinolones

TABLE 160.2 **ENVIRONMENTAL AND HOST FACTORS PREDISPOSING TO INFECTIONS WITH MISCELLANEOUS GRAM-NEGATIVE BACILLI**

Organism	Environmental factors	Host factors	Infection
Acinetobacter	Ventilator tubing, resuscitation bags, humidifiers, sinks, mist tents, dialysis bags, angiography and IV catheters, pressure transducers, plasma protein solutions	Severely debilitated, recent surgery, instrumentation prior colonization prior β-lactam use prior fluoroquinolone use prior ICU stay ESRD on hemodialysis	Septicemia, endocarditis, meningitis, pneumonia, UTI, wound infections, abscesses, peritonitis, osteomyelitis, eye infections
Achromobacter	Contaminant in disinfectants, diagnostic tracer solution, IV CT contrast, hemodialysis solutions, ventilators, humidifiers, pressure transducers	Severely debilitated, recent neurosurgery	Community-acquired bacteremia, meningitis, chronic otitis media, hospital-acquired meningitis, bacteremia, ventriculitis, endocarditis, endophthalmitis, corneal ulcers, pharyngitis, pneumonia, wound infections, peritonitis, UTI, abscesses
Alcaligenes	Dairy products, rotten eggs, hospital equipment	Severely debilitated	Septicemia, native and prosthetic valve endocarditis, meningitis, meibomianitis, chronic purulent otitis, pyelonephritis, hepatitis, appendicitis, diarrhea
Capnocytophaga	Normal oral, gastrointestinal, respiratory, and vaginal flora of humans; *C. canimorsus* in canine oral flora	Severely immunocompromised, children with malignancies, neutropenia, mucositis, asplenia, alcohol abuse	Bacteremia, septicemia, keratitis, conjunctivitis, endophthalmitis, corneal ulcer, endocarditis, pericardial abscess, mediastinitis, lung and subphrenic abscess, empyema, peritonitis, abdominal abscess, septic arthritis, lymphadenitis, juvenile periodontitis
Chromobacterium	Enters through the skin or ingestion of contaminated food or water	Neutrophil defects (e.g., chronic granulomatous disease)	Local cellulitis, lymphadenitis, septicemia, osteomyelitis, arthritis, meningitis, ocular infections, and pneumonia
Chryseobacterium	Soil, water, use of contaminated fluids in the hospital, nebulizers, flush solutions, pressure transducers, contaminated disinfectants and anesthetics, ice machines, peritoneal dialysis solutions	Neonates, premature infants, adult immunocompromised patients	Neonates: meningitis, hydrocephalus Adults: endocarditis, pneumonia, peritonitis, keratitis, wound infection, meningitis
Pseudomonas oryzihabitans/luteola	Soil, water, flushing solutions	Patients with indwelling foreign material, malignancies, immunosuppressive therapy, postsurgical state, history of IVDU, chronic renal failure, bone marrow transplant, cirrhosis	Septicemia, bacteremia, subdural empyema, pneumonia, peritonitis, biliary tract infection, abscesses, wound infection, empyema, line infections, prosthetic joint infections

Abbreviations: UTI = urinary tract infection; CT = computed tomography; IVDU = intravenous drug use.

immunosuppressed patients. The most common sites of isolation of *A. baumannii* are the respiratory and urinary tracts. The mortality can be as high as 40% to 60% in patients with septic shock and up to 30% in patients with ventilator-associated pneumonia, usually associated with underlying disease (e.g., diabetes, malignancy, and renal failure). *Acinetobacter* spp. play a significant role in the colonization of hospitalized patients, making it difficult to differentiate true infection from colonization.

A. baumannii is commonly multidrug-resistant due to expression of β-lactamases, altered porin channels, and efflux pumps. Treatment is best guided by specific antibiotic testing and sensitivity patterns within each hospital. Most *A. baumannii* strains are resistant to penicillin, ampicillin, first-generation cephalosporins, gentamicin, and chloramphenicol and show variable susceptibility to second- and third-generation cephalosporins, trimethoprim-sulfamethoxazole (TMP-SMX), and tetracyclines. Ampicillin-sulbactam and

sulbactam alone have intrinsic bactericidal activity and have been used with good success in susceptible strains. Other therapeutic options include broad-spectrum cephalosporins such as ceftazidime or cefepime, carbapenems, and minocycline. In recent years, many institutions have noted the emergence of carbapenem hydrolyzing strains of *A. baumannii* due to the production of OXA-type carbapenemases or metallo-β-lactamases including NDM (New Delhi metallo-β-lactamase). For pan-resistant strains of *A. baumannii*, colistin (or polymyxin B) and tigecycline either singly or in combination may offer reasonable therapeutic alternatives. Newer antibiotic combinations including ceftazidime-avibactam, ceftolozane-tazobactam and meropenem-varborbactam are not effective. *A. lwoffii* tends to be more susceptible than the other *Acinetobacter* spp.

Achromobacter

Epidemiology

Achromobacter spp. are widely distributed in nature, including in soil and water. They may be part of the normal flora of the lower gastrointestinal tract. *Achromobacter* spp. have been found as contaminants in disinfectants, diagnostic tracer solutions, intravenous CT contrast solutions, hemodialysis solutions, ventilators, humidifiers, and pressure transducers.

The genus *Achromobacter* consists of a number of species, of which two are of clinical relevance: *A. xylosoxidans* and *A. denitrificans*. These are gram-negative rods that are oxidase-positive and grow on MacConkey agar.

Clinical syndromes

Achromobacter spp. have been commonly reported as causative agents in a variety of nosocomial and community-acquired infections. *A. xylosoxidans* has been isolated from many types of specimens, including blood, cerebrospinal fluid (CSF), bronchial washings, urine, and wounds. It represents an opportunistic pathogen in immunosuppressed patients and has been reported to cause chronic otitis media, meningitis and ventriculitis after neurosurgical manipulation, bacteremia, endocarditis, endophthalmitis, corneal ulcers, pharyngitis, pneumonia, surgical wound infections, peritonitis and urinary tract infections, and abscesses. Mortality can approach 52% in patients with *A. xylosoxidans* bacteremia.

A. xylosoxidans colonizes the respiratory tract of cystic fibrosis patients and is associated with exacerbations of pulmonary symptoms. Antibiotic selection should be guided by susceptibility testing. Imipenem-cilastatin is the most consistently effective agent in vitro against *A. xylosoxidans*. Most strains are resistant to aminoglycosides and cephalosporins (including cefepime) except ceftazidime. Piperacillin-tazobactam, ticarcillin-clavulanate, fluoroquinolones, meropenem and TMP-SMX are generally effective. For severe infections, initial combination therapy may be necessary; synergistic activity has been established for combinations with meropenem.

A. denitrificans is reported to have been isolated from many clinical specimens, but its clinical significance remains controversial. It has been reported to cause urinary tract infections, otitis externa, and bacteremia associated with intravenous catheters.

Alcaligenes

Epidemiology

Alcaligenes consist of gram-negative rods or cocci that are oxidase-positive and obligate aerobes. *A. faecalis* is the most commonly isolated species in the clinical laboratory. Some *A. faecalis* (previously named *A. odorans*) produce a greenish color on blood agar plates and have a characteristic fruity, apple odor. These organisms are found in soil and water as well as on normal human skin and in gastrointestinal tract flora. Dairy products and rotten eggs have been sources of *Alcaligenes*. These organisms have also been isolated from hospital equipment.

Clinical syndromes

Clinically important infections are found in severely debilitated patients and patients with cystic fibrosis. Most infections are opportunistic and acquired from contaminated hospital equipment (e.g., nebulizers, respirators, and lavage fluid). *Alcaligenes* spp. are a rare cause of bacteremia (blood isolates have also been obtained from patients without clinical evidence of sepsis), native and prosthetic valve endocarditis, meningitis, chronic purulent otitis, keratitis, pyelonephritis, hepatitis, appendicitis, and urinary tract infection. *Alcaligenes* isolated from the blood of patients with septicemia is thought to be associated with contaminated hospital equipment. *A. faecalis* isolation from the urine is often considered to be a contaminant; it is also found in diabetic ulcers with mixed flora, and its clinical significance is difficult to determine.

A. faecalis is generally susceptible to the β-lactam drugs, fluoroquinolones, aminoglycosides, and TMP-SMX. On the basis of in vitro studies, third-generation cephalosporins or the addition of clavulanic acid to amoxicillin or piperacillin-tazobactam may be more consistently effective. Greater antibiotic resistance is seen in hospitals.

Capnocytophaga

Epidemiology

Capnocytophaga encompasses a group of capnophilic (CO_2 requiring), microaerophilic, gram-negative rods. The organisms are slow-growing, thin, and often fusiform bacilli that display gliding motility on agar media. The oxidase- and catalase-negative clinically relevant species include *C. ochracea, C. sputigena, C. haemolytica, C. granulosa, C. leadbetteri*, and *C. gingivalis* (formerly Centers for Disease Control and Prevention [CDC] group DF-1). These species are normal members of the human oral microbiota and can be

isolated from individuals with periodontal disease. *C. canimorsus* and *C. cynodegmi* are oxidase- and catalase-positive and found as part of the normal oral flora of domestic pets

Clinical syndromes

C. ochracea, C. sputigena, C. haemolytica, C. granulosa, C. leadbetteri, and *C. gingivalis* have been reported to cause septicemia and other infections including endocarditis, osteomyelitis, soft tissue infections, endophthalmitis, endometritis, and peritonitis. The clinical presentation includes fevers, chills, myalgia, nausea or vomiting and diarrhea, abdominal pain, mental confusion, and headache. In a Danish study, the mortality in 39 cases with septicemia was approximately 31%, with eight patients dying of fulminant sepsis complicated by disseminated intravascular coagulation (DIC) after admission. They are also causative agents of localized juvenile periodontitis (together with *Aggregatibacter* [formerly *Actinobacillus*] *actinomycetemcomitans*) and other periodontal disease. *Capnocytophaga* may cause systemic disease in both immunocompetent and immunocompromised patients, particularly with neutropenia and in the presence of oral mucositis. These patients usually present with bacteremia and septicemia. In immunocompetent patients, *Capnocytophaga* may be isolated from polymicrobial infections of the respiratory tract including pulmonary abscess and empyema or contaminated wounds (e.g., clenched fist injuries).

Human *Capnocytophaga* spp. are generally susceptible to clindamycin, erythromycin, tetracycline, chloramphenicol, quinolones, and imipenem-cilastatin. Susceptibilities are variable for penicillin, expanded-spectrum cephalosporins, and metronidazole. In general, these organisms are resistant to aztreonam, aminoglycosides, vancomycin, trimethoprim, and colistin. β-lactamase production has been reported in 2.5% to 32% of isolates (detected by the nitrocefin test). Clindamycin is thought to be the most active drug in vitro. In immunocompromised patients with bacteremia, antibiotics should be given for 10 to 14 days after documenting negative blood cultures. For immunocompetent patients, the duration of therapy should be dictated by the site and extent of infection, and therapy should be given in conjunction with adequate surgical drainage.

C. canimorsus and *C. cynodegmi* are part of the normal oral flora of dogs and cats. *C. canimorsus* is isolated more commonly and appears to be more virulent. It is generally associated with dog bites, causing a wide spectrum of illness ranging from mild to fulminant infection, including septic shock and death. The case fatality rate is approximately 25%. Predisposing factors to serious infection mainly include prior splenectomy, alcohol abuse, liver cirrhosis, and immunosuppression (steroids or hematologic malignancies). In these individuals, the infection tends to be fulminant, with shock, DIC, hemorrhagic skin lesions mimicking meningococcemia, gangrene, renal failure, and death. More than 75% of cases report exposure to a dog, either through contact or a bite. *C. canimorsus* has been reported to cause meningitis, endocarditis, pneumonia, empyema, corneal ulcer, septic arthritis, cellulitis, and wound infections after a dog bite or cat scratch.

The diagnosis is established by blood cultures although other specimens may also yield the organism (e.g., wound cultures, CSF). In most reports, cultures become positive within 3 to 7 days. Clinicians should alert the microbiology laboratory if infection due to *C. canimorsus* is suspected so that blind subculture of blood cultures on enriched media can be performed. In asplenic patients, the organism may be demonstrated on a Gram stain of the buffy coat. In one alcoholic patient, the organisms were seen on a peripheral blood smear.

Routine susceptibility tests of *C. canimorsus* are difficult to perform because of slow growth and lack of standardized methods. However, it is generally reported to be susceptible to most antibiotics, including penicillins, imipenem-cilastin, erythromycin, vancomycin, clindamycin, third-generation cephalosporins, chloramphenicol, rifampin, doxycycline, and quinolones. Susceptibility to aminoglycosides and trimethoprim is unclear and may depend on the method used. Penicillin is considered the drug of choice for *C. canimorsus* infections.

Chromobacterium

Chromobacterium violaceum is the species most commonly isolated in the clinical laboratory although it is seldom regarded as pathogenic. *C. violaceum* is a slightly curved, gram-negative rod with an almond-like smell, and it produces a distinctive water-insoluble violet pigment on blood agar. The organism grows within 24 hours on conventional media. *C violaceum* is included in the database of current MALDI-TOF MS systems. Humans with neutrophil defects (e.g., chronic granulomatous disease) may be particularly susceptible to infections with this organism.

Chromobacterium is generally found in the environment (soil, fresh water, and food). It grows optimally at 20°C/68°F to 37°C/98.6°F; hence, most infections have been documented in tropical or subtropical climates. It is a rare infection, thought to enter the body through contaminated wounds, although ingestion of contaminated food or water may play a role. The most common clinical presentation is a local cellulitis and regional or diffuse lymphadenitis. Widespread dissemination may occur, resulting in septicemia and multiorgan failure. Mortality is 60% to 70%, depending on the host and accuracy of diagnosis. Other presentations have included fever, skin lesions, abdominal pain, osteomyelitis, arthritis, meningitis, ocular infections, and pneumonia.

C. violaceum is generally resistant to most penicillins and colistin. It is susceptible to imipenem-cilastatin, fluoroquinolones, tigecycline, tetracyclines, and gentamicin. TMP-SMX has been used successfully as outpatient therapy after prolonged intravenous therapy with other agents.

Elizabethkingia

Elizabethkingia spp., formerly *Chryseobacterium* spp., are long, thin, slightly curved, oxidase-positive, indole-positive gram-negative rods. They are common inhabitants of soil and water and are found in hospital environments. *E. meningoseptica* is a

well-recognized human pathogen most commonly associated with nosocomial infections and outbreaks in intensive care units,. Two new species of *Elizabethkingia, E. miricola* and *E. anophelis* have been reported to cause human infections. *E. miricola* was initially identified from condensation water collected on the Russian Mir space station, while *E. anophelis* was recovered from the midgut of *Anopheles gambiae* mosquitoes in the Gambia. Misidentification of *Elizabethkingia* spp. is common using traditional biochemical and commercial phenotypic identification systems, but MALDI-TOF MS provides more reliable identification. In particular, *E. anophelis* is often misidentified as *E. meningoseptica* using traditional biochemical methods.

E. meningoseptica is an uncommon pathogen in adults and rarely causes infections in children beyond the newborn period. It is highly pathogenic for premature infants and has been associated with neonatal sepsis and meningitis. The development of meningitis may be insidious. The prognosis is extremely poor, with mortality >60%. Half of the survivors develop significant neurologic complications, including hydrocephalus. Although rarely encountered, it is important to diagnose the disease accurately because epidemics may occur in nurseries. Meningitis has also been reported in adults, particularly among immunocompromised patients. Other clinical presentations in adults include bacteremia, endocarditis, pneumonia, peritonitis, keratitis, and wound infections. Most of the described cases are nosocomial infections associated with the use of contaminated fluids in the hospital (nebulizers, flush solutions for arterial catheters, pressure transducers, ice machines, contaminated disinfectants, contaminated anesthetics, peritoneal dialysis). *E. anophelis* has been reported as a cause of severe sepsis particularly in Asian countries but also as a cause of large outbreaks in the Midwestern United States (Wisconsin, Illinois, and Michigan). The clinical presentation included bacteremia, pneumonia, meningitis, urinary tract infection, biliary sepsis, and skin and soft tissue infection. In the Wisconsin outbreak, 89% of cases were attributed to community-onset infection, and patients were usually elderly with comorbidities such as diabetes, cirrhosis, alcohol dependence, chronic kidney disease, and malignancy. The case fatality rate due to *E. anophelis* infection is high, ranging from 24% to 60%. *E. miricola* is a rare cause of pneumonia, bacteremia, and urinary tract infection and appears to be more prevalent in Asia.

Antimicrobial selection is difficult because *Elizabethkingia* are inherently resistant to multiple antibiotics, and susceptibilities vary with the method used. Results of testing, particularly with the disk diffusion, E-test, and agar dilution tests, are considered unreliable. The broth microdilution test is recommended for susceptibility determination for *Elizabethkingia* spp. Most isolates produce β-lactamases and are resistant to cephalosporins, carbapenems, aminoglycosides, and TMP-SMX. *E. meningoseptica* demonstrates variable susceptibility to piperacillin-tazobactam and quinolones

More recent studies have recommended use of levofloxacin for *E. miricola* strains based on in vitro results demonstrating low minimum inhibitory concentrations (MICs). *E. anophelis* isolates in the Wisconsin outbreak were highly susceptible to cefepime (90%) and minocycline (97.5–100%). Antimicrobial therapy should be continued for at least 2 weeks after sterilization of the CSF. Recovery is the rule in immunocompetent older patients infected with contaminated materials; however, the prognosis is poor in immunocompromised patients.

Pseudomonas oryzihabitans, *P. luteola*, *P. fluorescens*, *P. putida*, and *P. stutzeri*

Pseudomonas oryzihabitans and *P. luteola* are oxidase-negative, aerobic, gram-negative rods with a distinct yellow pigment. After 48 hours of incubation, colonies are typically rough or wrinkled. They are found in water, soil, and other damp environments. Eighty-four percent of the reported cases have been associated with the presence of a foreign material, including intravascular catheters, dialysis catheters, or artificial grafts. Other associated host factors include malignancy, immunosuppressive therapy, postsurgical state, chronic renal failure, previous antibiotic therapy, intravenous drug use, long-term corticosteroid use, liver cirrhosis, and bone marrow transplantation. Infections associated with these organisms include sepsis, bacteremia, line infections, pneumonia, prosthetic joint infections, subdural empyema, peritonitis, biliary tract infections, surgical wound infections, abscesses, and empyema.

In many studies, resistance has been shown to the first- and second-generation cephalosporins, and most isolates are also resistant to ampicillin and tetracycline. They are sensitive to the ureidopenicillins, third-generation cephalosporins, carbapenems, aminoglycosides, and quinolones. There is a difference in susceptibility to TMP-SMX: *P. luteola* is resistant and *P. oryzihabitans* is sensitive. Clinically, most patients have been treated with ciprofloxacin with a favorable outcome.

The increase in number of reported cases of *P. fluorescens* and *P. putida* infection is frequently related to the presence of intravascular catheters in immunocompromised patients and dialysis catheters in continuous ambulatory peritoneal dialysis. *P. fluorescens* can be isolated from the skin of blood donors and result in contaminated blood transfusions, infected flushes, pseudobacteremia, and pseudo-outbreaks. *P. putida* has been implicated in nosocomial bacteremia, pneumonia, peritonitis, and neonatal sepsis. *P. stutzeri* infections are uncommon, but this organism has been reported as a cause of bacteremia, nosocomial brain abscess, and meningitis in immunocompromised patients. Infections such as osteomyelitis, septic arthritis, and endophthalmitis after cataract surgery have also been reported. These organisms are generally susceptible to most antipseudomonal antibiotics.

Ochrobactrum

These are oxidase- and urease-positive, gram-negative coccobacilli formerly designated as CDC group Vd-1 and Vd-2 and *Achromobacter* groups A, C, and D. Two species are currently described as human pathogens, *Ochrobactrum anthropi* and *O. intermedium*, although other *Ochrobactrum* spp. have rarely been recovered from clinical samples. It may be difficult to differentiate the two pathogenic *Ochrobactrum* spp. using traditional phenotypic methods but *O.*

intermedium is colistin-resistant and grows at 41°C/105°F. Both *Ochrobactrum* species are closely related to *Brucella* species, leading to occasional misidentification by automated systems. *O. anthropi* is a low-virulence pathogen affecting immunocompromised patients and is often associated with vascular device-related infections, hemodialysis, urinary and respiratory tract infections, continuous ambulatory peritoneal dialysis peritonitis, activation-induced cell death, and pacemaker infections. Cases have been described where resolution of bacteremia has occurred without antibiotic administration or despite administration of resistant antibiotics. *O. anthropi* is usually resistant to most penicillins and cephalosporins, and is susceptible to carbapenems, aminoglycosides, fluoroquinolones, TMP-SMX, and tetracyclines.

Oligella, Ralstonia, Rhizobium, Shewenella, Sphingomonas, Roseomonas, Weeksella, and *Bergeyella*

Oligella are small coccobacilli and consist of two species, *O. urethralis* (formerly *Moraxella urethralis*) and *O. ureolytica*. Most isolates have been taken from urine, often associated with indwelling urinary catheters, and these can rarely cause bacteremia, septic arthritis, and pyelonephritis. *O. urethralis* is susceptible to most antibiotics including penicillin, while *O. ureolytica* exhibits variable susceptibility patterns.

Ralstonia pickettii is the only clinically significant member of the *Ralstonia* genus, and it has been implicated in pseudobacteremias and nosocomial outbreaks due to contaminated infusions.

Rhizobium spp. (former *Agrobacterium*) are occasionally isolated from clinical specimens but rarely linked with human infection. *R. radiobacter* is the only clinically significant species and produces pink, mucoid colonies on MacConkey agar. It has been most commonly isolated from blood followed by peritoneal dialysate or ascites fluid, and it is also associated with infections of transcutaneous devices in immunocompromised patients. Antibiotic susceptibility is variable, and treatment should be guided by individual susceptibility testing. Most isolates are susceptible to broad-spectrum cephalosporins, carbapenems, piperacillin-tazobactam, fluoroquinolones, and gentamicin (but not tobramycin).

Shewanella putrefaciens and *S. algae* are the type species most commonly isolated from human clinical specimens. The habitat for *S. algae* is saline, and *S. putrefaciens* has been isolated from fish, poultry, meats, and water samples. They are associated with skin and soft tissue infections and bacteremia, especially in immunocompromised patients. They are usually susceptible to most antibiotics except for penicillin and first-generation cephalosporins.

Sphingomonas (formerly *Pseudomonas*) *paucimobilis* and *S. paucimobilis* are yellow-pigmented, weakly oxidase-positive, gram-negative rods that classically infect immunocompromised patients. They can be isolated from a variety of clinical specimens, including blood, CSF, urine, wounds, and the hospital environment. Most strains are colistin-resistant but susceptible to vancomycin, tetracycline, TMP-SMX, aminoglycosides, and imipenem-cilastin, and have variable susceptibility to penicillins and quinolones.

Roseomonas are the most frequently isolated pink-pigmented gram-negative coccobacilli. They are an uncommon cause of human infection but are occasionally isolated from blood, usually due to device-associated bacteremia. They have also been isolated from abscesses, wounds, dialysis fluid, and genitourinary sites. Most strains are susceptible to imipenem-cilastatin, amikacin, and fluoroquinolones. *Roseomonas* spp. are usually resistant to penicillins and cephalosporins.

Weeksella virosa and *Bergeyella zoohelcum* are morphologically and biochemically similar organisms. Both species are oxidase-negative and susceptible to most antibiotics including penicillin. *W. virosa* is isolated mainly from urine and vaginal samples.

Bergeyella zoohelcum is part of the normal oral flora of dogs and cats, and human isolates frequently result from dog or cat bites.

Section 19

Specific organisms: Spirochetes

Syphilis and other treponematoses

Arlene C. Seña and Adaora A. Adimora

Treponemes are members of the family *Spirochaetaceae*, which also contains *Borrelia* and *Leptospira*. Although most treponemes do not cause disease in human beings, a few cause substantial morbidity. This chapter briefly reviews the clinical manifestations and treatment of syphilis in adults and the nonvenereal treponematoses: yaws, pinta, and bejel.

Syphilis

Transmission and stages of infection

Syphilis is primarily transmitted through sexual contact with infectious mucocutaneous lesions in primary and secondary syphilis. Mother-to-child transmission can occur from transfer of the spirochete through the placenta or, less commonly, from contact with infectious exudates or blood through the birth canal. Transmission of syphilis through blood products is now rare due to routine screening of donors.

Like other treponemal diseases, the clinical manifestations of syphilis are divided into early and late stages. Early syphilis is further divided into primary, secondary, and early latent stages. During the latent syphilis stage, patients have positive serologic tests for syphilis but no other signs of disease. Although clinical staging is useful for diagnosis and treatment, it is also imprecise; overlap between stages is relatively common. For reporting and surveillance purposes, the US Centers for Disease Control and Prevention (CDC) recently changed their terminology from early latent syphilis and late latent syphilis to "early non-primary non-secondary syphilis" and "unknown duration or late syphilis," respectively. These changes were made to remove the term "latent" from the case definitions in order to clarify that certain clinical manifestations (e.g., neurosyphilis, ocular syphilis) may occur during any stage of syphilis.

Primary and secondary syphilis

Treponema pallidum subsp. *pallidum*, the causative agent of syphilis, usually enters the body through breaks in the epithelium that occur during sexual contact. Some organisms persist at the site of entry, whereas others disseminate via the lymphatic system throughout the body, proliferating and stimulating an immune response. The incubation period of primary syphilis is usually about 21 days, although extremes of 10 to 90 days have been noted.

The first clinical manifestation is usually a chancre at the site of genital trauma. The chancre begins as a red macule that subsequently becomes papular and then ulcerates. The lesion is painless with a well-defined margin and thickened, rubbery base. If untreated, the chancre persists for 3 to 6 weeks and then heals. Nontender regional lymphadenopathy also develops.

In untreated individuals, *T. pallidum* disseminates throughout the body, and secondary syphilis develops about 4 to 10 weeks after the chancre's onset. Common symptoms include malaise, headaches, sore throat, fever, musculoskeletal pains, and weight loss. Physical examination of persons with secondary syphilis reveals rash in 75% to 100%, regional or generalized lymphadenopathy in 50% to 85%, and mucosal ulceration in 5%

to 30%. The appearance of the rash can vary greatly, but lesions are often maculopapular or papulosquamous and often involve the entire body, including the palms and soles (Figure 161.1). Broad, flat lesions, known as *condylomata lata*, may develop in warm, moist areas, such as the scrotum, vulva, or perianal regions. Patchy alopecia and shallow painless mucosa ulcerations, called *mucous patches*, may also be seen.

The diagnosis of primary or secondary syphilis is based on the characteristic chancres or mucocutaneous lesions, along with demonstration of *T. pallidum* by direct detection methods and/or serologic tests for syphilis. Like the chancre, these clinical manifestations of secondary syphilis resolve spontaneously with or without therapy. However, a small proportion of patients develop complications such as hepatitis, syphilitic glomerulonephritis with nephrotic syndrome, anterior uveitis, choroiditis, arthritis, bursitis, or osteitis.

Recent cases of ocular syphilis have occurred among patients with primary or secondary syphilis. Presenting symptoms vary and have included eye redness, pain, blurry vision, floaters, and vision loss—often with posterior uveitis.

Neurosyphilis

T. pallidum can invade the central nervous system during any stage of syphilis. Asymptomatic neurosyphilis can occur with laboratory abnormalities in the cerebrospinal fluid (CSF) during primary or secondary syphilis. These abnormalities may resolve spontaneously or with treatment, or result in early symptomatic neurosyphilis in 5% of patients.

FIGURE 161.1 Secondary syphilis. Papulosquamous lesions on soles. Courtesy of David Schlossberg, MD.

Syphilitic meningitis most commonly occurs during the first year of infection. Patients may present with headache, fever, stiff neck, and photophobia. Cerebral involvement may result in seizures or hemiplegia. Cranial nerve palsies are especially common. Characteristic CSF findings that support the diagnosis in patients with reactive syphilis serologies include a lymphocytic pleocytosis, increased protein, and hypoglycorrhachia, but a reactive CSF Venereal Disease Research Laboratory (VDRL) confirms the diagnosis. Other manifestations of early neurosyphilis may include cranial neuritis or ocular involvement.

Meningovascular syphilis usually occurs about 5 to 12 years after infection in patients between the ages of 30 and 50 years and may involve the cerebrum, brainstem, or spinal cord. The pathophysiology involves chronic meningitis and infarction due to syphilitic endarteritis. In cerebrovascular syphilis, the middle cerebral artery is most commonly involved, and hemiparesis, aphasia, and seizures commonly occur. CSF usually reveals a lymphocytic pleocytosis with increased protein and a positive CSF VDRL. The major parenchymatous forms of neurosyphilis are general paresis and tabes dorsalis, which tend to occur between 2 and 30 years and 3 and 50 years, respectively, after initial infection. Both are now uncommon diseases.

General paresis is a chronic meningoencephalitis that results from direct invasion of the brain by *T. pallidum* and combines both psychiatric and neurologic manifestations. Early symptoms, such as irritability, memory loss, headache, and personality changes, may evolve into emotional lability, paranoia, and confusion. Pupillary abnormalities occur in more than half of patients with general paresis. In untreated patients, the interval between onset of symptoms and death can range from a few months to about 5 years.

Serum non-treponemal serologic tests are reactive in 95% to 100% of patients with generalized paresis. CSF VDRL is usually positive, but a negative result alone does not exclude the diagnosis. Differential diagnosis includes Alzheimer's disease, chronic alcoholism, and multiple sclerosis.

Tabes dorsalis is characterized by lightning pains and various combinations of other neurologic signs and symptoms, such as ataxia, bladder disturbances, pupillary abnormalities, absent ankle or knee reflexes, Romberg's sign, impaired vibratory and position sense, and development of extremely large, unstable, painless joints known as Charcot's joints. Although most patients have positive serum non-treponemal tests, 10% of patients with tabes will have nonreactive non-treponemal titers but positive treponemal tests. CSF may be normal or may reveal lymphocytic pleocytosis and elevated protein.

Non-neurologic manifestations of tertiary syphilis

Syphilitic heart disease, now an uncommon cause of cardiovascular disease, occurs 15 to 30 years after initial infection. During the early phases of infection, *T. pallidum* can disseminate to the heart and lodge in the aortic wall, where they may cause endarteritis of the vasa vasorum of the aorta with resultant scarring and destruction of the vessel's wall. Major cardiac manifestations include thoracic aneurysm, aortic regurgitation (without associated aortic stenosis), and coronary ostial stenosis.

Late benign syphilis is another now uncommon form of tertiary syphilis. It results from the chronic inflammatory response to *T. pallidum* and the formation of a granulomatous lesion called a

gumma, which most commonly occurs in the skin and bones but may also invade the viscera, muscles, and other structures.

Syphilis in persons with HIV infection

In the past decade, there has been a dramatic increase in early syphilis among men who have sex with men, particularly those with coexistent HIV infection. Syphilis and HIV share common means of transmission and other risk factors, and syphilis, like other genital ulcer diseases, facilitates HIV transmission. Clinical observation and case reports suggest that patients with HIV may experience a more aggressive course of syphilis, with more frequent occurrence of neurosyphilis especially in the early stages of infection. Ocular syphilis and syphilitic hepatitis may occur more often among persons with HIV. Occasional unusual serologic reactions can occur in HIV-infected patients including very high or fluctuating nontreponemal antibody titers; false-positive non-treponemal tests and false-negative treponemal tests have also been documented. Nevertheless, available data suggest that HIV infection does not significantly change the presentation, clinical course, or response to treatment of syphilis. Markers of immune function such as CD4 count and HIV viral load also do not appear to affect serological outcomes among HIV-seropositive persons with syphilis.

Syphilis in pregnancy

The clinical manifestations of syphilis are not altered in pregnancy; however, syphilis has widespread complications for both the infected mother and the fetus. Adverse pregnancy outcomes include early fetal loss, preterm delivery, low birth weight, and congenital syphilis in the neonate. Recent increases in congenital syphilis underscore the importance of maternal syphilis screening and prenatal care.

Laboratory tests

Direct examination

Direct microscopic examination can provide immediate diagnosis of primary and secondary syphilis. Dark-field microscopy must be used because *T. pallidum*'s narrow width (0.15 μm) renders the organism below the level of resolution of light microscopy. Wet preparations can be made from the skin or mucous membrane lesions of primary or secondary syphilis. Examination reveals tightly coiled organisms 6 to 14 μm long and 0.25 to 0.30 μm wide, with corkscrew motility. When examination of specimens must be delayed or oral lesions evaluated, direct fluorescent antibody testing can be useful; however, this test is not widely available due to its complexity. Polymerase chain reaction (PCR) assays are most useful for genital ulcers and other exudative lesions, but no US Food and Drug Administration (FDA)-approved test is available. A real-time PCR is offered by some commercial laboratories for use on genital lesion swabs and cerebrospinal fluid.

Serologic tests

Serologic tests for syphilis measure either nonspecific non-treponemal antibody or specific treponemal antibody. Non-treponemal antibody tests measure immunoglobulin G (IgG) and IgM to lipoidal material released from damaged host cells as well as to lipoprotein-like material and cardiolipin released by the treponemes. Non-treponemal antibody titers generally correlate with disease activity; titers fall progressively over time and are expected to decrease fourfold in response to therapy. The following non-treponemal tests are commonly used: VDRL test, rapid plasma reagin (RPR), the toluidine red unheated serum test (TRUST), and the unheated serum reagin test (USR). Biologic false-positive non-treponemal test results occur in 1% to 2% of the general population and are associated with several conditions such as viral infections (including HIV and viral hepatitis), pregnancy, malignancy, autoimmune diseases, and advanced age. False-negative results can occur from the *prozone phenomenon* in which patients with high non-treponemal titers can have weak or negative results at low dilutions due to excess antibody, although this is rare.

Specific treponemal antibody tests are needed to confirm a current or past diagnosis of syphilis. These tests detect antibodies formed in response to treponemal antigens. Treponemal tests usually remain reactive after treatment, but a small proportion of infected persons can become seronegative. Commonly used treponemal tests include the fluorescent antibody absorption (FTA-ABS), microhemagglutination assay for *T. pallidum* (MHA-TP), and the *T. pallidum* particle agglutination (TP-PA) test for syphilis.

Several new automated treponemal enzyme immunoassays (EIAs), immunoblots, chemiluminescence immunoassays, and multiplex flow immunoassays for *T. pallidum* that detect treponemal IgM and/or IgG have been FDA approved as screening and confirmatory tests for syphilis diagnosis. The majority of the newer assays use recombinant *T. pallidum* antigens to detect treponemal antibodies from patient specimens. Rapid, point-of-care tests, which can provide results within 20 minutes, have also been developed primarily for detection of treponemal antibodies; one of the rapid tests has received FDA approval and may be useful in settings with limited laboratory capabilities.

Traditionally, non-treponemal tests are used for screening followed by a treponemal test for confirmation. However, with the development of automated treponemal-based assays, some larger laboratories are using a reverse screening algorithm for syphilis testing. In the reverse algorithm, a positive treponemal test result is followed by a non-treponemal test to determine active infection. If the non-treponemal test is negative, then a second treponemal assay is recommended to confirm the results of the initial treponemal test. An individual with a positive treponemal test but negative non-treponemal titer may have early syphilis, late latent syphilis, past treated syphilis, or a false-positive treponemal test. Therefore, obtaining a thorough patient history to determine risks for recent exposures or past infections is critical to determining patient management. Treatment is usually indicated for persons with positive treponemal tests and nonreactive non-treponemal tests unless a history of treatment exists.

CSF evaluation

CSF should be examined in all syphilis patients with neurologic signs or symptoms (e.g., acute or chronic meningitis, ophthalmic or auditory symptoms, cranial nerve palsies, motor or sensory deficits, cognitive dysfunction), evidence of active tertiary syphilis, and in those with probable treatment failure, especially among persons with HIV. Performance of lumbar puncture among asymptomatic

HIV-seropositive patients is controversial but may be considered among coinfected persons with a non-treponemal titer ≥1:32 and CD4 count of ≤350 cells/mm^3.

When CSF specimens are free of blood contamination, a positive CSF VDRL test confirms the diagnosis of neurosyphilis. However, the sensitivity of the CSF VDRL is limited and a negative test does not rule out neurosyphilis, especially in the presence of CSF pleocytosis and increased CSF protein levels. The CSF FTA-ABS is more sensitive than the CSF VDRL, but false-positive results have been reported.

Treatment and follow-up

Treatment and follow-up are outlined in Boxes 161.1 and 161.2 for adults with and without HIV. Benzathine penicillin G is the drug of choice for all stages of syphilis infection. Doxycycline is

BOX 161.1

Management of syphilis in adults including pregnant women without known HIV infection

Primary, secondary, or early latent syphilis (duration ≤1 yr)

Treatment

- Benzathine penicillin G, 2.4 million U IM once
- If penicillin-allergic:[a]
- Doxycycline 100 mg PO BID for 2 wks *or* tetracycline 500 mg PO QID for 2 wks
- Ceftriaxone 1 g IM *or* IV for 10–14 d (caution: some patients with penicillin allergy are also allergic to ceftriaxone)

Treatment (for pregnant women)

- Benzathine penicillin G, 2.4 million U IM once (if penicillin allergic, patients should be desensitized and treated with penicillin); some experts follow with benzathine penicillin G, 2.4 million U IM administered 1 wk after the initial dose

Management and follow-up

- HIV testing
- If evidence of neurologic or ophthalmic disease, evaluate for neurosyphilis and do slit-lamp examination
- Repeat serology and clinical examination at 6 and 12 mo for HIV-negative persons
- Repeat serology at 28–32 weeks' gestation and at delivery for pregnant women
- If symptoms persist or recur, or there is sustained fourfold increase in RPR or VDRL titers, consider treatment failure or reinfection. Repeat HIV testing, consider LP, and retreat
- If RPR or VDRL titers do not fall fourfold within 6–12 mo of treatment, conduct additional clinical and serologic follow-up

Late latent syphilis or syphilis of unknown duration

Treatment

- Benzathine penicillin G, 2.4 million U IM every wk, for 3 wks
- If penicillin-allergic[a]:
- Doxycycline, 100 mg PO BID for 4 wks or tetracycline, 500 mg PO QID for 4 wks

Treatment (for pregnant women)

- Benzathine penicillin G, 2.4 million U IM every wk for 3 wks (if penicillin-allergic, patients should be desensitized and treated with penicillin)

Management and follow-up

- HIV testing
- Examine CSF before treatment if any of the following are present:
- Neurologic or ophthalmic signs or symptoms
- Evidence of active tertiary syphilis (e.g., aortitis or gumma)
- Treatment failure
- Repeat quantitative VDRL or RPR at 6, 12, and 24 mo. Repeat serology at 28–32 weeks' gestation and at delivery for pregnant women
- Patients with a normal CSF examination should be retreated for latent syphilis if:
- Serologic titers have a sustained (>2 weeks) fourfold increase or
- An initially high titer (≥1:32) fails to fall at least fourfold within 12–24 mo or
- Patient develops signs or symptoms consistent with syphilis

Tertiary syphilis (gumma or cardiovascular syphilis without neurosyphilis)

Treatment

- Benzathine penicillin G, 2.4 million U IM weekly for 3 wks
- If penicillin-allergic, use treatment for late latent syphilis[a]

Treatment (for pregnant women)

- Benzathine penicillin G, 2.4 million U IM every wk for 3 wks (if penicillin-allergic, patients should be desensitized and treated with penicillin)

Management
HIV testing
Examine CSF

Neurosyphilis
Treatment
Aqueous crystalline penicillin G, 18–24 million U per day, given as 3–4 million U IV q4h or continuous infusion for 10–14 d; some experts follow with benzathine penicillin G, 2.4 million U IM weekly for 3 wks
Alternative (if compliance is certain):
Procaine penicillin, 2.4 million U IM every day for 10–14 d, plus probenecid, 500 mg PO QID for 10–14 d; some experts follow with benzathine penicillin G, 2.4 million U IM weekly for 3 wks
Management
HIV testing
Repeat CSF examination every 6 mo until CSF cell count is normal
Consider retreatment if cell count has not decreased after 6 mo or if CSF is not normal after 2 yr

Abbreviations: HIV = human immunodeficiency virus; RPR = rapid plasma reagin; VDRL = Venereal Disease Research Laboratory test; LP = lumbar puncture; CSF = cerebrospinal fluid.

[a] HIV-infected, penicillin-allergic patients who receive alternative therapies should be closely monitored. If compliance cannot be ensured, patients should be desensitized and treated with penicillin.

BOX 161.2

Treatment of HIV-positive patients with syphilis

Primary and secondary syphilis
Treatment
Benzathine penicillin G, 2.4 million U IM once
If penicillin-allergic: Manage according to recommendations for HIV-negative patients with primary and secondary syphilis (see Table 161.1)
Management
Clinical and serologic evaluation 3, 6, 9, 12, and 24 mo after therapy
Examine CSF if RPR or VDRL titers fail to show a fourfold decrease within 6–12 mo or there is other evidence of treatment failure
If CSF normal, retreat with penicillin G, 2.4 million U IM weekly × 3 wks
If CSF suggests neurosyphilis, treat for neurosyphilis as in Table 161.1
Early latent syphilis
Manage and treat according to recommendations for HIV-negative patients with primary and secondary syphilis (see Table 161.1). Patients with penicillin allergy whose compliance with alternative therapy or follow-up cannot be ensured should be desensitized and treated with penicillin
Late latent syphilis or latent syphilis of unknown duration
Treatment and management
Consider CSF examination
If CSF normal, give benzathine penicillin G, 2.4 million U IM weekly × 3 wks
If penicillin-allergic: Manage according to recommendations for HIV-negative patients with late latent syphilis or latent syphilis of unknown duration. However, patients with penicillin allergy whose compliance with alternative therapy or follow-up cannot be ensured should be desensitized and treated with penicillin
If CSF suggests neurosyphilis, treat for neurosyphilis as in Table 161.1
Management
Clinical and serologic evaluation 6, 12, 18, and 24 mo after therapy
Examine CSF and retreat accordingly if:
Clinical symptoms develop or RPR or VDRL titers rise 4-fold at any time or RPR or VDRL titer fails to fall fourfold between 12 and 24 mo
Neurosyphilis
Treatment and management as in Table 161.1

Abbreviations: CSF = cerebrospinal fluid; RPR = rapid plasma reagin; VDRL = Venereal Disease Research Laboratory test; HIV = human immunodeficiency virus.

an effective alternative therapy for patients with penicillin allergies, but there are limited data on other alternatives such as ceftriaxone. Because there are no proven alternatives to penicillin for treatment of maternal syphilis, pregnant women who are allergic to penicillin should undergo desensitization and be treated with penicillin. HIV-positive patients with syphilis should be treated with the same recommended treatment regimens as HIV-negative patients, according to the stage of syphilis. Patients should be informed about the possibility of a Jarisch-Herxheimer reaction, an acute febrile reaction frequently accompanied by headache and myalgia, that can occur within the first 24 hours after the initiation of therapy, especially for early syphilis. Antipyretics can be used to manage symptoms as needed.

Clinical and serologic follow-up of patients after syphilis treatment is essential due to the potential for treatment failure. For HIV-negative persons, repeat evaluation should be performed at 6 and 12 months after therapy for early syphilis, and at 6, 12, and 24 months for latent syphilis. For pregnant women, serologic titers should be repeated at 28 to 32 weeks' gestation and at delivery at a minimum, and monthly among those at risk for reinfection. Although non-treponemal titers may fall more slowly among HIV-positive patients than in individuals who are HIV-negative after treatment, more frequent follow-up in HIV-seropositive patients is recommended (see Box 161.2) due to the potential for treatment failure. Vigilant follow-up for patients coinfected with HIV is important to document resolution of infection or to prompt immediate evaluation if relapse, reinfection, or other complications occur.

Serologic response to therapy is demonstrated by at least a fourfold decrease in non-treponemal titers from baseline (two dilution decrease, i.e., from 1:64 to 1:16) or seroreversion to a nonreactive non-treponemal test. However, despite appropriate treatment, approximately 12% of HIV-seropositive and HIV-seronegative patients with syphilis will have serological non-response (less than fourfold decline in non-treponemal titers). A higher proportion of patients may remain serofast after therapy, defined as persistently positive low-level nontreponemal antibody titers without seroreversion. Patients who do not exhibit an appropriate serological response to therapy may warrant subsequent clinical and serologic monitoring. However, the benefit of retreatment remains unclear for persons with persistent non-treponemal antibody titers in the absence of reinfection or treatment failure. Patients who have evidence of treatment failure based on recurrent signs or symptoms or a sustained (>2 weeks) fourfold increase in non-treponemal titers should undergo HIV testing and CSF examination, especially when there are symptoms suggestive of neurosyphilis.

For patients with neurosyphilis and evidence of CSF pleocytosis, follow-up CSF examination should be repeated every 6 months after treatment. The CSF white cell count should decrease within 6 months; this may occur more slowly in HIV-infected patients than in HIV-negative persons. Regardless of HIV status, retreatment should be considered if the CSF cell count has not decreased after 6 months or if the CSF parameters do not normalize 2 years after therapy.

Nonvenereal treponematoses

Yaws, pinta, and bejel (endemic syphilis) are caused respectively by *T. pallidum* subsp. *pertenue*, *T. carateum*, and *T. pallidum* subsp. *endemicum*. These diseases, seen mainly in tropical and subtropical regions, are transmitted by direct contact with infected skin lesions and not primarily by sexual contact. Like venereal syphilis, these diseases have self-limited primary and secondary stages, a latent stage, and a late stage with destructive lesions. The causative agents are morphologically indistinguishable from *T. pallidum* subsp. *pallidum*, and the serologic responses they elicit are identical to those of venereal syphilis. Yaws and bejel are more common among children, while pinta occurs more frequently among adults.

Yaws occurs in the tropical regions of Africa, the Pacific, and Southeast Asia. About 3 to 5 weeks after infection, papules develop, which enlarge, erode, and then spontaneously heal. A generalized secondary eruption of similar lesions occurs weeks to months later, sometimes associated with osteitis or periostitis. In the late stage, infected persons may develop hyperkeratoses on the palms and soles; plaques, nodules, and ulcers of the skin; and gummatous bone lesions.

Pinta occurs in remote parts of Mexico, Central America, and South America. About 7 to 21 days after infection, small, red, pruritic papules develop, which enlarge, become squamous, and merge with other primary lesions. These lesions eventually heal, but residual hypopigmentation persists. Three to 12 months after the appearance of the primary lesions, small scaly papules known as *pintids* appear. These may eventually become brown, gray, or blue and may recur as long as 10 years after initial infection. Depigmented lesions develop in the late stage.

Bejel occurs in Africa and western Asia. Unlike yaws and pinta, bejel is spread not only by direct contact but also by eating and drinking utensils. Primary lesions are seldom seen. Secondary manifestations include mucous patches, condylomata lata, split papules at the angles of the mouth, and lymphadenopathy. Gummatous lesions of the skin, nasopharynx, and bones are common in the late stage.

Diagnosis can be made by dark-field examination of lesions or serologic testing, or, for yaws and bejel, by PCR testing. A rapid point-of care assay for antibody detection is available for diagnosis of yaws.

Long-acting penicillin G is the treatment of choice. Azithromycin is also recommended, although resistance has been reported during treatment of yaws.

Lyme disease

Janine Evans

Lyme disease, a systemic illness caused by the spirochete *Borrelia burgdorferi*, is the most common tick-borne disease in the United States. In 2011, 48 states reported 24 364 cases of Lyme disease using the Council of State and Territorial Epidemiologists (CTSE)/Centers for Disease Control and Prevention (CDC) surveillance case definition. Since the original discovery of Lyme arthritis in the mid 1970s the clinical spectrum of Lyme disease has expanded to include a wide variety of organ systems, primarily the skin, joints, nervous system, and heart. Protean symptoms, uncertainty in diagnosis due to lack of definitive testing methods, and public fear of late sequelae of disease often lead to overdiagnosis and overtreatment. Although optimal therapy of some of the clinical features of Lyme disease is unclear, better understanding of the natural history, epidemiology, and pathogenesis of Lyme disease helps in the often confusing and difficult decisions related to diagnosis and treatment.

B. burgdorferi has been isolated from blood, skin, cerebrospinal fluid (CSF) specimens, and (rarely) other specimens from infected patients although, with the exception of skin biopsy specimens, culture of *B. burgdorferi* from sites of infection is a low-yield procedure. *B. burgdorferi* displays phenotypic and genotypic diversity and has been classified into separate genospecies, five of which are pathogenic to humans: *Borrelia burgdorferi sensu stricto*, which includes all strains studied thus far from the United States and some European and Asian strains, and *Borrelia garinii*, *Borrelia afzelii, Borrelia spielmanii*, and *Borrelia bavariensis*, which are found in Europe and Asia. *B. afzelii* seems primarily associated with a chronic skin lesion, acrodermatitis chronica atrophicans, rare in the United States, and *B. garinii* is predominant among CSF isolates.

Lyme disease occurs in three principal foci in the United States: the Northeast, the upper Midwest, and the Pacific Coast. These areas correspond to the distribution of the predominant tick vectors of Lyme disease in the United States, *Ixodes scapularis* in the East and Midwest, and *Ixodes pacificus* in northern California. Lyme disease also occurs widely in Europe, where it is transmitted by the sheep tick, *Ixodes ricinus*, and *Ixodes persulcatus*, the taiga tick. The latter is distributed throughout eastern Europe and Asia.

The largest number of reported cases of Lyme disease in Europe are from Germany, Austria, Slovenia, Sweden, the Czech Republic, and the Baltic states. *I scapularis* have a 3-stage, 2-year life cycle. Transovarial passage of *B. burgdorferi* occurs at a low rate. Ticks become infected with spirochetes by feeding upon a spirochetemic animal, typically small mammals, during larval and nymphal stages. In highly endemic areas from 20% to more than 60% of *I. scapularis* carry *B. burgdorferi*. Humans are only an incidental host of the tick; contact is typically made in areas of underbrush or high grasses, but may occur in well-mown lawns in endemic areas. Lyme disease occurs most commonly during April through July when nymphal *I. scapularis* feed. Animal models show that transmission is unlikely to occur before a minimum of 36 hours of tick attachment and feeding.

Clinical manifestations

Clinical features of Lyme disease are typically divided into three general stages termed early localized, early disseminated, and late persistent infection. These stages may overlap, and most patients do not exhibit all

FIGURE 162.1 Classic erythema migrans lesion.

stages. Direct invasion of the organism with a resultant vigorous inflammatory reaction has been demonstrated to be responsible for many of the clinical manifestations associated with Lyme disease, so the manifestations respond to antibiotic therapy. Some features, such as late neurologic deficits and chronic arthritis, may respond poorly to treatment. It is not absolutely clear that live organisms are responsible for these later symptoms.

Early localized disease

Erythema migrans (EM), the hallmark of Lyme disease, begins at the site of a deer tick bite after 3 to 32 days (Figures 162.1 and 162.2). It is reported by 60% to 80% of patients, appearing as a centrifugally expanding erythematous macule or papule, often with central clearing. The thigh, groin, and axilla are common sites. The lesion may be warm, pruritic, and painful, but is often asymptomatic and easily missed if out of sight. Occasionally, these lesions may develop blistering or scabbing in the center, remain an even, intense red without clearing, or develop a bluish discoloration. Spirochetes are present in the EM lesion and can be readily cultured from the expanding edge. Mild musculoskeletal flu-like symptoms such as a low-grade fever, chills, malaise, headache, fatigue, arthralgias, and myalgias may accompany EM lesions. Theoretically such symptoms can occur without dissemination of the organism, via local generation of cytokines. Untreated EM resolves after several weeks and treated lesions clear within several days.

FIGURE 162.2 Erythema migrans lesion.

Early disseminated

In some patients the spirochete disseminates hematogenously to multiple sites causing characteristic clinical features. Secondary annular lesions, sites of metastatic foci of *Borrelia* in the skin, develop within days of onset of EM in about half of US patients. They are similar in appearance to EM, but are generally smaller, migrate less, and lack indurated centers. In addition to musculoskeletal flu-like

symptoms, mild hepatitis, splenomegaly, sore throat, nonproductive cough, testicular swelling, conjunctivitis, and regional and generalized lymphadenopathy may sometimes occur during early stages.

Diagnosis of early localized and early disseminated Lyme disease is based on clinical presentation, because serologic confirmation is often lacking and culture is not readily available. EM is diagnostic of Lyme disease although atypical lesions and rashes mimicking EM may be confusing. A history of a tick bite and residence or travel in an endemic area should be sought in patients presenting with rashes compatible with EM or a flu-like illness in summer. Specific immunoglobulin (Ig)M antibody responses against *B. burgdorferi* develop 2 to 6 weeks after the onset of EM. Immunoglobulin (Ig)G antibody levels appear approximately 6 weeks after disease onset but may not peak until months or even years into the illness. The highest titers occur during arthritis. Antibodies are typically detected using indirect immunofluorescence, enzyme-linked immunosorbant assay (ELISA), and immunoblotting (Western blot). Antibody responses may persist for months to years after successful eradication of infection. Two-tier testing is recommended, with ELISA screening done first and if positive an immunoblot performed.

Late disease

Late manifestations of Lyme disease typically occur months to years after the initial infection. In the United States, arthritis is the dominant feature of late Lyme disease, reported in approximately 60% of untreated individuals. Less often, individuals develop late chronic neurologic disease. Another late finding (years) associated with this infection is a chronic skin lesion, acrodermatitis chronica atrophicans, well known in Europe but rare in the United States. These late manifestations are discussed below.

Therapy

Early Lyme disease

The symptoms of early Lyme disease resolve spontaneously in most cases; therefore, the goals of therapy for early localized and mild early disseminated Lyme disease are to shorten the duration of symptoms and reduce the risk of developing serious late manifestations of infection. Treatment of these stages with oral antibiotics is adequate in the majority of patients (see Table 162.1). In patients with acute disseminated Lyme disease but without meningitis, oral doxycycline appears to be equally effective as parenteral ceftriaxone in preventing the late manifestations of disease. Initial studies of treatment for early Lyme disease reported therapy with phenoxymethyl penicillin, erythromycin, and tetracycline, in doses of 250 mg four times a day for 10 to 20 days, shortened the duration of symptoms of early Lyme disease. Phenoxymethyl penicillin and tetracycline were superior to erythromycin in preventing serious late manifestations of disease. Subsequent clinical trials have proven amoxicillin and doxycycline to be equally efficacious. Amoxicillin has largely replaced use of penicillin because of greater in vitro activity against *B. burgdorferi*. It is the preferred antibiotic choice in children under the age of 8 years. Concomitant use of probenecid has not been definitively shown to improve clinical outcome and is associated with a higher incidence of side effects. Doxycycline is usually selected over tetracycline because of its twice-daily dose schedule, increased gastrointestinal absorption and tolerability, and greater central nervous system (CNS) penetration. Doxycycline is effective in treating *Anaplasma phagocytophilum* (formerly known as *Ehrlichia phagocytophila*), an organism also transmitted by *I. scapularis* ticks; amoxicillin is not. Cefuroxime axetil, an oral second-generation cephalosporin, has been shown to be about as effective as amoxicillin and doxycycline in treating early Lyme disease; azithromycin, an azilide analog of erythromycin, somewhat less so. Macrolide antibiotics are not recommended as first-line therapy for early Lyme disease. Long-term follow-up of patients treated during early stages of Lyme disease support the current dosing regimens. Patients who received a 14- to 21-day course of a recommended antibiotic rarely developed late manifestations of illness. Recent studies have indicated that a 10-day course of doxycycline is adequate therapy for EM. Jarisch–Herxheimer-like reactions, an increased discomfort in skin lesions and temperature elevation occurring within hours after the start of antibiotic treatment, have been encountered in 14% of patients treated for early Lyme disease. They typically occur within 2 to 4 hours of starting therapy, are more common in severe disease, and are presumably due to rapid killing of a large number of spirochetes.

Minor symptoms including arthralgia, fatigue, headaches, and transient facial palsy are common following treatment and generally resolve over a 6-month period. Patients with disseminated disease are most likely to experience persistent symptoms. These symptoms may be due to retained antigen rather than due to ongoing infection with *B. burgdorferi*, since longer courses of antibiotics have not been shown to shorten their duration. Prolonged courses of antibiotics should be reserved for those patients with evidence of persistent infection with *B. burgdorferi*.

Lyme carditis

Cardiac involvement occurs in up to 10% of untreated patients. Transient and varying degrees of atrioventricular block several weeks to months after a tick bite are the most common manifestations. Other features are pericarditis, myocarditis, ventricular tachycardia, and on rare occasions, a dilated cardiomyopathy; valvular disease is not seen. Carditis is typically mild and self limited although patients may present quite dramatically in complete heart block, and some require the insertion of a temporary pacemaker. In most cases, carditis resolves completely, even without treatment with antibiotics. Studies examining endomyocardial biopsy specimens from patients with Lyme carditis have indicated that direct invasion of *B. burgdorferi* into myocardium and an associated inflammatory reaction are responsible for the clinical events. Although optimal treatment of carditis is unknown, oral therapy for mild forms of cardiac involvement is usually sufficient. Intravenous antibiotics and cardiac monitoring are recommended for patients with varying, high-degree heart block and more serious cardiac involvement. The benefit of concomitant use of aspirin or prednisone and antibiotics in treating patients with

TABLE 162.1 **TREATMENT GUIDELINES**

Antibiotic regimen	Comments
Erythema migrans	
Amoxicillin, 500 mg 3 times daily for 14–21 d	Pediatric dose is 25–50 mg/kg/d three times daily
Doxycycline (Vibramycin), 100 mg twice daily for 10–21 d	Also effective against *Anaplasma phagocytophium*; not recommended for children under 8 years of age, pregnant or lactating women
Cefuroxime axetil (Ceftin), 500 mg twice daily for 14–21 d	Pediatric dose 30 mg/kg/d twice daily
Azithromycin (Zithromax), 500 mg daily for 7–10 d	Not recommended as first-line therapy; less effective than other regimens
Early disseminated disease (without neurologic, cardiac, or joint involvement)	
Initial treatment is the same as for erythema migrans except duration of treatment may be extended to 21–28 d	
Neuroborreliosis Isolated seventh nerve palsy	
Initial treatment is the same as for erythema migrans except duration of treatment is 21–28 d. The need for cerebrospinal fluid examination remains controversial	
All other neurologic manifestations (including meningitis, radiculoneuritis, peripheral neuropathy, encephalomyelitis, chronic encephalopathy)	
Ceftriaxone (Rocephin), 2 g daily for 14–30 d	30-d regimen associated with fewer relapses in patients with chronic encephalopathy
Penicillin G, 20 million units daily for 14–28 d	Pediatric dose 200 000–400 000 units/kg/d every 4 h
Cefotaxime sodium (Claforan), 2 g every 8 h	Pediatric dose 150–200 mg/kg/d in 3–4 divided doses for 14–28 d
Doxycycline, 100 mg twice daily (oral or intravenous) for 14–28 d	No published experience in the United States
Carditis	
Doxycycline, 100 mg orally twice daily for 21 d	For first degree heart block, PR interval <0.3 s
Amoxicillin, 500 mg three times daily for 21 d	For first degree heart block, PR interval <0.3 s
Ceftriaxone, 2 g daily for 14–21 d	Optimal duration of therapy is unknown
Penicillin G, 20 million units daily for 14–30 d	Optimal duration of therapy is unknown, given in divided doses every 4 h
Arthritis Amoxicillin 500 mg four times daily for 30–60 d	Oral regimens should be limited to patients without evidence of neurologic involvement. Oral treatment may be extended for 60 d if no response to 30-d course
Doxycycline 100 mg two times daily for 30–60 d	
Cefuroxime axetil, 500 mg twice daily for 30–60 d	For patients with doxycycline and penicillin allergy
Ceftriaxone, 2 g daily for 14–30 d	
Lyme disease in pregnancy	
Amoxicillin, 500 mg three times daily for 21 d	For early localized disease only
Ceftriaxone, 2 g daily for 14–28 d	
Penicillin G, 20 million units daily for 14–28 d	Given in divided doses every 4 h
Asymptomatic tick bite	
No treatment or single dose of 200 mg doxycycline	For pregnant women, a 10-d course of amoxicillin may be considered
Asymptomatic seroconversion	No treatment necessary

Lyme carditis is uncertain. Despite the generally benign course of Lyme carditis, several cases of permanent heart block have been reported, presumably caused by a vigorous inflammatory response. Short courses of prednisone may be considered in patients with prolonged dense heart block despite adequate antibiotic therapy.

Dilated cardiomyopathy is a rare complication of Lyme disease reported in Europe but not yet in the United States. The majority of the patients were from endemic areas for Lyme disease, had other clinical features of disease, and were seropositive for anti-*B. burgdorferi* antibodies. Their myopathy was cured by antibiotic treatment.

Early neurologic disease

Early neurologic involvement occurs in 15% to 20% of untreated patients and appears within 2 to 8 weeks after the onset of disease. Manifestations include cranial nerve palsies, meningitis or meningoencephalitis, and peripheral neuritis or radiculoneuritis, often appearing in combination. Unilateral or bilateral seventh nerve palsies are the most common neurologic abnormalities. Presenting symptoms depend upon the area of the nervous system involved: patients with meningitis present with fever, headache, and a stiff neck; those with Bannwarth's syndrome (primarily in Europe) develop severe and migrating radicular pain lasting weeks to several months; and those with encephalitis have concentration deficits, emotional lability, and fatigue. In patients with early CNS involvement analysis of CSF typically reveals a lymphocytic pleocytosis. Specific antibodies against *B. burgdorferi* may also be present and concentrated in the CSF relative to the serum concentration; they are useful to confirm disease.

Intravenous antibiotics are recommended for all cases of neuroborreliosis except isolated seventh nerve palsy. Patients presenting with a Bell's-like palsy who have features that suggest possible CNS involvement, such as high fever, headache, or stiff neck, should undergo a lumbar puncture looking for evidence of more extensive disease. The most experience in the treatment of CNS Lyme disease has been with aqueous penicillin and third-generation cephalosporins. Although optimal duration of therapy is unknown, it is recommended that patients be treated for two to four weeks. Ceftriaxone, in doses of 1 to 2 g/day, is the agent of choice because of better CNS penetration and ease of administration. Patients with persistent symptoms after recommended antibiotic therapy pose a particular management problem. It is often unclear whether these symptoms are due to resolving inflammation or ongoing infection. Meningitis and sensory symptoms usually resolve within days to weeks; other features may take months to improve. In most cases it is not necessary to continue antibiotic therapy until complete recovery.

Late manifestations

Arthritis

Arthritis is the dominant feature of late Lyme disease, occurring in up to 60% of untreated patients days to years after initial infection (mean of 6 months). The initial pattern of involvement may be migratory arthralgias (early) followed in 60% of patients by intermittent attacks of arthritis lasting from days to months. Large joints, particularly the knee, are most commonly involved. Swelling is often prominent, with large effusions and Baker's cysts. Serologic testing in patients presenting with arthritis is positive in almost all cases.

Lyme arthritis has been treated successfully with oral and intravenous antibiotics. In early studies examining response to intravenous benzathine penicillin, 2.4 million units intramuscularly weekly for 3 weeks, 7 of 20 patients responded compared with 0 out of 20 in the control group. Intravenous ceftriaxone 2 to 4 g daily for 2 to 4 weeks has been thought to be superior to benzathine penicillin. Oral regimens using doxycycline, 100 mg twice a day for 4 weeks, and amoxicillin plus probenecid, 500 mg of each orally four times a day for 4 weeks, have reported success in 18 of 20 patients and 16 of 18 patients, respectively. Response to antibiotics is typically excellent but effusions may take months to resolve completely. An additional 4 weeks of oral antibiotic therapy has been recommended for patients with persistent arthritis following initial 4-week treatment.

A small subgroup of Lyme arthritis patients develop a chronic, potentially erosive arthritis unresponsive to antibiotics. These patients often have major histocompatability class II gene products, HLA DR4, accompanied by strong serum IgG responses to *Borrelia* outer surface proteins A or B (OspA or OspB). Repeated courses of antibiotics have not been shown to improve clinical outcome. Treatment with anti-inflammatory medications and intra-articular steroid injections can be helpful in reducing joint swelling. Surgical synovectomy has cured a number of such patients. Resolution of the arthritis eventually occurs; in some patients it may take up to 3 to 5 years.

Late neurologic lyme disease

Chronic neurologic syndromes, which are relatively uncommon, may occur months to years after initial infection. Cognitive dysfunction, affective changes, seizures, ataxia, peripheral neuropathies, and chronic fatigue have all been reported. The most common late-stage neurologic syndrome reported in the United States, called Lyme encephalopathy, is characterized by subtle cognitive impairment. Because these complaints are often nonspecific and may be associated with post-Lyme syndromes, it is important to look for and document evidence of ongoing *B. burgdorferi* infection. Lymphocytic pleocytosis is uncommon in late neurologic disease, but increased intrathecal *B. burgdorferi*-specific antibodies may well be present. Careful evaluation with neuropsychological testing can help to distinguish cognitive abnormalities in Lyme disease from those associated with chronic fatigue states and depression. Chronic neurologic dysfunction usually improves with antibiotics but may not completely reverse. Late neurologic manifestations of Lyme disease are treated with intravenous antibiotics. Agents with demonstrated efficacy are aqueous penicillin and third-generation cephalosporins. Doxycyline, both oral and intravenous forms, have been reported to be successful in treating late CNS Lyme disease in Europe.

Ocular disease

Ocular lesions in Lyme disease are rare, but have involved every portion of the eye and vary depending on the stage of the disease. The most common ophthalmic presentations in early disease

include conjunctivitis, photophobia, and neuro-ophthalmologic manifestations due to cranial nerve palsies. The incidence of seventh nerve palsies is similar in Europe and the United States. The most severe ocular manifestations occur in late stages; they include episcleritis, symblepharon, keratitis, iritis, choroiditis, panuveitis, and retinal vasculitis. Serologic testing in these patients is typically positive.

Experience treating late ocular lesions in Lyme disease is scanty. The most success has been with the use of intravenous ceftriaxone in doses of 2 to 4 g daily for 10 to 14 days.

Pregnancy

Intrauterine transmission of *B. burgdorferi* is uncommon, usually occurring in cases of obvious disseminated infection during pregnancy. No uniform pattern of congenital anomaly has been reported. Prenatal exposure to Lyme disease has not been found to be associated with an increased risk of adverse pregnancy outcome. Optimal treatment of the pregnant patient with Lyme disease is unknown, but the recommended regimens have not been associated with adverse outcomes. Oral antibiotics for early localized disease is sufficient, and intravenous antibiotics are recommended for patients with symptoms suggesting disseminated disease.

Tick bites

The risk of infection from a deer tick bite in a Lyme disease endemic area is low. In mice, infected ticks have been attached for over a 36-hour period before significant risk of developing Lyme disease occurred. In a controlled double-blind study in patients with tick bites, no patient asymptomatically seroconverted, no treated patient developed EM, and the 2 of 182 untreated patients who did develop EM were successfully treated with oral antibiotics. These results support marking and watching a tick bite, and should EM develop, treating it early, when antibiotics are most effective. A single dose of doxycycline has been shown to be effective in reducing the development of Lyme disease. The Infectious Diseases Society of America (IDSA) guidelines recommend offering the single-dose doxycycline if the attached tick can be reliably identified as an adult or nymphal *I. scapularis* tick, it is estimated to have been attached for >36 hours, prophylaxis can be started within 72 hours after tick detachment, and the local rate of infection of these ticks with *B. burgdorferi* is greater than 20%. Doxycycline prophylaxis for children under 8 years is not recommended.

Seropositive patient with nonspecific symptoms

Patients with nonspecific symptoms such as myalgias, arthralgias, concentration difficulties, and fatigue are frequently tested for Lyme disease. Some patients, especially those from endemic areas, test positively and are treated for presumed Lyme disease, often without improvement in their symptoms. In several studies over 50% of patients reporting to Lyme disease clinics did not have evidence of Lyme disease, and the reason for a lack of response to antibiotics was an incorrect diagnosis. Objective clinical evidence in support of the diagnosis of Lyme disease should be sought prior to initiating antibiotics, treatment should be given for the recommended duration and then discontinued, and the patient observed for resolution of symptoms.

Post-lyme disease syndrome

Some patients continue to have subjective symptoms after completion of recommended courses of antibiotics for Lyme disease. Symptoms typically include arthalgias, myalgias, fatigue, and neurocognitive difficulties. A study of patients treated for EM reported that approximately 5% to 15% of patients experienced subjective symptoms when evaluated 6 to 12 months after treatment. Such symptoms may persist for 5 or more years after treatment. This postinfectious syndrome does not appear to be related to persistent infection with *B. burgdorferi*. In a study of patients with post-Lyme disease syndrome there were no significant outcome differences between the groups who received either intravenous ceftriaxone for 30 days followed by oral doxycycline for 60 days and those that received placebo. The IDSA guidelines do not recommend antibiotic therapy for patients with chronic (>6 months) subjective symptoms after recommended treatment regimens for Lyme disease.

Prevention of lyme disease

Recommended personal protective measures against tick bites include wearing light-colored clothing, long-sleeve shirts, and long pants; tucking pant legs into socks; using a tick repellent on clothing and exposed skin; and performing regular body checks for ticks, strategies that require significant self-motivation. Environmental strategies include the application of acaricides onto vegetation where the ticks live, acaricides delivered directly to tick hosts to kill ticks on the animals, and excluding deer from areas. The last is not practical in most environments.

Public interest in human and veterinary vaccines prompted researchers to develop a safe and effective vaccine for the prevention of Lyme disease. The results of two large safety and efficacy trials using recombinant OspA preparations reported the vaccine to be safe and effective in preventing Lyme disease in most people. LYMErix™ was approved by the US Food and Drug Administration (FDA) for use in individuals aged 15 and older in 1999. The vaccine manufacturer discontinued production in 2002, citing insufficient consumer demand. Protection provided by this vaccine diminishes over time. Individuals that received the Lyme disease vaccine prior to 2002 are probably no longer protected against Lyme disease.

Summary

Antibiotic regimens are recommended according to results of clinical trials and evolving clinical judgments, and depend upon the stage of infection and the organ system involved. Successful eradication of the infecting organism, *B. burgdorferi*, appears to occur in the majority of patients with Lyme disease using these treatment guidelines. Patients with persistent symptoms following antibiotic therapy, particularly those with previous evidence of disseminated disease, pose a difficult management problem. Most persistent symptoms are likely due to retained antigens and not the result of persistent infection or to noninfectious sequelae such as fibromyalgia. In the former patients, resolution of symptoms occurs over the course of weeks to months and does not require prolonged courses of antibiotics; in the latter, treatment is that of the associated syndrome. Rarely, persistent or recurrent symptoms are due to continued or recurrent infection and require additional courses of antibiotics. Such patients require careful diagnostic evaluation to determine the need for additional treatment.

Borreliosis

Sally J. Cutler

Background

The relapsing fever spirochetes comprise a number of different species (Table 163.1) with many transmitted by specific tick species; classical relapsing fever species are transmitted by rapid-feeding soft tick species, whereas the more recently described *Borrelia miyamotoi* is transmitted by hard tick vectors. *B. recurrentis* is the notable exception in that it is transmitted by clothing lice.

Clinical presentation

The chief sign is that of fever, often accompanied by chills, headaches, arthralgia, myalgia, and tachycardia. Other signs may include jaundice, petechial rash, conjunctivitis, nausea, hepatosplenomegaly, and epistaxis. Infection with *B. duttonii* has been associated with significant perinatal mortality in endemic regions such as Tanzania. *B. miyamotoi*, like other relapsing fever infections, manifests with fever but does not typically produce the classical relapsing febrile episodes. Instead, infection is often accompanied by thrombocytopenia and nonspecific influenza-like symptoms, although immunocompromised individuals have presented with neurological signs.

Although eventually eliminated by the adaptive immune response, repeat infections can occur in a previously infected individual.

Treatment

Cases are usually managed with penicillin, doxycycline, or tetracycline treatment (Table 163.2). Some prefer penicillin as it is believed that this makes Jarisch–Herxheimer reactions (JHR) less likely. Less frequently, cephalosporins, erythromycin, and chloramphenicol have been used.

Jarisch–Herxheimer reactions

The JHR was first described by Adolf Jarisch in 1895 and later by Karl Herxheimer in 1902, in relation to another spirochetal infection, syphilis, but this also occurs in approximately 5% of relapsing fever patients upon treatment. Patients may show an exacerbation of symptoms or "therapeutic shock" during the initial 24 hours after commencing treatment. The JHR is mediated by a release of pyrogenic cytokines (including tumor necrosis factor-α [TNF-α], interleukin [IL]-6, and IL-8) and is treated symptomatically.

TABLE 163.1 **CHARACTERISTICS OF RELAPSING FEVER BORRELLIAE**

Organism name	Arthropod vector/reservoir	Vertebrate reservoirs	Clinical infection	Geographic region
B. recurrentis	*Pediculus humanus*	Man	LBRF–human	Africa (formerly worldwide)
B. baltazardii	Unknown	Unknown	TBRF–human	Iran
B. crocidurae	*Ornithodoros sonrai*	Rodents	TBRF–human	West Africa
B. duttonii	*Ornithodoros moubata*	Man	TBRF–human	Africa (Central, Eastern)
B. hermsii	*Ornithodoros hermsi*	Rodents	TBRF–human; canine	Canada, Western USA
B. hispanica	*Ornithodoros marocanus; Ornithodoros occidentalis; Ornithodoros kairouanensis* (formerly *Ornithodoros erraticus*[a])	Rodents	TBRF–human	Algeria, Morocco, Portugal, Spain, Tunisia
B. latyschewii	*Ornithodoros tartakovskyi*	Rodents; reptiles	TBRF–human	Central Asia, Iran, Iraq
B. mazzottii	*Ornithodoros talaje*	Armadillos; rodents	TBRF–human	Southern USA, Mexico, Guatemala
B. merionesi	*Ornithodoros costalis Ornithodoros merionesi*	Rodents	Unknown	North Africa
B. microti	*Ornithodoros erraticus*[b]	Rodents	TBRF human	Africa, Iran
B. parkeri	*Ornithodoros parkeri*	Rodents	TBRF–human	Western USA
B. persica	*Ornithodoros tholozani*	Rodents; bats	TBRF–human; cat	Asia, Middle East
B. turicatae	*Ornithodoros turicata*	Rodents	TBRF–human; canine; birds	USA, Mexico
B. venezuelensis	*Ornithodoros rudis*	Rodents	TBRF–human	Central and South America
Candidatus B. fainii	*Ornithodoros faini*	Bats	TBRF–human	Zambia

[a] *Ornithodoros erraticus* represented a complex. Recent taxonomic molecular studies redressed the phylogeny suggesting that *O. erraticus sensu stricto* is not an efficient vector for *Borrelia*.
[b] Molecular confirmation of *O. erraticus* identity unavailable at time of writing.
Abbreviations: LBRF = louse-borne relapsing fever; TBRF = tick-borne relapsing fever.

TABLE 163.2 **TREATMENT OF RELAPSING FEVER BORRELIOSIS**

Antibiotic	Dosage used	Duration	Comments
Penicillin	400,000–600,000 IU/d	7–14 d	Single dose can be curative for LBRF CNS involvement
Tetracycline	200–250 mg BID to 500 mg QID	7–14 d	Single dose can be curative for LBRF
Doxycycline	200–250 mg 4 mg/kg/d	7–14 d	Can be used as prophylaxis (200 mg/d on day 1, then 100 mg daily for 4 d postexposure)
Erythromycin	500 mg QID (50 mg/kg children)	7–14 d	During pregnancy or children
Chloramphenicol	500 mg QID (12.5 mg/kg children)	7–14 d	During pregnancy or children
Ceftriaxone	2 g/d	7–14 d	CNS involvement

Abbreviation: CNS = central nervous system.
Azithromycin shows promising *in vitro* activity, but the author is unaware of its evaluation clinically for treatment of relapsing fever patients.

Transmission and pathogenesis

Transmission of tick-borne relapsing fever (TBRF) occurs during the feeding of *Ornithodoros* soft ticks (up to 20–30 minutes), generally while their host is sleeping. The relapsing fever transmitted by hard ticks, though not as rapidly transferred as that in soft ticks, can result in infection with just 1 day of tick attachment. The spirochetes may be present within the tick salivary glands, coxal fluid, and feces, facilitating transmission to their vertebrate host. Transovarial transmission occurs for some TBRF borreliae.

Unlike TBRF, in louse-borne relapsing fever (LBRF), the borreliae within the louse vector penetrate the louse's gut epithelium where they can multiply in the louse hemolymph and are also able to be excreted in louse feces, but they do not undergo transovarial transmission. Human transmission occurs through crushing lice or their feces into skin abrasions often through scratching.

Once the human is infected, spirochetes multiply in the blood, sometimes to levels of up to 100,000/mm^3. This spirochetemia evokes the typical febrile response after which this infection is named. The induced antibody response clears the bloodborne infection; however, the spirochetes soon reemerge, having undergone antigenic variation. A new wave of infection follows that again is eventually controlled through the host's antibody response. Clinically, up to 4 to 5 febrile episodes can occur in LBRF, whereas up to 13 relapses have been recorded for TBRF. Persistence within the human host is a result of a complex interplay of antigenic variation, complement evasion strategies, erythrocyte rosetting, and potentially other mechanisms.

The spirochetes show varying neurotropic potential. This can promote cerebral hemorrhage, for example with *B. recurrentis*. They cross the placenta, with associated fetal loss through abortion or congenital infection, particularly *B. duttonii*. Myocarditis and hepatic failure may complicate infection with some of the more virulent members of the relapsing fever borreliae (*B. recurrentis/B. duttonii*), where mortality can reach 10% in untreated cases.

Laboratory diagnosis

Microscopy has been the primary diagnostic approach, with demonstration of the spirochetes in blood with Wright's or Giemsa stains, silver staining, or the use of dark-field microscopy for observing motile spirochetes (Figure 163.1). Although these methods can detect the causative species, sensitivity is poor, particularly for some species such as *B. crocidurae*, where the blood burden is lower than in, for example, *B. recurrentis*. This is further complicated by the need to collect blood during febrile episodes. It is not possible to differentiate species using microscopy.

Animal inoculation can recover and identify cultivable strains. Cultivation can also be achieved from clinical samples into specialized media (such as BSKII) but this is technically demanding. This has been largely superseded by molecular identification approaches, and molecular diagnostics are currently the mainstay for both detection and typing of relapsing fever borreliae.

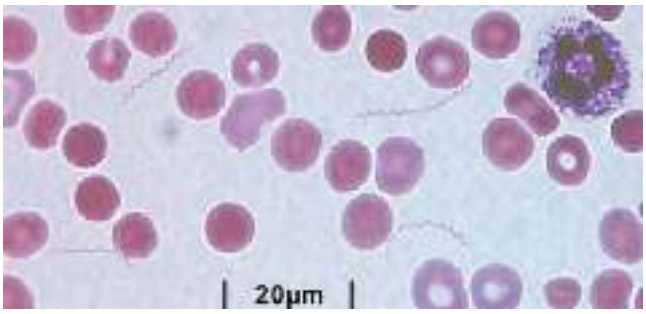

FIGURE 163.1 Giemsa-stained spirochetes in a blood film.

Current epidemiology

The relapsing fever spirochetes have been divided into Old World and New classes; however, with improving phylogenetic tools, this division now appears artificial. The prevalence of tick-borne strains correlates with specific regions, particularly African TBRF, probably resulting from climatic conditions conducive for its tick vector. This has not been the case for louse-borne *B. recurrentis*, which was formerly worldwide, but now is restricted to areas where clothing lice persist.

Figure 163.2 depicts the global location of relapsing fever.

It is increasingly apparent that the burden of relapsing fever infections in endemic regions is underdiagnosed. Recent reports from Senegal have suggested that this is the cause of some 13% of fevers presenting at local dispensaries, representing an alarming 11 to 25 cases per 100 person-years. Studies of febrile patients in Morocco have suggested that 20.5% were TBRF cases. Although not at these levels, cases are more frequently being detected in the United States.

Epidemiology of LBRF has changed drastically with the reduced level of infestation with clothing lice. The infection remains in areas of extreme poverty such as Ethiopia, sometimes spilling into adjacent regions, such as an outbreak in the Darfur region of Sudan. During this outbreak between 1999 and 2000, some 20,000 cases occurred with a 10% mortality rate.

Reservoirs of infection

The majority of relapsing fever spirochetes are zoonoses with vertebrate reservoir species (Table 163.1). In the majority of cases, these reservoir species are rodents; however, bats, birds, and reptiles may also play a reservoir role. The notable exceptions are *B. recurrentis* and *B. duttonii*, both of which have an exclusive human reservoir. Many also consider the tick vector a reservoir of infection for TBRF, facilitated by transovarial transmission of infecting

FIGURE 163.2 Global location of relapsing fever.

Borrelia to the next generation and the impressive longevity of these ticks, which can survive for many years with their infecting spirochetes.

Risk groups

Both LBRF and TBRF have their greatest burden among those living in extreme poverty. Occupational contact with tick-infested environments has resulted in clusters of infection, particularly among military personnel who have used caves during training activities, with a resulting clinical burden of up to 6.4 cases/100,000 in Israel. Similarly, conservation workers are at risk. Imported cases have been encountered through migration and tourism, typically in rural regions where intermittently used holiday accommodation has provided refuge for reservoir hosts and their associated tick vectors.

Control and prevention

Relapsing fever spirochetes remain susceptible to penicillin, tetracycline/doxycycline, chloramphenicol, ceftriaxone, and erythromycin (Table 163.2). Wide use of antimicrobials coupled with improvements in living conditions have reduced the incidence of infection. This is not so apparent for the tick-borne forms of disease that persist in their longer lived tick vector/reservoirs and through zoonotic vertebrate reservoir species. The burden of TBRF among subsistence agro-pastoralist communities in developing nations remains substantial. Use of acaricides has met with some success, but costs are prohibitive. If contact is unavoidable, doxycycline prophylaxis has been used for short-term prevention.

Leptospirosis

Daniela E. DiMarco

Overview

Leptospirosis is a zoonotic disease caused by spirochetes from the genus *Leptospira*, of which >200 serovars infect humans. Infections are most commonly caused by *L. interrogans,* one of at least 10 pathogenic species. Infection in humans typically occurs after exposure to a contaminated environmental source (e.g., water or soil contaminated by rodent urine) or an infected animal. *Leptospira* penetrate intact mucous membranes and abraded skin and disseminate widely via the bloodstream. Symptoms develop 5 to 14 days after exposure. Most patients have an abrupt onset of a self-limited, 5 to 7 day anicteric illness characterized by fever, headache, conjunctival suffusion, myalgias, chills, cough, neck stiffness, and/or prostration (Box 164.1), though frequency of symptomatology reported is highly variable across studies and regions.[1–3] An estimated 10% of patients will present with severe disease, having jaundice, hemorrhage, renal failure, and/or neurologic dysfunction (Weil's disease).[4] The major clinical manifestations of severe disease may result from secondary vasculitis (Box 164.2).

Classically, leptospirosis has been considered a biphasic illness. However, many patients with mild disease will not have symptoms of the secondary "immune" phase of illness, and patients with very severe disease may have progression from onset of illness to jaundice, renal failure, hemorrhage, hypotension, and coma. The incubation period from initial exposure ranges from days up to 4 weeks after exposure (mean 10–12 days). The illness is biphasic in about half of patients, with relapse occurring approximately 1 week after resolution of the initial febrile illness. A late complication is anterior uveitis, seen in up to 12% of patients months to years after convalescence.[5] Leptospirosis in pregnancy is associated with spontaneous abortion, but it is not known to increase the rate of congenital anomalies.[4]

Case fatality rates for leptospirosis are estimated at 5–15% in severe disease, while mild infection is usually self-limited.[4] Death often results from complications of renal failure, gastrointestinal and/or pulmonary hemorrhage, and acute respiratory distress syndrome (ARDS). Highest morbidity and mortality from leptospirosis is seen in more rural and resource-limited regions where the disease is thought to be underrecognized and underreported.[6]

Epidemiology

Leptospirosis is endemic to tropical environments, though infection also occurs in seasonally in temperate climates. According to the US Centers for Disease Control and Prevention (CDC), it is estimated that there are >1 million cases annually worldwide, with <200 of those occurring in the United States (primarily in Puerto Rico and Hawaii).[4] Globally, the majority of cases are among men (80%) and younger adults (aged 20–49).[7] Several outbreaks internationally and in the United States highlight the significance of recreational water activities and risks associated with exposure to floodwaters and travel, especially to Southeast Asia or for adventure tourism.[3,8,9] Occupational exposures remain a concern internationally, particularly related to

Symptoms and signs of leptospirosis

Fever (84–100%)
Headache (9–99%)
Myalgias, muscle tenderness (20–100%)
Vomiting and/or diarrhea (5–78%)
Conjunctival suffusion (4–99%)
Jaundice (5–93%)
Hepatomegaly (15–83%)
Splenomegaly (2–49%)
Meningeal signs (5–27%)
Oliguria (26%)
Cough (20–57%)
Skin rash (7–8%)

BOX 164.3

Epidemiology and exposure considerations for leptospirosis

Leptospira are excreted in animal urine and survive in the environment for up to 6 months
Common in the tropics, especially in urban slums
Recreational exposures: Windsurfing, kayaking, swimming, camping, and adventure tourism
Occupational exposures: Farmers, sewer workers, military personnel working in the tropics, veterinarians, abattoir workers, and others with exposure to rodent urine or bites (homeless population, rodent control workers)
Outbreaks seen after floods

farming.[1] Knowledge of epidemiologic risk factors is key to making the diagnosis (Box 164.3).

Diagnosis

An epidemiologic risk assessment is key to making a timely and accurate diagnosis of leptospirosis, particularly in the setting of fever in a traveler. Since the clinical presentation is often indistinguishable from influenza, acute viral hepatitis, malaria, and other viral and rickettsial vector-borne infections, these too should be included in the differential. The prominent myalgias, conjunctival suffusion, elevated serum creatine phosphokinase, and the relatively mild (two- to threefold) elevations in transaminases seen in leptospirosis may help to distinguish icteric leptospirosis from an acute viral infection (Box 164.4).

There are several different diagnostic assays for *Leptospira*, yet the diagnosis remains challenging due to test-specific technical limitations and availability. Serologic and culture-based testing methods remain the standard. Both are limited by low sensitivity in very early infection, and neither are species or serovar specific. Traditionally, the diagnosis is made retrospectively by a four-fold rise in titer from the acute to convalescent phase, as measured by the microscopic agglutination test (MAT).[10,11] Though the MAT is the gold standard, limitations include cross-reactivity with other spirochetes, technical performance challenges, lab requirements to maintain a culture supply, and overall limited availability; primarily found at reference labs like the CDC. Enzyme-linked immunosorbent assay (ELISA) kits are commercially available and detect immunoglobulin M (IgM) antibodies, thus enabling diagnosis during the first week of illness.[10] Culture of blood and cerebrospinal fluid is best if collected early in the acute phase and requires prolonged incubation for growth. Urine cultures may also be intermittently positive for several months.[10,11] Polymerase chain reaction (PCR) testing is available for more rapid diagnosis and has been demonstrated to be most sensitive in the early phase of illness in a selected populations with high pre-test probability of disease.[12] Due to limited availability of the MAT, commercial IgM assays have become first-line testing, with the MAT or PCR as the confirmatory assay. Immunohistochemical staining for pathology specimens and dark-field microscopy are also available. Within the World Health Organization Leptospirosis Guideline, it is noted that rapid screening tests are commercially available, which employ

BOX 164.2

Pathogenesis of leptospirosis

Vasculitis with damage to capillary endothelial cells contributes to the following:
Renal tubular dysfunction
Hepatocellular dysfunction
Pulmonary hemorrhage
Muscle focal necrosis
Coronary arteritis

BOX 164.4

Prominent diagnostic test abnormalities in severe leptospirosis

Renal failure, with or without acute interstitial nephritis
Liver injury: Two- to threefold elevations in transaminases and alkaline phosphatases, conjugated hyperbilirubinemia
Elevated creatine phosphokinase with myositis
Thrombocytopenia, elevated sedimentation rate
Cerebrospinal fluid lymphocyte predominant pleiocytosis, elevated protein, and normal glucose with aseptic meningitis
Abnormal chest radiographs: Patchy alveolar pattern in lower lobes with or without interstitial/alveolar hemorrhage
Electrocardiogram abnormalities: Sinus tachycardia, myocarditis, first-degree atrioventricular block

BOX 164.5

Treatment of leptospirosis

Outpatient treatment: Doxycycline, 100 mg PO BID for 7 days in adults

Severe infection: Penicillin G, 1.5 million units IV q6h, ampicillin 0.5–1g IV q6h, or ceftriaxone 1 g IV or IM daily

Chemoprophylaxis: 200 mg doxycycline PO once weekly while at high risk (e.g., travellers, military personnel)

various antibody detection technologies, though confirmatory testing for any result is advised using MAT.[13]

Treatment

Although the illness is self-limited and often mild, treatment is recommended. Doxycycline, 100 mg orally twice daily for 7 days is recommended for mild illness.[14] Alternative regimens for mild disease include azithromycin or amoxicillin.[11] Penicillin G at a dosage of 6 million units per day in divided doses has been successful for early treatment of severe disease, and ceftriaxone (1 g/d) appears to be equally efficacious and has the benefits of simpler dosing schedules and potential intramuscular administration (Box 164.5).[15,16] Jarisch–Herxheimer reactions (fever, rigors, hypotension, and tachycardia) may occur on initiation of antibiotic therapy. In cases of severe disease, supportive care and management of hypotension, renal failure, and hemorrhage are crucial for reducing morbidity and mortality from infection. There is insufficient evidence to support the use of steroids in severe disease.[17] Immunization of animals, chemoprophylaxis, and personal protective measures in high risk areas are keys to preventing infection.

Section 20

Specific organisms: Mycoplasma and Chlamydia

165

Mycoplasma

Ken B. Waites and Sixto M. Leal, Jr.

Mycoplasmas are the smallest free-living organisms and are unique among prokaryotes in that they lack a cell wall, a feature that is largely responsible for their biologic properties and lack of susceptibility to many commonly prescribed antimicrobial agents. Mycoplasmas are usually mucosally associated, residing primarily in the respiratory and urogenital tracts and rarely penetrating the submucosa except in the case of immunosuppression or instrumentation, when they may invade the bloodstream and disseminate to many different organs and tissues throughout the body. Intracellular localization occurs in some species, such as *M. genitalium* and *M. pneumoniae* and may contribute to the chronicity that characterizes many mycoplasmal infections.

There are at least 17 species of mycoplasmas and ureaplasmas for which humans are believed to be the primary host and numerous others of animal origin that have been detected occasionally, most often in the setting of immunosuppression. Several human mycoplasmal species are commensals in the upper respiratory or lower urogenital tracts. Five species are responsible for the majority of clinically significant infections that may come to the attention of the practicing physician. These species are *M. pneumoniae*, *M. hominis, M. genitalium*, *Ureaplasma urealyticum*, and *U. parvum*. *M. fermentans* is another mycoplasma of human origin that may behave as an opportunist. *M. fermentans* has been detected in throat cultures of children with pneumonia, in some cases when no other etiologic agent was identified, but the frequency of its occurrence in healthy children is not known. This mycoplasma has also been detected in adults with an acute influenza-like illness and in bronchoalveolar lavage specimens from patients with the AIDS and pneumonia. *M. amphoriforme* is the newest human mycoplasma to be described. It has been detected in persons with antibody deficiencies suffering from recurrent bronchitis as well as immunocompetent hosts with lower respiratory tract symptoms. However, its true role as a human pathogen has not yet been firmly established. Oral commensal species such as *M. salivarium* are known to cause arthritis in immunocompromised persons with antibody deficiencies. Other mycoplasmas of animal origin occasionally cause zoonotic infections.

Mycoplasma pneumoniae respiratory disease

M. pneumoniae occurs endemically and occasionally epidemically in persons of all age groups, most commonly in school-aged children, adolescents, and young adults. The common misconception that *M. pneumoniae* disease is rare among very young children and older adults has sometimes led to failure of physicians to consider this organism in differential diagnoses of respiratory infections in these age groups. Failure to consider *M. pneumoniae* as an etiologic agent in cases of severe pneumonia may also lead to misdiagnosis since this organism can cause severe respiratory disease that has caused death in some cases, usually in otherwise healthy persons. It is likely that serious disease occurs more often than is currently appreciated but goes undetected when specific tests to detect *M. pneumoniae* are not performed. *M. pneumoniae* is perhaps best known as the primary cause of "walking or atypical pneumonia," but the most frequent clinical syndrome is tracheobronchitis or bronchiolitis, often accompanied by upper respiratory tract manifestations. Typical complaints can persist for weeks to months and include hoarseness, fever, cough which is initially

nonproductive but later may yield small to moderate amounts of non-bloody sputum, sore throat, headache, chills, coryza, and general malaise. The throat may be inflamed but cervical adenopathy is uncommon. Bronchopneumonia, involving one or more lobes, often develops in infected persons, accounting for 20% or more of community-acquired pneumonias overall and an even greater percentage in closed populations such as college dormitories, military barracks, and prisons. The incubation period is generally 1 to 3 weeks and household spread is common. Epidemiologic studies have shown *M. pneumoniae* was second only to *Streptococcus pneumoniae* as an etiologic agent of pneumonia in adults requiring hospitalization. Hospital admission may be necessary in about 10% of children and adults with *M. pneumoniae* infection, but recovery is usually complete without sequelae. Coinfection and secondary infections can occur, increasing patient morbidity and mortality. Some people may experience extrapulmonary complications at variable time periods after onset or even in the absence of respiratory illness. Such complications most commonly include skin rashes, pericarditis, hemolytic anemia, arthritis, meningoencephalitis, peripheral neuropathy, and pericarditis. Other nonspecific manifestations include nausea, vomiting, and diarrhea. Mycoplasmal infection may also be associated with exacerbations of asthma. Whether the organism can act independently in the pathogenesis of asthma has not been firmly established, but the fact that it can induce a number of inflammatory mediators such as IgE and that administration of macrolide antibiotics improves lung function of asthmatic persons with evidence of mycoplasmas in their airways suggests this possibility is worthy of further study.

Following inhalation, *M. pneumoniae* moves by gliding motility to the ciliated respiratory epithelium where its polar organelle mediates cytadherence through a complex system of protein adhesins. The community-acquired respiratory distress syndrome (CARDS) exotoxin of *M. pneumoniae* is an adenosine diphosphate (ADP)-ribosyltransferase located over the entire surface of the cell that contributes to host cell damage by inducing ciliostasis, airway vacuolization, elicitation of a lymphocytic and eosinophilic airway exudate, and upregulation of various cytokines and chemokines. Clinical manifestations and host cell damage are also mediated by other virulence factors including nucleases, hydrogen peroxide, and production of autoantibodies that react with a variety of host tissues. Autoimmune reaction is thought to be responsible for many of the extrapulmonary complications associated with mycoplasmal infection. However, *M. pneumoniae* has been isolated from extrapulmonary sites such as synovial fluid, cerebrospinal fluid (CSF), pericardial fluid, and skin lesions, and it has also been detected by polymerase chain reaction (PCR) assays at additional extrapulmonary sites.

FIGURE 165.1 Chest radiograph of a female adolescent with polymerase chain reaction (PCR)-proven mycoplasmal pneumonia, demonstrating bilateral infiltrates.
Radiograph courtesy of T. Prescott Atkinson, MD, PhD.

The hemogram is often normal, but about one-fourth of patients may develop leukocytosis and one-third may demonstrate an elevated erythrocyte sedimentation rate. The cellular response of the sputum is mononuclear, with no bacteria visible by Gram stain (due to lack of a cell wall). In about 50% of patients, a cold agglutinin titer of ≥1:32 may develop by the second week of illness, disappearing by 6 to 8 weeks. Production of cold agglutinins is due to IgM autoantibodies directed against the I antigen on host erythrocytes. However, it is not a specific test for *M. pneumoniae*, since other microorganisms may induce similar reactions. Several viruses, *Chlamydia pneumoniae*, *S. pneumoniae*, *Haemophilus influenzae*, *Moraxella catarrhalis*, *Legionella* spp., and even some mycobacteria or fungi can produce infections which are clinically indistinguishable and may coexist with mycoplasmal infection.

Lung involvement tends to be unilateral, but can be bilateral. Diffuse reticulonodular or interstitial infiltrates involving the lower lobes and appearing as streaks radiating from the hilus to the base of the lung are the most common radiographic abnormalities. True lobar consolidation is uncommon, but pleural effusion may develop in about 25% of cases. Abnormalities on chest radiographs often appear more severe than the clinical condition of the patient would predict. A typical radiographic presentation of mycoplasmal pneumonia is shown in Figure 165.1.

Due to widespread lack of diagnostic services, length of time until results can be obtained, impracticality of obtaining diagnostic specimens, and similarity of clinical syndromes due to different microorganisms, clinicians often do not attempt to obtain a microbiologic diagnosis in mild to moderately ill outpatients suspected of having *M. pneumoniae* infection and elect to treat empirically. Rapid point-of-care diagnostics would enable same-visit diagnosis of *M. pneumoniae* infection in the outpatient setting and prompt appropriate antibiotic treatment and mitigation of disease progression. Unfortunately, such testing is not currently available. Progression of the illness to sufficient severity requiring hospitalization justifies the search for a specific microbiologic etiology. This testing is often performed with large molecular-based respiratory pathogen syndromic panels, by culture, and/or serologic tests for *M. pneumoniae*. Clinical laboratories may offer culture through a reference laboratory familiar with the complex cultivation requirements of mycoplasmas. Respiratory tract specimens suitable for culture include throat swabs, sputum, tracheal aspirates, bronchial lavage

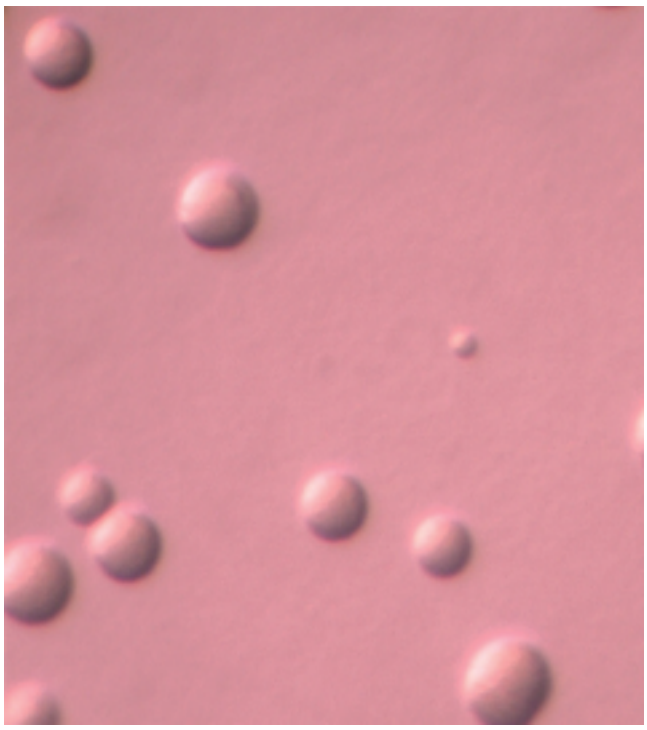

FIGURE 165.2 Spherical colonies of *Mycoplasma pneumoniae* approximately 100 μm in diameter growing on SP4 agar (126×).

fluid, pleural fluid, or lung biopsy tissue according to the patient's clinical condition. Care should be taken in specimen collection, inoculation into a suitable transport medium (such as SP4 broth) at bedside whenever possible, and not allowing desiccation. Freezing at −70°C/−94°F is advised if specimens cannot be transported to the diagnostic laboratory immediately after collection. Growth in culture is slow, requiring 3 to 6 weeks in some cases. Growth of a glucose-fermenting mycoplasma in SP4 broth and development of microscopic spherical colonies approximately 100 μm in diameter on SP4 agar, as shown in Figure 165.2, are presumptive evidence of *M. pneumoniae*. Since some of the upper respiratory commensal mycoplasmal species may also grow on this medium, it is necessary to confirm the identity of the organisms using PCR assay. Due to the turnaround time, expense, and limited availability, culture is rarely used for routine diagnosis of *M. pneumoniae* infection and is more useful for epidemiological purposes.

Serology has been used historically to confirm *M. pneumoniae* infection. Enzyme-linked immunosorbent assays are preferred over complement fixation assays or cold agglutinin titers. Since primary infection does not guarantee protective immunity against future infections and residual antibody may remain from earlier encounters with the organism, there has been a great impetus to develop sensitive and specific tests that can differentiate between acute or remote infection. Definitive diagnosis requires seroconversion documented by paired serum specimens obtained 2 to 4 weeks apart and assayed at the same time. Although single-titer qualitative and quantitative IgM or IgA assays purported to detect current infection are available, IgM can persist for many weeks after acute infection and as many as 50% of adults may not mount a detectable IgM response. Conversely, some children may not mount a measurable IgG response. Therefore, reliance on a single serologic test can be clinically misleading, and paired assays for both IgM and IgG are recommended. Even then, the interpretation of serologic results can often be confusing and inconclusive.

Molecular-based systems for rapid detection of *M. pneumoniae* alone or in combination with other respiratory pathogens are now available within institutions or through reference laboratories. The US Food and Drug Administration (FDA) has cleared assays targeting *M. pneumoniae* as part of a large panel of pathogens that include the BioFire (bio Mérieux), ePlex (GenMark), and MagPix (Luminex), and the QIAstat-Dx (Qiagen) platforms. Singleplex assays targeting *M. pneumoniae* include the FDA-cleared *Mycoplasma* Direct (Meridian) and laboratory-developed assays at reference labs such as the UAB Diagnostic Mycoplasma Laboratory and the Centers for Disease Control and Prevention (CDC). There are many other commercial molecular-based detection systems available in Europe and other locations. Given the limitations of culture and serology, molecular-based detection is the method of choice for detection of acute *M. pneumoniae* infection.

Treatment of *Mycoplasma pneumoniae* infections

Formerly it was believed that mycoplasmal respiratory infections were entirely self-limited and that no antimicrobial treatment was indicated. More recently it has been shown that appropriate antimicrobial therapy will shorten the symptomatic period and hasten radiologic resolution of pneumonia and recovery, even though organisms may be shed for several weeks. In general, the clinical efficacy of antimicrobial therapy is correlated with severity of pneumonia and elapsed time of illness before treatment is begun. A summary of treatment alternatives for *M. pneumoniae* respiratory infections is provided in Table 165.1.

M. pneumoniae is generally susceptible to macrolides, ketolides, tetracyclines, and fluoroquinolones such that in vitro susceptibility testing to guide therapy is not indicated at present. Susceptibility testing would also be impractical most of the time because clinical isolates are generally not available and because of the prolonged time that would be necessary to obtain the results. Macrolide resistance in *M. pneumoniae* has been known to occur for many years, but it was believed to be quite rare and of minimal clinical significance. Over the past two decades, the emergence of macrolide-resistant *M. pneumoniae* infections due to mutations in domain V of 23S ribosomal RNA that result in diminished clinical response to macrolide therapy is worrisome. This resistance now affects more than 90% of *M. pneumoniae* isolates in China and Japan and also occurs in the United States and Europe. Surveillance data from the United States from 2015 to 2018 found 7.6% macrolide-resistant infections overall, with resistance rates generally higher in the northeastern and southern regions than in the western states. Laboratory-developed PCR assays at the UAB Diagnostic Mycoplasma Laboratory and the CDC include high-resolution melt curve analyses to identify

TABLE 165.1 **TREATMENT OPTIONS FOR RESPIRATORY TRACT INFECTIONS CAUSED BY *MYCOPLASMA PNEUMONIAE*[a]**

Drug	Route	Dosage/24 h		Comments
		Pediatric	Adult	
Doxycycline	PO	4 mg/kg loading dose d 1, then 2–4 mg/kg/d in 1–2 doses × 10–14 d	200 mg loading dose d 1, then 100 mg q12h × 9–13 d	All tetracyclines have a detrimental effect on the skeletal development and bone growth of the fetus and should not be used in the second half of pregnancy or in children <8 yrs of age unless there is no other alternative
	IV	Same as PO	Same as PO	
Tetracycline	PO	25–50 mg/kg/d in 4 doses × 10–14 d	250–500 mg q6h × 10–14 d	
	IV	10–20 mg/kg/d in 2–4 doses × 10–14 d	500 mg–1 g q6–12h × 10–14 d	
Tigecycline	IV	Not recommended	100 mg loading dose, then 50 mg q 12h x7-14d	
Erythromycin	PO	20–50 mg/kg/d in 3–4 doses × 10–14 d	250–500 mg base/stearate q6h or 400–800 mg ethylsuccinate q6h × 10–14 d	Erythromycin is rarely used because newer macrolides are better tolerated and have longer half lives enabling once daily dosage.
	IV	25–40 mg/kg/d in 4 doses × 10–14 d	Same as PO	
Azithromycin	PO	10mg/kg/d on d 1, then 5 mg/kg/d × 4 d; not to exceed 250 mg/d	500 mg d 1, then 250 mg qd × 4 d or 2 g given as a single dose	IV formulation is not approved for use in persons <16 yrs of age
	IV	Not recommended	500 mg qd IV × 2 d, then 500 mg PO qd × 7–10 d	
Clarithromycin	PO	15 mg/kg/d in 2 doses × 7–14 d	250–500 mg q12h × 7–14 d (immediate release) or 1 g qd × 7 d (extended release)	No IV formulation is available
Levofloxacin	PO	6 mo–4 yrs: 8–10 mg/kg dose divided q12h × 10 d 5–12 yrs: 8–10 mg/kg dose divided q24h × 10d (max 750 mg per dose) Adolescents: 8–10 mg/kg divided q24h (max 750 mg per dose) × 10 d	750 mg qd × 5 d or 500 mg qd x -14d	Fluoroquinolones are not approved to treat respiratory tract infections in persons under 18 yrs of age, but levofloxacin has been used successfully to treat macrolide-resistant *M. pneumoniae* infections in children who failed treatment with macrolides.
	IV	Same as PO	Same as PO	
Moxifloxacin	PO	Not recommended	400 mg qd × 7–14 d	
	IV	Not recommended	Same as PO	
Gemifloxacin	PO	Not recommended	320 mg qd × 7 d	No IV formulation is available

[a] Treatment recommendations are primarily for management of community-acquired pneumonia with antibiotics approved for treatment of this condition although they are also appropriate for tracheobronchitis due to this organism. Choice of routes for administration depends on the severity of the clinical condition being treated. Most *M. pneumoniae* infections can be adequately treated with oral medication.

genotypes associated with macrolide resistance. Commercial PCR assays targeting macrolide resistance are in development but are not currently available.

The macrolides clarithromycin and azithromycin are broad-spectrum agents used primarily for treatment of community-acquired respiratory infections caused by a wide array of bacteria. These agents are very active in vitro against *M. pneumoniae* and inhibit its growth at comparable or lower minimum inhibitory concentrations (MICs) than those of erythromycin unless the strain has ribosomal mutations conferring

macrolide resistance. These drugs have proven clinical efficacy and approved therapeutic indications for pneumonia caused by this organism. Care must be taken because of numerous potential drug interactions with these macrolides. Clarithromycin and azithromycin are available as pediatric oral suspensions, and azithromycin is also available as an intravenous (IV) formulation. Tetracycline and its analogs are also effective in vivo and in vitro, but should not be used in children due to potential bone and tooth toxicity. Clindamycin is effective in vitro, but it may not be active in vivo and should not be considered a first-line treatment. None of the β-lactams, sulfonamides, or trimethoprim is effective in vitro or in vivo against *M. pneumoniae*.

Fluoroquinolones exhibit bactericidal anti-mycoplasmal activity but are less potent in vitro than the macrolides against *M. pneumoniae*. Development of quinolones with documented clinical efficacy and approved indications for treating *M. pneumoniae* has been driven largely by the need for therapeutic alternatives for β-lactam- and macrolide-resistant *S. pneumoniae* and the desire for agents that can be used as empiric monotherapy for respiratory infections due to other typical and atypical organisms. At present, fluoroquinolones are not approved for treatment of respiratory infections in persons <18 years of age, but these drugs are widely used for treatment of respiratory infections in adults and represent an alternative therapy for *M. pneumoniae* disease in children when there is treatment failure due to macrolide resistance.

Mycoplasmas are slow-growing organisms; thus one would logically expect respiratory infections to respond better to longer treatment courses than might be offered for other types of infections. Thus, a 14- to 21-day course of oral therapy is appropriate for some drugs, but some of the newer agents have shown clinical efficacy against mycoplasmal pneumonias with shorter durations. For example, a 5-day course of oral azithromycin is approved for treatment of community-acquired pneumonia due to *M. pneumoniae*.

In addition to the administration of antimicrobials for management of *M. pneumoniae* infections, other measures such as cough suppressants, antipyretics, and analgesics should be given as needed to relieve the headaches and other systemic symptoms. Since most extrapulmonary manifestations are diagnosed late in the course of disease, the benefit of early treatment is unknown. However, high-dose steroid therapy and/or IV immunoglobulin may help reverse neurologic symptoms, if present. If treatment of extrapulmonary mycoplasmal infections is necessary, and/or the patient is immunosuppressed, selection of an agent that exhibits bactericidal activity, such as a fluoroquinolone, is most appropriate and administration of the drugs for longer durations will be required.

Fortunately, the treatments of choice for *M. pneumoniae* are appropriate for many of the other microbial agents responsible for community-acquired respiratory infections. This is especially important in view of the fact that, in the major proportion of ambulatory patients seeking medical care, the identity of their infectious organism is never determined.

Genital *Mycoplasma* and *Ureaplasma* infections

Ureaplasma spp. and *M. hominis* can be isolated from the lower genital tract in the majority of sexually active women; their occurrence is somewhat less frequent in men. The presence of genital mycoplasmas in so many asymptomatic persons has made it difficult to prove their pathogenic potential. For some conditions in which ureaplasmas have been detected such as cystitis, male urethritis, urinary calculi *Ureaplasma* spp., and for cases of pelvic inflammatory disease (PID) in which *M. hominis* has been detected, evidence is sufficient to implicate these organisms as etiologic agents in a subset of clinical cases. For other conditions such as prostatitis and bacterial vaginosis the evidence is not as clear-cut. Only a subgroup of otherwise healthy adult men and women who are colonized will develop clinically significant genitourinary disease due to these organisms, but the risk factors are poorly understood. Table 165.2 summarizes diseases associated with or caused by genital mycoplasmas and ureaplasmas.

The ability of genital mycoplasmas to be transmitted vertically from mother to offspring in utero or at the time of delivery has led to considerable efforts to ascertain their role as perinatal pathogens. Isolation of *Ureaplasma* spp. from the chorioamnion of pregnant women has been consistently associated with histologic chorioamnionitis and is inversely related to birth weight, even when adjusting for duration of labor, rupture of fetal membranes, and presence of other bacteria. *Ureaplasma* spp. can be isolated from endometrial tissue of healthy, nonpregnant women, indicating that they may be present at the time of implantation and might therefore be involved in early pregnancy losses. Numerous studies have shown that the presence of ureaplasmas alone or with other bacteria in the chorioamnion is independently associated with birth at <37 weeks of gestation regardless of the duration of labor. The ability of ureaplasmas to invade the amniotic fluid early in gestation and initiate inflammation provides the setting through which they can also produce inflammation in the lower respiratory tract of the developing fetus and neonate. Over the past several years there has been increasing evidence that these organisms may cause congenital pneumonia and initiate events leading to chronic lung disease of prematurity or bronchopulmonary dysplasia. Superficial mucosal colonization in the newborn period tends to be transient and without sequelae, but neonates, especially those born preterm, have been shown to be susceptible to development of a variety of systemic conditions due to either *M. hominis* or ureaplasmas, including bacteremia and meningitis.

For many years *U. urealyticum* was the only species known to infect humans. However, this organism was eventually subdivided into two separate species, *U. urealyticum* and *U. parvum*, based on 16S rRNA sequences. *U. parvum* is the more common species isolated from clinical specimens, but both species may occur simultaneously. Many clinical studies have not distinguished between the two species except in recent years because nucleic acid amplification tests are necessary to discriminate between them. Evidence is

TABLE 165.2 **DISEASES ASSOCIATED WITH OR CAUSED BY GENITAL MYCOPLASMAS**

Disease	*Ureaplasma* spp.	*M. hominis*	*M. genitalium*
Male urethritis	+[a]	−	+

Extragenital disease in adults[b]	+	+	+
Posttransplant hyperammonemia	+	+	_

− = no association or causal role demonstrated. In some conditions for *M. genitalium* this may reflect the fact that no studies using appropriate techniques to detect this organism have been performed.
+ = causal role.
± = significant association and/or strong suggestive evidence, but causal role not proven.
[a] *U. urealyticum* is more commonly involved in urethritis than *U. parvum*
[b] these include conditions such as septic arthritis, bloodstream invasion, abscesses, wound infections, lung infections, endocarditis, and osteomyelitis.

accumulating to suggest that *U. urealyticum* may be more pathogenic in some conditions such as male urethritis.

Extragenital infection with *M. hominis* and/or *Ureaplasma* spp. beyond the neonatal period is usually associated with some degree of immunocompromise, such as congenital hypogammaglobulinemia, iatrogenic immunosuppression following solid organ transplantation, or with invasive procedures such as instrumentation of the urinary tract. Ureaplasmas and other mycoplasmas are etiologic agents of septic arthritis in the setting of congenital antibody deficiencies and should be considered early when attempting to diagnose these conditions.

While the virulence factors and pathogenesis of *M. pneumoniae* infections have been studied extensively, there is considerably less known about how urogenital mycoplasmas produce disease. *M. genitalium* has a polar organelle similar to that of *M. pneumoniae* that facilitates its attachment and internalization into host cells. Other known virulence factors of *M. genitalium* include nucleases that provide a source of nucleotide precursors and antimicrobial resistance. *M. hominis* and *Ureaplasma* spp. do not possess a recognizable polar attachment organelle. However, *M. hominis* has a variable adherence-associated antigen (Vaa) that is involved with cytadherence and avoidance of host immune response through antigenic variation. Additional surface proteins such as OppA are also involved in cytadherence and induction of apoptosis in host cells. Ureaplasmas are also capable of attachment to a variety of host cell types, including urethral epithelia, spermatozoa, and erythrocytes. As with *Mycoplasma* spp., variation in ureaplasma surface antigens facilitates their persistence in invasive sites. Production of ammonia by both *M. hominis* and *Ureaplasma* spp. is responsible for their production of hyperammonemia in lung transplant recipients and for formation of urinary calculi by ureaplasmas. Ureaplasmas also produce an IgA protease.

Genitourinary or extragenital diseases suspected to be due to mycoplasmas warrant appropriate diagnostic tests when available and treatment if infection is confirmed. This is of particular importance if the organisms are recovered in the absence of other possible microbial etiologies and if the infection is present in a normally sterile site (e.g., *M. hominis* isolation from joint fluid). Practitioners will usually have

to rely on familiarity with clinical syndromes typically due to genital mycoplasmas and treat empirically if facilities for laboratory diagnosis are not readily available. Many of the conditions associated with a mycoplasmal etiology can also be due to a variety of microbial agents and some conditions such as PID can be polymicrobial. Therefore, the selection of drugs must take into account multiple causes.

Both *M. hominis* and ureaplasmas grow rapidly and can be detected in cultures of appropriate specimens within 2 to 5 days. *M. hominis* can be suspected on routine bacterial media as pinpoint colonies that do not show up on Gram stain. Preferred culture methods require proper handling and bedside inoculation of transport broth to enhance recovery of these organisms. Urethral or wound swabs, cervicovaginal or prostatic secretions, urine, respiratory specimens such as those described for *M. pneumoniae*, CSF, and blood or other body fluids or tissues are appropriate for culture depending on the clinical setting. Cultures are available mainly through larger hospital laboratories or reference laboratories. *M. hominis* hydrolyzes arginine in liquid media, produces typical fried-egg colonies on SP4 or A8 agar, and can be presumptively identified by rate of growth and colony morphology (Figure 165.3). Definitive identification requires characterization by PCR. Ureaplasmas can be identified to the genus level by typical colony morphology on A8 agar and urease activity (Figure 165.4). Species determination for ureaplasmas grown in culture requires PCR but is not usually performed for diagnostic purposes.

Currently there are no commercial serologic assays or rapid molecular detection tests available for *M. hominis* and *Ureaplasma* spp. in the United States, but several PCR-based assays are sold in Europe, and reference laboratories in the United States offer laboratory-developed singleplex and multiplex PCR assays for organism detection. Antimicrobial susceptibility testing has been standardized for human mycoplasmas and ureaplasmas with interpretive breakpoints available in the Clinical and Laboratory Standards Document M43A. However, in vitro susceptibility testing is limited to reference laboratories capable of culturing these fastidious organisms. Susceptibility testing can be accomplished by a reference laboratory in 3 to 5 days for *M. hominis* and *Ureaplasma* spp. There are no rapid molecular assays capable of identifying antibiotic resistance in *M. hominis* and *Ureaplasma* spp.

FIGURE 165.3 Fried egg-type colonies of *Mycoplasma hominis* up to 110 μm in diameter (132×).

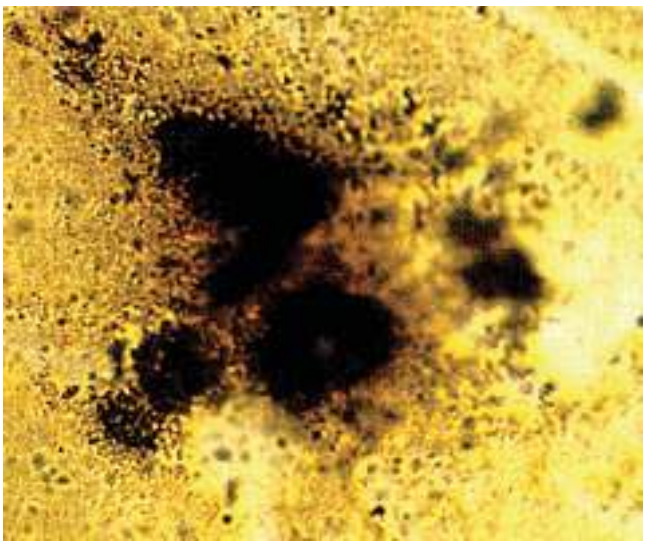

FIGURE 165.4 Granular brown urease-positive colonies of *Ureaplasma* species 15 to 60 μm in diameter from a vaginal specimen growing on A8 agar (100×).

M. genitalium was first isolated from urethral specimens in men with urethritis. It occurs much less commonly in the lower urogenital tract of asymptomatic persons than does *M. hominis* or *Ureaplasma* spp., affecting approximately 1% of young adults in the United States with a global prevalence range of 1% to 6.4%. Asymptomatic carriage is highest amongst sexually transmitted infection clinic attendees, ranging from 9% to >50%. Availability of the PCR assay has greatly enhanced the understanding of the role of *M. genitalium* in human disease. Several clinical studies support a causal role in male urethritis, indicating that it may be responsible for 15% to 25% of all cases and approximately 18% to 46% cases of non-chlamydial non-gonococcal urethritis. *M. genitalium* is also a cause of cervicitis and PID. Although it has been found in the respiratory tract and synovial fluid it has not been implicated in extragenital disease to the same extent as *M. hominis* and *Ureaplasma* spp. Younger age, black race, and non-Hispanic ethnicity have been identified as risk factors for *M. genitalium* infections.

M. genitalium culture is extremely slow, sometimes requiring several weeks to months for the organisms to form typical spherical colonies on SP4 agar. Thus, molecular identification and detection of genotypic resistance markers is essential to render a definitive diagnosis and guide antimicrobial treatment. Until recently, PCR tests to detect *M. genitalium* for clinical diagnostic purposes in the United States were available only through specialized reference laboratories. However, in January 2019, the first commercial molecular-based assay to detect *M. genitalium* (Hologic) obtained FDA clearance. Availability of *M. genitalium* detection on the widely utilized Panther platform will likely enable identification of more infected individuals and provide an accurate assessment of disease burden. Molecular assays targeting *M. genitalium* antimicrobial resistance markers are available at specialized reference laboratories, such as the UAB Diagnostic Mycoplasma Laboratory, although commercial tests for detection of macrolide resistance are under development.

Treatment of genital *Mycoplasma* and *Ureaplasma* infections

Oral tetracyclines have historically been the drugs of choice for use against urogenital infections due to *M. hominis*, but resistance may occur in up to 50% of isolates in some populations. It is important to note that although the association of treating mycoplasma infections with macrolides is imprinted in the minds of many clinical trainees, *M. hominis* is the important exception to this rule, with almost universal macrolide resistance. Clindamycin remains active against *M. hominis* in vitro and is clinically efficacious.

In contrast, *Ureaplasma* spp. are typically resistant to clindamycin and sometimes to tetracyclines but are almost always susceptible to macrolides. A survey of clinical isolates of *Ureaplasma* spp. from various states found that 45% possessed the *tetM* transposon conferring resistance to tetracyclines. The degree of resistance may vary according to geographic area, type of patient population, and previous exposure to antimicrobial agents. Occasional macrolide-resistant *Ureaplasma* spp. have been reported, and, despite in vitro susceptibility, tetracycline or macrolide treatment of vaginal ureaplasmas is not always successful.

There are reports of fluoroquinolone resistance in both *M. hominis* and *Ureaplasma* spp. caused by mutations in DNA gyrase and/or topoisomerase IV, usually after prolonged exposure to these drugs, but most isolates remain susceptible in vitro. Activity of fluoroquinolones is not affected by tetracycline or macrolide resistance. Ciprofloxacin and ofloxacin are generally less active in vitro than levofloxacin and moxifloxacin.

Occurrence of acquired resistance to tetracyclines, fluoroquinolones, and macrolides in *M. hominis* and *Ureaplasma* spp. lends support to the recommendation that in vitro susceptibility testing is indicated when these organisms are recovered from a normally sterile body site, from immunocompromised hosts, and/or from persons who have not responded to an initial treatment.

Treatment alternatives for urogenital infections in adult and neonatal infections are provided in Tables 165.3 and 165.4, respectively.

TABLE 165.3 **TREATMENT OPTIONS FOR UROGENITAL AND SYSTEMIC INFECTIONS IN ADULTS CAUSED BY *MYCOPLASMA HOMINIS*, *MYCOPLASMA GENITALIUM*, AND *UREAPLASMA* SPECIES**[a]

Drug	Route	Dosage/24 h	Comments
Doxycycline	PO	200 mg loading dose d 1, then 100 mg q12h × 7 d	All tetracyclines have a detrimental effect on the skeletal development and bone growth of the fetus and should not be used in the second half of pregnancy or in children <8 yrs of age unless there is no other alternative
	IV	Same as PO	Treatment failures have been described for *M. genitalium* urethritis.
Tetracycline	PO IV	250–500 mg q6h × 7 d 125–500 mg q6–12h × 7 d	Activity may be inhibited in some strains of *M. hominis* and *Ureaplasma* spp. possessing *tetM*
Minocycline	PO	100 mg q12h × 14d	Activity may be inhibited in some strains of *M. hominis* and *Ureaplasma* spp. possessing *tetM*. May be useful for treatment of macrolide and fluoroquinolone-resistant *M. genitalium* infections.
	IV	200 mg initially, then 100 mg q12h × 14 d	
Erythromycin	PO IV	250–500 mg q6h × 7 d Same as PO	Not active against M. *hominis*
Azithromycin	PO	500 mg × 1 d then 250 mg × 4 d or	Not active against *M. hominis*. In vitro resistance is common and treatment failures have been described for *M. genitalium* urethritis.
		1 g as a single dose	
	IV	500 mg/d × 2 d, then 500 mg PO qd	
Clindamycin	PO	150–450 mg q6h × 7 d	• Not active against *Ureaplasma* spp.
	IV	150–900 mg q6–8h × 7 d	
Ofloxacin	PO IV	200–400 mg q12h × 7 d Same as PO	• Fluoroquinolones are not approved for use in persons <18 yrs of age
Levofloxacin	PO	500 mg qd × 7–14 d	
	IV	Same as PO	
Moxifloxacin	PO IV	400 mg q12h × 10 d Same as PO	Moxifloxacin does not have approved indications for treatment of urogenital infections, but it has been effective in men with *M. genitalium* urethritis who failed treatment with azithromycin. In vitro resistance and treatment failures may also occur.

[a] Treatment options are based on accepted regimens for urogenital infections involving other microorganisms that are expected to be suitable for infections caused by genital mycoplasmas based on in vitro susceptibility data in circumstances where there are no approved microbiologic indications. Route and duration of treatment depend on the severity of the clinical condition being treated. For extragenital and/or systemic infections, particularly those involving immunocompromised persons, a longer duration of treatment may be necessary than those listed. Joint infections may require several weeks to months of antimicrobial administration. Recommendations are based primarily on published case reports due to the lack of objective data from clinical trials.

TABLE 165.4 **TREATMENT OPTIONS FOR NEONATAL INFECTIONS WITH *MYCOPLASMA HOMINIS* AND *UREAPLASMA* SPECIES**[a]

Drug	Route	Dosage/24 h	Comments
Doxycycline	PO IV	4 mg/kg loading dose d 1, then 2–4 mg/kg/d in 1–2 doses × 10–14 d Same as PO	Tetracyclines are contraindicated in children <8 yrs of age unless no other alternative is available. Activity may be inhibited in some strains of *M. hominis* and *Ureaplasma* spp. possessing *tetM*. This drug has been used to successfully treat neonatal meningitis due to *M. hominis* and *Ureaplasma* spp., but treatment failure has been reported with *Ureaplasma* spp.
Tetracycline	PO IV	25–50 mg/kg/d in 4 doses 10–20 mg/kg/d in 2–4 doses	Tetracyclines are contraindicated in children <8 yrs of age unless no other alternative is available. Activity may be inhibited in some strains of *M. hominis* and *Ureaplasma* spp. possessing *tetM*
Chloramphenicol	PO IV	Not recommended For neonates up to 2 wks of age, use 25 mg/kg/d in 1 dose, thereafter 50 mg/kg/d in 1 dose	Chloramphenicol has been used successfully to treat neonatal meningitis due to *M. hominis* and *Ureaplasma* spp., but there has also been a report of treatment failure with *M. hominis*. Frequent monitoring of hematologic parameters and blood levels of the antibiotic are necessary due to its potential toxicity.
Erythromycin	PO IV IV	20–50 mg/kg/d in 3–4 doses 25–40 mg/kg/d in 4 doses Same as PO	Not active against *M. hominis*. Despite poor CSF penetration, this drug has been used successfully to treat neonatal meningitis due to *Ureaplasma* spp., but treatment failure has also been reported. Oral erythromycin should be avoided if alternatives are available due to an association with infantile hypertrophic pyloric stenosis.
Azithromycin	IV	20 mg/kg/d in a single dose × 3 d	Azithromycin has been shown to eradicate *Ureaplasma* spp. From the respiratory tract of preterm neonates without adverse sequelae in a small number of cases.
Clindamycin	PO IV	10–25 mg/kg/d in 3–4 doses × 10–14 d 10–40 mg/kg/d in 3–4 doses. Do not exceed 15–20 mg/kg/d	Not active against *Ureaplasma* spp. This drug has been used to successfully treat neonatal infections due to *M. hominis*

[a] No treatment guidelines for neonatal infections with genital mycoplasmas are available. Treatment options have been compiled based on in vitro susceptibility data and information described in published case reports. No dosages have been approved for neonates, so amounts listed are based on data applicable to older infants and children.

Very few clinical antibiotic trials have included microbiologic data specific for genital mycoplasmas, and there have been no systematic comparative evaluations of treatment regimens for extragenital infections in adults or for neonatal infections. Thus, treatment recommendations in Tables 165.3 and 165.4, including dosages and duration, are based largely on in vitro susceptibility data, outcomes of treatment trials evaluating clinical response to syndromes such as PID and urethritis that may be due to genital mycoplasmas, and individual case reports. For infections such as urethritis that may be venereally transmitted, sexual contacts of the index case should also receive treatment.

Clinical studies have encountered frequent treatment failures with the tetracyclines for urethritis caused by *M. genitalium*, and it was initially believed azithromycin would be a better option. However, reports of treatment failures with azithromycin and detection of *M. genitalium* isolates with elevated MICs to this drug or mutations conferring macrolide resistance (42–80%) indicate it will not always be effective. Macrolide-resistant *M. genitalium* infections have been successfully treated with fluoroquinolones (e.g., moxifloxacin). However, *M. genitalium* fluoroquinolone resistance in the United States is approximately 30% in HIV-infected men who have sex with men, with 11% additionally exhibiting macrolide resistance, according to a study from Alabama. In Europe and Japan, fluoroquinolone resistance is approximately 5–8% and 47%, respectively. Treatment regimens for macrolide- and fluoroquinolone-resistant infections are limited. A 14-day course of minocycline has proved effective in some cases. Pristinamycin has also been used successfully to treat multidrug-resistant *M. genitalium,* but it is not generally available outside of France.

Experience with mycoplasmal or ureaplasmal infections in immunocompromised patients, especially those with hypogammaglobulinemia (who have been the best studied), demonstrate that even though mycoplasmas are primarily noninvasive mucosal pathogens in the normal host, they have the capacity to produce destructive and progressive disease. Infections may be caused by resistant organisms refractory to antimicrobial therapy and require prolonged administration of a combination of IV antimicrobials, IV immunoglobulin, and/or antisera prepared specifically against

the infecting species for weeks to months. Even with aggressive therapy, relapses are still likely to occur. Repeat cultures of affected sites may be necessary to monitor in vivo response to treatment and antimicrobial susceptibility testing should be obtained, if possible.

Isolation of *M. hominis* or *Ureaplasma* spp. from CSF in neonates with pleocytosis, progressive hydrocephalus, or other neurologic abnormality; pericardial fluid; pleural fluid; tracheal aspirate in association with respiratory disease; abscess material; or blood are justification for specific treatment in critically ill neonates when no other verifiable microbiologic etiologies of the clinical condition are apparent. Azithromycin has a number of advantages over erythromycin from the pharmacokinetic standpoint, but there has been very modest clinical experience with this drug in treatment of neonatal ureaplasmal infections. A recent study demonstrated that azithromycin given intravenously at a dosage of 20 mg/kg/d in a single dose for 3 days successfully eradicated ureaplasmas from the respiratory tract of a small number of preterm neonates. Parenteral tetracyclines have been used to treat neonatal meningitis due to either *M. hominis* or *Ureaplasma* spp. despite contraindications, but erythromycin or other macrolides such as azithromycin for *Ureaplasma* spp., clindamycin for *M. hominis*, or chloramphenicol for either species are alternatives. No single drug has been successful in every instance in eradication of these organisms from CSF of neonates. Duration of treatment and drug dosages for systemic neonatal mycoplasmal or ureaplasmal infections have not been critically evaluated, but a minimum of 10 to 14 days of therapy for invasive disease such as meningitis is suggested based on experience in individual cases where microbiologic follow-up has been assessed.

Other mycoplasmal species

A variety of mycoplasmal species can be isolated from the upper respiratory tract or urogenital tracts of humans. Some of them occur fairly commonly as commensals in healthy persons, whereas others are found less often. Some of these organisms have been implicated in case reports as agents of invasive disease, usually in immunosuppressed persons. No guidelines for their detection or treatment are possible due to the infrequency of isolation and lack of clinical isolates on which in vitro susceptibility tests have been performed. In the case of *M. fermentans*, its antimicrobial susceptibilities are generally similar to those of *M. hominis*, but scant information is available for other species. If a clinical isolate of one of these opportunistic mycoplasmal species is available, in vitro susceptibility tests can sometimes be performed to guide treatment providing the organism will grow well enough in vitro to perform the test. Otherwise, empiric use of drugs shown to be effective against other mycoplasmal species as shown in Tables 165.1, 165.3, and 165.4 should be considered, with the choice being based on the type of infection encountered and status of the host.

Chlamydia pneumoniae

Margaret R. Hammerschlag

The first isolates of *Chlamydia pneumoniae* were obtained serendipitously during trachoma studies in the 1960s. After the recovery of a similar isolate from the respiratory tract of a college student with pneumonia in Seattle, Grayston and colleagues applied the designation "TWAR" after their first two isolates, TW-183 and AR-39. *C. pneumoniae* appears to be a common human respiratory pathogen. The mode of transmission remains uncertain but probably involves infected respiratory tract secretions. Spread of *C. pneumoniae* within families and enclosed populations, such as military recruits, prisons, and nursing homes, has been reported. The proportion of community-acquired pneumonia in children and adults associated with *C. pneumoniae* infection has ranged from 0% to >44%, varying with geographic location, the age group examined, and the diagnostic methods used. Early studies that relied on serology suggested that infection in children <5 years was rare; however, subsequent studies using culture and/or polymerase chain reaction (PCR) have found the prevalence of infection in children beyond early infancy to be similar to that found in adults.

Studies that have used culture have found a poor correlation with serology, especially in children. Although 7% to 13% of children 6 months to 16 years of age enrolled in two multicenter pneumonia treatment studies were culture positive, and 7% to 18% met the serologic criteria for acute infection with the microimmunofluorescence (MIF) test, they were not the same patients. Only 1% to 3% of the culture-positive children met the serologic criteria, and approximately 70% were seronegative. By age 20, approximately 50% of persons will have detectable anti-*C. pneumoniae* immunoglobulin G (IgG). Seroprevalence may exceed 80% in some populations.

Prolonged culture positivity lasting from several weeks to several years after acute infection has been reported. Asymptomatic nasopharyngeal carriage also occurs in 2% to 5% of adults and children. The role that asymptomatic carriage plays in the epidemiology of *C. pneumoniae* is not known, but possibly these persons serve as a reservoir for spread of infection.

Most *C. pneumoniae* infections are probably mild or asymptomatic. Initial reports emphasized mild, atypical pneumonia clinically resembling that associated with *Mycoplasma pneumoniae*. Generally, pneumonia associated with *C. pneumoniae* is not clinically indistinguishable from other pneumonias. Coinfection with other pathogens, especially *M. pneumoniae* and *Streptococcus pneumoniae*, are frequent. *C. pneumoniae* pneumonia has been associated with severe illness and even death, although the role of preexisting chronic conditions as contributing factors in many of these patients is difficult to assess. In some cases, however, *C. pneumoniae* clearly appears to be implicated as a serious pathogen, even in the absence of underlying disease. *C. pneumoniae* has been isolated from the empyema fluid in several patients with severe pneumonia.

The role of host factors in *C. pneumoniae* infection remains to be determined. *C. pneumoniae* appeared to be responsible for 14% to 19% of episodes of acute chest syndrome in children with sickle cell disease. *C. pneumoniae* infection in these patients appeared to be associated with more severe hypoxia than infection with *M. pneumoniae. C. pneumoniae* is also an inflammatory trigger for asthma.

The role of *C. pneumoniae* in upper respiratory infections is less well defined. *C. pneumoniae* has been isolated from the middle ear fluid of children and adults with otitis media and has also been implicated as a cause of pharyngitis. *C. pneumoniae* infection has been implicated in a wide variety of chronic diseases and conditions, including atherosclerosis, Alzheimer's disease, macular degeneration, and arthritis. However, many of these studies are hampered by the lack of standardized methods for the diagnosis of *C. pneumoniae* infection.

Laboratory diagnosis

A specific laboratory diagnosis of *C. pneumoniae* infection can be made by identification of the organism from nasopharyngeal or throat swabs, sputa, or pleural fluid, if present, by culture or nucleic acid amplification test (NAAT). The nasopharynx appears to be the optimal site for isolation of the organism. The relative yield from throat swabs and sputum is not known. Isolation of *C. pneumoniae* requires culture in tissue; the organism cannot be propagated in cell-free media. *C. pneumoniae* grows readily in cell lines derived from respiratory tract tissue, specifically, HEp-2 and HL cells. Culture with an initial inoculation and one passage should take 4 to 7 days.

Nasopharyngeal cultures can be obtained with Dacron-tipped, wire-shafted swabs. Each lot of swabs should be treated in a mock infection system to ensure that no inhibitory effects occur on either the viability of cells or recovery of chlamydiae. Specimens for culture should be placed in appropriate transport media, usually a sucrose phosphate buffer with antibiotics and fetal calf serum, and stored immediately at 4°C/39°F for no longer than 24 hours. Viability decreases if specimens are held at room temperature. If the specimen cannot be processed within 24 hours, it should be frozen at −70°C/−94°F until culture can be performed. After 72 hours of incubation, culture confirmation can be performed by staining with either a *C. pneumoniae* spp.-specific or a *Chlamydia* genus-specific (antilipopolysaccharide [anti-LPS]) fluorescein-conjugated monoclonal antibody.

There are now three multiplexed PCR respiratory panels cleared by the US Food and Drug Administration (FDA) that include *C. pneumoniae*: BioFire FilmArray, GenMark ePlex, and Luminiex NxTAG Respiratory Pathogen Panel. Each includes respiratory viruses and *M. pneumoniae*. The BioFire FilmArray also includes *Bordetella pertussis*. Studies using these panels have found the performance in adults and children with respiratory illness to be generally equivalent. Identification of *C. pneumoniae* has been low, <1%, which is consistent with epidemiologic studies done over the past 10 years. If the assays are run onsite, the turnaround time is usually 1 to 2 hours.

Because isolation of *C. pneumoniae* was initially considered to be difficult and limited, emphasis was placed on serologic diagnosis. The MIF test is not standardized or FDA-approved. Although enzyme immunoassay (EIA) serology test kits offer the promise of standardized performance and objective endpoints, none has been evaluated adequately in comparison to culture or PCR. Most have been compared only with MIF. None has FDA clearance or approval for use in the United States. One commercial assay, the Medac rELISA, uses a recombinant LPS antigen; others are based on LPS-extracted EBs or synthetic peptides. These kits can measure IgG, IgM, and IgA antibodies, but cutoffs vary from kit to kit, and the criteria for a positive result (acute infection, past infection) can be very complex. The US Centers for Disease Control and Prevention (CDC) has proposed modifications of the serologic criteria for diagnosis of *C. pneumoniae* infection. Although the MIF test was considered to be the only serologic test currently acceptable, the criteria were made significantly more stringent. Acute infection as determined by MIF was defined as a fourfold rise in IgG or an IgM titer of ≥16, and the use of a single elevated IgG titer was discouraged. However, the use of paired sera also affords only a retrospective diagnosis, which is of little help in terms of deciding how to treat a patient. An IgG titer of ≥16 was considered to indicate past exposure, but neither elevated IgA titer nor any other serologic marker was thought to be a validated indicator of persistent or chronic infection. The CDC did not recommend the use of any EIA for detection of antibody to *C. pneumoniae*.

Therapy

C. pneumoniae is susceptible to tetracyclines, macrolides, and quinolones. Most of the treatment studies of pneumonia caused by *C. pneumoniae* published thus far have relied entirely on diagnosis by serology; consequently, microbiologic efficacy could not be assessed. Anecdotal reports have suggested that prolonged courses, up to 3 weeks, of either tetracyclines or erythromycin may be needed to eradicate *C. pneumoniae* from the nasopharynx of adults. The results of two pediatric multicenter pneumonia treatment studies found that 10-day courses of erythromycin and clarithromycin and 5 days of azithromycin suspension were equally efficacious; they eradicated the organism in 79% to 86% of children. Quinolones, including levofloxacin and moxifloxacin, also have been demonstrated to have 70% to 80% efficacy in eradicating *C. pneumoniae* from adults with community-acquired pneumonia. Most patients improved clinically despite persistence of the organism. Persistence does not appear to be secondary to the development of antibiotic resistance.

Based on these limited data, regimens for respiratory tract infection caused by *C. pneumoniae* are listed in Table 166.1. Some patients may require retreatment.

TABLE 166.1 **REGIMENS FOR RESPIRATORY TRACT INFECTION CAUSED BY *CHLAMYDIA PNEUMONIAE***

Adults	Children
Doxycycline, 100 mg 2 × a day for 14–21 d	Erythromycin suspension, 50 mg/kg/d for 10–14 d
Tetracycline, 250 mg 4 × a day for 14–21 d	Clarithromycin suspension, 15 mg/kg/d for 10 d
Azithromycin, 1.5 g over a period of 5 d	Azithromycin suspension, 10 mg/kg on day 1 followed by 5 mg/kg/d once daily on days 2 to 5
Levofloxacin, 500 mg/d orally or intravenously for 7–14 d	
Moxifloxacin, 400 mg/d orally for 10 d

Chlamydophila psittaci (psittacosis)

Thomas J. Marrie

Epidemiology and pathogenesis

The first description of a respiratory illness following exposure to a sick bird (a parrot) was by Ritter in 1879. In 1892, Morange described an outbreak of respiratory illness following exposure to sick parrots; he named this illness *psittacosis* (from *psittakos*, Greek for parrot). In 1930, investigators in the United Kingdom, the United States, and Germany isolated the causative agent which eventually was named *Chlamydia psittaci.*

Chlamydiae are gram-negative obligate intracellular bacterial pathogens. The phylum Chlamydiae has two genera—*Chlamydia* and *Chlamydophila*. *Chlamydophila* species are *C. pecorum*, *C. pneumoniae*, *C. psittaci*; *C. abortus*, *C. caviae,* and *C. felis*.

Chlamydophila psittaci spp. consists of at least 20 genotypes with isolates from a variety of mammals, reptiles, and many avian species. The genome of *C. psittaci* has 1,156,417 base pairs. There are 8 serovars (A to F, M56 and WC) and 9 genotypes of *C. psittaci*. Serovars A to F are of avian origin, and M 56 and WC are of mammalian origin. WC was isolated from Wolfsen cattle and M56 from muskrats. Genotype A is most commonly found in psittacine birds; Genotype B in feral pigeons and other bird species; it is endemic in European non-psittacine birds; Genotype C is found in ducks and dogs; Genotype D is found in poultry, especially turkeys; Genotypes E and F are uncommon but are found in various bird species. In one study of 10 human isolates of *C. psittaci* from the Netherlands genotype A accounted for 5 isolates; B for 3; C for 1, and there was 1 novel isolate that may represent a new genotype of *C. psittaci*.

C. psittaci along with other Chlamydiae has a unique development cycle with elementary (the infectious particle) and reticulate (the intracellular replicative particle) bodies. After infection elementary bodies (EBs) attach to and enter the host cell by endocytosis. Elementary bodies differentiate into reticulate bodies (RBs), and, after about 36 hours, the RBs differentiate back into EBs. About 500 to 1,000 EBs accumulate in the cell as intracytoplasmic inclusions. During this process, chlamydial antigens are released onto the host cell surface, inducing a host immune response. Release of EBs occurs by several processes including extrusion of the inclusion. The EB is metabolically inactive whereas the RB is metabolically active. In humans, following inhalation, *C. psittaci* reaches the alveoli and from there spreads to regional lymph nodes, the bloodstream, and the reticuloendothelial cells of the liver and spleen. A lymphocytic inflammatory response occurs in the alveoli and interstitium of the lungs resulting in edema of the alveolar walls and interstitial tissues. Occasionally necrosis occurs. Histologically the alveolar spaces are filled with fluid, red blood cells, and lymphocytes. The macrophages may contain Levinthal-Coles-Lille cytoplasmic inclusions (the RBs) that are characteristic of psittacosis.

In turkeys *C. psittaci* infects epithelial cells and macrophages in the respiratory tract. This is followed by spread via the bloodstream and localization of the organisms in epithelial cells and macrophages in various organs.

C. psittaci has been found worldwide in 467 species from 30 bird orders. Affected birds include members of the parrot family (macaws, cockatoos, parakeets, budgerigars), finches (canaries, bullfinches, goldfinches, sparrows), poultry (hens, ducks, geese, turkeys), pigeons, pheasants, egrets, gulls, puffins, swans, pheasants, and doves.

The organism is excreted in the feces of infected birds, and transmission to humans is via aerosolization of the organism. Transmission can occur in the absence of apparent illness in the birds. In a study conducted in a German chicken and turkey slaughterhouse, 85% of the chicken flocks were polymerase chain reaction (PCR)- and culture-positive for *C. psittaci*, as were 57% of the turkey flocks. Genotype D was isolated. Eighty-seven percent of the employees were positive for this organism by PCR and 61% by culture. Air sampling revealed viable *C. psittaci* organisms.

Person-to-person transmission can occur but is so uncommon that respiratory precautions for patients with psittacosis are not recommended. However, the case of a 73-year-old man who was admitted with severe pneumonia due to *C. psittaci* may change that. Subsequently, there were 10 cases of psittacosis due to exposure to this patient, 7 of whom were healthcare workers.

Pet store workers, veterinarians, poultry breeders, and others are at risk by virtue of occupation. Bird owners and even the public with casual contact with infected domestic or wild birds can also be at risk.

Clinical syndromes

Birds

In birds, psittacosis manifests as anorexia, apathy, ocular and nasal discharge, diarrhea, and conjunctivitis. The organism is present in high concentrations in the droppings of birds. A carrier state can occur and then there is intermittent shedding. Crowding and transportation of birds result in increased spread of the infection among a bird colony.

Humans

The clinical spectrum of *C. psittaci* infection in humans is wide, ranging from a subclinical illness to severe pneumonia. The incubation period ranges from 5 to 15 days. Fever, rigors, sweats, and headache are common. Cough, occurring in from 50% to 100% of patients, appears late in the course of illness and usually is nonproductive or productive of mucoid sputum. About 20% of patients have no respiratory symptoms. The wide range of clinical manifestations has led some workers in the field to indicate that there are six or seven presentations of psittacosis: (1) nonspecific manifestations consisting of fever with rigors, sweats, and constitutional symptoms but no localizing features, which occurs in 41% of patients; (2) a second form dominated by prominent cough and occasionally dyspnea in association with fever; this is the major presentation in one-third of patients; (3) a third form presents as severe headaches suggestive of meningitis; (4) a fourth, uncommon, form that presents with severe diarrhea; and (5) a form that presents as pharyngitis, which occurred in 21% of patients. An alteration of mental status was noted in 12%. A sixth presentation is that of a mononucleosis-like syndrome with fever, pharyngitis, hepatosplenomegaly, and lymphadenopathy. These distinctions serve to illustrate that the clinical spectrum of manifestations of *C. psittaci* infection is wide, and a high index of suspicion is necessary to make the diagnosis.

It is also critical to remember the extrapulmonary manifestations of psittacosis. These include Horder's spots (a pink, blanching maculopapular eruption resembling the rose spots of typhoid fever), acrocyanosis, superficial venous thrombosis, and splinter hemorrhages. Panniculitis, erythema multiforme, and erythema nodosum are other cutaneous manifestations. Neurological manifestations include encephalitis, meningitis, cerebellar involvement, cranial nerve palsies, intracranial hypertension, and transverse myelitis. Acute renal failure, interstitial nephritis, pancreatitis, and thrombocytopenic purpura have also complicated psittacosis. Other manifestations include reactive arthritis and hemophagocytosis. Rarely *C. psittaci* is a cause of endocarditis.

Psittacosis during pregnancy is uncommon, but when it occurs it may be severe.

The white blood cell count is usually normal in psittacosis. The radiographic features of pneumonia due to *C. psittaci* are not distinctive. The pleural fluid in psittacosis may have a high adenosine deaminase level. This could result in confusion with tuberculosis, since an adenosine deaminase level of >43 IU/L in pleural fluid is believed to be sensitive and specific for tuberculosis.

In a review of 57 studies of community acquired pneumonia with at least 100 cases as an inclusion criterion, the authors found that *C. psittaci* accounted for 1.03% (0.79–1.30) of cases.

In a study from the Netherlands, investigators estimated 1,640 cases of psittacosis and 9 deaths from this infection annually from 2012—2014. Using a model that estimates the burden of an infectious disease in terms of disability adjusted life years (DALY) and years of life lived with disability they found that psittacosis resulted in 222 DALY per year, a number comparable to that of rubella and shigellosis.

Chlamydophila psittaci and ocular adnexal mucosa-associated lymphoid tissue type (MALT) lymphomas

Lymphomas of the ocular adnexa (the eyelid, conjunctiva, orbit, lacrimal gland, and lacrimal sac) are not uncommon. Orbital lymphomas usually present as solitary, painless masses that cause displacement of the globe, ptosis, and diplopia. In one study 39/44 patients with such lymphomas had *C. psittaci* DNA detected by PCR. Treatment with doxycycline was associated with an improved response rate.

Diagnosis

Isolation

Chlamydiae are organisms that are easily damaged. To maximize the chance of isolating such organisms, the specimens should be

placed in transport media, kept cold, and transported to the laboratory as soon as possible. Sputum, bronchial washings, biopsy specimens, and blood are suitable specimens from which to isolate *C. psittaci*. This organism is quite infectious and has caused many laboratory-acquired infections. It should only be handled in a biocontainment level 3 laboratory. Specimens are inoculated onto cycloheximide-treated monolayers of McCoy cells in shell vials. Following incubation for 48 to 72 hours organisms are detected by staining with group-specific fluorescent monoclonal antibodies.

Serology

A fourfold increase in antibody titre between acute and convalescent serum samples is the most common method of diagnosis. The complement fixation test or the microimmunofluorescence (MIF) tests can be used. A single IgM titre of ≥1:32 by MIF is diagnostic, as is a fourfold rise in antibody titer between acute and convalescent serum samples. The MIF test has improved the sensitivity and specificity of testing for *C. psittaci.* However, cross-reactivity between *C. pneumoniae* and *C. psittaci* can be a problem. Cross-reactivity with *Legionella longbeachae* has also been reported.

Nucleic acid amplification

PCR has been used to amplify *C. psittaci* from a variety of specimens.

Therapy

Tetracyclines, macrolides, and fluoroquinolones have good activity against *C. psittaci*. Ciprofloxacin is the least active and should not be used. High-level azithromycin resistance occurs spontaneously due to a point mutation in the 23 S rRNA gene.

The treatment of choice is generally doxycycline administered in a dose of 100 mg twice daily for 14 days. Seriously ill patients should be treated with intravenous doxycycline.

Second-line therapy is with levofloxacin, moxifloxacin, or gatifloxacin.

Treatment failures are not uncommon when erythromycin is used. Azithromycin is effective probably due to its long half-life and intracellular concentration.

Prevention

All those who own pet birds or who work with birds should be familiar with the guidelines for preventing and controlling *C. psittaci* infections.

Specific organisms: Rickettsia, Ehrlichia, and Anaplasma

168

Rickettsial infections

Noah Wald-Dickler and Paul D. Holtom

The family *Rickettsiaceae* are small, aerobic, gram-negative coccobacilli that are obligate intracellular parasites of eukaryotic cells. Rickettsiae are divided into three groups based on clinical presentation: the spotted fever group, the typhus group, and scrub typhus. *Coxiella burnetii*, the causal agent of Q Fever, is covered in this chapter but is now classified in the γ-proteobacteria group, together with *Legionella* and *Francisella tularensis* (Table 168.1).

Rickettsial disease pathogenesis is characterized by systemic vasculitis whereby the organisms proliferate in vascular endothelial cells of host arterioles, capillaries, and veins. In Q fever the organisms are acquired by inhalation of dust contaminated by birth fluids of domestic ungulates and proliferate in the lungs, causing inflammation and bacteremic seeding of other organs, particularly the liver. All other medically relevant rickettsial diseases are vector-borne and acquired from a variety of arthropods including ticks, fleas, mites, and lice.

In the treatment of rickettsioses, one must stress that proper therapy cannot be given unless the diagnosis is suspected. Diagnostic confirmation is usually serologic and almost always delayed because antibodies occur no earlier than the second week of illness. Arthropod-borne rickettsioses are diseases of the spring and summer in temperate climates. Q Fever can occur in any season if exposure to aerosols of the organism occurs. Given an appropriate geographic, temporal, and/or occupational history, the clinical triad of fever, headache, and rash should raise suspicion of a rickettsial disease. As early treatment is important in preventing mortality, particularly in Rocky Mountain spotted fever (RMSF), therapy should be instituted when the diagnosis is suspected, even while awaiting serologic confirmation.

Rocky Mountain spotted fever

RMSF was first described in the late 1800s in the Bitterroot Valley of Montana. Prevalence was thought to shift from the western United States to the South Central and South Atlantic, but, since 2008, more cases have been reported in Mexico and Central America with immigration and ease of travel contributing to a resurgence of cases in the US Southwest. The causative agent is *Rickettsia rickettsii*, a member of the spotted fever group of rickettsial infections. In 2009, epidemiologic reporting reclassifications resulted in changing RMSF to the more broad "spotted fever rickettsiosis" (SFR), which includes RMSF as well as diseases caused by other rickettsial species, including *R. parkeri* and *R. philipii*. Using this new definition, there were 4,269 US cases of SFR reported in 2016, the majority of which were presumed to be RMSF. SFR incidence has increased from 4 to 8 per million in 2000 to 25 per million in 2015.

Ticks are both the vectors and the main reservoirs of *R. rickettsii*; the specific tick responsible for transmission varies from region to region. The dog tick, *Dermacentor variabilis*, and the wood tick, *D. andersoni*, predominate in the eastern and western United States, respectively. Humans are infected by *R. rickettsii* either by release of organisms from the salivary glands of a feeding tick or by exposure to infected tick hemolymph, which may occur during tick removal, especially if the tick is crushed. The incubation period of RMSF ranges from 2 to 14 days (with a median of 7 days) prior to symptom onset.

TABLE 168.1 **DISEASES CAUSED BY RICKETTSIAE**

Disease	Organism	Geographic distribution	Vector
Spotted Fever Group			
Rocky Mountain spotted fever	*Rickettsia rickettsii*	Western Hemisphere	Tick
Spotted fever	*Rickettsia parkeri*	United States	Tick
Boutonneuse	*Rickettsia conorii*	Africa, Mediterranean, India	Tick
Queensland tick typhus	*Rickettsia australis*	Australia	Tick
North Asian tick typhus	*Rickettsia sibirica*	Russia, Asia, Africa, France	Tick
Japanese spotted fever	*Rickettsia japonica*	Japan, China	Tick
Flinders Island spotted fever	*Rickettsia honei*	Australia, Thailand	Tick
African tick-bite fever	*Rickettsia africae*	Sub-Saharan Africa, West Indies	Tick
Fleaborne spotted fever	*Rickettsia slovaca*	United States	Tick
Rickettsialpox	*Rickettsia aeschlimannii*	Europe	Tick
	Rickettsia felis	Africa	Flea
	Rickettsia akari	Western Hemisphere, Europe, Russia, Korea, Africa	Mite
Typhus group			
Epidemic typhus	*Rickettsia prowazekii*	Western Hemisphere, Africa, Asia	Louse
Murine typhus	*Rickettsia typhi*	Worldwide	Flea
Scrub typhus	*Orientia tsutsugamushi*	Asia, Australia, South Pacific	Mite
Other			
Q fever	*Coxiella burnetii*	Worldwide	Airborne

Virtually all patients have fever, usually >38.9°C/102°F. The major diagnostic sign is the rash, seen in approximately 90% of patients, which usually occurs within 3 to 5 days after the onset of fever. Fewer than half of patients show the rash during the first 3 days of the illness; as a result rash is often absent when patients first seek medical care. The rash typically starts around the wrists and ankles, but it may start on the trunk or be diffuse at onset. Although involvement of the palms is considered characteristic, this does not occur in all patients and often occurs late in the course of the disease (Figure 168.1). Other common symptoms include severe headache, myalgias, and gastrointestinal complaints such as nausea, vomiting, and severe abdominal pain.

FIGURE 168.1 Petechial rash in Rocky Mountain spotted fever. Courtesy of David Schlossberg, MD.

Complications of RMSF include meningismus, meningitis, renal failure, pulmonary involvement, hepatic dysfunction with development of jaundice, splenomegaly, myocarditis, and thrombocytopenia. In early reports, RMSF case fatality rates were >20% in the absence of early therapy; in recent series, death occurs in 4% to 8% of the cases. In those with fulminant RMSF, death occurs 8 to 15 days after the onset of symptoms.

Diagnosis of RMSF is primarily based on a high clinical suspicion in the setting of a patient with fever, headache, and myalgias with exposure to ticks. A skin biopsy of a rash lesion (when present) can show *R. rickettsii* with immunohistochemistry staining or nucleic acid amplification test. This has a specificity of 100% and a sensitivity of 70% but is useful only in patients who have developed a rash. Serologic diagnosis is retrospective. The use of the polymerase chain reaction (PCR) is not well established for the diagnosis of RMSF.

Treatment of RMSF requires the administration of an effective antibiotic for 7 days, continuing for 2 days after the patient has become afebrile. Early therapy is important, as the risk of death is five times greater in patients treated after day 5 of illness. The antibiotic of choice for both adults and children is oral doxycycline, 100 mg every 12 hours for 7 days, or at least 2 days after the patient becomes afebrile. Tetracycline, 25 to 50 mg/kg/d in four doses, is also effective. In patients with hypersensitivity to tetracyclines and in pregnant patients, chloramphenicol, 50 to 75 mg/kg/d, is a

less effective alternative. Although fluoroquinolones have shown activity against *R. rickettsii*, they are not recommended because of a lack of clinical experience. Glucocorticosteroids have been given to severely ill patients in the past, but there is no documentation of their efficacy. No vaccine is currently available to prevent RMSF.

Other spotted fever group rickettsia

The SFRs include *R. rickettsiae*, but also *R. parkeri, R. felis, R. akari*, and *R. philipii*—all cause human infections in the United States. Except for *R. akari*, whose invertebrate host is a mite, all SFG rickettsiae reside in tick hosts. The change to SFR nomenclature reflects the inability to differentiate between spotted fever group *Rickettsia* spp. using commonly available serologic tests. Successful treatment for SFR members has been reported using doxycycline (200 mg/d), with alternatives including tetracycline, chloramphenicol, or ciprofloxacin for 5 to 7 days.

R. akari causes the nonfatal disease rickettsialpox, first reported in 1946 in New York but with worldwide distribution in Asia and Eastern Europe. The reservoir for *R. akari* is the house mouse, *Mus musculus*, and the vector for transmission to humans is the mouse mite (or "chigger") *Allodermanyssus sanguineus*. Clinically, a painless papule arises then ulcerates and forms an eschar at the site of the mite bite 3 to 7 days before the onset of systemic symptoms including chills, fever, headache, myalgia, backache, and photophobia. Rigors and profuse diaphoresis may be seen. Within 2 to 3 days after onset, a generalized papulovesicular rash occurs with multiple lesions leading to the term "rickettsialpox" which distinguishes the disease from other rickettsioses with only one or a few lesions. The rash begins as red papules 2 to 10 mm in diameter that vesiculate and heal by crusting. The disease is usually benign; death and complications are very rare. Mediterranean spotted fever is a similar disease caused by *R. conorii* in Italy, Greece, Turkey, and other Mediterranean regions.

Epidemic or louse-borne typhus

This classic plague of humanity is caused by *R. prowazekii* and transmitted by the human body louse *Pediculus humanus corporis*. The bacteria may remain latent in humans for many years after the initial infection and then relapse when persons are stressed by other disease or deprivations. Thus, during war and refugee exodus, where poverty, deprivation, and poor hygiene promote the spread of lice, a rickettsemic person may initiate the cycle and cause an epidemic. This relapsing disease is generally milder than an initial attack, presumably because it occurs in a person with some established immunity. This recrudescent typhus is called *Brill–Zinsser disease*. An extrahuman reservoir has been identified in southern flying squirrels, *Glaucomys volans*, throughout the eastern United States. Humans are infected by flying squirrel fleas.

The characteristic incubation period is 8 to 16 days. The onset is usually abrupt, with intense headache, progressive fever, chills, and severe myalgia. The rash begins around day 5 of illness, usually in the axillary folds and upper trunk, and spreads centrifugally. Unlike many rickettsial rashes, the rash of epidemic typhus characteristically lacks an initial eschar. Rather, the rash begins as blanching pink macules that progress to become maculopapular, darker, petechial, and nonfading on pressure. The rash may become confluent and involve the entire body, but the face, palms, and soles are spared. In the pre-antibiotic era, mortality was seen in 13%, occurring a median of 12.5 days after illness onset; survivors defervesced a median of 14 days after onset. Epidemic typhus from flying squirrel exposure is a similar but milder illness.

The established therapy for epidemic typhus is doxycycline (100 mg BID), tetracycline (25–50 mg/kg/d in four doses), or chloramphenicol (60–75 mg/kg/d in four doses) given for 7 to 10 days. In epidemic situations where the availability of doxycycline may be limited, a single dose of 200 mg of doxycycline may be effective, but a small proportion of patients may relapse. No vaccine is currently available for the prevention of typhus; the only prevention available is control of body lice by hygiene and insecticides such as permethrin.

Endemic or murine typhus

Murine typhus, caused by *R. typhi*, has worldwide distribution, especially in tropical and subtropical seaboard regions. Its most important reservoirs are *Rattus* spp. rats, and the classic vector that spreads the organisms from rats to people is the flea *Xenopsylla cheopis*. Although rats are the primary animal reservoir of *R. typhi*, other mammals (including opossums and domestic dogs and cats) can also serve as reservoirs. A recent outbreak of endemic typhus was identified in Los Angeles in 2018, primarily associated with homeless persons in downtown.

Murine (endemic) typhus is clinically less severe than epidemic typhus and often self-limited, with reported case fatality rates of 1% to 4%. Illness begins 1 to 2 weeks after an infected flea bite. Initial nonspecific symptoms of fever, headache, chills, myalgia, and nausea are accompanied by rash in about 20% of patients at presentation and in about 50% sometime during the illness. Skin lesions are macular or maculopapular. The trunk is most often involved, but extremity involvement is seen in about half of patients who develop the rash, which may also be seen on the palms and soles. The rash is usually salmon-colored and evanescent, but a frank hemorrhagic vasculitic rash may develop. Occasionally, patients develop central nervous system abnormalities, hepatic or renal failure, respiratory failure, or hematemesis. Diagnosis is suggested by risk factors and clinical findings and can be confirmed by a fourfold or greater rise in *R. typhi* antibody titers from paired serum specimens taken ≥3 weeks apart or by detection of *R. typhi* DNA in a clinical specimen (i.e., skin biopsy) by PCR.

R. typhi infection is treated with doxycycline, tetracycline, or chloramphenicol. Antimicrobial therapy should be continued for 2 to 3 days after defervescence.

Scrub typhus

Scrub typhus occurs when a larval stage trombiculid mite (chigger) infected with *Orientia tsutsugamushi* bites a susceptible human host. The disease occurs throughout the Asia-Pacific region and is endemic in Korea, China, Japan, Southeast Asia, and Australia; it is considered one of the most underdiagnosed causes of febrile illness in the Asian region.

Some 6 to 18 days after a chigger bite, patients develop high fever, severe headache, mental status changes, lymphadenopathy, and myalgia. An eschar may be found at the site of the bite. The severity of the signs and symptoms is widely variable depending on the virulence of the responsible strain and the degree of susceptibility of the host. After about 5 days, a macular rash, sometimes evanescent, may occur, beginning on the trunk and spreading to the extremities. Complications include multiple organ system dysfunction and hemorrhage, pneumonia, heart failure, respiratory failure, and renal failure. Case fatality rates as high as 30% in untreated patients have been reported, but treatment shortens the duration of illness and essentially eliminates fatalities.

Doxycycline and chloramphenicol are the recommended treatments. Doxycycline can be given as a single dose of 200 mg or for a course of 3 to 7 days. Alternative drugs include rifampin (600–900 mg/d) and azithromycin (500 mg initial dose, then 250 mg/d).

Q fever

Coxiella burnetii, the etiologic agent of Q fever, was discovered simultaneously in the 1930s in Montana as the cause of a human laboratory-acquired infection and in Australia, where researchers were investigating an outbreak of febrile illness among slaughterhouse workers they called "Query" (Q) fever. Q fever can present as an acute infection with an influenza-like illness, including pulmonary and hepatic involvement, or it can develop into a chronic infection with endocarditis and chronic granulomatous hepatitis. *C. burnetii* is an extremely infectious organism: a single inhaled organism is sufficient to initiate infection. It is endemic worldwide except in New Zealand. *C. burnetii* infects many species of animals, and the infection usually results in long-lasting parasitism. Q fever in humans is usually caused by the inhalation of aerosolized particles from infected domestic animals; these particles can be airborne over long distances. *C. burnetii* is asymptomatic in about half of those infected. Those with clinical illness most commonly have a nonspecific febrile illness, which may be associated with pneumonia, hepatitis, or meningoencephalitis. Patients can go on to develop a chronic illness characterized by endocarditis and granulomatous hepatitis.

The incubation period for Q fever can be as short as 4 to 5 days, but it typically ranges from 9 to 39 days. High fever is the most common symptom, occurring in almost all patients, with temperature often spiking to 40°C/104°F to 40.5°C/105°F). Pneumonia is the primary clinical manifestation, with a majority of patients showing abnormalities on chest radiography. Other signs and symptoms include chills, headache (often severe and debilitating), retrobulbar pain, myalgias and arthralgias, neck pain and stiffness, pleuritic chest pain, cough, nausea and vomiting, diarrhea, jaundice, hepatomegaly, and splenomegaly. Unlike the rickettsial diseases, Q fever does not usually present with a rash, although a transient erythematous macular rash has been noted in about 4% of patients. The manifestations of Q fever usually resolve within 2 to 4 weeks, although some patients have fever for as long as 9 weeks. Case fatality rates from acute Q fever are very low (none in most series), but in hospitalized patients the case fatality rate has been reported as 2.4%.

Chronic Q fever is uncommon (<5% of patients with acute infections) and usually manifested by endocarditis. Most patients have preexisting valvular heart disease, often a prosthetic valve. Other manifestations include chronic hepatitis, infections of vascular prostheses and aneurysms, osteomyelitis, and interstitial pulmonary fibrosis. The illness evolves slowly, manifesting any time from a few months to 20 years after the acute infection, and presents clinically as a culture-negative endocarditis, although fever is often absent in Q fever endocarditis. Post-Q fever fatigue syndrome, lasting for several years to life, is the most common chronic manifestation after acute infection, occurring in up to 20% of patients.

The diagnosis of Q fever is based on identifying risk factors and clinical suspicion. Culture is not recommended as it is difficult and dangerous, requiring a biosafety level 3 laboratory. Serologic testing of paired acute and convalescent sera, showing a fourfold increase of IgG to *C. burnetii* phase II antigen by an indirect immunofluorescence antibody assay, is the most common method for diagnosing acute Q fever. PCR testing of blood or tissue is another diagnostic method, but different tests vary in sensitivity and specificity.

Most acute Q fever infections resolve spontaneously, but, given concern about the development of chronic Q fever, specific antimicrobial therapy should be given. The treatment of choice is doxycycline orally for 2 weeks; some success has been reported with trimethoprim-sulfamethoxazole (TMP-SMX), chloramphenicol, rifampin, and (in vitro) telithromycin.

The treatment of chronic Q fever has never been the subject of controlled studies. Current recommendations are to give doxycycline together with hydroxychloroquine for at least 18 months, a regimen shown in retrospective data to be superior to long-term tetracycline plus a fluoroquinolone in Q fever endocarditis. A vaccine for people in at-risk professions is available in Australia but requires testing before vaccination to identify preexisting immunity, as it can lead to a severe local reaction.

Ehrlichiosis and anaplasmosis

Johan S. Bakken and J. Stephen Dumler

Ehrlichiosis is the collective name for infections caused by obligate intracellular gram-negative bacteria in the genera *Ehrlichia*, *Anaplasma*, and *Neoehrlichia*, family Anaplasmataceae. Members of these genera cycle between invertebrate (arthropod) and vertebrate hosts, and some cause human zoonoses. At least seven species cause human tick-borne infection in the United States and Europe, including *Ehrlichia chaffeensis*, the agent of human monocytic ehrlichiosis (HME), *Ehrlichia ewingii*, the agent of human ewingii ehrlichiosis (HEE), *Anaplasma phagocytophilum*, the agent of human granulocytic anaplasmosis (HGA), an *Ehrlichia muris*-like agent (EMLA), the Panola Mountain ehrlichia, an agent phylogenetically similar to *Ehrlichia ruminantium* that has caused fever in humans in the United States, *Ehrlichia canis*, thought limited to canids but identified as an agent of human febrile illness in Venezuela, and *Candidatus* Neoehrlichia mikurensis, which has caused severe sepsis-like conditions in Europe, but mild febrile disease in Asia. While human infection by *Neorickettsia sennetsu* periodically surfaces in Asia, the transmission and disease processes are distinct and it will not be considered here.

Most Anaplasmataceae reside in ixodid (hard-body) ticks, and the bacteria are acquired during the larval stage and passed transstadially with each successive tick stage. *Amblyomma americanum* (the Lone Star tick) is the vector for *E. chaffeensis* and *E. ewingii*, and its range is throughout the south and eastern United States from Maine to Texas. In addition, all documented reports of human infections are limited to North America, although some evidence suggests that they exist in ticks in South America and Asia. In contrast, *A. phagocytophilum* and the *E. muris*-like agent cycle within *Ixodes* species ticks. *Ixodes scapularis* (the black-legged or deer tick) is found in the eastern United States and is a vector for both species. In addition, *Ixodes pacificus* (the western black-legged tick), found in regions of the US Pacific coast (northern California, Oregon, and Washington), and *Ixodes ricinus* and *Ixodes persulcatus*, found in Europe and Asia, respectively, are competent vectors for *A. phagocytophilum*. *Ixodes* species ticks are also vectors for *Borrelia burgdorferi* (the agent of Lyme borreliosis), and most cases of HGA are reported from areas where Lyme borreliosis is endemic.

Thus far, HGA has been reported in 36 US states and in countries in western and central Europe, as well as Russia, China, Korea, and Japan. Active US surveillance in southeastern Missouri identified HME incidence as high as 414 cases per 100 000 population. The incidence for HGA varies from 25 up to 58 cases per 100 000 in endemic regions of Connecticut and Wisconsin. Only a limited number of cases of HEE have been recognized in central US states, but it is anticipated to be common. Clinical cases of infection by the *E. muris*-like agent were recently recognized in up to 48 patients in Wisconsin and Minnesota, and a small fraction of healthy blood donors in Minnesota and Wisconsin have evidence of past exposure. Less than 20 Venezuelan patients with *E. canis* infection, and only a small number of infections by *Candidatus* N. mikurensis, likely transmitted by *I. ricinus* ticks in Europe, have been identified; there is only a single report of Panola Mountain ehrlichia human infection. Most cases of ehrlichiosis present during the period between April and October, and as many as 75% of patients have noted one or more tick bites 1 to 2 weeks prior to the onset of symptoms. Male patients outnumber females by a factor of nearly 3 to 2, and even though HME and HGA affect all age groups, symptomatic infection is less frequent in children. The case-fatality rate is 0.6% and 2.7% for HGA and HME, respectively. Table 169.1 summarizes some of the

TABLE 169.1 **EPIDEMIOLOGIC CHARACTERISTICS, INCIDENCE RATES AND REPORTED CASES ASSOCIATED WITH HUMAN MONOCYTIC EHRLICHIOSIS (HME), HUMAN EWINGII EHRLICHIOSIS (HEE), HUMAN GRANULOCYTIC ANAPLASMOSIS (HGA), *EHRLICHIA MURIS*-LIKE AGENT (EMLA) INFECTION AND *CANDIDATUS* NEOEHRLICHIA MIKURENSIS INFECTION**

epidemiologic characteristics associated with HME, HEE, HGA, EMLA-associated illness, and *Candidatus* N. mikurensis infection.

When the tick takes a blood meal, bacteria become injected with the tick saliva into the host. Once injected, the bacteria infect specific circulating leukocytes and cause a nonspecific febrile illness. *Ehrlichia chaffeensis* and EMLA typically infect monocytes and macrophages, whereas *E. ewingii* and *A. phagocytophilum* infect neutrophilic granulocytes; *Candidatus* N. mikurensis has been observed only once in human neutrophils but its definitive target is not yet established. The bacteria adhere to leukocyte membrane receptors to enter cells by endocytosis. There are key differences in the vacuoles with *E. chaffeensis* and *A. phagocytophilum*, underscoring that the agents induce distinct pathogenetic pathways. Regardless, the bacteria reside within cytoplasmic vacuoles, where they interact with the host cell to access nutrients, delivering effector proteins to the host cytosol and nucleus that subvert host cell functions, including intracellular signaling, cell cycle regulation, innate immune responses such as respiratory burst or induction of immune activation, delayed induction of apoptosis, and subversion of autophagy, among others. During this interval, the bacteria multiply in the vacuole to form aggregates called morulae. Eventually, each morula fuses with the cell membrane through exocytosis or the cell is mechanically lysed, liberating bacteria to infect other cells. Most recent investigations of disease pathogenesis focus on the induction of innate, inflammatory, and immune-mediated injury as the major consequence of infection. This suggests that an important target for control of disease could include control of inflammatory and immune responses.

Even though they differ with respect to biology, epidemiology, and ecology, HME, HEE, HGA, and infection with EMLA present as clinically similar illnesses with characteristic, albeit nonspecific alterations in hematology and chemistry laboratory tests. The incubation period for HME, HEE, HGA, and EMLA varies between 1 and 2 weeks following tick exposure or tick bite. The symptoms and signs range from asymptomatic to fatal, and clinical severity increases with patient age and comorbid illnesses. Ehrlichiosis presents as a clinical syndrome most commonly manifest by abrupt onset of fever, shaking chills, severe headache, and myalgia (Table 169.2); a specific diagnosis can be difficult because of the undifferentiated nature of the signs and symptoms. Between one-third and one-half of symptomatic patients require hospitalization for 1 week or longer. Infection with *Candidatus* N. mikurensis can result in either a severe febrile illness that lasts for weeks in the absence of therapy, as observed in Europe where most patients had pre-existing immune compromise, or as a mild to moderate and self-limited illness, as observed in Asia where most patients were not immune compromised.

Laboratory abnormalities are nonspecific and include various leukopenia and thrombocytopenia with a differential leukocyte count that reveals increased proportions of band neutrophils and a corresponding decrease in relative and absolute lymphocyte concentrations. In addition, most patients manifest mild to moderate increases in serum transaminase activities reflecting underlying hepatocellular injury. Albeit relatively insensitive, the diagnosis can be confirmed by blood smear examination, because morulae can be observed in peripheral blood leukocytes of 1% to 20% of patients with HME and as many as 60% of patients with HGA during the first week of infection (Figure 169.1). Polymerase chain reaction (PCR) is an excellent tool for diagnosing HME, HEE, HGA, and EMLA during the early stage of infection, and sensitivity >90% and specificity >95% are regularly achieved. However, the availability of these PCR assays is limited to large commercial, academic medical, or public health reference laboratories. More than 95% of patients with HME and HGA form specific antibodies during the course of the infection, and testing of acute and convalescent sera using indirect fluorescent antibody (IFA) tests is currently the most sensitive method for laboratory confirmation of HME and HGA, even though the diagnosis is only retrospective. Antibody titers remain elevated for months to years after convalescence, and no evidence of persistent infection associated with clinical disease has ever been observed. Serologic cross-reactivity between *Ehrlichia*

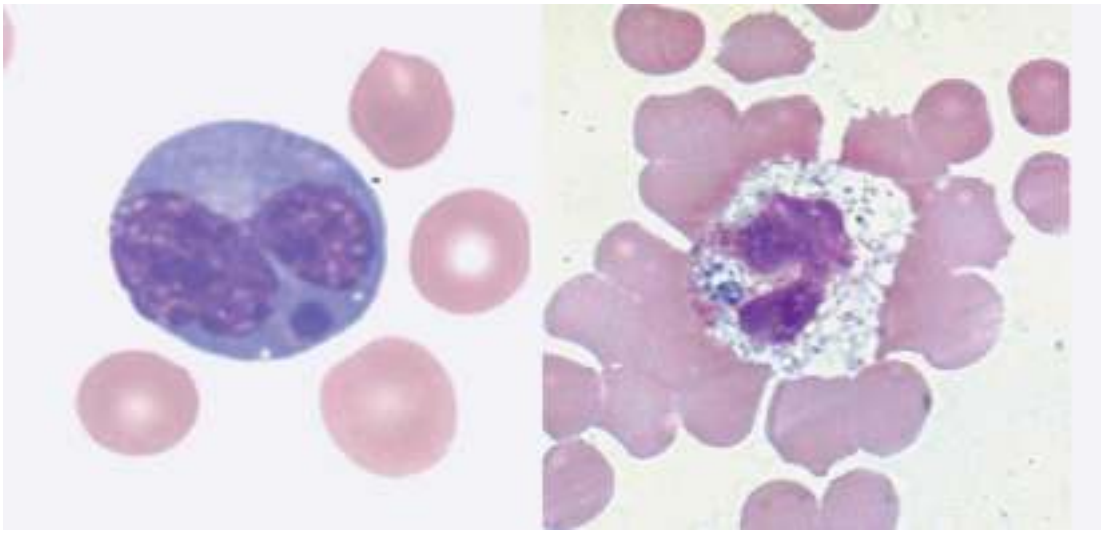

FIGURE 169.1

spp. and *Anaplasma phagocytophilum* is frequent, but differential titers can be helpful. No specific serologic tests exist for either HEE or EMLA. Most diagnoses of Panola Mountain ehrlichia and *Candidatus* N. mikurensis infections have been made by specific or broad-range PCR.

Laboratory criteria for *probable* HME and HGA include a compatible exposure history and clinical illness combined with (1) the detection of morulae in peripheral blood, (2) a single high positive IFA titer, or (3) positive PCR of acute phase blood. The criteria for a *confirmed* case of HME or HGA requires (1) demonstration of seroconversion (4-fold or greater change in serum antibody titer) with *E. chaffeensis* or *A. phagocytophilum*, (2) isolation of *E. chaffeensis* or *A. phagocytophilum* in culture from blood, or (3) a single elevated IFA titer combined with either detection of morulae in the peripheral blood smear or a positive PCR. Formal laboratory criteria for probable or confirmed HEE, EMLA or *Candidatus* N. mikurensis infection have yet to be established.

Therapy

Ehrlichia and *Anaplasma* are susceptible in vitro to tetracycline, tetracycline derivatives, and rifampin. However, no controlled clinical trials of antimicrobial agent efficacy have been conducted and treatment recommendations are therefore based on the experience from empirical antibiotic treatment of infected humans. Even though HME and HGA can manifest as self-limited febrile illnesses that resolve spontaneously without therapy, it is currently recommended that any patient diagnosed with acute infection should receive antibiotic treatment. Doxycycline, 100 mg administered twice daily (oral or intravenous route), is the treatment of choice for adults. Doxycycline, 2 mg/kg, maximum dose 100 mg, given twice daily, is the preferred treatment for children who are seriously ill. The response to doxycycline is rapid; most patients become afebrile and resolve symptoms within 24 to 36 hours. In fact, failure to respond to doxycycline should prompt further clinical evaluation of the patient for an alternative diagnosis. The optimal duration of therapy with doxycycline has not been established. Serologic surveys demonstrate that 15% to 20% of patients with active HGA also are seroreactive with *B. burgdorferi*, the agent of Lyme borreliosis. Doxycycline therapy should therefore be administered for 10 to 14 days to ensure adequate coverage for potential co-incubating Lyme borreliosis.

Treatment with rifampin can be considered for pregnant women, known hypersensitivity to tetracycline class drugs, and children younger than 8 years with mild to moderate illness suitable for outpatient management. The dose of rifampin is 300 mg given twice daily for adults and 10 mg/kg (maximum dose 300 mg) twice daily for children for 5 to 7 days. Chloramphenicol is not recommended for treatment of ehrlichiosis, since in vitro susceptibility assays with chloramphenicol demonstrate poor activity against *E. chaffeensis* and *A. phagocytophilum*, and treatment failures with fatal outcome have been noted. Fluoroquinolones have in vitro activity against *A. phagocytophilum*, but not *E. chaffeensis*; however, limited experience has shown that levofloxacin is apparently not bactericidal and should not be used to treat HGA.

Human ehrlichioses are for the most part self-limited clinical illnesses that resolve spontaneously, even without active antibiotic therapy. Unlike Lyme borreliosis and babesiosis, HME, HEE, HGA, and EMLA have not been reported to be associated with persistent infection, but several patients with *Candidatus* N. mikurensis infection had severe febrile illnesses that lasted as long as several weeks before treatment or death. The long-term prognosis after resolved HME, HEE, HGA, and EMLA appears favorable, and patients should expect to make a complete recovery.

Section 22

Specific organisms: Fungi

170

Candidiasis

Christopher F. Carpenter and Nicholas Gilpin

Candida spp. are small, unicellular yeasts that are found in a number of environments, including soil, hospital surroundings, food, and other inanimate objects. Most species also may live as commensal organisms, colonizing the skin, gastrointestinal tract, and vagina. They become opportunistic pathogens when the host has compromised immunologic or mechanical defenses or when there are changes in the host's normal flora, such as those triggered by broad-spectrum antibiotic use and chemotherapy. *Candida* spp. are common causes of disease ranging from superficial cutaneous and mucocutaneous infections to invasive infections such as candidemia and disseminated candidiasis. There are >150 species of *Candida*, with *Candida albicans* (Figure 170.1) being the most frequently implicated in human disease processes. Over the past two decades, however, there has been a noticeable increase in disease due to non-*albicans* species. Important non-*albicans* pathogens include *C. tropicalis* (Figure 170.2), *C. parapsilosis*, *C. glabrata* (Figure 170.3), *C. krusei* (Figure 170.4), *C. kefyr*, *C. lusitaniae*, *C. dubliniensis*, *C. guilliermondii*, and *C. auris*. This latter organism, *C. auris*, is an emerging multidrug-resistant pathogen that is causing healthcare-associated outbreaks of severe infections. Less commonly isolated species with medical significance include *C. lipolytica*, *C. famata*, *C. rugosa*, *C. viswanathii*, *C. haemulonii*, *C. norvegensis*, *C. catenulate*, *C. ciferri*, *C. intermedia*, *C. utilis*, *C. lambica*, *C. pulcherrima*, and *C. zeylanoides*.

Diagnosis of *Candida* infections continues to be primarily via culture, although a number of faster and more sensitive contemporary diagnostic methods have become available, including polymerase chain reaction (PCR), CHROMagar (Figure 170.5), and T2Candida. Indirect diagnostic methods have also become more widely used in clinical practice, such as the serum or plasma (1→3)-β-D-glucan (BDG) assay, which is specific for a unique component of the cell wall in many fungi that is detectable during invasive candidiasis. Given that several *Candida* species have intrinsic or acquired resistance to antifungal agents (Table 170.1), these tests may prove to be cost-effective approaches for guiding early appropriate antifungal therapy in certain clinical settings. Newer antifungal agents have become available for the treatment of *Candida* infections, including advanced-generation triazoles and the echinocandins (Table 170.2), which are particularly useful when antifungal resistance is suspected or proved.

Infectious syndromes and treatment/prophylaxis

Mucocutaneous *Candida* syndromes

Cutaneous candidiasis

Primary cutaneous candidiasis is commonly seen in normal hosts manifesting as diaper dermatitis and intertriginous infections. Other manifestations include balanitis, folliculitis, paronychia, and onychomycosis. Cutaneous candidiasis most commonly presents in skin areas that are moist and/or occluded or in areas of impaired skin integrity, such as burns or chronic wounds. Immunocompromised patients, including patients with diabetes mellitus, are also at increased risk. Cutaneous candidiasis is generally a clinical diagnosis,

FIGURE 170.1 *Candida albicans* on CHROMagar.

demonstrated by the presence of a confluent erythematous rash with satellite lesions in a typical warm, moist environment such as the perineum or axilla. Microscopic examination of skin scrapings revealing budding yeast cells and hyphae may be useful to confirm the diagnosis. Positive cultures for *Candida* species may also assist with diagnosis; however, positive results may occur because of colonization or contamination, and thus culture is generally not recommended. Bacterial superinfection may also coexist with cutaneous candidiasis and sometimes necessitates antimicrobial therapy. Non-antimicrobial methods are important in both prevention and treatment of cutaneous candidiasis, such as keeping skin surfaces clean and dry, frequent diaper changes, and control of hyperglycemia in patients with diabetes. Topical antifungals such as nystatin cream or an imidazole cream are the mainstay of treatment. Systemic therapy with fluconazole, itraconazole, or terbinafine is rarely required for severe or refractory cases.

Chronic mucocutaneous candidiasis

Individuals with chronic mucocutaneous candidiasis suffer from persistent and recurrent *Candida* infections of the skin, nails, and mucous membranes. It most commonly occurs within the first two decades of life. T-cell dysfunction is the primary immunologic abnormality associated with chronic mucocutaneous candidiasis, although other immune abnormalities such as immunoglobulin deficiency and cutaneous anergy have been described. Several endocrine disorders have been associated with chronic mucocutaneous candidiasis, such as hypoparathyroidism, Addison's disease, hypothyroidism, and diabetes. The disease is a complex disorder that may manifest as one of many different syndromes with variable severity, although associated invasive disease is quite rare.

Therapy for mucosal infections is typically accomplished with topical or systemic triazole antifungal agents. A significant problem with mucosal disease is its propensity for repeated relapses, particularly among immunocompromised hosts and persons with HIV infection. Chronic suppressive therapy is usually unnecessary but is occasionally employed in select cases, with the associated risk of emerging resistance.

Oropharyngeal and esophageal candidiasis

As normal members of the gastrointestinal tract flora, *Candida* spp. become pathogenic in the oropharynx and esophagus in patients with various risk factors, including impaired cell-mediated immunity (e.g., HIV infection, chronic mucocutaneous candidiasis, stem cell and solid organ transplant recipients), diabetes mellitus, extremes of age, or esophageal motility disorders. The use of certain medications, including progesterone, broad-spectrum antibiotics, or immunosuppressive agents is also a contributing factor in many cases.

Oral candidiasis most commonly presents as creamy white, plaque-like lesions on the oropharyngeal mucosa or tongue surface.

FIGURE 170.3 *Candida glabrata* on CHROMagar.
Courtesy of Dr. Barbara Robinson-Dunn and Ms. Mrudula Nandwana, Beaumont Health.

Candidiasis lesions are typically painless, but atypical and more symptomatic forms may exist, such as erythematous or pseudomembranous plaques (erythematous candidiasis), *Candida* leukoplakia, or hyperplastic candidiasis. Angular cheilitis, a painful condition with associated cracking and erythema at the oral commissure, can also be a result of *Candida* infection. As with cutaneous candidiasis, oropharyngeal candidiasis is usually a clinical diagnosis. Cultures are not usually recommended because of the potential for positive results due to colonization. For treatment of mild disease, clotrimazole troches or nystatin suspension for about 7 to 14 days are recommended first-line agents. For more moderate to severe oropharyngeal candidiasis, often seen in patients with HIV infection, systemic therapy with low-dose oral fluconazole for 7 to 14 days is generally recommended. Infections that are refractory to fluconazole should be managed with another systemic antifungal agent, such as an extended-spectrum azole or echinocandin.

FIGURE 170.4 *Candida krusei* on CHROMagar.
Courtesy of Dr. Barbara Robinson-Dunn and Ms. Mrudula Nandwana, Beaumont Health.

Esophageal candidiasis often presents as dysphagia or odynophagia, usually with retrosternal pain. Clinically, it can be difficult to distinguish *Candida* esophagitis from other causes of esophagitis, such as cytomegalovirus esophagitis, herpes simplex virus esophagitis, esophageal ulcers, eosinophilic esophagitis, or pill esophagitis. The presence of oral thrush coupled with dysphagia or odynophagia has relatively good predictive value for esophageal candidiasis, and a therapeutic trial is a reasonable alternative to endoscopy in such patients. Empirical therapy should include a systemic antifungal for about 14 to 21 days; typically, fluconazole in oral or parenteral form is prescribed. In rare circumstances, an alternative antifungal agent such as an echinocandin, extended-spectrum triazole, or low-dose amphotericin B may be required. In refractory cases, endoscopy with mucosal brushings or biopsy may be necessary to confirm the diagnosis, test for antifungal resistance, and evaluate for other potential concomitant pathogens or disorders (Figures 170.6 and 170.7).

Vulvovaginal candidiasis

Vulvovaginal candidiasis (VVC) is common in women of childbearing age and is the most common form of mucosal candidiasis. Several host risk factors can predispose to VVC, including pregnancy, oral contraceptive use, antibiotic use, diabetes mellitus, HIV infection, and the presence of an intrauterine device or a diaphragm. Often no precipitating factor can be found. The mechanism by which asymptomatic colonization transforms into symptomatic VVC remains unclear. For clinical purposes, VVC may be classified as complicated or uncomplicated (Table 170.3). About 90% of cases are classified as uncomplicated. The clinical manifestations of VVC are primarily vulvar pruritus, vaginal discharge, dyspareunia, dysuria, and vaginal irritation, although none of these symptoms is particularly sensitive or specific. Signs include erythema and edema of the vulva with erythema of the vagina and vaginal discharge of variable consistency, often described as thick and curd-like. As with other forms of mucocutaneous candidiasis, the diagnosis is typically made clinically, but confirmation is easily obtained by observing budding yeast, with or without pseudohyphae, on a wet mount or 10% potassium hydroxide preparation of vaginal secretions. Evaluation for concomitant pathogens or sexually transmitted infections is also prudent.

Uncomplicated VVC can be managed successfully with a number of topical antifungal agents, with courses ranging from single doses to short courses of 3 to 7 days. Alternatively, fluconazole as a single

FIGURE 170.5 Mixture of *Candida* species (*C. albicans, C. tropicalis, C. glabrata*, and *C. krusei*) on CHROMagar.
Courtesy of Dr. Barbara Robinson-Dunn and Ms. Mrudula Nandwana, Beaumont Health.

dose of 150 mg is also quite effective. Treatment with azoles results in symptomatic relief in about 80% to 90% of patients who complete therapy, and no agent is considered clearly superior.

Complicated VVC, including recurrent VVC (RVVC, usually defined as four or more episodes of symptomatic VVC in 1 year), affects a small percentage of women with VVC (≤5%). Vaginal cultures should be obtained to confirm the clinical diagnosis of RVVC and to identify unusual species, including non-*albicans* species such as *C. glabrata*, for which conventional antifungal therapies may not be as effective. Each individual episode of RVVC caused by *C. albicans* usually responds well to short-duration oral or topical azole therapy, but in some situations a course of induction therapy followed by a maintenance dose of suppressive antifungal therapy for several months is necessary for control of symptoms. Unfortunately, 30% to 50% of women will have recurrent disease after suppressive therapy is discontinued. For pregnant patients with VVC, topical therapy for 7 days is recommended.

Candidemia and disseminated candidiasis

Candidemia

Candida species are a significant cause of nosocomial bloodstream infections in the United States. Crude mortality rates of candidemia range from 30% to 61% with attributable mortality ranging as high as 49%. *Candida* species, like some bacterial pathogens, are capable of forming biofilms on catheters and other surfaces, leading to infections that are difficult to eradicate. Certain risk factors are known to predispose to candidemia, but it remains exceedingly difficult to clinically predict which patients will develop infection. For example, colonization with yeast remains a leading risk factor for infection in the intensive care unit (ICU). However, the prevalence of colonization in the ICU is high (50–70% or more), which corresponds to a low predictive value given the relatively low rate of invasive infection. Nevertheless, colonization in ICU patients

with unexplained fever, leukocytosis, and hypotension merits strong consideration of invasive candidiasis and candidemia as a potential cause of sepsis, as delay of antifungal treatment portends significantly high mortality. In all cases, candidemia requires antifungal treatment and removal of potential sources, such as vascular devices. Search for additional foci of infection is also critical, as dissemination to areas such as the eye, liver, spleen, kidney, heart, soft tissues, bone, central nervous system (CNS), and gastrointestinal tract may occur. This is of particular concern in patients who are immunocompromised. Given the high morbidity and mortality of candidemia and disseminated candidiasis, azole susceptibility testing is recommended for all bloodstream and invasive *Candida* isolates, and echinocandin susceptibility testing should be considered if previously treated with an echinocandin or if infected with *C. glabrata* or *C. parapsilosis*.

FIGURE 170.6 Endoscopic view, *Candida* esophagitis.

Echinocandins are recommended as empiric therapy for suspected invasive candidiasis, though fluconazole may be considered in select patients who are not critically ill and who are unlikely to harbor azole-resistant *Candida* spp. *C. albicans* is usually susceptible to most antifungals, including fluconazole, whereas other species are more likely to demonstrate reduced susceptibility or resistance to select antifungals. For example, *C. krusei* should be considered resistant to fluconazole and itraconazole, but it is usually susceptible to voriconazole, echinocandins (nearly 100% susceptible), and amphotericin B formulations (though higher doses may be required). *C. glabrata* has variable dose-dependent susceptibility to fluconazole and itraconazole, and it may be frankly resistant to these antifungals. It also typically shows some degree of cross-resistance to the newer triazoles, although voriconazole could be considered as step-down therapy if susceptible. The echinocandins have activity against most *Candida* spp., although *C. parapsilosis* typically has relatively higher minimum inhibitory concentrations to these antifungals. The clinical relevance of these in vitro data is not clear.

For non-neutropenic patients, potential antifungal choices include caspofungin (70 mg loading dose followed by 50 mg/d), micafungin (100 mg/d), or anidulafungin (200 mg loading dose followed by 100 mg/d). Fluconazole (800 mg [12 mg/kg] loading dose, followed by 400 mg [6 mg/kg] per day) may be considered in less ill individuals unlikely to have fluconazole-resistance. Amphotericin B or a lipid-based amphotericin B formulation is an alternative that is much less commonly used for this indication today, generally only if there is intolerance to the other antifungal agents. Most neutropenic patients should initially be managed with an echinocandin. Select circumstances may lead to use of a lipid-based amphotericin B formulation, fluconazole, or voriconazole or other extended-spectrum azole. All candidemia treatment should be extended for at least 2 weeks after clearance of candidemia and resolution of sepsis. For neutropenic patients, recovery of neutrophil counts is another important factor, and antifungal treatment should generally be continued until this occurs. Step-down oral therapy with an azole may be considered after 5 to 7 days in patients who are clinically stable with negative repeat blood cultures and who have isolates susceptible to the azole. Dilated ophthalmological examination should be performed in all patients within the first week after diagnosis, and it should be deferred until or repeated within the first week after neutrophil recovery for neutropenic patients.

Chronic disseminated candidiasis

Chronic disseminated candidiasis (CDC, formerly hepatosplenic candidiasis) is an indolent process most commonly found in patients with severe persistent neutropenia (e.g., in patients with acute leukemia or stem cell transplant recipients) that frequently becomes apparent when the neutrophil count begins to recover. It typically involves the liver and/or spleen, although other organs may be involved. CT or MR) studies are helpful in confirming the diagnosis (>90% sensitive), often by identifying small discrete lesions within the liver or spleen. Unfortunately, such lesions may be absent early in

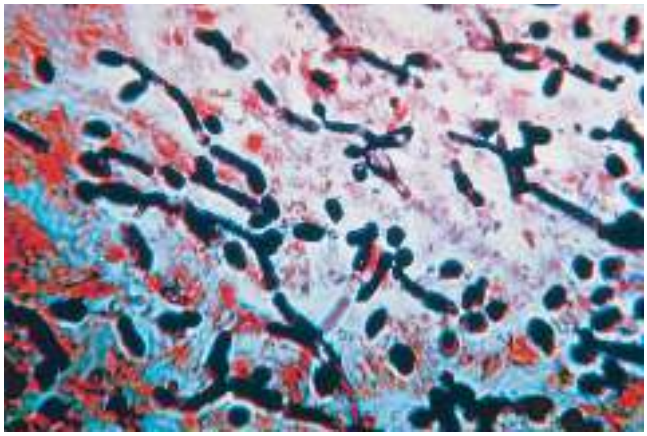

FIGURE 170.7 Photomicrograph of esophageal candidiasis (silver stain, ×100).
Courtesy of Sherry Brinkman, CDC Public Health Image Library.

the course of disease. Signs and symptoms of CDC are neither sensitive nor specific and may include right upper quadrant tenderness, elevated transaminases and alkaline phosphatase concentrations, and hepatosplenomegaly. Blood cultures are often negative, and biopsy may be required to confirm the diagnosis. Much of what is known about treatment of CDC has been gathered from case-series data. Amphotericin B, fluconazole, and echinocandins have been shown successful. Therapy should be continued until lesions appear calcified or cleared, a process which may take several months. Notably, in patients who receive repeated courses of antineoplastic therapy or who persistently remain immunosuppressed, prolonged treatment or suppression may be necessary.

Other forms of invasive candidiasis

Endocarditis and cardiac device infections

Patients with *Candida* endocarditis and patients with bacterial endocarditis share both risk factors (intravenous drug use, cardiac surgery, prosthetic heart valves, abnormal native heart valves, and central venous catheters) and clinical presentation (fever, nonspecific signs and symptoms, cardiac murmur, and congestive heart failure). Mycotic emboli to major arteries are more common in *Candida* endocarditis, and blood cultures are often negative initially. The diagnosis should be considered in all patients with candidemia. Evidence of a valvular vegetation by transthoracic or the more sensitive transesophageal echocardiogram establishes the diagnosis. Definitive treatment for native or prosthetic valve *Candida* endocarditis involves valve replacement in conjunction with a prolonged course of antifungal therapy, typically lipid-based amphotericin B formulation (3–5 mg/kg/d with or without flucytosine 25 mg/kg QID) or high-dose echinocandin (caspofungin 150 mg/d, micafungin 150 mg/d, or anidulafungin 200 mg/d) for at least 6 weeks after surgery. Chronic suppression with fluconazole is recommended if valve replacement cannot be performed and the yeast is susceptible. Following treatment, patients should be monitored closely for a minimum of 1 year due to the propensity for relapse.

Infections due to *Candida* spp. involving cardiac devices such as pacemaker and implantable cardiac defibrillator infections are fortunately uncommon. Therapy should include removal of the entire device as well as systemic antifungal therapy as recommended for endocarditis. If the infection is limited to the generator or pocket, 4 weeks of therapy is recommended. If the infection involves wires or leads, at least 6 weeks of therapy is recommended. Failure to remove the device completely should warrant long-term suppressive azole therapy.

Central nervous system infections

Meningitis is the most common form of CNS candidiasis, but numerous other forms of infection such as cerebral or epidural abscesses may occur. Low-birth-weight infants and immunosuppressed hosts are at particularly increased risk for meningitis. Nosocomial risk factors such as recent neurosurgery and the presence of ventricular shunts and drains are also significant in the development of *Candida* CNS infections. Signs and symptoms are similar to, but often less severe than, bacterial meningitis. Typically there is a more indolent and chronic course. Cerebrospinal fluid (CSF) analysis usually reveals a neutrophilic predominance, elevated protein, and either normal or depressed glucose. The diagnosis can be difficult because the organism is present in low numbers in the CSF and the yield of standard CSF cultures is poor; thus repeated CSF cultures may be required. Therapy with lipid-based amphotericin B (3–5 mg/kg/d) with or without oral flucytosine (25 mg/kg QID) is recommended

TABLE 170.3 CLASSIFICATION OF VULVOVAGINAL CANDIDIASIS (VVC)

Uncomplicated VVC	Complicated VVC
All of the following:	At least one of the following:
• Sporadic and infrequent VVC	• Recurrent VVC
• Mild to moderate VVC	• Severe VVC
• Likely to be *Candida albicans*	• Non-*albicans* VVC
• Nonimmunocompromised women	• Women with diabetes, immunocompromising conditions (e.g., HIV infection), debilitation, or immunosuppressive therapy (e.g., corticosteroids)

From Centers for Disease Control and Prevention (CDC). Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep*. 2015;64(No. RR-3):1–137.

initially. After there is clinical response to initial therapy (usually several weeks later), treatment may be adjusted to fluconazole (400–800 mg/d) until all signs and symptoms have resolved. Removal of any ventricular shunt or drain is highly recommended to achieve eradication.

Ocular infections

Up to 15% of patients with candidemia have retinal lesions, often visible within 1 week of the onset of illness. The mortality rate in ICU patients with *Candida* endophthalmitis is considerably higher than the mortality rate in patients with candidemia alone. Symptoms may include bulbar pain, scotomas, and blurred vision. Diagnosis requires a high degree of clinical suspicion, and thus all patients with candidemia should be screened at least once for endophthalmitis by an ophthalmologist. Additional screening is discretionary and may be required in cases of persistent candidemia or in patients who are unable to communicate regarding visual disturbances. Lesions may be sight-threatening; diagnosis relies on characteristic ocular findings such as white lesions on the retina with ill-defined borders with possible vitreal extension. A diagnostic vitreal aspiration is often necessary if endophthalmitis is suspected and the etiology is unknown. The sensitivity of vitreous humor cultures remains low, ranging from 33% to 50%, and PCR may increase diagnostic yield. Recommended systemic therapy follows that for candidemia. Endophthalmitis due to fluconazole-/voriconazole-resistant isolates should be treated with an amphotericin B formulation with or without flucytosine at doses used for candidemia, particularly for sight-threatening lesions. Fluconazole or voriconazole are treatment options for fluconazole-/voriconazole-susceptible isolates. Both have good vitreal penetration and less toxicity compared with amphotericin B. Caution is advised with the use of echinocandins because of poor ocular tissue penetration. Typically, about 4 to 6 weeks of therapy is anticipated for endophthalmitis in conjunction with close ophthalmology follow-up. Intravitreal injection of amphotericin B deoxycholate or voriconazole should be considered for macular involvement and, in patients with vitreitis vitrectomy, should be considered to decrease the burden of organisms and allow removal of fungal abscesses.

Intra-abdominal candidiasis

Candida peritonitis may develop in patients on peritoneal dialysis, after gastrointestinal surgery, as a complication of candidemia, or as an extension of local organ or tissue infection. In addition, gastric and duodenal mucosal infections may develop in patients with peptic ulcer disease or mucosal neoplasm. Other rare intra-abdominal manifestations of *Candida* infection include isolated pancreatic abscess, gangrenous cholecystitis, and obstruction of the common bile duct with a *Candida* fungus ball. *C. albicans* is the predominant species isolated in intra-abdominal infections, but *C. glabrata* plays a significant role. Diagnosis is made by paracentesis or by endoscopic, percutaneous, or open biopsy. Antifungal therapy targeting *Candida* is not recommended for all patients with community-acquired intra-abdominal infection, but antifungal therapy is recommended in patients with significant risk factors for candidiasis (e.g., recent abdominal surgery or anastomotic leaks). An echinocandin or fluconazole is most commonly recommended for empiric therapy. Amphotericin B formulations are not usually recommended due to significant toxicity. As with all intra-abdominal infections, appropriate source control measures (e.g., drainage of abscesses, removal of infected material, etc.) are also crucial in management and to help define the duration of therapy.

Bone and soft tissue infection

Bone and soft tissue infections are rare complications of *Candida* dissemination or direct extension of a local *Candida* infection and are diagnosed by needle aspiration or via surgical debridement. They also may result from exogenous inoculation during trauma, intra-articular injection, a surgical procedure, or injection drug use. Treatment usually requires a combination of surgical debridement/drainage and often prolonged systemic antifungals (6–12 months for osteomyelitis, 6 weeks for septic arthritis), and fluconazole or an echinocandin is recommended for initial therapy; lipid formulation amphotericin B is an alternative. If prosthetic joint hardware or other devices are involved, removal is highly recommended to achieve cure.

Respiratory tract candidiasis

Pneumonia due to *Candida* spp. is exceedingly rare as an isolated *Candida* infection. It is also poorly defined as a clinical entity because positive cultures cannot distinguish between true infection and either colonization or contamination of samples with oropharyngeal contents. Confirming a diagnosis of *Candida* pneumonia requires histopathologic confirmation, which is rarely performed. Growth of *Candida* from respiratory secretions alone is insufficient to warrant therapy and perhaps best serves to document colonization.

Patients with empyema involving *Candida* generally have an underlying predisposing condition such as malignancy, and esophageal perforation should be considered in appropriate clinical circumstances. Most cases are nosocomially acquired, occurring frequently with concomitant bacterial infection. Diagnosis is made with isolation of a fungal species from an exudative pleural effusion in association with clinical signs of infection. Treatment via drainage and systemic antifungals with an echinocandin or fluconazole is appropriate. The newer triazoles or lipid formulation amphotericin B may also be considered.

Genitourinary *Candida* infections

The isolation of *Candida* in the urine is common in hospitalized or nursing home patients, especially in those with indwelling urinary catheters. Most often catheter-related candiduria is asymptomatic, and although it generally does not require antifungal treatment, it may occasionally be difficult to distinguish patients with asymptomatic candiduria from those with true *Candida* urinary tract infections. Infections are more common and potentially more serious in patients who are taking broad-spectrum antibiotics or immunosuppressive agents, in patients with diabetes mellitus or who are otherwise immunosuppressed, and in patients with genitourinary

abnormalities (including obstructive uropathy and renal transplant recipients). The diagnosis is problematic as high colony count is not a strong indicator of infection, and pyuria in this setting is not always helpful. Frequently, the clinical suspicion combined with signs and symptoms of infection and culture results following removal of the catheter may be all that is available for the clinician. In most episodes of candiduria, catheter removal is often all that is required. *Candida* infection of the bladder also must be distinguished from infection of the kidney, although the two entities can coexist. Invasive infection of the kidney is unusual and is more difficult to treat. Other genitourinary syndromes (e.g., epididymo-orchitis) often require percutaneous culture for diagnosis.

Antifungal treatment for asymptomatic candiduria is only recommended for high-risk patients including those with neutropenia and very low-birth-weight infants, and they should be treated as recommended for candidemia. Treatment should also be recommended for patients undergoing urologic procedures with oral fluconazole 400 mg/d for several days before and after the procedure (amphotericin B deoxycholate may also be considered). Fluconazole is recommended for symptomatic *Candida* cystitis (200 mg/d) or symptomatic ascending candida pyelonephritis (200–400 mg) for 2 weeks is recommended if fluconazole-susceptible. For *C. glabrata* (fluconazole-resistant) or *C. krusei*, amphotericin B deoxycholate or flucytosine (*C. glabrata* only) could be considered. Amphotericin B bladder irrigations are not routinely recommended due to high relapse rates but may prove useful for treatment of resistant *Candida* isolates; other systemic antifungals (e.g., the echinocandins, posaconazole, isavuconazole, and voriconazole) do not achieve adequate urine levels to be considered optimal for treatment. Infections associated with fungus balls require surgical intervention.

Aspergillus

Stuart M. Levitz and Sanjay Ram

Aspergillus is readily isolated from environmental samples of soil, water, and air worldwide. *A. fumigatus*, followed by *A. flavus*, *A. niger*, and *A. terreus*, are the most common species that cause human disease. Aspergillosis follows exposure of a susceptible host to the ubiquitous conidia (spores). Germinating conidia form hyphae, the invasive form of the fungus. *Aspergillus* hyphae average 2 to 4 μm in diameter and are septate, with dichotomous (Y-shaped) branching (Figure 171.1). The spectrum of diseases caused by the aspergilli is wide and profoundly influenced by the underlying immune status of the host.

Clinical manifestations and diagnosis of invasive aspergillosis

Although inhalation of conidia is common, invasive disease is relatively rare. The vast majority of affected patients are severely immunosuppressed. Major risk factors include prolonged neutropenia and macrophage dysfunction secondary to cytotoxic chemotherapy and high doses of corticosteroids, respectively. In patients who have undergone hematopoietic stem cell transplantation, additional risk factors are graft-versus-host disease and cytomegalovirus infection. Recently, invasive aspergillosis cases have been described in patients receiving small molecule kinase inhibitors such as ibrutinib. Inborn mutations of genes controlling innate immune responses, particularly chronic granulomatous disease, a rare genetic disorder characterized by a defective phagocyte respiratory burst, predispose to invasive aspergillosis. Finally, critically ill patients and persons recovering from influenza may be at increased risk even without the aforementioned risk factors.

Invasive pulmonary aspergillosis, with or without dissemination, is the most common form of disease. Signs and symptoms of invasive aspergillosis are nonspecific. Fever is generally present. Radiographic features include patchy densities or well-defined nodules that may be single or multifocal and can progress to cavitation or consolidation. High-resolution CT scanning has greater sensitivity than plain films. Macronodules (nodules >1 cm in diameter) are present in the majority of patients with invasive pulmonary aspergillosis. Nodules may be surrounded by a perimeter of ground-glass opacity, the so-called *halo sign* (Figure 171.2). Cavitation ("air-crescent sign") is less common and tends to occur as a later manifestation of disease. Tracheobronchitis without alveolar invasion may be seen, particularly in lung transplant recipients and those with advanced AIDS. Invasive *Aspergillus* sinusitis is the second most common manifestation and must be distinguished from saprophytic colonization. Its clinical features include fever, localized pain, proptosis, and visual problems. Fungal keratitis due to direct inoculation of *Aspergillus* has been increasingly recognized as an important cause of visual loss, particularly among agrarian workers in developing countries. Less common manifestations include cutaneous aspergillosis, which may be seen at intravenous (IV) catheter insertion sites in neutropenic patients or at sites of burn wounds. While disseminated aspergillosis can involve any organ, cerebral involvement is a particularly common manifestation. Endocarditis due to *Aspergillus* is relatively rare and can be difficult to diagnose as blood cultures are often negative.

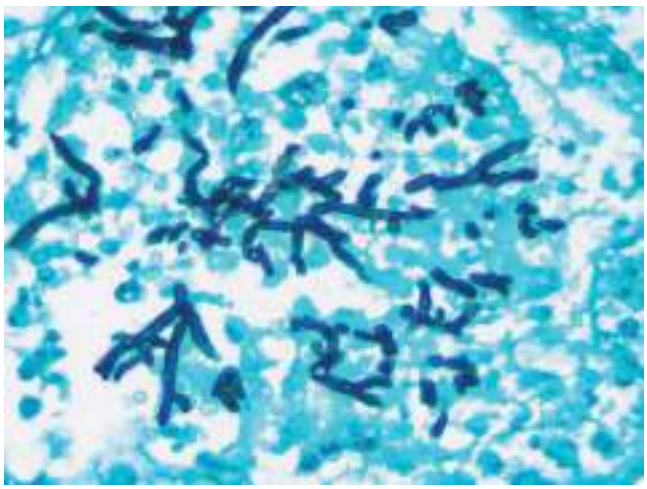

FIGURE 171.1 Photomicrograph demonstrating *Aspergillus* hyphae in a lung at autopsy in a liver transplant patient who died of systemic aspergillosis. The hyphae are stained with methenamine silver.
Courtesy of Dr. Barbara Banner, University of Massachusetts Medical School.

Invasive aspergillosis must be strongly suspected in any high-risk patient with fever unresponsive to broad-spectrum antibiotics, and empiric antifungal therapy should be considered. Although *Aspergillus* can be a laboratory contaminant or a colonizer, a positive culture for *Aspergillus* in an at-risk patient is predictive of invasive disease and should not be ignored. However, in patients with established disease, cultures and even biopsies are often negative.

To improve prognosis with earlier detection, nonculture methods have been studied to detect *Aspergillus* antigens and nucleic acids in specimens from high-risk patients. Tests to detect two cell wall antigens released by growing aspergilli, galactomannan and β-glucan, are clinically available. Serum galactomannan levels have excellent specificity but only moderate sensitivity. Sensitivity is higher in patients with hematologic malignancies, where positive results may precede clinical or radiologic manifestations, than in those with solid organ transplants. False positives have been noted in patients receiving piperacillin-tazobactam due to contamination of some lots with galactomannan. False negatives are considerably more common in patients receiving anti-mold prophylaxis. Assays to detect β-glucans in clinical specimens appear to perform comparably to those for galactomannan, with the caveat that elevated β-glucans may be seen in fungal infections other than aspergillosis. Detection of *Aspergillus* DNA by polymerase chain reaction (PCR) in clinical samples, while still investigational, has good sensitivity and specificity, especially when used in conjunction with galactomannan assays. It should be emphasized that surrogate markers cannot definitively establish or exclude a diagnosis of aspergillosis, and clinical correlation is required. Moreover, testing for antibodies, while useful for other forms of aspergillosis (see later discussion), is not helpful in invasive aspergillosis.

Treatment of invasive aspergillosis

Licensed drugs with activity against *Aspergillus* include amphotericin B (a polyene); the triazoles, itraconazole, voriconazole, posaconazole, and isavuconazole; and the echinocandins, caspofungin, micafungin, and anidulafungin. Fluconazole and ketoconazole do not inhibit *Aspergillus* at clinically obtainable concentrations and should not be used to treat aspergillosis. It is difficult to rank the active drugs in terms of relative efficacy because few randomized comparative trials have been performed. Studies based on comparisons to historical controls are problematic due to significant differences in the patient populations. A multicenter, randomized trial compared voriconazole with amphotericin B in 277 patients with definite or probable acute invasive aspergillosis. The voriconazole regimen demonstrated superior efficacy and a 22% relative survival benefit. Moreover, there were fewer treatment-related adverse events in the voriconazole group. The large survival benefit observed established voriconazole as the drug of choice for initial treatment of invasive aspergillosis. An important caveat though is that voriconazole is not effective therapy against mucormycosis (zygomycosis), which can present in a similar manner to aspergillosis.

In the preceding study, two doses of 6 mg/kg of IV voriconazole were administered on day 1, followed by 4 mg/kg/d. A switch to oral voriconazole at a dose of 200 mg twice a day was allowed after 1

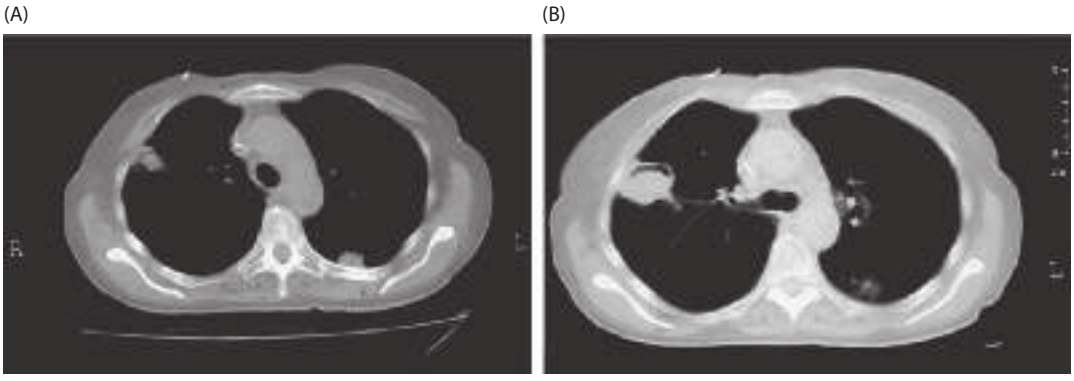

FIGURE 171.2 High-resolution CT scans from patients with invasive pulmonary aspergillosis. (A) Two pleural-based nodules can be seen. The one on the right is surrounded by a gray area of low-attenuation (halo sign). (B) Air-crescent sign in a patient recovering from neutropenia.

week. Transient visual disturbances, including blurred vision, altered color perception, and photophobia, are common with voriconazole and tend to resolve without incident. Other side effects that have been observed include rash and liver function test abnormalities. Voriconazole is a substrate and an inhibitor of CYP2C19, CYP2C9, and CYP3A4. Thus, drug interactions are common and dose adjustments of voriconazole and coadministered drugs may be needed. The authors recommend obtaining steady-state trough levels and adjusting the dosing if necessary to achieve levels between 1.0 and 5.5 μg/mL. In patients with an estimated creatinine clearance of <50 mL/min, accumulation of the IV vehicle occurs; these patients should be given oral voriconazole whenever possible.

In addition to voriconazole, other licensed triazoles with activity against *Aspergillus* are itraconazole, posaconazole, and isavuconazole. Itraconazole appears to be least potent and is mainly used for the treatment of aspergillomas and allergic bronchopulmonary aspergillosis (see later discussion). Posaconazole appears more promising and, along with isavuconazole, has the added advantage of having useful activity against the agents of mucormycosis. While clinical experience with posaconazole for primary treatment of invasive aspergillosis is limited, a randomized study compared isavuconazole with voriconazole as primary treatment of invasive aspergillosis and other filamentous mold infections. The all-cause mortality was similar in the two groups; however, there were fewer treatment-related adverse events in the group that received isavuconazole. Resistance of *Aspergillus* to triazole drugs can emerge during therapy, although the extent to which this leads to clinical failure is not clear. Ominously, primary resistance has been reported worldwide in both environmental and initial clinical isolates of *Aspergillus*, perhaps as a consequence of the agricultural use of antifungal azoles.

Amphotericin B is generally used for the treatment of invasive aspergillosis in patients who cannot take voriconazole and isavuconazole because of contraindications or intolerance. (Amphotericin B should not be used to treat *Aspergillus terreus* or *Aspergillus nidulans* due to decreased susceptibilities.) However, controversy exists regarding the optimal daily dosage and formulation. For the conventional amphotericin B desoxycholate formulation, following a test dose of 1 mg, dosages ranging from 0.6 to 1.5 mg/kg/d have been recommended, with higher dosages reserved for severely ill and/or profoundly immunosuppressed patients. Fevers, chills, and rigors, observed in a significant number of patients treated with amphotericin B, may be alleviated by premedication with acetaminophen, meperidine, 25 to 50 mg given intravenously, or the addition of 25 to 50 mg of hydrocortisone sodium succinate to the infusion solution. Amphotericin nephrotoxicity has been associated with sodium-depleted states and may be reduced by giving 1 L of normal saline per day to patients with no contraindications to volume expansion. As amphotericin B causes renal tubular losses of potassium and magnesium, their levels should be monitored closely and supplementation provided as needed. The dosage of amphotericin B must be individualized depending on factors such as the expected duration and degree of immunosuppression and the extent of the disease.

To reduce the toxicity associated with the conventional amphotericin B preparation, lipid-associated formulations have been developed. Currently available formulations include amphotericin B lipid complex, amphotericin B colloidal dispersion, and a liposomal preparation. Comparisons between the different formulations of amphotericin B are difficult to make due to the lack of well-designed randomized trials. However, at the usual daily dosages recommended for the treatment of invasive aspergillosis (3 to 5 mg/kg/d), the lipid formulations appear to be at least as efficacious as amphotericin B deoxycholate. The lipid formulations are less nephrotoxic than the conventional preparation but cost considerably more, a factor that limits their use in resource-poor settings. A clinical trial comparing 3 and 10 mg/kg/d of liposomal amphotericin B as primary therapy for invasive aspergillosis found the lower dose was equally effective but less toxic.

Three members of the echinocandin class of antifungal drugs, caspofungin, micafungin, and anidulafungin, are licensed for use. All have modest activity against *Aspergillus* in vitro and in animal models, although none has been adequately studied in comparative clinical trials for primary treatment of invasive aspergillosis. In an open-label study of 83 patients with invasive aspergillosis who were refractory or intolerant to amphotericin B, a favorable response to caspofungin therapy was observed in 37 (45%) of the subjects. Due to poor oral absorption, the echinocandins must be administered intravenously. Although infusion-related reactions and liver function test elevations are relatively common, serious side effects of this class of drugs are rare.

Due to the high failure rate associated with monotherapy for invasive aspergillosis, combination regimens as initial and salvage therapy have been tried. A randomized, double-blind study comparing voriconazole and anidulafungin combination therapy with voriconazole monotherapy in the treatment of invasive aspergillosis revealed a trend, which did not reach statistical significance, toward improved overall survival in the group that received combination therapy. It is the authors' practice to treat most cases of invasive aspergillosis with voriconazole monotherapy but to add an echinocandin if progression ensues or resistance is suspected.

Regardless of whether monotherapy or combination therapy is utilized, the duration of treatment should be individualized depending on the extent of disease and degree of immunosuppression. Most patients will require several months of treatment. Surgery should be considered as an adjunct to treatment in instances where there is localized disease, particularly in cases where there is progression despite antifungal therapy or further courses of neutropenia-inducing chemotherapy are anticipated. Whenever possible, immunosuppression should be withdrawn or decreased. In neutropenic patients, recombinant granulocyte colony-stimulating factor (G-CSF) may improve outcome by decreasing the duration of neutropenia and increasing the functional activity of neutrophils. Finally, patients with filamentous fungal keratitis should be treated with 5% natamycin eyedrops initially applied every hour. Surgical intervention by ophthalmology is often required.

Prophylaxis and preemptive treatment of invasive aspergillosis

Given the high mortality associated with established disease, strategies for the prevention of invasive aspergillosis have been advocated and are summarized in Table 171.1. Numerous studies

TABLE 171.1 **PREVENTION OF INVASIVE ASPERGILLOSIS**

Preventive strategy	Comments
1. Avoidance of exposure to *Aspergillus* conidia a. Avoidance of environmental exposure b. High-efficiency particulate air (HEPA) filters or laminar air flow (LAF)	Heavily contaminated areas include compost heaps, grain silos, moldy hay, and marijuana Although expensive, HEPA and LAF may be considered for hospitalized patients at very high risk of invasive aspergillosis, particularly if mold counts are high
2. Prophylaxis of high-risk patients	Posaconazole or other mold-active antifungals should be considered in very high-risk groups[a]
3. Administration of colony-stimulating factors to neutropenic patients	Expensive and not proved to be beneficial.
4. Preemptive, empirical administration of antifungals to neutropenic patients with fevers despite broad-spectrum antibacterial agents	Strongly recommended[a]
5. Secondary prophylaxis (antifungal treatment to prevent recrudescence of invasive aspergillosis in patients who will become immunosuppressed)	Due to high relapse rates, a mold-active antifungal agent should be given at the onset of chemotherapy or neutropenia. Consider surgical resection of localized disease[a]

[a] See text for details.

have examined empiric antifungal therapy in neutropenic patients with persistent or recurrent fevers despite empiric antibacterial therapy. This group is at high risk for invasive fungal infections, particularly aspergillosis and candidiasis, but also other opportunistic mycoses, including mucormycosis and fusariosis. Thus, ideal agents will have activity against a broad spectrum of opportunistic fungi. However, for those for whom the duration of neutropenia is expected to be short, candidiasis is the main concern, with aspergillosis and other mold infections being less common.

Studies published in the 1980s established that amphotericin B deoxycholate could decrease the incidence of invasive fungal infections in patients with persistent neutropenic fevers. Subsequent noninferiority studies compared amphotericin B (either deoxycholate or lipid-based formulations) with fluconazole, itraconazole, voriconazole, and caspofungin. Later studies compared different antifungal azoles. An important caveat in interpreting these studies is the variability in inclusion criteria and endpoints defining success.

A study compared posaconazole (200 mg TID) with either fluconazole (400 mg/d) or itraconazole (200 mg/d) in 602 patients undergoing intensive chemotherapy for acute myelogenous leukemia or myelodysplastic syndrome. Patients received antifungal medications with each cycle of chemotherapy until complete remission or for up to 12 weeks. Remarkably, during the treatment phase of the study, only 2 cases of aspergillosis were seen in the posaconazole arm compared with 20 in the fluconazole-itraconazole arm. Moreover, there was a significant overall survival benefit in favor of posaconazole. Similarly, a significant reduction in cases of aspergillosis and in mortality was seen in a study comparing posaconazole with fluconazole for allogeneic hematopoietic stem cell transplant recipients with graft-versus-host disease.

Prophylaxis can be expensive, associated with side effects, and lead to antifungal drug resistance. Rather than administer mold-active prophylaxis, some centers prefer a preemptive approach whereby antifungal therapy is administered based on criteria including fevers, positive serum antigen markers (galactomannan, β-D-glucan, and/or PCR) and suggestive chest CT scans.

Aspergillomas

Pulmonary aspergillomas are the result of saprophytic colonization of *Aspergillus*, usually within preexisting lung cavities such as might result from sarcoidosis, tuberculosis, or bullous emphysema. The diagnosis is most often made by chest radiography, where a round to oval intracavitary mass partially surrounded by a radiolucent crescent of air is seen. Some patients have chronic cavitary pulmonary aspergillosis without radiographically visible intraluminal fungus balls. Serum precipitins and sputum cultures for *Aspergillus* are positive in about 90% and 50% of cases, respectively. Hemoptysis is the most common symptom and, in most cases, is mild and self-limited. Rarely, extrapulmonary aspergillomas can form, particularly in the sinuses.

Therapy for aspergillomas must be individualized according to the pulmonary and immunologic status of the host, but in most cases a conservative approach with close clinical follow-up is recommended. Resection generally is reserved for those with life-threatening hemoptysis. However, many patients are not surgical candidates due to poor baseline lung function. Bronchial artery embolization can be tried as a temporizing measure for massive hemoptysis in patients with a high operative risk. Other measures, including intracavitary instillation of amphotericin B, oral itraconazole, and oral voriconazole, have been associated with reduction in cavity size and severity of hemoptysis in case reports. In one series of 40 patients, all patients had short-term resolution of hemoptysis following instillation of a locally formulated paste consisting of amphotericin B, fatty acids, and emulsifying wax.

A subset of patients with aspergillomas tends to be chronically ill, with fever, weight loss, pulmonary symptoms, and leukocytosis. This entity, termed "subacute invasive pulmonary aspergillosis," is seen in patients with chronic pulmonary disorders; most have mild systemic immunocompromise such as diabetes mellitus, alcoholism, low-dose corticosteroids, or malnutrition. Whenever possible, host defenses should be strengthened by diminishing factors responsible for immunosuppression. Other patients have "chronic cavitary pulmonary aspergillosis" characterized by progressive expansion of *Aspergillus*-infected pulmonary cavities, often in the absence of known immunocompromise. With both entities, dramatic clinical responses have been observed in some patients following a course of antifungal therapy as is given for invasive aspergillosis. Resection may be considered in the small subset of patients with focal disease whose pulmonary function and underlying disease do not preclude surgery.

Allergic manifestations of *Aspergillus*

Extrinsic allergic alveolitis occurs in nonatopic individuals who are exposed to *Aspergillus* conidia, as in "malt-worker's lung" or "farmer's lung," following their exposure to moldy grain or hay. Spontaneous recovery usually occurs over several weeks, without the need for antifungal agents or corticosteroids. Exposure to *Aspergillus* in individuals with asthma can result in an exacerbation of their disease (extrinsic asthma).

Allergic bronchopulmonary aspergillosis (ABPA) is a syndrome characterized by asthma, proximal bronchiectasis, immediate cutaneous reactivity to *Aspergillus*, elevated serum immunoglobulin E (IgE) concentrations, and elevated serum immunoglobulin G (IgG) and IgE antibodies specific to *A. fumigatus*. An increase in T_H2 CD4+ cells that respond to *Aspergillus* antigens and generate interleukin (IL)-4, -5, and -13 may contribute to the eosinophilia and high IgE levels seen in ABPA. Pulmonary infiltrates, peripheral eosinophilia, serum precipitins against *Aspergillus* antigens, and expectoration of fungus-laden mucus plugs may also be seen. Major predisposing factors are asthma and cystic fibrosis.

The goals of therapy are to reduce acute inflammation and minimize long-term lung damage. For patients with ABPA and pulmonary infiltrates, the primary treatment is corticosteroids. Although randomized clinical trials have not been performed, a commonly used regimen is prednisone given in doses of 0.5 mg/kg/d for 2 weeks, followed by an alternate-day regimen and then a gradual taper over a 3- to 6-month period. Total IgE levels in the serum directly correlate with disease activity and response to corticosteroids. In clinical trials, itraconazole in doses of 200 mg twice daily was associated with fewer exacerbations, improved immunologic parameters, and a reduced requirement for corticosteroids. Although it has not been studied in comparative trials, based on its superiority in invasive aspergillosis plus its better tolerability, voriconazole is increasingly being used in the treatment of ABPA.

Currently, two oral formulations of itraconazole are available: capsules and an oral aqueous acidified solution in 5% hydroxypropyl-β-cyclodextrin. Absorption of the capsular form is best in an acidic environment, and in the presence of a meal. Histamine-2 blockers and antacids may interfere with absorption. In contrast, the oral aqueous hydroxypropyl-β-cyclodextrin solution should be taken without food. This preparation achieves higher peak serum concentrations compared with the capsules but is associated with a higher incidence of gastrointestinal side effects. Drugs that induce hepatic microsomal enzymes (e.g., rifampin, isoniazid, phenytoin, phenobarbital, and carbamazepine) may significantly reduce serum itraconazole levels. Itraconazole itself slows hepatic drug metabolism and may increase the toxicity of phenytoin, oral hypoglycemics, digoxin, warfarin, and cyclosporine. Plasma concentrations of itraconazole can be measured in patients for whom absorption or drug metabolism problems are suspected, although therapeutic levels have not been established. An inhaled formulation of itraconazole is under investigation.

Allergic *Aspergillus* sinusitis often responds to endoscopic surgical debridement and drainage, particularly when there are obstructive symptoms. Intranasal corticosteroids may provide symptomatic relief, but long-term use should be avoided as it can be detrimental to the nasal mucosa. There are anecdotal reports that itraconazole may be of benefit in refractory cases.

Mucormycosis (and entomophthoramycosis)

Scott F. Davies

The term mucormycosis refers to a group of highly lethal angioinvasive fungal infections, mostly in immunocompromised hosts, caused by members of the order Mucorales, which include various species of the genera *Rhizopus*, *Lichtheimia* (formerly *Absidia*), *Mucor*, and *Saksenaea*. Other genera of Mucorales have also been implicated in human disease including *Cunninghamella*, *Apophysomyces*, and *Rhizomucor*. Most infections (50%–65% of total) are caused by *Rhizopus* species.

Classification is in flux because of extensive molecular phylogenetic analysis that has been ongoing for more than 10 years. Note that it is incorrect to use the term mucormycosis to refer only to infections caused by species of the genus *Mucor*, which are only a small minority of the total number of cases. Rather, mucormycosis refers to infection by any of the organisms within the seven genera of the order Mucorales as noted.

The term entomophthoramycosis refers to infections by members of the separate genera *Conidiobolus* and *Basidiobolus*. These organisms generally occur in tropics and cause chronic subcutaneous infection mostly in immunocompetent hosts. Only rarely (less than 15 reported cases) have they ever caused clinical syndromes overlapping with mucormycosis.

For the remainder of this chapter the term mucormycosis will be used to refer to the range of clinical infections caused by organisms in the seven genera of the order Mucorales. In recent usage this term is generally preferred over the term zygomycosis, because of elimination of Zycomycetes from the taxonomic structure and the very different clinical syndrome as compared to entomophthoramycosis with virtually no clinical overlap.

Pathogenesis

The causative agents of mucormycosis are found throughout the world, associated with decaying organic matter. They grow as a mycelium (broad nonseptate hyphae with short stubby right-angle branches) in nature and in infected mammalian tissue.

Airborne spores of the fungi settle on the skin or are inhaled into the nose, the pharynx, and the lung. The organism has little chance of invading healthy tissue defended by neutrophils. *Rhizopus* organisms grow best at acid pH in a high-glucose environment. A specific enzyme, ketone reductase, plays an important role. Thus diabetic ketoacidosis provides a favorable opportunity for the fungus to locally invade tissues of the upper airway, resulting in the fulminant rhinocerebral form of mucormycosis. Once established, the fungus is angioinvasive, leading to infarction of tissues and wider areas of necrosis, in which the fungus thrives. The tissue response to the fungus includes pyogenic inflammation, but there is little tendency for granuloma formation. A second form of disease is pulmonary mucormycosis, in which infection occurs in the lung or, less commonly, in proximal airways. The disease resembles invasive pulmonary aspergillosis and occurs, although much less commonly, in the same substrate: patients with profound neutropenia and patients in whom phagocyte function is depressed by high-dose glucocorticoid therapy. Like *Aspergillus* species, agents of mucormycosis are angioinvasive in the lung, leading to tissue necrosis and eventually to pyemic spread

to distant sites, including the skin, kidney, and brain. Rare forms of mucormycosis include a direct cutaneous infection that can complicate severe burns and contaminated wounds and the gastrointestinal form of the illness, associated with profound protein malnutrition (usually in infants), in which organisms directly invade the bowel wall, causing hemorrhage, bowel infarction, peritonitis, and death.

When uncontrolled diabetes is the main predisposing factor, rhinocerebral mucormycosis is more common. When hematologic malignancy and organ transplantation are the predisposing factors, pulmonary mucormycosis is more common. Patients being treated for leukemia and bone marrow transplantation recipients appear to have an increasing risk of pulmonary mucormycosis. Early use of fluconazole for these indications reduced *Candida* infections but likely shifted what was once a reasonably even split between disseminated candidiasis and invasive aspergillosis more heavily toward aspergillosis. More recently, other triazoles, including itraconazole and now voriconazole, that are highly active against *Aspergillus* species have been used for prophylaxis, reducing *Aspergillus* infections but likely resulting in higher relative frequency of mucormycosis. There are several studies implicating itraconazole and voriconazole prophylaxis as independent risk factors for development of invasive mucormycosis.

Clinical manifestations

Rhinocerebral mucormycosis is an extremely fulminant infection. Infection begins in the nose, sometimes manifested by dark, blood-tinged discharge from one or both nostrils. Necrosis of the nasal septum and turbinates then follows, with spread to the paranasal sinuses. In sequence, the disease accelerates with ulceration and necrosis of sinus walls, periorbital cellulitis, and direct invasion of the orbit, eye, cavernous sinuses, and brain. Arterial thrombosis adds to the extent of tissue destruction. Early clinical findings include eye pain, decreased visual acuity, and cranial nerve palsies. A black eschar from ischemic necrosis, either in the nose or on the palate, is a strong signal of disease presence. Early symptoms and signs may be followed by seizures and progressive decrease in level of consciousness. Death may occur in 1 week.

Pulmonary mucormycosis is acquired by inhalation or possibly by microaspiration from colonized sinuses. The disease presents as an acute or subacute pneumonia, with fever, cough, and purulent sputum. Some patients have pleuritic pain and hemoptysis from superimposed pulmonary infarction caused by invasion of pulmonary vessels. The most characteristic finding on chest radiograph is an area of consolidation, often peripheral and sometimes wedge-shaped. Focal areas of consolidation often cavitate as the infection progresses. The spectrum of radiographic abnormalities also includes large masses (even to 6 to 10 cm in size), multiple nodules, and multiple peripheral infiltrates. The computed tomography (CT) halo sign (ground-glass changes surrounding a dense central nodule) was first reported in invasive pulmonary aspergillosis (the most common cause of this finding in immunosuppressed patients), but also occurs in mucormycosis (with similar frequency as in aspergillosis) and in other infections and conditions, including bronchoalveolar carcinoma (the most common cause in immunocompetent patients). The CT reverse halo sign (central ground-glass area surrounded by denser consolidation) seems to be relatively more common in mucormycosis (the most common cause in immunosuppressed patients) than in aspergillosis, but also occurs in other infections and conditions, including cryptogenic organizing pneumonia (the most common cause in immunocompetent patients). The CT halo signs may be helpful in individual patients, but lack great sensitivity and specificity.

Metastatic abscesses may develop in the brain, liver, spleen, kidney, and skin. Metastatic skin lesions often show extensive necrosis (ecthyma gangrenosum) and offer easy diagnosis with a simple punch biopsy. Clinically, pulmonary mucormycosis with or without pyemic dissemination cannot easily be distinguished from invasive aspergillosis. Most cases occur in patients with hematologic malignancy with prolonged neutropenia. Cases of pulmonary mucormycosis also occur in organ transplant recipients, in patients receiving prolonged courses of high-dose glucocorticoid therapy for malignant or nonmalignant disorders, and even in diabetic patients.

Deferoxamine therapy, used for chelation in some patients receiving long-term dialysis and in other iron-overloaded states, is also a risk factor for mucormycosis because it is a siderophore, mobilizing iron from peripheral storage sites and making it more available to the fungus as a growth factor.

Endobronchial mucormycosis is a rare form of pulmonary mucormycosis that has been reported mainly in patients with advanced acquired immunodeficiency syndrome (AIDS). Patients have cough, purulent sputum, and often hemoptysis. Physical findings may include a localized wheeze. The chest radiograph may be normal or may show segmental or even lobar infiltrates with significant volume loss distal to the obstructed airway. Several other unusual forms of mucormycosis have also been reported in this population. Isolated renal mucormycosis has been described in AIDS patients who abuse drugs intravenously or have long-term intravascular access catheters for various therapeutics. Nodular skin lesions have also been reported in AIDS patients who abuse drugs intravenously. Cerebral mucormycosis of the basal ganglia has also been reported in similar patients.

Cutaneous mucormycosis can also complicate contaminated wounds via direct inoculation, rather than pyemic spread. This has been reported from war theaters including those in Afghanistan. It can also complicate civilian trauma; a total of 13 cases were reported following a tornado in Joplin, Missouri, in 2011. The causative organism in all cases was an *Apophysomyces* species. There was an association between fungal infection and penetrating wounds containing wood, soil, gravel, and other foreign material. The patients developed a cutaneous necrotizing infection within a few days of the trauma; 5 of the 13 patients died.

Diagnosis

The diagnosis of rhinocerebral mucormycosis can often be strongly suspected based on the setting of diabetic ketoacidosis and the clinical features of the illness. Specific diagnosis usually depends on

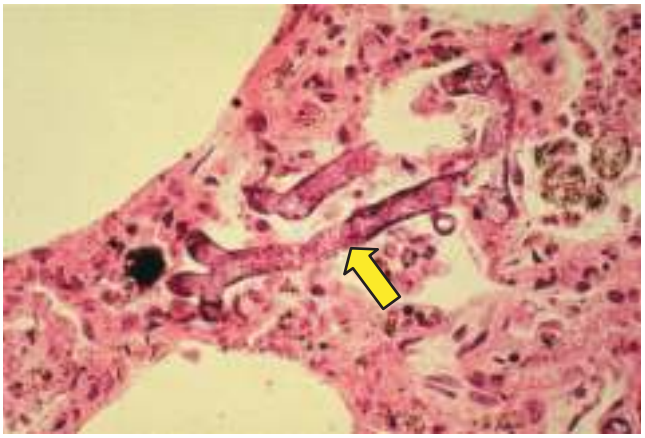

FIGURE 172.1 Mucormycosis: Hyphae (*arrow*) vary from 6 to 50 μm in diameter, are nonseptated, and typically branch at 90-degree angles. Courtesy of www.doctorfungus.org, copyright 2007.

demonstration of characteristic broad nonseptate hyphae in biopsies of diseased tissue (Figure 172.1). Positive cultures are confirmatory and also serve to define the exact species causing the infection. PCR may play an increasing role in the future for species identification. Positive cultures for causative organisms of mucormycosis must be interpreted cautiously and in clinical context because the organisms are ubiquitous in the environment and occasionally can be recovered from the skin, pharynx, and sputum of patients without disease. No useful skin tests or serologic tests are available.

The diagnosis of pulmonary mucormycosis is also highly dependent on clinical awareness in high-risk clinical settings, with leukemia and bone marrow transplantation most important predispositions, followed by organ transplantation. Prior use of itraconazole or voriconazole for prophylaxis or empiric antifungal therapy may also be a risk factor. The disease resembles invasive aspergillosis in similar hosts and can be distinguished only by histopathology or by culture.

Treatment

Rhinocerebral mucormycosis has a very high mortality, beyond 50% of cases in many series. Successful therapy is most likely if the diagnosis is made early and initiation of therapy is based entirely on clinical findings, before confirmation by histopathology or culture. There are three aspects to the treatment. First, the diabetic ketoacidosis must be controlled. Second, and most importantly, aggressive surgical debridement of all necrotic tissue must be done. Sometimes several procedures are needed as the limits of the diseased tissue become more apparent. Finally, full doses of amphotericin B (AMB) must be given quickly. Use of lipid-based formulations of AMB (AMB-L) have become standard because of lower toxicity and likely superior efficacy. Usual dose of AMB-L is 5 mg/kg/day—higher dosing to 7.5 or 10 (or even higher) mg/kg/day has been used in select cases, but has higher toxicity.

Pulmonary mucormycosis is also highly lethal. Once there is spread to distant sites and particularly to the brain, fatal outcome is nearly certain. Localized pulmonary disease can sometimes be managed successfully. Again, a three-pronged approach is necessary. First, the predisposing causes must be reversed. This means return of neutrophils (either spontaneously or aided by marrow-stimulating biologicals) and/or rapid taper of glucocorticoid therapy to the extent it is possible. Second, AMB-L should be started and escalated quickly to full dosages. Third, if the patient stabilizes, strong consideration should be given to surgical resection of necrotic lung tissue, if the lung disease is localized and the risk of thoracotomy is reasonably low. There are anecdotal reports of successful treatment of pulmonary mucormycosis by surgical resection alone. In those rare cases, the preoperative diagnosis was uncertain, total excision of all involved lung was accomplished, the diagnosis was established by histopathology of the resected tissue, and the patient recovered fully without other therapy.

When possible, isolated renal mucormycosis in patients with AIDS should be treated with nephrectomy combined with AMB-L. When nephrectomy is either not possible or is not a reasonable option given the overall condition of the patient, AMB-L alone should be used. There are some anecdotal successes using AMB-L without surgery.

Cutaneous mucormycosis is treated with aggressive surgical debridement and aggressive antifungal therapy, with AMB-L the first-line therapy.

As mentioned above, itraconazole and voriconazole are triazoles with activity against *Aspergillus* but no activity against Mucorales species. Wide use of these agents for prophylaxis and empiric antifungal therapy in patients with hematologic malignancy likely has increased the incidence of mucormycosis.

A possible advance in treatment of mucormycosis is posaconazole, the first triazole compound with activity against Mucorales species. Compassionate use in a large series of 91 patients with mucormycosis (69 proven disease, 22 probable) who had failed or were intolerant to prior antifungal treatment (usually a form of AMB) showed a success rate of 60% at 12 weeks. That exceeds historical success rates with prior standard therapy. Although posaconazole is not yet approved for use in mucormycoses, one approach pending further data might be to start patients with proven disease on AMB-L plus posaconazole until clinical response, and then extending posaconazole to 12 or more weeks. However, posaconazole is available only in oral formulation, limiting its use in critically ill patients. For now, AMB-L remains standard treatment with posaconazole used as an adjunctive, salvage, or continuation therapy on an individual case basis.

Echinocandins are another possible candidate for combination therapy. *Rhizopus oryzae* (the most common *Rhizopus* species causing infection) expresses the enzyme 1,3 β-glucan synthetase, which is the target enzyme for the echinocandins. Use of echinocandins in animal models has shown additional benefit when combined with AMB-L. There are anecdotal reports of successful use in selected cases, usually in combination with AMB-L. At present there is more experience and a larger number of positive clinical reports with posaconazole as a second agent or for salvage, and

for now echinocandins should not be used as an alternate therapy versus AMB-L.

As mentioned, iron availability is an important promoter of growth for Mucorales species and deferoxamine, which mobilizes iron and also increases availability of iron to the organisms, is a risk factor for mucormycosis. However, newer iron chelators such as desferasirox bind iron but are not used as siderophores by Mucorales and thus deprive the fungus of iron availability. In models of mucormycosis in mice, desferasirox was as effective as AMB-L and it also had additive effects when used together with AMB-L. Anecdotal reports have suggested some benefit in patients, but a very small (20 patients) randomized prospective trial showed poorer outcome (more frequent death at 30 and 90 days and lower global success) when desferasirox was used in combination with AMB-L for initial therapy of mucormycosis. At present desferasirox should not be used as combination therapy with AMB-L or other agents.

Finally, hyperbaric oxygen therapy has been proposed, based on limited and anecdotal reports, as an adjunctive therapy for some patients with mucormycosis. As for other unproven therapies, hyperbaric oxygen can be considered for selected patients.

Sporotrichum

Ronald A. Greenfield†

Sporotrichosis is a subacute or chronic fungal infection caused by *Sporothrix schenckii* and related species. It occurs most commonly in cutaneous or lymphocutaneous forms resulting from direct inoculation of the pathogen but also occurs in a variety of extracutaneous forms. Among the extracutaneous forms, a primary sporotrichotic pneumonia, presumably acquired by inhalation, occurs rarely. More commonly, musculoskeletal or osteoarticular sporotrichosis occurs, either as a result of direct inoculation into tendons, bursae, and joints or as a result of hematogenous dissemination. Hematogenous dissemination may result in disseminated cutaneous sporotrichosis and/or infection of a variety of unusual sites, including the meninges.

Epidemiology

Sporothrix schenckii is widely distributed in nature; it grows on plant debris in soil, and on the bark of trees, shrubs, and garden plants. The fungus and the disease occur in much of the world, primarily in the tropical and temperate zones. The abundance of the organism and the reported incidence of the disease show great geographic variation, perhaps related to genotypic differences between organisms in different locales. The penetrating trauma that introduces the fungal conidia into the human host is most commonly accomplished by splinters, thorns, or woody fragments of plants, but any contact with plants or plant products (e.g., sphagnum peat moss, mulch, hay, timber) accompanying minor skin trauma may initiate infection. Activities most frequently associated with acquisition of sporotrichosis include gardening (particularly rose gardening), landscaping, farming, berry-picking, horticulture, and carpentry. Skin test and serologic surveys demonstrate that most *S. schenckii* inoculations promote the development of immunity without clinically apparent infection. Zoonotic transmission also occurs from infected animals, particularly cats with extensive skin lesions, but may result from the scratch of any digging animal. Both pulmonary and disseminated sporotrichosis appear to occur more commonly in patients with a history of alcoholism.

Patients with immunosuppression due to human immunodeficiency virus (HIV) infection and acquired immunodeficiency syndrome (AIDS) appear to more frequently develop disseminated cutaneous sporotrichosis and hematogenously disseminated sporotrichosis, including sporotrichotic meningitis, than immunocompetent hosts. Although the incidence of HIV/AIDS-associated sporotrichosis is not precisely known, it is less than that of other endemic mycoses. Patients treated with immunosuppressive agents, including tumor necrosis factor-α antagonists, have also developed disseminated sporotrichosis.

Laboratory diagnosis

Definitive diagnosis of sporotrichosis requires the isolation of *Sporothrix* spp. in culture specimens from a normally sterile body site. Occasionally, the organism can be visualized in biopsied tissue specimens stained with periodic acid–Schiff, Gomori methenamine silver, or immunochemical stains (Figure 173.1). The

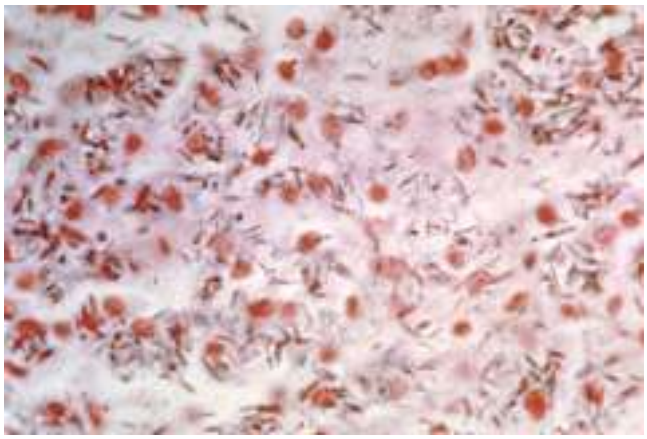

FIGURE 173.1 Histopathologic demonstration of the cigar-shaped yeasts of *Sporothrix schenckii*.
Courtesy of the CDC and Dr. Lucille K Georg, CDC Public Health Image Library.

organism can be recovered by fungal culture from sputum, pus, synovial fluid, bone drainage, and surgical specimens. Concentrations of organisms in joint fluid and particularly cerebrospinal fluid may be relatively low. Therefore, repetitive large-volume cultures may be required for diagnosis. Serologic techniques for measurement of antibody are available but exhibit significant interlaboratory variability in sensitivity and specificity; they are best used to suggest the need for more aggressive attempts at definitive diagnosis.

Clinical manifestations

Cutaneous sporotrichosis

The primary lesion develops at the site in the skin, 20 to 90 days after inoculation, most typically distally in the upper extremities. Over a few weeks, the initial small nodule enlarges, reddens, becomes pustular, and ulcerates, releasing purulent material from which the organism is readily cultured. Patients are typically afebrile and not systemically ill. In the lymphocutaneous form of the disease, an ascending chain of nodules develops along lymphatic channels of the skin, with the older distal lesions ulcerating and draining and the younger, more proximal lesions forming subcutaneous nodules that attach to the skin as they age and begin to ulcerate (Figure 173.2). The lesions are usually minimally painful, but extensive disease may result in functional impairment. Some patients exhibit no lymphangitic spread, and the disease presents as an indolent ulcerating plaque that persists for years if untreated (fixed cutaneous sporotrichosis). Patients often have received courses of antibacterial therapy without benefit before the process is recognized as sporotrichosis. The lymphocutaneous form of sporotrichosis can be mimicked by infection with *Nocardia*, *Mycobacterium marinum* and other mycobacteria other than tuberculosis, *Leishmania*, and *Francisella tularensis*.

FIGURE 173.2 Lymphocutaneous sporotrichosis.

Pulmonary sporotrichosis

Pulmonary sporotrichosis is a subacute or chronic pneumonitis with cavitation, usually in the upper lobes, clinically indistinguishable from mycobacterial infection or chronic pulmonary histoplasmosis. Almost all patients have underlying chronic obstructive pulmonary disease. They present with productive cough, sometimes with weight loss and increasing dyspnea, but rarely with fever, chills, or sweats. Diagnosis requires isolation of *S. schenckii* from sputum cultures or its histopathologic recognition in biopsy specimens.

Osteoarticular sporotrichosis

Lesions of deeper tissues may occur in almost any organ, but there is a distinct predilection for the joints, particularly of the extremities, and the long bones adjacent to these joints. The resulting chronic arthritis is often confused with rheumatoid or other chronic inflammatory arthritis, not infrequently for 10 or more years, until destruction of adjacent bone or development of draining fistulas encourage efforts to establish the microbial etiology of the chronic osteomyelitis. Cutaneous or lymphocutaneous lesions are unusual in these patients. The process generally begins in a single joint, but additional joints may be involved successively. The patient usually has pain on motion, and the involved areas may be warm and red. Functional impairment resulting from osteoarticular sporotrichosis can become very severe.

Disseminated sporotrichosis

Sporotrichotic lesions occur infrequently in many other organs such as the eye, the prostate, the oral mucosa, and the larynx, and the clinical manifestations in these patients depend on the organ involved. Involvement of the central nervous system (CNS) and meninges, which was distinctly rare in the pre-AIDS era, has become more common but is still rare in persons living with AIDS. Patients may present with subtle changes in mental status as the only symptom and are found to have chronic lymphocytic meningitis. Recovery of the fungus from extracutaneous lesions may be difficult, particularly in meningitis.

Therapy

Spontaneous healing of the cutaneous forms of sporotrichosis has been reported, but without treatment, the lesions usually progress slowly with draining and scarring. In immunocompetent patients, the infection is not life threatening. Treatment options are presented in Table 173.1. Historically, cutaneous and lymphocutaneous sporotrichosis have been treated with saturated solution of potassium iodide (SSKI), although the mechanism of action has not been determined. An initial dose of 5 to 10 drops diluted in liquid, preferably fruit juice, is given three times daily after meals, and increased dropwise to 120 drops per day or the maximum tolerated by the individual patient (frequently <60 drops per day). Although relatively inexpensive, this form of therapy is poorly accepted by many patients due to adverse effects, including increased lacrimation, increased salivation, metallic taste perversion, salivary gland swelling, gastrointestinal upset, and frequent rash.

Itraconazole is the treatment of choice for lymphocutaneous sporotrichosis; 100 mg orally daily for 3 to 12 months, determined by continuing treatment for 2 to 4 weeks beyond resolution of all lesions. Itraconazole can be given either as capsules that must be taken with food and must not be coadministered with therapies that suppress gastric acidity and that have somewhat erratic absorption or as an itraconazole oral solution, which is less palatable and generally more expensive but avoids these drawbacks. In patients who do not respond to itraconazole initially, one can consider increasing the dosage of itraconazole to 400 mg/day. Therapy with terbinafine, 250 mg orally daily, appears to be as effective as itraconazole therapy. By historical comparison, treatment with fluconazole, 200 to 400 mg orally daily, was less effective than itraconazole. The effectiveness of higher doses of fluconazole is subject to speculation. Amphotericin B preparations should only be necessary as a treatment of last resort for patients with cutaneous or lymphocutaneous sporotrichosis. Because many strains of *S. schenckii* that cause fixed cutaneous sporotrichosis grow poorly in the laboratory at 37°C, local application of heat may be an effective adjunct to antifungal therapy.

Pulmonary sporotrichosis should be treated with either itraconazole, 200 mg orally twice daily, for patients with non-life-threatening infection or with an amphotericin B preparation (preferably a liposomal amphotericin B preparation because of better tolerability) in patients with life-threatening or extensive pulmonary infection. For the latter patients who have the lung capacity to tolerate such a procedure, treatment with an amphotericin B preparation with subsequent surgical resection of involved lung areas may be the best therapy.

Itraconazole, 200 mg orally twice daily, should be initial therapy for patients with osteoarticular sporotrichosis. As with other joint and bone infections, drainage and debridement may be important surgical adjuncts to antimicrobial therapy. Conventional amphotericin B therapy appears to be approximately as effective as itraconazole but is less convenient and associated generally with more frequent adverse reactions; therefore, it is generally used only after failed itraconazole therapy. The role of liposomal amphotericin B preparations in osteoarticular sporotrichosis has not been defined. Fluconazole has been used with only modest success in osteoarticular sporotrichosis. Itraconazole treatment should generally be continued for 12 months, therapy with amphotericin B preparations for 6 to 10 weeks. Voriconazole has poor activity in vitro against sporotrichosis and should not be used. Posaconazole has in vitro activity, but its role in vivo is undefined.

Sporotrichotic meningitis should be treated with amphotericin B, based on limited numbers of anecdotally reported cases; liposomal amphotericin B is preferred because of increased penetration into the cerebrospinal fluid. Based on possible in vitro synergy and anecdotal reports, the addition of flucytosine may be beneficial for patients with recalcitrant meningitis. Itraconazole may offer effective step-down therapy after clinical improvement.

An amphotericin B preparation should be considered initial therapy for patients with disseminated sporotrichosis with or without AIDS. Itraconazole might be used for non-life-threatening infection and in cases in which meningitis has been actively excluded. Itraconazole may also play a role in lifelong suppressive therapy for patients with disseminated sporotrichosis and AIDS after initial induction therapy with an amphotericin B preparation.

Cryptococcus

William G. Powderly

Cryptococcus neoformans, which is found worldwide as a soil organism and thought to be transmitted by inhalation, most often causes disease in patients with abnormal cell-mediated immunity, notably patients with HIV infection and solid organ transplant recipients, but the infection also occurs with increasing frequency in apparently immunocompetent persons. It is the most common systemic fungal infection in patients infected with HIV. It is estimated that as many as 300,000 cases of invasive cryptococcal infection occur annually in patients with AIDS worldwide, with >150,000 deaths each year. Most of these cases occur in resource-poor settings, especially in sub-Saharan Africa. With the advent of effective antiretroviral therapy (ART), cryptococcal infections have become much less common in the United States.

Two varieties of *C. neoformans* exist, distinguishable by serology: *C. neoformans var. neoformans* (serotypes A and D) and *C. neoformans var. gattii* (serotypes B and C). Virtually all HIV-associated infection is caused by *C. neoformans var. neoformans*. *C. neoformans var. gattii* is endemic in Australia, and recent outbreaks of *C. neoformans var. gattii* infection have occurred in the Pacific northwestern parts of North America.

Presentation and diagnosis

The most common manifestation of cryptococcal infection is meningitis. Most patients develop insidious features of a subacute meningitis or meningoencephalitis, with fever, malaise, and headache, and are generally symptomatic for at least 2 to 4 weeks before presentation. In patients with a more subacute or chronic course, mental status changes such as forgetfulness and coma can also be seen. Classic meningeal symptoms and signs such as stiff neck and photophobia occur in only about one-quarter to one-third of all patients and generally are less likely to occur in HIV-positive patients. The typical pattern in the cerebrospinal fluid (CSF) is chronic meningitis with a lymphocytic pleocytosis. However, the CSF may appear normal in HIV-positive patients with cryptococcal meningitis because the usual response to infection is usually markedly blunted. In fact, fewer than half of HIV-positive patients with cryptococcal meningitis have an elevated protein level, only about one-third have hypoglycorrhachia, and only about 20% have >20 white blood cells per cubic millimeter of CSF. The opening pressure is usually elevated in patients with cryptococcal meningitis (up to 70% of patients present with pressures >20 cm H_2O), and this is an important issue associated with therapy. The cryptococcal antigen titer in the CSF is almost invariably positive with sensitivity of 93% to 100% and specificity of 93% to 98%. Serum cryptococcal antigen (sCRAG) is elevated in 95% of patients with meningitis. A positive sCRAG raises the possibility of disseminated cryptococcosis and such patients should be evaluated for possible meningeal involvement. Culture of *C. neoformans* from any body site should also be regarded as an indication for further evaluation and initiation of therapy. However, colonization of *Cryptococcus* can be found in the respiratory system. Patients with isolated positive respiratory cultures for *C. neoformans* should be carefully evaluated for disseminated infection; therapy might not

be necessary in immunocompetent patients with no symptoms and negative sCRAG, but careful follow-up is essential.

C. neoformans can invade sites other than the meninges. Isolated pulmonary disease has been well-described. It usually presents as a solitary nodule in the absence of other symptoms. Cryptococcal pneumonia has also been described. In immunocompromised patients, especially those with AIDS, disseminated disease is common. About half of HIV-positive patients with cryptococcal meningitis have evidence of pulmonary involvement at presentation, with clinical symptoms such as cough or dyspnea and abnormal chest radiographs. The chest radiographic finding is usually diffuse interstitial infiltrates in immunocompromised patients or focal lesions in immunocompetent patients. Concomitant opportunistic infections, especially with *Pneumocystis jirovecii* (*carinii*) or with *Mycobacterium tuberculosis* (especially in resource-poor settings) can occur. Cutaneous involvement is common and, with this presentation, suggests disseminated disease. The most common skin involvement resembles that of molluscum contagiosum. As many as three-quarters of patients with cryptococcal meningitis have positive blood cultures. Infection of bone, eye, adrenal glands, prostate, and urinary tract has also been described. The prostate gland represents a reservoir of infection and potential source of reinfection after completion of therapy.

Therapy

Management of cryptococcal infection depends on the extent of disease and the patient's immune status. A solitary pulmonary nodule in a normal host may not need treatment provided the patient has careful follow-up. The availability of relatively safe antifungals such as fluconazole permits a short course of therapy for most patients with localized disease. Extrapulmonary disease is generally managed in the same way as meningitis. A search for potential underlying problems should be initiated in patients who are not known to be immunosuppressed, including an HIV antibody test and consideration of undiagnosed secondary immunodeficiency including the development of auto-antibodies directed at interferon or granulocyte-macrophage colony-stimulating factor, as well as isolated cases of CD4 lymphopenias. Drugs generally used in the treatment of cryptococcal infection are summarized in Table 174.1.

Cryptococcal infection in "normal" hosts

Untreated cryptococcal meningitis is uniformly fatal, so all patients with meningitis must be treated. Indeed, the non-HIV/non-transplant population experiences poorer outcomes, including increased mortality, than traditionally immunosuppressed groups,

TABLE 174.1 **DRUGS USED IN THE TREATMENT OF CRYPTOCOCCAL INFECTION**

Drugs	Dosage	Side effects	Drug interactions	Comments
Amphotericin B	0.7–1.0 mg/kg/d; 3–6 mg/kg/d (liposomal) 5 mg/kg/d (lipid complex)	Immediate hypersensitivity reaction, fever, hypotension, nausea and vomiting during administration, hypokalemia, and nephrotoxicity	Nephrotoxic drugs (e.g., aminoglycosides, foscarnet, cidofovir)	Liposomal or lipid complex formulation are preferred in available to minimize renal toxicity
Flucytosine (5-FC)	25 mg/kg q6h	Gastrointestinal, bone marrow suppression	Nephrotoxic drugs	Dosage must be reduced in patients with renal dysfunction; drug level should be monitored
Fluconazole	400 mg/d (acute therapy), 200 mg/d (suppressive therapy)	Nausea, rash, and hepatitis	Rifabutin (increased rifabutin levels); rifampin (decreased fluconazole levels)	Dosage may need to be adjusted in renal dysfunction
Itraconazole	200–400 mg BID	Nausea, abdominal pain, rash, headache, edema, and hypokalemia	Rifamycins, ritonavir, phenobarbital, phenytoin all decrease itraconazole levels The drug should not be used concomitantly with terfenadine or astemizole Antacids, histamine blockers decrease itraconazole absorption Itraconazole itself acts as a moderate inhibitor of cytochrome P450 system and can increase levels of some protease inhibitors, cyclosporin, digoxin, and phenytoin	Absorption of itraconazole is dependent on food and gastric acid and may be erratic; newer formulations are better absorbed

in part because of delayed diagnosis. Most of the available evidence suggests that amphotericin B–based therapy remains the gold standard, and the combination of an amphotericin B preparation plus flucytosine (5-FC) should be regarded as the best initial treatment. This combination is most likely to lead to more effective and more rapid clearance of the fungus from the CSF, which is probably the best surrogate marker for ultimate successful therapy. This conceptual approach is consistent with clinical trial data in AIDS that amphotericin B–based therapy is superior to initial therapy with azoles. The different amphotericin B preparations have not been shown to have important differences in response rates of cryptococcal meningitis, although clearly the lipid-based formulations are less toxic than amphotericin B deoxycholate. Current recommendations suggest that liposomal amphotericin at a dose of 5 mg/kg is the preferred treatment for cryptococcal meningitis in normal hosts. Although it is unclear whether 5-FC is necessary in normal hosts, extrapolation from trials in patients with AIDS would suggest that it accelerates clearance of the fungus and improves mortality. The recommended dosage is 37.5 mg/kg four times daily. Levels must be measured to minimize toxicity (especially bone marrow suppression), and dosages must be adjusted for renal insufficiency.

The duration of therapy is not well defined for patients with cryptococcal infection. Normal subjects with no evident risk factors for a poor outcome respond well to 4 weeks of combination therapy, and this is often curative. Prolonged therapy should be considered for patients at risk of relapse, such as those who present with more severe neurological symptoms or those with underlying conditions such as cancer or end-stage liver disease. With current data, amphotericin B plus 5-FC is still recommended as standard therapy for cryptococcal meningitis. Fluconazole can be used to treat patients (or to complete a course of treatment) in patients who cannot tolerate amphotericin B. In many circumstances (need for intravenous access, difficulties with outpatient parenteral therapy, toxicity) a full course of parenteral amphotericin B is impractical or undesirable, and a switch to fluconazole is preferred. Timing of such a switch is uncertain. There is insufficient evidence to advocate using changes in cryptococcal antigen as a guide to making treatment decisions, but it is probably reasonable to consider using the clearance of yeast from CSF as an indicator for switching treatment from polyene to oral azole therapy. In most patients, this is likely to take 2 to 3 weeks to achieve, suggesting this is probably the minimum amount of amphotericin B therapy that should be used. Pulmonary cryptococcosis without meningeal involvement can be treated initially with fluconazole.

Once patients have been switched to fluconazole, the next question becomes how long to treat? Unfortunately, there are absolutely no well-controlled studies to answer this question. Given the potential severity of cryptococcal infection, the most prudent recommendation would be to treat with fluconazole for 6 to 12 months after clearance of CSF has been documented.

Cryptococcal infection in AIDS

In patients with AIDS, the acute mortality with cryptococcal meningitis ranges from 10% to 25%. Multiple clinical factors have been identified in studies as predictors of a poor outcome, as summarized in Box 174.1. The current recommendations for the treatment of cryptococcal meningitis in AIDS are to use a combination of amphotericin B (usually a liposomal preparation) plus 5-FC (25 mg/kg q6h) for at least 2 weeks followed by at least 8 weeks of fluconazole, 400 mg PO daily. This approach has been validated by a large randomized trial comparing amphotericin B plus 5-FC to amphotericin B plus fluconazole and to amphotericin B alone. There were fewer deaths among patients receiving amphotericin B and 5-FC compared with those receiving amphotericin B alone, whereas combination therapy with fluconazole had no significant effect on survival as compared with amphotericin B alone. In resource-poor settings, there has been considerable interest in evaluating shorter duration of amphotericin B, and a more recent trial conducted in Africa suggested that 1 week of amphotericin B plus flucytosine and 2 weeks of fluconazole plus flucytosine were effective as induction therapy.

There have been a number of controlled comparative trials of the orally active antifungal triazoles, fluconazole and itraconazole. In each trial, the azole antifungals were effective in about 50% of patients. Similarly, in a study directly comparing fluconazole and itraconazole, <50% of patients responded to either drug. Thus, at least 50% of patients treated initially with azole antifungals will fail to respond. Most studies of amphotericin B report response rates of 70% to 80% or more, reinforcing the current guidelines that recommend an initial period of amphotericin B–based treatment. Voriconazole and posaconazole are active against *C. neoformans*, but clinical experience is limited and they are rarely used.

An important aspect of management of acute cryptococcal meningitis in AIDS is the recognition that clinical deterioration may be caused by increased intracranial pressure (ICP), which may not respond rapidly to antifungal therapy. Analyses have shown a relationship between baseline opening pressure and long-term outcome, with the median survival in patients with the highest pressures being significantly less than that in patients whose pressures were normal. I believe that all patients with cryptococcal meningitis should have opening pressure measured when a lumbar puncture is performed, and strong consideration should be given to reducing such pressure if the opening pressure is high (>25 cm H_2O). Lumbar puncture with removal of 30 mL of spinal fluid daily is often effective.

BOX 174.1

Factors at baseline predictive of a poor outcome in AIDS patients with cryptococcal meningitis

Decreased mental status at diagnosis
CSF leukocyte count ≤20 cells/mm^3
High titer of CSF cryptococcal antigen
Positive blood culture for *C. neoformans*
Age ≤35 yr
Hyponatremia

Abbreviations: AIDS = acquired immunodeficiency syndrome; CSF = cerebrospinal fluid.

If elevated opening pressure persists with neurologic symptoms despite serial lumbar puncture, lumbar drainage should be considered. Some patients have required placement of lumbar peritoneal shunts for persistently elevated ICP despite successful antifungal therapy. Neither acetazolamide nor corticosteroids are effective in this situation, and may be detrimental, so they should not be used.

The advent of effective ART has changed the natural history of AIDS-related cryptococcal infection. Prior to effective HIV therapy, lifelong maintenance therapy was required in AIDS patients with cryptococcal infection to prevent relapse of infection. Relapse rates of 50% to 60% and a shorter life expectancy were reported in patients who did not receive long-term suppressive therapy. Fluconazole, 200 mg/d, is the drug of choice. Routine monitoring by measurement of sCRAG has not been shown to predict relapse. It is now clear that long-term suppressive treatment can be stopped after at least 12 months of antifungal therapy if the patient's immune system recovers with ART (usually defined as the CD4+ T-cell count increasing to >200 cells/mm^3).

All HIV-positive patients with cryptococcal meningitis should receive ART. Recent studies evaluating the timing of ART in AIDS patients with cryptococcal meningitis suggest a higher mortality if given during the acute treatment for cryptococcal infection. Consequently ART initiation should be deferred for 6 to 8 weeks after initiation of antifungal therapy.

It is thought that a likely mechanism for increased mortality with early initiation of ART is immune reconstitution inflammatory syndrome (IRIS), which is a more vigorous inflammatory response to the underlying infection associated with restoration of the immune system. The pathogenesis of IRIS is unclear but is thought to represent an overexuberant immunologic response to a high antigen load in the context of an immune response that is recovering but not yet fully normal. Clinically there can be considerable morbidity and even mortality. In the case of cryptococcal meningitis, IRIS may manifest as an apparent recurrence of meningitis, with all the features of the initial meningitis presentation. Lumbar puncture will typically show inflammation but, by definition, will remain culture negative. Rarely, the syndrome may present outside the central nervous system (CNS) as pulmonary infiltrates or hilar/mediastinal lymphadenitis due to extra-CNS *Cryptococcus*. Typically, IRIS presents following an initial clinical improvement. The majority of cases of IRIS occur within 30 days of starting ART, and the frequency of IRIS following initiation of ART in cryptococcal meningitis has varied from 10% to 50% in different series. IRIS has been found more frequently in patients who are antiretroviral naïve before ART. It is also more commonly seen in those with a higher CSF cryptococcal antigen level, probably due to increased antigen producing a greater inflammatory response. Starting ART within 30 days of diagnosis of cryptococcal meningitis is also associated with a higher likelihood of IRIS, presumably due to a greater antigenic burden. If IRIS develops in a patient receiving ART, the patient should remain on antiviral therapy and continue antifungal treatment. Anti-inflammatory treatment may be needed for symptom management, and, in some cases, immunosuppressive therapy such as corticosteroids has been used.

Fluconazole, 200 mg PO daily, has been shown to be effective as primary prophylaxis in patients with advanced HIV disease. However, this has not been regarded as cost-effective in developed countries such as the United States. However, a strategy of primary prophylaxis may be appropriate in patients with advanced HIV disease (CD4+ T-cell count <100 cells/mm^3) in resource-poor settings; alternatively, screening patients using cryptococcal antigen testing and treating asymptomatic patients with positive serum antigen tests may also be effective.

Cryptococcal infection in other immunocompromised hosts

Management of cryptococcal meningitis in the setting of organ transplantation or lymphoma has not been well studied prospectively. An approach similar to that used with AIDS patients (i.e., an initial period of treatment with amphotericin B plus 5-FC followed by fluconazole) is recommended. Because nephrotoxicity is an issue in many of these patients, liposomal amphotericin B is generally preferred, again for at least 2 to 3 weeks. However, there is very little published experience with the use of fluconazole, itraconazole, voriconazole, or fluconazole plus 5-FC in this setting, and these agents are also associated with significant drug interactions. An area of considerable uncertainty is the duration of fluconazole therapy after acute therapy. Suppressive antifungal therapy for at least 1 year after the completion of acute treatment is recommended. In some patients with persistent immunosuppression, such as solid organ transplant recipients, many clinicians continue treatment indefinitely, although again there are very limited data on which to base a recommendation. In transplant recipients and other patients on immunosuppressive therapy, consideration may be given to reduction or discontinuation of immune-modulating drugs including steroids and calcineurin inhibitors. However, there is increasing evidence that discontinuation of immunosuppressive therapy in the setting of cryptococcal infection may worsen outcomes by increasing the risk of immune reconstitution.

Finally, there is increasing attention being paid to the long-term morbidity (as opposed to acute mortality) of cryptococcal meningitis. Recent data from the Cryptococcus Infection Network in non-HIV Cohort (CINCH) study showed significant cumulative neurologic morbidity and impaired cognition at 1 year of follow-up. This remains an important area for future research.

Histoplasmosis

Cole Beeler and Mitchell Goldman

Introduction

Histoplasma capsulatum is a thermally dimorphic fungus found most frequently in soil in the midwestern United States. The fungus is also found in Central and South America, Africa, Asia, and Australia. Bird and bat excreta rich in organic nitrogen support the growth of the organism. Recent evidence supports an expansion of the endemic region in the United States to areas north and west of the originally described Ohio River Valley to the upper Missouri River Basin. Sites associated with blackbird roosts are the most common sources of outbreaks currently, whereas domestic chicken coops were a common source in the past. Recent outbreaks have occurred after cleaning a campsite contaminated by bat excreta, rototilling soil in a schoolyard below a bird roost, whitewater rafting, and digging for buried treasure. In the United States, workplace exposures are implicated in 40% of outbreaks. When sites are disturbed, the spores become airborne, producing an infective aerosol. The lung is the portal of entry in almost every case of histoplasmosis. Following inhalation of *H. capsulatum* spores into alveoli, the fungus converts to a yeast, the tissue-invasive form. The yeasts are then phagocytosed by alveolar macrophages that are initially incapable of killing the fungus. During the pre-immune phase of the illness, ingested yeast cells multiply inside macrophages and spread throughout the body via the lymphatics to reticuloendothelial organs. Once adequate cell-mediated immunity (CMI) develops, the now "armed" macrophages can either kill or wall off the infecting organisms. Following a strong immune response, as is seen in immunocompetent individuals, tissue necrosis occurs, which, in time, becomes calcified. These calcified granulomas are seen in the lung, hilar lymph nodes, liver, and spleen of individuals who successfully limit the infection.

Most individuals infected with *H. capsulatum* develop adequate CMI. If CMI fails to develop, progressive dissemination will occur. In the United States, histoplasmosis-associated hospitalizations have increased during the past two decades as has the proportion of hospitalizations in those with histoplasmosis associated with transplants, diabetes, and autoimmune conditions requiring biologic therapies.

Clinical manifestations

Localized pulmonary and self-limited infections

Most *H. capsulatum* infections are asymptomatic. After low-inoculum exposure, some patients develop a localized form of infection with fever, chills, headaches, myalgia, anorexia, cough, and chest pain. Erythema multiforme or erythema nodosum may develop. The incubation time following low-inoculum exposure is approximately 14 days. This form of acute localized pulmonary infection is self-limited; after 2 to 4 weeks, most immunocompetent patients will have recovered completely, and treatment is usually not necessary. Chest radiographs usually demonstrate localized pneumonitis but may be normal. Ipsilateral hilar lymph nodes are usually enlarged. Healing may be complete with normalization of the radiograph, but frequently multiple cycles of central necrosis and peripheral calcification occur, leaving the characteristic "coin" lesion as proof of prior infection.

When the infective aerosol is unusually large, fulminant infection may occur, with severe hypoxemia and respiratory failure that requires prompt and aggressive treatment. Patients who inhale a large inoculum may develop nodular lesions of variable sizes. The radiologic appearance of an overwhelming inoculum is diffuse micronodular infiltrates that may appear miliary.

Patients with emphysema may develop upper lobe infiltrates after exposure. The resultant infection may result in cavitation. The radiographic appearance of this infection mimics reactivation tuberculosis. Low-grade fever and anorexia with weight loss are common. Without treatment, most of these patients develop progressive destructive lung disease. The clinical and radiologic similarities to tuberculosis make the diagnosis challenging.

Late complications of healed and calcified histoplasmosis are related to the location of the calcified lymph nodes, which may envelop and compress various mediastinal structures. A rare late complication is the development of mediastinal fibrosis, which can lead to crippling complications, such as the superior vena cava syndrome and constrictive pericarditis.

Progressive disseminated histoplasmosis

During the pre-immune phase of the infection, the fungus disseminates widely. With the development of adequate CMI, the cells of the reticuloendothelium limit the spread of the disease.

In immunosuppressed patients or at the extremes of age this dissemination becomes progressive. This form of the disease is known as progressive disseminated histoplasmosis (PDH), and prognosis is poor without treatment. Fever and weight loss are the most common symptoms, and hepatosplenomegaly is frequent.

Dissemination to the oropharyngeal or gastrointestinal mucosa (causing ulcerations), the skin (causing a plethora of skin findings), and the adrenal glands (potentially causing adrenal insufficiency) may occur. Severe cases may be complicated by respiratory distress, hepatic failure, renal failure, coagulopathy, shock, and even hemophagocytic lymphohistiocytosis (HLH). Central nervous system (CNS) involvement occurs in% 5 to 10% of patients with disseminated disease and presents as either a chronic meningitis or focal lesion. In PDH, the mortality is close to 100% without treatment. In severely ill patients, mortality may still be high despite treatment.

Prior to the widespread use of cytotoxic agents and glucocorticoids, most patients with PDH had underlying lymphoreticular malignancies, most commonly Hodgkin's disease. Currently, the most common underlying disease of patients with PDH is AIDS. Organ transplantation and immune-modulating treatments (such as the tumor necrosis factor [TNF] blocking agents) have increasingly contributed to the pool of patients at risk for disseminated disease (Figure 175.1).

FIGURE 175.1 Chest radiograph demonstrating diffuse infiltrates in a patient with rheumatoid arthritis with progressive disseminated histoplasmosis following initiation of treatment with a tumor necrosis factor (TNF-α) inhibitor.

Diagnosis

The gold standard in diagnosis is recovery of the organism, but this is time-consuming, requiring up to 30 days for identification.

Sputum cultures are not very useful in cases of suspected acute pulmonary infection because of the low inoculum of infecting organisms and the rarity of productive cough in this syndrome. In contrast, acute disseminated histoplasmosis and chronic pulmonary or cavitary infections have a higher likelihood of positive cultures. When bronchoscopy with bronchoalveolar lavage is employed with appropriate stains, the sensitivity of respiratory cultures increases. Biopsy of accessible lesions (Figure 175.2) and bone marrow can be used in cases of disseminated infection.

Detection of histoplasma polysaccharide antigen in urine, serum, or cerebrospinal fluid offers high sensitivity and rapid diagnosis for patients with large-inoculum acute pulmonary disease, PDH, and CNS disease. Antigen sensitivity is higher in disseminated infections than in isolated pulmonary disease. The highest sensitivity of histoplasma antigen testing is in patients with AIDS and PDH when compared

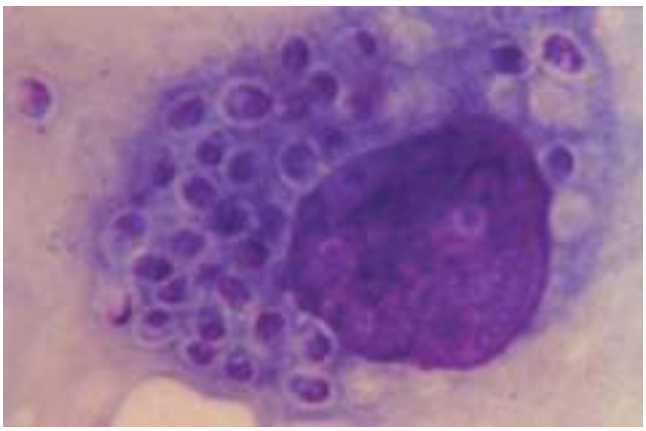

FIGURE 175.2 Histiocyte containing numerous yeast cells of *Histoplasma capsulatum*. Giemsa stain.

to other immunosuppressed or immunocompetent individuals with PDH. Since the levels of antigen are highest in the urine for most patients, urine testing is a helpful initial strategy. Antigen testing from blood may be particularly useful in anuric patients. Urine antigen levels correlate with disease severity and are useful when monitoring response to treatment or investigating for relapse.

Serologic testing using complement fixation and immunodiffusion is also helpful in some cases and may be the only means by which an infection can be diagnosed in immunocompetent individuals. In these patients, it frequently takes 2 to 6 weeks to develop detectable antibodies. The use of these antibodies for diagnosis of histoplasmosis is most helpful in chronic pulmonary histoplasmosis and for those with persistent symptoms following recent infection. In a recent study of those with acute pulmonary infection, a strategy of testing using serum *Histoplasma* IgM and IgG antibody detected by enzyme immunoassay (EIA*) along with* serum *Histoplasma* antigen testing appears to have the greatest diagnostic yield for this acute form of the disease.

Similar to antigen levels, there is also clinical correlation between the severity of the disease and the height of antibody response. In immunosuppressed patients, antibody response may be weaker and, in some cases, absent.

Molecular techniques like polymerase chain reaction demonstrate high sensitivities from the blood and may be an option for patients who are immunosuppressed without antigenemia or antigenuria. Unfortunately, these tests are relatively new and not currently widely available.

Treatment

The vast majority of patients with acute histoplasmosis are asymptomatic or have a mild self-limited disease and do not require antifungal treatment. In the few patients where treatment is required, therapy depends on the clinical scenario (Table 175.1).

Acute localized pulmonary infection resolves without therapy in the majority of cases, and treatment is only indicated when symptoms persist for more than 4 weeks. In these patients oral itraconazole, 200 mg three times daily for 3 days, followed by oral itraconazole, 200 to 400 mg/d for 6 to 12 weeks, is recommended. In more severe cases of acute diffuse pulmonary histoplasmosis in the immunocompetent host who requires hospitalization, lipid formulations of amphotericin B in doses of 3 to 5 mg/kg/d are recommended for up to 2 weeks, followed by oral itraconazole, 200 mg three times daily for 3 days, followed by oral itraconazole, 200 mg twice daily for an additional 12 weeks. Some studies support the use of methylprednisolone, 0.5 to 1.0 mg/kg/d intravenously in severely ill, hypoxemic, or ventilated patients for up to 2 weeks.

The treatment of chronic pulmonary histoplasmosis is oral itraconazole, 200 mg three times daily for 3 days, followed by 200 to 400 mg/d for at least a year. Therapy may be extended if resolution is slow. Amphotericin B is also effective when used for 12 to 16 weeks but is rarely necessary. Relapses after apparently successful treatment may occur, and close follow-up is essential.

The treatment of severe PDH is liposomal amphotericin B at the dose of 3 mg/kg/d for 1 to 2 weeks or until clear clinical improvement. This is followed by oral itraconazole, 200 mg three times daily for 3 days, followed by oral itraconazole, 200 mg twice daily for at least 12 months. Other lipid preparations may be substituted in appropriate doses. Mildly ill patients with PDH may be treated with itraconazole alone for at least 12 months. PDH in AIDS patients is treated in a similar fashion. Chronic suppressive therapy with itraconazole is recommended for patients who do not recover immune function. CNS histoplasmosis is treated with liposomal amphotericin B, 5 mg/kg/d, for a total of 175 mg/kg over 4 to 6 weeks, followed by oral itraconazole, 200 mg two to three times daily for at least 1 year.

Due to erratic absorption (though better with the oral suspension), itraconazole requires therapeutic drug level monitoring. Generally, itraconazole levels should be measured after 2 weeks of therapy. Many labs report both itraconazole and hydroxyitraconazole

TABLE 175.1 **RECOMMENDATIONS FOR TREATMENT OF PATIENTS WITH HISTOPLASMOSIS**

Manifestation	Treatment
Acute pulmonary: moderately severe or severe when symptoms persist for ≥4 weeks	Itraconazole, 200 mg 3× daily for 3 d, followed by itraconazole, 200–400 mg/d for 6–12 wk
Acute pulmonary with severe manifestations	Liposomal amphotericin, 3–5 mg/kg/d for up to 2 wk, followed by itraconazole, 200 mg 3× daily for 3 d, then itraconazole, 200 mg 2× daily for 12 additional wk
Chronic cavitary pulmonary	Itraconazole, 200 mg 3× daily for 3 d, followed by itraconazole, 200 mg 2× daily for at least a year. Itraconazole levels should be measured in patients where resolution is slow Amphotericin B deoxycholate may also be used at the dose of 0.7 mg/kg/d for 12–16 wk
Progressive disseminated: moderately severe/severe, with or without HIV/AIDS	Liposomal amphotericin B, 3 mg/kg/d for 1–2 wk or until stability, followed by itraconazole, 200 mg 3× daily and then 200 mg 2× daily for at least 1 yr
Progressive disseminated mild to moderate	Oral itraconazole, 200 mg daily for 3 d followed by 200 mg 2× daily for at least 1 yr
Central nervous system	Liposomal amphotericin B, 5 mg/kg/d for a total of 175 mg/kg, followed by itraconazole, 200 mg 2–3× daily for at least 1 yr

levels (an active metabolite). The sum of these two values should be at least 1 μg/mL, and drug dosing should be adjusted to achieve this value. Absorption may improve with administration of an acidic beverage like Coca-Cola.

Blastomycosis

Todd P. McCarty and Peter G. Pappas

Blastomycosis is a systemic pyogranulomatous disease caused by the thermally dimorphic fungus *Blastomyces dermatitidis*. While *B. dermatitidis* causes the vast majority of disease, two other species have also recently been identified as pathogenic agents: *B. gilchristii* and *B. helicus*. The disease is endemic to parts of the midwestern and south-central United States and Canada; however blastomycosis has been reported worldwide, including isolated reports from Africa, Asia, and Central and South America. Within the United States and Canada, the disease is concentrated in areas along the Mississippi and Ohio River basins and the Great Lakes. In endemic areas, small point-source outbreaks of blastomycosis have been associated with recreational and occupational activities occurring in wooded areas along waterways. Current evidence indicates that *B. dermatitidis* exists in warm moist soil enriched by organic debris, including decaying vegetation and wood.

Most infections with *B. dermatitidis* occur through inhalation of aerosolized spores, although infection through direct inoculation has been reported rarely. Primary infections are usually asymptomatic or may result in a self-limited flu-like illness. Hematogenous dissemination of organisms from the lung can result in extrapulmonary manifestations.

Blastomycosis is usually recognized as a chronic, indolent systemic fungal infection associated with various pulmonary and extrapulmonary manifestations. Pulmonary blastomycosis usually manifests as a chronic pneumonia syndrome characterized by productive cough, chest pain, hemoptysis, weight loss, and low-grade fever. There are no distinguishing radiologic features of pulmonary blastomycosis, although nodular and mass lesions, with or without cavitation, often mimicking other granulomatous diseases or bronchogenic carcinoma, are common. Hilar adenopathy and pleural effusions are uncommon. Rarely, diffuse interstitial infiltrates consistent with acute respiratory distress syndrome (ARDS) can occur secondary to blastomycosis.

Clinical manifestations of blastomycosis are highly variable. The lungs are involved in up to 90% of cases, and the skin is involved in 40% to 60% of cases. Multiple organ involvement is common, occurring in approximately 50% to 60% of cases. Osteoarticular disease is the next most common manifestation, followed by male genitourinary tract (especially the prostate and epididymis) involvement. Central nervous system (CNS) involvement occurs in fewer than 5% of patients and can present as either granulomatous meningitis or an intracerebral mass lesion. *B. dermatitidis* is an uncommon opportunistic pathogen but may cause overwhelming disease in the immunocompromised host. Among patients with predisposing factors, chronic glucocorticosteroid use, solid organ transplant, and advanced HIV disease are the most common underlying conditions.

Diagnosis

The definitive diagnosis of blastomycosis requires a positive culture for *B. dermatitidis* from clinical specimens. A presumptive diagnosis is based on the finding of classic-appearing broad-based budding yeasts with doubly refractile cell walls compatible with *B. dermatitidis* on histopathologic examination of clinical specimens (Figure 176.1). Ten percent potassium hydroxide (KOH) is used to prepare wet specimens

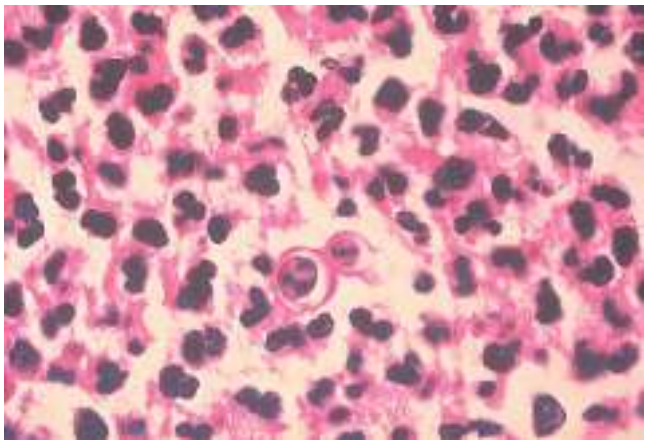

FIGURE 176.1 Histopathology of blastomycosis of skin. Cell of *Blastomyces dermatitidis* undergoing characteristic broad-based budding, surrounded by neutrophils. Multiple nuclei are visible.

Public Health Image Library, Centers for Disease Control and Prevention.

for examination, whereas fixed specimens are usually stained with hematoxylin and eosin, periodic acid–Schiff (PAS), or Gomori's methenamine silver (GMS) reagents. Serologic assays are of limited value in the diagnosis of blastomycosis. The complement fixation assay for serum antibody is highly cross-reactive and of little diagnostic value. Recent studies suggest that immunodiffusion or enzyme immunoassay (EIA) tests for A antigen of *B. dermatitidis* or antibody to more purified antigens have potential as serologic markers of disease. The *Blastomyces* EIA urine antigen assay is sensitive but nonspecific and gives false-positive results among patients with active histoplasmosis, paracoccidioidomycosis, and penicilliosis. The blastomycin skin test antigen lacks sufficient sensitivity and specificity and should not be used as a diagnostic test. Polymerase chain reaction (PCR) is being evaluated as an additional diagnostic tool, but there is not currently a commercialized assay available that is specific to blastomycosis. Universal fungal ribosomal PCR is an option when the specific fungal pathogen is not known at the time of tissue acquisition and can provide results very quickly.

Treatment

Presently, three drugs are approved for the treatment of blastomycosis: amphotericin B, itraconazole, and ketoconazole. Originally, amphotericin B was the mainstay of therapy for all forms of blastomycosis, but studies and experience gained since the early 1990s indicated that ketoconazole, itraconazole, and fluconazole are highly effective alternative oral therapies. Ketoconazole is no longer manufactured for systemic use because of hepatotoxicity concerns. Although no comparative trials have been performed, itraconazole appears to have greater efficacy and less toxicity than either fluconazole or ketoconazole and therefore is the oral agent of choice. In a published trial, 95% of patients with non–life-threatening, non-CNS blastomycosis were treated successfully with itraconazole, 200 to 400 mg/d for 2 to 6 months. This approximates the observed efficacy seen with amphotericin B. Clinical data regarding the use of fluconazole suggest similar efficacy of this agent, with at least 80% of patients responding to 400 to 800 mg/d for 6 months. Most patients with blastomycosis can be started on oral itraconazole, 200 mg/d and advanced by 100 mg increments at monthly intervals to a maximum of 400 mg/d in patients with persistent or progressive disease. In patients with more aggressive disease, an initial dose of 400 mg is appropriate. Therapy with any of the azoles should be given for a minimum of 6 months. More recently, newer mold-active triazoles (voriconazole, posaconazole, and isavuconazole) have been reported to have success in treatment when other agents are not tolerable. Voriconazole is recommended as the azole of choice for blastomycosis involving the CNS. Based on in vitro susceptibility data, one would anticipate excellent clinical activity from all of these compounds.

A formulation of amphotericin B is generally reserved for patients with overwhelming life-threatening and/or CNS disease, patients who are severely immunocompromised, and for those in whom oral therapy has failed. In selected patients, an induction dose of amphotericin B for a rapid fungicidal effect to gain control of the disease may be useful, followed by oral therapy with itraconazole for at least 6 months. For patients with CNS involvement, several reports suggest that fluconazole and voriconazole, two azoles with significant CNS penetration, are effective therapeutic agents among individuals who have had an initial favorable response to amphotericin B. There is substantial clinical experience but few published data concerning the use of the lipid formulations of amphotericin B in the treatment of blastomycosis. There are no data to suggest superior efficacy of these agents compared with conventional (deoxycholate) amphotericin B. However, the use of the lipid formulations of amphotericin B, at doses ranging from 3 to 6 mg/kg/d to treat blastomycosis has become a standard approach in many developed countries where there is broad access to these compounds. Despite their greater expense, the lipid formulations are associated with significantly less nephrotoxicity and infusion reactions than deoxycholate amphotericin B.

The treatment of acute pulmonary blastomycosis remains controversial. Many investigators suggest close observation without therapy in patients who are not immunocompromised; however, this approach has become less acceptable to many clinicians given the extensive safety and efficacy profiles of the azole compounds. Available data suggest that most cases of acute pulmonary blastomycosis resolve spontaneously without therapy, although careful long-term evaluation of these untreated patients is important to monitor for evidence of active disease.

All patients with chronic blastomycosis should receive antifungal therapy. Cure rates of at least 90% should be expected, with relapse rates of <10%. Mortality is uncommon and is usually seen among patients with extensive pulmonary involvement and acute respiratory distress syndrome (ARDS). A few patients, especially chronically immunocompromised individuals such as organ transplant recipients, patients receiving chronic glucocorticosteroid treatment,

and patients with AIDS require long-term suppressive therapy to prevent relapse.

Coccidioidomycosis

Trung T. Vu, Jose Cadena, and Gregory M. Anstead

Introduction

Coccidioidomycosis (CM) is caused by dimorphic fungi of the genus *Coccidioides*. It typically presents as acute and chronic pulmonary disease. The infection may disseminate widely, especially to cutaneous, osseous, and central nervous system (CNS) sites. CM is a significant health problem in the southwestern United States and Latin America, with approximately 150,000 infections per year in the United States, about 50,000 of which are symptomatic.

Microbiology

In routine fungal culture, at 25°C to 30°C/77°F to 86°F, *Coccidioides* grows as a mold; colonies are usually white but may be tan to brown, pink, purple, or yellow. The hyphae are thin, septate, and hyaline. Side branches produce unicellular, barrel-shaped arthroconidia (3–4 × 3–6 μm), alternating with empty disjunctor cells. At 37°C/98.6°F, in tissue or special media, the arthroconidia become spherical, enlarge, and develop into spherules (20–60 μm) that contain many endospores (2–4 μm). Conversion to spherules is not routinely performed in the laboratory; definitive identification is established by a DNA probe or exoantigen testing. Unlike *Histoplasma capsulatum* and *Blastomyces dermatitidis*, *Coccidioides* grows rapidly (usually in 3–7 days) and sporulation may be seen after 5 to 10 days. Clinicians should notify the laboratory when CM is suspected to ensure proper infection control practices. Plates with suspected *Coccidioides* mycelia should be sealed and opened only in biohazard hoods. Careless handling of culture plates has caused CM in laboratory personnel. The risk of inadvertent exposure of laboratory staff is especially high in nonendemic areas in which *Coccidioides* is not expected.

Epidemiology

Based on molecular genetics, the genus *Coccidioides* has been divided into *C. immitis* (mostly California isolates) and *C. posadasii* (other areas); both species are similarly pathogenic, but may differ in thermo- and halotolerance. The mycelial form of the fungus grows just beneath the soil surface and is composed of arthroconidia intercalated with nonviable segments. In addition to wind-borne arthroconidia, another route of soil colonization with *Coccidioides* is the decomposition of the carcasses of small mammals that were infected with the fungus.

The endemic area of CM is the Lower Sonoran Life Zone, marked by arid or semi-arid climates (annual rainfall 5–20 inches), sandy alkaline soil, and mild winters. These conditions are found in the southwestern United States (primarily Arizona, California, New Mexico, and Texas), Bolivia, Paraguay, Argentina, and

Mexico (Figure 177.1). Cases occur infrequently in Guatemala; Honduras, Nicaragua, Venezuela, Brazil, and Colombia. Overall, the epidemiology of CM in Latin America is poorly defined and is based primarily on skin test surveys; the real incidence is unknown because it is not reportable and cases may be misdiagnosed as tuberculosis.

The incidence of CM in the United States is increasing. In Arizona, the number of cases increased 40-fold in 19 years, from 255 in 1990 (incidence 7/100,000 population) to 10,233 cases in 2009 (155/100,000). Cases in Arizona reached an all-time high in 2011 with 16,467 cases. The increasing incidence is due to soil disturbance from construction for its rising population and an influx of susceptible individuals into the state. Furthermore, the frequency of dust storms has increased in the American Southwest by 240% from the 1990s to 2000s, and this has been proposed as a factor in the rise in the incidence of CM. Arizona accounts for 60% of all US cases; the highest rates occurred in its most populous counties (Maricopa, Pima, Pimal). In Tucson, *Coccidioides* causes 29% of community-acquired pneumonia.

In California, from 1995 to 2009, the annual incidence ranged from 1.9 to 8.4 per 100,000, increasing to 13.8 per 100,000 in 2011. Cases in California reached an all-time high in 2017 of 6,925; most occur in the Central Valley and Central Coast. The reasons for the increased rates are uncertain but may be due to a period of rainfall after years of drought and soil disturbance due to construction. In 2017, there were 14,364 cases reported to the US Centers for Disease Control and Prevention, mostly among residents of Arizona and California. However, this is likely to be a significant underestimate because many individuals with apparent community-acquired pneumonia are not tested for CM.

Risk factors for increased severity of CM include receiving immunosuppressive medications (corticosteroids, transplant

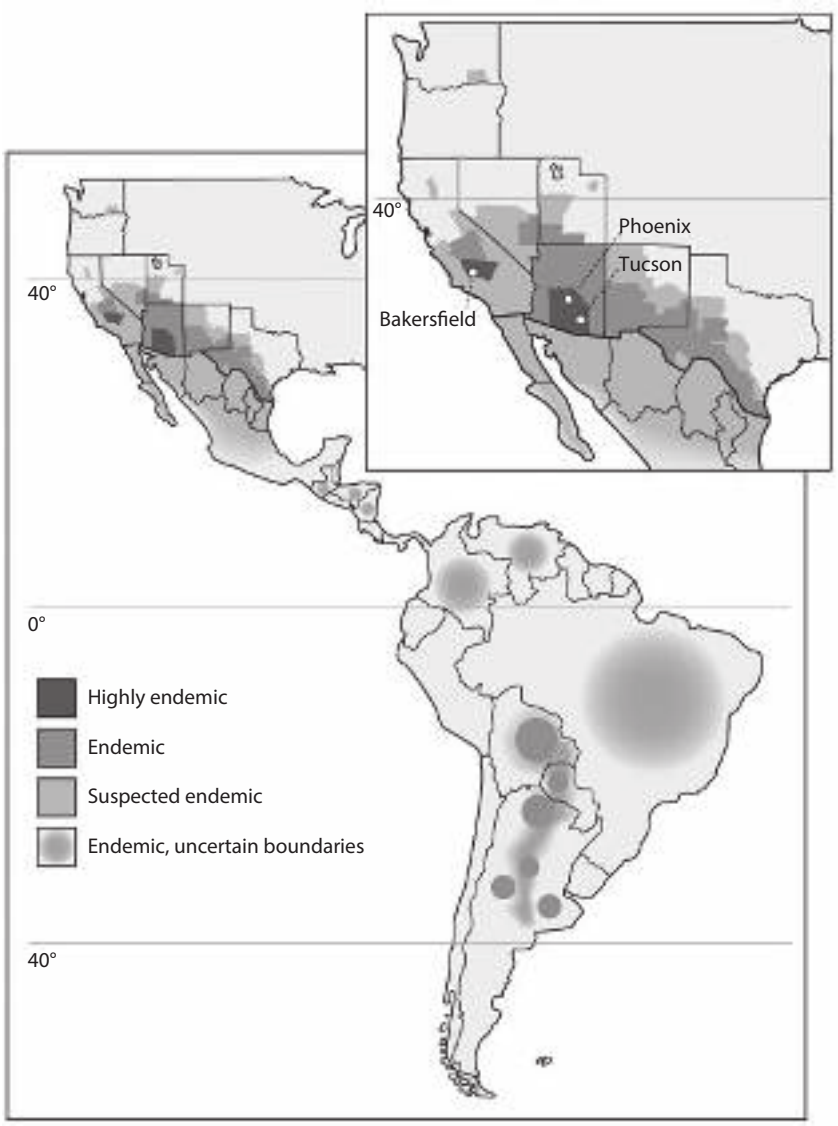

FIGURE 177.1 Map of the distribution of *Coccidioides* spp.

drugs, and tumor necrosis factor [TNF-α] antagonists), diabetes mellitus, pregnancy (especially the third trimester), genetic factors (i.e., defects in the interleukin [IL]-12/interferon-γ axis and the STAT3 pathway, certain ABO blood groups and HLA types), and specific races/ethnicities. The incidence of CM per 100,000 in Arizona in 2009 among different ethnic/racial groups was African American, 67; Asian-Pacific Islander, 36; Caucasian, 28; and Hispanic, 21. Filipinos and Native Americans are also considered to be high-risk groups. Persons with occupations with soil exposure (farm and construction workers, archeologists, military personnel, miners, and oil and gas workers) are also at risk for CM.

Natural history, pathogenesis, and pathologic findings

When the soil is disturbed, the fragile mycelia disintegrate into a cloud of conidia which may be carried for miles by the wind. Inhaled conidia are phagocytosed by alveolar macrophages and, over several days, convert into the characteristic large spherule (Figure 177.2). The spherules elaborate endospores, which multiply, and, after 3 to 4 days, hundreds of daughter cells (endospores) burst from the mature spherule. The endospores are ingested by neutrophils but not killed. These gradually enlarge into the next generation of spherules.

Arthroconidia, endospores, and spherules are resistant to killing by phagocytic cells, which may be due to components of the outer cell wall of the organism, such as spherule outer wall glycoprotein (SOWgp). Host exposure to SOWgp biases the immune response in a Th2 manner, compromising cell-mediated immune pathways. Other virulence factors of *Coccidioides* include melanin and extracellular urease. Melanin protects the fungus from the reactive oxygen species produced by leukocytes. The urease generates an alkaline microenvironment, which impairs granuloma formation and pathogen clearance. Pulmonary infection with *Coccidioides* also alters surfactant production, which promotes disease progression.

Early in the course of infection, *Coccidioides* may hematogenously disseminate to the skin, bones, and CNS. Clinical manifestations of these remote lesions may appear soon after the acute infection or months later, sometimes without evidence of the primary infection. Uncontrolled infection often presents as suppurating abscesses, with draining exudates containing abundant neutrophils and spherules, whereas chronic low-grade infection manifests as better-formed granulomas containing few organisms. Both B- and T-lymphocytes are essential for host defense, indicating that a balanced Th1/Th2 response is necessary for protective immunity.

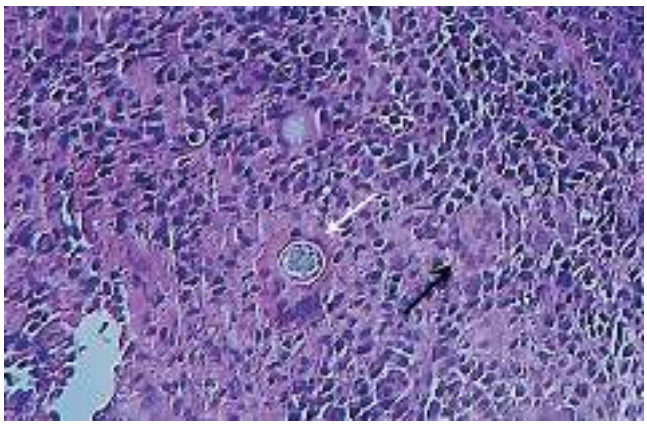

FIGURE 177.2 Hematoxylin and eosin stain of the biopsy specimen from a nodular skin lesion showing a coccidioidal spherule (*white arrow*), chronic inflammatory cell infiltrates, as well as surrounding granuloma formation with multinucleated giant cells.

Clinical features

Primary infection

CM is asymptomatic in more than half of patients. Hypersensitivity reactions may occur with primary infection, including fever, toxic erythema, erythema nodosum, erythema multiforme, arthralgias, arthritis, conjunctivitis, or episcleritis, known as "Valley Fever" after the San Joaquin Valley of California, a major endemic focus. These may be the only manifestations of primary CM, or they may blend into the invasive forms of disease. Occasional case clusters may occur 10 to 14 days after a group of susceptible persons is exposed to dust in an endemic area.

Pulmonary infection

Most symptomatic patients have a transient pulmonary infection occurring 1 to 3 weeks after exposure, manifesting as fever, dry cough, and pleuritic chest pain. This is usually indistinguishable from community-acquired pneumonia. Radiographically, there may be infiltrates, hilar adenopathy, and pleural effusions. Typically, the symptoms of acute pulmonary CM resolve spontaneously in less than a month. Alternatively, the pulmonary infiltrates may condense into nodules that may resolve or persist asymptomatically. While primary pneumonia usually resolves, in 5% to 19% of patients, the disease may linger for months, with chronic pulmonary infiltrates, cough, and pleuritic chest pain. Coccidioidal pleuritis with pleural effusion may also occur, often with spontaneous resolution. Immunocompromised patients are more likely to develop chronic progressive pulmonary infection, characterized by the presence of extensive thin-walled cavities that may be complicated by rupture, with bronchopleural fistula and empyema formation. Cavitary disease may be asymptomatic or cause chronic productive cough and hemoptysis (Figure 177.3). Cavities may also develop secondary to bacterial or *Aspergillus* (fungus ball) infection. The cavity may contract into a nodule within a year in about half of the cases. Small cavities (<5 cm in diameter) are more likely to resolve spontaneously

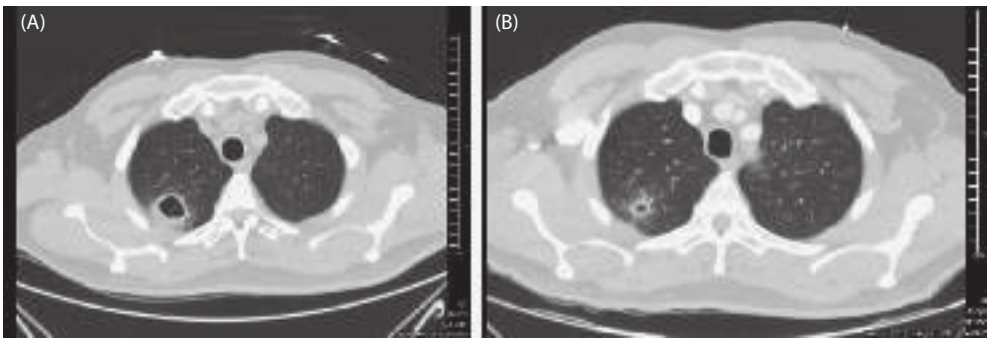

FIGURE 177.3 A 50-year-old Hispanic man presented with a 5-day history of productive cough, chills, and night sweats. (A) Chest CT with contrast showed a single thick-walled right upper lobe cavitary lesion with surrounding ground-glass opacities. A fungal culture of the bronchoalveolar lavage fluid yielded *Coccidioides* spp. (B) Six weeks after receiving daily fluconazole (800 mg), the patient's symptoms resolved, and a repeat chest CT with contrast showed a contracting cavitary lesion.

than larger ones. Chronic pulmonary CM may follow a waxing and waning course or be slowly progressive over years. Uncommonly, patients have fulminating pneumonia, with diffuse reticulonodular infiltrates, fever, and hypoxia. Aggressive pulmonary disease can occur in pregnancy, especially the last trimester, and in other immunocompromising conditions.

Extrapulmonary disease

Disseminated CM occurs in about 1% of those infected, with a fatal course in one-third of these patients. Extrapulmonary CM usually presents as skin lesions, lymphadenitis, deep abscesses, osteoarticular disease (which presents as lytic bone lesions and thickened synovia), or CNS disease, but nearly any organ can be involved. Dissemination may occur years after an apparently resolved primary infection if the individual becomes immunocompromised.

Meningitis and other CNS disease

CNS manifestations of CM include meningitis, encephalitis, mass lesions, and vasculitis (Figures 177.4 and 177.5). Coccidioidal meningitis presents as progressive headache, cranial neuropathies, and altered mental status. Typical CSF findings include a lymphocytic or eosinophilic pleocytosis (100–500 cells/mm^3), hypoglycorrachia, and elevated protein (>150 mg/dL). Elevated opening pressure of >20 cm H_2O may be observed, often associated with hydrocephalus. Granuloma formation may cause focal neurologic signs. CSF eosinophilia is a helpful diagnostic clue, and the CSF is usually positive for immunoglobulin (IgG) antibody. CSF cultures are positive in <50% of cases. Untreated, coccidioidal meningitis is fatal within 2 years. CNS vasculitis due to CM may present as a stroke-like syndrome. Not all patients with CM require a lumbar puncture; however, for those with headache or other CNS signs or symptoms, a lumbar puncture is necessary.

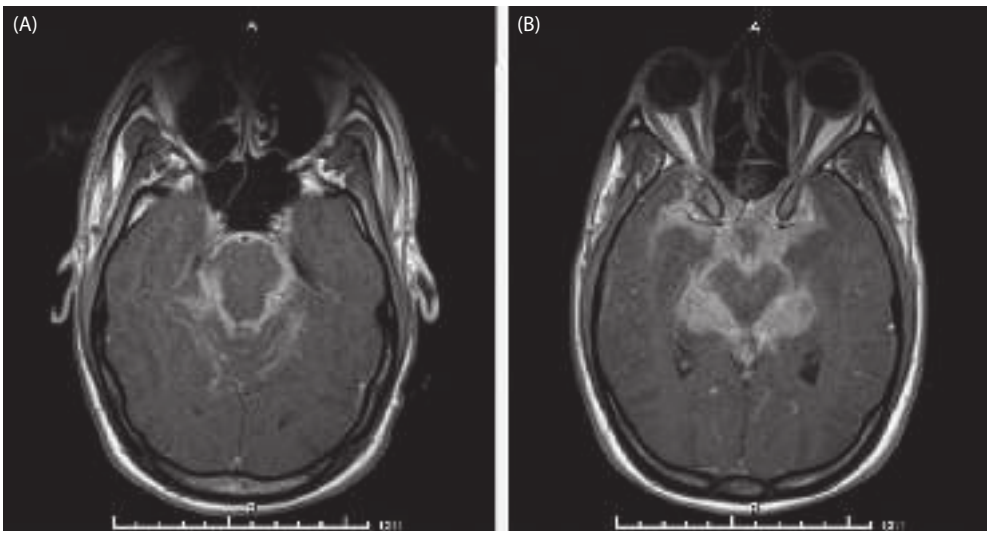

FIGURE 177.4 The patient is a 30-year-old African American man with disseminated coccidioidomycosis. Four weeks after visiting the Grand Canyon, he was treated for an upper respiratory infection. Two months after the trip, he developed a headache and was diagnosed with aseptic meningitis. He later developed a nodule near his left nasolabial fold. Four months after the trip, he presented with altered mental status. Clinical evaluation revealed coccidioidal meningitis with obstructive hydrocephalus, vertebral osteomyelitis, and fungal septic arthritis of his knee.

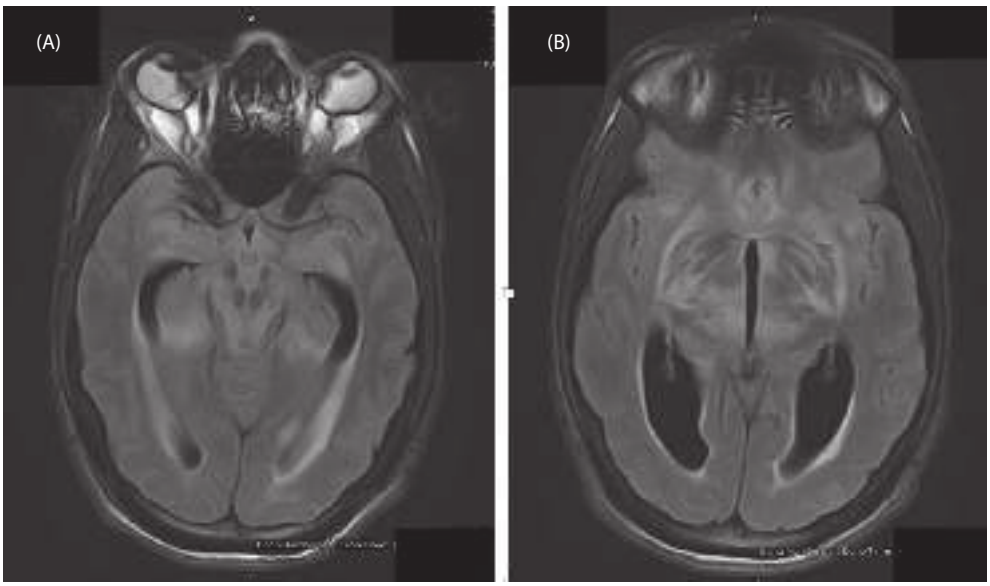

FIGURE 177.5 (A and B) These images are from the same patient as described in Figure 177.4. T2-weighted MRI axial images showing enlarged lateral and third ventricles in obstructive hydrocephalus, a dreaded complication of coccidioidomycosis. Also note the surrounding white matter edema. The patient was not shunted but responded to liposomal amphotericin B, followed by voriconazole.

Soft tissue and osteoarticular disease

Soft tissue involvement in disseminated CM includes papules, nodules, abscesses, and ulcers that may drain purulent fluid or verrucous lesions that may progress to ulceration. In general, lesions with purulent drainage are associated with a worse prognosis.

Osteoarticular involvement accounts for 20% to 50% of extrapulmonary CM. Axial skeletal structures (vertebrae, skull, sternum, and ribs) are more commonly affected than is the appendicular skeleton. The spine is the most frequent site of osteoarticular dissemination (Figure 177.6). Vertebral infection starts in the central cancellous bone of the vertebral body and then may invade into the periosteum and adjacent soft tissue. Vertebral CM may be confused with Pott's disease (vertebral tuberculosis), and, like Pott's disease, it can cause vertebral collapse and spinal cord compression. In appendicular skeletal infection with *Coccidioides*, the ends of long bones, especially at bony prominences, are most commonly involved. Radiographically, there are typically lytic lesions with osteopenia. Technetium bone scans are considered 100% sensitive for the identification of areas of coccidioidal osteomyelitis. Joint involvement is less common than osteomyelitis; it is usually mono-articular and most commonly involves the leg, especially the knee (Figure 177.7). Arthrocentesis reveals an exudative synovial fluid and the synovium shows granulomata with spherules. A synovial specimen is more likely to yield a positive culture for *Coccidioides* than is joint fluid.

FIGURE 177.6 This image is from the same patient as described in Figure 177.4. T2 MRI sagittal image showing T11-T12 osteomyelitis and discitis with extension of infection into the anterior epidural space.

Fungemia

Coccidioides fungemia, which manifests as a systemic inflammatory response syndrome with progressive cardiorespiratory failure,

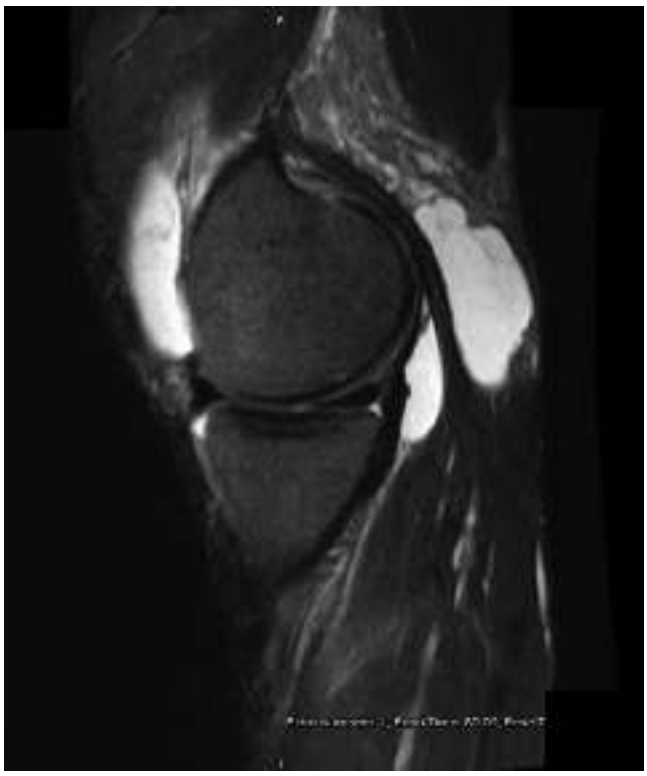

FIGURE 177.7 This image is from the same patient as described in Figure 177.4. T2 MRI sagittal image showing left knee synovial enhancement. Synovial fluid culture grew *Coccidioides* spp.

has been described in immunocompromised patients and carries a high mortality rate. In one series of 33 patients with coccidioidal fungemia, 73% died within 28 days of the diagnosis.

Coccidioidomycosis, the "great imitator"

CM has been termed a "great imitator" disease and has many diverse disease manifestations. In addition to the usual pulmonary, cutaneous, osteoarticular, and nervous system manifestations of CM, various uncommon presentations are listed in Table 177.1. In general, unusual manifestation most often occur in the immunosuppressed host or in those prone to dissemination such as African Americans, Filipinos, and pregnant women.

Coccidioidomycosis in children

Children are susceptible to CM, with a reported incidence of hospitalization in endemic regions of 8 to 12/100,000. In one series, 56% of hospitalized children had pulmonary disease, 14% had progressive disease, and 7% had meningitis. About one-third of pediatric CM patients had underlying conditions, usually immunodeficiency or malignancy; none died during their first hospitalization. Coccidioidal serologic tests are not reliable for the evaluation of infants during the first 3 months of life and positive tests must be interpreted cautiously during the first year. Breastfeeding is not recommended for mothers with CM taking azoles other than fluconazole. It uncertain if transplacental infection of the fetus occurs, and the very rarely observed neonatal infections are likely the result of aspiration of amniotic fluid or vaginal secretions.

TABLE 177.1 **UNUSUAL MANIFESTATIONS OF COCCIDIOIDOMYCOSIS**

Site or organ system	Manifestation
Skin and soft tissue	Purpura; bullae; subcorneal pustulosis; mesh infection; tenosynovitis
Neurologic	Brain aneurysms; brain abscess; cerebral arteritis and infarction
Hematologic	Immune thrombocytopenia; hemophagocytic lymphohistiocytosis
Head and neck	Massive cervical lymphadenopathy; laryngeal abscess; retropharyngeal abscess; thyroiditis; preauricular cyst; glossitis
Ocular	Endophthalmitis; iridocyclitis; granulomatous conjunctivitis; choroiditis; uveitis
Cardiac	Endocarditis, pericarditis, myocarditis
Intra-abdominal	Peritonitis; hepatitis; pelvic mass; adrenal mass; duodenitis
Female genital/ reproductive system	Placentitis with or without fetal demise; salpingitis; uterine involvement
Male genital/ reproductive system	Prostatitis, epididymitis, orchitis

Diagnosis

CM should be considered in the differential diagnosis of a compatible illness occurring in a resident or visitor to an endemic area. Rapid diagnostic methods include examination of sputum or exudates from purulent lesions for spherules or detection of spherules on histopathologic exam of cutaneous lesions, bronchoscopy specimens, or lymph nodes. The morphology of *Coccidioides* spherules is nearly pathognomonic.

The gold standard technique for the diagnosis of CM is culture of the organism from clinical specimens. The spherules in sputum, exudates, or tissue convert to mycelia in culture, which usually grow in 3 to 7 days.

The immunodiffusion (ID) technique detects IgG and IgM antibodies indicating exposure to *Coccidioides* with high specificity. IgM antibodies develop within weeks after infection but are not sustained. IgG antibodies take 1 to 2 months to appear (in blood and CSF) and persist for many months. Complement fixation (CF) tests detect IgG and are useful for both diagnosis and monitoring

the activity of the infection; CF titers of >1:16 suggest disseminated infection. Antibody concentrations may decrease over time to undetectable levels upon resolution of the infection. Thus, a positive antibody assay indicates recent infection, chronic disease, or reactivation. There may be false-negative serologic studies early in the course of infection, in localized disease (i.e., a pulmonary nodule), or in immunocompromised patients. Serologic assays may be applied to blood, CSF, and pleural and synovial fluid. Enzyme immunoassays (EIA) are available outside of reference laboratories and detect both IgM and IgG. There is controversy regarding the false-positivity rates of isolated EIA IgM measurements; serial measurements have been used to differentiate false-positive from true-positive results. A positive EIA IgG, either alone or with a positive EIA IgM, should be sent to a reference laboratory for confirmation.

A urinary antigen test is available from MiraVista Laboratories (Indianapolis, IN), with 71% sensitivity in moderate to severe disease versus 87% for culture. The urinary antigen test has some cross-reactivity with *Histoplasma* antigens. There is a commercially available PCR test (Mayo Medical Laboratories, Rochester, MN) that can utilize either body fluids or tissue.

Treatment

Treatment guidelines for CM were published in 2016. *Coccidioides* isolates are generally susceptible to amphotericin B and azoles in vitro, but treatment responses are highly dependent on host factors (immunocompetence and race/ethnicity). In a study of the in vitro susceptibility of 581 *Coccidioides* isolates, elevated MIC values were observed for 37% of isolates to fluconazole (≥16 g/mL) versus 1% of isolates for itraconazole, posaconazole, and voriconazole. However, studies of the relationship between MIC values and patient outcomes are necessary to determine the relevance of these data in antifungal selection. Clinical experience with echinocandins is limited.

Treatment courses for any form of CM are prolonged and should continue for months after improvement. Because some lesions can progress while others wane, a scoring system was developed by the Mycosis Study Group (Catanzaro, Galgiani, and coworkers) that incorporated signs and symptoms, cultures, radiographically apparent lesions, and serologic titers with a reduction of a cumulative score to <50% of baseline considered as response to therapy. As cultures are often not repeated (especially if invasive methods are required) and serologic titers change slowly, the total burden of disease has recently been measured using clinical signs and symptoms and radiographic evaluation of lesion size. In coccidioidal meningitis, normalization of CSF findings indicates an appropriate treatment response.

Selection of the antifungal agent depends in part on the involved site and the severity of disease. No treatment is recommended for asymptomatic coccidiomas (noncalcified nodular densities) which are often resected incidentally by a biopsy for presumed lung cancer. The nephrotoxicity of amphotericin B initially discouraged physicians from treating primary coccidioidal pneumonia, which usually resolves spontaneously. However, all patients require observation for at least 2 years to document resolution of infection and promptly identify complications. Liposomal amphotericin B (AmBisome) has several advantages over amphotericin B deoxycholate, including lower nephrotoxicity, attainment of higher levels in the reticuloendothelial system, and better CNS penetration. Fluconazole has been increasingly deployed to treat primary coccidioidal pneumonia. Nevertheless, there are no clear data to indicate its efficacy in this setting or in the prevention of dissemination.

For patients at risk for disseminated disease, antifungal treatment of primary coccidioidal pneumonia is appropriate. Other indications for treatment are severe disease: infiltrates involving both lungs or more than half of one lung, hilar or mediastinal lymphadenopathy, IgG titers of >1:16, and highly symptomatic disease (weight loss >10%, night sweats >3 weeks, symptoms >2 months). Patients with signs of chronic pulmonary infection, such as weight loss, night sweats, and multilobar infiltrates and symptoms for more than 2 months should also be treated.

Based on its excellent tolerability, linear renal clearance, limited drug interactions, and efficacy, fluconazole is the drug of choice for less severely ill patients. In one trial, the response rate in chronic pulmonary and disseminated disease was 50% for fluconazole versus 63% for itraconazole. Fluconazole doses of 400 mg/d are often used initially, but slow responses and failures in meningitis may necessitate doses as high as 1,000 to 1,200 mg/d. Treatment for 6 months has been suggested for primary pneumonia and >12 months after response for severe or chronic pulmonary or disseminated disease.

Although itraconazole is superior to fluconazole in patients with skeletal disease, its less predictable pharmacokinetics and more frequent adverse events have demoted itraconazole to a second-line drug. Itraconazole is administered orally either as capsules with a fatty meal or as a cyclodextrin solution (Sporanox) in the fasted state, at 400 to 600 mg/d. The larger studies have been conducted with the capsules, which are better tolerated but less predictably absorbed. Itraconazole inhibits and is metabolized by cytochrome 3A4, so its drug interactions are extensive. There is limited experience with itraconazole in the treatment of meningitis.

For life-threatening CM, amphotericin B or a lipid formulation is recommended. The latter is preferred because of its decreased risk of nephrotoxicity. There is no evidence that high doses of the lipid formulations (e.g., 10 mg/kg) are more effective than doses of 3 to 6 mg/kg. Responses to amphotericin-based therapy on the order of 50% to 70% are seen. When the patient has improved or when nephrotoxicity occurs, treatment is shifted to azoles for ongoing therapy. Because the azoles may be teratogenic, amphotericin B is preferred during the first trimester of pregnancy. If nephrotoxicity develops, azole treatment may be necessary for at least a limited time, preferably later in pregnancy.

A challenge in the management of CM is the selection of a salvage agent when initial therapy fails or when the patient relapses (which may be years later). For azole failures, the 2016 guidelines recommend amphotericin B. However, voriconazole or posaconazole may also be considered. Voriconazole, at doses of 400 to 600 mg/d, has proved successful in some patients with refractory disease. Another salvage option is posaconazole. Published clinical experience for posaconazole is limited to its suspension form, given 200 mg four times per day with a fatty meal. More than half of salvage patients responded to posaconazole. Posaconazole has also

been used as primary therapy with responses of 85% in 20 patients. Unfortunately, relapses occurred in a third of patients who initially responded. Both voriconazole and posaconazole show high in vitro activity against *Coccidioides*, but the posaconazole suspension has variable oral bioavailability. A posaconazole tablet with improved oral bioavailability and an intravenous preparation are now available, and these new forms may prove to be more efficacious. Experience with isavuconazole is limited; in a series of nine patients with pulmonary CM, complete or partial success was observed in 56% of patients, but only 22% had complete resolution.

For meningitis, treatment has changed dramatically with the availability of fluconazole; previously, intrathecal amphotericin B was required. However, intrathecal amphotericin B can cause arachnoiditis and vasculitis and should be administered with corticosteroids to suppress these adverse events. It is seldom used in the post-fluconazole era except for coccidioidal meningitis in the first trimester of pregnancy. There are concerns that intravenous amphotericin B has poor CNS penetration. However, intravenous AmBisome has been used successfully in the treatment of other CNS mycoses. Further data are required to define its role in the management of coccidioidal meningitis. Posaconazole and voriconazole have also been used with success in meningitis. For patients with increased intracranial pressure at the time of meningitis diagnosis, repeated lumbar punctures are recommended. Hydrocephalus may require ventriculoperitoneal shunting. In patients with CNS vasculitis with cerebrovascular accident due to CM, those who received corticosteroids were less likely to develop additional infarcts compared to those who did not.

Reduction of immunosuppression is an important adjunct to antifungal therapy, including the initiation of antiretroviral therapy in HIV patients. In patients with AIDS and non-meningeal CM, antifungal therapy can be discontinued when the CD4 count exceeds 250 cells/mm^3. All patients with coccidioidal meningitis require lifelong antifungal therapy. Vertebral osteomyelitis may require surgical stabilization or spinal cord/nerve root decompression. For patients with a ruptured coccidioidal cavity, resection and decortication are recommended. For chronic coccidioidal arthritis, synovectomy may be beneficial.

Prevention

Vaccines. Among the endemic mycoses, CM has generated the most interest for the development of a vaccine, because (1) prior infection engenders immunity, (2) it produces a considerable burden of morbidity, and (3) it exists in a defined endemic zone, growing in population. Multiple vaccine candidates have been evaluated since the 1960s, but no vaccine has been approved for human use. These vaccine candidates have included inactivated spherules, spherule extracts, individual antigens (proline-rich antigen [Ag2/PRA], β-glucanosyltransferase, calnexin, aspartyl protease, phospholipase, and α-mannosidase, among others, using multiple different adjuvants), and live attenuated mutants (inactivated by radiation or by deletion of genes required for sporulation). Recombinant proteins, such as Ag2/PRA were found to be protective in some mouse studies, but the protection is variable, likely due to a lack of standardization of testing. One clinical trial of a killed spherule vaccine involving 2,867 persons was conducted from 1980 to 1985, with no significant reduction in the incidence of positive coccidioidin skin reaction or CM between the vaccine and control groups.

A recent study in mice compared the effectiveness of killed *Coccidioides* spores to mutant avirulent spores (*Δcps1*) in which the virulence gene CPS1 was replaced with the hygromycin resistance cassette. The attenuated strain produced long-term immunity whereas the killed spores failed to do so. The mice immunized with the *Δcps1* mutant spores had increased IFN-γ production and an enhanced Th1 response, and they were protected from lethal challenge with *C. posadasii*.

Antifungal prophylaxis. CM has been described among transplant patients in endemic regions, with an incidence of 1.4% to 6.9%. Risk factors include pre-transplant seropositivity, a history of CM, and African American race; disease can result from either primary infection or reactivation. During pre-transplant evaluation, patients should be queried about a history of traveling to or living in an endemic region and may require clinical assessment, serological testing, and chest radiography. If serologic studies are positive, transplant candidates should be evaluated by an infectious diseases specialist, and clearance for transplantation should be determined on a case-by-case basis. In endemic areas, postoperative prophylaxis with fluconazole is recommended (200 mg/d if seronegative pre-transplant, and 400 mg/d if seropositive). Duration of prophylaxis is usually 6 to 12 months. If the organ donor is seropositive, then azole prophylaxis is also warranted. Lung transplant recipients of infected or seropositive donors require life-long suppression with fluconazole 400 mg/d, and other organ recipients should receive at least 6 to 12 months of therapy, followed by the option to decrease to 200 mg/d or discontinuation after 6 to 12 months based on clinical assessment and with subsequent clinical and serological monitoring.

For patients with HIV infection and low CD4 counts living in endemic areas, primary prophylaxis against CM is not recommended. However, for HIV patients living in endemic regions, annual or biannual serologic screening for CM is recommended. If the patient is seropositive and asymptomatic (with no abnormalities consistent with active disease), and has a low CD4 count (<250 cells/mm^3), antifungal therapy with fluconazole 400 mg/d should be prescribed and continued until the HIV viral load is suppressed and the CD4 count increases to ≥250 cells/mm^3. For patients living in endemic areas, in which TNF-α antagonist therapy is planned, screening for asymptomatic coccidioidomycosis before the patients begin TNF-α antagonist therapy decreases the risk of developing symptomatic CM.

Occupational prevention. Occupational CM outbreaks in California from 2007 to 2014 have led to prevention strategies to reduce the infection among at-risk workers. Work practices to limit occupational exposure to dust include safer project design, frequent soil wetting during dust-generating activities, enclosed cabs on construction equipment with HEPA-filtered air conditioning, suspending work during periods of excessive dust, having onsite personnel able to implement additional control measures during dusty conditions, and necessary respiratory protective equipment. At-risk workers should have access to occupational medicine providers; ill workers should be advised to promptly report concerning symptoms

to supervisors and physicians. The systematic collection and analysis of occupational CM cases by public health authorities may prevent future workplace-associated outbreaks.

Conclusion

CM is a mycosis geographically restricted to arid areas of the New World. Nevertheless, it exacts a great toll of human suffering from acute and chronic respiratory disease, osteoarticular destruction, and neurologic invasion. The severity of CM is highly dependent on host factors (immunocompetence and race/ethnicity). Due to travel and the influx of susceptible persons into the American Southwest, the incidence is increasing. Diagnostic methods include culture, serologic testing, histopathologic exam, and antigen detection, but all have limited sensitivity. CM can be successfully treated with azoles and amphotericin B; however, the duration of treatment is prolonged, relapse is common, and permanent disability or death may occur despite aggressive treatment. Additional resources are needed to develop more effective therapeutic modalities and to conduct randomized, controlled clinical trials for the treatment of this potentially devastating disease.

Pneumocystis jirovecii (carinii)

Shelley A. Gilroy and Nicholas J. Bennett

Background

Pneumocystis jirovecii (pronounced "yee-row-vet-zee"), formerly known as *Pneumocystis carinii*, is an opportunistic pathogen that causes pneumonia in the immunocompromised individual. The initials "PCP" stood for *Pneumocystis carinii* pneumonia but were kept for a while for ease of use after the organism was renamed (PneumoCystis Pneumonia). The condition is more correctly abbreviated as PJP. Disease occurs when both cellular and humoral immunity are impaired. Serologic studies have shown that *Pneumocystis* has a worldwide distribution, but the prevalence of antibodies to specific antigens varies among different geographic regions. PJP first came to attention when it caused interstitial pneumonia in severely malnourished and premature infants in Central and Eastern Europe during World War II. Prior to the AIDS epidemic in the 1980s, <100 cases were reported annually in the United States. PJP is one of several life-threatening opportunistic infections in patients with HIV infection worldwide and is still the most common AIDS-defining illness in patients with advanced HIV infection. The decline in the number of PJP cases in the United States occurred after the introduction of anti-pneumocystis prophylaxis in 1989 and highly active antiretroviral therapy (HAART) in 1992. In patients without HIV infection, the incidence of PJP has increased in those being treated with immunosuppressive and chemotherapeutic agents and in hematopoietic stem cell (HSCT) and solid organ transplant recipients.

The taxonomic classification of the *Pneumocystis* genus and the organism's name has changed throughout the years. In the 1980s, biochemical analysis identified the organism as a unicellular fungus. *P. jirovecii* is found in three distinct morphologic stages: the trophozoite, in which it often exists in clusters; the sporozoite (precystic form); and the cyst, which contains several intracystic bodies (spores). The cyst is the diagnostic form of *P. jirovecii* and stains with Giemsa, Papanicolaou, and Grocott methenamine silver nitrate (GMS) and immunocytochemical techniques using monoclonal antibodies. Giemsa- and Papanicolaou-stained smears show indirect evidence of *P. jirovecii* infection by the demonstration of foamy exudates in the form of alveolar casts.

The environmental source for *Pneumocystis* is unknown. Studies in animals and humans suggest that it is transmitted by the airborne route. The organism can be found in the respiratory tracts of hospitalized patients with viral or bacterial infections and healthy individuals without pneumonia. These individuals may serve as a reservoir for infection to susceptible hospitalized patients. The time necessary from colonization to infection is unknown. Once *Pneumocystis* enters the lungs it attaches to the alveoli. Alveolar macrophages are the first line of defense and are responsible for clearing the organism from the lung. This function is impaired in patients with HIV or cancer and in transplant recipients receiving immunosuppressive therapy. Tumor necrosis factor-α (TNF-α) and interleukin-1 (IL-1), proinflammatory cytokines, have been shown to be important in host defenses against the organism in the early stages of infection. As the host defenses become compromised, *Pneumocystis* organisms proliferate and fill alveolar lumens, subsequently leading to interstitial plasma pneumonia.

Extrapulmonary *Pneumocystis* infection is rare. Dissemination may occur via direct spread, hematogenous spread, or via lymphatic vessels in the absence of pneumonia. It can occur in HIV-infected patients receiving

aerosolized pentamidine for prophylaxis. The most common organs or tissues infected are the lymph nodes, spleen, liver, bone marrow, and the small intestine.

Clinical manifestations

PJP is an AIDS-defining illness, typically occurring in HIV-infected patients not taking HAART, with a T-helper cell count (CD4) of <200 cells/mm^3. Symptoms include insidious onset of dyspnea with a dry cough, fever, diarrhea, and weight loss. Acute dyspnea with chest pain may indicate a pneumothorax. Physical examination typically reveals tachypnea, tachycardia, and fever with normal findings or mild crackles or rhonchi on lung auscultation. Oral thrush or oral hairy leukoplakia may also be present. A resting PaO_2 of <80 mm Hg occurs in 80% of cases. Desaturation with exercise is a highly sensitive marker of PJP, even if the PaO_2 is normal. A clinical picture of PJP in HIV-infected patients with a high CD4 count should prompt consideration of immune reconstitution inflammatory syndrome (IRIS), defined as a clinical deterioration caused by restoration of a patient's capacity to mount an inflammatory immune response against infectious and noninfectious agents once HAART has begun.

In children, early signs are poor feeding, diarrhea, and coryza. Physical findings include nasal flaring, intercostal retraction, and cyanosis.

Immunocompromised patients without AIDS typically present with acute respiratory insufficiency or shorter duration of illness and fewer days of dyspnea and fever. PJP can occur with or without lymphopenia or low CD4 counts.

The most significant risk factors for PJP are defects in cell-mediated immunity, prolonged glucocorticoid use, cancer (particularly hematologic malignancies), HSCT, rheumatologic diseases, severe combined immunodeficiency, and severe malnutrition. The most common chemotherapeutic drugs associated with increased risk of PJP are fludarabine, temozolomide, vincristine, temsirolimus, and cyclophosphamide. Patients receiving biologic agents, particularly alemtuzumab and the TNF inhibitor infliximab, and kinase inhibitors (ibrutinib, idelalisib) are also at risk for infection.

In early mild disease the chest radiograph will be normal. High-resolution CT scanning (HRCT) is more useful. Typical findings are diffuse micronodules, patchy ground-glass, symmetric or asymmetric opacities, reticulation, septal thickening, and/or airspace consolidation (Figure 178.1). Apical interstitial infiltrates and pneumothorax occur more often in patients receiving prophylactic treatment with aerosolized pentamidine. Solitary or multiple nodules, which may cavitate, and pneumatoceles are less common. Pleural effusions and intrathoracic adenopathy are rare.

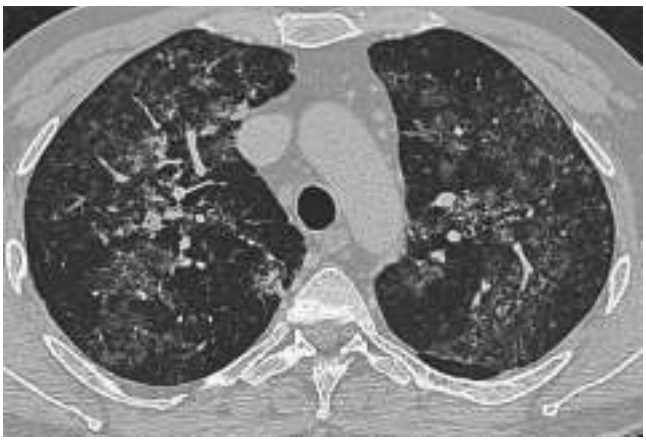

FIGURE 178.1 High-resolution CT image of the upper lung zones demonstrates diffuse micronodules and patchy ground-glass opacities, as well as some fine reticulation, all suggestive of an interstitial process consistent with *Pneumocystis* pneumonia.

Diagnosis

Pneumocystis has no effective culture-based test and the diagnosis, if suspected on clinical grounds, usually relies on obtaining invasive respiratory specimens. Tests on routine sputum specimens are insensitive and should not be performed, although induced sputum (performed with a respiratory therapist after inhalation of nebulized hypertonic saline) is about 50% sensitive. The sensitivity varies but approaches 90% in some institutions depending on technique proficiency and the experience of the laboratory. A negative result would not rule out PJP. Optimal testing requires bronchoscopy and bronchiolar lavage (BAL). Lung biopsy is diagnostic.

The classic histology findings are "foamy alveolar casts," in which there is proteinaceous fluid within the alveoli (Figure 178.2). With a silver stain such as GMS, pneumocystis can be visualized as teacup-shaped organisms (Figure 178.3). Immunofluorescence techniques, such as direct fluorescent antigen (DFA), can also be employed and are sensitive and specific. Single-copy real-time polymerase chain reaction (PCR) assays rapidly identify patients with infection rather than colonization and are more useful in clinical settings. PCR of BAL fluid or induced sputum can increase the diagnostic yield over conventional staining alone in HIV-uninfected immunocompromised patients.

In certain clinical settings, it may not be practical or safe to obtain invasive specimens, and noninvasive specimens are preferred. Serologic testing specific to PJP is available but cannot reliably distinguish between past and present infection. The majority of people will, at some point, become colonized with *Pneumocystis* and seroconvert, although some efforts have been made toward using the specific antibody titers or responses to specific proteins as being more indicative of active infection.

The *Pneumocystis* cell wall contains the same 1–3 β-D-glucan (BDG) as *Candida* and *Aspergillus*, and an assay for serum levels of BDG (known as Fungitell commercially) has proved to be sensitive and specific for PJP when appropriate cutoff levels are used. It can be used as an adjunct to the diagnosis of PJP. It has a high negative predictive value, making it unlikely that a patient with a negative β-D-glucan result has PJP. Although the assay is not specific for PJP

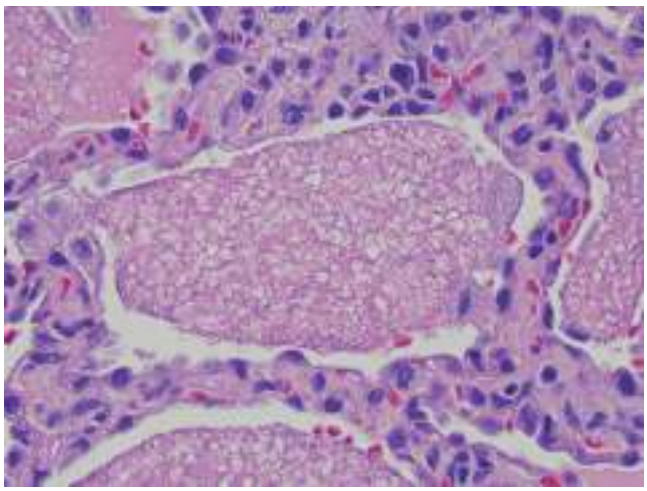

FIGURE 178.2 Hematoxylin and eosin stain of lung alveolae showing foamy infiltrates (foamy alveolar casts).

it may be useful in certain settings where BAL sampling cannot be safely performed. Because of the cross-reactivity of the assay to multiple fungi, bacteria (*Pseudomonas*), or exposure to intravenous immunoglobulin, interpretation of assay results should be done in the clinical context of the patient. PJP may be associated with somewhat higher levels of BDG than are seen in invasive candidiasis or aspergillosis. In patients with non-HIV PJP, and in children with PJP, levels tend to be higher than in HIV-associated PJP but there are no levels at which PJP can be reliably ruled in or out. In all cases, serum levels can be used to track response to treatment.

Treatment and prophylaxis

Recommended antimicrobial regimens are detailed in Table 178.1. The mainstay treatment of PJP is TMP-SMX. The dosing is usually 15 to 20 mg/kg/d in three divided doses for 14 to 21 days, orally or intravenously depending on severity of illness. Adjunct corticosteroids have been shown to have benefit in HIV-associated PJP with significant hypoxemia (an alveolar–arterial oxygen gradient of >35 mm Hg, or an arterial oxygen partial pressure of 70 mm Hg on room air). The role of steroids is in blunting the immune reaction to microorganism degradation which can result in an acute respiratory distress syndrome-like process. Guideline dosing for methylprednisolone is 40 mg twice daily on days 1 to 5, 40 mg once a day on days 6 to 10, 20 mg once a day on days 11 to 21.

Alternative medications, for instance in the case of allergy to sulfa-based antibiotics, include atovaquone, pentamidine, clindamycin-primaquine, and dapsone, of which the latter is usually given in combination with trimethoprim or pyrimethamine and leucovorin. A glucose-6-phosphate dehydrogenase (G6PD) level should be tested when using a regimen that contains dapsone or primaquine since a G6PD deficiency can lead to hemolytic anemia when such patients are exposed to these agents. Certain patients with severe PJP whose sulfa allergy is non–life-threatening can be "desensitized" using a gradual dose escalation of TMP-SMX. Of note, in one study assessing salvage therapy after failing initial treatment, the combination of clindamycin and primaquine appeared to be inferior to TMP-SMX.

TMP-SMX, pentamidine, or dapsone can all be used for prevention of PJP (Table 178.2). Prophylaxis is recommended for high-risk individuals, particularly those with HIV infection and CD4+ T-cell counts of <200 (or a history or previous PJP regardless of CD4 count). Other causes of immune suppression or deficiency also increase the risk of *Pneumocystis* to varying degrees. Neonates with severe combined immune deficiencies (SCID) and recipients of bone marrow transplants are at particularly high risk. Individuals with CD40 ligand deficiency are associated with an increased risk of PJP and should be placed on prophylaxis. Interestingly, although the 22q11 deletion syndrome (also known as *DiGeorge* or *velocardiofacial syndrome*) is primarily a T-cell deficiency and may result in CD4 counts similar to those seen in end-stage HIV infection, PJP has not been convincingly reported in patients with 22q11del. In these patients T-cell function is often intact and the CD4/CD8 ratio is preserved, whereas in HIV infection T-cell responses are blunted and the CD4/CD8 ratio is inverted. Nevertheless, some experts recommend PJP prophylaxis in individuals with 22q11del and very low CD4+ T-cell counts (<500), especially if T-cell function has not yet been assessed or if any form of immune modulation or suppression is also present.

The use of steroids and other immunosuppressive agents is associated with varying levels of risk for PJP, and the indications for

TABLE 178.1 **TREATMENT**

Drug	Adult dose	Pediatric dose	Notes
Trimethoprim-sulfamethoxazole (TMP-SMX)	15–20 mg/kg/d trimethoprim IV or PO in 4 divided doses for 21 d	As adult dose. Off-label use <2 mo of age	Drug of choice. Risk of anemia, kernicterus in neonates under 28 d old
Pentamidine	4 mg/kg/d IV for 21 d	≥4 mo of age, as adult dose	
Dapsone	100 mg PO once daily, in combination with trimethoprim 15 mg/kg/d PO in 3 divided doses for 21 d	No pediatric data for treatment	
Atovaquone	1,500 mg PO daily (or divided twice daily) for 21 d	Age >13 dose as adult	Take with food
		Age 3–24 mo 45 mg/kg/d (max 1,500 mg/d) in 2 divided doses PO for 21 days	
		Other ages 30–40 mg/kg/d (max 1,500 mg/d) in 2 divided doses	
Methylprednisolone	40 mg BID on days 1–5, 40 mg once a day on days 6–10, 20 mg once a day on days 11–21; begin as early as possible and within 72 h of PCP therapy	<12 yr 1 mg/kg every 6 h on days 1–7, 1 mg/kg twice daily on days 8–9, 0.5 mg/kg twice daily on days 10–11, 1 mg/kg once a day on days 12–16; begin as early as possible and within 72 h of PCP therapy	Best evidence in patients with moderate to severe HIV-related PCP
Clindamycin with Primaquine	1,800 mg/d PO clindamycin divided 3–4 times a day *Plus* 30 mg primaquine base PO once daily	Not studied in pediatrics, but equivalent doses are 10 mg/kg/dose clindamycin 3–4 times daily and 0.5 mg/kg/dose primaquine base once daily	Patients who fail TMP-SMX may be more likely to fail Clindamycin and Primaquine

TABLE 178.2 **PROPHYLAXIS**

Drug	Adult	Pediatric	Notes
Trimethoprim–sulfamethoxazole	One DS tab (160 mg trimethoprim) PO daily or 3 days a week (may be consecutively or every other day)	(≥2 months of age) 150 mg/m^2/d trimethoprim (max 320 mg/d) in 2 divided doses PO 3 times a week	Drug of choice
Pentamidine	300 mg by inhalation, monthly	≥5 yrs, same as adult	May require specialized equipment and respiratory therapists to administer
Dapsone	100 mg PO daily or 200 mg PO weekly	(≥1 month) primary and secondary prophylaxis, 2 mg/kg PO once a day (max 100 mg/d); or 4 mg/kg PO once weekly (max 200 mg/dose)	
Pyrimethamine	50 mg PO once weekly *Plus* leucovorin 25 mg PO once weekly *Plus* dapsone 50 mg PO once daily *Or* 75 mg PO once weekly *Plus* leucovorin 25 mg PO once weekly *Plus* dapsone 200 mg PO once weekly		
Atovaquone	1,500 mg PO daily	Age >13, dose as adult. Age 3–24 mo, 45 mg/kg PO daily (max 1,500 mg/d) Other ages, 30 mg/kg PO daily (max 1,500 mg/d)	Take with food

prophylaxis are often dictated by the specific combination and duration of therapy rather than the use of any one particular drug.

Miscellaneous (emerging) fungi and algae

Obinna N. Nnedu and George A. Pankey

Many nonendemic fungi and algae cause disease among an increasing population of individuals at risk. These microorganisms, known as *opportunistic agents*, can cause disease if two major criteria are met: (1) the patient suffers from some predisposing factor that has mechanically or immunologically decreased the capacity to resist infection, and (2) the infecting agent can survive and multiply at body temperature. At present, >200 of these opportunists have been reported to cause infection.

Some opportunistic fungal infections are associated with predisposing factors such as ketoacidosis, iron overload state, neutropenia, and defects in cell-mediated immunity. However, any trauma or pharmacologic insult to the host's defenses increases the chance of fungal invasion, even from the patient's own resident flora.

The microorganisms considered here are ubiquitous in nature but uncommon causes of disease in humans. Therefore, the diagnosis is usually made in one of the following scenarios: (1) a patient with an infection does not respond to antibacterial therapy; (2) the microbiology laboratory isolates one of these agents; or (3) the pathologist identifies a fungus or algae in tissue, bronchoalveolar lavage, or cerebrospinal fluid. When a physician suspects a fungal pathogen, the laboratory should be informed and special requests made, such as for lysis centrifugation to maximize the yield from blood cultures or for specific fungal media to be inoculated.

Diagnosis

Identification of these pathogens requires cultures. Some species require special media or conditions for culture. Virtually all these species grow readily at 25°C/77°F to 30°C/86°F. Most of these opportunistic fungi can be identified down to the genus name in the clinical microbiology laboratory. Treatment for all species within a genus is usually the same. Molecular methods such as polymerase chain reaction (PCR) and matrix-assisted laser desorption/ionization time of flight (MALDI-TOF) mass spectrometry are new techniques for species identification, but further work is needed to standardize these procedures. Reliable serologic tests are not available for these pathogens.

Isolating these pathogens does not prove causation of the disease process. To prove causation, the culture must be associated with tissue invasion as seen on biopsy or repeated positive cultures from sterile body fluid. The appearance of these agents in tissue is extremely variable and is typically broken down into hyalohyphomycoses (Table 179.1), phaeohyphomycoses (Table 179.2), opportunistic yeasts (Table 179.3), and protothecosis (Table 179.4). Hyalohyphomycoses generally have long septate hyphae in tissue. They include *Fusarium* spp., *Talaromyces marneffei, Scedosporium* spp., and *Lomentospora prolificans*. Phaeohyphomycoses (dematiaceae) are pigmented environmental molds with irregular septated hyphae. These include *Exserohilum rostratum*, *Exophiala,* and *Cladosporium*. Opportunistic yeasts include *Candida auris*, *Pichia (Hansenula) anomala*, *Rhodotorula*, *Saccharomyces cerevisiae*, *Malassezia furfur*, and *Trichosporon beigelii*. Protothecosis are achlorophyllic algae that are pervasive in nature. They look like fungi microscopically. Only two species are known to infect humans: *Prototheca wickerhamii* and *Prototheca zopfii*.

TABLE 179.1 **HYALOHYPHOMYCOSES**

Pathogen	Characteristics	Diagnosis	Therapy
Fusarium spp.	Purpuric skin lesions with central necrosis, keratitis, pulmonary disease	Blood cultures (positive in 50% of cases) Histopathology	Reversal of immunosuppression or correction of neutropenia LAmB + voriconazole Duration dependent on site of infection
Talaromyces (Penicillium) marneffei	Endemic in Southeast Asia, Southern China, Taiwan, and Hong Kong Pulmonary disease, osteomyelitis, adenitis, skin lesions, AIDS-defining illness	Cultures of tissue samples and BAL Histopathology from biopsy	LAmB for 2 weeks, followed by itraconazole
Scedosporium spp,	Normal host by traumatic implantation Mycetoma, meningitis, osteomyelitis, pneumonia (near drowning), sinusitis, endocarditis, spondylodiskitis, keratitis	Culture from tissue Histopathology Molecular: cross-reactivity with *Aspergillus* galactomannan	Surgical resection No optimal antifungal agent Voriconazole LAmB is not effective Isavuconazole has some in vitro activity against some isolates
Lomentospora prolificans	Causes similar spectrum of diseases as *Scedosporium* spp.	Culture from tissue Histopathology	Surgical resection No optimal antifungal agent Voriconazole

Abbreviations: AIDS = acquired immunodeficiency syndrome, BAL = bronchoalveolar lavage, LamB = liposomal amphotericin B.

Therapy

Treatment of these infections can be challenging. Total excision, whenever feasible, should accompany any treatment regimen. No solid data on optimal drug therapy for many of these fungal infections are available because of the lack of controlled randomized trials, and the relatively low number of clinical cases make it difficult to conduct a randomized clinical trial. When possible, antifungal therapy should be guided by results of susceptibility testing. An infectious diseases consultation should be obtained when treating these infections.

Antifungal therapy may fail for one of the following reasons: (1) the drug has no in vivo activity, (2) neutropenia or other immunosuppressed state could not be reversed, (3) oral itraconazole

TABLE 179.2 **PHAEOHYPHOMYCOSES (DEMATIACEAE)**

Pathogen	Characteristics	Diagnosis	Therapy
Exserohilum rostratum	Skin and subcutaneous tissue, sinusitis, occasional dissemination Local infection from skin and eye trauma in immunocompetent host Responsible for multistate meningitis outbreak from contaminated steroid injection	Molecular PCR Culture of tissue	LAmB for 6 weeks, then voriconazole for 4 months
Exophiala	Inhalation or traumatic implantation, subcutaneous nodules, keratitis, and/or skin abscess	Melanin in dematiaceous fungi with Fontana-Masson staining	Surgical excision 12-week therapy with voriconazole or posaconazole or itraconazole ± LAmB for first 2 weeks
Cladosporium	Distributed in air or as rotten organic material and contaminant on food Keratitis, onychomycosis, skin abscesses, chromoblastomycosis	Molecular: antigen cross-reacts with *Aspergillus* galactomannan	Surgical excision 6 months of itraconazole or voriconazole

Abbreviations: LamB = liposomal amphotericin B, PCR = polymerase chain reaction.

TABLE 179.3 **YEAST OR YEAST-LIKE FUNGI**

Pathogen	Characteristics	Diagnosis	Therapy
Candida auris	Invasive healthcare-associated infections Outbreaks reported at healthcare centers	Culture Some automated systems may misidentify *C auris* If suspected, contact CDC or local health department	Echinocandins such as micafungin, anidulafungin, or caspofungin are preferred If no response to echinocandin, may switch to LAmB Resistance has been reported to azoles and to LAmB Susceptibility should be performed Remove intravascular catheters
Pichia (Hansenula) anomala	Catheter-related fungemia, prosthetic valve endocarditis, NICU outbreaks	Culture	LAmB, if unresponsive: voriconazole or itraconazole + flucytosine Remove intravascular catheters
Rhodotorula "red yeast"	Contaminant of air, soil, lakes, and dairy products Colonizes plants and humans Fungemia, meningitis, peritonitis	Culture Molecular: cross-reacts with *Aspergillus* latex agglutination test	LAmB or posaconazole Remove intravascular catheters
Saccharomyces cerevisiae	Colonizer of mucosal surfaces Fungemia, prosthetic valve endocarditis, liver abscess, oral leukoplakia Associated with probiotic use	Culture	LAmB ± flucytosine Resistant to fluconazole and itraconazole Remove intravascular catheters
Malassezia furfur	Lipophilic fungus Fungemia associated with lipid infusion, folliculitis in AIDS, tinea versicolor	Culture in lipid-rich media Potassium hydroxide	Bloodstream infection should be treated with LAmB, with voriconazole as an alternative Remove intravascular catheters in bloodstream infection Folliculitis may be treated with voriconazole or itraconazole
Trichosporon beigelii	Fungemia, prosthetic valve endocarditis, chronic meningitis, peritonitis	Cross-reacts with cryptococcal latex agglutination	LAmB Voriconazole for LAmB-resistant strains Correct neutropenia

Abbreviations: AIDS = acquired immunodeficiency syndrome, CDC = Centers for Disease Control and Prevention, LAmB = liposomal amphotericin B, NICU = Neonatal Intensive care unit.

or posaconazole were taken while fasting or with antacids, (4) adequate blood levels were not obtained, (5) the dosage was too low or combination therapy was not used, (6) the drug is fungistatic rather than fungicidal, and (7) the drug is unable to concentrate in the area of concern, such as the brain. Voriconazole, itraconazole, and posaconazole trough levels must be monitored to ensure that therapeutic blood levels are achieved. Liposomal formulations of amphotericin B allow much higher dosages without increasing toxicity.

TABLE 179.4 **PROTOTHECOSIS**

Pathogen	Characteristics	Diagnosis	Therapy
Prototheca	Systemic infection, algaemia, peritonitis	Culture	Excise isolated lesion Remove intravascular catheter Optimal therapy is unclear LAmB and/or voriconazole

Abbreviations: LamB = liposomal amphotericin B.

Prevention

Immunocompromised patients should be educated on preventive measures regarding the risk of fungal infection from the environment. Prompt recognition of these pathogens in infected skin lesions after trauma is necessary for early therapy. Proper intravascular catheter care and neutropenia precautions are critical for hospitalized patients.

Candida auris has been associated with outbreaks in hospitals. Patients with *C. auris* should be placed in a single-patient room with standard and contact precautions observed. Hand hygiene is critically important. The patient care environment and any reusable devices should be disinfected daily.

Section 23

Specific organisms: Viruses

180

Cytomegalovirus

Rima I. El-Herte and Jeffrey L. Meier

Human cytomegalovirus (CMV) is a member of the herpesvirus family and only replicates in humans. Once a person is infected with CMV, they are forever carriers of the virus. Past or recent CMV infection is marked by presence in serum of immunoglobulin G (IgG) antibody against CMV. The proportion of people having CMV IgG varies according to age, socioeconomic status, sexual activity/practice, and race/ethnicity. In the United States, 55% of women are CMV-seropositive by age 30 and >90% of all persons are seropositive by age 80. Women of reproductive age have an annual CMV seroconversion rate of approximately 2%. Maternal–fetal transmission of CMV afflicts 1 out of 154 babies born. CMV is the leading infectious cause of birth defects and the most common nongenetic cause of sensorineural hearing loss. Preexisting immunity to CMV even in healthy people does not fully protect from reinfection with a different CMV strain.

Close mucosal contact with infectious body fluids is the most common way CMV is acquired. Infectious virus is shed into saliva, urine, breast milk, semen, and cervical secretions. Adults intermittently shed virus with a frequency that depends on body site, the person's age, a recent versus past CMV infection, and predisposing factors such as pregnancy, immunosuppression, and critical illness. Condom use decreases CMV transmission risk from sexual contact. Healthy infants and young children typically shed CMV into urine and saliva for weeks to months after the first (primary) CMV infection. Breast milk of CMV-seropositive mothers commonly contains CMV DNA, and breast milk is a potential source of CMV transmission. Primary CMV infection during pregnancy carries a risk of maternal–fetal CMV transmission that is 10-fold greater than the risk of maternal–fetal CMV transmission from CMV reinfection or reactivation. CMV resides in a latent state in virtually all tissues and in circulating cells of myeloid lineage. This makes viable tissues and blood leukocytes from CMV-seropositive donors potential sources of CMV transmission.

Most primary CMV infections in healthy people go unnoticed. When illness develops, it often manifests as self-limited heterophile-negative mononucleosis, a nonspecific viral syndrome, or fever with hepatitis. In rare cases, a protracted illness or tissue-invasive disease results. Rare cases of CMV colitis in the "immunocompetent" host are associated with older age or having received a corticosteroid or blood transfusion. A mother acquiring a primary CMV infection in the first trimester of pregnancy is at greater risk of having a baby with symptomatic congenital CMV infection than if the maternal infection occurred after the first trimester of pregnancy. Approximately 13% of all congenitally infected newborns will have sensorineural hearing loss.

Profound impairment of cellular immunity allows unchecked CMV replication that damages tissue and produces end-organ disease. This situation is more often encountered in people having AIDS, receiving hematopoietic stem cell transplantation (HSCT) or solid-organ transplantation (SOT), or treated with potent immunosuppressive drugs for reasons other than transplantation. CMV end-organ disease manifests with clinical symptoms and signs and laboratory testing and/or medical imaging abnormalities attributable to the specific organ affected. Common presentations include retinitis, upper or lower gastrointestinal disease, hepatitis, pneumonia, and encephalitis. In transplantation, CMV may also indirectly promote allograft dysfunction, superinfection, and posttransplant lymphoproliferative disorder. CMV decreases survival of people living with HIV who are receiving effective antiretroviral treatment (ART) and have not had overt CMV disease.

Diagnosis

The tentative diagnosis of primary CMV infection in an acutely ill immunocompetent person is based on evidence of serum IgM antibody reacting to CMV antigen. However, CMV IgM positivity by itself does not prove primary CMV infection because CMV reactivation and reinfection also elicits CMV IgM, and false-positive IgM results are common. Primary Epstein–Barr virus (EBV) infection in children is an example of a condition that commonly produces false-positive CMV IgM results. A very high level of CMV IgM may better predict a primary CMV infection. CMV IgG is usually detectable when a person first seeks medical attention for a primary CMV infection. These newly induced CMV IgG antibodies bind to CMV antigens with low avidity. Documenting a low-avidity CMV IgG index confirms a primary CMV infection diagnosis should CMV IgG be initially detected. If CMV IgG is not initially detectable, the primary CMV infection diagnosis can be confirmed by documenting the seroconversion to CMV IgG positivity during convalescence. The probability of a primary CMV infection is strengthened by having the combined findings of CMV DNA in blood plasma or serum (CMV DNAemia) and CMV IgM positivity. CMV DNAemia is not generally present in the plasma or serum of CMV-seropositive immunocompetent persons experiencing a mono-like illness from another cause. Pregnant women suspected of having a primary CMV infection should be referred to an obstetrician for further evaluation. The pretransplant assessment of CMV IgG status of donor and recipient determines posttransplant risk of CMV disease and the management strategy going forward. Serology has no role in the diagnosis of active CMV infection or disease in immunocompromised persons.

CMV end-organ disease is proved by documenting presence of active CMV infection in tissue of the diseased organ producing clinical, laboratory test, or medical imaging abnormalities that are consistent with the diagnosis. The histological finding of an enlarged "cytomegalic" cell containing intranuclear and intracytoplasmic inclusions (Figure 180.1) is pathognomonic of an active CMV infection. Tissue-invasive infection is usually determined from histopathological findings combined with immunohistochemical detection of CMV replication proteins. Less commonly, viral culture or CMV nucleic acid detection is used to document CMV replication in tissue. Proof of CMV retinitis does not require evidence of CMV in tissue. Experienced ophthalmologists accurately diagnose CMV retinitis based on funduscopic findings of characteristic retinal changes that include perivascular infiltrate, atrophy, and hemorrhage. Detection of CMV DNA in vitreous fluid aids in the diagnosis of atypical or unclear presentations of CMV retinitis. The diagnosis of probable CMV syndrome is unique to SOT recipients and is defined as evidence of CMV DNAemia (or CMV antigenemia) together with at least two of the following: (1) fever ≥38°C/100.4°F for ≥2 days, (2) new or increased malaise or fatigue, (3) leukopenia or neutropenia, (4) thrombocytopenia, (5) ≥5% atypical lymphocytes, or (6) elevation of liver enzymes. Probable CMV disease is defined as illness and organ dysfunction likely attributed to CMV and supported by evidence of CMV in blood, bronchoalveolar lavage fluid (BALF), or cerebral spinal fluid (CSF). For example, the diagnosis of probable CMV pneumonia is based on detection of CMV by culture or CMV DNA in BALF from a patient with clinical and radiographic findings of pneumonia. A high CMV viral load in BALF increases the probability of CMV pneumonia, whereas the absence of detectable CMV DNA in BALF by quantitative nucleic acid testing (QNAT) rules out CMV pneumonia. Detection of CMV DNA in CSF supports the diagnosis of probable CMV encephalitis, polyradiculopathy, or myelitis if the clinical context is appropriate. Importantly, not all patients with detectable levels of CMV in tissue, blood, BALF, or CSF have CMV disease.

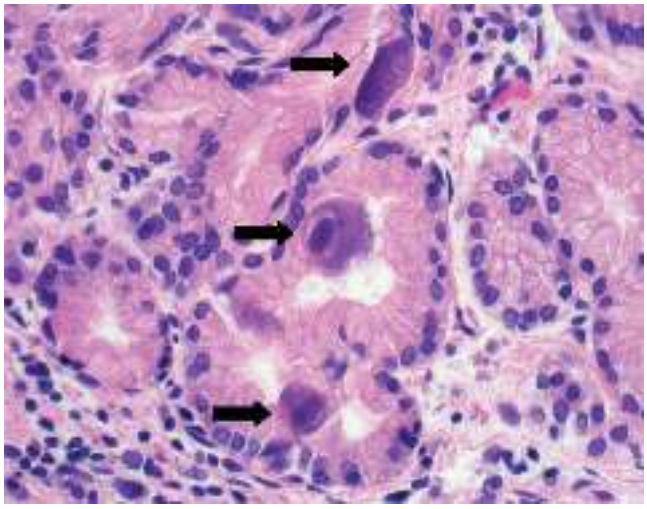

FIGURE 180.1 Cytomegalic inclusion disease. Arrows point to characteristic cytomegalovirus (CMV) infected cells, which contain intranuclear and ground-glass cytoplasmic inclusions. Hematoxylin and eosin staining.

* DIC: Disseminated intravascular coagulation.

Use of QNAT to determine CMV DNA level in blood enables diagnosis and monitoring of CMV infection and disease in HSCT and SOT recipients. While QNAT calibration with the WHO International Standard and the IU/mL report improves agreement of viral load values, different QNATs and methods produce significant interlaboratory variability in the results. CMV DNAemia does not accompany all CMV end-organ disease and is commonly absent in gastrointestinal CMV disease. Regardless of the type of patient population, QNAT detection of CMV DNA in blood, CSF, BALF, vitreous fluid, or amniotic fluid signals CMV replication because the level of latent viral DNA is below the threshold of detection by these assays. In the setting of AIDS, the monitoring of CMV DNAemia is not recommended for diagnosing CMV disease because CMV DNAemia has poor predictive value for end-organ disease and does not help predict progression or relapse of AIDS-associated CMV retinitis, the most common AIDS-associated CMV disease. In the pivotal clinical trial comparing oral valganciclovir with IV ganciclovir for treatment of AIDS-associated CMV retinitis, half of the CMV retinitis cases did not have CMV DNAemia. Detection of CMV DNA in amniotic fluid or in a newborn's saliva, urine, or blood indicates congenital CMV infection. The CMV pp65 antigen assay of CMV antigen-positive leukocytes in blood has largely been supplanted by QNAT because the latter is more sensitive, less labor-intensive, and not affected by neutropenia. Assessment of

CMV-specific T-cell response (e.g., interferon [IFN]-γ release in response to CMV antigens) is useful for predicting CMV DNAemia and disease in HSCT and SOT but should be combined with viral load monitoring.

Therapy

The US Food and Drug Administration (FDA) has approved use of ganciclovir, valganciclovir, foscarnet, and cidofovir for various CMV treatment indications. Ganciclovir and valganciclovir are also approved for prophylaxis in SOT recipients. Letermovir is approved for prophylaxis to prevent CMV replication and disease in adult CMV-seropositive allogeneic HSCT recipients. First-line treatment of an active CMV infection usually consists of either intravenous (IV) ganciclovir or oral valganciclovir. Table 180.1 summarizes the recommended dosing schedules for these agents and their use in clinical practice. Fomivirsen, a therapeutic antisense oligonucleotide administered by intraocular injection, and the intraocular ganciclovir implant are no longer manufactured. Oral ganciclovir is not available in the United States. Investigational anti-CMV drugs (e.g., maribavir) are in the clinical stage of development.

AIDS

In HIV/AIDS, CMV end-organ disease usually does not develop until the $CD4^+$ T lymphocyte count falls below ≤50 cells/μL in conjunction with an uncontrolled HIV viral load. CMV retinitis accounts for 85% of all AIDS-associated CMV disease. Initial treatment of CMV retinitis is selected from options of oral valganciclovir alone, oral valganciclovir plus intravitreal injection with foscarnet or ganciclovir, or IV ganciclovir. IV foscarnet and IV cidofovir are also effective but risk greater toxicity. Treatment selection is based on individual patient characteristics (ability to absorb oral medication, adhere to treatment, achieve immune recovery, etc.) and extent/location of the retinal lesion. Systemic anti-CMV therapy prevents CMV disease from developing in the contralateral eye and in other organs. Treatment of HIV with ART results in immune recovery that controls the CMV infection. CMV retinitis is treated for 14 to 21 days at induction therapy dosing. Maintenance therapy (secondary prophylaxis) is continued for at least 3 to 6 months after the CD4+ count is >100 cells/μL. Ophthalmology follow-up looking for relapse of retinitis and post-retinitis sequela is also important. Immune recovery uveitis may develop as an ART–induced inflammatory response to CMV, which can be managed with periocular, intravitreal, or oral corticosteroids. Secondary prophylaxis is resumed when the CD4+ count falls below 100 cells/μL. An early first relapse (≤3 months) of CMV retinitis will often respond to reinstituting the same initial treatment regimen. Ganciclovir-resistant CMV may emerge with prolonged use of ganciclovir/valganciclovir. Genotypic resistance testing of CMV in blood enables determination of mutations in the viral phosphotransferase (UL97) and polymerase (UL54) genes that confer antiviral resistance. A virus with mutations conferring low-level ganciclovir resistance may be contained by intravitreal injection of ganciclovir, whereas a virus with mutations conferring high-level ganciclovir resistance requires treatment with a different class of anti-CMV drug.

CMV esophagitis and colitis are treated initially with IV ganciclovir (or IV foscarnet). Oral valganciclovir is an option if absorption is not a concern. Treatment duration is 21 to 42 days or until the disease resolves. Secondary prophylaxis is not always needed. CMV pneumonitis is treated with IV ganciclovir, oral valganciclovir, or IV foscarnet. CMV neurological disease may initially require double therapy with IV ganciclovir and IV foscarnet; both agents fall short in achieving target drug levels in CSF.

Transplantation

SOT patients at highest risk for CMV disease are CMV-seronegative recipients of organs of CMV-seropositive donors (D+/R−) and recipients of CMV-positive donor lung, heart, or intestine. In contrast, CMV-seropositive HSCT recipients of cells from CMV-seronegative donors are at highest risk of CMV disease. Use of either chemoprophylaxis or preemptive therapy in the first 3 to 6 months after transplant prevents CMV disease in at-risk HSCT and SOT recipients. Chemoprophylaxis entails giving the antiviral drug to all patients to suppress CMV replication. Preemptive therapy involves monitoring of CMV DNAemia at regular intervals (usually weekly) and beginning valganciclovir/ganciclovir treatment when CMV DNAemia exceeds a threshold level. The viral load threshold differs among the different at-risk groups. Oral valganciclovir is administered at treatment dose for at least 2 weeks and until the CMV DNAemia has resolved. Viral load monitoring is resumed after the treatment because nearly one-third of these patients will have a second episode of CMV DNAemia. Published guidelines on prevention and management of CMV infection and disease in HSCT and SOT recipients have helped standardize approaches, but practice varies between centers and continues to evolve with advances in transplant medicine. Chemoprophylaxis is usually preferred over preemptive therapy in the highest risk patients. Oral valganciclovir/IV ganciclovir is commonly used for chemoprophylaxis in HSCT and SOT recipients. Letermovir (IV or oral) is effective chemoprophylaxis in allogenic HSCT recipients but does not have activity against herpes simplex virus (HSV) and varicella-zoster virus (VZV). High-dose acyclovir or valacyclovir is less effective than ganciclovir for chemoprophylaxis, although it is sometimes used in low-risk renal transplant recipients. Late-onset CMV disease in HSCT and SOT recipients is more likely to occur in patients having received chemoprophylaxis or experiencing graft-versus-host disease. CMV replication during or after having received ganciclovir/valganciclovir for ≥6 weeks increases probability that the virus has become resistant to ganciclovir.

CMV disease in HSCT and SOT recipients is treated with IV ganciclovir or oral valganciclovir. IV ganciclovir is preferred in patients having life-threatening CMV disease and when absorption of oral valganciclovir is compromised. Immune suppression should be decreased if possible. Weekly measurements of the level of CMV DNAemia provides an assessment of treatment response and guides duration of treatment. Treatment is continued until CMV

TABLE 180.1 **PREVENTIVE AND TREATMENT REGIMENS FOR CYTOMEGALOVIRUS (CMV) INFECTION**

Agent	Indications	Dosing regimen	Toxicities	Monitoring	Comments
Intravenous					
Ganciclovir	Treatment of visceral or disseminated disease Preemptive therapy in transplant recipients Prophylaxis therapy in transplant recipients	Treatment: 5 mg/kg q12h × 14–21 d or until disease resolves. Maintenance: 5 mg/kg qd (modify dose in renal failure) 5 mg/kg qd (modify dose in renal failure)	Catheter-related complications, neutropenia, thrombocytopenia, renal failure Causes infertility, teratogenicity, and embryotoxicity in animals	Treatment: CBC 2×/wk, Cr weekly Maintenance: CBC every wk, Cr q1–3wk	Adjust dosage for reduced renal function. If ANC 500–750, consider SQ G-CSF If ANC ≤500 or platelets ≤25 K, hold ganciclovir.
Foscarnet	Treatment of visceral or disseminated disease	Treatment: 90 mg/kg q12h (or 60 mg/kg q8h) × 14–21d or until disease resolves. Maintenance: 90–120 mg/kg qd (modify dose in renal failure) Maximum dose is 120 mg/kg qd	Catheter-related complications, nephrotoxicity, paresthesia, cation chelation, genital ulcerations, nausea, marrow suppression	Treatment: CBC, Cr, cations (K^+, Mg^{2+}, Ca^{2+}), and phosphate 2–3× every wk Maintenance: Cr, cations, and phosphate every wk, CBC q2wk	Adjust dosage for reduced renal function If Cr >2.8, hold foscarnet until Cr ≤2.1 mg/dL. Hydration reduces renal toxicity. Caution if seizures.
Cidofovir	Treatment of retinitis (limited experience with use for salvage therapy for CMV disease in other viscera)	Treatment: 5 mg/kg/wk × 2; infuse over 1 h Maintenance: 5 mg/kg q2wk; infuse over 1 h (reduce dose to 3 mg/kg if Cr increase 0.3 mg/dL)	Nephrotoxicity with Fanconi syndrome, neutropenia, uveitis, ocular hypotony, probenecid rash Probenecid contraindicated in persons with severe sulfa allergy	Treatment: Cr and UA every dose Maintenance: Same plus intraocular pressure every mo	1–2 L saline hydration, with 1 L given before cidofovir infusion; probenecid, given 3 h before (2 g), at 3 h (1 g) and 8 h (1 g) after cidofovir infusion Caution if diabetes mellitus Do not use if Cr >1.5 mg/dL CrCl ≤55 mL/min, ≥100 mg/dL proteinuria or receiving other nephrotoxic agents.
Letermovir	Prophylaxis in allogeneic HSCT recipients (up to day 100 post-transplantation)	480 mg/d. 240 mg/d when used with cyclosporin. Data lacking in patients with CrCl ≤10 mL/min	Accumulation of IV vehicle, hydroxypropyl betadex, with CrCl <50 mL/min. Not recommended for patients with severe hepatic impairment.	Closely monitor Cr in patients with CrCl <50 mL/min	Potential for drug–drug interaction; inhibitor of OATP1B1/3 transporters and CYP34A. Not active against HSV and VZV.
Intraocular					
Foscarnet intravitreal injection	Treatment of CMV retinitis	2.4 mg every week for up to 4 weeks	Transient blurred vision, hemorrhage, infection	Experienced Ophthalmologist	Requires addition of systemic therapy to reduce CMV disease risk in contralateral eye and other organs.

TABLE 180.1 CONTINUED

Agent	Indications	Dosing regimen	Toxicities	Monitoring	Comments
Ganciclovir intravitreal injection	Treatment of CMV retinitis	2–3 mg every week for up to 4 weeks	Transient blurred vision, hemorrhage, infection	Experienced Ophthalmologist	Requires addition of systemic therapy to reduce CMV disease risk in contralateral eye and other organs.
Oral					
Valganciclovir	Treatment of visceral or disseminated disease Prophylaxis or preemptive therapy in transplant	Induction: 900 mg BID × 14–21 d or until disease resolves. Maintenance: 900 mg/d (modify dose in renal failure 900 mg/d or BID, with food (modify dose in renal failure)	Neutropenia, thrombocytopenia Causes infertility, teratogenicity, and embryotoxicity in animals	Induction: CBC 2×/wk, Cr weekly Maintenance: CBC every wk, Cr q1–3wk	If ANC 500–750, consider SQ G-CSF If ANC ≤500 or platelets ≤25 K If Hg<8 mg/dL consider holding dose.
Letermovir	Prophylaxis in allogeneic HSCT recipients (up to day 100 post-transplantation). Not active against HSV and VZV.	480 mg/d. 240 mg/d when used with cyclosporin. Data lacking in patients with CrCl ≤10 mL/min.	Not recommended for patients with severe hepatic impairment.	Closely monitor Cr in patients with CrCl <l50 mL/min	Potential for drug–drug interaction; inhibitor of OATP1B1/3 transporters and CYP34A.
Valacyclovir	Prophylaxis in solid organ transplant recipients	2 g QID (modify dose in renal failure)	Hallucinations, confusion, marrow toxicity	CBC and Cr q2wk	Less effective than ganciclovir; therefore, use limited to low-risk patients
CMV Hyperimmunoglobulin					
CMV immunoglobulin intravenous (Cytogam)	Treatment of CMV pneumonitis in bone marrow transplant recipient Prophylaxis in solid organ transplant recipients	400 mg/kg days 1, 2, and 7 200 mg/kg day 14 plus IV ganciclovir (see IV ganciclovir) 50–150 mg/kg q2–4wk (various dosing regimens have been used) until delivery	Fever, myalgia, arthralgia, nausea, wheezing, hypotension, aseptic meningitis	Vital signs before, during, and after infusion	Derived from pooled adult human plasma Increase infusion rate as tolerated, 15–60 mg/kg/h Caution if IgA deficiency

Abbreviations: SQ = subcutaneous injection; CBC = complete blood count; Cr = serum creatinine; CrCL = creatinine clearance; ANC = absolute neutrophil count; CMV = cytomegalovirus; UA = urine analysis; AIDS = acquired immunodeficiency syndrome; G-CSF = granulocyte colony- stimulating factor.

DNAemia ceases or is at very low level and the CMV end-organ disease resolves. Genotypic antiviral resistance testing of CMV phosphotransferase (UL97) and DNA polymerase (UL54) genes should be done if persistent or recurrent CMV DNAemia develops against a background of extensive exposure history to valganciclovir/ganciclovir. A higher dose of IV ganciclovir may be effective against a virus with phosphotransferase gene mutations conferring low-level ganciclovir resistance. Most ganciclovir-resistant CMV strains are susceptible to IV foscarnet. IV cidofovir may be an option when the virus is resistant to both ganciclovir and foscarnet but is susceptible to cidofovir. The use of letermovir for treatment of CMV disease has not been adequately studied and may be compromised by CMV's greater tendency to develop resistance to this drug.

Other immunocompromising conditions

Treatment of CMV end-organ disease in other immunocompromised patient populations largely follows the strategy applied to transplant recipients. Patients with inflammatory bowel disease (IBD) are prone to developing active CMV infection in colonic

mucosa that is fueled by corticosteroid or thiopurine therapy for IBD. Tumor necrosis factor antagonists do not appear to increase risk of CMV infection in IBD. Low-level CMV activity commonly accompanies IBD flares and may resolve without antiviral treatment. Moderate to high levels of CMV activity in colonic tissue or blood of hospitalized patients is generally treated initially with IV ganciclovir for 3 to 5 days while IBD therapy is continued. The IV ganciclovir is then changed to oral valganciclovir for a total treatment duration of 2 to 3 weeks.

Congenital infection

Routine screening of pregnant women for CMV infection is not standard of care in the United States. There is no antiviral treatment or passive immunization for prevention of intrauterine fetal CMV infection. Ganciclovir should not be used in pregnancy because it causes birth defects in animals. While anecdotal reports suggest that fetal abnormalities do not result from use of ganciclovir/valganciclovir in humans during pregnancy (including the first trimester), rigorous studies are needed to evaluate safety and outcome. Six weeks of IV ganciclovir therapy given to neonates with symptomatic congenital CMV infection appears to decrease risk of hearing impairment, but dose-limiting bone marrow toxicity is common.

The otherwise normal host

Symptomatic CMV illness in otherwise healthy people is usually self-limiting (e.g., heterophile-negative mononucleosis, viral syndrome, or hepatitis). Sometimes, symptoms resolve slowly over several weeks, and relapsing symptoms may occur until the illness abates. Use of IV ganciclovir or oral valganciclovir is reserved for debilitating protracted illness or tissue-invasive disease. CMV is a potential cause of anterior uveitis in immunocompetent people, as well as the Posner-Schlossman and Fuchs iridocyclitis syndromes. These ocular infections are generally treated with oral valganciclovir. Low-level CMV DNAemia is common in critically ill patients and not an indication for antiviral treatment.

Antiviral agents

Ganciclovir and valganciclovir

Ganciclovir is a guanosine analog that must be phosphorylated by the CMV phosphotransferase (UL97 gene product) to be active. The CMV phosphotransferase adds the first phosphate to ganciclovir and then cellular enzymes add two more phosphates to produce ganciclovir triphosphate. The ganciclovir triphosphate inhibits CMV DNA polymerase (UL54 gene product) function and disrupts viral DNA chain elongation via ganciclovir incorporation into the new viral DNA strand. Ganciclovir also has activity against HSV-1, HSV-2, VZV, EBV, human herpesvirus 6 (HHV-6), HHV-8, and herpes B virus. The intracellular half-life of the ganciclovir triphosphate is 16.5 hours. Ganciclovir concentration in vitreous fluid and CSF is somewhat lower and more variable than in serum. Valganciclovir is an orally administered prodrug of ganciclovir that attains levels similar to that of the standard IV dose of ganciclovir. Oral ganciclovir and the ocular ganciclovir implant are no longer available. Intravitreal ganciclovir is used off-label for treatment of CMV retinitis at a reduced-dose to decrease risk of adverse effects.

Circulating ganciclovir metabolites are cleared by the kidneys, requiring adjustment of ganciclovir dose according to creatinine clearance (CrCl). Granulocytopenia is a common adverse effect that can be managed with avoidance of other marrow-suppressive agents and, if severe, use of granulocyte colony-stimulating factor. Thrombocytopenia, anemia, CNS toxicity (e.g., headache, seizures, and confusion), and renal failure may also be observed. Ganciclovir caused infertility, teratogenicity, and embryotoxicity in animal studies. The IV route of administration risks catheter-related infection. The intravitreal injection risks subconjunctival hemorrhage, pain, transient visual loss, and, rarely, endophthalmitis and permanent visual loss.

Foscarnet

Foscarnet (phosphonoformic acid) selectively inhibits CMV DNA polymerase activity and is administered by IV or intravitreal injection. Foscarnet also inhibits the replication of HSV, VZV, EBV, HHV-6, and HHV-8. The drug is cleared by the kidneys and requires dose adjustment according to CrCl. Foscarnet is toxic to kidneys, and hydration may aid in reducing this toxicity. Use of other nephrotoxic agents (e.g., amphotericin B and aminoglycosides) should be avoided. Mineral and electrolyte abnormalities are also common and include hypocalcemia, hyperphosphatemia, hypophosphatemia, hypokalemia, and hypomagnesemia. Although manageable, these abnormalities can precipitate seizures. Symptoms of numbness, tingling, and other abnormal sensations signal the chelation of ionized calcium by the IV foscarnet that can be mitigated by slowing the infusion rate of foscarnet. Other notable adverse effects include anemia, granulocytopenia, genital ulcers, and IV catheter-related sepsis.

Cidofovir

Cellular enzymes add two phosphates to cidofovir that enables cidofovir to inhibit the CMV DNA polymerase and terminate viral DNA chain elongation. Cidofovir is administered IV, and its active form has an intracellular half-life of 17 to 65 hours. Cidofovir is nephrotoxic and contraindicated in persons with renal insufficiency (CrCl ≤55 mL/min, or ≥2+ proteinuria) or receiving other nephrotoxic agents. Nephrotoxicity is minimized by IV prehydration and administration of probenecid. Probenecid is contraindicated in persons with history of a severe sulfa allergy. Neutropenia, ocular hypotony, and metabolic acidosis (Fanconi's syndrome) are other potential toxicities of the drug. Cidofovir is gonadotoxic, embryotoxic, and carcinogenic in animals.

Letermovir

Letermovir selectively inhibits the CMV terminase complex to block packaging of the viral DNA genome into the viral capsid.

Letermovir is not active against the other herpesviruses. The drug is administered by either the oral or IV route and mostly cleared unchanged in stool through the hepatobiliary system. Letermovir should not be used in severe hepatic impairment or if CrCl is ≤10 mL/min. The IV vehicle, hydroxypropyl betadex, may accumulate when CrCl is <50 mL/min. Letermovir is an inhibitor of OATP1B1/3 transporters and a moderate inhibitor of CYP34A. This increases the number of drug–drug interactions that are possible when adding letermovir to other medications. Letermovir dose reduction is required when given with cyclosporin. Letermovir is generally well tolerated and does not have significant renal or bone marrow toxicity.

Cytomegalovirus hyperimmune globulin

CMV hyperimmune globulin IV (CMVIG) is pooled human IgG enriched four- to eightfold in anti-CMV antibody compared with standard preparations of IV immunoglobulin. CMVIG is used at some centers for passive immunoprophylaxis to prevent or attenuate CMV disease in high-risk (D+/R−) lung, heart, and intestine transplant populations or in transplant recipients who have developed hypogammaglobulinemia. Clinical trial results do not support the use of CMVIG for prevention of CMV transmission from mother to fetus or in the treatment of fetal infection.

Primary prevention

Primary prevention strategies target CMV-seronegative persons who, if become infected by CMV, risk passing the virus on to their unborn baby or themselves developing serious CMV disease. CMV vaccines in development are not likely to be a prevention option in the near future. Use of CMV-seronegative or leukocyte-depleted donor blood products prevents CMV transmission by blood product transfusion. Abstinence and condoms prevent sexual transmission of the virus. Breastfeeding premature (<30 weeks gestational age) and low-birth weight (<1500 g) infants risks development of a CMV-related sepsis-like syndrome as a result of CMV transmission via breast milk. Pasteurization of breast milk eliminates the CMV transmission risk associated with breast milk. Because young children are a common source of CMV, measures taken to lessen CMV transmission include use of good hand hygiene after changing diapers and wiping oral secretions and avoidance of close mucosal contact with the child's saliva that occurs during kissing or immediate sharing of utensils or food.

Dengue

Nguyen Thanh Hung

Dengue is caused by any of four closely related viruses or serotypes (dengue 1–4). Dengue viruses are small, single-stranded RNA viruses belonging to the genus *Flavivirus*, family *Flaviviridae*. Dengue is transmitted between people by the mosquitoes *Aedes aegypti* and *A. albopictus*, which are found throughout the world. In the past 50 years, there has been a dramatic increase in the global incidence of dengue virus infections. It is estimated that 3 billion people live in areas at risk of contracting dengue, and some 390 million infections (96 million symptomatic) and 20,000 deaths from dengue occur every year. Dengue virus infections may cause symptomatic infections or asymptomatic seroconversion. Symptomatic dengue infection has a wide range of clinical presentations which include severe and nonsevere manifestations. Two major pathophysiological features are associated with severe dengue infection: plasma leakage leading to hypovolemic shock and/or abnormal hemostasis (thrombocytopenia, vasculopathy, disseminated intravascular coagulation) leading to hemorrhage (Figure 181.1). While most patients recover following a self-limiting nonsevere clinical course, a small proportion progress to severe disease, mostly characterized by plasma leakage with or without hemorrhage.

Clinical manifestations

After an incubation period of 3 to 7 days, the illness begins abruptly and is followed by three phases: a febrile phase, a critical phase, and a recovery phase.

Febrile phase

The febrile phase is characterized by high temperature (≥38.5°C/101.3°F) accompanied by headache, vomiting, myalgia, joint pain, and a transient macular rash. High fever may cause neurologic disturbances and febrile seizures in young children. Hemorrhagic manifestations include a positive tourniquet test, easy bruising and bleeding at venipuncture sites, fine petechiae, epistaxis, gingival bleeding, and mild gastrointestinal bleeding (Figure 181.2, Panels A, B, and C). A palpable liver may be noted, especially in young infants and children. The CBC reveals leukopenia, mild to moderate thrombocytopenia, and normal hematocrit value. This acute febrile phase usually lasts 2 to 7 days, and most patients recover spontaneously after this phase.

Critical phase

During the transition from the febrile to afebrile phase, patients without an increase in capillary permeability will improve uneventfully. In a small proportion of patients, systemic vascular leak syndrome becomes apparent, evidenced by increasing hemoconcentration, pleural effusions, and ascites (Figure 181.3, Panel A). The degree of increase above the baseline hematocrit often reflects the severity of plasma leakage. A right lateral decubitus chest radiograph or ultrasound detection of free fluid in the chest or abdomen or gall bladder

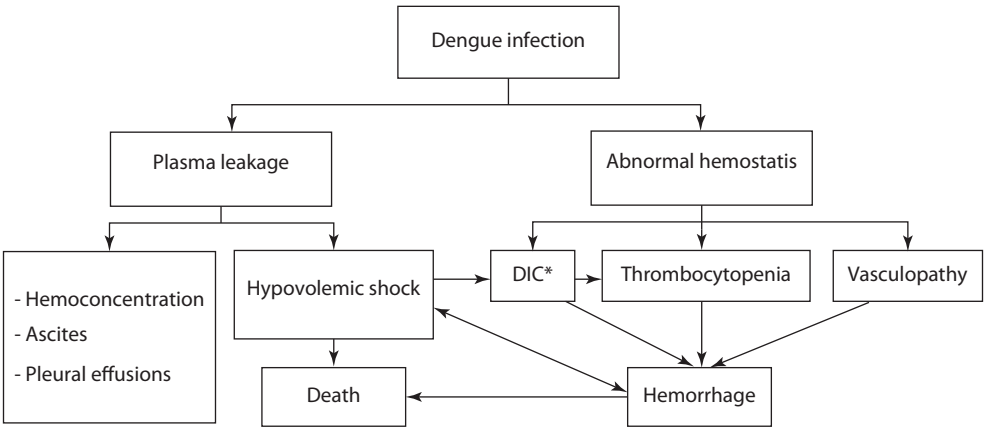

FIGURE 181.1 The correlation between pathophysiology and clinical manifestations of severe dengue.

wall edema may precede clinical detection of pleural effusion and ascites (Figure 181.3, Panels B, C, and D). In less severe cases, these changes are minimal and transient, reflecting a mild degree of plasma leakage, and patients will recover spontaneously. In more severe cases, when plasma loss is critical, hypovolemic shock ensues. Shock (dengue shock syndrome) is often preceded by warning signs. The warning signs of impending deterioration include intense abdominal pain or tenderness, persistent vomiting, mucosal bleeding, lethargy or restlessness, liver enlargement >2 cm, fluid accumulation (ascites, pleural effusion, pericardial effusion), and progressive increase in hematocrit concurrent with a rapid decrease in platelet count.

The patient in shock may die within 12 to 24 hours if appropriate treatment is not promptly administered, or they may recover rapidly following proper intravenous (IV) fluid therapy. Uncorrected shock can lead to severe complications with development of multiple organ dysfunctions, respiratory failure, metabolic acidosis, severe gastrointestinal bleeding, and a poor prognosis.

Hemorrhagic manifestations are most common during this critical period. In children, significant bleeding is usually associated with profound and prolonged shock. However, major skin bleeding and/or mucosal bleeding may occur in adults with only

FIGURE 181.2 Hemorrhagic manifestations in dengue patients. (A) Petechial rash in a child with dengue. (B) Minor bleeding around injection sites. (C) Hematoma in a patient with severe dengue. (D) Characteristic confluent petechial rash in the recovery phase.

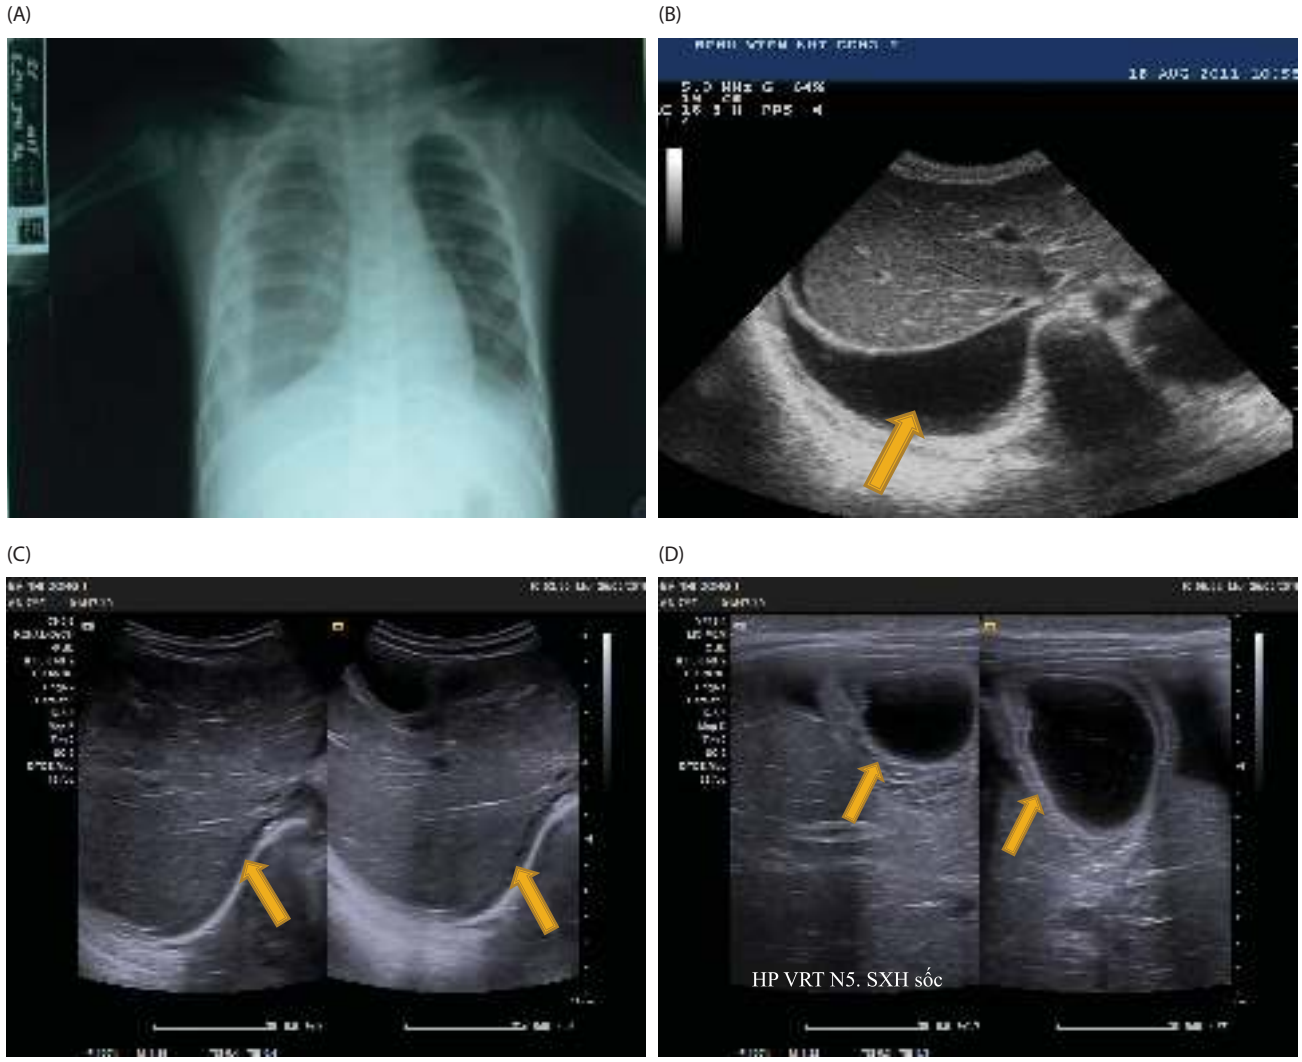

FIGURE 181.3 Systemic vascular leak syndrome in dengue patients. (A) Pleural effusion through chest X-ray in an infant dengue patient. (B) pleural effusion through ultrasound scan of the abdomen in a 7-year-old patient with dengue shock syndrome. (C) Hepatic subcapsular fluid collections through ultrasound scan of the abdomen in a 7-year-old patient with dengue shock syndrome. (D) Edematous gall bladder wall thickening through ultrasound scan of the abdomen in a 7-year-old patient with dengue shock syndrome.

minor plasma leakage (Figure 181.2, Panel C). Moderate to severe thrombocytopenia, transient increase in the activated partial thromboplastin time, and a decrease in fibrinogen levels are frequently noted.

Severe organ impairment such as acute liver failure, encephalitis, myocarditis, kidney failure, and/or severe bleeding may infrequently occur without obvious plasma leakage or shock.

Convalescent phase

Most dengue patients will recover rapidly and uneventfully within 24 to 48 hours after shock has been reversed. Indicators of recovery include improved general condition, stable vital signs, and the return of appetite, diuresis, and sinus bradycardia. Some patients develop a characteristic confluent petechial rash with small round areas of normal skin on their lower extremities (Figure 181.2, Panel D). Some patients have signs of fluid overload (respiratory distress, pulmonary edema, or heart failure associated with gross peripheral edema, large pleural effusions, and ascites) due to excessive IV therapy and reabsorption of extravasated plasma from the interstitial compartment.

Diagnosis

Clinicians should suspect dengue in persons who live in or travel to a dengue-endemic area (South-East Asia, the Americas, the Western Pacific, and the Eastern Mediterranean) with acute febrile syndromes associated with two of these signs/symptoms: nausea or vomiting, rash, aches and pains, a positive tourniquet test, leukopenia, and any warning sign mentioned earlier. Laboratory diagnosis of dengue is made by detecting the virus and/or any of its components, such as virus genome and dengue antigen, or by investigating the serologic

responses present after infection. Clinicians should keep in mind that laboratory diagnosis is usually not necessary for clinical management except in atypical cases or when constructing a differential diagnosis. A diagnosis of dengue infection is confirmed by the detection of the virus, the viral genome, or nonstructural protein 1 (NS1) antigen in the acute sera, which are collected during the febrile phase, or seroconversion of immunoglobulin (IgM/IgG) from negative to positive or a fourfold increase in antibody titer in paired sera. A positive IgM serology or a hemagglutinin inhibition test (HIA) antibody titer of ≥1,280 are considered a probable dengue infection. Both probable and confirmed dengue cases should be notified to health authorities.

Dengue case classification

Patients were previously classified as having either dengue fever or dengue hemorrhagic fever. Dengue hemorrhagic fever was further classified into four severity grades, with grades III and IV being defined as dengue shock syndrome. There have been many reports of difficulties in the use of this classification. With the 2009 revision of the World Health Organization dengue classification scheme, patients are now classified as having either dengue with/without warning signs or severe dengue. Patients who recover without major complications are classified as having dengue, whereas those who have any of the following conditions are classified as having severe dengue: severe plasma leakage leading to shock (dengue shock syndrome), accumulation of serosal fluid sufficient to cause respiratory distress, severe bleeding, and severe organ impairment (Figure 181.4).

Differential diagnosis of dengue

Early in the febrile phase, the differential diagnosis of dengue includes other arboviral infections, measles, rubella, enterovirus infections, adenovirus infections, and influenza. Depending on local frequency and epidemiologic characteristics of febrile diseases, other diseases such as typhoid, malaria, leptospirosis, viral hepatitis, rickettsial diseases, bacterial sepsis, and meningococcal disease should be considered as part of the differential diagnosis. Clinicians should also remember that some dengue patients with liver enlargement and severe abdominal pain may mimic surgical conditions such as acute appendicitis and hepatic abscess. Misdiagnosing and performing unnecessary surgery will put these dengue patients at risk of severe hemorrhage.

Management

Treatment is supportive, with special emphasis on careful fluid management. Patients without complications can be managed as outpatients and followed closely every day from day 3 of their illness until they have been afebrile for more than 48 hours without the use of antipyretics. Practically the hematocrit and platelet count should be determined at the first visit and then checked once to twice daily. Oral rehydration should be encouraged with oral rehydration solution (ORS), fruit juice, and other fluids containing electrolytes and sugar. Give acetaminophen/paracetamol for high fever if the patient is uncomfortable. Do not give acetylsalicylic acid (aspirin), ibuprofen, or other nonsteroidal anti-inflammatory agents (NSAIDs) because of the risks of gastritis or bleeding. Instruct the

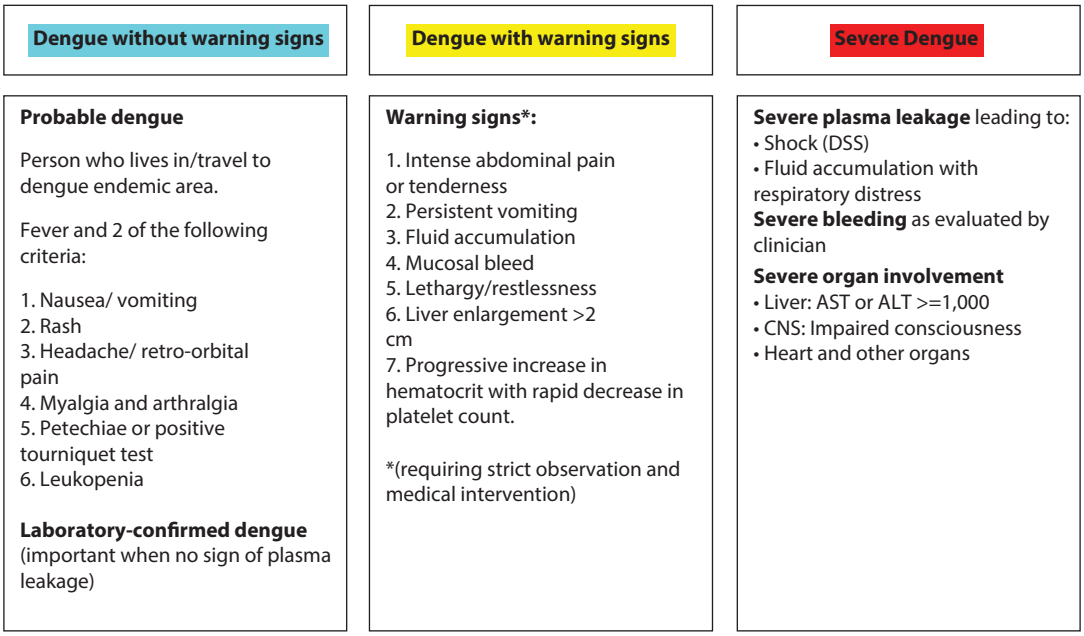

FIGURE 181.4 Dengue severity classification.
Adapted from the World Health Organization and Pan American Health Organization.

patients or caregivers to return to the nearest hospital immediately if the patients have any of the warning signs.

For those patients with warning signs, judicious volume replacement of lost plasma by IV fluid therapy with isotonic crystalloid solutions from this early stage may modify the course and severity of disease. Parenteral fluid therapy is only required for 24 to 48 hours in most patients since the capillary leak resolves spontaneously after this time.

Patients with dengue shock syndrome need emergency treatment with fluid resuscitation. The recommended regimen for the treatment of dengue shock patients is the immediate and rapid replacement of the plasma loss with isotonic crystalloid solutions or, in the case of profound shock, colloid solutions; continued replacement of further plasma losses to maintain effective circulation for 24 to 48 hours; correction of metabolic and electrolyte disturbances; and blood transfusion in patients with severe bleeding. Platelet concentrates, fresh frozen plasma, and cryoprecipitate may also be used in cases of severe bleeding. Dengue shock patients should be under close observation around the clock until it is certain that danger has passed. Generally, the duration of IV therapy should not exceed 24 to 48 hours after the patient is out of shock. Electrolyte levels and blood gases should be determined periodically in severe cases. In patients with severe and complicated dengue, mechanical ventilation, vasopressor and inotropic therapies, renal replacement therapy, and other treatment of organ impairment may be required.

Currently, efficacious and safe antiviral agents and immunomodulatory therapies for dengue have not yet been developed. Careful clinical detection and improvement of case management of dengue patients can significantly reduce case fatality rates among hospitalized cases from 20% to <0.5% in many endemic countries.

Prevention

Vaccination should be considered as part of an integrated dengue prevention and control strategy. The live attenuated dengue vaccine CYD-TDV (Dengvaxia) is currently licensed in 20 countries for use in endemic areas in persons ranging from 9 to 45 years of age. CYD-TDV has been shown in clinical trials to be efficacious and safe in persons who had exposure to dengue before vaccination (seropositive individuals), and there was evidence of a higher risk of severe dengue in vaccinated persons who had not been exposed to dengue (seronegative individuals). The World Health Organization position is that for countries considering vaccination as part of their dengue control program, pre-vaccination screening is the recommended strategy. With this strategy, only persons with evidence of a past dengue infection would be vaccinated.

Dengue is transmitted between people by the mosquitoes *A. aegypti* and *A. albopictus*, so the best measure to prevent dengue is to reduce mosquitoes and avoid mosquito bites. Eliminating the places where the mosquito lays her eggs, such as artificial containers that hold water in and around the home, and cleansing water containers, help reduce mosquitoes. The adult mosquitoes like to bite indoors during the day and at night when the lights are on. Travelers in dengue-endemic areas should avoid mosquitoes during the day by using insect repellents and sleeping under a mosquito bed net or using air conditioning. Improving community participation and mobilization for sustained vector control, applying insecticides as space spraying during outbreaks as one emergency vector-control measure, and active monitoring and surveillance of vectors should be carried out to determine effectiveness of control interventions.

Enteroviruses

Penelope Dennehy

Introduction

Enterovirus is derived from the Greek word "enteron" meaning intestine. Enteroviruses (EV) are so named because they infect the gastrointestinal tract and are shed in the feces. These viruses are found worldwide and can cause a wide variety of illnesses, ranging from asymptomatic infection to severe illness and death. Infection occurs in all age groups. Non-polio EVs cause about 10 to 15 million infections and tens of thousands of hospitalizations each year in the United States.

Virology

The human EVs belong to the family *Picornaviridae* which also includes rhinoviruses, hepatitis A, and parechoviruses. EVs are small (~27 nm), spherical, non-enveloped viruses with icosahedral symmetry. These viruses have a linear single-stranded, positive-sense RNA of approximately 7.5 kB which functions as mRNA. The RNA genome is surrounded by a protein shell consisting of 60 subunits. Each subunit is formed from four virus-encoded structural proteins (VPs 1–4).

EVs are relatively acid resistant and stable over a wide range of pH (3–10) which allows passage through the gastrointestinal tract. They are resistant to alcohol but are inactivated by phenol and formaldehyde and by temperatures >50°C/122°F. They retain infectivity for days at room temperature.

EVs replicate intracellularly. Viruses attach to specific cell membrane receptor proteins which determine host cell susceptibility (Table 182.1). Some serotypes have more than one receptor. Attachment is followed by penetration and uncoating with release of viral RNA into the cytoplasm of the cell. Rapid replication over 5 to 10 hours follows. Inside the cytoplasm of the cell the viral genome is translated to a single polyprotein which is cleaved by viral-encoded proteases into structural proteins VPs 1–4, an RNA polymerase, proteases, and other nonstructural proteins. These proteins are assembled into new viruses producing about 10^4 to 10^5 progeny viruses per infected cell. Only 0.1% to 10% of these progeny viruses are infectious.

Classification

Originally serotypes were distinguished by their host range and neutralization with specific antisera (Table 182.2). By 1969, 67 serotypes had been described. These serotypes were assigned to five subgroups: polioviruses, group A Coxsackieviruses, group B Coxsackieviruses, echoviruses, and EVs. All serotypes discovered after 1970 are simply designated as EV and are numbered sequentially beginning with serotype 68. Multiple new serotypes have been identified, with the number of known serotypes now >100.

In 2013, reclassification of EVs was done based on molecular serotyping determined by the RNA sequence encoding the VP1 protein. Molecular serotyping led to several new genera being named and viruses being reassigned. Echovirus serotypes 22 and 23 were reclassified as parechoviruses, enterovirus 72 became

TABLE 182.1 **ENTEROVIRUS RECEPTORS**

hepatitis A, and a new genus, *Cardiovirus* was described. EVs are now grouped into 4 species (*Enterovirus A, B, C*, and *D*) on the basis of genetic similarity (Table 182.3) although traditional serotype names are retained for some individual serotypes.

Epidemiology

Enterovirus infections are common and have a worldwide distribution. Humans are the only known reservoir for human EVs, although some primates can become infected. The majority of infections are asymptomatic.

In the United States, one to three serotypes predominate each year. A small number of serotypes are seen every year while others emerge to cause widespread outbreaks and then disappear before reemerging years later. Recent serotypes that have emerged include Coxsackie A6, causing hand-foot-mouth disease (HFMD), and EV-D68, associated with respiratory disease and acute flaccid myelitis.

The occurrence of enteroviral infections varies by season, climate, and with the age and socioeconomic status of the population. In temperate climates infections are seen in the summer and early fall. In tropical and semitropical regions infections are seen throughout the year. Infection incidence, clinical attack rates, and disease severity are greatest in infants and young children. Infections occur more frequently in areas where poor sanitation, poor hygiene, and high population density are present. In the United States, geographic and socioeconomic factors affect the prevalence of enteroviral infections. Enterovirus isolation rates from young children are two- to threefold higher in southern than in northern cities and three- to sixfold higher in lower than in middle and upper socioeconomic areas.

EVs are transmitted person to person either directly by the fecal-oral route or less often by virus shed in respiratory secretions. EVs may survive on environmental surfaces, allowing transmission from fomites. Transmission via contaminated water and food can occur. The respiratory route is the principal mode of transmission for some serotypes including Coxsackie A21 and EV-D68. EV 71 is an exception as the virus is shed in tears and spread by fingers or fomites.

Viral shedding occurs after both asymptomatic and symptomatic infection. Virus is shed from 2 to 8 weeks in the feces and 1 to 3 weeks in respiratory secretions. Infants, especially those in diapers, are effective vehicles for transmission. Secondary infections occur at high rates in susceptible household contacts.

The usual incubation period for enterovirus infections is 3 to 6 days, except for acute hemorrhagic conjunctivitis (AHC), where the incubation period is 24 to 72 hours. The prevalence of unrecognized infection far exceeds that of clinical disease.

Pathogenesis

Enteroviral infection begins by ingestion of fecally contaminated material (Figure 182.1). After an incubation period of 1 to 3 days, limited replication occurs in the mucosa and lymphoid tissue of the tonsils and pharynx. Virions, which are impervious to stomach acid, proteases, and bile, are able to pass through the stomach and small bowel to the primary site of infection, lymphoid cells of Peyer's patches, which underlie the intestinal mucosa of the terminal ileum. One to two days after ingestion, virus is released from these initial sites of replication

TABLE 182.2 **CONVENTIONAL HUMAN ENTEROVIRUS CLASSIFICATION AND HOST RANGE**

		Host range		
Group	**Serotypes**	**Primates**	**Newborn mice**	**Cell culture**

Enteroviruses	68–72	variable	variable	Variable

TABLE 182.3 **2013 HUMAN ENTEROVIRUS CLASSIFICATION BASED ON PARTIAL SEQUENCING OF VP1 RNA**

Species	Number of serotypes infecting humans	Serotypes included
Group A enteroviruses	21	Coxsackie A 2–8, 10, 12, 14, 16 Enterovirus A 71, 76, 89–92, 114, 119–121
Group B enteroviruses	59	Coxsackie A 9 Coxsackie B 1–6 Echovirus 1–7, 9,11–21, 24–27, 29–33 Enterovirus B 69, 73–75, 77–88, 93, 97, 98, 100, 101, 106, 107, 111
Group C enteroviruses	23	Poliovirus 1–3 Coxsackie A 1, 11, 13, 17, 19–22, 24 Enterovirus C 95, 96, 99, 102, 104, 105, 109, 113, 116- 118
Group D enteroviruses	4	Enterovirus D 68, 70, 94, 111

into the bloodstream, causing a transient minor viremia which infects regional lymph nodes. In most cases, infection is contained at this stage by host defense mechanisms with no further progression, resulting in asymptomatic infection. In a minority of infected persons, replication takes place in the regional lymph nodes with subsequent dissemination of virus into the bloodstream causing a heavy sustained viremia ("major viremia"). During the major viremia, which usually occurs by the fifth day of infection, nonspecific symptoms of fever may be seen. The major viremia disseminates large amounts of virus to target organs bearing receptors for the infecting serotype. Target organs include the spinal cord, brain, meninges, heart, skeletal muscles, and skin. The tissue targeted by the particular enterovirus determines the predominant clinical illness caused by that virus. Further virus replication results in cell necrosis in target tissues. In most patients, host defense mechanisms quickly terminate the major viremia and halt virus replication in target organs; only rarely is virus replication in target organs extensive enough to be clinically apparent.

Serotype-specific neutralizing antibodies may be detected in the serum within 4 or 5 days of infection and generally persist for life. These antibodies play a critical role in terminating infection, which is highlighted by the occurrence of chronic persistent enteroviral infections in children with agammaglobulinemia. Host defenses do not terminate virus replication in the intestine, and fecal shedding continues for weeks after both symptomatic and asymptomatic enteroviral infections.

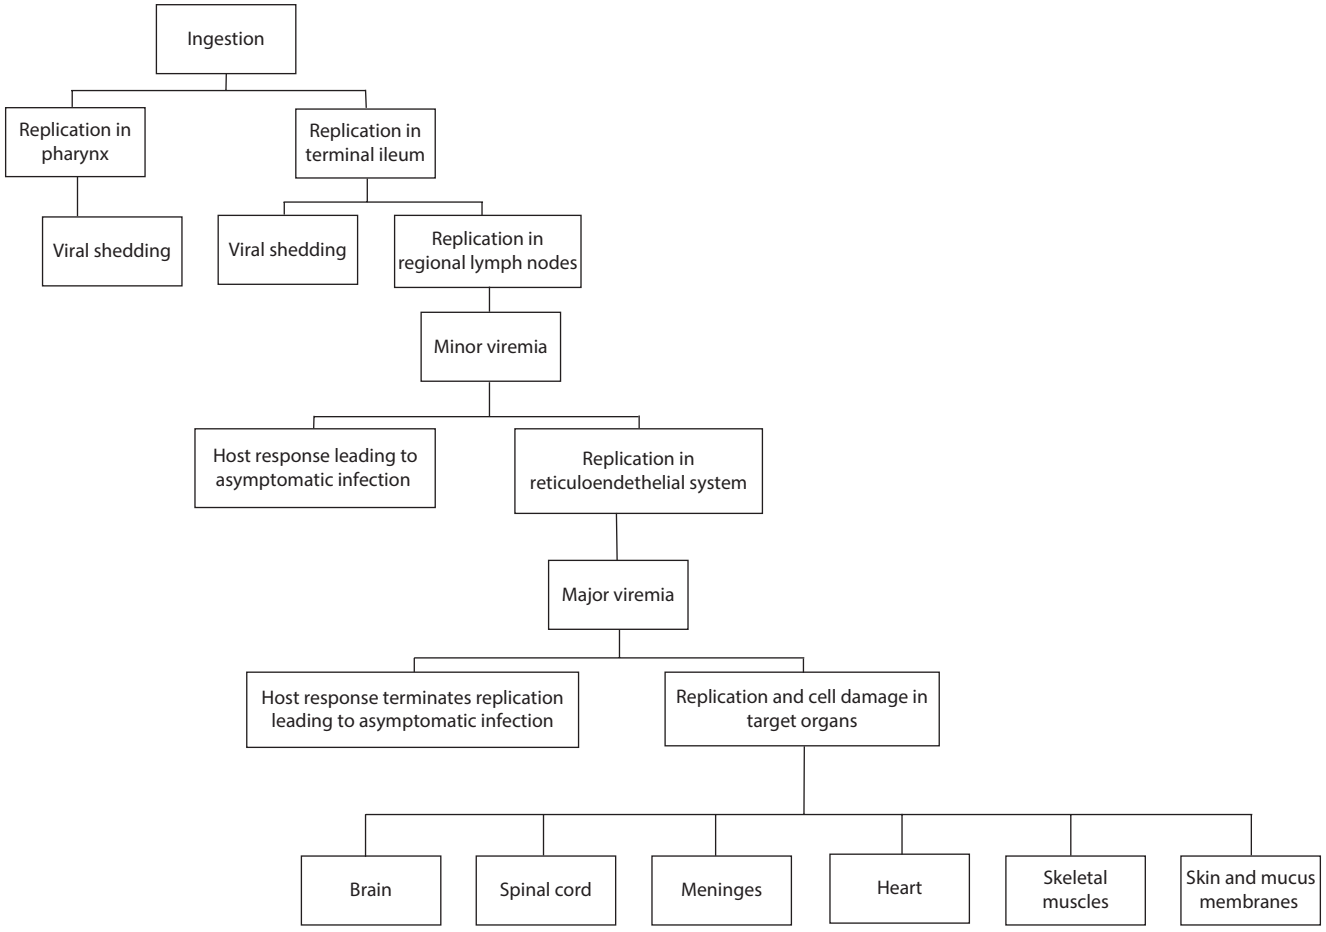

FIGURE 182.1 Pathogenesis of enteroviral infections.

Immunity to enteroviral infection is serotype-specific, with neutralizing antibodies in the blood preventing enteroviral dissemination and disease. Reinfection is relatively uncommon and is generally asymptomatic. Infection is most often confined to the gastrointestinal tract, and the duration of virus shedding is markedly reduced.

Clinical presentation

EVs cause a wide spectrum of diseases in all age groups, with infection and illness occurring most commonly in infants. When more serious disease occurs, the clinical spectrum and disease severity vary with the age, gender, and immune status of the host. The majority (50–80%) of infections caused by EVs are asymptomatic. Most symptomatic infections consist of undifferentiated febrile illnesses often accompanied by upper respiratory symptoms. Other manifestations are uncommon and can include (1) respiratory: coryza, pharyngitis, herpangina, stomatitis, parotitis, croup, bronchiolitis, pneumonia, and bronchospasm; (2) skin: HFMD, onychomadesis (shedding of nails), and nonspecific exanthems; (3) neurologic: aseptic meningitis, encephalitis, and acute flaccid myelitis; (4) gastrointestinal/genitourinary: vomiting, diarrhea, abdominal pain, hepatitis, pancreatitis, and orchitis; (5) eye: AHC and uveitis; (6) heart: myopericarditis; and (7) muscle: pleurodynia and other skeletal myositis. Some syndromes are associated with certain EV serotypes or subgroups, but even these associations are not specific. The same syndrome may also be caused by a number of enteroviral serotypes, and a single enteroviral serotype may cause several different syndromes, even within the same outbreak.

Nonspecific, febrile illness

Most EVs cause a brief febrile illness with no other symptoms or signs. Usually, there is a sudden onset of fever which may last up to 3 days. Biphasic illness, characterized by an initial day of fever and a recurrence 2 to 3 days later for 2 to 4 days, can also be seen. Younger children can have malaise and older children can experience headache or a sore throat. Physical findings are those of a general viral illness, and mild pharyngeal erythema or conjunctivitis may be seen.

Central nervous system infections

Aseptic meningitis

EVs are responsible for >80% of cases of aseptic meningitis, with almost every EV serotype implicated. Although attack rates are generally highest in children, cases also occur in adults. Symptoms of fever, headache, malaise, myalgia, and sore throat are usually followed within a day by signs and symptoms of meningitis, including a more severe headache, photophobia, and stiffness of the neck and back. Nausea and vomiting may occur, especially in children.

The cerebrospinal fluid (CSF) in enteroviral meningitis is usually clear, with a total cell count varying from <10/mm^3 to >3,000/mm^3, but usually averaging 50 to 500/mm^3. Initially neutrophils predominate but are quickly replaced by mononuclear cells within the second day of illness. Pleocytosis may persist for ≥2 weeks or more. Pleocytosis may be absent in up to 30% of infants and children with positive enteroviral reverse transcription-polymerase chain reaction (RT-PCRs) from the CSF. The glucose concentration in CSF is usually normal, although levels of <40 mg/dL are occasionally seen. The protein concentration is normal or slightly elevated but rarely exceeds 100 mg/dL. Fever and signs of meningeal inflammation subside in 3 to 7 days in most children, although symptoms often persist longer in adults. Some cases may be accompanied by a rash, which may be petechial and resemble that of meningococcemia. Most children and adults recover fully without sequelae.

Acute flaccid myelitis

Acute flaccid myelitis (AFM) may occur with nonpolio enteroviral infections. It is similar to but usually less severe than that caused by poliovirus. Muscle weakness is more common than paralysis, and recovery is usually complete, although an occasional patient may develop cranial nerve palsies or severe, sometimes fatal, bulbar involvement. In contrast to paralytic poliomyelitis, which in the prevaccine era occurred in epidemics, cases of paralysis associated with nonpolio EVs are generally sporadic. However, several nonpolio EVs can cause local outbreaks and epidemics of AFM. A variant of Coxsackievirus A7 has caused outbreaks as well as numerous sporadic cases of AFM. Paralytic disease resembling poliomyelitis, with a significant incidence of residual paralysis and muscle atrophy, has been observed in patients with AHC caused by EV-70. EV-A71 has been responsible for large outbreaks of AFM in Eastern Europe, Russia, and Asia.

Since 2014, there have been seasonal, biennial increases in the incidence of AFM cases in the United States. The CDC has reported >600 confirmed cases over that time period. The nationwide increases in AFM in 2014, 2016, and 2018 have coincided temporally and geographically with outbreaks of EV-D68 and EV-A71 infections. Despite the temporal association between EV-D68 and EV-A71 outbreaks and AFM and a mouse model of spinal cord infection and paralysis caused by clinical isolates of EV-D68, the etiology of AFM has been difficult to confirm. Fewer than half of children with AFM have had EV detected in a non-sterile specimen (nasopharyngeal or oropharyngeal swabs most commonly, rectal and stool samples less commonly). In addition, only 2% of children with AFM have EV nucleic acid detected in CSF.

Encephalitis

Encephalitis is an uncommon manifestation of EV infection. Enteroviral infection accounts for only 10% to 20% of the cases of encephalitis of proven etiology in the United States. In most cases, encephalitis complicates the course of aseptic meningitis, with 5% to 10% of patients with aseptic meningitis developing encephalitis. Manifestations range from lethargy, drowsiness, and personality change to seizures, paresis, coma, motor seizures, hemichorea, and acute cerebellar ataxia. Cerebral involvement is usually generalized, but focal encephalitis does occur and may be clinically indistinguishable from herpes simplex encephalitis. Recovery from enteroviral

encephalitis is usually complete, although neurologic sequelae and deaths do occur, especially in young infants and during EV-71 epidemics.

Other reported neurologic complications

EVs, particularly Coxsackie A viruses, appear to be an important cause of febrile seizures in children during EV season. Other neurologic syndromes, including Guillain–Barré syndrome, transverse myelitis, and Reye's syndrome, have been reported in patients with EV infections caused by a number of different serotypes.

Epidemic pleurodynia

Pleurodynia is an acute illness characterized by fever and paroxysmal spasms of the chest and abdominal muscles. Group B Coxsackieviruses, particularly B3 and B5, are the most important causes of epidemic pleurodynia. Clinically, pleurodynia presents with sudden onset of fever accompanied by pain in the chest and abdominal muscles. The chest pain is spasmodic in nature, with spasms lasting 15 to 30 minutes and worsening during inspiration or coughing. The paroxysmal pain is characteristically associated with fever that peaks within 1 hour after onset of each paroxysm and subsides with the subsequent paroxysm. Headache, nausea, and vomiting are also frequently reported.

Acute hemorrhagic conjunctivitis

AHC is an acute, highly contagious, self-limited disease of the eye characterized by sudden onset of pain, photophobia, conjunctivitis, swelling of the eyelids, and prominent subconjunctival hemorrhages. AHC has occurred in explosive epidemics worldwide. During epidemics, all age groups are affected. The most frequent causes of AHC, EV-70 and the Coxsackie A24, are temperature-sensitive and replicate optimally at 33°C/91°F to 35°C/95°F, the temperature of the conjunctivae.

AHC is highly contagious. In contrast to most enteroviral infections, it is transmitted by direct inoculation of the conjunctivae with virus-contaminated fingers or ophthalmologic instruments. Transmission can be prevented by careful handwashing, avoidance of contaminated washcloths and towels, and sterilization of all ophthalmologic instruments.

AHC begins with the sudden onset of eye pain and foreign-body sensation, lacrimation, photophobia, blurred vision, and bulbar conjunctivitis. Signs and symptoms rapidly increase in severity with the development of palpebral conjunctivitis, conjunctival edema, swelling of the eyelids, subconjunctival hemorrhages in the bulbar conjunctivae, and a serous or seromucoid ocular discharge containing large numbers of polymorphonuclear leukocytes. Subconjunctival hemorrhages are the hallmark of the disease. Preauricular lymphadenopathy is an associated finding. AHC often begins unilaterally, but it rapidly spreads to the other eye. Signs and symptoms peak within 24 to 36 hours of onset.

Poliomyelitis-like motor paralysis occurs as a rare complication of AHC caused by EV-70, but not in AHC caused by Coxsackie A24. Paralysis occurs predominantly in adult males and generally does not occur until 2 to 5 weeks after onset of AHC.

Mucocutaneous disease

Enteroviral lesions in the oropharyngeal mucosa and skin are manifestations of a systemic virus infection. Almost all EVs can cause maculopapular eruptions, and most serotypes may cause petechial or papulovesicular exanthems and enanthems. EVs may cause more than one pattern of mucocutaneous disease, even within a single household. Consequently, except for HFMD, which is usually caused by Coxsackie A16 or EV-71, there are no clinical or epidemiologic characteristics of any given EV rash that point to a specific EV as its cause. The vast majority of EV exanthems and enanthems occur during the summer and early fall. The incidence of enanthems and exanthems varies among different EVs and even among different strains of the same EV. Host factors, especially age, are important. Infants and young children are more likely to develop mucocutaneous lesions.

Enanthems

The oropharyngeal mucosa is involved to some degree during most symptomatic enteroviral infections. This is usually manifest by mild pharyngitis and mucosal erythema, but it may also result in a variety of enanthems. These may consist of macules, papules, vesicles, petechiae, or ulcers, and they may occur alone or in association with exanthems and other manifestations of systemic enteroviral infection. They are often transient and frequently unrecognized.

Two unique enanthems are caused by enteroviral infections.

Herpangina

Herpangina is characterized by sudden onset of fever, sore throat, pain on swallowing, and a vesicular enanthem of the posterior pharynx. Outbreaks are common during the summer, and sporadic cases are also observed. Group A Coxsackieviruses account for the majority of outbreaks. Herpangina is most often seen in children between ages 3 and 10 years.

Herpangina begins abruptly with fever, sore throat, and pain on swallowing. Anorexia, vomiting, and abdominal pain may also be seen. Fever tends to be greater in younger children. Older children and adults frequently complain of headache and myalgia.

On examination there is pharyngeal erythema but little or no tonsillar exudate. The characteristic lesions are discrete 1 to 2 mm vesicles and ulcers surrounded by 1 to 5 mm zones of erythema. Lesions are few, averaging 4 to 5 per patient, with a range of 1 or 2 to 20. They occur on the anterior tonsillar pillars, the posterior edge of the soft palate, and the uvula, and, less frequently, on the tonsils, the posterior pharyngeal wall, and the posterior buccal mucosa. They begin as small papules, progress to vesicles, and ulcerate within 24 hours. The shallow ulcers, which are moderately painful, may enlarge over the next 1 or 2 days to a diameter of 3 to 4 mm. Symptoms generally disappear in 3 or 4 days, but the ulcers may persist for up to a week. Most cases are mild and resolve without complications, but herpangina is occasionally associated with exanthems, aseptic meningitis, or other serious manifestations of systemic EV infection.

Herpangina is most often confused with bacterial pharyngitis, tonsillitis, or pharyngitis caused by other viruses. Other considerations include HFMD and primary herpes simplex virus (HSV) infections, particularly acute herpetic pharyngotonsillitis.

Hand-foot-mouth disease

HFMD is a common illness typically affecting children <10 years during the late summer and fall months. It presents as a self-limited febrile illness with malaise, oral ulcerations causing throat or mouth pain, and a vesicular rash on the hands and feet. HFMD begins with fever, malaise, and sore throat. Fever is typically low-grade and resolves in 48 hours. Painful oral lesions begin to appear within 1 to 2 days after onset of fever and are usually located on the tongue, palate, and buccal mucosa. Erythematous oral macules evolve into vesicles that rupture and cause painful ulcerations. Patients may develop dehydration because of refusal to eat and drink because of pain. A vesicular rash subsequently develops on the palms and soles, and also on the buttocks and in the genital region. The skin lesions are often painful. The illness typically resolves within 7 to 10 days. Some patients may exhibit only one or two of the classic findings, such as the oral-cutaneous findings without fever or systemic symptoms.

In children with atopic dermatitis, a vesicular rash concentrated in areas previously or currently affected by the dermatitis has been called *eczema coxsackium*. Eczema coxsackium is clinically indistinguishable from eczema herpeticum. HSV testing should be performed to rule out herpes infection requiring treatment with acyclovir.

Onychomadesis, separation of the proximal nail plate from the nail matrix and nail bed due to arrest of nail matrix growth, was first reported in association with HFMD in 2000. It most often occurs 3 to 8 weeks after HFMD onset. The pathogenesis of onychomadesis in HFMD is not known and may be a direct effect of the viral infection or due to a post viral immunological mechanism. Onychomadesis is usually asymptomatic, and the nails regrow normally within several months.

The vesicular lesions of HFMD resemble those caused by herpes simplex and varicella-zoster viruses. Patients with primary herpetic gingivostomatitis usually have more toxicity, cervical lymphadenopathy, and more prominent gingivitis. Their cutaneous lesions are usually perioral but may occasionally involve a finger, especially in thumb suckers. Recurrent herpes simplex (herpes labialis) usually involves the vermillion border of the lip or the adjacent skin, is rarely accompanied by lesions on the hands or feet, often has a neuralgic prodrome, and frequently has a history of recurrent episodes. The cutaneous lesions of varicella are generally more extensive and are centrally distributed, sparing the palms and soles. Oral lesions are far less prominent in varicella, and its prevalence in winter and spring further distinguish it from HFMD.

In the United States, Coxsackie A16 and EV 71 have been the most common causes of HFMD. Recently Coxsackie A6 has emerged in Asia and in Europe (2008) and in the United States (2011) as a cause of outbreaks of HFMD characterized by an atypical presentation. Patients with Coxsackie A6 HFMD usually have more severe cutaneous involvement, with vesiculobullous lesions involving the dorsum of hands and feet, calves, forearms, trunk, and neck. Involvement of the perioral area is common. Young adults may present with erythematous papulovesicular lesions on the face, oral mucosa, extensor surfaces of the upper and lower extremities, and palms and soles. Confluent, hemorrhagic, and crusted lesions can also be seen on the extremities.

Exanthems

The most common cutaneous manifestation of an enteroviral infection is an erythematous maculopapular rash that appears with fever and other manifestations of systemic infection. Only certain EVs, such as echovirus 9, frequently cause this syndrome, but almost all EVs can cause it occasionally. The rash begins on the face and quickly spreads to the neck, trunk, and extremities. It consists of 1 to 3 mm erythematous macules and papules that may be discrete (*rubelliform*, resembling rubella) or confluent (*morbilliform*, resembling measles). The rash usually lasts for 2 to 5 days and does not itch or desquamate. Enteroviral exanthems are generally not accompanied by significant lymphadenopathy. Enteroviral rashes are sometimes petechial and occasionally purpuric, most frequently in echovirus 9 and Coxsackievirus A9 infections.

Vesicular exanthems are most often seen as a component of HFMD, but several EVs, including echovirus 11, Coxsackievirus A9, and EV-71, may cause vesicular exanthems without an associated enanthem. The lesions resemble those caused by varicella-zoster and HSV. In contrast to varicella, however, vesicular rashes caused by EV are usually peripheral in distribution and consist of relatively few lesions that heal without crusting. When they are not associated with HFMD, vesicular lesions caused by EV are often confused with insect bites or poison ivy. Echovirus 11 and several Coxsackievirus serotypes have been associated with skin lesions resembling papular urticaria.

Enteroviral rashes are generally accompanied by fever and develop at the time of or within 1 or 2 days of fever onset. In some cases, the rash does not develop until the fever subsides, a pattern resembling that of *roseola infantum* (exanthem subitum) caused by human herpesvirus 6.

Enteroviral enanthems and exanthems are generally benign, self-limited illnesses that require only symptomatic therapy for headache and sore throat. While EV exanthems are benign, they may be confused with other diseases that may have more serious consequences and require specific control measures and/or anti-infective therapy. When enteroviral rashes are maculopapular they may be confused with drug reactions; when they are petechial, they may be confused with bacterial or rickettsial rashes. When enteroviral rashes are petechial or purpuric, it is impossible to rule out meningococcemia on clinical grounds alone, and when the rash is associated with aseptic meningitis, it is clinically indistinguishable from meningococcal meningitis.

Maculopapular exanthems caused by EV are distinguished from measles and rubella by their summertime occurrence; the usual absence of posterior cervical, suboccipital, and postauricular lymphadenopathy; and their relatively short incubation period. The absence of significant coryza and conjunctivitis further distinguishes the typical enteroviral exanthem from measles. In addition, the probability of measles and rubella is markedly reduced by appropriate immunization. When illness mimics meningococcemia or meningococcal meningitis, antimicrobial chemotherapy should be initiated until bacterial infection is ruled out.

Myocarditis/Pericarditis

EVs are a major infectious cause of myocarditis and pericarditis. Age is an important factor in disease presentation. Neonatal infections frequently result in severe myocarditis, widespread involvement of other organs, and high mortality. In older children and adults, pericarditis often predominates, and the disease is generally benign and self-limited. Most cases occur in males, but in females the risk of cardiac involvement is increased during pregnancy and immediately postpartum.

The most common symptoms of enteroviral myopericarditis are dyspnea, chest pain, fever, and malaise. Precordial pain may be sharp or dull and is often exacerbated by lying down. A pericardial friction rub, if present, is transient. Signs of congestive heart failure are present in 20% of cases.

Endomyocardial biopsy, with in situ hybridization and RT–PCR, has improved identification of the infectious etiology of myocarditis and pericarditis. The group B Coxsackieviruses have been the most common etiologic agents identified, accounting for 50% of sporadic cases of acute myocarditis and for all cases in epidemics. Human adenoviruses, dengue, and parvovirus B19 are other important causes of myocarditis. Group B Coxsackieviruses account for 30% or more of sporadic cases of acute nonbacterial pericarditis.

Treatment of EV myopericarditis is supportive. It includes control of pain and monitoring for arrhythmias, heart failure, and hemodynamic compromise. Bed rest is an important component of therapy because of evidence in mice with Coxsackievirus B3 myocarditis that exercise increases myocardial necrosis and mortality during the acute disease. Corticosteroids should not be administered since their use during the acute phase of viral myocarditis has been associated with rapid clinical deterioration.

The majority of children and adults with enteroviral myopericarditis recover without sequelae. Acute mortality is low (0–5%), and deaths result from arrhythmias or congestive heart failure in patients with myocarditis. Cardiac tamponade is extremely rare in enteroviral pericarditis.

Approximately 20% of patients experience one or more episodes of recurrent myopericarditis within 1 year of their initial illness, and persistent electrocardiographic (ECG) abnormalities are observed in 10% to 20% of patients. Cardiomegaly persists in 5% to 10% of patients, and long-term follow-up suggests that ≥10% may develop chronic cardiomyopathy. Constrictive pericarditis rarely occurs following enteroviral pericarditis.

Respiratory infections

A number of EVs have been associated with mild upper respiratory tract illness in children and adults, especially Coxsackieviruses A21, A24, and B1 through B5 and echoviruses 9 and 11. Many produce illnesses that resemble the common cold. In contrast to most other EVs, Coxsackievirus A21 is shed primarily from the upper respiratory tract rather than in feces. EVs have also been associated with tracheitis, bronchitis, croup, bronchiolitis, and pneumonia in children. Surveillance data indicate that EVs account for 2% to 10% of viral respiratory disease and that 10% to 15% of symptomatic EV infections are associated with respiratory symptoms. The respiratory illnesses caused by EVs are clinically indistinguishable from similar illnesses caused by viruses more commonly considered to be respiratory tract pathogens, such as rhinoviruses, influenza viruses, parainfluenza viruses, respiratory syncytial virus, and adenoviruses. However, infections with these viruses occur most frequently during the winter, whereas EV infections occur primarily in the summer and early fall.

EV-D68 was responsible for a large multinational outbreak of respiratory disease in 2014. Disease was characterized by exacerbation of preexisting asthma or new-onset wheezing in children without any history of asthma, often requiring hospitalization and, in some patients, intensive care.

Infections in special hosts

Neonatal infections

Neonates whose mothers develop an enteroviral infection in the perinatal period are at high risk for disseminated disease, especially if this is the mother's primary infection with the infecting serotype. Most neonatal infections are caused by Echoviruses 6, 9 and 11, or Coxsackievirus B 1–5. Neonatal enteroviral infections present in the first week of life and can cause a wide range of clinical disease. Milder infections may present as a nonspecific febrile illness, rash, or aseptic meningitis. More severe manifestations of neonatal infection include viral sepsis, meningoencephalitis, myocarditis, hepatitis, coagulopathy, and pneumonitis. The outcome is influenced by the presence or absence of maternal antibody to the infecting serotype. Lack of antibody is associated with severe disease. Neonatal enteroviral infections must be distinguished from neonatal bacterial sepsis and disseminated neonatal herpes simplex infections.

Infection in immunocompromised hosts

Patients with humoral and combined immune deficiencies can develop persistent central nervous system (CNS) infections, a dermatomyositis-like syndrome, and/or disseminated infection. Severe neurologic and/or multisystem disease is reported in hematopoietic stem cell and solid organ transplant recipients, children with malignancies, and patients treated with anti-CD20 monoclonal antibody. ECHO 11 is responsible for most chronic infections. Clinically, these infections most often manifest as chronic meningoencephalitis. The presentation is often insidious, with initial symptoms of headache, fatigue, and mild neck stiffness or seizures. Symptoms may fluctuate in severity and may disappear completely or slowly progress. CSF studies show persistent pleocytosis with a high protein. The prognosis is poor.

Maintenance administration of intravenous immunoglobulin (IVIG) in patients with severe combined immunodeficiency syndrome or X-linked agammaglobulinemia may prevent chronic enterovirus infection of the CNS.

Diagnosis

Diagnosis of enteroviral disease is often clinical. Laboratory diagnosis is usually unnecessary but is warranted when identification of the causative organism has management implications, as in some CNS infections, myopericarditis, neonatal infection, and infections in immunocompromised patients, or when there are public health implications.

RT-PCR is the most frequently used modality for enterovirus detection. PCR is more sensitive than isolation of EVs in cell culture for CSF and respiratory secretions. Depending on the symptoms, other specimen types such as blister fluid and blood can be collected for testing. PCR can detect all serotypes of EVs, including serotypes that are difficult to cultivate in viral culture. A positive PCR test for EVs from specimens, such as stool or respiratory secretions, does not necessarily mean the virus is the cause of infection because EVs can be shed for several weeks after the symptoms have resolved.

RT-PCR assays for detection of enterovirus RNA are available at many reference and commercial laboratories for CSF, blood, and

other specimens. There are four commercially available multiplex PCR assays for respiratory secretions which identify rhino and EVs. However, these assays do not distinguish EVs from rhinoviruses and at least one identifies rhinoviruses only. EV-D68 is demonstrated primarily in respiratory tract specimens and can be detected with most multiplex respiratory RT-PCR assays. Definitive identification of EV-D68 requires partial genomic sequencing or amplification by an EV-D68-specific RT-PCR assay.

In the past, viral culture was used for isolation of EVs from tissues or body fluids. Currently, cell culture–based methods are useful when isolate serotyping is important for investigation of disease clusters or outbreaks. Most hospital laboratories no longer maintain cell culture capability so viral culture is done primarily at state public health laboratories or the US Centers for Disease Control and Prevention (CDC). EVs grow rapidly in culture and exhibit a cytopathic effect in 3 to 8 days. The serotype of enterovirus may be identified either by partial genomic sequencing or by serotype-specific antibody staining or neutralization assay of a viral isolate. A variety of specimens, including stool, rectal swabs, throat swabs, nasopharyngeal aspirates, conjunctival swabs, tracheal aspirates, blood, urine, and tissue biopsy specimens, and CSF may be used for culture. Sensitivity of culture ranges from 0% to 80% depending on serotype and cell lines used. Many group A Coxsackieviruses grow poorly or not at all in vitro.

Serology is of limited use in diagnosing enteroviral infections.

Treatment

There are no specific antiviral agents available to treat enteroviral infections. The mainstay of therapy continues to be supportive care. Pleconaril, an antiviral developed to treat enteroviral and rhinoviral infections, has been evaluated in studies treating neonatal enteroviral sepsis and meningitis in adults but is currently not licensed or available in the United States. Pocapavir, another antiviral drug being developed primarily for the treatment of polioviruses, has activity against some EVs, but it also is not commercially available.

IVIG, administered intravenously or via intraventricular administration, may be beneficial for chronic enterovirus meningoencephalitis in immunodeficient patients. IVIG also has been used for life-threatening neonatal enterovirus infections (maternal convalescent plasma has also been used), severe enterovirus infections in transplant recipients and people with malignancies, suspected viral myocarditis, and EV-71 neurologic disease, but proof of efficacy for these uses is lacking.

The CDC has developed a comprehensive website for assessing and managing patients with acute flaccid myelitis (www.cdc.gov/acute-flaccid-myelitis/hcp/index.html).

Infection control and prevention

Simple measures, such as hand washing, are important to prevent the spread of EVs. As with other non-enveloped viruses, alcohol-based hand sanitizers may not be optimally effective.

In hospitalized patients, standard precautions are indicated. Contact precautions are indicated for infants and young children for the duration of enterovirus illness. Droplet precautions also are indicated for EV-D68 respiratory infections.

Hand hygiene, especially after diaper changing, and respiratory hygiene/cough etiquette (particularly for EV-D68) are important in decreasing the spread of EVs within families and institutions. Other measures include avoidance of contaminated utensils and fomites and disinfection of surfaces. Chlorination of drinking water and swimming pools may help prevent transmission.

Effective vaccines against non-polio EVs are not yet clinically available outside of China. Three inactivated EV-A71 vaccines are licensed in China and have demonstrated high efficacy in randomized clinical trials against the predominant genotype circulating in that country. The efficacy of these vaccines in other parts of the world, where other genotypes predominate, is unknown. Vaccines for other enterovirus serotypes associated with more severe disease are under investigation.

Epstein-Barr virus and other causes of the infectious mononucleosis syndrome

Jeffrey L. Meier

Epstein–Barr virus (EBV) is a gammaherpesvirus that will infect nearly everyone at some point during his or her lifetime. In a representative cohort of the United States population from 2003 to 2010, approximately 85% of non-Hispanic black and Mexican American children and 52% of non-Hispanic white children had already acquired EBV by age 14. An estimated 90% to 95% of all persons will have acquired EBV by the end of their third decade of life. Lower socioeconomic status increases likelihood of acquiring EBV in childhood.

Oropharyngeal epithelial cells (e.g., in tonsillar crypts) are the source of infectious EBV in saliva. Close oral contact with infectious saliva is the primary mode of EBV transmission. Deep kissing during sexual intimacy that ordinarily begins in adolescence and early adulthood increases EBV transmission risk. Casual contact does not transmit the infection. EBV-seropositive donor blood products and tissues may transmit infection when EBV reactivates from latently infected B lymphocytes.

Infectious mononucleosis

Presentation

Most EBV infections go unnoticed. EBV-related disease, should it develop, varies in presentation (Box 183.1). Infectious mononucleosis (IM) is the paradigmatic illness most commonly ascribed to EBV. This is an acute or subacute illness occurring 5 to 7 weeks after EBV is initially acquired (primary infection) and corresponds to an overly exuberant immunologic reaction. Rates of IM are highest for adolescents and young adults aged 15 to 25, and 50% to 80% of susceptible college students experience an IM-like illness after a primary EBV infection. Infants and young children seldom exhibit a classical IM illness after a primary EBV infection. Older adults retain the ability to develop the illness, but most persons in this age group have already been EBV-infected.

The EBV IM diagnosis generally rests on identifying a distinctive combination of clinical symptoms and signs, characteristic abnormalities on a CBC with differential, and presence of heterophile antibody in blood (Table 183.1). EBV is highly likely to be the cause of the IM syndrome in patients presenting with the clinical triad of fever, pharyngitis, and cervical lymphadenopathy; absolute peripheral lymphocytosis; atypical lymphocytosis that is >10% of the differential; and heterophile antibodies that are detected by the mononucleosis spot (Monospot) test. As these criteria are relaxed, the probability of EBV as the cause of the illness decreases commensurately. Notably , the acute illness from a primary EBV infection commonly does not fulfill all these criteria. The IM case definitions applied in contemporary prospective studies of primary EBV infection and EBV candidate vaccines have been fashioned to only require the presence of two or more typical symptoms (e.g., sore throat, cervical lymphadenopathy, fever, or fatigue) in conjunction with EBV-specific serological evidence of an acute EBV infection. Although the result of a heterophile antibody

BOX 183.1

Epstein–Barr virus (EBV)-related disease

Acute
- Infectious mononucleosis (IM)
- Atypical IM presentations or complications

Chronic
- Chronic active infection (rare)
- Oral hairy leukoplakia

Lymphoproliferative disorders
- From congenital or acquired immunosuppression
- X-linked (Duncan disease)

Other disorders
- African Burkitt's lymphoma
- Nonkeratinizing nasopharyngeal carcinoma
- Primary central nervous system lymphoma in AIDS
- Rare types of smooth muscle cell tumors and thymomas
- Hodgkin's disease (EBV DNA in 40%–65% of tumors)

Abbreviations: EBV = Epstein–Barr virus; AIDS = acquired immunodeficiency syndrome.

test is commonly sought in clinical practice to support the clinical diagnosis of EBV IM, heterophile antibodies are not detected in 5% to 20% of EBV IM cases, may not become detectable until later in the illness, and are rarely detected in non–EBV-related medical conditions. Atypical lymphocytosis may also not be appreciable until later in the illness. Unusual clinical presentations are more likely to occur in infants, young children, older adults, and immunosuppressed persons.

Malaise and fatigue are often prominent IM symptoms, may take more time to resolve than other symptoms, and tend to linger for longer periods in patients having higher severity of acute illness. Fatigue and impaired functional status occasionally extend to 6 months after the acute illness. The chronic fatigue is not because of ongoing EBV activity or reflected in findings on physical examination, EBV-specific serologies, or other clinical laboratory tests. Sore throat and enlarged cervical lymph nodes are also very common in IM. Mild retro-orbital headache is common and short-lived. Body aches and upper respiratory tract symptoms may be present.

Fever in the range of 38°C/100.4°F to 39.5°C/103°F (+/− sweats and chills) is common, subsides in 1 to 2 weeks, and rarely persists for up to 4 weeks. Fever >40°C/104°F should prompt a search for superimposed bacterial infection (i.e., bacterial pharyngitis or peritonsillar abscess). The physical exam finding of exudative tonsillopharyngitis is a common in EBV IM and usually resolves in the first 2 weeks of illness. Petechiae may appear on the uvula and at the junction of soft and hard palates. The detection of bilateral posterior cervical lymphadenopathy elevates EBV IM in the differential diagnosis, whereas a wide variety of etiologies produce anterior cervical lymphadenopathy. EBV IM-related lymphadenopathy may take several weeks to resolve. Splenomegaly is common. Mild abdominal discomfort may be present. Severe abdominal pain or left upper quadrant abdominal pain radiating to the left shoulder raises concern of splenic rupture or infarction. Rash is infrequent in adolescents and adults unless they are given ampicillin. The EBV IM rash typically appears as a faint morbilliform eruption. Periorbital or eye lid edema may also be observed but occurs infrequently. Laboratory findings of mild to moderate hepatitis are common, and transaminase levels of >500 IU/L and jaundice are possible. Peripheral blood lymphocytosis often peaks during the second or third week of illness. Mild neutropenia and thrombocytopenia are also common.

In elderly persons, the illness of primary EBV infection is less likely to include pharyngitis, lymphadenopathy, splenomegaly, and atypical lymphocytosis and is more likely to have unusual features (i.e., jaundice or prolonged febrile course). Infants and young children are more likely to have a heterophile-negative illness with coryza, exudative pharyngitis, rash, and hepatosplenomegaly.

TABLE 183.1 **CLINICAL AND LABORATORY FINDINGS IN UNCOMPLICATED EPSTEIN–BARR VIRUS (EBV) INFECTIOUS MONONUCLEOSIS**

Percentage of patients	>50%	10–50%	≤10%
Symptoms	Sore throat, malaise, fatigue, swollen lymph nodes in neck, headache, sweats	Decreased appetite, body aches, chills	URI symptoms, cough, arthralgias, abdominal discomfort
Signs	Lymphadenopathy, fever, pharyngitis	Splenomegaly, hepatomegaly,	Rash, jaundice, palatal petechiae, periorbital edema, oral or genital ulcers
Labs	>50% mononuclear cells	Mild neutropenia	Bilirubinemia >3 mg/100 mL
	>10% atypical lymphocytes	Antinuclear antibodies	Hematuria
	Heterophile antibodies	Rheumatoid factor	Pyuria
	Mild LFT increase	Cardiolipin antibodies	Proteinuria
	Mild thrombocytopenia		
	Cold agglutinins		

Abbreviation: LFT = liver function test.

Complications

Approximately 1% of persons with EBV IM experience a complication. Various types of complications are possible (Box 183.2). In some cases, the complication overshadows the other IM features or is not accompanied by typical IM symptoms or signs. Most complications resolve without sequelae. Rare fatalities have resulted from encephalitis, splenic rupture, hepatic failure, myocarditis, or neutropenia-associated sepsis. Impending airway obstruction results from tonsillar lymphoid hyperplasia and edema. Enlarged spleens are susceptible to traumatic rupture; spontaneous rupture or infarction is rare. Hemolytic anemia, thrombocytopenia, or neutropenia may develop in relation to autoantibody production. Cytopenia is usually self-limiting. Aplastic anemia and hemophagocytic lymphohistiocytosis (HLH) are rare, life-threatening complications. Neurologic complications take on forms of encephalitis, cerebellitis, meningitis, optic neuritis, peripheral neuritis, facial nerve palsy, and Guillain–Barré syndrome. Chronic fatigue syndrome may sometimes follow an acute EBV IM episode, but this is not driven by ongoing EBV activity.

BOX 183.2

Complications of infectious mononucleosis

Neurologic
Encephalitis, meningitis, cerebellitis, Guillain–Barré syndrome, Bell's palsy, optic neuritis, psychosis, polyradiculitis, transverse myelitis, Reye's syndrome

Splenic
Rupture of enlarged spleen (traumatic or spontaneous), splenic infarction

Respiratory
Upper airway obstruction from hypertrophy of lymphoid tissue, interstitial pneumonitis

Hematologic
Autoimmune hemolytic anemia, severe thrombocytopenia, agranulocytosis, aplastic anemia, hemophagocytic syndrome

Hepatic
Fulminant hepatitis, hepatic necrosis

Cardiac
Myocarditis, pericarditis

Immunologic
Anergy, lymphoproliferative syndromes, hypogammaglobulinemia

Dermatologic
Cold-mediated urticaria, leukocytoclastic vasculitis, ampicillin-associated rash, erythema multiforme, erythema nodosum

Other
Chronic fatigue syndrome

EBV IM may evolve into a life-threatening lymphoproliferative disorder in solid organ and hematopoietic stem cell transplant recipients with profound cellular immunodeficiency. In a rare inherited X-linked lymphoproliferative disease, young males with a mutated signaling lymphocyte activation molecule-associated protein gene develop fulminant EBV IM or HLH. Survivors may be afflicted with aplastic anemia, hypogammaglobulinemia, and lymphoma. Other rare genetic defects have also been linked to life-threatening EBV-associated lymphoproliferative disorders or HLH. EBV very rarely causes a chronic active infection that results in interstitial pneumonitis, massive lymphadenopathy, hepatosplenomegaly, bone marrow failure, dysgammaglobulinemia, Guillain–Barré syndrome, and uveitis. These patients have high EBV burden in blood or tissues, as well as very high titers of EBV-specific antibodies.

Laboratory testing

Serum heterophile immunoglobulin M (IgM) antibodies of the Paul–Bunnell–Davidsohn type are a proxy indicator of EBV IM. These antibodies are distinguishable from Forssman and serum sickness heterophile antibodies (that also bind to animal red blood cell components), may not be detected until the second or third week of illness, and fade away in 3 to 6 months. Their levels do not correlate with severity of illness. Rarely do present-day heterophile antibody tests yield false-positive results, which have been reported to occur in settings of viral hepatitis, primary HIV infection, malaria, babesiosis, autoimmune diseases, and lymphoma.

EBV-specific antibody testing is how EBV IM is definitively diagnosed in the immunocompetent patient population. Measurements of antibodies against viral capsid antigen (anti-VCA) and EBV nuclear antigens (anti-EBNA) usually provide the information needed to confirm or reject the primary EBV infection diagnosis. Detection of anti-VCA IgM supports the diagnosis because it is present in 85% to 95% of acute EBV IM cases, fades away in weeks to months after the acute illness, and generally does not re-present once gone. The occasionally encountered false-positive anti-VCA IgM result makes this assay an imperfect stand-alone test for the definitive diagnosis of a primary EBV infection. Primary cytomegalovirus (CMV) infection is another cause of the mononucleosis syndrome in a normal host that sometimes produces EBV VCA IgM positivity as a result of either nonspecific IgM reactivity or EBV immune-reactivation. Finding undetectable levels of anti-EBNA antibodies in conjunction with presence of anti-VCA IgM substantiates the primary EBV infection diagnosis because anti-EBNA antibodies usually do not become detectable until convalescence and then persist for life. Seroconversion in anti-VCA IgG status from negative to positive between the times of acute illness and convalescence, respectively, is confirmation of the diagnosis. However, anti-VCA IgG is often near peak level during the acute illness and persists for life. This renders the detection of anti-VCA IgG seroconversion an uncommon option. Presence of VCA IgM, VCA IgG, and anti-EBNA antibodies is consistent with EBV immune reactivation or prior EBV infection with a false-positive VCA IgM result.

Interpret the levels of EBV-specific antibodies cautiously because these values differ by method used and are confounded by certain

types of preexisting or coincident conditions. Performing EBV-specific antibody tests in immunosuppressed patient populations may produce misleading or ambiguous results.

When the acute EBV infection of an immunocompetent person yields inconclusive EBV-specific serology results, the detection of EBV DNA in serum or plasma by quantitative nucleic acid testing (QNAT) may aid in arriving at an EBV IM diagnosis. This is because EBV IM releases EBV DNA in serum or plasma that does not circulate for long in otherwise healthy people, unlike the EBV DNA in whole blood that also consists of latent EBV genomes that persist. Although an international World Health Organization (WHO) standard reference for EBV DNA quantification has helped standardize results of different EBV QNAT methods, major questions remain about the positive and negative predictive values of the different EBV QNATs used in clinical practice. QNAT-based measurements of EBV DNAemia levels are commonly used in immunocompromised patients to predict presence of or manage EBV-related lymphoproliferative disorders.

Other causes of mono syndrome

An infectious mononucleosis-like (mono) syndrome may result from other etiologies. This is reflected in the International Classification of Diseases (ICD-10, 2019) Diagnosis Codes of Other infectious mononucleosis (B27.8), Infectious mononucleosis, unspecified (B27.9), and Cytomegalovirus mononucleosis (B27.1). EBV IM is coded as Gammaherpesviral mononucleosis (B27.0). Acute infections with CMV, toxoplasma, HIV, rubella, hepatitis viruses, and other etiologies of acute pharyngitis are often considered in the list of possible causes of the mono syndrome. Clinical and nonspecialized laboratory findings may help distinguish these other etiologies from EBV (Table 183.2). However, the definitive diagnosis usually rests on the results of pathogen-specific laboratory tests (Table 183.3). EBV should be included in the differential diagnosis of a heterophile-negative mono syndrome.

Primary CMV infection accounts for the majority of heterophile-negative mono episodes (see Chapter 180, "Cytomegalovirus"). CMV mono may closely resemble EBV IM. Both CMV and EBV characteristically produce fever, hepatitis, and atypical lymphocytosis. In CMV mono, cervical lymphadenopathy and pharyngitis tend to be milder, and exudative tonsillitis is uncommon. Atypical lymphocytosis is more common in EBV IM than in CMV mono. Primary CMV infection in the immunocompetent person is confirmed by serologic evidence of a positive anti-CMV IgM plus low-avidity anti-CMV IgG index or CMV IgG seroconversion. Detection of CMV DNA in peripheral blood also supports the diagnosis.

TABLE 183.2 **DIFFERENTIAL DIAGNOSIS OF MONONUCLEOSIS-LIKE SYNDROME**

Abbreviations: EBV = Epstein–Barr virus; CMV = cytomegalovirus; Toxo = toxoplasma; HIV = human immunodeficiency virus; HAV = hepatitis A virus; HBV = hepatitis B virus; HCV = hepatitis C virus; VCA = EBV viral capsid antigens; EA = EBV early antigens; EBNA = EBV nuclear antigens; EIA = enzyme-linked immunoassay; HBc = HBV capsid antigens; HBs = HBV surface antigen; p24 = HIV core protein; PCR = polymerase chain reaction.
[a] Applies primarily to group A streptococcus; special media required to culture *Corynebacterium diphtheriae*, *Neisseria gonorrhoeae*, and *Arcanobacterium haemolyticum*.
[b] Applies primarily to influenza virus, adenovirus, metapneumovirus, picornaviruses (non-polio enteroviruses and rhinovirus), and parainfluenza viruses.
[c] IgM and heterophile status determined with acute serum. Paired acute and convalescent sera are best analyzed simultaneously to accurately determine change in antibody titer but this is usually not practicable.

Acute retroviral syndrome (ARS) caused by primary HIV infection may manifest as a mono syndrome. In ARS, rash is anticipated, exudative pharyngitis is infrequent, tonsillar hypertrophy is minimal, and oral or genital ulcers are sometimes observed. A transient peripheral lymphopenia may be followed 2 to 3 weeks later by lymphocytosis, in which a small proportion of cells may be reactive. Detection of HIV RNA or p24 antigen in blood in conjunction with a negative or indeterminate HIV antibody result is indicative of a primary HIV infection.

Streptococcal pharyngitis is more frequently abrupt in onset compared to that of EBV pharyngitis. Viruses of various types, such as respiratory viruses and non-polio enteroviruses, are the most common cause of acute pharyngitis. These viral etiologies, like the bacterial causes of acute pharyngitis, do not typically produce hepatosplenomegaly, atypical lymphocytosis, or prominent posterior cervical lymphadenopathy. Adenovirus is an exception in causing of mono-like symptoms in young children that can be accompanied by atypical lymphocytosis. Toxoplasma-induced mono syndrome is uncommonly encountered in the United States and does not produce exudative pharyngitis or peripheral atypical lymphocytosis exceeding 10% of the differential. Rubella also presents with fever and lymphadenopathy, but the characteristic combination of rash, coryza, arthralgias, and minimal atypical lymphocytosis helps distinguish the German measles from EBV IM. The hepatitis viruses A to E are usually not accompanied by a bothersome pharyngitis or a marked lymphadenopathy. Acute mono-like illness has also been described for etiologies of human herpesvirus 6 (HHV-6), herpes simplex virus, parvovirus B19, West Nile virus, tick-borne diseases, lymphohematologic disorders, and systemic drug reactions (e.g., phenytoin, carbamazepine, minocycline, and sulfa drugs).

Management

Epstein–Barr virus

The management of EBV IM rarely demands more than general supportive care, which includes adequate rest, hydration, antipyretics, and analgesics. Acetaminophen is commonly used. Aspirin should be avoided because of the potential risk of bleeding or thrombocytopenia. Complications of IM may require additional supportive measures (e.g., maintenance of airway during obstructive tonsillar enlargement or encephalitis, transfusions for severe hemolytic anemia or thrombocytopenia, splenectomy for splenic rupture_. Activity should be restricted in proportion to the degree of symptoms and any splenomegaly. Most students can return to school in less than 2 to 3 weeks.

Enlarged spleens are structurally weakened by mononucleosis and at risk of rupture by trauma. Reported cases of splenic

rupture have almost always occurred within the first month after illness onset, though splenic rupture at 7 weeks has been reported. Ultrasonography detects splenomegaly that is not appreciated on physical examination, and nonpalpable splenomegaly usually resolves in 4 to 6 weeks. This supports expert opinion that contact sports should be avoided for 4 to 6 weeks after symptom onset or until absence of splenomegaly is verified. A 2008 consensus statement in sports medicine warns against using one-time ultrasonography imaging for determining presence of splenomegaly and risk of rupture. Normal spleen size may be larger for tall athletes, and spleen size in IM-associated splenomegaly may not exceed the normal range. In a prospective study, serial use of ultrasonography in 17 college-aged athletes with EBV IM revealed splenic enlargement in all subjects that peaked within 23 days from time of symptom onset (mean 12.3 days; standard deviation [SD] 5.3 days), and subsequently decreased in size at approximately 1% per day on average. While serial use of ultrasonography may increase accuracy in determining the time-frame for resolution of splenomegaly, the cost-effectiveness and reliability of this strategy have been questioned. The athlete (or legally authorized representative) should be informed about issues pertaining to risk of splenic rupture when deciding together whether he or she can return to contact sports.

EBV IM-associated exudative tonsillopharyngitis commonly leads to a search for β-hemolytic streptococci. Anywhere from 3% to 30% of surveillance throat cultures obtained during IM grow group A streptococci, reflecting the range in prevalence of community streptococcal carriage. Up to 30% of individuals harboring this bacterium eventually show serologic evidence of streptococcal infection. Streptococcal pharyngitis is treated with penicillin V (500 mg BID) for 10 days or an alternative antibiotic selected according to recommendations issued by the Infectious Disease Society of America (IDSA) Practice Guidelines, which are publically accessible. This treatment also prevents poststreptococcal sequelae. One retrospective study concluded that EBV IM does not increase the risk of rash from oral amoxicillin, unlike early reports for ampicillin.

Acyclovir, ganciclovir, and foscarnet inhibit EBV replication during lytic infection but do not inhibit amplification of latent EBV genomes in proliferating B cells. Acyclovir and valacyclovir, an orally administered prodrug of acyclovir, inhibit oropharyngeal shedding of EBV in persons with IM, but the shedding resumes after discontinuation of the antiviral agent. Antiviral therapy is not clinically beneficial in acute EBV IM, and the proportion of circulating B cells containing EBV is not consistently reduced. Some clinicians may use antiviral therapy as an adjunct to corticosteroid therapy for life-threatening complications of EBV IM.

Use of a corticosteroid for treatment of uncomplicated IM is not recommended. Several small controlled trials of varying design have not consistently found corticosteroids to be clinically beneficial and have not fully addressed their potential adverse effects. Studies showing benefit reveal modest reduction in duration of fever and tonsillopharyngeal symptoms. In a double-blinded, placebo-controlled study, the combination of prednisolone and acyclovir did not significantly decrease duration of IM symptoms. Corticosteroids have not been shown to decrease lymphadenopathy or hepatosplenic disease. Rare anecdotal reports have associated corticosteroid use with encephalitis, myocarditis, and peritonsillar abscess. The possibility of corticosteroid adversely affecting long-term immunity or number of latently infected cells with malignancy potential is a theoretical concern that has not been adequately addressed.

Corticosteroids appear to be useful in the management of certain IM complications. Corticosteroids may quickly ameliorate impending airway obstruction from tonsillar enlargement. A short course of a corticosteroid may also be considered in exceptional situations of severe protracted IM (i.e., fever, prostration, weight loss). Corticosteroids may reduce the severity of autoimmune thrombocytopenia and hemolytic anemia, and their use can be considered for intractable cases of encephalitis, myocarditis, and pericarditis. When used, corticosteroid therapy is given for a short course and commonly initiated at a dose of 40 to 60 mg of prednisone equivalent per day. Treatments of complications of EBV-associated lymphoproliferative disorders and HLH are beyond the scope of this chapter.

Therapy of other causes of mono syndrome

The mono-like symptoms of acute infections with CMV, toxoplasma, HIV, rubella, and the hepatitis viruses are usually self-limiting. Additional details about individual case are sought to determine whether interventions other than supportive care should be applied. Pregnancy and cellular immunodeficiency are important factors to consider in the decision. Profound cellular immune deficiency usually requires use of antiviral and antiparasitic treatments for acute CMV (see Chapter 180, "Cytomegalovirus") and toxoplasma (see Chapter 198, "Toxoplasma") infections, respectively. Primary CMV, toxoplasma, and rubella infections in pregnancy pose a risk to the baby (TORCH syndrome), warranting a consultation with an obstetrician with expertise in this area. Primary toxoplasmosis of pregnancy necessitates antimicrobial therapy (see Chapter 198, "Toxoplasma"). Immediate antiretroviral therapy is recommended in persons with acute HIV infection (see Chapter 98, "HIV-1 infection: Antiretroviral therapy"). Antiretroviral therapy given during pregnancy can substantially reduce perinatal HIV transmission, but its use requires knowledge of the attendant toxicities and risks (see Chapter 94, Infections in pregnancy and the puerperium").

Prevention

There is no vaccine for prevention of EBV infection or disease. Hospitalized patients with IM need not be isolated. Asymptomatic viral shedding long after the acute illness remains a potential risk for EBV transmission. Restricting intimate contact can decrease EBV transmission but is not practical unless the EBV infection would be intolerable.

Hantavirus cardiopulmonary syndrome

Gregory Mertz

Introduction

Hantavirus cardiopulmonary syndrome (HCPS), also called hantavirus pulmonary syndrome, is a viral zoonosis that may result in cardiogenic shock and respiratory failure with significant associated mortality. Hantavirus infections in humans have been identified throughout much of North, Central, and South America. In the United States approximately 25 cases (range 11–48) are reported annually, with an overall case fatality rate of 35%. Most cases occur west of the Mississippi River, with more half reported in New Mexico, Colorado, Arizona, and California. Case fatality rates are similar in South America, in particular in Argentina, Brazil, and Chile, but the number of cases reported annually in each of these countries exceeds the number reported in the United States.

Virology

Hantaviruses are enveloped, single-stranded, negative-strand RNA viruses. More than 20 New World hantaviruses have been identified since HCPS was first recognized in 1993. Although there is some overlap, the cardiopulmonary disease caused by New World hantaviruses differs from the disease with predominant renal manifestations—hemorrhagic fever with renal syndrome—that results from infection with Old World hantaviruses and occurs primarily in Asia and Europe. New World hantaviruses include highly pathogenic hantaviruses with high case fatality rates such as Sin Nombre virus (SNV) and Andes virus (ANDV); viruses such as Choclo virus, which largely causes a febrile illness and uncommonly causes fatal infection; and viruses such as Prospect Hill virus that do not cause disease in humans. The most common hantavirus causing HCPS in Canada and the United States is SNV, whereas hantaviruses that cause significant disease in South America include ANDV in Chile and Argentina and Laguna Negra virus in Paraguay.

Epidemiology

Although there is some spillover between rodent species, each hantavirus is associated with a primary rodent host that sheds the virus in urine, feces, and saliva. Humans are thought to be infected when the aerosolized excreta are inhaled, often when cleaning enclosed, rodent-infested areas. Less commonly, infection may result from rodent bites and exposures in research laboratories. Human-to-human transmission has only been documented with ANDV infections in Chile and Argentina, largely in family clusters. In a prospective study of household contacts of patients with HCPS in Chile, Ferrés et al. reported a significantly higher risk of HCPS in sex partners and other close household contacts as compared to members of the

household who slept in different rooms and denied sexual contact. Human infections in the Americas with the Old World hantavirus, Seoul virus, have also been reported in isolated outbreaks in persons working in rodent breeding facilities as well as in persons living in or near seaports.

Clinical syndrome

Most human cases lack a defined exposure, and the incubation period generally cannot be determined. However, in a series from Chile where individuals had brief periods of exposure in high-risk areas, the median incubation period between exposure and onset of clinical disease was 18 days, with a range of 11 to 32 days. Incubation periods were also determined in the Yosemite National Park outbreak in 2012 among visitors who stayed in the high-risk "signature tents" in Curry Village for only a few days. In the Yosemite outbreak, the median incubation period was 30.5 days with a range of 20 to 49 days.

Clinical disease begins with a febrile prodrome with 2 days to a week of fevers and myalgias, often with associated headache, backache, abdominal pain, nausea, and diarrhea. After several days with nonspecific prodromal symptoms, the cardiopulmonary phase starts abruptly with cough and dyspnea. This stage of disease may be mild, requiring only supplemental oxygen, or severe, causing rapid pulmonary edema and respiratory failure requiring mechanical ventilation. Severe disease is also characterized by cardiogenic shock, hemoconcentration, and lactic acidosis that may result in profound shock, cardiac arrhythmias, and death. The cardiopulmonary phase usually lasts 2 to 4 days. The cardiopulmonary phase is followed by a diuretic phase with rapid resolution shock and the pulmonary edema. Convalescence may be prolonged and may include weakness, fatigue, and impaired exercise tolerance with abnormal diffusion capacity.

Diagnosis

Early presumptive diagnosis is critical because patients with severe disease typically progress to shock and death before results of serologic testing are available. An exposure history may helpful but is usually absent. Clinical diagnosis during the febrile prodrome is exceedingly difficult since there is no cough, the chest radiograph is normal, and there are no routine laboratory abnormalities other than thrombocytopenia. In an unpublished series in Chile conducted when there was high awareness of hantavirus infections among clinicians, almost half of patients with hantavirus infection sought medical evaluation during the febrile prodrome. None had serologic testing for hantavirus infection, and none was admitted to the hospital until they returned during the cardiopulmonary phase (P. Vial, personal communication). In the controlled trial of ribavirin conducted in North America reported by Mertz et al., patients from rural areas who had thrombocytopenia and symptoms consistent with the febrile prodrome of HCPS were eligible for enrollment in the trial. None of the subjects with suspected hantavirus infection in the febrile prodrome phase had hantavirus infection, whereas hantavirus infection was confirmed in 23 of 24 subjects enrolled in the cardiopulmonary phase.

A definitive diagnosis of HCPS is based on serologic testing for hantavirus-specific immunoglobulin G (IgG) and IgM antibodies, which first become detectable during the febrile prodrome. The serologic tests available in the United States include enzyme-linked immunosorbent assay (ELISA), which are available at many state health departments and in commercial laboratories. An acute infection is characterized by a positive IgM and IgG antibody results; IgM-positive/IgG-negative results commonly represent a false-positive result, in particular if repeat testing after 24 to 48 hours still lacks detectable IgG antibody. In most commercial and state laboratories in the United States, there is an interval of approximately 7 days between the time the sample is drawn and the results are reported.

More specific Western immunoblot assays are currently restricted to research laboratories, as is nested reverse transcription–polymerase chain reaction (RT-PCR) detection of hantavirus RNA in peripheral mononuclear cells and serum. Hantavirus RNA has been detected in peripheral blood cells up to 2 weeks before the onset of symptoms or detection of anti-hantavirus antibodies and for up to 13 weeks after onset of illness. Postmortem diagnosis may also be established by detection of hantavirus antigens in tissue by immunohistochemistry.

A presumptive diagnosis can generally be made at the onset of the cardiopulmonary phase on the basis of the clinical presentation, radiologic findings, and a review of the peripheral blood smear (Figure 184.1). Characteristic hemodynamic findings may also be helpful in establishing a diagnosis. The chest radiograph will show findings consistent with pulmonary edema, including bilateral pulmonary infiltrates, Kerley B lines, indistinct hilar borders, and peribronchial cuffing, which progress rapidly over the next 12 hours. A CBC should be obtained, and the peripheral blood smear should be evaluated by an experienced pathologist. Criteria suggesting hantavirus infection in the cardiopulmonary phase include (1) thrombocytopenia (platelet count $\leq 150 \times 10^3$ mm^3), (2) left-shift (presence of myeloblasts), (3) lack of toxic granulation in neutrophils, (4) hemoconcentration (hematocrit >50 in men and >48 in women), and (5) >10% immunoblasts among lymphocytes.

When evaluating a patient in whom there is a high clinical suspicion of HCPS, the presence of four of five of these criteria has a sensitivity of 96% and a specificity of 99%. Unfortunately, these criteria apply only once the patient is already in the cardiopulmonary phase and therefore cannot be used for diagnosis in the prodromal stage. Other findings in the cardiopulmonary phase include a low cardiac index associated with a high systemic vascular resistance, in contrast to parameters found in septic shock. Alanine aminotransferase and aspartate aminotransferase levels, while often normal or slightly elevated during the prodrome, are generally abnormal at the onset of the cardiopulmonary phase and often peak during the diuretic and convalescent phases as the patient is improving.

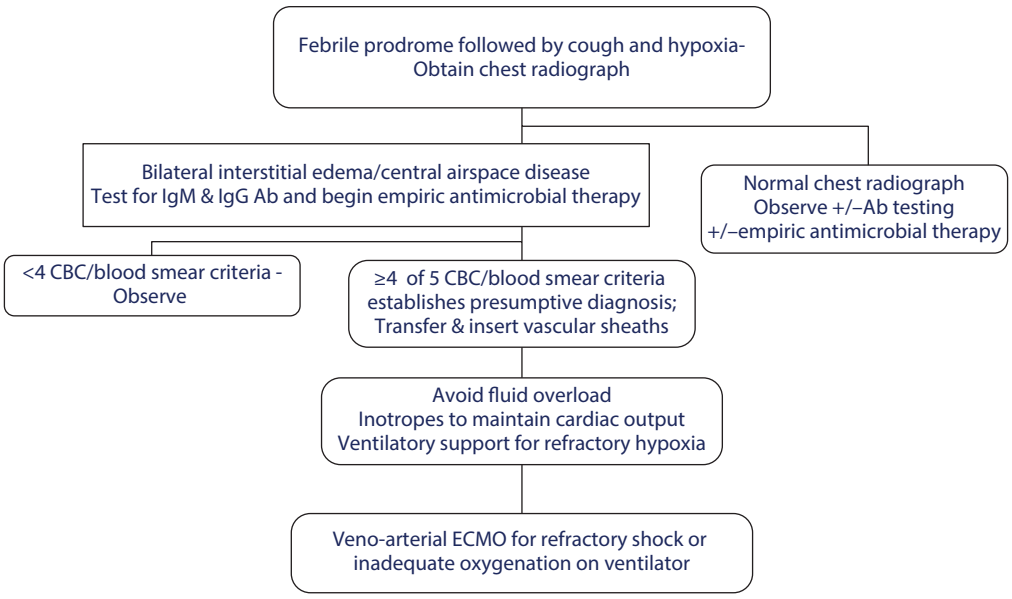

FIGURE 184.1 Flow diagram for diagnosis and management of hantavirus cardiopulmonary syndrome. See Hallin et al. for a description of characteristic hemodynamic findings, Ketai et al. for radiologic findings, Koster et al. for CBC and peripheral smear evaluation and criteria for presumptive diagnosis, and Wernly et al. for extracorporeal membrane oxygenation (ECMO) management.

Treatment

When there is clinical suspicion of HCPS (Figure 184.1), the patient should be admitted to a center in which cardiovascular and ventilatory support, including extracorporeal membrane oxygenation (ECMO) when feasible. Volume resuscitation should be avoided as this can exacerbate the pulmonary edema. Supplemental oxygen should be provided, including ventilatory support if necessary. Pending serologic confirmation, antibiotic therapy should be initiated for other infections in the differential diagnosis.

Cardiac output should be monitored either directly via thermodilution or approximated by methods such as arterial pulse waveform analysis. Echocardiography is less useful because cardiac output may drop precipitously during the cardiopulmonary phase. Early use of pressors should be utilized when appropriate. Norepinephrine is preferred as the initial agent in patients with hypotension, whereas dobutamine is preferred when there is a decrease in cardiac output but blood pressure is maintained. High-dose norepinephrine can be used in addition to dobutamine, if necessary.

If ECMO is available, the patient should be evaluated by the critical care and ECMO team, including cardiothoracic or vascular surgery, as soon as a presumptive diagnosis is made. The University of New Mexico Hospital (UNMH) in Albuquerque, New Mexico, other hospitals in the United States, and several hospitals in Santiago, Chile, have substantial experience with treatment of HCPS with veno-arterial ECMO for HCPS. Among 51 patients treated with ECMO at UNMH between 1994 and 2010, 34 (67%) survived to discharge. Furthermore, survival was 80% among the 25 patients treated between 2003 and 2010 who underwent elective insertion of arterial and venous vascular sheaths once a presumptive or definitive diagnosis of HCPS was established, were intubated nearly concurrently with vascular sheath placement, and then placed on ECMO if decompensation occurred.

For patients admitted to a medical facility without ECMO capability, immediate consultation should be sought with the nearest ECMO center as soon as hantavirus infection is considered. A listing of ECMO centers, including contact information, is maintained by the Extracorporeal Life Support Organization at www.elso.org/Membership/CenterDirectory.aspx. In practice, hantavirus infection is rarely considered prior to the onset of the cardiopulmonary phase, and progression to shock and death may occur within hours of the onset of this stage. As such, the window of opportunity for transfer to an ECMO center is generally measured in hours. Factors that may be discussed with the ECMO center include the likelihood of hantavirus infection, the patient's clinical status, distance to the ECMO center, availability of a mobile ECMO team that can initiate ECMO at the referring hospital prior to transportation to the ECMO center, and experience at the ECMO center with veno-arterial ECMO in the patient's age group.

There is no approved therapy for the treatment of HCPS. Intravenous ribavirin did not lead to survival benefit in a small placebo-controlled trial in North America, and treatment with high-dose methylprednisolone was ineffective in a randomized, placebo-controlled trial in patients with HCPS in Chile. An open, phase 1 trial of treatment with fresh frozen plasma containing anti-ANDV neutralizing antibodies was conducted in Chile, but no controlled trial of neutralizing antibody treatment has been performed, and there are no neutralizing antibody products available at this time for any of the major pathogenic hantaviruses in North or South America.

Herpes simplex 1 and 2

Richard J. Whitley and Abdulsalam Alsulami

The virus

Herpesviruses are generally defined as large, enveloped virions with an icosapentahedral nucleocapsid consisting of 162 capsomeres arranged around a double-stranded DNA core. The two antigenically distinct types of herpes simplex virus (HSV) are HSV-1 and HSV-2. Considerable homology exists between the HSV-1 and HSV-2 genomes, with most of the polypeptides specified by one viral type being antigenically related to polypeptides of the other viral type. Although this results in considerable cross-reactivity between HSV-1 and HSV-2, glycoproteins G (gG) are unique antigenic determinants that allow for differentiation between these two viruses (e.g., gG-1 and gG-2). Surrounding the viral genome and nucleocapsid is a tightly adherent membrane known as the *tegument*. A lipid envelope containing the viral glycoproteins loosely surrounds the tegument.

Pathology and pathogenesis

Cutaneous HSV infection causes ballooning of infected epithelial cells, with nuclear degeneration, loss of intact cellular membranes, and the formation of multinucleated giant cells. Ultimately, cells lyse and release clear fluid containing large quantities of virus, with subsequent accumulation of cellular debris and inflammatory cells between the epidermal and dermal layers. Multinucleated giant cells are usually present at the base of the vesicle. An intense inflammatory response extends from the base of the vesicle into the dermis, producing the erythema that classically surrounds a cluster of HSV vesicles. With lesion healing, vesicular fluid becomes purulent as more inflammatory cells are recruited to the site of infection. Scab formation then follows. Scarring is uncommon.

When infection involves mucous membranes, shallow ulcers are more common than vesicles because of rapid rupture of the very thin cornified epithelium present at mucosal sites. Nevertheless, the histopathologic findings of mucosal lesions are similar to those of skin lesions.

Epidemiology

Although HSV-1 is found most commonly in the oropharynx, it is an increasingly common cause of first-episode genital herpes, accounting for at least half of all new infections, and, additionally, can infect any organ system. Factors that influence the frequency of primary HSV-1 infection include geographic location, socioeconomic status, and age. The US seroprevalence of HSV-1 infection during childhood and adolescence is around 27% (age 14–19 years). This prevalence increases with age to 59.7% in people 40–49 years of age, and is generally higher in females than males (50.9% vs. 45.2%). HSV-1 antibody prevalence is highest

among Mexican Americans (71.7%) followed by non-Mexican blacks (58.8%), and is lowest in non-Hispanic whites (36.9%). HSV-1 remains a common infection despite recent decreases in prevalence (overall prevalence of 59.4% in 1999–2004 decreasing to 48.1% in 2015–2016).

Recurrences of herpes labialis have been associated with physical or emotional stress, fever, exposure to ultraviolet light, tissue damage, and immune suppression. As with primary infections, recurrent disease may occur in the absence of clinical symptoms. At any given time, 1% of healthy children and 1% to 5% of normal adults asymptomatically excrete HSV-1, as demonstrated by viral culture. Recent studies employing polymerase chain reaction (PCR) suggest that these numbers may be at least threefold higher.

Although HSV-2 causes the majority of recurrent genital HSV infections in the United States, recent data show that HSV-1 is increasingly responsible for more primary genital herpes infections; however, recurrences are less common than those infections caused by HSV-2. As would be expected, antibodies to HSV-2 are rarely found before the onset of sexual activity. Among adolescents and adults, factors that correlate with HSV-2 seroprevalence include sex (higher for women than for men), race (higher for African Americans than for whites), marital status (higher for persons previously married than for single or married persons), number of sexual partners (increasing likelihood with increasing number of partners), and income level (higher probability for those persons earning lesser amounts of money).

The propensity for recurrence of genital HSV infection depends on a variety of factors, including sex (more common in men), viral type (more common with HSV-2), and the presence and titer of neutralizing antibodies (more common in the presence of high neutralizing antibody titers). Overall, 60% to 90% of patients with primary genital HSV-2 infection will experience clinically apparent recurrence of infection.

Clinical manifestations

Oropharyngeal HSV infection

Primary oropharyngeal infection with HSV-1 occurs most commonly in young children between 1 and 3 years of age and is usually asymptomatic. The incubation period ranges from 2 to 12 days, with an average of 4 days. Symptomatic disease is characterized by fever to 40°C/104°F, oral lesions, sore throat, fetor oris, anorexia, cervical adenopathy, and mucosal edema. Oral lesions initially are vesicular but rapidly rupture, leaving 1- to 3-mm shallow gray-white ulcers on erythematous bases. These lesions are distributed on the hard palate, the anterior portion of the tongue, along the gingiva, and around the lips (Figure 185.1). In addition, the lesions may extend down the chin and neck due to drooling. Total duration of illness is 10 to 21 days.

Primary infection in young adults has been associated with pharyngitis and often a mononucleosis-like syndrome. In such patients, ulcerative lesions on erythematous bases frequently are apparent on the tonsils.

FIGURE 185.1 Herpes simplex gingivostomatitis.

Primary gingivostomatitis results in viral shedding in oral secretions for an average of 7 to 10 days. Virus is also shed in the stool.

Recurrent herpes labialis

Recurrent orolabial HSV lesions are often preceded by a prodrome of pain, burning, tingling, or itching. These symptoms generally last for <6 hours, followed within 24 to 48 hours by the appearance of painful vesicles, typically at the vermillion border of the lip (Figure 185.2). Lesions usually crust within 3 to 4 days, and healing is complete within 8 to 10 days. Recurrences occur only rarely in the mouth or on facial skin of immunocompetent patients.

Genital HSV infection

Genital HSV disease (Figure 185.3) is acquired by sexual contact with an infected partner. Historically, virtually all cases of genital herpes were caused by HSV-2 but, with changing sexual behavior, at least 50% of cases today are the consequence of HSV-1. The incubation period of primary disease ranges from 2 to 12 days. Lesions with primary infection persist for an average of 21 days. In 70% of patients, symptomatic primary infections are associated with fever, malaise, myalgias, and inguinal adenopathy, as well as other signs and symptoms of systemic illness. Complications include extragenital lesions, aseptic meningitis (which could be recurrent and known as *Mollaret's meningitis*), and sacral autonomic nervous system dysfunction with associated urinary retention. Women tend to experience more severe primary infections and are more likely to develop complications.

In males, primary genital HSV infection usually manifests as a cluster of vesicular lesions on erythematous bases on the glans or shaft of the penis. In females, primary genital HSV lesions usually involve the vulva bilaterally. Concomitant HSV cervicitis occurs in 90% of women with primary HSV-2 infection of the external

FIGURE 185.2 Recurrent herpes labialis.

genitalia. In women, the lesions rapidly ulcerate and become covered with a gray-white exudate. Lesions may be exquisitely painful. Recurrent genital HSV-2 infection can be either symptomatic or asymptomatic. A prodrome of itching, burning, tingling, or tenderness may be noted several hours before a recurrence. The duration of disease is shorter during recurrent infection (7 to 10 days), and fewer lesions are present. In men, lesions usually appear on the glans or shaft of the penis. In women, lesions occur most commonly on the labia minora, labia majora, and perineum. Cervical excretion of HSV occurs in 10% of women with recurrent genital lesions. Systemic symptoms are uncommon in recurrent genital HSV disease. Genital HSV-1 infections are much less likely to recur.

Transmission usually occurs in the absence of clinical symptoms and occurs more often from men to women. Importantly, HSV-2-seropositive but asymptomatic individuals are just as likely to transmit infection as those who are symptomatic.

Other primary HSV skin infections

Alteration in the barrier properties of skin, as occurs in atopic dermatitis, can result in localized HSV skin infection (eczema herpeticum). Most cases resolve over a 7- to 9-day period without specific therapy. Localized cutaneous HSV infection after trauma is known as *herpes gladitorium* (wrestler's herpes or traumatic herpes). HSV infection of the digits results in *herpetic whitlow*. Such lesions may be the result of autoinoculation, as in the case of infants, or exogenous exposure, as occurs among medical and dental personnel who fail to wear gloves.

Ocular HSV infection

Herpetic infection of the eye usually presents as either a blepharitis or a follicular conjunctivitis. As disease progresses, branching dendritic lesions develop. Symptoms include severe photophobia, tearing, chemosis, blurred vision, and preauricular lymphadenopathy. An ophthalmologist should always be involved in the care of such patients.

Central nervous system HSV infection

Central nervous system (CNS) signs and symptoms of HSV disease in older children and adults can begin suddenly or can follow a 1- to 7-day period of nonspecific influenza-like symptoms. Prominent CNS features include headache, fever, altered consciousness, and focal neurologic findings such as focal seizures. Clinical signs and symptoms may reflect the characteristic frontal and temporal lobe localization, such as memory loss,

FIGURE 185.3 Genital herpes simplex infection in woman (primary infection) and man (recurrence).

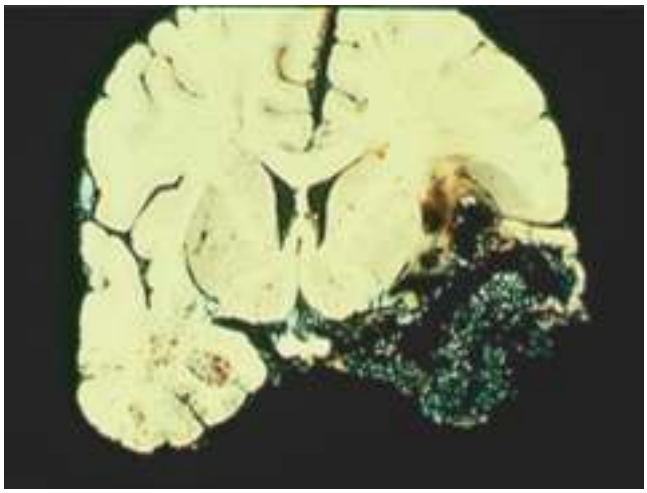

FIGURE 185.4 Brain with temporal lobe necrosis.

anosmia, olfactory hallucinations, speech disorders, and behavioral disturbances, often accompanied pathologically by focal necrosis (Figure 185.4).

Neonatal HSV infections

Neonatal HSV infection can be classified as (1) disease localized to the skin, eye, and/or mouth (SEM) (45% of cases); (2) encephalitis, with or without SEM involvement (30% of cases); and (3) disseminated infection that involves multiple organs, including the CNS, lung, gastrointestinal tract, liver, adrenals, skin, eye, and/or mouth (25% of cases). Infants with disseminated and SEM disease usually present for medical attention within the first 2 weeks of life, whereas infants with disease localized to the CNS usually present between the second and third weeks of life. Presenting signs and symptoms can include any combination of irritability, seizures (both focal and generalized), lethargy, tremors, poor feeding, temperature instability, bulging fontanelle, respiratory distress, jaundice, disseminated intra-vascular coagulopathy, shock, and cutaneous vesicles. It is important to note that >40% of infants with disseminated disease and >30% of infants with encephalitis will never develop skin vesicles during the course of illness. Even in cases of SEM disease, almost 20% of neonates do not have skin lesions. Intrapartum acquisition of the virus is responsible for approximately 85% of cases and usually occurs in the absence of symptoms. Less commonly, neonates acquire the infection postnatally (10%) or rarely (~5%) in utero, which is associated with distinctly worse disease and outcome.

HSV in the immunocompromised host

Patients compromised by immunosuppressive therapy, underlying disease, or malnutrition are at increased risk for severe HSV infection. Disseminated disease may occur with widespread dermal, mucosal, and visceral involvement. Alternatively, disease may remain localized but persist for much longer periods of time than would be evident in immunocompetent hosts.

Diagnosis

Type-specific serologic tests allow the distinction between HSV-1 and HSV-2. Such tests distinguish between gG-1 and gG-2. These tests can be utilized to determine those people at risk for infection or those previously infected but who remain unaware of their status. The diagnosis of HSV is best achieved by either the isolation of HSV by culture or the detection of viral DNA by PCR. If skin lesions are present, a scraping of the vesicles should be transferred in appropriate viral transport medium on ice to a diagnostic virology laboratory. Other sites from which virus may be isolated include the cerebrospinal fluid (CSF), though rarely, and the urine, throat, nasopharynx, conjunctivae, and duodenum. The presence of intranuclear inclusions and multinucleated giant cells on a Tzanck prep are indicative of, but not diagnostic for, HSV infection. The application of PCR to lesion scrapings is the most sensitive test for detection of HSV, especially late in the course of vesicular evolution and in the CSF. Of note, if resistance testing is necessary, a culture is essential.

In HSV encephalitis, CSF findings are variable but often include a moderate pleocytosis with a predominance of mononuclear cells, elevated protein level, and normal or slightly decreased glucose. The electroencephalogram (EEG) generally localizes spike and slow wave activity to the temporal lobe, even when obtained very early in the disease course. CT of the brain may initially be normal or reveal only edema, but, as the disease progresses, temporal lobe involvement becomes prominent. MRI of the brain is more helpful in delineating the degree and extension of CNS disease. Detection of HSV DNA in the CSF by PCR has become the diagnostic method of choice; however, it must be performed only by a reliable laboratory. Rarely, an initial early negative CSF PCR does not exclude HSV encephalitis and should be repeated especially if the clinical suspicion remains high.

Treatment

Herpes labialis

The treatments of choice for herpes labialis are acyclovir, valacyclovir, or famciclovir. Orally administered acyclovir at a dosage of 400 mg five times daily for 5 days reduces the duration of pain and time to the loss of crusts by about one-third, but only if treatment is started during the prodromal or erythematous stage of recurrent infection. Similar benefit is achieved with valacyclovir (2 g BID for 1 day, taken about 12 hours apart). Clinical benefit is achieved only if therapy is initiated very early after recurrence. Recently, 1-day therapy with famciclovir was approved by the US Food and Drug Administration. When administered during prodrome, 1,500 mg administered once accelerates healing.

Topical therapies provide little benefit in the management of herpes labialis. Although these therapies are licensed, the authors do not recommend their use. Similarly, data do not support the use of long-term suppressive treatment with acyclovir for the prevention of herpes labialis.

Genital herpes

The treatments of choice include acyclovir (oral or intravenous [IV]), valacyclovir (oral), or famciclovir (oral). Although topical acyclovir is approved for treatment of genital herpes, it is not recommended. Treatment of primary genital herpes in the normal host decreases the duration of symptoms, viral shedding, and time to healing of lesions (Table 185.1). However, neither systemic nor topical treatment of primary HSV lesions reduces the frequency or severity of recurrences. Episodic administration of oral or topical acyclovir for the treatment of recurrent genital HSV lesions provides only a modest benefit, with duration of lesions being shortened at most by 1 to 2 days. However, daily administration of oral acyclovir, valacyclovir, or famciclovir can effectively suppress recurrences of genital herpes in 60% to 90% of patients. Importantly, suppressive therapy does not totally prevent reactivation; thus, transmission can occur, albeit less frequently. Treatment should be interrupted approximately yearly to reassess the need for continued suppression.

Both valacyclovir and famciclovir are now licensed for the treatment and suppression of genital HSV. There is a pharmacokinetic advantage with these medications. For recurrent infection, valacyclovir is usually administered at 500 mg twice daily for 3 days, and famciclovir is administered at 1 g twice daily for 1 day.

The transmission of genital HSV infection can be decreased but not eliminated by administration of valacyclovir (500 mg once daily) to the infected partner.

Mucocutaneous HSV infections in immunocompromised patients

In immunocompromised patients, the three aforementioned antiviral drugs all diminish the duration of viral shedding as well as substantially accelerate the time to cessation of pain and to total healing of HSV lesions. In addition, prophylactic administration of these drugs to such patients significantly reduces the incidence of symptomatic HSV infection (see Table 185.1).

Herpes simplex keratoconjunctivitis

Idoxuridine (Stoxil), trifluridine (Viroptic), and vidarabine ophthalmic drops all are effective and licensed for treatment of HSV

TABLE 185.1 **ANTIVIRAL THERAPY IN HERPES SIMPLEX VIRUS (HSV) INFECTIONS**

Type of infection	Drug	Route and dosage[a]	Comments
Genital HSV	Acyclovir	200 mg PO 5×/d ×10 d	Preferred route in normal host
Initial episode		5 mg/kg IV q8h ×5 d	Reserved for severe cases
Recurrent episode	Valacyclovir	500mg PO BID ×3 d	
Suppression	Famciclovir Acyclovir	250 mg PO TID ×10 d 200 mg PO 5×/d ×5 d	
	Valacyclovir	500 mg PO BID × 3 d	
	Famciclovir	1 g PO BID × 1 d	
	Acyclovir	400 mg PO BID	
	Valacyclovir	500 mg or 1 g PO qd	
	Famciclovir	250 mg PO BID	
Herpes labialis	Acyclovir	400 mg PO 5×/d × 5 d	
	Valacyclovir	2 g PO BID for 1 d, taken about 12 h apart	
	Famciclovir	1500 mg administered once	
Mucocutaneous HSV in immunocompromised patient	Acyclovir	200–400 mg PO 5×/d ×10 d 5–10 mg/kg IV q8h ×7–10 d	
	Valacyclovir	500 mg BID PO	
	Famciclovir	500 mg TID PO	
HSV encephalitis	Acyclovir	10–15 mg/kg IV q8h ×14–21 d	
Neonatal HSV	Acyclovir	20 mg/kg IV q8h ×14–21 d	14 days for SEM. Minimum of 21 days in disseminated and CNS disease
Suppression		300 mg/m^2 q8h × 6 mo	
Herpetic conjunctivitis	Trifluridine	1 drop q2h while awake × 7–14 d	Alternative: vidarabine ointment

[a] The dosages are for adults with normal renal function unless otherwise noted.
SEM: Skin, eye and mouth disease.
Adapted from Workowski KA, Bolan G. Sexually transmitted diseases treatment guidelines, 2015. *MMWR Recomm Rep*. 2015;64(3):1–137; and American Academy of Pediatrics. Non-HIV Antiviral Drugs. In Kimberlin DW, Brady MT, Jackson MA, Long SS, eds. *Red Book: 2018 Report of the Committee on Infectious Diseases*. 31st ed. Itasca, IL: American Academy of Pediatrics; 2018: 966–984.

keratitis. Trifluridine is the most efficacious and the easiest to administer and, as such, is the drug of choice for HSV ocular disease (see Table 185.1). Involving an ophthalmologist in managing HSV eye infections is essential.

Herpes simplex encephalitis

In patients with HSV encephalitis, acyclovir administration reduces mortality and has a modest impact on morbidity. Dosage and length of therapy are shown in Table 185.1. Outcome is more favorable when therapy is instituted early in the disease course.

Neonatal HSV infections

IV acyclovir is the drug of choice in the treatment of neonatal HSV infection (see Table 185.1). Therapy is most efficacious if instituted early in the course of illness. Because of the exceptional safety profile of acyclovir, an IV dosage of 60 mg/kg/d divided every 8 hours should be given. Duration of therapy is 14 days if the disease is limited to skin, eye, and mouth. The minimum duration of IV therapy is 21 days in neonatal disseminated and CNS disease. Confirming negative CSF HSV PCR before the end of the initial 21 days should be established before switching to suppressive therapy. Consultation with a pediatric infectious disease specialist is strongly recommended. Suppressive therapy with acyclovir is indicated after completion of IV therapy. The dosage is 300 mg/m^2 every 8 hours for 6 months.

Infants with ocular involvement caused by HSV should receive topical antiviral medication in addition to parenteral therapy. Trifluridine is the treatment of choice for ocular HSV infection in the neonate (see Table 187.1).

Human herpes virus 6, 7, 8

Eleni E. Magira

Introduction

Of the >100 known herpesviruses, eight types of herpesviruses infect humans: herpes simplex virus types 1 and 2 (HSV-1, -2), varicella-zoster virus or human herpesvirus-3 (VZV/HHV-3), Epstein–Barr virus or human herpesvirus-4 (EBV/HHV-4), cytomegalovirus or human herpesvirus-5 (CMV/HHV-5), human herpesvirus-6 (HHV-6) (variants A and B), human herpesvirus-7 (HHV-7), and Kaposi's sarcoma virus or human herpesvirus-8 (KSV/HHV-8). Herpesviruses consist of large double-stranded DNA packaged inside an icosahedral capsid. The capsid is surrounded by a mixture of protein tegument and an outer lipid envelope where the viral glycoprotein spikes. The diameter of complete virions is about 200 nm. These herpesviruses produce lytic and latent infection of lymphocytes and other cell types. When latency is established, these cells serve as reservoirs for endogenous viral reactivation during times of immune suppression or as potential vectors of transmission to susceptible individuals. HHV-6, HHV-7, and HHV-8 constitute a diverse group concerning their biology, pathogenesis, and the diseases they produce; HHV-6 and HHV-7 are able to infect a broader array of cell types than HHV-8. Clinical presentation of these herpesviruses ranges from asymptomatic infection or mild illnesses febrile exanthems extending to life-threatening disease in the immune compromised host.

Human herpesvirus-6 (HHV-6)

HHV-6 is a globally dispersed linear, double-stranded DNA molecule that encompasses two distinct variants, the HHV-6A and the HHV-6B. In 2012, the International Committee on Taxonomy of Viruses (ICTV) classified HHV-6A and HHV-6B as separate viruses, replacing species *human herpesvirus-6* with HHV-*6A* and *HHV-6B* in the genus *Roseolovirus*, family *Herpesviridae,* order Herpesvirales. Distinct and common immunological properties and diseases association exist among the two variants (Table 186.1).

Genomic sequencing of these two viruses has shown an overall genetic identity of 90%, with high divergence and functional differences of specific genetic sequences. Interestingly, HHV-6A and HHV-6B demonstrate a unique ability to integrate into human chromosomes in the subtelomeric region (inherited chromosomally integrated HHV-6 [iciHHV-6]). This allows the virus to continue to replicate while other human herpesviruses maintain their genome as a circular episome in latently infected cells. HHV-6 DNA integration is associated with persistent high-level viremia. High-level viremia is uncommon but not rare as it was reported in 3% of blood donors in a British study. One percent of newborns suffer congenital HHV-6 infection; the majority of instances occur in the setting of maternal chromosomal integration. If viral integration occurs in immunocompetent patients, elevated levels of viral DNA in blood, sera, and hair follicles will be found.

TABLE 186.1 **DISTINCT AND COMMON IMMUNOLOGICAL PROPERTIES AND DISEASES ASSOCIATION AMONG THE HHV-6 VARIANTS (A, B)**

	HHV-6A	HHV-6B
CD4+T-lymphocyte tropism	+	+
Neurotropism	+	+
Detection in vitreous fluid samples	+	+
CD8+ T, natural killer, gamma/delta T cells tropism	+	-
Associated more with multiple sclerosis	+	-
Associated more with rhombencephalitis	+	-
Resistant to the antiviral effects of interferon-α and -β	-	+
Most primary infections	-	+
Associated with temporal lobe epilepsy/ status epilepticus	-	+
Associated with Hashimoto's thyroiditis	+	-
Associated with hepatitis in liver transplant patients	+	-
Associated with exanthema subitum	-	+

Epidemiology, shedding, and tissue tropism of HHV-6

HHV-6 maintains a worldwide distribution, and 70% to 100% of adults possess serologic evidence of HHV-6 infection. Seroprevalence is almost 100% in Europe and the United States but in Morocco, seroprevalence comprises 20%. Infection follows 10 to 15 days after the incubation period, and it is generally acquired between the ages of 6 and 15 months. After primary infection, HHV-6A and HHV-6B remain in the host lifelong and viral replication may occur in salivary glands. Shedding of the virus from this site is considered the principal route of transmission. Although different cell surface receptor the CD46 and the CD134 serve as essential entry receptors for HHV-6A and HHV-6B, respectively, other proteins (e.g., GP96), are involved in HHV-6 infection. The cell surface receptors determine the fate of the virus inside the host (e.g., endocytosis). In addition to saliva, HHV-6 DNA could be identified in cord blood, peripheral blood, nasal mucosa, and olfactory bulb specimens, urine, and hair. The HHV-6 can infect a variety of cells like $CD8^+$/CD4+ T lymphocytes, natural killer, liver, endothelial, astrocytes, oligodendrocytes, and microglial cells. Although seroepidemiologic data indicate that breast milk constitutes a not significant source of HHV-6 infection in infancy in the United States, investigators from India found HHV-6 in breast milk in either healthy or HIV-positive women. Saliva remains the presumptive vehicle of transmission from mother to child. The HHV-6 virus may cause serious diseases, particularly in immunocompromised individuals but in immunocompetent as well.

HHV-6 infections in immunocompetent hosts

Primary infection. Primary infection with HHV-6 is experienced by up to 90% of children by the age of 3 years. It is a leading cause of skin rash and fever in children <2 years. Up to 20% of those children will develop an infection associated with high fever (40°C/104°F) for 3 to 5 days. At that point, suddenly the child will experience a rapid defervescence with an accompanying nonpruritic pink papular or maculopapular rash (exanthema subitum, roseola infantum, or sixth disease) on the trunk, face, and neck. The most likely complication from infection with HHV-6 is febrile seizures due to the ability of the virus to pass the blood–brain barrier. Malaise, otitis media, and gastrointestinal and respiratory symptoms are equally common.

Encephalitis. HHV-6 encephalopathy/encephalitis with rash can occur at primary infection in children and adults. It is intriguing that molecular testing revealed HHV-6 DNA in the CSF of 40% of 35 immunocompetent patients with encephalitis of unknown etiology. The spectrum of clinical presentations is broad and could include an altered level of consciousness, seizures, psychosis, acute cerebellar ataxia, and cranial nerve deficits or hemiparesis. Both HHV-6 variants can be recovered from cerebrospinal fluid (CSF), although the A variant is thought to be more neurotropic.

Opsoclonus-myoclonus syndrome (OMS) associated with human herpesvirus-6 rhomboencephalitis. Immunocompetent pediatric patients have been diagnosed with HHV-6 rhombencephalitis. Opsoclonus-myoclonus syndrome characterized by opsoclonus and arrhythmic-action myoclonus predominantly involving the trunk, limbs, and head has been described in adults.

POLG mutations (Alpers-Huttenlocher syndrome). POLG mutations are associated with Alpers-Huttenlocher syndrome, which is an uncommon mitochondrial disease reported in two previously healthy young boys with HHV-6–associated encephalitis. They gradually developed encephalopathy with a refractory movement disorder concurrent with the acquisition of acute HHV-6 infection.

Tick-borne encephalitis and enteroviral meningoencephalitis. In a small recent study of laboratory-proved tick-borne encephalitis, HHV (HSV1, HSV2, VZV, and HHV6) DNA was found in the CSF. This finding implied a possible impact of herpesviruses coinfection on the clinical course and patient outcomes.

Severe, infectious, mononucleosis-like syndrome resulting from a primary HHV-6 infection in immunocompetent adults. As in many other viral illnesses, the severe complications are more common in adults with primary infection; these include a mononucleosis-like syndrome, hepatitis, hemophagocytosis, thrombocytopenia, encephalitis, and/or fatal disseminated disease. HHV-6 may influence the occurrence of demyelinating diseases such as multiple sclerosis and Guillain–Barré syndrome, but a causal role has not been proved and research findings are often contradictory.

HHV-6 infections in immunocompromised hosts

Cytomegalovirus-like illness. Active HHV-6B replication is frequently detected in immunocompromised hosts, such as hematopoietic cell

and solid organ transplant recipients. Most infections are identified 2 to 4 weeks posttransplantation. Clinical syndromes result from reactivation and replication of the HHV-6. These syndromes mimic cytomegalovirus (CMV) infection, including pneumonitis, colitis, hemorrhagic cystitis, encephalitis (most frequently involving the temporal lobe), hepatitis, bone marrow suppression, and graft-versus-host disease. HHV-6 contributes to the frequent occurrence of a skin rash after bone marrow grafting as histology can demonstrate lymphocytic basophilic inclusions and viral DNA. HHV-6 is associated with bronchiolitis obliterans among lung transplant recipients and eventually linked with graft failure. Inherited chromosomally integrated HHV-6 (iciHHV-6) can cause a confusing clinical picture resembling HHV-6 activity concurrently with CMV or HHV-7, making the distinction of the clinical manifestations due to each virus complex.

Viremia in patients with serologic evidence of prior infection. The intensity of HHV-6 viremia is related to the occurrence of clinical manifestations and graft-versus-host disease in allogeneic bone marrow transplant recipients. The extent of viremia is linked to graft failure after solid organ transplantation. Viremia may be extremely common following hematopoietic cell transplantation.

HHV-6 as an opportunistic pathogen in AIDS. HHV-6 could be identified as an opportunistic pathogen in AIDS patients with reported cases of encephalitis, pneumonitis, and retinitis. Combination antiretroviral therapy (cART) appears to have reduced the incidence of serious HHV-6 infections in AIDS.

Drug-induced hypersensitivity syndrome (DIHS)/drug rash with eosinophilia and systemic symptoms (DRESS) in either immunocompromised or immunocompetent patients. Drugs associated with HHV-6 reactivation causing DIHS/DRESS (possibly through various mechanisms) are variable (e.g., carbamazepine, dapsone, allopurinol, trimethoprim-sulfamethoxazole, vancomycin, and naproxen). The skin reaction is characterized by acute, widespread erythema with high fever and multiorgan dysfunction. HHV-6 reactivation associated with DIHS/DRESS may respond to antiherpes treatment although definitive studies have not been performed.

Detection of HHV-6 infection

Detection of HHV-6 DNA in serum or CSF generally means that the patients acquired an active infection. Identification of immunoglobulin M (IgM) antibodies by enzyme-linked immunosorbent assay (ELISA) or indirect immunofluorescence assay (IFA) can differentiate active from latent infection because these antibodies appear during an active infection or 2 to 3 months after. Chronic infections in various tissues can persist with no evidence of IgM antibodies. Primary infection can be demonstrated by serologic conversion in children and adults or by the presence of IgM antibodies in children. The presence of IgM in adults may indicate either primary infection or reactivation from latency. A fourfold increase in serum IgG by IFA indicates recent infection. In classic childhood exanthema subitum, etiologic diagnosis is seldom necessary.

Quantitative polymerase chain reaction (PCR) DNA testing on whole blood can differentiate active from latent infection. An active infection results when the viral load is >200 copies/mL or 20 copies/microgram of DNA. A quantitative tissue biopsy can differentiate between low-level latent virus and active virus. Immunohistochemistry can detect cells with active infection in biopsy or cytologic specimens. While viral culture from peripheral blood remains the gold standard for viral detection, it is not routinely performed. Physicians need to be aware that a negative finding in the serum does not exclude a localized infection in an organ. Additionally, 1% of the population might have iciHHV-6 and therefore, even if they are asymptomatic, a positive HHV-6 DNA test by PCR is crucial.

Treatment of HHV-6 infection

Treatment is recommended for virologically confirmed infection in the setting of posttransplant bone marrow suppression, encephalitis, or pneumonitis. Therapy is usually unnecessary for primary infection in immunocompetent hosts, whereas in infants with exanthema subitum treatment is mainly supportive. The International Herpesvirus Management Forum and American Society of Transplantation Infectious Disease Community of Practice have recommended the initiation of foscarnet therapy in cases of HHV-6 encephalitis. Administration of ganciclovir constitutes an additional risk of hematological toxicity. Because CMV is closely related to both HHV-6A and HHV-6B, clinicians utilize anti-CMV agents such as ganciclovir, cidofovir, and foscarnet against both HHV-6 variants. Another drug with anti-HHV-6 variants activity is artesunate (used for the treatment of malaria), which recently has indicated excellent efficacy against HHV-6 in vitro. Also, brincidofovir (CMX001), a derivative of cidofovir, increased in vitro activity against HHV-6 by a factor of 100. Reduction in the intensity of immunosuppression is recommended when possible. Immunotherapies, such as transfer of HHV-6-specific T cells, proved useful in life-threatening infections among bone marrow transplant recipients. A bank of virus-specific T cells that recognized EBV, adenovirus, CMV, BK virus, and HHV-6 has been developed as an effective approach to combat severe and drug-refractory infections in hematopoietic cell transplant recipients.

Human herpesvirus-7 (HHV-7)

HHV-7 is, in addition, a member of the genus *Roseolovirus*, subfamily *Betaherpesvirinae*, family *Herpesviridae*, and order Herpesvirales. Is similar in terms of morphology and genome sequence to HHV-6; the viruses resemble each other more than they do CMV.

Epidemiology, shedding, and tissue tropism of HHV-7

Infection with HHV-7 predominantly occurs during childhood, and HHV-7 is shed throughout life in saliva. Salivary shedding occurs even more frequently than in the case of HHV-6, and exposure to oral secretions is likely the major mode of transmission. The virus can be detected in breast milk, CSF, cervical tissue, and peripheral blood lymphocytes. Congenital infection is rare if it occurs at all.

HHV-7 infects CD4+ T lymphocytes and, less frequently, CD8+ and immature T cells; it produces latent infection. Reactivation of the virus results from macrophages and/or CD4+ T cells.

HHV-7 infections

Primary infection occurs predominantly in young children, but delayed primary HHV-7 infection can also present in adolescent (e.g., associated with encephalitis or to Guillain-Barré syndrome). The virus has also been linked to febrile seizures and in rare cases with seizures and acute hemiplegia. Coinfection with HHV-6 may play a role in the pathogenesis of this clinical manifestation. Cases of acute encephalitis rarely occur in immunocompetent adults. Exanthem subitum has also been linked to HHV-7 that presented with several days of fever followed by a exanthem subitum pink macular rash that was lighter than that seen with HHV-6, and finally with defervescence. Some evidence indicates that asymmetric periflexural exanthema (atypical exanthem subitum), a unilateral maculopapular eruption mostly seen in children, is associated with HHV-7 infection. An association of HHV-7 with pityriasis rosea and lichen planus has also been suggested.

The detection of HHV-7 DNA in transplant recipient serum is reported variably, and the role of this virus in posttransplant morbidity is not clear. This is because the majority of infections are transient, low-level, and not associated with any clinical manifestations. While HHV-7–related disease in hematopoietic cell transplant recipients is considered rare, the virus has been implicated in fever, rash, bone marrow suppression, thrombocytopenia, acute myelitis, and organ involvement.

Detection of HHV-7 infection

Infection is ubiquitous; serum antibodies can be identified in >85% of adults. Also, cross-reactivity between HHV-6 and HHV-7 in some assay systems may have complicated early studies of the viruses. A multiplex PCR method was developed and indicated a marked distinction between the amplicons of HHV-6 and HHV-7 without loss of sensitivity or specificity. ELISA might remain a valuable tool for the serological study of HHV-7 infection since the glycoprotein of the HHV-7 is highly conserved and induces a specific human immune response.

Treatment of HHV-7 infection

Few research data are available to guide treatment. Foscarnet or cidofovir are recommended for the clinically evident disease. HHV-7 appears resistant to ganciclovir, acyclovir, and penciclovir.

Human herpesvirus-8 (HHV-8)

HHV-8 is a member of the *Gammaherpesviruses* family along with HHV-4. HHV-8 or Kaposi's sarcoma–associated herpesvirus (KSHV) causes Kaposi's sarcoma (KS), primary effusion lymphoma (PEL), and multicentric Castleman disease (MCD).

Epidemiology, shedding, and tissue tropism of HHV-8

HHV-8 DNA has been recovered in semen and prostate samples as well as from oropharyngeal secretions. Transmission via blood products and tissue grafts is possible. For example, HHV-8 is transmitted to 25% to 33% previously uninfected recipients of solid organ grafts taken from an HHV-8-seropositive donor. Moreover, HHV-8 can be identified in blood from healthy donors, thus implying transmission from blood products, but this did not appear to occur commonly. The virus targets a variety of cell types, including B lymphocytes and Langerhans, monocyte-derived dendritic, and vascular endothelial cells. Lytic and latent infections occur. Lytic infection is characterized by the transcription of a wide array of viral genes producing gene products with immunomodulatory functions that participate in the pathogenesis of HHV-8–related conditions. Relatively few viral gene products are expressed in latently infected cells. In 2010, HHV-8 was declared a Group 1 carcinogenic agent by the International Agency for Research on Cancer, highlighting its public health significance. HHV-8 seroprevalence varies among geographic regions; for example, prevalence is high in Uganda (50%) and relatively low in the United States or Switzerland (6%). In central Africa, where KS was common before the HIV epidemic, the prevalence of HHV-8 infection increased from 39% to 48% in adolescents. In the United States, men who had sex with men and persons with HIV infection were at increased risk for HHV-8 infection.

In the absence of deficiencies of T-lymphocyte function, HHV-8 infection is clinically unremarkable. A viral version of interleukin-6 (*v*IL-6) appears to carry out a particularly important role in the inflammatory nature of HHV-8–related malignancies. The prevalence of HHV-8 infections in various populations and geographic regions is summarized in Table 186.2.

TABLE 186.2 **ESTIMATED PREVALENCE OF HHV-8 INFECTION IN VARIOUS GEOGRAPHIC REGIONS AND POPULATIONS**

Population	Prevalence[a]
General population in United States	1–5%
General population in sub-Saharan Africa	50%
General population in the Mediterranean	10–40%
General population in most parts of Asia	0–20%
MSM in United States and Europe	20–60%
Women in the general population in Nigeria	46.02%
Women in the general population in Spain	3.65%
FSWs in Central Africa	51%
FSWs HIV-positive in Honduras	36%
HIV pregnant women in Central Africa	37%
General population HIV-negative in Cameroon	80%
General population HIV-positive in Cameroon	81%
Solid organ recipients	5–10%

[a] Prevalence rates depend on type of diagnostic test, are higher with lytic antigen.
FSWs, female sex workers; MSM, men who have sex with men.

HHV-8–associated malignancies

Kaposi's sarcoma. Moritz Kaposi first described classic KS in 1872 as a rare skin tumor seen primarily in elderly men of Mediterranean or Ashkenazi Jewish origin. KS could present as (1) indolent classic KS that typically affects elderly men from the Mediterranean region with slow-growing lesions confined to the skin, (2) endemic KS in men and women from sub-Saharan African regions that is very aggressive and not related to HIV infection, and (3) AIDS-related or epidemic KS that can range from isolated skin lesions to more aggressive and rapidly disseminated disease. AIDS-related KS is more prevalent among men who have sex with men than in other HIV exposure groups (injection drug users). cART plays a protective role in the development of KS. An immune reconstitution phenomenon occurs either by the onset of KS or in worsening of existing KS lesions after initiation of cART. Generally, cART can be continued through immune reconstitutional KS but fatal disease has been reported. The incidence of KS among HIV-infected persons has considerably decreased in recipients of cART. Finally, KS could present as iatrogenic-associated KS occurring primarily in solid organ transplant recipients due to corticosteroids and/or cyclosporine A and/or other immunosuppressive drugs.

The occurrence of KS is associated with impaired natural killer lymphocyte responses characterized by altered surface receptor expression; resolution of this immune impairment can result in clinical regression. Early KS lesions appear as painless, faint red-violet or brown macules on legs, feet, or face that increase in size. Typically, untreated KS evolves from the skin to mucosal tissues; to lymphatics, often with lymphedema; and then to internal organs (e.g., colon and lungs). While KS remains a relatively typical form of cancer among solid organ transplant recipients, it occurs infrequently.

Multicentric Castleman's disease (MCD and MCD-associated plasmablastic lymphoma). MCD is a rare lymphoproliferative B-cell condition characterized by multicentric angiofollicular hyperplasia. It is associated with fever, lymphadenopathy, weight loss, and hepatosplenomegaly. Laboratory abnormalities include polyclonal hypergammaglobulinemia, hypoalbuminemia, cytopenias, elevated C-reactive protein, and high serum levels of IL-6. HHV-8–related MCD appears to be distinct from types unlinked to the virus and virtually inevitably occurs with HIV infection. By contrast with KS, the occurrence of MCD has not declined in the era of potent antiretroviral treatment. HHV-8 DNA sequences are found in the polyclonal plasmacytoid cells within lymph nodes that are diagnostic for HHV-8–associated MCD. The unique microRNA signatures of the virus sequences in patients with MCD may contribute to viral pathogenesis. Survival with MCD is variable, and the clinical course is remissive with severe flares associated with the intensity of HHV-8 viremia. No standard therapy exists for HHV-8 MCD though responses to antiretroviral and antiherpes drugs, humanized monoclonal anti-IL-6 receptor antibody, cytotoxic chemotherapies, anti-CD20 monoclonal antibody (rituximab), and/or glucocorticoids do occur. MCD can transition to a large B-cell non-Hodgkin's lymphoma. MCD has also been reported in allograft recipients.

Primary effusion lymphomas (PEL) or body cavity-based lymphoma (BCBL). This is a rare non-Hodgkin's lymphoma of B-cell origin occurring among persons with marked immunologic dysfunction, most commonly due to HIV infection. It is also involved in the posttransplantation setting and in elderly patients in areas where HHV-8 is endemic. PELs present as a neoplastic effusion of the pleural (most common site), pericardial, and peritoneal cavities in the absence of a solid tumor mass. PEL diagnosis requires typical body cavity malignant effusions and the presence of HHV-8; no other lymphomatous effusion expresses HHV-8. Solid lymphomas have been reported prior to and subsequent to PEL. In general, the prognosis of PEL is poor, though some HIV-infected patients demonstrate improvement after initiation of cART. In addition, noncurative but significant responses have been reported after the intracavitary administration of cidofovir, an antiviral drug with broad efficacy. PEL has also been reported in allograft recipients.

Detection of HHV-8 infection

Immunohistochemical staining of tumors with antibodies recognizing the HHV-8–encoded latency-associated nuclear antigen (LANA) and tissue examination are needed for the diagnoses of KS, MCD, and PEL. Also, molecular techniques can identify HHV-8 DNA within tumor tissue. Standardized methods for the detection of HHV-8 infections have yet to be established. Prevalence rates depend on the testing method as well as the population being evaluated. Indirect immunofluorescence and enzyme immunoassays have been developed for the detection of antibodies to lytic and latent HHV-8 antigens. Antibody assays range from 80% to 98% sensitivity in KS patients when compared to molecular techniques. The pattern of reactivity to lytic versus latent antigens does not appear to impart much clinical information.

Treatment of HHV-8 infection

Traditional treatment for KS, MCD, and PEL include reduction or elimination of any immunosuppressive treatment, chemotherapy, and/or radiation therapy. cART should be administered to all patients with HIV and KS, PEL, or MCD, although insufficient evidence exists. The clinical course of AIDS-related KS has improved considerably in the years since the introduction of cART, especially in patients with visceral or disseminated cutaneous KS involvement. Also, liposomal doxorubicin is preferred as first-line therapy for KS. Although limited data are available for PEL treatment, a combination of cyclophosphamide, doxorubicin, vincristine, and prednisolone (CHOP) with ART chemotherapy should be administered. For patients with concurrent diagnoses of KS and MCD, use of both rituximab and liposomal doxorubicin is recommended. Therapeutic monoclonal antibodies targeting either IL-6 or the IL-6 receptor have also proved effective for some MCD patients. Ganciclovir, cidofovir, and foscarnet effectively inhibit HHV-8 and may be used with modifications of immune suppression.

Influenza

Ramin Sedaghat Herati and Harvey M. Friedman

Influenza infections have caused significant morbidity and mortality throughout recorded human history. Each year, seasonal influenza is estimated to cause around 500,000 excess deaths worldwide. At least 32 pandemics have occurred since 1580 in addition to the seasonal waves of influenza infection. In 1918, a particularly severe pandemic, dubbed the "Spanish flu," led to the rapid spread of influenza and resulted in at least 20 million deaths worldwide. Recently, the possibility of a worldwide pandemic due to pathogenic avian influenza viruses has become of great concern. Significant resources worldwide have been dedicated to the detection and containment of influenza outbreaks and the development of response plans to influenza epidemics at international, national, and local levels.

Influenza viral structure

Influenza viruses are enveloped, single-stranded, negative-sense RNA viruses in the family Orthomyxoviridae, which include the genera Influenzavirus types A, B, and C. Influenza viruses are spherical and 80 to 120 nm in diameter. Influenza A and B viruses cause the majority of human infections with influenza, whereas influenza C virus causes only sporadic upper respiratory infections. Influenza A viruses can cause infections in birds as well as humans, swine, and other mammals.

Influenza virus has an envelope composed of a lipid bilayer, with a layer of matrix protein on the inner surface and spike-like surface projections of glycoproteins on the outer surface. These glycoproteins include hemagglutinin and neuraminidase. Hemagglutinin is responsible for binding to those cells of the respiratory tract expressing sialic acid. Once endocytosed, hemagglutinin then fuses with the endosome membrane and releases viral ribonucleoproteins into the cytoplasm, which leads to viral replication. In contrast, neuraminidase primarily functions in the last stage of cellular infection by enzymatic cleavage of sialic acid and release of mature virions from the cell surface. Within the envelope of influenza A and B are eight segments of viral RNA encoding polymerase proteins A, B1, and B2; hemagglutinin; neuraminidase; matrix proteins M1 and M2; nucleocapsid protein; and nonstructural proteins NS1 and NS2.

Epidemiology

Antigenic drift and shift

One of the most remarkable features of influenza virus is the frequency of its antigenic changes, known as *antigenic drift* and *antigenic shift*, which contribute to incomplete immunity to future influenza viral infections. Antigenic shift and antigenic drift principally involve the two external glycoproteins of the virus, hemagglutinin and neuraminidase. Antigenic drift occurs commonly and is due to point mutations in the hemagglutinin or neuraminidase genes, which may result in alteration of the immunological targets

for antibodies generated by prior infections. Antigenic shift, on the other hand, occurs infrequently and results from major genetic reassortments between human and animal viral strains. Antigenic drift is primarily seen in influenza A viruses but can be seen in influenza B viruses as well.

Antigenic shifts can produce immunologically novel strains of influenza A that herald the epidemics and worldwide pandemics. In 2009, infections with a novel H1N1 virus, thought to derive from reassortment of avian, swine, and human influenza viruses, resulted in a pandemic. First recognized as a major threat in April 2009, the virus spread rapidly and may have resulted in >300,000 deaths within 15 months worldwide. Three subtypes of hemagglutinin, H1 (variants H0, H1, Hsw1), H2, and H3, and two subtypes of neuraminidase, N1 and N2, are recognized among human influenza A viruses. Only a few strains of influenza A or B virus tend to dominate during each annual influenza season. The World Health Organization (WHO) is leading the global effort to detect and characterize influenza outbreaks before they become pandemics.

Pathogenic avian influenza strains can sometimes cross species and cause human infections. For example, avian H5N1 was originally thought to be endemic in many wild bird populations and not pathogenic in humans. However, beginning in 1997, multiple cases of laboratory-confirmed human H5N1 infection have been reported annually. Unfortunately, humans have little preexisting immunity to H5N1, and an overall case fatality rate of 60% has been observed. Isolated human-to-human transmission has been observed, but the vast majority of cases have occurred in individuals in close contact with infected birds without subsequent human-to-human transmission. In 2013, another avian-origin virus, H7N9, was identified in China as a cause of severe respiratory tract infections with a 39% case fatality rate. In contrast to H5N1, infected birds are asymptomatic and thus environmental surveillance has been challenging. For both H5N1 and H7N9, significant effort has been placed into surveillance and rapid culling of bird populations as a means to limit spread.

Transmission

Most influenza infections are acquired through human-to-human transmission of small-particle aerosols. Localized clusters of infection begin rather abruptly, reach a sharp peak in 2 to 3 weeks, and wane in incidence over the subsequent 5 to 6 weeks. Attack rates during such outbreaks can approach 10% to 40%. Although influenza is virtually always active somewhere in the world, seasonal influenza is most common during the winter months. The peak influenza season typically extends from December through April in the Northern Hemisphere. *Influenza season* is defined by viral isolation, whereas an *epidemic* is defined by a rise in pneumonia and influenza deaths above the epidemic threshold in the US Centers for Disease Control and Prevention (CDC)'s nationwide mortality surveillance system. Although influenza can affect all individuals in a population, severe infections resulting in hospitalization during most influenza seasons generally occur among adults >65 and children aged 0 to 4 years.

Immunology

Influenza infection results in activation of the innate and adaptive arms of the immune system. Upon initial infection, innate pattern-recognition receptors including Toll-like receptor 7 (TLR7) "sense" the infection and lead to pro-inflammatory cytokine production. Dendritic cells acquire and present influenza antigens to T cells, which leads to stimulation of the adaptive immune system. Naïve and memory T cells, including CD4 and CD8 subsets, then mediate a variety of responses including recruitment of additional immune effectors, direct killing of infected cells, and B-cell help. Neutralizing antibodies are produced by B cells and block the ability of free influenza virions from infecting additional cells. After a successful immune response, tissue repair takes place and inflammation returns to baseline, along with the death or egress of most of the responding immune cells. Memory T and B cells are established that respond more quickly to subsequent infections. For many decades, neutralizing antibody titers have been used as a strain-specific correlate of protection against future infections. A titer of ≥1:40 indicates that an individual is likely protected. However, this correlate has limitations. Some individuals with low titers of neutralizing antibodies are resistant to infection in experimental challenge models, whereas some with very high titers become infected. Work to develop better correlates of protection is ongoing.

Clinical manifestations

Uncomplicated influenza

Classic influenza is characterized by the abrupt onset of symptoms including fever, headaches, and myalgias after an incubation period of 1 to 4 days. Systemic symptoms predominate initially, including chills or rigors, malaise, and anorexia. Severe intraocular muscle pain can often be elicited on lateral gaze. Calf muscle myalgia may be particularly prominent in children. The systemic symptoms usually persist for approximately 7 days and then wane. Respiratory symptoms, such as dry cough and nasal discharge, emerge early during the illness and begin to dominate the clinical presentation as fever resolves. Cough is the most common symptom and can take several weeks to resolve.

Complications of influenza

The complications of influenza can be classified as pulmonary and nonpulmonary and result either from progression of the viral process itself or from secondary bacterial infections. Influenza can be associated with a primary influenza viral pneumonia and/or a secondary bacterial pneumonia (Table 187.1). Nonpulmonary complications of influenza occur less often and are most prevalent during large outbreaks. These include myositis (more common with influenza B infection), myocarditis, pericarditis, transverse myelitis, encephalitis, and Guillain–Barré syndrome. A toxic shock–like syndrome has occurred in previously healthy children and adults during outbreaks of influenza A or B. This syndrome has been attributed to

TABLE 187.1 **PULMONARY COMPLICATIONS OF INFLUENZA**

Feature	Primary viral pneumonia	Secondary bacterial pneumonia
Setting	Cardiovascular disease, pregnancy, young adults (in large outbreaks)	Age >65 years, chronic pulmonary, cardiac, or metabolic disease
History	Rapid progression after typical onset	Biphasic illness, with worsening after initial clinical improvement
Physical examination	Diffuse crackles	Diminished breath sounds, egophony, bronchophony
Sputum culture	Normal oral flora	Streptococcus pneumoniae Staphylococcus aureus *Haemophilus influenzae*
Isolation of influenza virus	Yes	No
Chest radiograph	Diffuse bilateral interstitial disease	Lobar consolidation
Response to antibiotics	No	Yes
Mortality	Variable, high during some pandemics	Variable, generally low

the effects of the viral infection on the colonization and replication characteristics of toxin-producing staphylococci. Reye's syndrome has also been described in children treated with aspirin during influenza outbreaks. The major causes of death are pneumonia and exacerbation of chronic cardiopulmonary conditions. Of those who die, 80% to 90% are aged 65 years or older.

H5N1 infection

Most cases of H5N1 have occurred in healthy young adults, approximately 2 to 4 days after exposure to infected birds. Initial symptoms include high fever and an influenza-like illness. In contrast to infection with human influenza viruses, lower respiratory tract involvement and clinically apparent pneumonia are almost universal. Watery diarrhea may be present before the development of respiratory symptoms. Progression to multiorgan failure, including respiratory, renal, and cardiac failure is common. Atypical presentations, such as encephalopathy, gastroenteritis, and mild respiratory disease, have been reported, but frequencies of such presentations are unknown. Death occurs on average 9 to 10 days after the onset of illness. Asymptomatic infection likely occurs as well, as indicated by antibody screens in populations at risk, but the true incidence is unknown.

Diagnosis

A clinical diagnosis based on fever, headache, myalgias, and cough during influenza season has an accuracy of 60% to 85%. However, influenza cannot be distinguished from other respiratory viruses by symptoms alone, and typically other respiratory viruses are often in circulation concurrently during the winter months. Reverse transcriptase-polymerase chain reaction (RT-PCR) assays are extremely sensitive, specific, and rapid, which has made them the standard for diagnosis. Other rapid assays include immunofluorescence, which requires skilled expertise and has lower sensitivity than RT-PCR, and viral antigen studies that are rapid but typically do not give information on the specific viral strain. Viral culture is utilized in some areas but can take days for a result. Serologic tests to measure hemagglutinin neutralizing antibody titers in acute and convalescent sera are not recommended by the CDC for diagnosis due to difficulty in obtaining a convalescent serum and the delay required to establish the diagnosis.

Therapy

Multiple classes of antiviral drugs are available for treatment of influenza. Zanamivir and oseltamivir are two neuraminidase inhibitors (NIs) approved for treatment of both influenza A and B infection by inhibiting neuraminidase activity and thereby preventing viral particle release from infected cells. Zanamivir has poor oral bioavailability and is formulated for oral inhalation using a disk inhaler. Oseltamivir is the ethyl-ester prodrug of the active compound and is well absorbed orally. A third NI is peramavir, which is available as an intravenous formulation. When given within 48 hours after the onset of symptoms, NI decrease the duration of symptoms by about 24 hours. Meta-analyses indicate a reduction in the incidence of influenza-related complications including pneumonia and bronchitis when administered early during the course of an infection. There are insufficient data as to whether NIs are effective treatment of these complications once they occur, but they may have some modest benefit. These agents are generally well tolerated, although zanamivir can cause bronchospasm and respiratory compromise in patients with chronic respiratory diseases. Despite resistance developing during treatment with oseltamivir in up to 25% of individuals, transmission of resistant strains is uncommon.

The M2 inhibitors, amantadine and rimantadine, are an older class of drugs used for treatment of influenza A. The M2 inhibitors prevent viral replication by blocking the M2 protein ion channel, thus preventing fusion of the virus and host cell membranes. Both drugs have been shown to reduce the duration of symptoms of clinical influenza but have been associated with several adverse effects. For example, amantadine causes reversible central nervous system

(CNS) toxicities, including insomnia, dizziness, nervousness, and difficulty concentrating, especially in the elderly. Viral resistance to M2 inhibitors has increased over time among influenza A isolates, and their use has not been recommended during recent influenza seasons.

Baloxavir represents the first drug in a new class of influenza antivirals. Approved in 2018 for the treatment of influenza A, baloxavir inhibits influenza cap-dependent endonuclease. In the studies that led to its approval, a single dose of baloxavir reduced duration of symptoms by 1 day compared to placebo and was similar in effect to oseltamivir. Moreover, baloxavir has shown activity against avian H7N9 and H5N1 strains. Other agents in development include the polymerase basic protein 1 (PB1) inhibitor favipiravir, and the polymerase basic protein 2 (PB2) inhibitor pimodivir.

Prevention

Vaccine

Vaccination is the mainstay of influenza prevention. Because influenza viruses undergo frequent antigenic alterations, the vaccine is reformulated annually with strains predicted to predominate in the upcoming winter epidemic. The CDC, in conjunction with the WHO, tracks influenza activity throughout the world to predict the components of the annual influenza vaccine. Vaccines generally target two strains of influenza A and one or two strains of influenza B. The protective efficacy of influenza vaccination depends on the similarity between the viruses used in the vaccine and those in circulation, as well as an individual's age and immune status. In young healthy adults, a well-matched vaccine is 60% to 70% effective at preventing influenza illness. During poorly matched seasons, efficacy decreases substantially. In adults >65, efficacy is often much lower than in young healthy adults. Among people living with HIV, efficacy is lowest among those with low CD4 counts (≤200/mm^3) and uncontrolled HIV viremia. Individuals receiving antiretroviral therapy probably derive protection from vaccination but not as effectively as HIV-uninfected adults. Similarly, solid organ transplant recipients likely also derive less benefit from vaccination. However, vaccination may still be effective at decreasing hospitalization, secondary complications, and death due to influenza even if efficacy against primary infection is poor.

Several options exist for influenza vaccination. The inactivated influenza intramuscular vaccine (IIV) is the most commonly administered version and is more immunogenic in adults, whereas the live attenuated intranasal vaccine (LAIV) is less frequently used and is more immunogenic in children. Several options for IIV exist, including a high-dose IIV vaccine that is more immunogenic in older adults than conventional IIV and a recombinant IIV that reduces vaccine production time and eliminates the need for eggs. Influenza vaccines are generally unadjuvanted, but a new vaccine combining the oil-in-water adjuvant MF59 with three inactivated strains was approved in 2015 for adults ≥65 years.

Contraindications to influenza vaccination are few. Individuals who have a severe allergic reaction to influenza vaccination should not be vaccinated, although such cases are exceedingly rare. Individuals with moderate or severe acute febrile illnesses usually have vaccination delayed until their symptoms have abated, due to likely reduced effectiveness. However, minor illnesses with or without fever are not a contraindication. The LAIV is approved only for healthy, nonpregnant individuals between ages 2 and 49 years. Although a history of Guillain–Barré syndrome after vaccination and egg allergies is not a formal contraindication to vaccination, extra precautions should be taken when vaccinating these individuals. The optimal time for organized vaccination campaigns for persons in high-risk groups is typically October through December. Recommendations for the use of influenza vaccine are listed in Table 187.2.

Chemoprophylaxis

Chemoprophylaxis is an important adjunct to vaccination. Vaccination-induced neutralizing antibodies to influenza peak

TABLE 187.2 **AVAILABLE SEASONAL INFLUENZA VACCINES.**

Vaccine	Recommended recipients	Contraindications
Inactivated influenza vaccine (IIV)	All individuals >6 months of age	History of severe allergic reaction to this vaccine[a]
Inactivated influenza vaccine (IIV), high dose	Age 65 and older	History of severe allergic reaction to this vaccine[a]
Live attenuated influenza vaccine (LAIV)	Healthy, nonpregnant, ages 2–49 years	History of severe allergic reaction to this vaccine[a] Immunosuppressed patients, healthcare personnel in close contact with immunosuppressed populations, children with history of asthma or severe wheezing
Recombinant influenza vaccine	Ages 18–49	History of severe allergic reaction to this vaccine[a]
Adjuvanted influenza vaccine	Age 65 and older	History of severe allergic reaction to this vaccine[a]

[a] Individuals with active moderate or severe febrile illness usually should not be vaccinated until symptoms have abated. Individuals with a history of egg allergy may receive these vaccines if administered with additional observation and safety measures. History of Guillain–Barré syndrome within 6 months of receipt of an influenza vaccine is considered to be a precaution for future vaccinations.
Adapted from Interim Recommendations: Prevention and Control of Influenza with Vaccines: Recommendations of the Advisory Committee on Immunization Practices (ACIP), 2013.

at 2 to 3 weeks after vaccination. Thus chemoprophylaxis may be considered in high-risk individuals until immunity develops. Some high-risk individuals, such as organ transplant recipients, have poor responses to vaccination and should be considered for additional protection with chemoprophylaxis. Chemoprophylaxis may also be effective at controlling outbreaks in chronic care settings.

Oseltamivir and zanamivir are available for prophylaxis of influenza A and B for patients at high risk of influenza complications or those who cannot receive influenza vaccine. Zanamivir, at a dosage of 10 mg/d over a 4-week period, and oseltamivir, at 75 mg/d over a 6-week period, reduced laboratory-confirmed cases in healthy adult volunteers by 82% and 84%, respectively. Both drugs are also effective at decreasing secondary spread of influenza. Lower rates of influenza among household contacts of suspected cases of influenza were documented in patients who took zanamivir for 10 days or oseltamivir for 7 days compared with placebo. In addition to neuraminidase inhibitors, baloxavir marboxil has been approved for chemoprophylaxis as well.

Pandemic preparedness

The emergence of the avian influenza virus, H5N1, has raised awareness of the possibility of a severe, worldwide influenza pandemic. By some estimates, 30% or more of individuals could become ill during a pandemic. Healthcare systems will likely become overwhelmed, and supplies such as vaccines, antivirals, antibiotics, ventilators, and personal protective equipment will be in short supply. Very likely, there will not be adequate hospital beds to meet healthcare needs. Public health measures, including school closings, travel bans, and individual quarantine, may cause significant social disruption. Absenteeism could exceed 40% and have profound effects on commerce, the economy, and the supply of goods and services.

Proper planning could lessen the effects of a pandemic on society. Preparedness on federal, state, and local levels is crucial, but business and healthcare sectors as well as individuals must also prepare. Hospitals, clinics, and long-term care facilities are encouraged to develop pandemic preparedness plans that include the development of surveillance systems for identifying potential outbreaks, plans for communication (i.e., with public officials, employees, and patients), strategies for dealing with surges in patient volume (including triage, admissions, cohorting, and facility access), and protocols for dealing with sick and exposed employees and the reassignment of worker duties. Other important issues include developing guidelines for the distribution of antivirals, vaccines, and medical supplies that may be limited. Healthcare workers should also encourage patients to develop their own pandemic preparedness plans with their families.

The CDC provides checklists, guidelines, and suggestions for pandemic planning in healthcare, family, school, business, and community, state, and local government settings. Given the likely limited availability of vaccine and antiviral medication during the initial waves of a pandemic, the CDC is also promoting nonpharmacologic interventions to limit transmission of the virus. This strategy has been termed *targeted layered containment* and includes isolation of ill persons and voluntary quarantine of household contacts, social distancing measures (i.e., school closure, increased use of telecommuting in the workplace, and masks in public settings), cancellation of public events and public gatherings (including closure of houses of worship), and individual infection control measures (such as hand hygiene and cough etiquette). These measures may help limit viral spread during a pandemic and reduce morbidity and mortality. The COVID-19 pandemic has demonstrated the value of public health measures to help mitigate morbidity and mortality during a pandemic.

Coronavirus-19

Smitha Gudipati, Gina Maki, Marcus Zervos, and Mayur Ramesh

Overview

Coronaviruses are a large group of viruses that can infect humans as well as many animal species. They result in a wide range of primarily respiratory illnesses in humans. Coronavirus epidemics first originated in 2002, with the severe acute respiratory syndrome coronavirus (SARS-CoV), first reported in Guangdong Province and thought to have originated in bats. The second large epidemic from a coronavirus occurred 10 years later, in 2012, in Saudi Arabia, now referred to as the Middle East respiratory syndrome coronavirus (MERS-CoV). MERS-CoV is also a zoonotic disease thought to originate in bats and was transmitted to a large reservoir, the dromedary camel. Most recently, a third coronavirus has swept around the globe from 2019 to 2020, now termed the severe acute respiratory syndrome coronavirus 2 (SARS-CoV-2) causing hundreds of thousands of deaths.

Epidemiology

The coronavirus-19 disease (COVID-19) caused by SARS-CoV-2 was declared a pandemic by the World Health Organization (WHO) on March 11, 2020. The first cases were reported in the city of Wuhan, Hubei Province, in December 2019, after presenting as a cluster of pneumonia cases of unknown etiology. By January 23, 2020, Wuhan declared a state of emergency and implemented a travel ban, with a reported 571 cases of COVID-19 across 25 provinces (districts and cities) in China. By January 30, 2020, China had confirmed 7,734 cases, with 90 other cases reported across a number of countries including Taiwan, Thailand, Vietnam, Malaysia, Nepal, Sri Lanka, Cambodia, Japan, Singapore, Republic of Korea, United Arab Emirates, United States, The Philippines, India, Australia, Canada, Finland, France, and Germany. Over the following months, the virus continued to spread rapidly around the world. As of September 1, 2020, there were 25,602,665 confirmed cases and 852,758 deaths worldwide, with every continent affected except Antarctica.

The original cases were traced back to the Huanan seafood market where seafood as well as exotic animals such as snakes, birds, and bats were sold. With genome sequencing finding a 96% match to a known bat coronavirus, it was suspected that bats were the original source of the SARS-CoV-2 virus. By February, a study from China revealed the possibility of person-to-person transmission of the virus. Current data suggest the virus is spread by respiratory droplets, with a range of transmission of 6 feet (or about 2 meters). Droplets, however, have also been noted to spread further and possibly become aerosolized with activities such as coughing and sneezing. Fomites are also a noted source, with transmission from an infected surface to a person's hands and subsequently to mucous membranes. SARS-CoV-2 has been detected in nonrespiratory specimens, including stool, blood, ocular secretions, and semen. However, the role of transmission via these routes is unclear. To date there has been no evidence to support the transmission through contact with non–mucous membrane sites. Few reports suggest the possibility of vertical transmission from mother to baby,

however this is thought to be rare, with a more common cause of neonatal COVID-19 disease from respiratory droplets after birth. SARS-CoV-2 transmission has been well documented from asymptomatic individuals and has played a major role in the spread of the COVID-19 pandemic.

Microbiology

Coronaviruses are members of the Coronaviridae family. They are divided into alphacoronavirus and betacoronavirus that can only infect mammals, and gammacoronavirus and deltacoronavirus, which mostly infect birds. SARS-CoV-2 is a betacoronavirus, an enveloped, positive, single-stranded RNA surrounded by spike glycoproteins that can infect animals and humans (Figure 188.1).

Pathogenesis

SARS-CoV-2 enters the cell through membrane fusion. The first step of the SARS-CoV-2 replicative cycle is attachment of the virus to angiotensin-converting enzyme-2 (ACE-2) glycoprotein, which has a preference for lung epithelial cells. However, ACE-2 is also expressed in the small intestine, kidneys, heart, thyroid, and adipose tissue. The receptor binding domain of the spike protein then latches onto the ACE-2 receptor, followed by cleavage of the spike protein by host transmembrane protease, serine 2 proteases (TMPRSS2), to expose fusion peptides able to fuse the viral and cell membranes.

Once SARS-CoV-2 enters a human cell, the virion releases its RNA in the cytoplasm. Translation and replication occur, and new virions are then released from the cell through exocytosis. In COVID-19, the immune response can be explosive, creating a hyperinflammation syndrome during the second week of the COVID-19 infection.

A cytokine response usually occurs approximately 8 days after symptom onset, and this often requires intensive care support, mechanical ventilation, and is associated with inflammatory factor elevation including interleukin (IL)-6, IL-1B, IL-8; interferon (INF)-y, tumor necrosis factor (TNF)-α; monocyte chemoattractant protein (MCP)-1, and interferon γ-induced protein (IP-10). IL-6 elevation in the serum correlates with acute respiratory distress syndrome and multiple-organ failure.

Clinical manifestations

The incubation period ranges from 2 to 14 days, with an average of 5 days. The mode of transmission is through respiratory droplets (primary mode) or contact with contaminated objects and surfaces. Aerosolized particles (<5 microns) can be generated during certain procedures. The virus can survive <24 hours on cardboard, <72 hours on plastic or steel. Symptoms and risk factors associated with COVID-19 are listed in Table 188.1.

The WHO has stratified COVID-19 disease based on severity. Although approximately 15% of patients are asymptomatic, the spectrum ranges from mild to critical disease (Table 188.2).

Other complications that have been described in COVID-19 patients include acute, life-threatening conditions such as acute pulmonary embolism, acute coronary syndrome, myocarditis, acute stroke, and delirium. Clinical suspicion for these complications should be heightened when caring for COVID-19 patients, and appropriate diagnostic and treatment protocols are available.

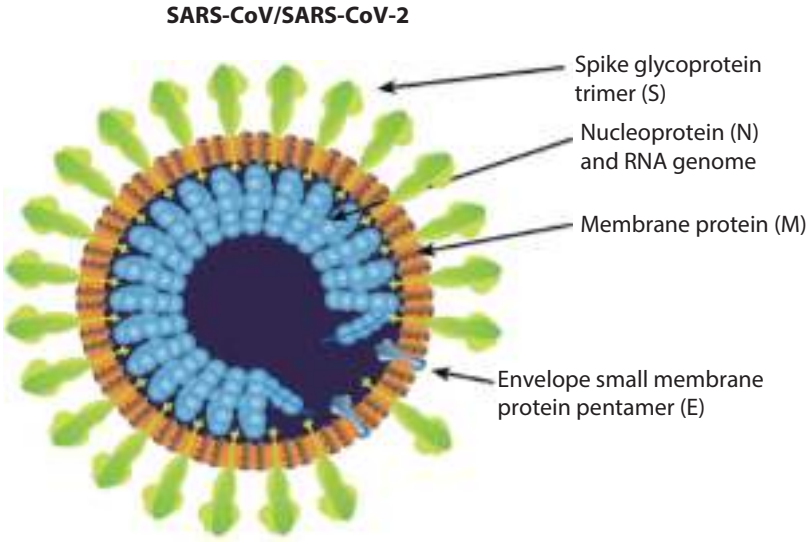

FIGURE 188.1 Molecular image of SARS-CoV-2, which is a Betacoronavirus, enveloped, positive single-stranded RNA surrounded by spike glycoproteins.

TABLE 188.1 **SYMPTOMS AND RISK FACTORS ASSOCIATED WITH COVID-19**

Clinical presentation	Most persons experience fever (83–99%), cough (59–82%), fatigue (44–70%), anorexia (40–84%), shortness of breath (31–40%), myalgias (11–35%). Other nonspecific symptoms, such as sore throat, nasal congestion, headache, diarrhea, nausea, and vomiting, have also been reported. Loss of smell (anosmia) or loss of taste (ageusia) preceding the onset of respiratory symptoms has also been reported.
Risk factors for severe disease	Age >60 years (increasing with age). Underlying noncommunicable diseases (NCDs): obesity, smoking, diabetes, hypertension, cardiac disease, chronic lung disease, cerebrovascular disease, chronic kidney disease, immunosuppression, and cancer have been associated with higher mortality.

COVID-19 in special populations

Transplant population

Early reports have suggested poorer outcomes in solid organ transplant recipients with COVID-19 because of chronic immunosuppression and higher rates of comorbidities. In a case control study done at Henry Ford Hospital in Detroit, Michigan, a greater proportion of COVID-19–positive solid organ transplant recipients had coexisting conditions, particularly congestive heart failure, diabetes, chronic kidney disease, and hypertension, compared to non-transplant patients. Interestingly, despite this observation, mortality and other

TABLE 188.2 **SPECTRUM OF COVID-19 DISEASE SEVERITY**

Symptomatic infection	
Mild to moderate disease (80% of patients)	Symptomatic patients (Table 188.1) meeting the case definition for COVID-19 without evidence of viral pneumonia or hypoxia. Adolescent or adult with clinical signs of pneumonia (fever, cough, dyspnea, fast breathing) but no signs of severe pneumonia, including SpO_2 ≥90% on room air. Child with clinical signs of non-severe pneumonia (cough or difficulty breathing + fast breathing and/or chest indrawing) and no signs of severe pneumonia. Increased respiratory rate (in breaths/min): <2 months: ≥60; 2–11 months: ≥50; 1–5 years: ≥40.
Severe disease (14% of patients)	Adolescent or adult with clinical signs of pneumonia (fever, cough, dyspnea, fast breathing) plus one of the following: respiratory rate >30 breaths/min; severe respiratory distress; or SpO_2 <90% on room air. Child with clinical signs of pneumonia (cough or difficulty in breathing) + at least one of the following: 1. Central cyanosis or SpO_2 <90%; severe respiratory distress (e.g., fast breathing, grunting, very severe chest indrawing); general danger sign: inability to breastfeed or drink, lethargy or unconsciousness, or convulsions. 2. Increased respiratory rate (in breaths/min): <2 months: ≥60; 2–11 months: ≥50; 1–5 years: ≥40.
Critical disease (6% of patients) **Sepsis** **Septic shock**	Acute life-threatening organ dysfunction caused by a dysregulated host response to suspected or proved infection. Signs of organ dysfunction include altered mental status, dyspnea, tachypnea, hypoxia, anuria, tachycardia, feeble pulse, hypotension, skin mottling, laboratory evidence of coagulopathy, thrombocytopenia, acidosis, high lactate levels, or hyperbilirubinemia. Persistent hypotension despite volume resuscitation, requiring vasopressors to maintain a mean arterial pressure (MAP) of ≥65 mm Hg and serum lactate level of >2 mmol/L.
Acute respiratory distress syndrome (ARDS)	**Onset**: Within 1 week of a known clinical insult (i.e., pneumonia) or new or worsening respiratory symptoms. **Chest imaging**: Radiograph, CT scan, or lung ultrasound: Bilateral opacities, not fully explained by volume overload, lobar or lung collapse, or nodules. **Origin of pulmonary infiltrates**: Respiratory failure not fully explained by cardiac failure or fluid overload. Need objective assessment (e.g., echocardiography) to exclude hydrostatic cause of infiltrates/edema if no risk factor present. **Oxygenation impairment in adults**: • Mild ARDS: 200 mm Hg < PaO_2/FiO_2a ≤300 mmHg (with PEEP or CPAP ≥5 cm H_2O). • Moderate ARDS: 100 mm Hg < PaO_2/FiO_2 ≤200 mm Hg (with PEEP ≥5 cm H_2O) • Severe ARDS: PaO_2/FiO_2 ≤100 mm Hg (with PEEP ≥5 cm H_2O)

Abbreviations: CPAP = continuous positive airway pressure, PEEP = positive end-expiratory pressure.

adverse outcomes did not occur more frequently among solid organ transplant recipients. The reasons for this are currently unknown but may be related to blunting of inflammatory cascades and cytokine release due to chronic immune suppression in transplant recipients. Mortality in COVID-19–positive solid organ transplant recipients is likely driven by the severity of illness at presentation rather than transplant status. More research is needed to elucidate these theories further.

Patients living with HIV

Current retrospective studies and case and cohort series have suggested that patients living with HIV are not at a greater risk of severe disease or death as compared to patients without HIV. Germany presented 33 virally suppressed people living with HIV and infected with COVID-19; 76% had mild infection, 27% had severe infection, and 3% died. Additionally, an observational prospective study from Madrid, Spain, analyzed 51 patients living with HIV and diagnosed with COVID-19, of whom 69% required hospitalization, 63% had one comorbidity, and 12% were critically ill. Patients living with HIV at Henry Ford Hospital in Detroit, Michigan, had similar comorbidities and hospital admissions compared with non-HIV patients admitted with COVID-19. In a recent publication of 463 patients infected with COVID-19 but without known HIV infection, the investigators from Henry Ford Hospital found that the three most common comorbidities were hypertension (63.7%), obesity (57.6%), and diabetes (38.4%). Patients in this study also had a 16% overall 30-day mortality rate. These comorbidities were also the three most common in the Henry Ford Hospital HIV population (57%, 57%, and 43%, respectively) with a 21% overall 30-day mortality rate. Based on multiple retrospective and cohort and case series, patients living with HIV should not be considered to be protected from COVID-19 or to have a lower risk of severe disease. Therefore, they should receive the same treatment approach applied to the general population.

Pregnancy

There are limited data on the clinical presentation and outcomes of pregnant individuals with COVID-19. Per the WHO, pregnant patients exhibit the same clinical presentation as the general population. As stated earlier, there are a few reports suggesting the possibility of vertical transmission from mother to baby. However, this is thought to be rare, with a more common cause of neonatal COVID-19 disease occurring from respiratory droplets after birth.

Pediatrics

Acute COVID-19 is less severe and results in lower hospitalization rates in children based on limited data. However, on May 14, 2020, the US Centers for Disease Control and Prevention (CDC) issued a national health advisory to report on cases meeting the criteria for multisystemic inflammatory syndrome in children (MIS-C). This syndrome is a rare late complication of COVID-19 that exhibits a clinical presentation that is similar to that of Kawasaki's disease. Symptoms include fever and mucocutaneous manifestations, and children >5 years of age have been found to have an association with cardiovascular involvement.

Radiological findings

The majority of patients show bilateral pneumonia, and only a small percentage of COVID-19 patients show unilateral pneumonia on chest imaging (Figure 188.2). The most frequent CT findings are bilateral patchy shadows and ground-glass opacities. Multilobe involvement and focal lesions (patches, stripes, or nodules) are also very characteristic. Less characteristic CT findings include centrilobular nodules, tree-in-bud sign, cystic change, pleural effusion, interstitial fibrosis, or lymphadenopathy. CT examinations show that lesions are more likely to be localized in the periphery than in the center of the lungs, and the lesions are more likely to be patchy than oval-shaped (Figure 188.3).

Laboratory diagnosis

The information in this section is valid as of September 1, 2020. Accurate molecular diagnostic tests are necessary to confirm a diagnosis of COVID-19 because clinical assessment alone is not accurate in predicting COVID-19 diagnosis due to its nonspecific symptoms. Direct detection of SARS-CoV-2 nucleic acid in respiratory tract specimens assists in patient-, healthcare institution–, and public health-level decision-making.

Nucleic acid amplification test

A SARS-CoV-2 nucleic acid amplification test (NAAT) is recommended in symptomatic individuals in the community

FIGURE 188.2 Chest x-ray revealing bilateral bibasilar infiltrates suggestive of COVID-19.

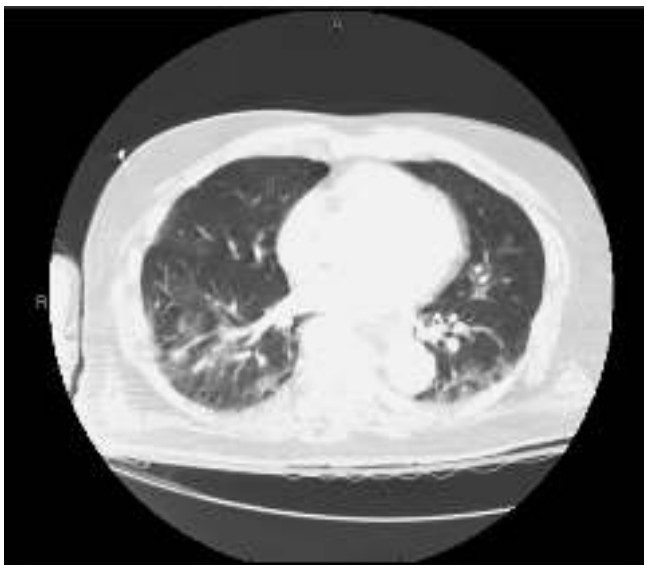

FIGURE 188.3 Peripheral parenchyma changes on CT imaging suggestive of COVID-19.

suspected of having COVID-19 or in individuals with known high-risk exposures to SARS-CoV-2. This test should be collected through nasopharyngeal, mid-turbinate, or nasal swabs rather than oropharyngeal swabs or saliva alone for SARS-CoV-2 RNA testing, with no recommendation of combination testing. Sensitivity and specificity of each test is noted in Table 188.3. The Infectious Disease Society of America (IDSA) panel suggests initially obtaining an upper respiratory tract sample rather than a lower respiratory sample for SARS-CoV-2 RNA testing in hospitalized patients with suspected COVID-19 lower respiratory tract infection. Results within 48 hours of collection are preferable so that they can be used to determine individual care and public health decisions. False negatives may result from improper sampling or handling, low viral load, or viral mutations.

In asymptomatic individuals who are either known or are suspected to have exposure to COVID-19, it is recommended that SARS-CoV-2 RNA testing be performed in the following situations:

1. A *known exposure*, defined as direct contact with a laboratory-confirmed case of COVID-19
2. A *suspected exposure*, defined as working or residing in a congregate setting (i.e., long-term care, correctional facility, cruise ship, factory) experiencing a COVID-19 outbreak
3. The individual exposed was not wearing appropriate personal protective equipment (PPE)
4. Immunocompromised asymptomatic individuals are being admitted to the hospital regardless of exposure of COVID-19
5. Any immunocompromised individuals, defined as receiving procedures such as cytotoxic chemotherapy, solid organ or stem cell transplantation, long-acting biologic therapy, cellular immunotherapy, or high-dose corticosteroids
6. Asymptomatic individuals before immunosuppressive procedures regardless of known exposure to COVID-19
7. Asymptomatic individuals who are undergoing major time-sensitive surgeries, defined as medically necessary surgeries that need to be done within 3 months. This does not include only aerosol-generating procedures (i.e. bronchoscopy) when proper PPE is unavailable

Serology

Serologic testing is not recommended to diagnose SARS-CoV-2 infection during the first 2 weeks (14 days) following symptom onset (Figure 188.4). Immunoglobulin G (IgG) or total antibody testing is only recommended 3 to 4 weeks after symptom onset to detect evidence of past SARS-CoV-2 infection for clinic or epidemiological purposes or if the individual has had repeatedly negative NAAT testing. It should not be used as the sole basis for diagnosing acute SARS-CoV-2 infection or to determine whether an individual is immune to SARS-CoV-2 infection.

Other supporting laboratory findings

Normal or decreased white blood cell counts, lymphopenia, or thrombocytopenia have all been associated with COIVD-19. Higher levels of C-reactive protein (>150 mg/L) and increased D-dimer levels (>1 mg/L) are also strongly associated with an increased risk of COVID-19 pneumonia. Additional laboratory indicators of increased risk include elevated alanine aminotransferase (ALT) (>80 U/L), aspartate aminotransferase (AST) (>80 U/L), α-hydroxybutyrate dehydrogenase (>540 U/L), lactate dehydrogenase activity (>720 U/L), and creatine kinase activity (>600 U/L), and lower total protein level (<60 g/L).

The decrease in the number of lymphocytes is generally observed in the CD4+ subpopulation. No significant changes

TABLE 188.3 **SENSITIVITY AND SPECIFICITY FOR EACH COVID-19 DIAGNOSTIC MODALITY**

	Oral	Nasal	Nasopharyngeal	Saliva	Mid–turbinate
Sensitivity % (95% CI[a])	56 (35–77)	76 (59–94)	97 (92–100)	85 (69–94)	100 (93–100)
Specificity % (95% CI[a])	99 (99–100)	100 (99–100)	100 (99–100)	100 (99–100)	100 (99–100)

are noted in the CD8+ and B-cell subpopulations. Among many cytokines, IL-6 may exceed the upper limit in severe COVID-19 patients.

Therapy

There are currently no FDA-approved drugs for the treatment of COVID-19. Table 188.4 lists the current classes of agents that are in development for treatment of COVID-19.

Based on the current literature, treatment of COVID-19 as per the NIH guidelines issued by the National Institutes of Health is given here.

Use of antivirals in patients with COVID-19

1. Patients with COVID-19 on supplemental oxygen should receive remdesivir for 5 days or until hospital discharge, whichever is first (evidence level AI).
2. Patients with COVID-19 on high-flow oxygen, noninvasive or invasive mechanical ventilation, or extracorporeal membrane oxygenation (ECMO), there are no recommendation for or against using remdesivir.
3. The guidelines recommend against use of chloroquine, hydroxychloroquine, or other antivirals except in a clinical trial (evidence level AII–AIII).

Corticosteroid use in patients with COVID-19

1. Patients with COVID-19 on mechanical ventilation should receive dexamethasone, 6 mg/d for up to 10 days (evidence level AI).
2. Patients with COVID-19 on oxygen but not ventilated should receive dexamethasone, 6 mg/d for up to 10 days (evidence level BI).
3. For patients with COVID-19 not requiring oxygen, the guidelines recommend against using dexamethasone (evidence level AI).
4. Alternatives if dexamethasone is not available include prednisone, methylprednisolone, and hydrocortisone (evidence level AIII).

Prevention

As per the CDC, there is currently no vaccine to prevent COVID-19. To prevent illness, avoidance of exposure to the virus by washing hands often with soap and water for at least 20 seconds is essential. If soap and water are not readily available, use of hand sanitizer that contains at least 60% alcohol is recommended. Avoiding touching the eyes, nose, and mouth with unwashed hands is also beneficial, and maintaining a social distance of 6 feet between individuals who do not live in the same household will

TABLE 188.4 **THERAPEUTIC AGENTS IN DEVELOPMENT FOR TREATMENT OF COVID-19**

Class of agents	Agents	Mechanism of action	Comments
Antivirals	Remdesivir	Inhibits RNA synthesis by binding to RNA- dependent RNA polymerase	In Phase 3 trial, reduced length of stay in patients. Mortality data pending. The FDA has authorized EUA of this drug for adult and pediatric patients hospitalized with suspected or confirmed COVID-19.
	Hydroxychloroquine Chloroquine	Inhibits MHC class II expression, antigen presentation, immune activation and various pro-inflammatory cytokines	Open-label RT showed no improvement. Some observational studies showed benefit alone and with azithromycin. FDA withdrew EUA. 180 ongoing studies
	Lopinavir + ritonavir	Inhibits HIV protease enzyme by forming an inhibitor-enzyme complex	No benefit an RCT
	Favipiravir	Inhibits RNA synthesis by binding to RNA- dependent RNA polymerase	Anti-influenza drug, viral clearance, Phase 3 ongoing
	Ivermectin	Interacts with glutamate-gated chloride channels	In vitro and human studies
	MK-4482	Antiviral action through introduction of copying errors during viral RNA replication	Influenza drug, in vitro and animal studies, phase 3 pending
	Recombinant ACE-2	Blocks SARS-CoV-2 from binding to the ACE-2 receptor	In vitro
Immune modulators	Convalescent plasma	Neutralizes spike-driven entry of SARS-CoV-2 into host cells	Phase 3 RCT ongoing, reduced length of stay in patients. Mortality data pending
	Monoclonal antibodies	Inhibitors of receptor binding that prevents viral attachment to target cells	In vitro and animal studies. Human trails phase 2/3
	Interferons	Interfere with viral replication and spread by several mechanisms including secretion of cytokines which promotes adaptive immunity	Open label trials—may prevent infection or reduce progression. RCT in combination with remdesivir
Immune suppressants	Corticosteroids	Attenuate progression to hyperinflammatory phase	Dexamethasone improved mortality in patients on mechanical ventilation and needing supplemental O_2. Methylprednisolone reduced progression, ICU transfer, mortality and length of stay
	Cytokine inhibitors	IL-6 inhibitor	Tocilizumab Phase 3 randomized control trial did not improve clinical status. Other IL-6 blockers alone or in combination ongoing
	Cytokine filtration	Inhibiting cytokine response	Trials ongoing
	Mesenchymal stromal stem cells	Inhibiting cytokine response	Trials ongoing

EUA, emergency use authorization; FDA, US Food and Drug Administration; RTC, randomized control trial; RT, randomized trial.

TABLE 188.5 **PHASE 3 VACCINE TRIALS FOR COVID-19**

	Phase	Type	Trial sites
Moderna	3	mRNA	USA
Biontech—Pfizer—Fosun	3	mRNA	USA, Argentina, Brazil, Germany
CanSinoBIO	3	Ad5	China, Saudi Arabia
Oxford: AstraZeneca	2/3	ChAdOx1	England, India, Brazil, South Africa
Wuhan: Sinopharm	3	Inactivated virus	UAE
Beijing: Sinopharm	3	Inactivated virus	UAE
Sinovac	3	Inactivated virus	Brazil, Indonesia
Murdoch	3	BCG	Repurposed vaccine
Johnson and Johnson-Jansen	3	Adeno associated virus 26	Argentina, Brazil, Chile, Colombia, Mexico, Peru, South Africa, USA

help reduce transmission of the virus. Finally, wearing a mask that covers the mouth and nose is crucial to protect individuals when in public settings.

Although there is currently no vaccine available at the time of publications, there are many Phase 3 clinical trials taking place as of September 2020 (Table 188.5).

Papillomavirus in oro-genital infection

Lawrence J. Eron

Human papillomaviruses (HPV) cause >10,000 cases of squamous cell carcinoma (SCC) of the cervix each year in the United States, as well as >4,000 deaths annually. It is the third most common cancer in women worldwide. The virus also causes genital warts (condylomata acuminata) and other subclinical disease, making it the most common sexually transmitted disease (STD) in the United States with an annual incidence of >6 million cases and a prevalence of as many as many as 20 million infections (Figure 189.1). Peak prevalence of infection occurs during the first 10 years following sexual debut. The National Health and Nutrition Examination Survey (NHANES) study reported a 25% prevalence of HPV DNA from vaginal swabs of 20- to 24-year-olds. Because HPV produces persistent infection that in most cases is subclinical and because the virus is easily transmitted via intercourse, 80% of sexually active people become infected during their lifetime.

Rates of transmission differ according to body site: Transmission from penis to cervix is 58.8 cases per 100 patient years; from cervix to penis is 208.8 cases per 100 patient years. Nonpenetrative intercourse may also transmit HPV from the anus to the scrotum and from the hand to the penis.

Genital HPV infection

Of the >100 different DNA types of HPV, distinguished on the basis of relatedness of their genomes, 40 infect the genital area. These 40 genital types fall into two groups distinguished by the type of disease that they produce. The first group, which includes the two most common HPV types, 6 and 11, causes exophytic condylomata acuminata, referred to as *genital warts* (Figure 189.2), as well as low-grade dysplasia of the vulva, vagina, cervix, and penis.

The second group, typified by types 16 and 18, causes SCC as well as high-grade dysplasia of the cervix, vagina, vulva, and penis, which appears as white areas of skin after the application of acetic acid (Figure 189.3). Low-grade dysplasia is referred to as *squamous intraepithelial lesions* (SIL) grade I, moderate dysplasia as SIL grade II, and severe dysplasia as SIL grade III. When the cervix is affected, it is termed *cervical intraepithelial neoplasia* (CIN) with similar grading as SILs. All HPV viruses may produce asymptomatic infection, subclinical disease, or clinically apparent disease (Figure 189.4).

HPV may also infect the perianal region and the distal rectum above the dentate line. In people infected with HIV, HPV may produce small, innocent-appearing ulcers that on biopsy are proved to be SCC. HIV infection, as well as other immunodeficiency states, increases the likelihood that dysplastic lesions of the cervix may evolve into invasive carcinomas. Recurrent or refractory genital warts may be surrogate markers for concomitant infection by HIV, and it is important to test for HIV in patients with HPV infection.

Despite the enormous prevalence, HPV infections in the majority of woman usually resolve in 6 to 12 months. Up to 30% of infections caused by low-grade HPV types 6, 11, 40, 42, 43, 44, 53, 54, 61, 72, 73, and 81 may be transient and will not evolve into a malignant state. Women with persistent infection by the oncogenic HPV types 16 and 18 are at risk for developing pre-cancerous and cancerous lesions

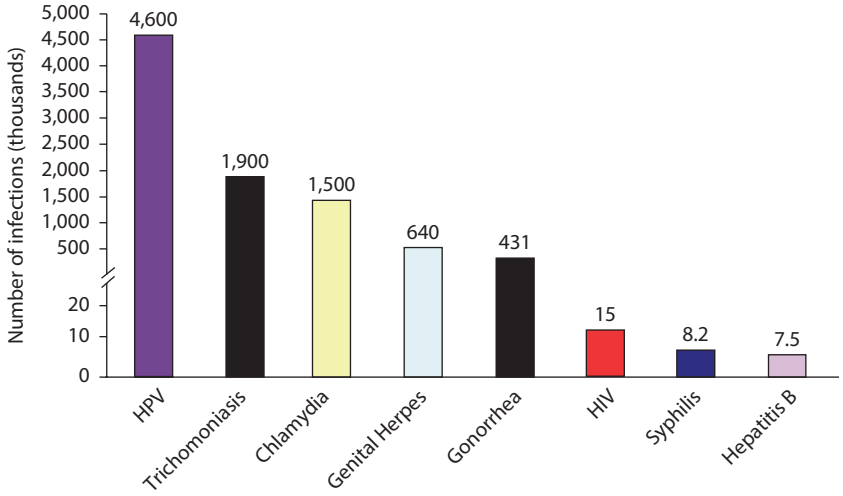

FIGURE 189.1 Human papillomaviruses (HPV) are the cause of the most common sexually transmitted disease, genital warts, with an annual incidence of 6.2 million and a prevalence of 20 million infections. HIV, human immunodeficiency virus.

(Figure 189.5). Although moderate or severe dysplasia may also remit without treatment, women with these lesions should be evaluated by colposcopy to detect the development of carcinoma in situ.

HPV causes most cancers of the oropharynx

SCC of the oropharynx is associated with either tobacco, alcohol, or betel nut use or HPV infection. HPV type 16 and, less commonly, types 18, 31, 33, 35, 39, 45, 51, 52, 56, 58, 59, and 68 are found in 80% of these tumors. In SCC of the tobacco, alcohol, betel nut type, the host p53 and retinoblastoma oncogenes (pRb) are altered by the virus, while p16, a tumor suppressor, is decreased. In contrast, HPV-associated SCC of the oropharynx contains no mutations of the p53 oncogene, and expression of pRb is downregulated, while p16 is upregulated. HPV+ tumors arise in the base of the tongue and tonsillar region and show a much better response to chemotherapy than the other type.

HPV may be transmitted through open-mouthed kissing as well as oral sex. Among men with no oral sexual contacts, the risk of oral HPV transmission varies with the number of kissing partners. While the overwhelming majority of oral HPV infection clears with no intervention, the increasing prevalence of HPV-positive SCC of the oropharynx suggests a benefit to vaccinating boys as well as girls, and at even earlier ages, to prevent oral as well as sexual transmission of HPV.

Diagnosis of HPV infection

Genital warts are flesh-colored papules with a cauliflower-like appearance. Other papules may be mistaken for genital warts, such as pearly penile papules and skin tags. When doubt exists, healthcare providers should consider other methods to diagnose HPV

FIGURE 189.2 Exophytic condylomata acuminata, also referred to as genital warts.

FIGURE 189.3 High-grade dysplasia of the cervix, vagina, and vulva appears as white areas after the application of acetic acid.

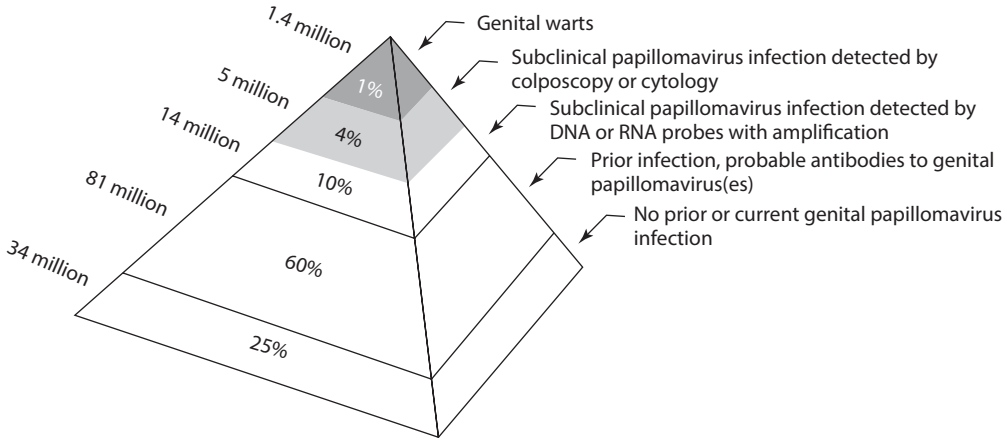

FIGURE 189.4 Human papillomaviruses may produce asymptomatic infection, subclinical disease, or clinically apparent disease.

infection, including cytologic exam via the Pap smear, colposcopy, biopsy, and tests for HPV DNA. Colposcopy of the cervix is useful when there is moderate to severe dysplasia. While HPV DNA testing improves the sensitivity of detecting infection, it lacks specificity, leading to unnecessary colposcopy.

Principles of therapy

While the main goal of treating HPV genital disease is usually to extirpate clinically evident disease, these treatments do not eliminate the underlying HPV infection, which may lead to recurrent disease. The epithelium of healthy-appearing skin surrounding a condyloma may be subclinically infected with HPV up to 1.0 cm from the actual lesion. Therefore. the removal of a wart or dysplastic tissue does not guarantee removal of the adjacent reservoir of virus and therefore does not prevent transmission of HPV infection. Although infections are often asymptomatic and in many cases will resolve spontaneously, nonetheless, patients with genital warts often experience depression, hopelessness, and a sense of social isolation. They should be offered counseling by a healthcare provider and a treatment program. While many patients readily accept treatment, they may need to be educated on the subclinical carriage of HPV and its prolonged incubation period. Given that sexual contact and infection with HPV may have occurred weeks to many months prior to the development of clinically evident lesions, patients with HPV should understand that the presence of condylomata acuminata may not imply infidelity.

Treatment of smaller exophytic condylomata acuminata can be readily accomplished by self-applied imiquimod, podophyllotoxin, trichloroacetic acid, or sinecatechins (an herbal product made from green tea leaves). Larger genital warts may require more intensive treatments that are clinician-administered, such as cryotherapy, surgical excision, electrocautery, and laser treatment. Studies of self-applied treatments of imiquimod report efficacy rates of 35% to 75% and recurrence rates of 6% to 26%. Studies of podophyllotoxin, the least expensive treatment, report efficacy rates of 43% to 70% but recurrence rates of 13% to 100%. Placebo-controlled trials of sinecatechins report complete clearance in 55% compared to 35%

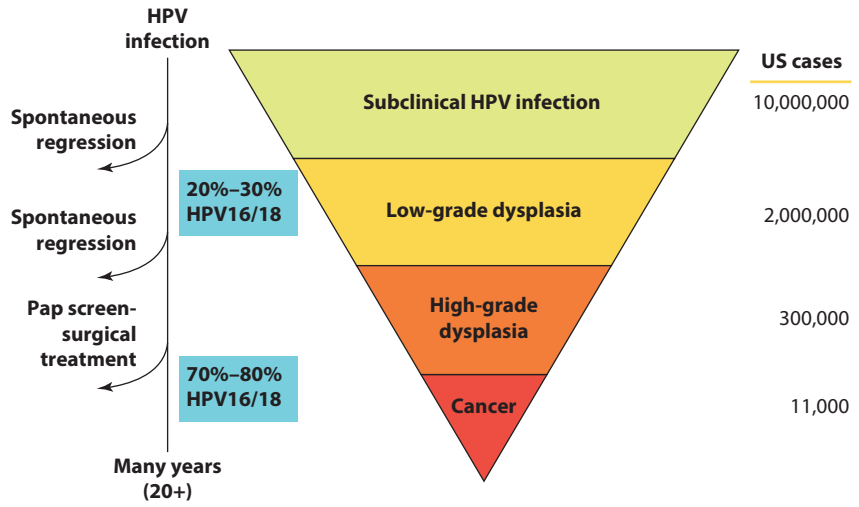

FIGURE 189.5 Infection by low-grade human papillomavirus (HPV) types may be transient.

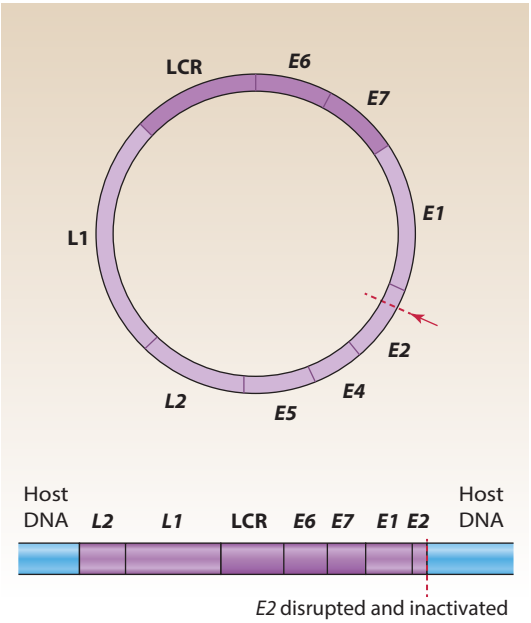

FIGURE 189.6 Human papillomavirus contains a circular, double-stranded DNA genome, consisting of eight structural genes in two distinct regions.

for placebo. Clinician-administered treatments such as cryotherapy report efficacy rates of 44% to 75% and recurrence rates of 5% to 30%. Surgical excision is successful in 89% to 100% of cases, but with recurrences in up to one-third of cases.

For moderate to severe dysplasia of the cervix, vagina, vulva, and the penis, cytodestructive procedures such as surgical excision and cryotherapy using liquid nitrogen may be effective. Both surgical excision and cryotherapy are equally effective and have similar relapse Loop electrical excisional procedure (LEEP) and laser ablation of dysplastic tissue of the cervix may be as effective as surgical excision or cryotherapy. However, recurrences still occur. Modulating the immune response to decrease persistent infection and recurrence rates following treatment is the "holy grail" of HPV treatment.

Immunity to HPV infection

Although the prevalence of HPV infection is high in young women, only a minority (≤5%) of infected women develop persistent infection and progress to SIL. In most cases, infection may be transient if the individual develops a sufficient immune response to the virus. When infection of the cervix by HPV 16 or 18 becomes persistent, SILs and CIN may evolve to SCC, usually several decades later.

Seroconversion following HPV infection occurs in only 60% of infected females and far less frequently in males. HPV may evade the immune system since its replication does not induce cytolysis, necrosis, or viremia. Viral proteins are released only in terminally differentiated epithelial cells, which are programmed for apoptosis and thus evade immune surveillance. Furthermore, HPV inhibits the synthesis of interferon and other cytokines.

Viral, environmental, and host factors play a role in the evolution of infection to the development of SIL/CIN and thence to SCC. Polymorphisms among HPV type 16 variants are associated with longer persistence, more aggressive infection, and higher frequency of SCC. Environmental factors that are associated with progression of SIL to SCC include smoking, long-term oral contraceptive use, high parity, and coinfection with other STDs. Host factors associated with increased susceptibility to SCC include genetic polymorphisms in the major histocompatibility complex (MHC) genes which decrease class I MHC cell surface expression and in TAP proteins associated with antigen processing, thereby interfering with host immune response.

The HPV genome and carcinogenesis

HPV contains a circular, double-stranded DNA genome consisting of eight structural genes in two distinct regions (Figure 189.6). The early region is composed of six genes (E1–E2 and E4–E7) that control viral replication, transcription, and cell transformation. The late region is composed of two genes (L1 and L2) that encode the viral coat proteins. The "long control region" regulates the expression of these eight genes. In productive infection, as is the case for types 6 and 11, both early and late regions of the virus are transcribed into messenger RNA (mRNA), which codes for proteins essential for viral DNA replication and for coat proteins. Many copies of HPV DNA are produced in each infected cell as circular, extrachromosomal plasmids. The net result is mature infectious virions.

In contrast to productive infection, when type 16 or 18 infects a cell, late genes are not transcribed, viral coat proteins are not synthesized, and no mature virions are produced. Instead the circular HPV genome inserts itself into the host chromosome, disrupting its E2 gene, resulting in the loss of E1 and E2 gene functions (Figure 189.6). Normally E1 and E2 downregulate E6 and E7 expression, but, with the loss of E1 and E2 control, E6 and E7 functions are upregulated. The E6 and E7 gene products then alter host oncogenes (p53 and pRb, respectively) that normally control cell growth and differentiation by arresting host cell division in the G1 phase. This normally allows the cell time to repair damaged DNA before progressing to the S (DNA replication) phase. The loss of this repair mechanism results in cell transformation, which renders the host genome susceptible to other carcinogens, such as smoking. The time between initial HPV infection and the development of SCC is between 10 and >20 years.

HPV prevention

Because the viral genome is highly conserved and because HPV uses cellular enzymes to replicate (and thus cannot easily develop resistance, in contrast to HIV, for example), effective vaccines (Gardasil and Cervarix) have been developed that produce neutralizing

antibodies that protect against viral infection. In addition the vaccines also produce cytotoxic CD8 lymphocytes that eliminate nascent HPV-infected cells. The vaccines are approximately 95% effective in the prevention of infection by HPV types 16 and 18 (which represent 70% of oncogenic HPV types). The Gardasil vaccine is also highly effective (close to 100%) against HPV types 6 and 11 that produce condylomata.

Vaccine administration is recommended for females aged 11 to 26 years to induce immunity prior to the female sexual debut, which in 77% occurs by age 19. Following the sexual debut, the incidence of HPV infection rises to 40% within 2 years and to >50% within 4 years, at which point the vaccine may be less effective. Widespread vaccination of males prevents oropharyngeal cancers caused by HPV 16 and 18. The vaccines offer durable protection against HPV types contained in the vaccines for at least 5 years but are woefully underutilized in the United States as compared to Australia, where an 80% vaccination rate of young girls has very nearly eliminated condylomata from not only females but also males <21 years of age, due to the development of herd immunity. Furthermore, high-grade lesions have also decreased in girls <18 years old. Between 2005 and 2015, the percentage of Australian women 18 to 24 years old with HPV decreased from 22.7% to 1.1%. Already Australia has noted a decrease in HPV-associated oral cancers in men. In the United States, only 50% of girls 13 to 17 years old and 38% of boys have been vaccinated, with far less reduction in HPV prevalence. It is anticipated that Australia will become the first country to eliminate HPV-associated cancer.

In addition to vaccines, the most cost-effective strategy for reducing HPV infection is the consistent use of condoms. In a well-designed and executed study, condoms reduced the incidence of genital HPV infection from 89.3 per 100 patient-years to 37.8. In those women whose partners used condoms 100% of the time, there were no cervical SILs observed in 32.1 patient-years, whereas 14 SILs were detected in 96.8 patient-years among women whose partners used condoms less than 100% of the time.

Because the HPV genome contains two oncogenes, E6 and E7, that are involved in the production of SCC, vaccines against the products of these genes could be used theoretically to prevent or treat cervical cancer. While in animals such a vaccine can protect against challenge with tumors expressing E6 and E7 antigens, no such results have been reported in humans.

Acute and chronic parvovirus infection

Neal S. Young

Parvoviruses are small viruses with unenveloped icosahedral capsids that contain a single-stranded DNA genome. These physical properties contribute to viral resistance to heat, solvents, and extreme chemical conditions. Because of their limited genome, parvoviral propagation depends on infection of mitotically active cells. B19 parvovirus is the only member of the Parvoviridae family known to cause diseases in humans (although other parvoviruses recently have been isolated from human blood and tissue, their pathogenicity remains uncertain). In the taxonomy of the parvovirus family, B19 and closely related simian parvoviruses constitute the *Erythrovirus* genus, separated from autonomous animal parvoviruses, dependoviruses (which require coinfection with a second virus for efficient propagation in cell culture), and insect parvoviruses called densoviruses.

B19 parvovirus has a peculiar and extreme tropism for human erythroid progenitor cells, which are responsible for the generation of circulating erythrocytes. In tissue culture, B19 has been propagated in hematopoietic cells: bone marrow, fetal liver, peripheral blood, and (rather inefficiently) in a few leukemic cell lines. B19 viral DNA replication in patients has been detected in blood and marrow. Specificity for erythroid cells follows from the cellular receptor for the virus, globoside or P antigen, a tetrahexose ceramide present on erythroid cells, megakaryocytes, endothelial cells, and some placental cell types, as well as fetal liver and heart. Parvovirus infection is terminated by host production of neutralizing antibodies. Failure to produce neutralizing antibodies can result in persistent infection. Cellular immune responses to parvoviruses have been measured and some CD4 and CD8 T-cell epitopes defined.

B19 diseases

Serologic studies have shown that more than half of the adult population has antibodies to B19 parvovirus; although most infection occurs during childhood, the seropositivity rate continues to rise with age. Probably the majority of infections are asymptomatic. Reliable diagnostic assays are now widely available. The presence of immunoglobulin G (IgG) to virus only signifies past infection. Immunoglobulin M (IgM) or virus DNA detected by direct hybridization testing indicates recent infection. The interpretation of a positive DNA study obtained by gene amplification (polymerase chain reaction) is more problematic, as individuals may not clear small amounts of virus for many months after an acute infection, and laboratory contamination can produce false positives.

Fifth disease

This common childhood exanthem is caused by acute parvovirus infection. The slapped-cheek rash and the evanescent maculopapular eruption over the trunk and proximal extremities are typical

FIGURE 190.1 Fifth disease; note characteristic maculopapular rash with "slapped cheek" appearance.

(Figure 190.1). Children may be febrile but usually have few symptoms. Meningitis and encephalitis have been reported as very rare complications. The blood of children with fifth disease contains IgM antibody to B19 but little if any virus; because the syndrome is due to immune-complex formation between virus and antibodies, affected individuals are not considered infectious. Reassurance and antipyretics as needed are sufficient for this self-limited illness.

In adults, acute parvovirus infection may be more serious. Adults have more rheumatic complaints than do children, and there may be frank joint inflammation and a pattern of distribution and chronicity mimicking rheumatoid arthritis; occasionally rheumatoid factor will be present. In most cases, symptoms resolve within a few days or weeks, but in some individuals the arthropathy and systemic symptoms become chronic and debilitating, although there is no joint destruction. The pathophysiology of the rheumatic manifestations after B19 infections is not well understood, but symptoms usually can be addressed with conventional anti-inflammatory drug therapy. Parvovirus is not a cause of rheumatoid arthritis.

Transient aplastic crisis and other hematologic syndromes

Transient aplastic crisis is caused by parvovirus infection in patients who have hemolytic anemia, compensated hemolysis (as in many cases of hereditary spherocytosis), or an increased demand for red cell production (iron deficiency, acute hemorrhage). B19 briefly interrupts erythropoiesis in most persons infected but without consequence because of the long survival of circulating red blood cells. Transient aplastic crisis is manifested by anemia, reticulocytopenia, and red cell aplasia in the marrow. There may be moderate thrombocytopenia and neutropenia in addition to the severe anemia, especially in patients with functioning spleens. The syndrome may be accompanied by marrow necrosis and has been fatal, especially in young children. As the anemia is self-limited, transfusion is adequate therapy. Specific antibody production terminates the episode and likely prevents recurrence.

Hydrops fetalis and congenital infection

Parvovirus infection of the pregnant woman may be transmitted to the fetus. Midtrimester events have been best characterized; first trimester infection may result in abortion, and third trimester infection has not been associated with adverse outcomes. Infection of the fetus is predominantly in the liver, the site of red cell production; the heart may also be affected (fetal myocardial cells express P antigen). Untreated, the fetus develops severe anemia and heart failure leading to the massive edema of hydrops and death at birth or shortly afterward (Figure 190.2). In utero blood transfusions have apparently been successful in a few instances; however, untreated fetal infection need not result in mortality or morbidity. As ultrasound diagnosis may not be definitive, a conservative recommendation is to document progressive hydrops on serial testing before intervention.

Congenital parvovirus infection after transfusion treatment of hydrops can produce chronic anemia from birth. Only a few infants have been described: In all, virus was localized to the marrow and did not circulate, and gene amplification was required to detect the low levels of B19 DNA. The pathology of the marrow was erythroid hypoplasia (Diamond–Blackfan anemia) or erythroid dysplasia resembling congenital dyserythropoietic states. Immunoglobulin therapy has not been effective.

Persistent infection

In the absence of an appropriate immune response, B19 infection can become chronic. Persistent infection has been observed in congenital immunodeficiency (Nezelof syndrome), acquired immunodeficiency syndrome (AIDS) secondary to human immunodeficiency virus (HIV) 1 infection, and during therapy with cytotoxic

FIGURE 190.2 Hydrops fetalis (see text).

or immunosuppressive drugs. The deficit in the immune response may be subtle; B19 infection may be the only evidence of constitutional immunodeficiency and the first sign of AIDS. Clinically, the patients have typical pure red cell aplasia with severe anemia, absent reticulocytes in the blood, and a paucity of red cell precursors in the marrow. Scattered giant pronormoblasts, a morphologic feature of B19 infection, may signal the diagnosis, which is established by DNA hybridization studies of serum.

Persistent infection results from inability to mount an effective humoral immune response, measured either as neutralizing antibodies in functional tissue culture experiments or by immunoblot binding of viral capsid proteins. Most AIDS patients lack any antibodies to B19; some congenital cases may have circulating IgM to B19 suggestive of a class-switch abnormality. Fortunately, commercial immunoglobulin preparations are a good source of effective antibodies to parvovirus. Administration of IgG 0.4 g/kg/day intravenously for 5 to 10 days terminates infection. The reticulocyte count dramatically increases after the first week, the marrow shows healthy normoblastic erythroid proliferation, and the hemoglobin rises to a level appropriate for the patient. Treatment can be curative, and the virus may no longer be detectable in some patients who have congenital immunodeficiency or whose immunosuppressive therapy is discontinued. AIDS patients have intense chronic parvoviremia, and IgG treatment appears to reduce but not eliminate the virus (Figure 190.3). Although relapse after some months is common, recurrent anemia responds to a second course of IgG. Monthly maintenance injections of IgG have been used in a few patients.

Other possible associations

Accumulated case reports are suggestive of a link between B19 and neonatal and childhood myocarditis (P antigen is present on fetal heart cells), a variety of pediatric neurologic syndromes, and some cases of acute, self-limited hepatitis. The association of B19 parvovirus with other clinical syndromes is less secure. Apparent links to childhood neutropenia, idiopathic thrombocytopenic purpura, vasculitis, and juvenile rheumatoid arthritis have not been reproducible.

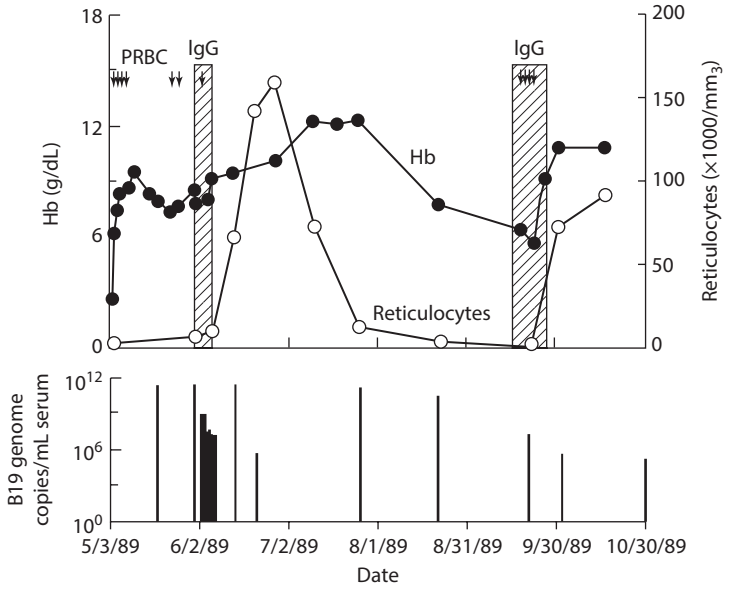

FIGURE 190.3 Immunoglobulin G (IgG) treatment of B19 persistence in acquired immunodeficiency syndrome (AIDS), illustrating recurrence predicted by molecular studies and the effectiveness of repeated treatment. PRBC = packed red blood cells.

A major technical problem has been the use of gene amplification methods, which not only are susceptible to false-positive results but also are positive in a high proportion of normal individuals: Viral DNA has been found in almost half of knee joints biopsied for trauma and in 20% of normal bone marrows using this sensitive method. Polymerase chain reaction-derived data that are reported without other clinical or serologic evidence of recent infection should be especially suspect. In addition, paroxysmal cold hemoglobinuria, a severe childhood hemolytic anemia that usually follows a viral illness, is a good candidate as a B19 parvovirus syndrome because of the presence of the pathogenic Donath–Landsteiner antibody, directed against erythrocyte P antigen, the virus's cellular receptor.

Vaccine development

Effective vaccines to prevent parvovirus infection in animals have been produced by tissue culture modification of virus. For B19, which resists conventional cell culture, recombinant empty capsids have been produced in a baculovirus system by expression of a portion of the parvovirus genome; they contain no viral DNA. Capsids enriched for the highly immunogenic VP1 protein elicit strong neutralizing antibody responses in test animals and, with the appropriate adjuvant, in normal volunteers. The limitation to development of a vaccine is commercial—the perceived market—rather than scientific.

Rabies

Anita Mahadevan, Susarla K. Shankar, and Avindra Nath

History

The first clear reference to rabies was from writings by Aristotle in c. 380 BC in which he described the symptoms and transmission of rabies in dogs. Despite centuries of observations on the transmission, symptoms, and a myriad of unsuccessful remedies, the disease remained invariably fatal until approximately 1885, when Louis Pasteur developed the first rabies vaccine in Paris. Unable to identify the organism—indeed unaware of even the difference between bacteria and viruses—he serially passaged the virus 90 times by intracerebral inoculation in rabbits and then air-dried the spinal cord samples from infected rabbits. This process made the virus less virulent—or attenuated—and it could be used to protect dogs from the infection. He ultimately injected an emulsion of the infected rabbit spinal cord into Joseph Meister, a young boy attacked by a rabid dog on his way home from school. Given the severity of his wounds on his face, hands, and legs he undoubtedly would have died; however, he received a series of 13 injections, survived, and subsequently spent his life working as a guard at the Pasteur Institute. Although this vaccine protected many patients, it also caused an immune-mediated encephalomyelitis and neuritis in some.

Epidemiology

In 2010, the US Centers for Disease Control and Prevention (CDC) reported 6,153 cases of rabies in animals and 2 human cases in the United States. A total of 25 human cases were reported in the years 2009–2018. The number of animal cases have also been decreasing with 5,508 cases in 2015, 4,910 cases in 2016, and 4,454 cases in 2017. However, in 2018, there were 4,951 cases reported, suggesting an increase in cases. Hawaii has been the only state free of rabies infection in humans and animals. Ninety-two percent of animal cases were in wild animals. In Europe, the World Health Organization (WHO) reported 6,065 cases of animal rabies and 9 human cases in 2012. Most of these occurred in Eastern Europe. In Latin America, there were 111 cases of human rabies reported between 2010 and 2012. The highest prevalence of rabies worldwide is still in developing countries, with India being in the lead followed by China, Nepal, and Myanmar. A rising incidence has also been seen in some African countries such as Malawi. Children between the ages of 5 and 14 years are the most common victims. About 60,000 cases of human rabies are reported to the WHO each year but the WHO estimates that the true incidence is much higher in these countries and that cases are grossly underreported. In the United States, while bats are the most common mode of transmission of rabies to humans, the largest reservoirs remain in raccoons followed by skunks, bats, foxes, and coyotes. Raccoon and fox reservoirs are mainly from the eastern states; bat and skunk cases were also found in parts of the south, Pacific Northwest, and California. Domestic animals only accounted for about 6.8% of rabies. Interestingly, cats are found to be infected with rabies at almost double the infection rate of dogs. The cases of rabid cats continue to rise, whereas cases in other animals are declining yearly. This paradox may be due to administration of vaccines in certain animals, especially dogs. In Europe, the rabies reservoir is mainly the fox,

whereas the bat is the main reservoir in Australia, Mexico, and parts of South America. Worldwide, death from rabies is usually from a rabid dog. In countries where dogs are commonly infected with rabies virus, nearly 99% of transmission occurs through dog bites.

Pathogenesis and pathology

Rabies is caused by a number of different species of neurotropic viruses in the *Rhabdoviridae* family, genus *Lyssavirus* named after Lyssa, the Greek goddess of madness, rage, and frenzy. The virus is typically transmitted by saliva of the infected animal through a bite or scratch. Mucosal exposure to the virus such as through the eyes, nose, or mouth could also transmit the virus. Drinking raw milk from infected animals can also transmit the infection. For bat-acquired rabies, the site of exposure is most commonly the face. The virus replicates at the wound site for a period of days and then, via retrograde axoplasmic flow, moves up the peripheral nerves to the anterior horn cells in the spinal cord and then transsynaptically to the brain. Both sensory and motor nerves can propagate the infection. Once the central nervous system (CNS) is seeded with the virus, it then centrifugally spreads back to the periphery. This process involves infection of non-neural tissues, especially the salivary glands, whereby the viral transmission occurs. This extraneuronal spread can also occur in the heart, autonomic plexus causing dysautonomia, skin, and serous glands of the tongue. For this reason, skin from the nape of the neck and hair follicles can serve as diagnostic tools, and the virus can be transmitted by organ transplantation.

Histologic examination of the brain shows perivascular inflammation of the gray matter, neuronal degeneration, and the characteristic cytoplasmic inclusions called Negri bodies (Figure 191.1A). Negri bodies are membraneless compartments within the cell where viral replication takes place. These compartments arise from a liquid–liquid phase separation and represent a new class of liquid organelle in which viral replication takes place. Renal tubular necrosis has also been demonstrated at autopsy. In 2005 and in 2012, cases of rabies were also reported in organ transplant recipients. Neuropathologic features in the latter showed Duret hemorrhages, widespread neuronal loss, perivascular lymphocytic infiltration, and extensive spinal cord pathology. The case in 2012 was unusual in that rabies occurred 18 months after the kidney transplant, and

three others who received organs from the same donor remained asymptomatic, likely due to a low dose of the inoculum.

Clinical symptoms

The clinical course in humans is acute, usually progressing from initial symptoms to death within 2 to 3 weeks, even with intensive supportive care. The incubation period of rabies can vary from a few days to several years with an average of 1 to 2 months. The length of the incubation period varies with the infecting strain and is thought to be inversely related to the size of the inoculum and the proximity of the bite to the CNS. Approximately half of the patients develop pain or paresthesias at the wound site. A diagnosis of rabies should not always depend on a history of an animal bite. Exposure may not be obvious in bat-acquired rabies, which is often misdiagnosed. The prodrome includes low-grade fevers, loss of appetite, and anxiety. Most patients have "furious rabies," which resembles an intense anxiety reaction or acute psychosis that can be aggravated by sensory stimuli such as touch, light, and sound. Three categories of symptoms are pathognomonic of furious rabies. (1) *Altered mental status that fluctuates between severe agitation and normality and depression*. The acute psychosis with hallucinations can result in an initial psychiatric evaluation. Seizures are more common in children. (2) *Inspiratory spasms caused by sensitivity of movement of air through the respiratory tract* resulting in spasm of the accessory respiratory muscles and diaphragm causing dyspnea. Hydrophobia (spasm of the pharynx and larynx provoked by drinking or the sight of water) and aerophobia (similar effect produced by blowing air on the face of the patient) are considered hallmarks of the disease. The inability to swallow from paralysis of bulbar muscles may also result in hypersalivation. (3) *Autonomic dysfunction* that manifests as hypersalivation, pupillary abnormalities, piloerection, sweating, priapism, and repeated ejaculation as well as neurogenic pulmonary edema. Rarely, there may be respiratory distress with medullary involvement. A few patients die during this stage, but most go on to develop progressive paralysis and eventually coma. Abnormal cranial nerve, motor, and sensory examinations; tremor; myoclonus; and local sensory symptoms at the exposure site are more common in bat-acquired rabies. In some patients, the paralytic state dominates the entire clinical picture; hence, it is termed "paralytic rabies." Paralysis or paresis involves the proximal muscles and can be accompanied by constipation, urinary retention, and respiratory failure. Alternatively, inflammation with demyelination and axonal dysfunction of the peripheral nerve causes an ascending lower motor neuron weakness without anterior horn cell involvement. Physical exam shows a motor weakness involving the respiratory muscles and loss of deep tendon reflexes with maintained consciousness which may mimic an acute axonal Guillain–Barré syndrome. This lack of involvement of spinal cord motor neurons and brainstem is called an "escape phenomenon." Most patients may eventually develop CNS symptoms. In some patients, however, the clinical manifestations can be nonspecific; hence, in all patients with an unknown cause of progressive encephalitis, the possibility of rabies should be considered. Hydrophobia, aerophobia, and encephalopathy are more common in dog-acquired rabies, whereas bat-acquired rabies more frequently has symptoms at the exposure site, tremor, myoclonus, and abnormal cranial nerve, motor, and sensory examinations. In patients receiving intensive supportive care, the average duration of illness between onset of paralysis and death is 7 days. Once neurologic symptoms have developed, survival is rare. Cardiopulmonary complications and multiorgan failure are common in the terminal stages of the illness in patients aggressively managed in intensive care units.

Diagnosis

Prior to available accurate laboratory tests, a potentially infected animal was placed in isolation for observation. If it died a characteristic rabies death, the diagnosis was established. With the advent of the microscope in 1903, intracytoplasmic inclusion bodies were discovered in infected brain tissue by Aldelchi Negri, who at the time was an assistant of Camillo Golgi. These structures were subsequently called *Negri bodies*. In the 1980s, the direct fluorescent antibody (DFA) test was developed, which remains to this day the diagnostic gold standard (Figure 191.1). For postmortem diagnosis in animals, fresh unfixed brain tissue is necessary for DFA testing because fixed tissue with agents such as formalin may yield inaccurate results. Brain tissue is the only sample tissue type for diagnosis because saliva and salivary gland excretion of the virus can be intermittent. The predictive value of a negative brain DFA test is 100%.

Routine laboratory tests and diagnostic studies are of little value in the diagnosis of rabies. Examination of the cerebrospinal fluid (CSF) may show leukocytosis, but protein and glucose assays are often normal. Antibodies to the virus in an unvaccinated patient with encephalitis confirms the diagnosis. In addition, saliva samples can be cultured and then tested for viral nucleic acid. A tissue diagnosis can be made in premortem humans using the DFA test on a skin sample from the back of the neck. Polymerase chain reaction (PCR) can also be used in diagnosis, but DFA is still considered the gold standard because PCR is hampered by obtaining universal *Lyssavirus* primers. Due to the ability to detect low copy numbers of viral nucleic acid, rapid turnaround time, and falling costs, it is likely that PCR-based techniques may become a viable diagnostic test in the near future.

In 2006, the CDC reported a case of encephalitis in a 15-year-old girl from Wisconsin who was bitten by a bat. Antibody titers to rabies virus were found in CSF and serum. She survived the infection. Another young boy developed encephalitis of undetermined etiology that progressed rapidly. He developed rabies-specific immunoglobulin G (IgG) antibodies in increasing titers. Rabies virus could not be detected in the CSF by PCR; however, antibodies to the rabies virus were present.

MRI changes most likely occur in the early stages of the infection. More extensive involvement of various regions of the brain has been shown in advanced stages on serial imaging. There are no specific features attributable to the rabies virus. Patients with acute rabies encephalitis have T2 hyperintense lesions in the brainstem, thalami, temporal cortex, hippocampus, and subcortical white matter. Some patients may develop signs of hypoxic damage and

cerebral hemorrhagic infarcts. Mild signal changes can also be seen in the spinal cord and nerve roots corresponding to the site of injury of some patients. This may involve only the anterior horns or both gray and white matter. Enhancement with gadolinium contrast is not present until the patient is comatose.

Treatment

Treatment efforts are concentrated on preventing and treating complications of established infection and protecting those who come in contact with the patient from virus exposure. Neither vaccine nor rabies immunoglobulin increases survival in symptomatic patients and should be avoided. Attempts to treat symptomatic patients infected with dog rabies with therapeutics and intensive care support are usually unsuccessful. A few patients who survived infection with good functional recovery had evidence of an early immune response to rabies virus in blood and CSF, with absence of virus in biologic fluids or hair follicles. Thus, a good outcome likely depends on a prompt host response in eradication of virus. Steroids should also be avoided in the treatment of cerebral edema if it develops. Universal precautions should be followed by hospital staff, and respiratory precautions are recommended for suctioning. Postexposure prophylaxis is recommended for contacts who were bitten or had clear contamination of mucous membranes to the patient's saliva, urine, or other body tissue.

Symptomatic treatment

Benzodiazepines, barbiturates, ketamine, or intravenous morphine may be used for treatment of the pharyngeal spasms. However, impairment of consciousness to the extent that ventilatory support is needed should be avoided. Autonomic symptoms should be monitored and treated.

Postexposure prophylaxis

Once an individual is bitten by an animal presumed to have rabies, it is vital to immediately begin the immunization. Raccoons, skunks, foxes, and coyotes are most often infected with the rabies virus. Patients exposed to these animals should receive postexposure prophylaxis as soon as possible. Transmission of rabies virus can occur from minor, even unrecognized, bites from bats. Therefore, rabies postexposure prophylaxis is recommended for all persons with bite, scratch, or mucous membrane exposure to a bat and should be considered if the history indicates that a bat was physically present, even if the person is unable to reliably report contact that could have resulted in a bite. An unprovoked attack by a domestic animal is more likely than a provoked attack to indicate that the animal is rabid. If the animal has been vaccinated, it is unlikely to be infected; if not vaccinated but otherwise healthy, the animal should be confined and observed for 10 days. Any illness during this time should be evaluated by a veterinarian and the public health department. Vaccination can be withheld if the animal remains healthy during this time. Small rodents (e.g., squirrels, hamsters, guinea pigs, gerbils, chipmunks, rats, mice) and lagomorphs (including rabbits and hares) are almost never infected with the virus and have not been known to transmit rabies to humans. Large rodents such as woodchucks are sometimes infected. Therefore, in cases involving rodent exposure, the state or local health department should be consulted before initiating prophylaxis. Postexposure therapy for rabies is highly effective, and no failures have been recorded in patients who have received all three arms of treatment. Failures have occurred only on deviation from the recommended protocol.

Local wound care

The abraded skin after a bite must be cleaned immediately and thoroughly by soap and water or povidone-iodine solution for a minimum of 15 minutes. Even scratches or contaminated skin from saliva should be cleaned the same way. It has been found that cleaning the wound would help reduce the chances of developing rabies. There are no areas that are deemed more susceptible after a bite. All bites in any area should be treated with the same level of care. Tetanus prophylaxis and antibiotics may be necessary to prevent secondary infection.

Vaccination

Postexposure therapy includes both passive immunization with rabies immune globulin (RIG) and active immunization with the vaccine in those who have not been vaccinated previously. RIG is administered as a one-time dose and should be given within the first 7 days of the vaccine because after this time period the vaccine production of antibody is thought to have occurred. The recommended dose of RIG is 20 IU/kg body weight for any age group. It is typically administered around the bite wound. The RIG and vaccine should not be given at the same site. Vaccine alone is indicated in persons who have had pre-exposure prophylaxis with a cell culture vaccine series or who had been vaccinated with other types of rabies vaccine with a documented neutralizing antibody response.

In the United States, there are currently two Food and Drug Administration (FDA)-approved vaccines. The human diploid cell vaccine (HDCV), trade name Imovax, and the purified chick embryo cell vaccine (PCEC), trade name RabAvert, which are both administered intramuscularly (IM). Outside the United States, there are a purified vero cell rabies vaccine (PVRV) and a purified duck embryo vaccine available in addition to the HDCV and PCEC vaccines.

The vaccine should be given as a 1.0 mL IM injection in the deltoid area (the outer thigh may be used in younger children, but vaccine should not be given in the gluteal area) on days 0, 3, 7, and 14 according to CDC guidelines. All of these vaccines are used for both pre- and postexposure prophylaxis. The WHO still recommends a five-dose immunization (with an additional dose on day 28) in cases of higher exposure, and both the WHO and CDC recommend five doses in immunocompromised individuals.

HDCV is the most expensive rabies vaccine, but PCEC and PVRV are just as efficacious and safe and can be administered at lower doses intradermally in resource-limited settings. Older vaccines that are produced in sheep, goat, or mouse nervous tissue have unreliable potency and a high incidence of neurologic complications but are still used in some developing countries because they are cheaper.

Pre-exposure vaccination

Pre-exposure prophylaxis should be offered to persons at high risk for exposure to rabies. Persons who work with rabies virus in research laboratories or vaccine-production facilities are at highest risk for exposure and should have rabies antibody titers checked every 6 months. Other laboratory workers (e.g., those performing rabies diagnostic testing), spelunkers, veterinarians and staff, and animal-control and wildlife officers in areas where animal rabies is enzootic should also have antibody measurements done every 2 years. Outdoor travelers to and expatriates living in remote areas with a high rabies exposure risk should be vaccinated. This should include children since they are at risk for more severe bites and they often play with animals and may not report bites.

Booster doses (IM or ID) of vaccine should be administered to maintain an adequate serum titer. The Immunization Practices Advisory Committee (ACIP) recommends three pre-exposure doses of the HDCV given IM at 0, 7, and 21 or 28 days. This ensures both seroconversion and adequate duration of protective antibody. Routine serologic testing after vaccination is not needed as seroconversion has been uniform. Patients who are immunosuppressed or taking medications such as chloroquine, which may interfere with antibody response to the vaccine, should postpone pre-exposure vaccinations and consider avoiding activities for which rabies pre-exposure prophylaxis is indicated. When this is not possible, they should be vaccinated and their antibody titers checked.

Education

Prevention is the best cure. Knowledge is extremely vital in this disease. People should be informed of preventative measures if they are considered to be a high-risk group. The CDC has immensely resourceful web-based information for individuals who have concerns or common questions related to a dog bite. They have recommendations for people who would like to have a dog or cat as a household pet. Casual handshaking or standing next to someone who may be infected are not considered to be risks for acquiring the infection. Changing bed linen from an infected individual does not pose a threat, either. Certain risks seen in the domestic setting, barring animal bites, would also be from sexual activity, sharing utensils or cigarettes, and saliva contact from an infected source (CDC). A healthy person undergoing postexposure prophylaxis (PEP) does not constitute a potential threat for infecting others. If a person is found to be infected, the local health department should be notified once the infection is documented. In an unknown case of encephalitis, especially in children, a history must be ascertained about recent animal bites. Patients may not recognize that certain animals can be a threat for a rabies virus infection.

Because there is currently no cure for rabies infection once it has reached the CNS, determining a definitive, positive diagnosis does not aid the patient directly. However, it is an important part of the workup and differential for acute encephalitis in that a negative result points toward a different cause for the encephalitis. Alternatively, a positive result is important from a public health perspective and makes patient isolation a necessity. It also aids in establishing a more detailed history for possible exposure in other family members.

Varicella-zoster virus

Jeffrey M. Weinberg

Varicella-zoster virus (VZV) is a member of the herpesviruses family and is the etiologic agent of varicella and varicella zoster. Varicella, the exanthem caused by primary infection with VZV, generally occurs in childhood. Shingles, the clinical syndrome of segmental, unilateral exanthem and neuralgic pain due to reactivation of latent VZV infection, usually occurs many years after the primary infection. In the immunodeficient person, both primary and reactivated VZV infection can lead to severe generalized virus dissemination, the life-threatening form of VZV infection. The availability of antiviral agents for management of VZV infection has raised the importance of recognizing this infection in high-risk groups. Prior to the introduction of the VZV vaccine in the United States in 1995, approximately 4 million cases of chickenpox occurred each year, 83% in children >9 years. The association between aging and VZV vulnerability is apparent in the epidemiology of the disease: of the estimated 1 million cases of herpes zoster in the United States each year, approximately 50% occur in individuals aged 50 years or older. A VZV vaccine was approved in 2006 for the prevention of shingles. A newer, more effective vaccine was approved in 2017.

Clinical presentation

Varicella (chickenpox)

In healthy unvaccinated children, VZV infection manifests as a vesicular exanthem often associated with prodromal malaise, pharyngitis, rhinitis, and abdominal pain. The rash generally appears 15 days after VZV exposure; the range is 10 to 21 days. The vesicular eruption emerges in successive crops over the first 3 to 4 days of illness, usually with concomitant enanthem. Each skin vesicle appears on an erythematous base, resulting in the descriptive image of a dewdrop on a rose petal.

The eruption most commonly originates on the head and quickly progresses to the trunk, arms, and, finally, the legs. It is common to observe all cutaneous stages, including macules, vesicles, papules, and crusts, in the same area of the skin (Figure 192.1). Varicella often is associated with fever, headache, sore throat, or stomachache. These symptoms may last for a few days, with fever in the 38.3°C/101°F to 38.8°C/102°F range. Primary VZV infection may involve the mucosal surfaces of respiratory, alimentary, and genitourinary systems; therefore those with varicella can have severe laryngitis, laryngotracheobronchitis, vaginitis, urethritis, pancreatitis, and enteritis. In immunocompromised individuals, severe abdominal pain or back pain can be an indicator of progressive VZV infection.

Varicella vaccine was licensed in the United States in 1995 for individuals ≥12 months of age. A second dose was recommended in the United States in June 2006. Since the introduction of the vaccine, the age-unadjusted incidence of chickenpox has been approximately 3 cases per 1,000 population, and the hospitalization rate for complications of varicella has decreased dramatically. Complications of varicella occur most frequently in those younger than 1 year and older than 15 years. These complications include bacterial superinfection of skin, dehydration, pneumonia, encephalitis, and hepatitis. With the availability of the

FIGURE 192.1 Varicella. Note various stages of lesions in each area of eruption.

Courtesy of David Schlossberg, MD.

vaccine, hospitalizations for chickenpox have significantly decreased and VZV-associated mortality is at an all-time low of <0.1 per million population.

Varicella zoster (shingles)

Although 10% to 20% of Americans overall will develop zoster in their lifetimes, 50% of persons reaching age 85 can be expected to do so; the incidence of herpes zoster rises dramatically, from a low of between 1.1 and 2.9 per 1,000 person-years in people <50 to 4.6 and 6.9 per 1,000 person-years, respectively, in the age groups 50–59 and 60–69. The age groups 70–79 and ≥80 years old have the highest incidence, with 9.5 and 10.9 per 1,000 person-years, respectively.

The principal risk factor for herpes zoster is prior history of VZV exposure. Any person who has had chickenpox or received the varicella vaccine as a child, which includes >90% of the US adult population, is at risk for herpes zoster. The association with advancing years, as previously described, is due to the age-related decline in VZV-specific cell-mediated immunity. Childhood zoster is rare but not unheard of, with cases reported in children as young as 4 months. The incidence of zoster in children younger than 10, however, is only 0.74 per 1,000 person-years.

Immunocompromised people or those receiving immunosuppressive drugs are also at increased risk for zoster. Thus, HIV patients have a higher incidence of zoster disease than do individuals with a healthy immune system, reported in one longitudinal study as 29.4 cases per 1,000 patient-years. Patients undergoing bone marrow or organ transplant and treated with immunosuppressives are known to develop zoster with increased frequency.

Genetics may play a role in the development of herpes zoster, as suggested by the finding that elderly white men are four times more likely to develop zoster than elderly black men. Some reports have suggested that systemic steroid therapy can incite VZV reactivation as well, placing persons with conditions such as rheumatoid arthritis or lupus at increased risk. Finally, both trauma and stressful life circumstances have been suggested to play a role in development of herpes zoster, further increasing the population at risk.

The characteristic feature of herpes zoster is a vesicular rash of unilateral distribution limited to one to three adjacent dermatomes. The onset of the rash, however, often is preceded by a prodromal phase. Beginning 4 days to 2 weeks before lesions appear, patients often note pain and paresthesia in what will become the zoster-affected dermatome. The pain can be intermittent or continuous, and has been described by patients variously as throbbing, sharp, stabbing, burning, or shooting pain. Malaise, dysesthesia, and itching are frequent elements of the prodrome, as well.

The most common site of infection is the trigeminal nerve. Most patients exhibit thoracic distribution of zoster rash, with >50% of cases presenting with cutaneous lesions of the trunk. The rash generally appears proximally, then spreads distally along the affected dermatome. The initial lesions appear as erythematous maculopapules, which turn into vesicles within 12 to 24 hours. The vesicles become pustules in about 3 days, and form scabs 7 to 10 days later. New lesions generally appear over no more than 3 to 7 days, but the duration of the rash has been correlated with patient age (advancing age associated with longer duration) and site of infection (face healing more rapidly than other loci).

Zoster affecting the first division of the trigeminal nerve, as occurs in 10% to 15% of cases, can lead to herpes zoster ophthalmicus (HZO), which produces the characteristic zoster rash on the forehead, periocular area, and nose and can be accompanied by local pain. Ocular complications of HZO are among the most dangerous morbidity of zoster disease, placing patients at risk for sight impairment or vision loss due to nerve damage or ocular pathology.

Approximately 60% to 90% of zoster patients experience local neuritic pain and hypersensitivity in association with the acute herpetic rash. This pain is likely due to an immediate nociceptive response: local inflammation and tissue damage stimulate the primary afferent neurons of the skin and subcutaneous tissue, which neurologically manifests as pain. In addition, allodynia and hyperalgesia may be present, adding to patient discomfort during acute herpes zoster.

Pain associated with zoster disease resolves within several days for many patients, although the degree of pain can be variable; one report has suggested that more extensive pain during the acute phase might predict the prolonged pain of postherpetic neuralgia (PHN), and another indicates that early pain therapy might limit the central development of chronic PHN pain following herpes zoster.

Diagnosis

The features of varicella and varicella zoster are so characteristic that a diagnosis is generally made clinically. In chickenpox, lesions in all stages of development (macules, vesicles, pustules, and crusted lesions) may be a suggestive finding. The differential diagnosis of varicella includes herpes simplex virus, Coxsackie and other enteroviruses, mycoplasma, streptococcal impetigo, rickettsialpox, insect bites, and allergic contact dermatitis.

For herpes zoster, the diagnosis can be made based on the presence of prodromal pain and/or itching and the defining zoster rash. For patients presenting in the prodromal period, the pain and

dysesthesia may require differentiation from other pain sources, such as trauma, myocardial ischemia, renal colic, gallbladder disease, or dental pain. Atypical lesions, furthermore, may require laboratory confirmation, which sometimes is obtained from viral culture (often difficult to recover from swabs) or more readily from direct immunofluorescence assay. Recently, nested and real-time polymerase chain reaction (PCR) testing of samples from skin lesions have proved valuable for identifying VZV, with more rapid amplification than other methods and high sensitivity. These laboratory techniques are most valuable for differentiating VZV from zosteriform herpes simplex, a herpes simplex viral infection that mimics zoster disease.

Prevention and therapy

Varicella vaccine

The live, attenuated varicella vaccine (Varivax) was approved in the United States in 1995 and is recommended for persons >12 months. Every person in the United States who does not have indicators for VZV immunity should have two doses of varicella vaccine. The first dose should be administered at the age of 12 to 15 months. The second dose should be given between the ages of 4 and 6 years. People 13 years of age and older who have never had chickenpox or received chickenpox vaccine should get two doses, at least 28 days apart.

Each dose, for infants and adults, is 0.5 mL administered subcutaneously.

Other populations may benefit from varicella vaccine, including eligible healthcare and daycare workers, college students, prisoners, military recruits, nonpregnant women of childbearing age, and international travelers.

Prior to the introduction of the vaccine, about 11,000 people were hospitalized for chickenpox each year in the United States, and about 100 people died each year as a result of chickenpox in the United States. As noted previously, since the introduction of the vaccine, the incidence of chickenpox and the hospitalization rate for complications of varicella has decreased dramatically.

The vaccine is not recommended for infants <1 year old, for those on salicylate therapy, for pregnant women, or those allergic to components of the vaccine, including neomycin, gelatin, and monosodium glutamate. Immunosuppressed individuals should confer with their physician about the risks and benefits of vaccination.

Zoster live vaccine

The herpes zoster vaccine is a live attenuated preparation of the Oka/Merck strain of VZV that boosts the recipient's immunity to VZV, thus increasing the chance that their latent VZV will remain dormant and that they will not develop herpes zoster. Its efficacy and safety in reducing the risk of herpes zoster disease in adults >60 were established in a pivotal trial, on the basis of which the US Food and Drug Administration (FDA) approved the vaccine in May 2006 for clinical use. On March 24, 2011, the FDA approved Zostavax for individuals 50 to 59 years of age.

Recombinant zoster vaccine

In October 2017, the Advisory Committee on Immunization Practices (ACIP) of the Centers for Disease Control and Prevention issued a recommendation for use of a new shingles vaccine, known as the recombinant zoster vaccine (Shingrix). This vaccine is recommended for adults ≥50. Based on published data, the recombinant zoster vaccine appears to be more effective than the live vaccine. The newer vaccine reduces the risk of both shingles and postherpetic neuralgia by about 90% in adults ≥50. In contrast to the older vaccine, the newer product is not a live vaccine. The recombinant zoster vaccine involves a series of two shots given 2 to 6 months apart.

Chickenpox

Overall assessment

The goal in management is to treat the symptoms of primary VZV infection and prevent complications if possible. The three stages of management are (1) establishing the likelihood of the diagnosis, (2) determining whether antiviral therapy is indicated, and (3) ruling out secondary bacterial infection, other complications, and failure of previous antiviral treatment.

Symptomatic therapy

Itching is the major symptom of chickenpox, and antipyretic management is important. Warm baths containing baking soda (1/3 cup per bathtub) or emulsified oatmeal (Aveeno) can temporarily relieve pruritus. This can be combined with the oral administration of either diphenhydramine (Benadryl), 1.25 mg/kg every 6 hours, or hydroxyzine (Atarax, Vistaril), 0.5 mg/kg every 6 hours. In older children, cold pramoxine HCl 1% lotion with calamine 8% (Caladryl) can be used, but this should be avoided in infants because of the risk of excessive surface exposure and absorption of drug or vehicle (alcohol 2.2%). Fever should be controlled with acetaminophen, but salicylates should not be used because administration of certain salicylates to children with chickenpox increases the risk of subsequent Reye's syndrome. For severe dysuria, a cold compress on the genital area during urination will ease the pain and minimize the likelihood of a functional bladder obstruction.

Antiviral therapy

Acyclovir (Zovirax) is the only agent licensed in the United States for the treatment of chickenpox. It is indicated for treatment of chickenpox in certain normal persons, for disseminated VZV infection in immunosuppressed persons, and for treatment of shingles. Oral acyclovir should be used in otherwise healthy persons with chickenpox who are at risk for moderate to severe disease, such as those >12 years, those with chronic cutaneous or pulmonary disorders, those receiving chronic salicylate therapy, and those receiving short, intermittent, or aerosolized courses of corticosteroids or aerosolized corticosteroids (Table 192.1). The American Academy of Pediatrics

TABLE 192.1 **ANTIVIRAL TREATMENT OF VARICELLA-ZOSTER VIRUS (VZV) INFECTION**[a]

Agent	Indication	Creatinine clearance (mL/min/1.73 M^2)	Dose	Dosing interval	Duration (days)
Oral acyclovir	Chickenpox >age 12 yr	>25	20 mg/kg up to 800 mg	4 times/d	5
		10–25	Same	q8h	5
		0–10[b]	Same	q12h	5
	Shingles	>25	20 mg/kg up to 800 mg	5 times/d	5–7
		10–25	Same	q8h	5–7
		0–10[b]	Same	q12h	5–7
IV acyclovir	Life-threatening VZV infection	>50	500 mg/M^2 or 10 mg/kg[c,d]	q8h	7
		25–50	Same	q12h	7
		10–25	Same	q24h	7
		0–10[b]	250 mg/M^2	q24h	7
Famciclovir	Shingles >age 18 yr	>60	500 mg	q8h	7
		40–59	500 mg	q12h	7
		20–39	500 mg	q24h	7
		≤20	250 mg	q24h	7
Valacyclovir	Shingles >age 18 yr	>50	1000 mg	q8h	7
		30–49	1000 mg	q12h	7
		10–29	1000 mg	q24h	7
		≤10	500 mg	q24h	7
Foscarnet	Acyclovir-resistant VZV[e]	>100[f]	60 mg/kg	q8h	7–10

[a] See package insert for recommended dose adjustment of all drugs.
[b] An additional dose is recommended after each hemodialysis treatment.
[c] To minimize renal toxicity an adequate urine output is required. This can be assured if the acyclovir is infused at a concentration of approximately 4 mg/mL over 1 hour and the same volume of fluid is given over the next hour.
[d] Use ideal body weight for height to calculate dose in obese person: M^2, square meter of body surface area.
[e] Foscarnet is recommended by experts for treatment of life-threatening acyclovir-resistant VZV infection, but this is not a US Food and Drug Administration (FDA)-approved indication for foscarnet use. Appropriate informed consent should be obtained before such use.
[f] Foscarnet is nephrotoxic, and dosage should be based on creatinine clearance. Guidelines for dosage adjustment are listed in the package information.

(AAP) does not recommend that otherwise normal children <12 years receive oral acyclovir for chickenpox.

All adults with chickenpox should receive oral acyclovir, and those with rapidly progressive infection should be treated with intravenous (IV) acyclovir. Valacyclovir (Valtrex) and famciclovir (Famvir), both of which are approved for treatment of shingles, are not approved in the United States for treatment of chickenpox. All immunosuppressed persons with chickenpox should be treated with IV acyclovir until the course of infection is defined. However, as noted by the AAP, some experts have used oral acyclovir in highly selected immunocompromised persons who are at relatively low risk for developing complications and in whom follow-up is assured. Case-by-case evaluation of risks versus benefits is necessary, but for many groups the risk of disseminating infection is sufficiently high and so unpredictable that IV treatment should be recommended in nearly all cases. IV acyclovir should be used for the pregnant patient with serious complications of varicella, but, if acyclovir is used routinely for the pregnant woman with uncomplicated chickenpox, it should be recognized that the risk and benefits to the fetus and mother are mostly unknown. Varicella-zoster immune globulin (VZIG) is licensed for use in high-risk individuals at the time of exposure to VZV infection but is not recommended for treatment of chickenpox.

Complications

Pyoderma is the most frequently observed bacterial complication of varicella. It can be minimized by attention to good hygiene, including daily bathing with bacteriostatic soap or dilute bleach baths. Streptococcal and staphylococcal bacterial infections can be associated with bacteremia and subsequent osteomyelitis, with scarlet fever, and with bacterial synergetic gangrene.

Bacterial superinfection can affect the lower respiratory tract, producing pneumonia and bronchitis. Viral pneumonia is more likely to be a problem in older persons with chickenpox. Therefore, it is important to monitor pulmonary status during treatment.

It is important to monitor for gastrointestinal tract involvement, including bleeding and vomiting. Mild asymptomatic hepatitis is observed in a majority of children with varicella, usually asymptomatic elevation of hepatic enzymes for which no treatment is necessary. However, elevation of serum or urinary amylase may indicate pancreatitis, which may require supportive treatment. Although rare today, Reye's syndrome and other metabolic diseases must be considered in any child with varicella in whom there is vomiting and changes in mental status.

Neurologic complications include cerebral or cerebellar abnormalities; the latter is a more benign disease. Cerebellar ataxia, the most common syndrome associated with varicella encephalitis, is most often a benign entity due to postinfectious demyelination. There is no evidence that acyclovir treatment is necessary in postchickenpox cerebellitis, but it is prudent to include antiviral therapy in any cerebral presentation of VZV infection, especially if it may be associated with continued viral replication, as in AIDS or other immunosuppressive states.

Bleeding disorders associated with varicella include disseminated intravascular coagulation, vasculitis, and idiopathic thrombocytopenic purpura (ITP). These should be managed according to conventional treatment, and there is no VZV-specific management regimen.

Immunosuppressed patients

As noted, acyclovir is the only indicated drug for the treatment of VZV infections in the immunosuppressed patient. These infections include disseminated chickenpox, disseminated shingles, or localized shingles. Three other antiviral medications, valacyclovir, famciclovir, and foscarnet (Foscavir), have activity against VZV. Valacyclovir and famciclovir are indicated for the treatment of shingles as described later (see Table 192.1). Foscarnet is recommended for the treatment of acyclovir-resistant VZV.

Shingles

Overall assessment

The development of shingles in and of itself does not produce substantial morbidity; rather, it is the potential for neurologic and inflammatory complications of zoster disease that cause patients—and physicians—the greatest difficulty. The relationship between zoster infection and destruction of neurons and satellite cells has been well established, with neurologic damage beginning even before the characteristic zoster rash appears. PHN (Box 192.1), the most frequent complication of VZV, can cause debilitating pain and impaired quality of life among the otherwise healthy elderly. The associated pain, furthermore, can continue long after the rash resolves, despite aggressive antiviral and/or pain therapy.

Symptomatic therapy

Individuals with zoster should be instructed to keep the cutaneous lesions clean and dry to reduce the risk of bacterial superinfection. A sterile, nonocclusive, nonadherent dressing placed over the involved dermatome will protect the lesions from contact with clothing. Acute pain can be very severe and refractory to therapy. Sympathetic nerve blockade can provide rapid, temporary relief of severe pain. Scheduled short-acting narcotic analgesics can be prescribed. For persistent pain, long-acting, controlled-release formulations are preferred. If the eye is involved, an ophthalmologist should be consulted for use of topical anti-inflammatory or antiviral medication and for long-term evaluation.

BOX 192.1

Postherpetic neuralgia (PHN) can present with a range of neurologic features

Pain can be intermittent or continuous, deep or superficial
Pain described as throbbing or stabbing
Spontaneous aching or burning
Paroxysmal shooting pain
Allodynia
Hyperalgesia
Intense itching

Adapted from Johnson and Whitton. *Expert Opin Pharmacother*. 2004;5:551–558.

Treatment with corticosteroids may in the short term reduce herpes-related pain intensity, but it is associated with a risk of serious adverse effects. Longer term studies have demonstrated that corticosteroids, administered orally or intrathecally, offer acute benefits but fail to prevent PHN. Corticosteroids may reduce pain intensity, but the high prevalence of diabetes, hypertension, and glaucoma among adults ≥50 years, those most likely to develop herpes zoster, severely limits the number of patients for whom corticosteroids would be helpful.

Antiviral therapy

Antiviral drugs have been consistently found to effectively reduce the severity and duration of herpes zoster and are safe and well-tolerated, with minimal adverse effects. They do not, however, reliably prevent the development of PHN. Nearly all study protocols require initiation of antiviral therapy within 72 hours of rash onset. Although 72 hours is frequently mentioned as a cutoff for therapy, there are no data showing that antiviral therapy initiated >72 hours after rash onset is not helpful, and there are observational data to suggest that it is quite helpful.

Acyclovir, valacyclovir, and famciclovir are licensed in the United States for the treatment of shingles in otherwise normal persons (see Table 192.1). Acyclovir is the agent of choice for immunocompromised persons and is the only IV agent available for treatment of shingles. Valacyclovir is the prodrug of acyclovir and, because of better bioavailability, is preferred over acyclovir for oral therapy of shingles. Famciclovir is an oral prodrug of the antiviral agent penciclovir, which has potent activity against VZV, and famciclovir undergoes rapid biotransformation to the active antiviral compound. Safety and efficacy in children has not been established for either valacyclovir or famciclovir. Also, because of the potential for

tumorigenicity in rats, famciclovir should not be given to pregnant or nursing mothers unless nursing is discontinued.

Management of exposure to VZV

The spread of infectious VZV from a person with chickenpox is by air droplets from nasopharyngeal secretions, which usually requires face-to-face exposure indoors for an hour but can also be via air currents to susceptible individuals without direct contact. The period of respiratory infectivity is generally considered to begin 48 hours prior to the onset of exanthem and to continue for 4 days after onset. In addition, the vesicular fluid can spread the virus by direct contact, so infectivity by contact with skin lesions is possible until they are crusted. Shingles can also spread by direct contact or by exposure to airborne infectious material. The incubation period for chickenpox following exposure to shingles is the same as for exposure to chickenpox: 15 days with a range of 10 to 21 days. The varicella attack rate in susceptible children on household exposure to chickenpox is approximately 90% and is 25% on exposure to household shingles.

Immunocompromised host exposed to VZV

Prior to the introduction of the varicella vaccine, the only protection from VZV infection was passive immunization at the time of exposure. Families and school personnel must continue to be aware of exposure to VZV in high-risk persons so that VZIG can be administered within 96 hours. Any susceptible person at risk for complications of VZV (Box 192.2) should receive passive immunization if exposure was adequate to communicate disease and occurred within approximately 4 days.

BOX 192.2

Groups at risk for complications of varicella-zoster virus (VZV) infection[a]

Susceptible persons on immunosuppressive therapy[b]
Persons with congenital cellular immunodeficiency
Person with an acquired immunodeficiency, including AIDS
Persons >20 years
Newborn infants exposed to onset of maternal varicella <5 days before or 2 to 7 days after birth
Premature infants weighing <1 kg[c]

[a] Susceptible (antibody negative) persons exposed to VZV by indoor face-to-face contact with an infected person <2 days before or anytime during vesiculopustular stage of chickenpox are at highest risk and should receive VZIG.

[b] All cytoreductive chemotherapy and radiotherapy is considered immunosuppressive. The immunosuppressive dose of prednisone equivalent can vary in individual cases but is in the range of 1 to 2 mg/kg/d.

[c] The risk of complications of VZV infection in this group, which is poorly defined, is based on the likelihood of protective maternal antibody versus gestational age at birth.

AIDS, acquired immunodeficiency syndrome; VZIG, varicella-zoster immune globulin; VZV, varicella-zoster virus.

Individuals receiving immunosuppressive therapy should have this discontinued during the incubation period, although this precaution is waived if the underlying disease requires continued treatment. Although not approved for such use, especially in children ≤12 years, valacyclovir, given at a dose of 1,000 mg orally three times daily or 500 mg in those weighing <40 kg, can be effective in settings of acute exposure to VZV to prevent the development of chickenpox.

Normal adults exposed to VZV

More than 90% of adults have had VZV. Susceptible adults are at risk for life-threatening chickenpox, and they are the source of unexpected epidemics. The decision to use VZIG in susceptible healthy adults following close exposure to VZV should be made on an individual basis, taking into consideration the person's health, the type of exposure, and the likelihood of previous chickenpox.

Nosocomial VZV

Control of nosocomial infections requires three actions: (1) routine, continuous surveillance of VZV susceptibility among hospital staff, with VZV vaccination as indicated; (2) adequate isolation of contagious VZV infections; and (3) rapid evaluation of and response to exposure. Hospitals that care for immunodeficient children should screen staff at the time of employment for susceptibility. This can be done efficiently by performing antibody tests on those who have a negative or unknown history of chickenpox. Susceptible employees should be vaccinated and excluded from care of patients with VZV infection until approximately 1 month after the second dose of vaccine. Exposed susceptible healthcare workers should be furloughed from the eighth day after initial exposure until 21 days after the last exposure.

If the VZV exposure is from a patient, he or she should be discharged if possible. If not possible, the patient should be placed in isolation designed to prevent spread of infection by both air and direct contact. Isolation should remain in effect until skin lesions are crusted.

After control of the source of infection comes quick assessment of three types of information: (1) the nature of the exposure and whether it is likely to result in secondary infections, (2) the susceptibility to VZV of the exposed patients or staff, and (3) the risk for complications in these exposed patients. Thus, the initial step is to define the hospital areas in which a definitive VZV exposure has occurred and then to focus on which patients in these areas are at risk for infection. Those patients remaining in the hospital should be placed in respiratory isolation between days 8 and 21 postexposure or for 8 to 28 days for those receiving VZIG.

Management of the pregnant woman

A syndrome of congenital varicella consisting of low birth weight, cutaneous scarring, limb hypoplasia, microcephaly, and other brain and eye abnormalities can occur in the baby of a pregnant woman who has chickenpox. Teratogenic damage results only from first- and second-trimester infection, and clinically apparent disease

occurs only in approximately 2% of infants born after maternal varicella in early pregnancy. For this reason, experts advise that maternal chickenpox is not a medical indication for abortion. There is no reliable diagnostic method, including amniocentesis and ultrasound, for determining teratogenic intrauterine infection. VZIG should be offered to pregnant, varicella-seronegative women with significant exposure to VZV infection. Oral antiviral prophylaxis should be considered for susceptible pregnant women exposed to VZV who did not receive VZIG or have risk factors for severe disease. IV acyclovir should be given to pregnant women who develop complicated varicella at any stage of pregnancy. However, it is generally recommended that these agents be used only if the benefit to the pregnant woman clearly exceeds the potential risk to the fetus.

Acknowledgments

I would like to acknowledge Dr. John A. Zaia for this update to his prior version of this chapter.

Viral hemorrhagic fevers

Daniel G. Bausch

Introduction

The term *viral hemorrhagic fever* (VHF) refers to an acute systemic illness classically involving fever, a constellation of initially nonspecific signs and symptoms, and a propensity for bleeding and shock. VHFs are caused by small, single-stranded, lipid-enveloped RNA viruses from four families (Table 193.1).

Epidemiology

Natural maintenance and transmission to humans

With the exception of dengue virus (see Chapter 183, Dengue), for which humans can now be considered to be the reservoir, hemorrhagic fever viruses are zoonotic and maintained in nature in mammals (Table 193.1). The endemic area of any given VHF is thus restricted by the distribution of its natural reservoir and/or arthropod vector, although the distribution of the virus and disease are often less vast than that of the reservoir. Infection is presumed to most often result from inadvertent inoculation of virus-contaminated reservoir excreta into mucous membranes or broken skin or, in the case of the arbovirus VHFs, mosquito or tick bite. Aerosol transmission has been suggested but there are few data to confirm or refute this route of exposure and empiric field observations suggest that aerosol transmission is not a predominant mode of spread, if it occurs at all. Nevertheless, artificially produced aerosols can infect laboratory animals, with obvious implications for potential use as bioweapons.

Human-to-human transmission

Secondary human-to-human transmission occurs in many VHFs, usually through direct contact with contaminated blood or body fluids (Table 193.1), although secondary attack rates are generally low (15%–20%). Infection probably occurs most often through oral or mucous membrane exposure. Again, there are few data on aerosol spread. Large outbreaks are almost always the result of amplification in healthcare settings in which basic infection control measures have broken down, usually in areas of extreme poverty or civil strife. The risk of transmission during the incubation period or from asymptomatic persons is negligible, although a case of Argentine hemorrhagic fever was reported due to blood transfusion from a donor who was asymptomatic. Although rare, sexual transmission during early convalescence has been suspected, best documented for Ebola, Marburg, Lassa, and Junín viruses. Despite the ease of modern-day travel, imported VHF cases remain extremely rare.

Flaviviridae						
Yellow fever	Yellow fever	Sub-Saharan Africa, South America up to Panama	Monkey/mosquito *(Aedes aegypti,* other *Aedes* and *Hemagogus* species)	5000-200 000[1]	**1**:2-20	None
Dengue	Dengue HF	Tropics and subtropics worldwide	Human/mosquito *(Ae. aegypti and As. albopictus)*	100 000-200 000[1]	1:10-100 depending on age, previous infection, genetic background, and infecting serotype	None
Omsk HF	Omsk HF	Western Siberia	Rodent/tick (primarily *Dermacentor* and *Ixodes* species)	100-200	Unknown	Not reported
Kyasanur Forest disease	Kyasanur Forest disease	Karnataka state, India; Yunnan Province, China; Saudi Arabia	Vertebrate (rodents, bats, birds, monkeys, others)/tick *(Haemophysalis* species and others)	-500	Unknown	Not reported, but laboratory infections have occurred
Alkhumra HF	Proposed name: Alkhumra HF	Saudi Arabia, Egypt	Ticks?	<50	Unknown	Not reported

Abbreviation: HF = hemorrhagic fever.
[a] Six species or subtypes of Ebolavirus are recognized with varying associated case-fatality ratios (see Table 193.2). All are endemic to sub-Saharan Africa, with the exceptions of Reston ebolavirus that is found in the Philippines and
Lloviu ebolavirus which was detected in bats in Spain.
[b] Although some endemic transmission of the filoviruses (Ebolavirus >Marburgvirus) and Rift Valley fever virus occurs, these viruses have most often been associated with outbreaks. Filovirus outbreaks are typically less than
100 cases and have never been greater than 500.
[c] The virus families Arenaviridae and Bunyaviridae are serologically, phylogenetically, and geographically divided into Old World (i.e., Africa) and New World (i.e., the Americas) complexes.
[d] In addition to the arenaviruses listed in the table, Flexal and Tacaribe viruses have caused human disease as a result of laboratory accidents. Another arenavirus, Whitewater Arroyo, has been noted in sick persons in California but its
role as a pathogen has not been clearly established.
[e] Discovered in 2008. Only 5 cases (4 of them fatal) from one outbreak have been noted. The index case came to South Africa from Zambia.
[f] Discovered in 1990. Only 3 cases (1 fatal) have been noted, 2 of them from laboratory accidents.
[g] Discovered in 2003 from a small outbreak from which blood was obtained from one fatal case and Chapare virus isolated. Few other details have been reported.
[h] Although Rift Valley fever virus can be found throughout sub-Saharan Africa, large outbreaks usually occur in East Africa's Rift Valley region.
[i] Based on estimates from the World Health Organization. Significant underreporting occurs. Incidence may fluctuate widely in place and time.
[j] Alkhumra is considered by some to be a variant of Kyasanur Forest disease virus. Disagreement exists over the proper spelling of the virus, written as "Alkhurma" in some publications.

Pathology and pathogenesis

Microvascular instability, increased vascular permeability, and impaired hemostasis are the pathophysiologic hallmarks of VHF, although the mechanisms vary with each virus. Mortality usually results not from exsanguination but from a process akin to septic shock, with insufficient effective circulating intravascular volume leading to cellular dysfunction and multiorgan system failure. In fact, external bleeding is seen in a minority of cases of some VHFs (Table 193.2).

After inoculation, virus typically replicates in dendritic cells before disseminating to regional lymph nodes and then through the

Abbreviations: ECMO = extracorporeal membrane oxygénation; HF = hemorrhagic fever.

[a] Six species or subtypes of Eboiavirus are recognized with varying associated case-fatality ratios: Zaire – 85%, Sudan – 55%, Bundibugyo – 40%, Tai Forest (also called Cote d'Ivoire) – 0 (only one recognized case, who survived),
Reston – 0 (not pathogenic to humans), Lloviu – no human infections recognized.

[b] The case fatality ratio was 22% in the first recognized outbreak of Marburg HF in Germany and Yugoslavia in 1967 but has been consistently over 80% in outbreaks in central Africa where the virus is endemic. Possible reasons for
this discrepancy include differences in quality of care, strain pathogenicity, route and dose of infection, underlying prevalence of immunodeficiency and comorbid illnesses, and genetic susceptibility.

[0] A morbilliform or maculopapular skin rash almost always occurs in persons with lighter skin, who are usually expatriates, but, for unclear reasons, is rarely present in darker-skinned Africans from the endemic area.

[d] Data are insufficient to distinguish between the syndromes produced by the various arenavimses found in the Americas. They are thus frequently grouped as the "South American hemorrhagic fevers."

[e] HF, encephalitis, and retinitis may be seen in Rift Valley fever independently of each other.

[f] The incubation period of Crimean-Congo HF varies with the mode of transmission: typically 1–3 days after tick bite and 5–6 days after contact with infected animal blood or tissues.

[g] Based on preliminary observations. Fewer than 100 cases have been reported.

Key: 0 = sign not typically noted/organ not typically affected, + = sign occasionally noted/organ occasionally affected, ++ = sign commonly noted/organ commonly affected, +++ = sign characteristic/organ involvement severe.

lymph and blood monocytes to a broad array of organs, including liver, spleen, lymph node, adrenal gland, lung, and endothelium. The particular organs most affected vary with the VHF (Table 193.2). Virus interaction with immune cells, especially macrophages and endothelial cells, results in cell activation and the unleashing of an inflammatory vasoactive process consistent with the systemic inflammatory response syndrome. Impaired hemostasis may entail endothelial cell, platelet, and/or coagulation factor dysfunction. Disseminated intravascular coagulation (DIC) is frequent in some VHFs (Table 193.2). The degree of tissue damage varies with the VHF and may be mediated either through necrosis or apoptosis. Cardiac inotropy may be inhibited in some VHFs, further impairing organ perfusion. Adrenal or pituitary gland necrosis with consequent vascular collapse has been postulated but not specifically demonstrated. Virus is cleared rapidly from the blood in survivors but may remain for weeks or months in a few immunologically protected sites, such as the chambers of the eye, central nervous system, and gonads, the latter resulting in the aforementioned sexual transmission during convalescence.

The pathogenesis of most VHFs appears to be related to unchecked viremia, with most fatal cases failing to mount a significant antibody response, in some cases due to virus-induced suppression of the host adaptive immune response. Virus can be found in a wide variety of body fluids during the acute illness, including blood, saliva, stool, and breast milk. Inflammatory cell infiltration is usually mild, consisting of a mix of mononuclear cells and neutrophils. However, in dengue, yellow fever, and hantavirus infections (see Chapter 186, Hantavirus cardiopulmonary syndrome in the Americas), in which viremia is usually cleared prior to the most severe phase of the disease, the host immune response may play a detrimental role. The unique process of antibody-mediated enhancement may facilitate the development of dengue hemorrhagic fever (see Chapter 183, Dengue).

Clinical presentation

VHF is seen in both genders and all ages. Although the clinical manifestations of each VHF may differ as disease progresses, distinction in the early phases is rarely possible. Most patients present with nonspecific signs and symptoms difficult to distinguish from other common febrile illnesses, including fever, general malaise, anorexia, headache, chest or retrosternal pain, sore throat, myalgia, arthralgia, and lumbosacral pain (Table 193.2). The pharynx may be erythematous or even exudative, especially in Lassa fever, resulting in misdiagnosis of streptococcal pharyngitis or mononucleosis (Figure 193.1A). Conjunctival injection or hemorrhage is frequent but not typically accompanied by itching, discharge, or rhinitis (Figures 193.1B and C). Hiccups may be seen early in Ebola hemorrhagic fever. Gastrointestinal signs and symptoms ensue in the first few days, including nausea and vomiting, epigastric and abdominal pain and tenderness (especially in the right upper quadrant in Ebola hemorrhagic fever), and non-bloody diarrhea. Appendicitis or other acute abdominal emergencies are sometimes suspected, prompting potentially hazardous (in terms of risk of bleeding and nosocomial spread) surgical interventions. Morbilliform, maculopapular, petechial, or ecchymotic skin rashes may be seen, depending on the specific VHF (Table 193.2 and Figure 193.1D). Hepatosplenomegaly is frequently noted but may simply represent high underlying prevalence in populations in sub-Saharan Africa where most clinical observations have been made. Relative bradycardia (Faget's sign) and orthostatic hypotension may be noted, especially in yellow fever and dengue virus infections. Biphasic illnesses are described with a quiescent period of days (yellow fever, dengue hemorrhagic fever, and Rift Valley fever) to weeks (Kyasanur Forest disease and Omsk hemorrhagic fever) after which the most severe manifestations may set in, but not uniformly noted. Distinct progressive phases of prodrome, hypotension, oliguria/renal failure, diuresis, and convalescence are classically described for hemorrhagic fever with renal syndrome (HFRS), but again not uniformly seen. Neck pain and stiffness, retro-orbital pain, and photophobia and other meningeal signs are common in Rift Valley fever, Kyasanur Forest disease, and Omsk hemorrhagic fever.

In severe cases, patients progress towards the end of the first week of illness to vascular instability that may be manifested by facial flushing, edema, bleeding, hypotension, shock, and proteinuria (Figures 193.1E–H). The likelihood of hemorrhage varies with the VHF (Table 193.2) and may be manifested as hematemesis, melena, hematochezia, menometrorrhagia, petechiae, purpura, epistaxis, and bleeding from the gums and venipuncture sites (Figures 193.1E–G). Hemoptysis and hematuria are infrequent. Hemorrhage is almost never present in the first 48 hours of illness. Facial and neck swelling are classic signs of severe Lassa and Lujo virus infection. Central nervous system manifestations, including delirium, tremor, gait anomalies, convulsions, and hiccups may be noted in end-stage disease. Renal insufficiency or failure may occur, especially in HFRS. Pregnant women often present with spontaneous abortion and vaginal bleeding. A dry cough, sometimes with a few scattered rales on auscultation, is frequently noted, but prominent pulmonary symptoms early in the course of disease are uncommon, with the exception of with hantavirus pulmonary syndrome. With the exception of yellow fever, jaundice is not typical in the absence of underlying Gilbert's syndrome, drug reaction, or coinfection. Radiographic and electrocardiographic findings are generally nonspecific.

Disease usually progresses rapidly, with death 7 to 14 days after symptom onset in fatal cases. Common indicators of a poor prognosis include shock, bleeding, neurologic manifestations, high viremia (or surrogate measurements of antigen or genome copies), and elevated levels of aspartate aminotransferase (>150 IU/L). Maternal and fetal mortality are elevated in pregnancy, especially during the third trimester, where they approach 100%. However, mild and even asymptomatic cases have been reported even for what are considered the most virulent VHFs, possibly related to differences in route and dose of infection, underlying comorbid illness, and host genetic predisposition. Specific human genotypes or histocompatibility markers have been associated with risk of Lassa fever and hantavirus infection.

FIGURE 193.1 Continued

Differential diagnosis

The nonspecific early clinical presentation makes clinical diagnosis difficult, with a long differential diagnosis (Table 193.3). Recognition of case clusters, often involving healthcare workers, is a common first clue. A detailed epidemiologic history and physical exam and preliminary laboratory results (Table 193.4) are critical, including details of travel, exposures, occupational risks, and disease progression (for example, timing of hemorrhage relative to onset of illness). VHF should be considered in patients who (1) reside in or traveled to an endemic area (Table 193.1); (2) had potential direct contact with blood or body fluids of someone with a VHF during their acute illness (this group most often is composed of healthcare workers, persons caring for family members at home or preparing bodies for burial, and laboratory personnel); (3) had contact with live or recently killed wild animals (especially nonhuman primates) in or recently arriving from an endemic area, including veterinarians, hunters, farm and abattoir workers, and taxidermists. Food potentially recently contaminated by these animals could also be a source of infection, although this remains to be clearly documented; (4) worked in a VHF research laboratory or animal facility; or (5) had sexual relations with someone recovering from a VHF in the last 3 months. Most VHFs are rare even in persons meeting the above criteria so alternative diagnoses, especially malaria and typhoid fever, should always be aggressively sought. Acts of bioterrorism must be considered if VHF is strongly suspected in a patient without any of the above criteria, especially if clusters of cases occur.

Laboratory diagnosis

Prompt laboratory confirmation of VHF is imperative but testing is unfortunately only available in a few specialized laboratories since no commercial assays exist, with the exception of various kits for dengue fever and hantavirus pulmonary syndrome. In the United States, testing can be arranged through the Centers for Disease Control and Prevention (phone 404–639–1115, after hours 770–488–7100; e-mail dvd1spath@cdc.gov). Commonly used diagnostic assays include enzyme-linked immunosorbent assay (ELISA) for viral antigen and IgM antibody, polymerase chain reaction, virus culture, immunofluorescent antibody assay, and immunohistochemistry on postmortem tissues. Research is underway on a variety of new diagnostic approaches.

Clinical management

Patients should generally be treated in an intensive care unit. For most VHFs, only supportive therapy is available. Treatment guidelines generally follow those recommended for septic shock, given the overlap in the pathogenesis of that condition and severe VHF, and considering that results from controlled trials on VHF are rare. Consultation with infectious disease specialists with experience treating VHF should be sought as soon as the diagnosis is considered. The process of performing a workup for non-VHF etiologies while assuring staff and patient safety and avoiding undue panic is a delicate one. Knowledge that most VHFs are rare and that routinely practiced universal and contact precautions are protective in the vast majority of cases should offer reassurance. Confirmed cases of VHF should be reported immediately to government health authorities.

Fluid management

Fluid management in VHF poses a particular challenge. Severe microvascular instability, often complicated by vomiting, diarrhea, decreased fluid intake, and third-spacing, often dictates aggressive fluid replacement, which may prevent shock and DIC. However, overaggressive and unmonitored rehydration may lead to pulmonary edema, especially given the impaired cardiac function

TABLE 193.3 **DIFFERENTIAL DIAGNOSIS OF THE VIRAL HEMORRHAGIC FEVERS**

Disease	Distinguishing characteristics and comments
Parasites	
Malaria	Classically shows paroxysms of fever and chills; hemorrhagic manifestations less common; malaria smears or rapid test usually positive; coinfection (or baseline asymptomatic parasitemia) common; responds to antimalarials
Amebiasis	Hemorrhagic manifestations other than bloody diarrhea generally not seen; amebic trophozoites identified in the stool by microscopy and/or antigen assays; responds to antiparasitics
Giardiasis	Positive stool antigen test and/or identification of trophozoites or cysts in stool; responds to antiparasitics
African trypanosomiasis (acute stages)	Especially the east African form. Examination of peripheral blood smear/buffy coat may show trypanosomes
Bacteria (including Spirochetes, *Rickettsia, Ehrlichia, and Coxiella*)	
Typhoid fever	Hemorrhagic manifestations other than bloody diarrhea generally not seen; responds to antibiotics
Bacillary dysentery (including shigellosis, campylobacteriosis, salmonellosis, and enterohemorrhagic *Escherichia coli* and others)	Hemorrhagic manifestations other than bloody diarrhea generally not seen; respond to antibiotics
Capnocytophaga canimorsus	Associated with dog and cat bites, typically in persons with underlying immunodeficiency, notably asplenic patients; responds to antibiotics
Meningococcemia	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; bleeding within the first 24–48 hours after onset of illness and rapidly progressive illness typical; large ecchymoses typical of meningococcemia are unusual in the VHFs except for Crimean-Congo HF; rapid serum latex agglutination tests can be used to detect bacterial antigen in meningococcal septicemia; may respond to antibiotics (critical to administer early)
Staphylococcemia	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; may respond to antibiotics
Septic abortion	History of pregnancy and positive pregnancy test
Septicemic or pneumonic plague	Bacterial-induced DIC may mimic the bleeding diathesis of VHF; large ecchymoses typical of plague are unusual in the VHFs except for Crimean-Congo HF; pneumonic plague may mimic hantavirus pulmonary syndrome; may respond to antibiotics
Streptococcal or Epstein–Barr virus pharyngitis	May mimic the exudative pharyngitis sometimes seen in Lassa fever
Tuberculosis	Hemoptysis of advanced pulmonary tuberculosis may suggest VHF, but tuberculosis generally has a much slower disease evolution
Tularemia	Ulceroglandular and pneumonic forms more common; responds to antibiotics
Acute abdominal emergencies	Appendicitis, peritonitis, and bleeding upper gastrointestinal ulcer
Pyelonephritis and poststreptococcal glomerulonephritis	May mimic HF with renal syndrome
Anthrax (inhalation or gastrointestinal)	Prominent pulmonary manifestations and widened mediastinum on chest x-ray in inhalation form; responds to antibiotics
Atypical bacterial pneumonia (*Legionella*, *Mycoplasma*, *Chlamydia pneumoniae* and *Chlamydia psittaci*, others)	May mimic hantavirus pulmonary syndrome; exposure to birds; symptoms often not present until late in the illness in psittacosis; respond to antibiotics
Relapsing fever	Recurrent fevers and flu-like symptoms, with direct neurologic involvement and splenomegaly; spirochetes visible in blood while febrile; responds to antibiotics

(continued)

TABLE 193.3 CONTINUED

Disease	Distinguishing characteristics and comments
Leptospirosis	Jaundice, renal failure, and myocarditis in severe cases; responds to antibiotics
Spotted fever group rickettsia (including African tick-bite fever, Boutonneuse fever, Rocky Mountain spotted fever)	Incubation period of 7–10 days after tick bite, compared with 1–3 days in Crimean-Congo HF; necrotic lesions (eschar) typically seen at site of tick bite in some rickettsial diseases while there may only be slight bruising at the bite site in Crimean-Congo HF; rash (if present) of rickettsial infection classically involves palms and soles
Q fever *(Coxiella burnetii)*	Broad spectrum of illness, including hepatitis, pneumonitis, encephalitis, and multisystem disease with bleeding; responds to antibiotics
Ehrlichiosis	Diagnosis by serology and PCR; blood film may be useful; responds to antibiotics
Viruses	
Influenza	Prominent respiratory component to clinical presentation; no hemorrhagic manifestations; influenza rapid test may be positive; may respond to anti-influenza drugs
Arbovirus infection (including dengue and West Nile fever)	Encephalitis unusual, but when present may mimic the VHFs with significant neurologic involvement (Kyasanur Forest disease, Omsk HF); usually less severe than VHF; hemorrhage not reported
Viral hepatitis (including hepatitis A, B, and E, Epstein–Barr, and cytomegalovirus)	Jaundice atypical in HF except yellow fever; tests for hepatitis antigens positive; fulminant infection resembling VHF may be seen in persons with underlying immune deficiencies
Herpes simplex or varicella-zoster	Fulminant infection with hepatitis (with/without vesicular rash); elevated transaminases and leukopenia typical; disseminated disease may be noted in otherwise healthy persons; poor response to acyclovir drugs unless recognized early
HIV/AIDS	Seroconversion syndrome or HIV/AIDS with secondary infections, especially septicemia
Measles	Rash may mimic that seen in early stages of some VHFs and may sometimes be hemorrhagic; prominence of coryza and upper respiratory symptoms in measles should help differentiate; vaccine preventable
Rubella	Rash may mimic that seen in early stages of some VHFs; usually a mild disease; vaccine preventable
Hemorrhagic or flat smallpox	Diffuse hemorrhagic or macular lesions; in contrast to the VHFs, the rash may involve the oral mucosa, palms, and soles; smallpox in the wild has been eradicated
Alphavirus infection (including chikungunya and o'nyong-nyong)	Joint pain typically a predominant feature
Fungi	
Histoplasmosis	Pulmonary disease may mimic hantavirus pulmonary syndrome; recent entry into mines or caves
Noninfectious etiologies	
Heat stroke	History for extreme heat exposure; absence of sweating; bleeding not typical but DIC may occur
Idiopathic and thrombotic thrombocytopenic purpura (ITP/TTP)	Presentation usually less acute than VHF; may have prominent neurologic symptoms in TTP; coagulation factors normal and DIC absent; often respond to corticosteroids (ITP) or plasma exchange (TTP)
Acute glaucoma	May mimic the acute ocular manifestations of Rift Valley fever
Hematologic malignancies (leukemia, lymphoma)	May resemble leukemoid reaction occasionally seen in HF with renal syndrome
Drug sensitivity or overdose	Stevens–Johnson syndrome and anticoagulant (warfarin) overdose
Industrial and agricultural chemical poisoning	Especially anticoagulants, although other symptoms of VHF absent
Hematoxic snake bite envenomation	History of snake bite

Abbreviations: AIDS = acquired immunodeficiency syndrome; DIC = disseminated intravascular coagulopathy; HF = hemorrhagic fever; HIV = human immunodeficiency virus; PCR = polymerase chain reaction; VHF = viral hemorrhagic fever.

TABLE 193.4 **INDICATED LABORATORY TESTS AND CHARACTERISTIC FINDINGS IN THE VIRAL HEMORRHAGIC FEVERS**

Test	Characteristic findings and comments
Leukocyte count	Early: moderate leukopenia (except for hantavirus infection, in which early leukocytosis with immunoblasts are classically noted); later: leukocytosis with left shift; granulocytosis more suggestive of bacterial infection
Hemoglobin and hematocrit	Hemoconcentration (especially noted in hemorrhagic fever with renal syndrome and hantavirus pulmonary syndrome)
Platelet count	Mild-to-moderate thrombocytopenia
Electrolytes	Sodium, potassium, and acid–base perturbations, depending upon fluid balance and stage of disease Often increased
BUN/creatinine	Renal failure may occur late in disease
Serum chemistries (AST, ALT, amylase, gamma-glutamyl transferase, alkaline phosphatase, creatinine kinase, lactate dehydrogenase, lactic acid)	Usually increased, especially in severe disease; AST > ALT; a lactate level greater than 4 mmol/L (36 mg/dL) may indicate persistent hypoperfusion and sepsis. Lactate dehydrogenase is typically markedly increased in hantavirus pulmonary syndrome
Sedimentation rate	Normal or decreased
Blood gas	Metabolic acidosis may be indicative of shock and hypoperfusion
Coagulation studies (PT, PTT, fibrinogen, fibrin split products, platelets, D-dimer)	DIC common in Ebola, Marburg, Lujo virus, Crimean-Congo HF, and New World arenavirus infections. D-dimers appear to be an especially early and sensitive indicator
Urinalysis	Proteinuria common; hematuria may be occasionally noted; sediment may show hyaline-granular casts, and round cells with cytoplasmic inclusions
Blood culture	Useful early to exclude VHF and later to evaluate for secondary bacterial infection; blood should be drawn before antibiotic therapy is instituted
Stool culture	Useful to exclude VHF (in favor of hemorrhagic bacillary dysentery)
Thick and thin blood smears	May aid in the diagnosis of blood parasites (malaria and trypanosomes), bacterial sepsis (meningococcus, capnocytophaga, and anthrax) and ehrlichiosis; all negative in VHF unless coinfection
Rapid test, PCR, or other assay for malaria	Negative in VHF unless coinfection with malaria

Abbreviations: ALT = alanine aminotransferase; AST = aspartate aminotransferase; DIC = disseminated intravascular coagulation; VHF = viral hemorrhagic fever; BUN = blood urea nitrogen; PT = prothrombin time; PTT = partial thromboplastin time; PCR = polymerase chain reaction.

present in some VHFs, particularly hantavirus pulmonary syndrome. Although invasive hemodynamic monitoring would seem to be in order, with the exception of peripheral intravenous lines, indwelling vascular devices are contraindicated due to the risk of bleeding at the site, although they have been occasionally placed without reported complications. Intramuscular and subcutaneous injections should be avoided due to the risk of hematoma. It is probably best to rely on frequent sphygmomanometer readings and fluid balance assessment from capillary refill and urine output.

Early goal-directed therapies have been shown to mitigate both mortality and organ dysfunction in shock. Crystalloids (normal saline or Ringer's lactate), blood products (see below), and, if necessary, vasopressors (norepinephrine, adding epinephrine when warranted) should be infused to maintain mean arterial blood pressure above 65 mm Hg in adults. Vasopressin (0.03 U/min) can be added to decrease the norepinephrine dose but should not be used as the initial vasopressor. Dobutamine should be considered if there is evidence of myocardial dysfunction but dopamine is not recommended. Peritoneal and hemodialysis have been employed extensively in patients with HFRS without frequent complications, but there is little published experience with the other VHFs. Specific World Health Organization (WHO) guidelines exist for the fluid management of dengue shock syndrome (see Chapter 183).

Blood products and management of DIC

Despite profuse bleeding in some VHFs (Table 193.2), blood products should not be given empirically but rather only to meet defined clinical and laboratory parameters in the face of clinically significant hemorrhage. Transfusions, preferably with packed red blood cells, should be used to maintain a hemoglobin over 7.0 g/dL while avoiding volume overload, taking into account that chronic anemia due to malaria and malnutrition may be frequent in patients in certain geographic areas. Whole blood may be substituted if

packed cells are not available. Transfusion of platelet concentrate (1–2 U/10 kg) and/or fresh frozen plasma (FFP) (15–20 mL/kg) may be required if DIC is present (Table 193.2). Treatment should not be based on laboratory results alone except in preparation for an invasive procedure or when platelet levels fall to dangerously low levels (<50 000/mm^3 in a bleeding patient or 20 000/mm^3 without bleeding). The platelet count should generally rise by at least 2000/mm^3 per unit of platelets transfused, although the response will be less if there is ongoing DIC and platelet consumption. Impaired platelet aggregation may promote hemorrhage in some VHFs, especially Lassa fever, even when platelet counts are not drastically low. Fibrinogen concentrate (total dose 2–3 g) or cryoprecipitate (1 U/10 kg) may be administered instead of FFP, although FFP has the theoretical advantage of containing all coagulation factors and inhibitors deficient in DIC but no activated coagulation factors. Vitamin K (10 mg intravenous or orally for 3 days) and folic acid may be given, especially if underlying malnutrition or liver disease is suspected, although their efficacy is unknown.

Oxygenation and ventilation

With the exception of hantavirus pulmonary syndrome, for which early mechanical ventilation is often lifesaving, impaired gas exchange is not typically a prominent feature of VHF, especially in the early phases of disease and in the absence of iatrogenic pulmonary edema. Most patients can be supported with oxygen administered via a nasal cannula or face mask. In neurologically intact patients, noninvasive positive pressure ventilation may be a useful adjunct to forestall intubation. When mechanical ventilation is required, lung-protective tidal volumes (6–8 mL/kg of ideal body weight) should be employed to avoid ventilator-induced lung injury (i.e., barotrauma) and pulmonary hemorrhage. Extracorporeal membrane oxygenation has been used with apparent benefit in hantavirus pulmonary syndrome. Due to the risk of bleeding, arterial puncture for blood gas determination should be minimized, relying on respiratory rate and pulse oximetry if possible.

Antiviral drugs

The guanosine analog ribavirin is the only currently available antiviral therapy for any VHF (Table 193.2). Early treatment is imperative for maximum benefit. The best data are for the arenaviruses, especially Lassa fever, and HFRS (Table 193.2). Ribavirin also appears to be efficacious in Crimean-Congo HF, although few randomized controlled clinical trials have been performed. A prospective trial of ribavirin in Rift Valley fever in Saudi Arabia in 2000 was stopped after an increase in encephalitis was noted in the treatment group, but significant baseline discrepancies between the treatment and control groups make definitive conclusions difficult. In vitro data generally show activity of ribavirin against dengue, yellow fever, and Omsk hemorrhagic fever viruses, but clinical studies have not been performed. Ribavirin is not efficacious against Ebola or Marburg viruses. The main side effects of intravenous ribavirin are a mild-to-moderate hemolytic anemia, which infrequently necessitates transfusion and disappears with cessation of treatment, and rigors when the drug is infused too rapidly. A number of experimental therapies have shown in vitro activity and therapeutic benefit in animal studies and have been used on a compassionate-use basis in humans, but are not yet approved or widely available.

Convalescent plasma and antibody therapy

Although cellular immunity is thought to be the primary arm of protection in most VHFs, treatment with convalescent immune plasma has often been tried, especially for arenavirus infections. Transfusion of appropriately titered convalescent plasma within the first 8 days of illness reduces the case fatality of Argentine hemorrhagic fever to less than 1%. However, this therapy has been associated with a convalescent-phase neurologic syndrome characterized by fever, cerebellar signs, and cranial nerve palsies in 10% of those treated 7 to 80 days (mean 20 days) after initial symptom resolution. Animal studies show convalescent plasma to be efficacious in Lassa fever as well, but only if it contains a high titer of neutralizing antibody (which is not automatically the case) and there is a close antigenic match between the infecting viruses of the donor and recipient. Convalescent plasma or blood has been given to numerous patients with Ebola hemorrhagic fever, but their efficacy is still unknown. Risk of concomitant transmission of other bloodborne pathogens and lack of an existing bank of immune plasma for VHF treatment are significant impediments to this approach in most countries. With the exception of for Argentine hemorrhagic fever, this therapy should be reserved for severe and refractory cases when ribavirin is not an option. Numerous mono- and polyclonal antibody preparations show promise in VHF animal models.

Coagulation modulators

A growing body of literature suggests that disturbances in the procoagulant–anticoagulant balance play an important role in the mediation of septic shock. Coagulation-modifying drugs that have been explored anecdotally in humans or in animal models of sepsis and/or VHF, with varying degrees of efficacy, included rNAPc2 (a potent experimental recombinant inhibitor of the tissue factor/factor VIIa coagulation pathway), recombinant factor VIIa itself (paradoxically, since it would have the opposite effect of rNAPc2), heparin sulfate, and antithrombin III. Lower mortality was recently noted in heparin-treated patients with severe sepsis in a phase III clinical trial. Nevertheless, use of coagulation modulators for VHF should still be considered experimental. Despite early promise, recombinant activated protein C is no longer recommended for septic shock or VHF.

Immune modulators

Trials of various immune modulators in septic shock or VHF, including ibuprofen, corticosteroids, anti-tumor necrosis factor-α (TNF-α), nitric oxide inhibitors, statins (HMG-CoA reductase inhibitors), and interleukins, have not shown conclusive benefit. Ribavirin combined with interferon (IFN) alfacon-1, a consensus IFN, diminished mortality in a hamster arenavirus model. Although approved for clinical use in humans, IFN alfacon-1 has not been tested in human VHF. In a small study, recombinant interleukin-2 reduced renal insufficiency in HFRS, but confirmation is needed before this can be considered the standard of care. There has been renewed interest in the use of corticosteroids for possible adrenal insufficiency in septic shock. Interestingly, viral infection of the adrenal cortex and adrenal gland necrosis have been reported in various VHFs. Results of a few clinical trials of corticosteroids in shock as well as in HFRS have been mixed. Furthermore, their use might exacerbate the immunosuppression common in some VHFs. Until more conclusive studies are conducted, corticosteroids should probably not be administered unless adrenal insufficiency is strongly suspected, the target blood pressure is not maintained despite adequate fluid repletion and vasopressors, or if cerebral edema is suspected. If necessary, a dose of 200 mg intravenous hydrocortisone per day in adults should be used, divided into two to four daily doses or administer by continuous infusion.

Antibiotics and secondary infection

Patients should be immediately covered with appropriate antibacterial and/or antiparasitic therapy, with specific consideration of malaria and rickettsial disease, until VHF can be confirmed (Table 193.3). These drugs should then be stopped unless there is evidence of coinfection. Secondary bacterial infection should be suspected when patients have persistent or new fever after about 2 weeks of illness, when most VHFs have either resulted in death or are resolving.

Pain control, gastrointestinal stress ulcer prophylaxis, and management of seizures and other central nervous system manifestations

Oral or parenteral acetaminophen, tramadol, opiates, or other analgesics should be used as needed for pain control, adjusting as necessary for hepatic insufficiency. Avoid salicylates and nonsteroidal anti-inflammatory drugs because of the risk of bleeding. Prophylactic therapy for gastrointestinal stress ulcers with proton pump inhibitors or histamine-2 receptor antagonists is recommended. Antiemetics, such as the phenothiazines, are frequently warranted. Seizures can usually be managed with standard use of benzodiazepines, phenytoins, or levetiracetam, with careful attention to possible respiratory depression and hypotension. These drugs should not be given prophylactically.

Clinical laboratory testing

A broad range of clinical laboratory parameters should be monitored in patients with VHF (Table 193.4). Laboratory tests for DIC should be performed. Third-spacing, vomiting, diarrhea, decreased fluid intake, and the administration of intravenous fluids may result in significant electrolyte imbalance, especially hypokalemia, so regular potassium supplementation may be needed, keeping a close eye on renal function, which is often compromised in late disease. Although hyperglycemia has not been reported frequently in VHF, glucose should be monitored and levels kept <180 mg/dL via the use of intravenous insulin.

Nutrition

Gut feeding is preferable to parenteral alimentation when possible. Nasogastric tubes may be theoretically indicated for patients unable to eat, but there is little practical experience with their use in the VHFs. Exacerbation of gastrointestinal bleeding and heightened risk of transmission to healthcare workers during tube placement are concerns.

Management of pregnancy

Uterine evacuation in pregnant patients appears to lower maternal mortality and should be considered given the extremely high maternal and fetal mortality associated with VHF. However, this procedure must be performed with extreme caution, since it can be considered high risk with regard to nosocomial transmission. Although technically contraindicated in pregnancy (US Food and Drug Administration [FDA] Category X), ribavirin should nevertheless be considered, in consultation with the patient, as a lifesaving measure for the mother in VHFs for which the drug is efficacious (Table 193.2).

Convalescence and sequelae

Since patient clinical status and infectivity generally correlate with the level of viremia, patients who have recovered from their acute illness can safely be assumed to have cleared their viremia and discharged without concern of subsequent transmission at home. RT-PCR testing of blood and other body fluids has sometimes revealed residual nucleic acids, but the significance of this is unclear without cell culture confirming the presence of infectious virus.

Sexual abstinence or condom use is recommended for 3 months because of the delayed virus clearance in the urine and semen, as well as simple precautions to avoid contact with excretions, including separate toilet facilities and regular hand washing, although transmission through toilet facilities has not been noted. Breastfeeding should be avoided unless there is no other way to support the baby.

Survivors usually suffer no obvious long-term sequelae, with the exceptions of deafness in Lassa fever and optic retinopathy with vision loss in Rift Valley fever, both of which appear during early convalescence and may persist for life to varying degrees. Nevertheless, convalescence may be prolonged, with persistent myalgia, arthralgia, anorexia, weight loss, alopecia, pancreatitis, uveitis, and orchitis up to a year after infection. The psychological effects may also be significant, with some patients experiencing irritability, depression, post-traumatic stress disorder, or social stigmatization. Clinical management during convalescence is supportive.

Infection control

Patient isolation, personal protective equipment, and nursing precautions Although normal barrier nursing and precautions to prevent parenteral and droplet exposure to blood and body fluids suffice in most instances, for added safety these should be upgraded to "VHF precautions" once the diagnosis is suspected, which includes patient isolation and the use of surgical masks, face shields, double gloves, gowns, head and shoe covers, and protective aprons. It is prudent to place the patient in a negative airflow room if available. Hermetically sealed isolation chambers are not required and may have profound negative psychological effects. Patient access should be limited to essential designated trained staff and family members. Use of sharps should be minimized. Small particle aerosol precautions, such as the use of high-efficiency particulate air filter masks, should be employed when performing procedures which may generate aerosols, including endotracheal intubation. The hospital laboratory should be alerted before sending specimens so that appropriate precautions can be implemented. Blood samples can be inactivated by the addition of detergents, such as Triton X-100, although their effect on the various laboratory parameters to be measured has not been firmly established. Use of point-of-care diagnostic assays at the bedside can further limit exposure to laboratory personnel. Disinfection of items coming into direct contact with the patient is advised, including chemical or heat inactivation of human waste.

Contact tracing

Given the generally low secondary attack rates, widespread contact tracing, laboratory testing, or postexposure prophylaxis are not indicated for casual contacts. Contacts should be defined as persons with unprotected direct contact with someone during the symptomatic phase of a human-to-human communicable VHF. Contacts should be monitored daily for the duration of the longest possible incubation period starting after their last contact (Table 193.2), checking and recording their temperature daily. It is usually recommended that exposed persons avoid intimate contact and sharing of utensils with household members for the duration of the incubation. Confinement of asymptomatic persons is not warranted. Persons who develop signs and symptoms suggestive of VHF should be immediately isolated and tested.

Postexposure prophylaxis

Postexposure prophylaxis should be considered in persons with distinct high-risk exposure defined as one of the following: (1) penetration of skin by a contaminated sharp instrument (e.g., needlestick injury), (2) exposure of mucous membranes or broken skin to blood or body secretions (e.g., blood splashing in the eyes or mouth), (3) participation in emergency procedures without appropriate personal protective equipment (e.g., resuscitation after cardiac arrest, intubation, or suctioning), and (4) prolonged (i.e., hours) and continuous contact in an enclosed space without appropriate personal protective equipment (e.g., a healthcare worker accompanying a patient during medical evacuation in a small airplane). Most infections come from contact with severely ill patients late in the course of illness.

Postexposure prophylaxis with oral ribavirin has been recommended for Lassa fever and other arenavirus infections and Crimean-Congo HF, although no systematically collected data on its efficacy are available. Because of the high first-pass metabolism of oral ribavirin, relatively high doses are needed to provide serum levels in the range of the minimum inhibitory concentration of most hemorrhagic fever viruses (Table 193.5). Persons taking prophylaxis who develop manifestations of VHF should also be immediately laboratory tested and converted to intravenous ribavirin unless the syndrome can be readily excluded. Convalescent plasma is also routinely given as postexposure prophylaxis for Argentine hemorrhagic fever. Numerous experimental approaches have shown efficacy as postexposure prophylaxis in VHF animal models but are not yet approved for use in humans.

Vaccines

The 17D live attenuated yellow fever vaccine has an excellent protection and safety profile, despite recent recognition of rare serious adverse events in elderly persons. Confirmed previous vaccination should essentially rule out yellow fever. Candid 1, a highly efficacious live attenuated vaccine for Argentine hemorrhagic fever (only licensed in Argentina) may also be effective in Bolivian hemorrhagic fever but does not protect against other arenaviruses. Vaccines for HFRS, Rift Valley fever, and Kyasanur Forest disease exist but most are not widely tested, approved, or available. A number of experimental vaccines are efficacious in animal models of VHF. Clinical trials of various Ebola vaccines are underway.

TABLE 193.5 **RIBAVIRIN THERAPY FOR VIRAL HEMORRHAGIC FEVER**

Indication	Route	Dose[a]	Interval
Treatment	IV[b]	30 mg/kg (maximum 2 g)[c]	Loading dose, followed by:
	IV[b]	15 mg/kg (maximum 1 g)[c]	Every 6 h for 4 days, followed by:
	IV[b]	7.5 mg/kg (maximum 500 mg)[c]	Every 8 h for 6 days
Prophylaxis	PO	35 mg/kg (maximum 2.5 g)[c]	Loading dose, followed by:
	PO	15 mg/kg (maximum 1 g)[c]	Every 8 h for 10 days

Abbreviations: IV = intravenous; PO = oral administration.
[a] Pharmacokinetic and sensitivity testing for ribavirin has not been extensively performed for each VHF. The intravenous dose used is derived from that found efficacious in Lassa fever. Oral ribavirin has also been reported to be efficacious in many VHFs, especially for Crimean-Congo HF, but few controlled data are available. IV administration is strongly suggested whenever possible.
[b] The drug should be diluted in 150 mL of 0.9% saline and infused slowly.
[c] Reduce the dose in persons know to have significant renal insufficiency (creatinine clearance of less than 50 mL/min).

Acknowledgments

The author thanks Ryan Maves and Simon Pollett for critical review of this chapter and Cecilia Gonzales for administrative assistance.

Section 24

Specific organisms: Parasites

Intestinal roundworms

Kathryn N. Suh, Anne E. McCarthy, and Jay S. Keystone*

Nematodes (roundworms) are the most common parasites infecting humans worldwide. Of almost half a million species of roundworms, approximately 60 are known to be pathogenic to humans. Among the most prevalent human infections are those due to the intestinal (lumen-dwelling) nematodes.

Ascaris lumbricoides, Trichuris trichiura, and hookworms (*Ancylostoma duodenale* and *Necator americanus*), collectively referred to as *geohelminths* (soil-transmitted helminths), infect approximately 1.5 billion people—one-quarter of the world's population. Coinfection, in particular with *A. lumbricoides* and *T. trichiura*, is common. Geohelminths share the requirement for eggs or larvae to mature in soil in order to be infective to humans. Due to this obligate soil stage of maturation, these parasites cannot be transmitted from person to person. Geohelminths are unaffected by host immune responses, leading to chronic infection if untreated, although the natural history of such infections is usually one of decreasing worm burden over time; even with treatment, however, reinfection is common.

Other important nematodes of humans include *Strongyloides stercoralis* and *Enterobius vermicularis*. *S. stercoralis* is able to complete its entire life cycle within the human host, and like *E. vermicularis*, both person-to-person transmission and autoinfection can occur.

The prevalence and intensity of helminthic infections, and in particular geohelminthic infections, are primarily related to poverty, educational and agricultural standards, population density, and sanitary (public health) conditions, all of which have a far greater impact on the burden of disease than do ecologic factors. Most infections occur in Africa, the Americas, China, and southeast Asia. The majority of geohelminthic infections is asymptomatic and associated with low worm burdens, whereas the minority (10–35%) of infected individuals harbors most of the worm burden and suffers from more intense symptoms. Geohelminthic infections are important contributors to growth and cognitive delay in children; >800 million children live in endemic regions. Mass anthelminthic therapy for populations living in endemic areas is recommended by the World Health Organization; in 2015, an estimated 60% of children received preventive therapy. With improved disease control efforts, geohelminthic infections have decreased significantly over the past 25 years. Conclusively proving the benefit of large-scale anthelminthic therapy in endemic areas is challenging for a number of reasons, however.

Ascariasis

Ascariasis is among the earliest recorded and most prevalent helminthic infections of humans. King Richard III's remains, discovered in 2012 in the United Kingdom, contained *Ascaris* eggs. Disease is caused by *A. lumbricoides*; infection due to the closely related porcine ascarid *A. suum* has been reported following accidental ingestion of ova. Ascariasis is widely distributed throughout the world, with the highest prevalence in Asia and in young children. In 2013, an estimated 800 million people were infected. Complications of

*Dr. Jay S. Keystone is deceased.

infection are generally related to a high worm burden and thus only a minority of infected individuals is at risk of serious morbidity. The prevalence of ascariasis is attributable in part to the prodigious output of eggs by each adult female and the ability of these eggs to survive in a diverse range of environmental conditions.

The life cycle of *Ascaris* is shown in Figure 194.1. Fertilized eggs are excreted in stool, embryonate, and become infective after a period of weeks to months in soil, depending on environmental conditions. One to two days after infective eggs are ingested, larvae are released in the small bowel, penetrate the intestinal wall, travel to the pulmonary circulation, and enter the lungs, where they ascend the trachea and are swallowed. Approximately 10 weeks after ingestion of eggs, larvae mature into adults in the small intestine, where they live for up to 18 months. Egg production occurs 3 to 4 months after initial ingestion; females can produce >200,000 eggs per day.

Most *Ascaris* infections are asymptomatic. Adult worms may be seen in emesis or stool and are occasionally coughed up or extruded through the nose. *Loeffler's syndrome*, characterized by migratory pulmonary infiltrates and peripheral eosinophilia, results from larval migration through the pulmonary parenchyma and may develop within 2 weeks of ingestion. Clinical manifestations include fever, dyspnea, wheezing, and dry cough. Gastrointestinal complications are generally due to a heavy adult worm burden (e.g., intestinal obstruction from worm masses) or to migration of a single adult worm into the bile or pancreatic duct or the appendix. Complications from worms in other organs are rare.

Ascariasis is diagnosed by the demonstration of ova, larvae, or adult worms. Eggs are generally readily demonstrated in stool, although the interval between ingestion and egg production, and the variability in the distribution of eggs in stool, may be limiting factors. Molecular testing (specifically polymerase chain reaction [PCR]) for diagnosis of *Ascaris* (and other roundworm) infections can be highly sensitive and specific but is limited by the lack of an appropriate gold standard, cost, and practical limitations for use in endemic areas. Adult worms can be visualized with imaging studies

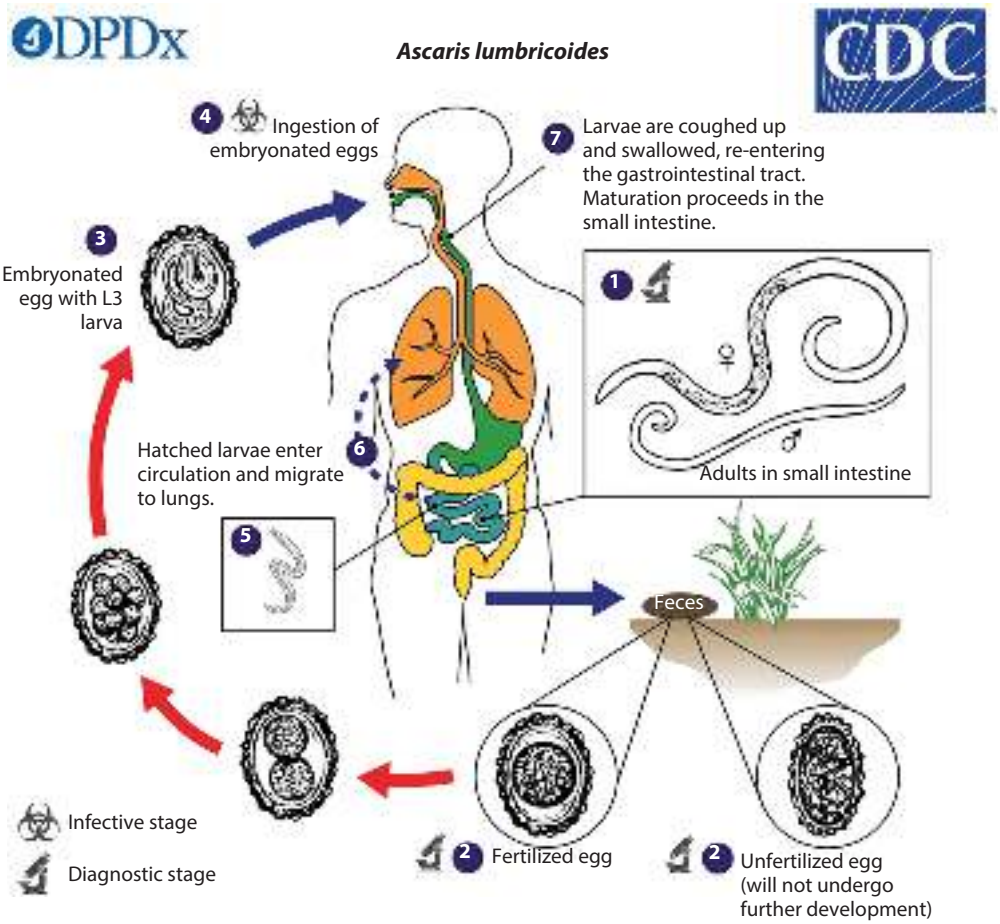

FIGURE 194.1 Life cycle of *Ascaris lumbricoides*. Adult worms (1) live in the lumen of the small intestine. A female may produce approximately 200,000 eggs per day, which are passed with the feces (2). Unfertilized eggs may be ingested but are not infective. Fertile eggs embryonate and become infective after 18 days to several weeks (3), depending on the environmental conditions (optimum: moist, warm, shaded soil). After infective eggs are swallowed (4), the larvae hatch (5), invade the intestinal mucosa, and are carried via the portal then systemic circulation to the lungs (6). The larvae mature further in the lungs (10–14 days), penetrate the alveolar walls, ascend the bronchial tree to the throat, and are swallowed (7). Upon reaching the small intestine, they develop into adult worms (1). Between 2 and 3 months are required from ingestion of the infective eggs to oviposition by the adult female. Adult worms can live 1 to 2 years.

From Division of Parasitic Diseases and Malaria, Centers for Disease Control and Prevention, Atlanta, Georgia. https://www.cdc.gov/dpdx/ascariasis/index.html

(e.g., ultrasound, barium studies) or during endoscopy or surgery. Eosinophilia is not a feature of adult ascariasis but is a common finding during the migration phase.

Because of the potential for worm migration, all infections, whether symptomatic or not, should be treated. When mixed helminthic infections are being treated, *Ascaris* should always be treated first because medications may stimulate worms to migrate. Mebendazole or albendazole is appropriate first-line therapy (Table 194.1). Single-dose therapy with either achieves high cure rates.

Trichuriasis

Like ascariasis, trichuriasis is a widely distributed disease, affecting almost 500 million individuals. Humans are the only hosts of *T. trichiura* (whipworm, so named for the characteristic morphology of adult worms). It is most common in tropical climates, with the highest prevalence in children. Human disease may rarely be caused by related species of porcine (*T. suis*) and canine (*T. vulpis*) whipworm.

Eggs passed in stool embryonate after 2 to 4 weeks of maturation in soil. There is no tissue (pulmonary) phase; eggs are deposited directly in the cecum, where larvae hatch and mature into adults over several days. Adult worms survive for up to 8 years in the cecum, where they remain attached to the intestinal mucosa. Egg production begins 2 to 3 months after initial infection, with females releasing up to 20,000 eggs per day.

Most infected individuals are asymptomatic. Moderate worm burdens may cause nonspecific gastrointestinal symptoms, including abdominal pain or distension or diarrhea. Heavy worm burdens more often affect children and may lead to failure to thrive, growth delay, profuse bloody diarrhea, or rectal prolapse, the hallmark of trichuriasis in endemic areas. Iron deficiency anemia may also be present, but peripheral eosinophilia is uncommon.

The diagnosis of *T. trichiura* infection rests on demonstration of eggs or adult worms, with similar limitations as for ascariasis. Endoscopy may reveal colitis and the presence of visible worms hanging within the intestinal lumen. Treatment with a 3-day course of mebendazole or albendazole is recommended (Table 194.1); single-dose therapy leads to suboptimal cure rates.

Hookworm infection

Hookworm infection affects approximately 500 million individuals, with most cases in sub-Saharan Africa, Asia, and the Americas. Disease due to *Necator americanus* is most common and is found predominantly in tropical climates in the Americas, China and southeast Asia, and Africa. *Ancylostoma duodenale* infection is more geographically restricted, mainly occurring in the Mediterranean, northern India, North Africa and the Middle East, and parts of Asia. Prevalence increases throughout early childhood and then peaks and plateaus in adulthood, with worm burden remaining essentially constant (or declining modestly) throughout the life of the infected host. Other hookworm species, including *Ancylostoma ceylanicum* and *A. caninum*, rarely cause enteritis, although *A. ceylanicum* is known to be prevalent in India and southeast Asia. *A. braziliense* infection typically causes cutaneous larva migrans.

TABLE 194.1 **TREATMENT OF INTESTINAL ROUNDWORM INFECTIONS**

Disease	Drug	Adult and pediatric dose
Ascariasis	Albendazole	400 mg 1×
	or	
	Mebendazole	500 mg 1× or 100 mg BID × 3 d
	or	
	Pyrantel pamoate	11 mg/kg (max 1 g) daily × 3 d
	or	
	Ivermectin	150–200 μg/kg 1×
Trichuriasis	Albendazole	400 mg/d × 3 d
	or	
	Mebendazole	100 mg BID × 3 d
	or	
	Ivermectin	200 μg/kg/d × 3 d
Hookworm	Albendazole	400 mg 1×
	or	
	Mebendazole	100 mg BID × 3 d
	or	
	Pyrantel pamoate	11 mg/kg (max 1 g) daily × 3 d
Strongyloidiasis: Immunocompetent	Ivermectin or Albendazole	200 μg/kg/d × 2 d 400 mg BID × 7 d
Strongyloidiasis: Hyperinfection	Ivermectin	200 μg/kg/d, until stools negative × 2 wk
Pinworm[a]	Albendazole	400 mg 1×
	or	
	Mebendazole	100 mg 1×
	or	
	Pyrantel pamoate	11 mg/kg (max 1 g) 1×
Trichostrongyliasis	Ivermectin	200 μg/kg 1×
	or	
	Pyrantel pamoate	11 mg/kg (max 1 g) 1×
	or	
	Albendazole	400 mg × 3 d
	or	
	Mebendazole	100 mg BID × 3 d
Anisakiasis	Albendazole	400 mg BID × 3–21 d

[a] Regardless of the agent used, therapy must be repeated 2 to 4 weeks after the first course.

Hookworm eggs are excreted in stool and hatch in soil; within 7 days larvae become infective. Following penetration of intact skin, larvae migrate through lymphatics to enter the bloodstream and travel to the lungs, ascend the trachea, and are swallowed. *A. duodenale* larvae may also cause infection by the oral route. Within the small intestine, larvae mature into adults and attach themselves to the intestinal mucosa. *A. duodenale* adults survive for up to 1 year, and *N. americanus* for up to 9 years. Egg production begins 1.5 to 2 months after infection. Females release 5 to 30,000 eggs per day, depending on the infecting species.

Infection is often asymptomatic. An intensely pruritic erythematous maculopapular eruption, "ground itch," may develop at entry points of filariform larvae, typically on the hands or feet. Dermatitis is more likely with repeated exposure and can be complicated by secondary infection. Loeffler's syndrome may occur 10 to 14 days after infection and may be accompanied by an urticarial eruption. Nausea, epigastric pain, or abdominal tenderness may be present early in the course of disease and with heavy worm burdens. Infection by the oral route may lead to pharyngeal irritation, hoarseness, cough, and nausea (Wakana disease). The hallmark of hookworm infection is chronic iron deficiency anemia, which results from local blood loss at the site of attachment of the adult worms as well as from their ingestion of blood. The occurrence and severity of anemia depend on the infecting species of hookworm (*A. duodenale* causes more blood loss than *N. americanus*), the intensity of infection, the iron reserves of the host, and the availability of iron in the diet; therefore, hookworm anemia is mostly seen in developing countries. Complications of severe anemia, including weakness, fatigue, and high-output cardiac failure, are common. Infection and resultant anemia during pregnancy are associated with low birth weight and increased neonatal mortality.

In addition to laboratory findings of iron deficiency anemia, eosinophilia is common. Hypoalbuminemia may result from protein-losing enteropathy. The diagnosis is made by identification of hookworm ova in the stool; fecal concentration techniques are not usually required. Occasionally, rhabditiform larvae may be present in stool and must be differentiated morphologically from those of *Strongyloides*. Mebendazole and albendazole are drugs of choice for treatment (Table 194.1); single-dose mebendazole has poor cure rates and should not be used. Efforts to develop an effective hookworm vaccine are ongoing.

Strongyloidiasis

Human strongyloidiasis is caused primarily by *S. stercoralis*, which is endemic to Africa, Asia, Southeast Asia, and Central and South America, where 20% or more of the population may be infected. Disease is also found in the Caribbean and, to a much lesser extent, in Europe, Japan, Australia, and parts of the southern United States. Infection caused by *S. fuelleborni*, found sporadically in Africa and Papua New Guinea, is relatively rare. Strongyloidiasis may affect up to 600 million individuals worldwide; the true prevalence is unclear given the challenges associated with diagnosing this infection.

The life cycle of *S. stercoralis* is complex (Figure 194.2). Rhabditiform larvae released in the stool of infected hosts mature into infective (filariform) stages in soil. Infection usually results from the penetration of intact skin by filariform larvae. These travel via the circulatory system to the lungs where they penetrate the alveoli, ascend the trachea, are swallowed, and then mature into adult worms in the small intestine. Although sexual reproduction does take place within the intestine, adult females are also parthenogenetic (capable of reproduction without males). Eggs are deposited in the intestinal mucosa, hatch, and release rhabditiform larvae, which are excreted in the stool to begin another cycle. Rhabditiform larvae in the bowel may also transform directly into filariform larvae that enter the circulation and begin another cycle of infection (autoinfection) or, in the appropriate clinical setting (i.e., immunosuppression), may lead to disseminated disease (hyperinfection syndrome). Rhabditiform larvae have the capacity to develop into adults in soil, where they reproduce sexually (heterogonic development) and give rise to infective filariform larvae (Figure 194.2).

Infection is common in childhood, and prevalence continues to increase with age. Most infected persons have low worm burdens and are persistently infected for life, often with minimal or no symptoms. If symptoms are present they are generally intermittent, with long asymptomatic periods between episodes. Acute infection may be apparent with very rapid (1–2 cm/h) migratory serpiginous skin lesions (larva currens) or urticaria at the sites of larval penetration; cutaneous larva migrans from dog or cat hookworms may produce a similar picture, but with much slower migration in skin (1–2 cm/d). Larva currens in the perianal area is pathognomonic of chronic strongyloidiasis. Urticarial rashes may occur over many years during chronic infection. Pulmonary manifestations of disease are unusual due to the small numbers of larvae passing through the lungs, except at the onset of a heavy infection or, more commonly, when hyperinfection syndrome is present (see later discussion). Epigastric pain mimicking peptic ulcer disease, persistent abdominal pain, diarrhea, and anorexia are common manifestations of symptomatic chronic infection. Abdominal bloating, distension, and intestinal malabsorption can also occur.

Hyperinfection syndrome, in which unregulated parasitic proliferation occurs, results in disseminated infection and most often occurs in the presence of impaired cellular immunity, typically due to the use of systemic steroids. Other chemotherapeutic agents, hematologic malignancies (notably lymphoma), organ transplants, malnutrition, chronic alcoholism, and coinfection with human T-lymphotropic virus 1 (HTLV-1) are also predisposing factors. Interestingly, HIV infection is not associated with an increased risk of disseminated disease. Insidious gastrointestinal symptoms may be present. Pulmonary disease is the most common extraintestinal manifestation of hyperinfection syndrome and is characterized by diffuse pulmonary infiltrates with dyspnea, cough, wheezing, or hemoptysis. In uncontrolled hyperinfection, filariform larvae also penetrate organs not normally involved in the *Strongyloides* life cycle, including the urinary tract, liver, and brain. Gram-negative and occasionally gram-positive bacterial infections, including bacteremia, peritonitis, meningitis, and sepsis, may result from the concurrent migration of bacteria and larvae across the bowel wall. The triad of hemorrhagic pneumonitis, enteritis, and gram-negative bacteremia

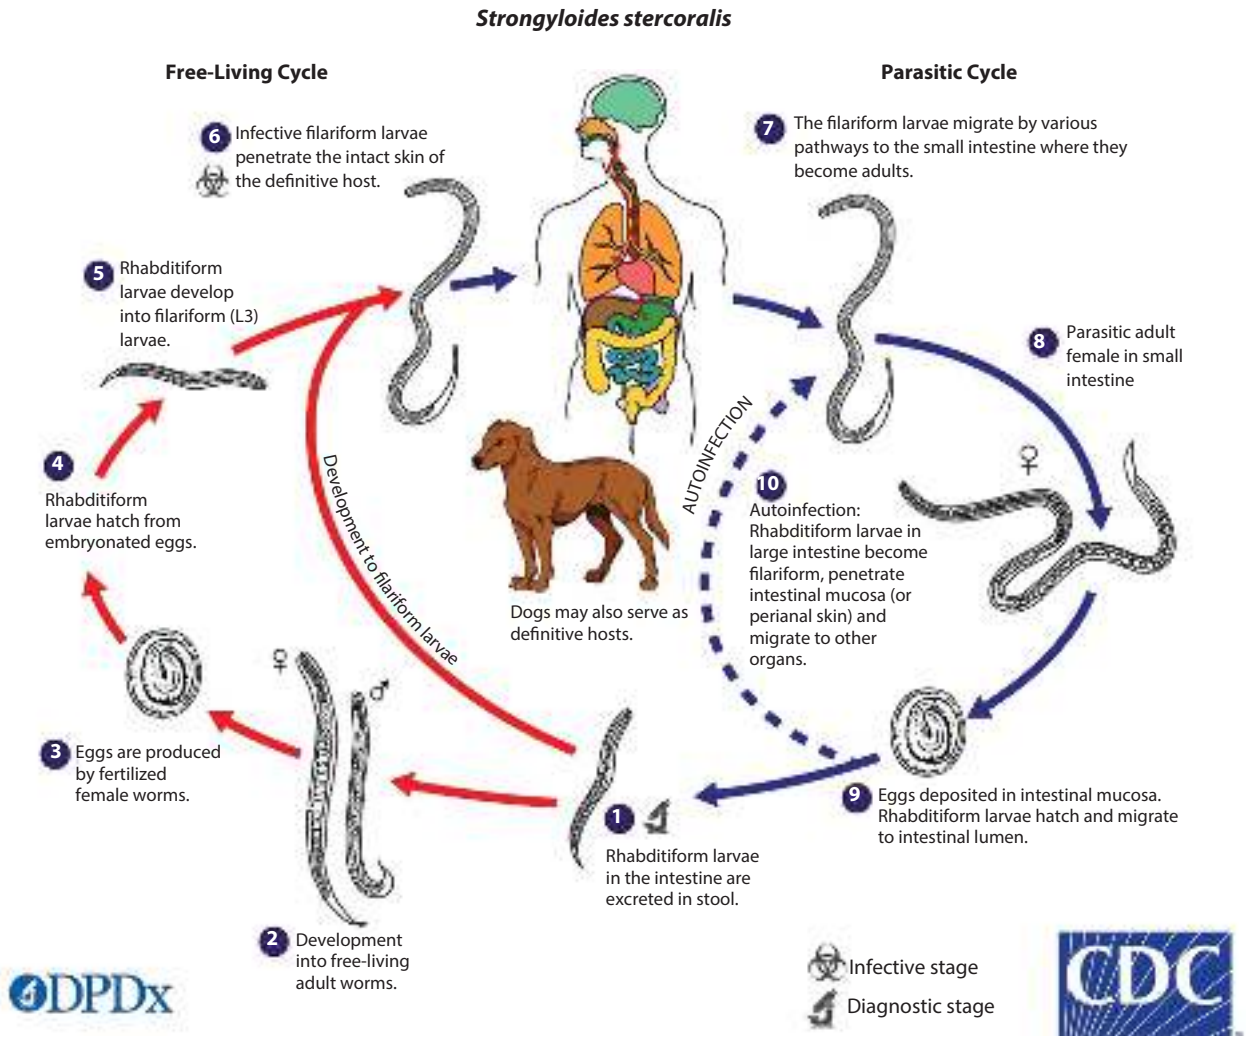

FIGURE 194.2 Life cycle of *Strongyloides stercoralis*. The *Strongyloides stercoralis* life cycle is complex, alternating between free-living and parasitic cycles and involving autoinfection. In the *free-living cycle*: Rhabditiform larvae are passed in the stool of an infected definitive host (1), develop into either infective filariform larvae (direct development) (6) or free-living adult males and females (2) that mate and produce eggs (3), from which rhabditiform larvae hatch (4) and eventually become infective filariform (L3) larvae (5). The filariform larvae penetrate the human host skin to initiate the parasitic cycle (see later discussion) (6). This second generation of filariform larvae cannot mature into free-living adults and must find a new host to continue the life cycle.

Parasitic cycle: Filariform larvae in contaminated soil penetrate human skin when skin contacts soil (6) and migrate to the small intestine (7). It has been thought that the L3 larvae migrate via the bloodstream and lymphatics to the lungs, where they are eventually coughed up and swallowed. However, L3 larvae appear capable of migrating to the intestine via alternate routes (e.g., through abdominal viscera or connective tissue). In the small intestine, the larvae molt twice and become adult female worms (8). The females live embedded in the submucosa of the small intestine and produce eggs via parthenogenesis (parasitic males do not exist) (9), which yield rhabditiform larvae. The rhabditiform larvae can either be passed in the stool (1; see *Free-living cycle*" above), or can cause autoinfection (10).

Rhabditiform larvae in the gut become infective filariform larvae that can penetrate either the intestinal mucosa or the skin of the perianal area, resulting in autoinfection. Once the filariform larvae reinfect the host, they are carried to the lungs, pharynx, and small intestine as described above, or disseminate throughout the body. The significance of autoinfection in *Strongyloides* is that untreated cases can result in persistent infection even after many decades of residence in a non-endemic area, and may contribute to the development of hyperinfection syndrome.

From Division of Parasitic Diseases and Malaria, Centers for Disease Control and Prevention, Atlanta, Georgia. https://www.cdc.gov/dpdx/strongyloidiasis/index.html

in an immunocompromised individual from an endemic area should raise suspicion of disseminated strongyloidiasis. The mortality rate for disseminated disease is approximately 50%.

The diagnosis of chronic strongyloidiasis is difficult due to the nonspecific symptoms of the disease and the minimal, irregular larval output in stool. Peripheral eosinophilia is present in up to 80% of patients with intestinal disease and can be a clue to diagnosis, but it is rarely a feature of disseminated infection (although pulmonary eosinophilia may be noted in the latter). Demonstration of larvae in clinical specimens (e.g., stool, bronchial washings in disseminated infection) is diagnostic but insensitive. In gastrointestinal infection, a single stool specimen may fail to detect larvae in up to 70% of cases, although sensitivity approaches 100% with seven consecutive stool samples. Specialized laboratory techniques

(e.g., Baermann concentration, Harada–Mori filter paper test) and duodenal aspirates are more sensitive than single stool examinations but are impractical to perform. The agar plate method, in which stool is plated on solid medium and incubated for up to 72 hours, is highly sensitive (90%) but has a slow turnaround time. Agar plate specimens containing *S. stercoralis* larvae will, after incubation, reveal linear tracks formed by bacteria that have been carried by motile larvae. While PCR is highly specific, the reported the sensitivity is around 70%, in part reflecting the variable larval output in stool but also the absence of a clear gold standard for diagnosis.

Strongyloides serology has a reported sensitivity of 70% to 95% and specificity of 39% to 99%. Its use is limited by cross-reactivity with other helminthic infections (in particular filariasis, ascariasis, and acute schistosomiasis), and the inability of a positive result to distinguish between treated or ongoing infection because antibodies may persist for years following effective treatment. However, serologic tests are invaluable in diagnosing chronic infection. In addition, antibody levels drop significantly over the first year following successful therapy, making serology useful as a test of cure. Newer methods, such as luciferase immunoprecipitation assays, are promising approaches to improved serodiagnosis but are currently not widely available.

Treatment of strongyloidiasis in asymptomatic individuals is often successful, whereas those with disseminated disease may require prolonged or repeated courses of therapy. Currently, ivermectin is considered the treatment of choice. If possible, immunosuppressant therapy should be discontinued in those with hyperinfection. Recommended regimens are summarized in Table 194.1.

Prevention of disseminated disease in at-risk individuals is strongly recommended. Serology is the most reliable test for screening in this population, with treatment offered to those with positive results. Presumptive treatment can be considered if immune-suppressing therapy cannot be delayed while awaiting serologic results.

Enterobiasis

In contrast to other gastrointestinal helminthic infections, *E. vermicularis* infection (pinworm, threadworm) does not respect socioeconomic or geographic boundaries. *E. vermicularis* is ubiquitous, found in both urban and rural settings worldwide. Enterobiasis is the most common helminthic infection in North America and is among the most prevalent throughout the world. Humans are the only hosts, with infection occurring most commonly in young children.

Eggs are ingested, either by the fecal–oral route or by exposure to contaminated fomites. There is no tissue phase of infection. Larvae hatch in the upper gastrointestinal tract and mature into adults. Adult worms mate in the small intestine before migrating to the appendix and cecum, where they survive for up to 13 weeks. Gravid females migrate to the perianal area, where they release >10,000 eggs daily, beginning 3 to 7 weeks after infection.

Symptoms are rarely serious but may be problematic. Nocturnal pruritus ani is the most common symptom and can lead to insomnia and irritability. Local bacterial infection as a result of scratching can occur. Gastrointestinal and other attributable symptoms appear to be infrequent. Abdominal pain or diarrhea should prompt a search for *Dientamoeba fragilis*, because the coinfection rate with *E. vermicularis* may be as high as 50%; recent studies suggest that *D. fragilis* is transmitted in or on pinworm eggs. There is no evidence of an association between pinworm infection and behaviors such as tooth grinding, nail biting, or enuresis.

Eosinophilia is not a feature of enterobiasis. The diagnosis is established by identifying adult worms or eggs. The most reliable approach is the cellulose tape test using transparent adhesive tape to demonstrate eggs on perianal skin. A wooden tongue depressor draped with tape (sticky side out) is firmly pressed against the perianal skin immediately on waking in the morning, before defecation or bathing. The tape is removed, placed sticky side down on a slide, and examined under a microscope. Ninety percent of infections can be detected with three slides obtained on consecutive mornings, and seven tests detect 100% of infections. In contrast, routine stool examination for ova and parasites is positive in only 10% to 15% of infected persons. Presumptive treatment of suspected infection may be a more practical approach than using cellulose tape (or pinworm paddles).

The treatment of enterobiasis is summarized in Table 194.1. In the absence of reinfection or autoinfection, a primary infection will clear without treatment in 30 to 45 days. Because intrafamilial transmission is common, treatment of the entire family is recommended. A second course of therapy should be administered 2 to 4 weeks after the first to treat possible autoinfection or reinfection as medications are relatively ineffective against developing larvae and newly ingested eggs. Specific personal hygiene measures such as good hand hygiene, daily bathing in the morning, the use of underwear and pyjamas for sleeping at night, daily change of underwear, and regular laundering of bedclothes are also important for eradication of infection. Recurring infections should be treated at least 4 times at 2-week intervals.

Trichostrongyliasis

Trichostrongylus spp. are parasites of herbivores such as sheep, cattle, and goats, primarily in the Middle East and Asia; humans are accidental hosts, with infection most commonly due to *T. colubriformis* or *T. orientalis*. Ova released in the feces of infected animals hatch in soil within 1 to 2 days and pass through three free-living stages before becoming infective. Human infection typically results from ingestion of larvae in contaminated food or water, although larvae can also penetrate skin. There is no tissue phase, and adults reside embedded in the duodenal or upper jejunal mucosa. Little is known about the pathology of human trichostrongyliasis.

Most human infections are mild or asymptomatic, but anorexia, diarrhea, flatulence, and epigastric pain may occur. Peripheral eosinophilia may be marked but is more commonly absent. Diagnosis depends on identification in stool of ova, which are often difficult to differentiate from hookworm ova. Treatment is outlined in Table 194.1.

Anisakiasis

Anisakiasis (anasakidosis; herring worm or cod-worm disease), caused by infection with the third-stage larvae of *Anisakis simplex* or *Pseudoterranova decipiens*, is most prevalent in Japan and less frequent in Hawaii and the coastal areas of North America and northern Europe (in particular, Spain). It is acquired by consumption of raw or inadequately cooked marine fish or squid, as found in sushi or ceviche, for example. The primary hosts of anisakids are sea mammals, including dolphins, porpoises, whales, seals, sea lions, and walruses. Eggs released in feces mature in seawater. Free-swimming second-stage larvae are ingested by small marine crustacea and develop into third-stage (infective) larvae in squid and predatory fish. Herring, salmon, mackerel, halibut, cod, and squid are important sources of infection for humans. Larvae ingested by consumption of raw or inadequately cooked fish invade the submucosa of the stomach or intestine but cannot mature into adult worms in the human host. The larvae cause local inflammation and hemorrhage that generally last about 10 days.

Anisakiasis is categorized into gastric, intestinal, or extraintestinal disease. The presentation varies depending on both geography and the infecting species. Gastric anisakiasis usually presents acutely after ingestion of infected food with severe epigastric pain, nausea, and vomiting. Acute symptoms subside in a few days, but intermittent nausea, vomiting, and vague abdominal pain may persist for weeks to months. Symptoms of intestinal anisakiasis develop 1 to 5 days after the infecting meal and are due to invasion of the distal ileum. Abdominal pain, nausea, vomiting, and mild leukocytosis occur. Extraintestinal complications include peritonitis and pleurisy caused by larval perforation of the intestinal wall. Hypersensitivity reactions, including anaphylaxis, have also been associated with anisakiasis.

With the appropriate history and presenting symptoms, the diagnosis of gastric anisakiasis can be most easily confirmed by endoscopy. An ulcerated lesion and the protruding larva may be visualized. Intestinal and extraintestinal anisakiasis are difficult to differentiate from other causes of acute abdomen, and patients often undergo laparotomy. Serologic diagnosis may be helpful but is not readily available. Peripheral eosinophilia is common. Treatment includes removal of the parasite and supportive care, although even untreated infection subsides in a few days. Anthelmintic therapy for human anisakiasis is not well established, although albendazole has been reported to be effective (Table 194.1).

Tissue nematodes

Ian C. Michelow and Daniel B. Blatt

Tissue-dwelling nematodes are considered neglected tropical diseases that frequently cause debilitating illness in the most marginalized communities of the world. Infected travelers, immigrants, and refugees from endemic regions may present in the United States with a wide variety of clinical manifestations. Invasive nematode infections tend to result in eosinophilia and elevated serum immunoglobulin E (IgE), but normal blood tests do not rule out parasitic diseases. The diagnostic considerations can be focused through an understanding of the invading parasite's geographic distribution and its prevalence in endemic areas, incubation periods, and clinical manifestations. Treatment strategies must be tailored to the individual parasitic infection. Additional information about the availability of diagnostic tests and treatment is available from the US Centers for Disease Control and Prevention (CDC; dpdx@cdc.gov) and the Laboratory of Parasitic Diseases, National Institutes of Health (301-496-5398).

Trichinellosis

Trichinellosis develops when raw or inadequately cooked meat containing the encysted larvae of one of nine *Trichinella* spp. is consumed. Larvae are released from the ingested cysts by digestive enzymes in the stomach of the host; they migrate to the small intestine villi, where they penetrate the intestinal mucosa and develop into male and female adult worms in 1 to 2 days (enteral phase). Within 1 to 8 weeks, infective larval progeny are released and invade striated muscle via the circulation. There, they encyst within individual muscle fibers (parenteral phase) and can persist for months to years. In invasive infections, humans serve as both the definitive and intermediate host for this parasite.

Epidemiology

Trichinellosis has a worldwide distribution, occurring in temperate and tropical climates. Internationally, it is considered an emerging zoonosis, with increased rates of infection attributed to changing human dietary habits and the breakdown in some developing countries of veterinary management practices. In the United States, the principal mode of transmission historically has been consumption of undercooked *Trichinella*-infected pork, most frequently *T. spiralis*. The incidence has decreased from a median of 360 cases per year in the decade from 1947 to 1956 to a median of 14.5 cases annually from 2006 to 2015. Factors contributing to these favorable trends include improved observance of standards and regulations in the US commercial pork industry, increased usage of home freezers, and improved knowledge about safe cooking practices. The number of reported cases from eating wild boar, bear, and, rarely, walrus and deer meat currently far exceeds the number of reported cases related to eating commercial or farm-raised pork products. In the United States, the accuracy of surveillance was enhanced after the disease became notifiable in 1966.

Among US travelers, most cases of trichinellosis have been associated with consumption of wild pigs, especially the bush pig and warthog. Most reported travel-related infections have been associated with visits to Mexico, Southeast Asia, and sub-Saharan Africa.

Clinical presentation

The severity of symptoms depends on the number of ingested larvae, host immune status, and history of a previous infection that may have induced immunological priming. Because most infections result from ingestion of a small number of larvae, most infected persons are asymptomatic. The adult worm in the small intestine may cause gastrointestinal symptoms within a week of infection. Early symptoms may include abdominal discomfort, nausea, vomiting, and diarrhea, which may evolve into fulminant enteritis in unusually heavy infections. However, most clinical manifestations are related to systemic invasion by larvae, and they usually begin in the second week after infection, peak over a week's time, then slowly subside over weeks to months if the infection is not treated early in its course. Classical features of trichinellosis include myalgia (90% of cases), progressive eosinophilia (75%), fever (70%), and periorbital edema (45%). Myositis usually begins in the extraocular muscles and progresses to involve the masseters, neck muscles, and limb flexors. Other symptoms and signs include cough, headache, rash, pruritus, subungual splinter hemorrhages, thromboembolic events, and weakness. In fulminant infection encephalitis, myocarditis, and pneumonia may be fatal.

Diagnosis

Eosinophils may increase to a maximum of 20% to 90% of the total white blood cell count, although this is not pathognomonic for trichinellosis. Elevated creatine phosphokinase and lactate dehydrogenase levels reflect extensive muscle involvement. A diagnosis is usually made on the basis of clinical characteristics and a positive result for one of several types of *Trichinella*-specific serologic assays. A definitive diagnosis may be established by identifying larvae in a muscle biopsy, but this is usually unnecessary. Antibodies are not detectable until at least 3 weeks after infection and can persist for years. Infection with other helminths can cause false-positive test results.

Therapy

The goal of treatment in the enteral phase of infection is to prevent muscle invasion by larvae; the goal during the parenteral phase is to reduce muscle inflammation. However, the effectiveness of delayed initiation of antiparasitic therapy once parasites are encysted in muscle is markedly reduced. For mild *Trichinella* infections, only symptomatic therapy may be required because the clinical course is usually uncomplicated and self-limited. Specific treatment includes albendazole (400 mg with fatty food BID for 10–14 days) or mebendazole (200–400 mg TID for 3 days, followed by 400–500 mg TID for 10 days; available only at compounding pharmacies in the United States). Prednisone (30–60 mg/d for 10 to 14 days including a taper) is effective for severe symptoms. Postexposure prophylaxis with mebendazole (5 mg/kg BID for 5 days) may be effective to prevent trichinellosis in individuals who consumed contaminated meat within the past 6 days.

Filariasis

Of the eight filarial species capable of infecting humans, the four that cause the most disease worldwide are *Wuchereria bancrofti* (lymphatic filariasis), *Brugia malayi* (lymphatic filariasis), *Onchocerca volvulus* (onchocerciasis), and *Loa loa* (loiasis). Because only a small proportion of insect bites is infective, the risk of transmission is proportionate to the duration of exposure in an endemic area. The clinical manifestations of filariasis depend in part on the immune response of the host. The response to the parasite in endemic populations is downregulated because of immunosuppression and immunological tolerance, and a large parasite burden is common. In contrast, individuals who have grown up outside of endemic regions and become infected manifest prominent signs and symptoms and usually have a low parasite burden.

Lymphatic filariasis

Lymphatic filariasis is caused by infection with one of the lymph-dwelling filariae, *W. bancrofti, B. malayi*, or *Brugia timori*. An infected female mosquito of several species deposits larvae in subcutaneous tissue during a blood meal. Over a period of at least 6 months, the larvae mature into adult worms (macrofilariae) that live for 5 to 7 years. These threadlike adults reside in afferent lymphatic channels or sinuses of lymph nodes. All lymph-dwelling filariae contain *Wolbachia*, an intracellular bacterial endosymbiont that is essential for their growth, development, fertility, and survival, and can be targeted with antimicrobial agents for therapy of lymphatic filariasis. The filariae reproduce sexually in the lymphatics and their progeny (larvae or microfilariae) circulate in the bloodstream.

Epidemiology

W. bancrofti, found in tropical and subtropical regions throughout the world, is the most widely distributed human filaria and is responsible for 90% of cases of lymphatic filariasis. In most of the world, the parasite is nocturnally periodic, with the microfilariae scarce in peripheral blood during the day but increased at night. In the Pacific Islands, however, the microfilariae are subperiodic; microfilaremia is seen throughout the day, reaching maximal levels in the afternoon. Brugian filariasis occurs throughout Asia, including India and the Philippines. This form of filariasis is nocturnally periodic, except in forested areas, where it is subperiodic. Short-term tourists to endemic areas have a very low risk of acquiring infection.

Clinical presentation

Among endemic populations, most people infected with lymphatic filariasis are asymptomatic. Presence of microfilariae in the bloodstream and death of adult worms in lymph vessels are responsible for the common early manifestations, which include acute

filarial fevers, lymphadenopathy, and lymphangitis with transient lymphedema. More than half of these patients have hematuria, proteinuria, or both. The episodes abate after 7 to 10 days but can recur. A hallmark of lymphatic filariasis is lymphangitis that develops in a retrograde fashion, spreading distally, which is opposite to that seen in cellulitis. Genital involvement, which may manifest as tender epididymitis, funiculitis, or orchitis, is found exclusively with *W. bancrofti*.

Inflammation of lymphatic tissues caused by adult worms leads to long-term damage and lymphatic obstruction years after the infection has cleared in up to 30% of infected people. Pitting edema is an early manifestation of obstruction that heralds chronic lymphedema, most commonly affecting the legs, but it can also occur in arms, genitals, and breasts. Scrotal edema can be severe (Figure 195.1). The edema eventually causes characteristic features of elephantiasis, with thickening of subcutaneous tissues, hyperkeratosis, and fissuring of skin. Chyluria can develop in *W. bancrofti* infections if retroperitoneal lymphatics are obstructed. Lymphedema renders patients susceptible to recurrent bacterial and fungal infections, which cause pain and fever and exacerbate the lymphatic damage.

Persons new to endemic areas who acquire lymphatic filariasis usually develop acute lymphatic inflammation with lymphangitis, lymphadenitis, and, in the case of *W. bancrofti*, genital pain, but they may also develop allergic phenomena such as hives, urticaria, and eosinophilia.

FIGURE 195.1 Massive scrotal swelling in lymphatic filariasis.

Diagnosis

A diagnosis of lymphatic filariasis is supported by compatible epidemiologic risk factors, clinical features, and laboratory tests. However, a definitive diagnosis requires visualization of the parasite. Microfilariae can be detected in blood by microscopic examination of thick and thin blood smears stained with Giemsa or hematoxylin-and-eosin. Concentration techniques such as blood filtration (e.g., Nuclepore membranes) or centrifugation of blood lysed with 2% formalin (Knott's technique) may improve the diagnostic yield. The timing of blood collection is critical and should be based on the periodicity of the microfilariae in the endemic region in question. For nocturnally periodic microfilariae, blood should be collected between 10 PM and 2 AM. A 10- to 14-day period is required for microfilarial periodicity to adjust to the local time zone if the patient has left the endemic area.

A sensitive but nonspecific serologic screening test (filarial IgG4) is available to rule out filarial infections (including *Wuchereria*, *Brugia*, *Onchocerca*, and *Loa loa*). Assays to detect circulating parasite antigens of *W. bancrofti* are not approved in the United States. Polymerase chain reaction (PCR)-based assays that detect DNA of *W. bancrofti* and *B. malayi* have been developed but are not commercially available in the United States.

In general, laboratory data supporting a diagnosis of filarial infections include eosinophilia, elevated serum IgE levels, and antifilarial IgG4 antibodies in the serum. However, serology tests may be falsely positive because of cross-reactivity of antibodies with other helminths. False-negative test results may occur because lymphedema may develop many years after infection, by which time antibody levels have declined.

Adult worms in lymphatics are generally inaccessible and excisional biopsies are unhelpful. Ultrasonographic examination of the scrotum or breast in females using a high-frequency transducer with Doppler may demonstrate motile adult worms within dilated lymphatics (the so-called *filarial dance sign*).

Therapy

To select an appropriate and safe therapy, it is important to be aware of possible coinfections with other filariae. The geographic distributions of lymphatic filariasis, loiasis, and onchocerciasis overlap in West Africa and coinfection can occur. Diethylcarbamazine (DEC) is contraindicated in regions where onchocerciasis is endemic because DEC can exacerbate onchocercal skin and eye disease (Mazzotti reaction). Since treatment of loiasis with DEC or ivermectin can result in severe adverse effects, it is imperative to diagnose *Loa loa* before initiating therapy for patients with lymphatic filariasis.

The main goal of therapy is to kill adult worms that are responsible for lymphedema. For individuals not coinfected with onchocerciasis, the CDC recommends DEC, which is both microfilaricidal and active against adult worms, at a dose of 6 mg/kg in a single dose or 6 mg/kg/d in three divided doses for 12 days. For single-dose DEC therapy, the WHO recommends adding a single dose of albendazole (400 mg). For individuals coinfected with onchocerciasis, singles dose of albendazole (400 mg) and ivermectin

(200–400 μg/kg) are recommended. DEC is not commercially available in the United States but can be obtained through the CDC Drug Service under an Investigational New Drug protocol (telephone 404–639–3670). Doxycycline (100 mg PO BID × 4 weeks) targets the intracellular *Wolbachia* and also demonstrates macrofilaricidal activity.

The severity of adverse reactions correlates with the pretreatment level of microfilaremia, but the etiology is unclear and may represent either an acute hypersensitivity reaction to massive antigen release or an inflammatory reaction induced by the release of *Wolbachia*. Usually, the reactions, which include fevers, headache, lethargy, arthralgia, and myalgia, can be managed with antipyretics and analgesics.

Antiparasitic treatment of chronic lymphatic obstruction is ineffective. If the infection is recognized early, some signs of lymphatic obstruction can be reversed. Severe chronic lymphedema (elephantiasis), however, requires supportive measures. Therapies include elevation of the affected limb, use of elastic stockings, skin hygiene, and skin and wound care with antifungal ointment and antibacterial antiseptics in consultation with a lymphedema therapist. There is no proven role for prophylactic antibiotics to prevent recurrent bacteremia and cellulitis. Hydroceles can be managed surgically, and surgical decompression with a nodo-venous shunt may provide relief for patients with severely affected limbs.

Infection can be prevented by using insect repellants that contain N,N-Diethyl-meta-toluamide (DEET), covering exposed body parts to prevent mosquito bites, and treating clothes with permethrin.

Tropical pulmonary eosinophilia

Tropical pulmonary eosinophilia (TPE) is a rare but serious variant of lymphatic filariasis caused by immunologic hyperresponsiveness to *W. bancrofti* or *B. malayi*. The syndrome affects men four times as commonly as women, most commonly from the ages of 15 to 40 years. Most cases have been reported from Pakistan, India, Sri Lanka, Southeast Asia, and Brazil.

The signs and symptoms of TPE are attributed to trapping of microfilariae in pulmonary vasculature, with resultant eosinophilic alveolitis; patients develop paroxysmal cough, dyspnea, and wheezing that is often misdiagnosed and treated as asthma. The characteristic nocturnal worsening of symptoms is due to the nocturnal periodicity of the microfilariae. Other symptoms include fever, malaise, and weight loss. The majority of cases have reticulonodular or interstitial infiltrates on chest radiographs. Typical symptoms in combination with extreme eosinophilia (>3,000/mm^3), high polyclonal IgE levels, elevations of antifilarial antibodies, and a prompt response to DEC establish the diagnosis. Untreated, TPE can lead to lung fibrosis and progressive respiratory compromise.

Therapy

The CDC recommends DEC at a dose of 6 mg/kg/d in three divided doses for 14 to 21 days. Symptoms usually resolve within 1 week. However, adjunctive treatment with corticosteroids may improve outcomes if the disease persists or relapses. As many as 20% to 40% of treated patients relapse, requiring retreatment.

Loiasis

Also known as *African eye worm*, loiasis results from infection with *Loa loa* acquired in the rainforests of West and Central Africa. After the bite of daytime-active infected female deer or mango flies, the filarial larvae are inoculated into the subcutaneous tissue, where they mature over several months and migrate throughout the body, including the CNS. The adult parasites reproduce sexually, and their progeny reside mostly in humans' lungs. The microfilariae then enter the bloodstream intermittently with a diurnal periodicity. Adult worms can survive longer than a decade.

Epidemiology

The countries with reported transmission include Angola, Cameroon, Central African Republic, Chad, Congo, Democratic Republic of Congo, Equatorial Guinea, Ethiopia, Gabon, Nigeria, and Sudan. In some regions, individual histories of eye worm exceed 40%.

Clinical presentation

Clinical manifestations differ between indigenous people and nonimmune travelers. In the native population, microfilaremia is generally asymptomatic, remaining subclinical until the adult worm visibly migrates through the subconjunctival tissues of the eye (over hours to days) or causes Calabar swellings, which are localized, nontender angioedematous lesions in the extremities (Figure 195.2) that are reactions to migrating worms. Nephropathy, encephalopathy, and cardiomyopathy are rare. In travelers, hypersensitivity responses predominate (e.g., pruritus, hives, myalgia, arthralgia), microfilaremia is rare, and Calabar swellings occur more frequently and can be debilitating. Eye worm can cause eye congestion, itching, pain, and sensitivity to light.

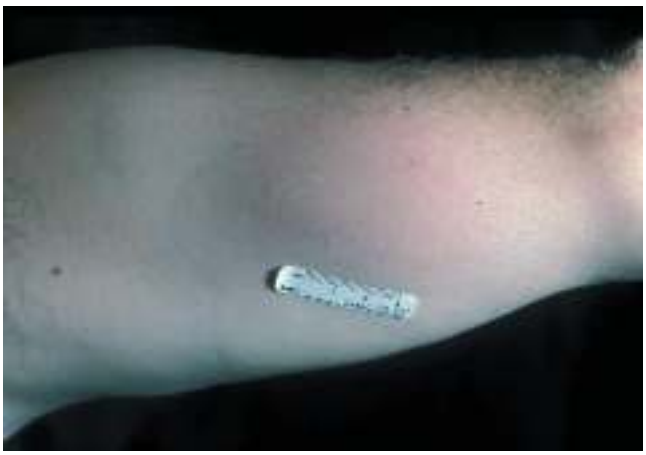

FIGURE 195.2 Calabar swelling of loiasis.

Diagnosis

A presumptive diagnosis is supported by characteristic clinical features associated with elevated filarial IgG4 antibodies and blood eosinophilia. *Loa*-specific antibody and antigen tests, and PCR assays are available in research laboratories. A definitive diagnosis can be made by (1) identifying microfilariae in peripheral blood with microscopy, as for lymphatic filariasis; (2) a healthcare professional visualizing an adult worm migrating across the eye; or (3) confirming the identity after extraction from the subcutaneous tissue or eye. Because the microfilariae of *Loa loa* exhibit diurnal periodicity, blood must be drawn from the patient between 10 AM and 2 PM in the time zone of the endemic region or 10 to 14 days after leaving that time zone. Quantification of the parasite load (microfilariae/mL) in the blood smear is required to guide therapy. The worm is not found in Calabar swellings, and biopsy of these lesions is not indicated.

Therapy

Surgery to remove worms from the eye is not curative. The drug of choice to treat loiasis is DEC, which is effective against both the adult worm and microfilariae. The recommended dose is 8 to 10 mg/kg/d in three divided doses for 21 days. A single course of therapy is curative in the majority of patients, although multiple courses may be required. In refractory cases, albendazole 400 mg twice per day for 21 days may be effective.

Extreme caution is warranted in patients who have microfilaremia of >8,000/mL because treatment with standard dosages of DEC has resulted in life-threatening complications including encephalopathy and renal failure due to rapid killing of microfilariae. Asymptomatic individuals with high parasitic loads should not receive DEC until the blood parasite density has been reduced to <2,500/mL by means of apheresis of blood or albendazole 200 mg twice per day for 21 days. In patients without microfilaremia, the DEC dose should be escalated gradually: day 1, 50 mg; day 2, 50 mg three times a day; day 3, 100 mg three times a day; day 4 to 21, 9 mg/kg/d in three divided doses. Pretreatment with steroids has not been proved to reduce the risk of serious complications. Doxycycline is not effective for loiasis because these filarial worms do not contain endosymbiotic *Wolbachia*, unlike lymphatic filariae and *Onchocerca*.

It is not unusual for treated patients to develop transient pruritus, fever, anorexia, or localized inflammatory reactions such as subcutaneous papules or hives. These reactions, which are distinct from Calabar swellings, are a response to dying adult worms.

It is important to consider the possibility of *Loa loa* coinfection in anyone who will be treated for lymphatic filariasis or onchocerciasis because of the risk of fatal encephalopathy during treatment with DEC or ivermectin for the other filarial infections, particularly if there is a high density of *Loa loa* in the bloodstream.

Prophylaxis should be considered for travelers and nonresident workers with longer term exposures. Once-weekly treatment with DEC 300 mg is effective prophylaxis.

Infection can be prevented by avoiding habitats of deerflies, using insect repellants that contain DEET, covering exposed body parts during the day, and treating clothes with permethrin.

Onchocerciasis

Infection with *O. volvulus* is second only to trachoma as a leading infectious cause of blindness worldwide. Areas of transmission are focal because the *Simulium* blackfly vector has a limited range near the fast-flowing streams and rivers where it breeds; hence the name "river blindness." After the bite of daytime-active infected female blackflies, larvae penetrate the skin and migrate into the subcutaneous tissue, where they mature into adults over 3 to 12 months. Aggregates of adults live in visible subcutaneous fibrous nodules for up to 15 years. For approximately 9 years, gravid females produce millions of microfilariae that migrate throughout the dermis, lymphatics of subcutaneous tissue, and eyes where they have a life span as long as 2 years.

Epidemiology

Onchocerciasis occurs predominantly in sub-Saharan Africa in the savannah of rural agricultural areas. It is also found in Yemen and in limited regions of Venezuela and Brazil. Because risk of transmission is proportionate to the number of bites, short-term travelers (generally <3 months) are at low risk.

Clinical presentation

Most infected individuals experience symptoms caused by the hosts' response to dead or dying larvae in the skin, lymph nodes, and eyes. Pruritus is the most frequent manifestation of onchocerciasis, and it can be debilitating. An itchy, erythematous, papular rash prominent early in the infection is also seen (Figure 195.3). With chronic infection, pigmentary skin changes can have a "leopard skin" appearance; epidermal atrophy with loss of elasticity and exaggerated wrinkling can lead to a "cigarette paper" appearance. Loose, redundant skin with inguinal and femoral lymphadenopathy may lead to a "hanging groin" effect in people from endemic regions. Nonmigratory subcutaneous fibrous nodules containing aggregates of adult worms are typical of onchocerciasis.

Infection of the eye may involve several structures. A common early finding is conjunctivitis with photophobia. Inflammation of

FIGURE 195.3 Papular eruption in onchocerciasis.

the cornea leads to painful punctate keratitis (snowflake opacities) that are reversible, but sclerosing keratitis, which develops later if treatment is not initiated early, is the most common cause of blindness in onchocerciasis. Other manifestations include anterior uveitis, iridocyclitis, secondary glaucoma, chorioretinal lesions, and optic atrophy.

Diagnosis

Compatible clinical features associated with eosinophilia and elevated IgE and nonspecific filarial IgG4 antibodies are suggestive of onchocerciasis. Definitive diagnosis rests most commonly on the detection of microfilariae that emerge from skin snips during incubation in saline. Typically 6 skin snips are obtained by sampling superficial skin layers either using a corneoscleral punch or a scalpel while tenting the skin with a needle. The sensitivity of skin snips is limited in the pre-patent period, which can last up to 1.5 years or in travelers who may have low-density infections. Alternative methods of diagnosis include identification of adult worms in an excised nodule or visualization of microfilariae with slit-lamp examination of the anterior chamber of the eye. Specific serological tests and PCR assays have been developed but are not commercially available.

Therapy

Ivermectin is the drug of choice for onchocerciasis control programs. Ivermectin kills microfilariae, and, although it doesn't kill adult worms, it sterilizes the females. The treatment dosage is 150 μg/kg every 3 to 6 months until there is no evidence of pruritus or ongoing infection. In endemic countries, ivermectin is administered annually to affected people for 15 years or longer to interrupt transmission. Reactions to ivermectin (Mazzotti reaction) are associated with death of the microfilariae and are usually mild, including transient pruritus, dizziness, headache, arthralgia, rash, or edema. Antihistamines and/or analgesics have been used for mild to moderate Mazzotti reactions. More serious reactions are rare and have only been reported in patients who were coinfected with *Loa loa*. Therefore, *Loa loa* should be ruled out before initiating therapy for onchocerciasis. Some strains of *O. volvulus* have been reported to have relative resistance to ivermectin.

Moxidectin, widely used in veterinary medicine, was approved by the FDA in 2018 as the first new treatment for onchocerciasis in 20 years. Approval was based on two randomized controlled trials conducted in endemic African countries that clearly demonstrated superiority of a single 8 mg dose of moxidectin over a single dose of ivermectin to rapidly reduce or eradicate microfilariae. Like ivermectin, it does not kill adult worms and is contraindicated in *Loa loa* coinfected patients. However, moxidectin has a more sustained reduction in microfilarial levels because it has a longer half-life (23 days vs. 18 hours for ivermectin). In addition to adverse reactions (Mazzotti reactions) similar to those for ivermectin, it may cause transient symptomatic orthostatic hypotension in the first 2 days after treatment.

Doxycycline at a dose of 100 to 200 mg/d for 6 weeks exhibits macrofilaricidal activity and induces cessation of embryogenesis by eliminating *Wolbachia*, a bacterial endosymbiont. Doxycycline does not kill the microfilariae and therefore needs to be used in conjunction with ivermectin for symptomatic relief. The safety of concurrent treatment is unknown, but it is suggested that ivermectin be given 1 week before initiation of doxycycline and 6 months after treatment.

DEC is contraindicated because it can exacerbate onchocercal eye disease. Historically, nodulectomy was performed to reduce parasitic load. However, this approach is impractical and ineffective because multiple or inaccessible nodules result in persistence of worms.

Other filarial infections

Humans can harbor infections with other filariae, most notably *Mansonella* spp.: *M. streptocerca*, *M. perstans*, and *M. ozzardi*. The majority of infected individuals are asymptomatic and these organisms are discovered incidentally. However, clinical disease may be associated with a variety of nonspecific manifestations frequently including pruritus. As with other filariases, eosinophilia, elevated IgE, and nonspecific antifilarial antibodies are commonly found even in the absence of symptoms. Infection of travelers occurs infrequently.

M. streptocerca, found in western and central Africa, is transmitted by biting midges. Clinical manifestations resemble onchocerciasis with papular rashes, pigmentation changes, pruritus, and inguinal adenopathy, but adult worms do not aggregate in subcutaneous nodules. Diagnostic PCR assays are not commercially available. Diagnosis is made by finding the characteristic unsheathed microfilariae in skin snips, as for onchocerciasis. Treatment with DEC (6 mg/kg/d in divided doses for 21 days) kills adult worms and microfilariae. Ivermectin (150 μg/kg) is effective against the microfilariae only. Both drugs can produce Mazzotti reactions. It is not known if *Wolbachia* is an endosymbiont of *M. streptocerca*.

M. perstans, also transmitted by biting midges, is found in western and central Africa as well as South America. Clinical manifestations resemble loiasis, with transient angioedema, arthralgias, Calabar swellings, fatigue, fever, headache, and pruritus. Occasionally pericarditis, pleuritis, meningoencephalitis, hepatitis, and eye lesions occur. A PCR assay to detect microfilaremia is available at the Laboratory of Parasitic Diseases at the US National Institutes of Health (NIH). The diagnosis is established by the demonstration in the blood of the microfilariae, which do not exhibit periodicity. Treatment options include DEC combined with mebendazole or doxycycline to target *Wolbachia* that can be found in some strains of *M. perstans*.

M. ozzardi is found in Central and South America and the Caribbean. This parasite is transmitted by biting midges and blackflies. Attributable symptoms and signs are nonspecific and include arthralgias, fever, headache, hepatomegaly, pruritus, and urticaria. Diagnostic PCR assays are not commercially available. Diagnosis relies on finding the microfilariae in the peripheral blood, which circulate without periodicity, or in skin snips. A single dose of ivermectin (200 μg/kg) is effective. Although *M. ozzardi* does harbor *Wolbachia*, there are no data to support treatment with doxycycline.

Dirofilaria spp. are filarial nematodes that primarily infect dogs, wild canids, and raccoons. *D. immitis* causes heartworm disease in

dogs throughout the United States, with the highest incidence in the southeast. Humans are incompetent hosts because infecting parasites cannot grow to maturity and the worms are usually found incidentally. In humans, the bite of an infected mosquito deposits parasites in the subcutaneous tissues where they commonly form subcutaneous nodules. *D. immitis* worms migrate to the pulmonary vasculature, where they are trapped and die, resulting in a solitary lung granuloma, often asymptomatic, that appears as a nonspecific coin lesion on chest film. Eosinophilia is seen in fewer than 15% of infected persons at an early stage of infection. Often no treatment is required. If needed, surgical removal of lung granulomas and subcutaneous nodules is curative.

Brugia of small mammals can cause isolated lymph node enlargement in humans, but eosinophilia and antifilarial antibodies are uncommon. These zoonotic infections are diagnosed and cured by excisional biopsy.

Dracunculiasis

Dracunculiasis or Guinea worm disease is a neglected tropical disease caused by *Dracunculus medinensis*, which occurs only in remote, poor parts of Africa. This parasite is on the verge of global eradication through the coordinated efforts of the highly effective Guinea Worm Eradication Program under the auspices of the WHO, UNICEF, and the Carter Center.

Epidemiology

During the mid-1980s, 20 countries worldwide reported Guinea worm disease. Currently, residual pockets of disease (30 cases in 2017) affects poor communities in Chad and Ethiopia where people bathe or wade in stagnant surface water sources used for drinking. The infection develops after consumption of water contaminated with water fleas (copepods) infested with *D. medinensis* larvae. The larvae are released in the stomach, pass into the small intestine, and penetrate the mucosa, ultimately reaching retroperitoneal tissues, where they mature and sexually reproduce.

Clinical presentation

The infection remains asymptomatic until 10 to 14 months after infection, when the adult female worm migrates to the subcutaneous tissues of the legs in 90% of cases. A painful papule forms and is occasionally associated with low-grade fever, pruritic rash, dizziness, nausea, and vomiting. The lesion develops into a vesicle that ruptures and ulcerates, exposing a portion of the gravid worm. Affected people often immerse the infected extremity in water to soothe the burning sensation. On contact with water, hundreds of thousands of larvae are discharged and ingested by water fleas to complete the life cycle.

Diagnosis

Once the worm protrudes from the skin, a clinical diagnosis is sufficient to confirm the disease.

Therapy

There are no specific antiparasitic drugs or vaccines available. Treatment of dracunculiasis has remained unchanged for thousands of years. It consists of slow extraction of the emerging worm by securing the end to a small stick or gauze and gradually winding it a few centimeters daily until it is removed over a period days to weeks. If the worm ruptures during removal, the remaining part of the dead worm can exacerbate local inflammation. Proper wound care and topical antibiotics are essential to prevent secondary bacterial infections, which can cause greater debilitation.

Interruption of transmission is achieved through surveillance, case containment, provision of safe drinking water, vector control with chemical larvicides, and health education.

Unusual tissue helminth infections

Visceral and ocular larva migrans

Visceral larva migrans (VLM) or toxocariasis is 1 of 5 neglected parasitic diseases in the United States prioritized by the CDC for public health action. The others include Chagas disease, cysticercosis, toxoplasmosis, and trichomoniasis. VLM is a syndrome caused by nematodes that typically parasitize dogs or cats. Humans are incompetent incidental hosts and therefore cannot sustain the maturation of larvae, which elicit eosinophilic inflammation as they migrate through human tissues. Most human infections are caused by *Toxocara canis* from dogs or less commonly by *T. cati* from cats.

Epidemiology

Worldwide, people of all ages, especially children, acquire toxocariasis by accidentally ingesting infective *Toxocara* eggs, or soil, food, or water contaminated with eggs that are shed in the stool of host animals (e.g., sandboxes). It takes 2 to 4 weeks for *Toxocara* eggs in the environment to become infective. Rarely, humans can be infected by eating undercooked meat from intermediate hosts such as a rabbit or lamb. *Toxocara* is more prevalent in people who own pet dogs and in hot, humid regions where eggs remain viable longer.

Clinical presentation

VLM is usually asymptomatic and is referred to as *covert toxocariasis*. Clinical manifestations of visceral toxocariasis may include abdominal pain, anorexia, cough, fever, malaise, rash, and wheezing. Hepatomegaly is commonly seen. Less common severe complications include eosinophilic meningoencephalitis (neurotoxocariasis), myocarditis, and pneumonitis.

Ocular larva migrans (OLM) or ocular toxocariasis may be associated with symptomatic VLM, but it often occurs in isolation. Typically, OLM presents with unilateral visual deficits, ocular pain,

leukocoria, photophobia or strabismus caused by chorioretinitis, uveitis, and/or retinal scarring. The features may be confused with retinoblastoma.

Diagnosis

Marked eosinophilia and elevated IgE levels are nonspecific features of VLM, but they may be absent in OLM. An enzyme-linked immunosorbent assay (ELISA) that detects antibodies to *Toxocara* excretory/secretory (TES) larval antigens and that minimizes cross-reactivity with antigens of *Ascaris* and other parasites is commercially available. Nevertheless, results must be interpreted with caution as broad variations in antibody responses occur and levels may remain elevated for years after infection. Detection of rising antibodies with acute and convalescent serologic testing confirms acute infection but the assay cannot distinguish between *T. canis* and *T. cati*. Serum antibodies may be absent in OLM, but finding antibodies in vitreous or aqueous humor may help confirm the diagnosis. The symptoms and signs of VLM may be caused by migrating larvae of other helminths, including *Baylisascaris procyonis*, *Paragonimus* spp., *Strongyloides* spp., and certain filariae.

Therapy

The majority of patients with toxocariasis do not require treatment because they have no or mild symptoms. Treatment with albendazole (400 mg BID for 5 days; preferred) or mebendazole (100–200 mg BID for 5 days) is generally reserved for patients with severe VLM. The optimal duration of therapy is unknown. Use of adjunctive prednisone (0.5—1.0 mg/kg/d) may reduce inflammation during treatment of severe VLM with neurological, cardiac, or pulmonary manifestations.

Treatment of OLM with the same medications as for VLM is recommended, although longer therapy may be needed. The administration of topical and systemic steroids may improve visual outcomes. Surgical intervention in quiescent disease may be indicated.

Cutaneous larva migrans ("creeping eruption")

Cutaneous larva migrans (CLM), also known as "creeping eruption," is a zoonosis caused by larval stages of animal hookworms, most often those of the dog (*Ancylostoma caninum*) or cat (*A. braziliense*). As with human hookworms, the infection starts when the worm enters the skin from contaminated soil or sand, as found on beaches or in sandboxes where domestic animals may roam. The incubation period is 1 to 5 days but can be longer than 1 month.

Epidemiology

The infection is seen in short- and long-term travelers to Africa, Asia, the Caribbean, and South America.

Clinical presentation

As in visceral larva migrans caused by *Toxocara* spp., the worm cannot complete the infective cycle in humans, who are incidental hosts, so it continues to burrow through the subcutaneous tissues, resulting in the characteristic serpiginous, erythematous, mildly swollen, and intensely pruritic skin lesion (Figure 195.4). The worms may create tracks several centimeters in length each day, typically on the feet and buttocks. Systemic symptoms are rare.

Diagnosis

Diagnosis is based on characteristic clinical findings. Eosinophilia is not a usual feature. Skin biopsy is not recommended.

Therapy

CLM is a self-limiting disease because the larvae usually die spontaneously after 5 to 6 weeks. Treatment with a 3-day course of albendazole (400 mg/d) or a single dose of ivermectin (200 μg/kg) is highly effective. Symptomatic treatment of severe pruritus is indicated.

Eosinophilic meningitis due to helminths

Eosinophilic meningitis due to infection with helminths is most often caused by the rat lungworm *Angiostrongylus cantonensis*, followed by the nematode *Gnathostoma spinigerum* and the raccoon ascarid *Baylisascaris procyonis*. However, the condition has been reported to be a consequence of infection with other helminths, specifically *Schistosoma japonicum*, *Paragonimus* spp., and *Taenia solium* cysticerci.

Angiostrongyliasis, caused by *Angiostrongylus cantonensis*, is naturally transmitted between rats and mollusks (e.g., snails and slugs). Humans acquire the nematode incidentally by eating raw

FIGURE 195.4 Cutaneous larva migrans.

or undercooked infected mollusks, vegetables contaminated with mollusks or their slime, or possibly raw or undercooked freshwater shrimps, crabs, or frogs that eat infected mollusks.

The disease is prevalent mostly in Southeast Asia and Pacific islands, but it has also been identified in Africa, Australia, the Caribbean, Hawaii and the US (Louisiana). *A. costaricensis* is found in Latin America.

The average incubation period is 1 to 3 weeks. Individuals present with symptoms and signs of meningitis such as headache, meningism, nausea, and vomiting. The clinical illness lasts typically for 2 to 8 weeks.

Peripheral blood eosinophilia (>5%) is prominent and lasts for about 3 months, although it may be absent in the early stages of infection. Typical cerebrospinal fluid (CSF) findings consist of an elevated opening pressure, pleocytosis with at least 10% eosinophilia, and elevated protein content with low or normal glucose levels. Visualization of the larvae from CSF is diagnostic but rare. Serological tests and PCR assays have been developed but are not commercially available. Findings from neuroimaging studies are nonspecific but may be helpful to rule out focal lesions caused by other parasites associated with eosinophilic meningitis such as neurocysticercosis and gnathostomiasis.

Antihelminthic agents have not been proved to be safe and effective. There is a theoretical concern that antiparasitics may lead to an exacerbation of the neurological symptoms caused by an immunological response to dying worms. Treatment is symptomatic with analgesics and corticosteroids (60 mg/d for 2 weeks with a taper). Intermittent removal of CSF affords symptomatic relief.

B. procyonis, a raccoon nematode, rarely causes human disease that can be severe if the parasite invades organs (visceral larva migrans), the eye (ocular larva migrans or diffuse unilateral subacute neuroretinitis), or the brain and spinal cord (neural larva migrans). Humans are infected by accidentally ingesting *B. procyonis* eggs in contaminated soil, sand, or water. Eggs in the environment take 2 to 4 weeks to become infective and can remain viable for years.

Infected humans have been identified in the United States (<25 cases), Europe, and Japan. Children are at greatest risk. Worms may also infect some dogs that ingest infected small mammals, and eggs shed in their feces may become infective.

The incubation period is 1 to 4 weeks. Infections may be asymptomatic. Symptoms and signs depend on parasitic load and location, and include cough, fatigue, nausea, hepatomegaly, visual defects, and a variety of neurological deficits including signs of meningoencephalitis that may cause death or permanent disability in a substantial proportion of patients.

Laboratory tests demonstrate peripheral eosinophilia, CSF eosinophilic pleocytosis, nonspecific abnormalities of white matter on brain neuroimaging, and positive *B. procyonis* serologic testing of serum and CSF, which can be performed at the CDC. Ophthalmologic examination may reveal evidence of larvae.

Prompt therapy with albendazole (25–50 mg/kg/d for 10–20 days) after exposure to infected material or early in the disease process in conjunction with corticosteroids may be effective. Mebendazole and ivermectin are less effective. Laser therapy may be indicated for retinal infections.

FIGURE 195.5 Angioedema of left hand in gnathostomiasis.

Gnathostomiasis, is caused by *Gnathostoma spinigerum*, an intestinal nematode of domestic and wild dogs and cats. These and other animals become parasitized when they feed on infected copepods (water fleas), which are intermediate hosts. Humans are incidental hosts in the life cycle. Other *Gnathostoma* species infect a variety of other mammals.

Gnathostoma spp. cause human infections predominantly in Southeast Asia, but also elsewhere in Asia, Central and South America, and southern and eastern Africa. Humans accidentally acquire the infection by eating raw or undercooked freshwater fish, eels, frogs, birds, and reptiles that harbor encysted larvae.

The most common manifestation is intermittent subcutaneous swelling associated with pruritus that lasts for 1 to 2 weeks (Figure 195.5), mimicking the Calabar swelling of loiasis. Severe complications of gnathostomiasis include vision loss, hepatitis, and eosinophilic encephalomyelitis. CNS disease manifests as severe headache or radicular pain that may be followed by paralysis of the legs, urinary retention, coma, and death.

Gnathostomiasis is commonly associated with hypereosinophilia. The diagnosis is usually established clinically. Serologic testing is not available in the United States; the CDC can coordinate testing of serum at specialty laboratories in Thailand and Japan.

Both albendazole (400 mg BID for 21 days) and ivermectin (200 μg/kg/d for 2 days) are effective for cutaneous manifestations. Because albendazole may cause larvae to migrate and ivermectin may cause a disease flare, the safety and effectiveness of these agents for CNS or ocular disease have not been proved. There is concern that antihelminthics may exacerbate neurological disease and cause permanent sequelae. Adjunctive treatment with steroids has not been proved to be beneficial.

Schistosomes and other trematodes

James H. Maguire

The trematode flatworms that infect human beings include the schistosomes, which live in venules of the gastrointestinal or genitourinary tract, and other flukes that inhabit the bile ducts, intestines, or bronchi. The geographic distribution of each species of trematode parallels the distribution of the specific freshwater snail that serves as its intermediate host (Table 196.1). Schistosomes infect approximately 235 million persons worldwide; infections caused by the other flukes are more limited in distribution and number. Trematode infections last for years; most are subclinical, and in general only the small proportion of persons who have heavy worm burdens develops severe disease.

Schistosomiasis

Clinical presentation

A history of contact with possibly infested freshwater in an endemic area should prompt an evaluation for schistosomiasis, even in the absence of symptoms (Figure 196.1). Clinical manifestations that suggest the diagnosis vary according to the stage of infection. Some persons complain of intense pruritus or rash shortly after the infective cercariae penetrate the skin. Previously uninfected visitors to endemic areas may develop acute schistosomiasis, or Katayama fever, 2 to 12 weeks after exposure, as the immune system responds to maturing worms and eggs. Symptoms range from mild malaise to a serum sickness-like syndrome that lasts for weeks and may be life-threatening. Common features include fever, headache, abdominal pain, myalgia, dry cough, diarrhea, hepatosplenomegaly, lymphadenopathy, urticaria, and marked eosinophilia.

Chronic infections with schistosomes usually are asymptomatic; slight or moderate eosinophilia occurs frequently. Long-term residents of endemic areas may harbor heavy infections for long periods and thus are more likely than transient visitors to have symptoms. Disease results from egg deposition in tissues and the ensuing inflammatory and fibrotic response (Figure 196.2). In infections due to *Schistosoma mansoni*, *Schistosoma japonicum*, *Schistosoma mekongi*, *Schistosoma intercalatum*, and *Schistosoma guineensis*, involvement of the bowel leads to mucosal inflammation and microulcerations, diarrhea, bleeding, polyps, and strictures. Embolization of eggs to the liver results in hepatosplenomegaly, periportal fibrosis, portal hypertension, and esophageal varices. Hematuria and dysuria are early symptoms of chronic infection by *Schistosoma haematobium;* later, fibrosis and calcification of the bladder and lower ureters results in hydroureter and hydronephrosis (Figure 196.3), and squamous cell carcinoma of the bladder may develop. Ectopic deposition of eggs in the skin, genitalia, and other organs occurs during both the acute and chronic stages of infection. Transverse myelitis, seizures, and other serious sequelae result from egg deposition in the central nervous system. In endemic areas, chronic infections of even moderate intensity have been associated with anemia, poor nutritional status, and cognitive impairment.

TABLE 196.1 **GEOGRAPHIC DISTRIBUTION OF IMPORTANT TREMATODES**[a,b]

Schistostomes	
Schistosoma mansoni	South America, Caribbean, Middle East, Africa
Schistosoma japonicum	China, Philippines, Indonesia, Thailand
Schistosoma mekongi	Cambodia, Laos
Schistosoma intercalatum, Schistosoma guineensis	West and Central Africa
Schistosoma haematobium	Africa, Middle East
Biliary and liver flukes	
Clonorchis sinensis	China, Taiwan, Korea, Japan, Vietnam
Opisthorchis viverrini	Thailand, Laos, Cambodia
Opisthorchis felineus	Eastern Europe, former Soviet Union
Fasciola hepatica	Europe, North Africa, Asia, western Pacific, Latin America
Lung flukes	
Paragonimus westermani and other species	Far East, South Asia, Philippines, Central and South America, West Africa, Mississippi River Basin (USA)
Intestinal flukes	
Fasciolopsis buski	Far East
Heterophyes heterophyes	Far East, Egypt, Middle East
Metagonimus yokogawai	Far East
Nanophyetus salmincola	Pacific Northwest

[a] Parasites may be limited to certain countries in the regions listed and certain foci within these countries.
[b] Many less common trematodes that infect human beings are not listed here.

Diagnosis

The most direct method of diagnosis is microscopic examination of stool or urine for schistosome eggs (Figure 196.4). Because egg output is low in light infections, concentration techniques and examination of several specimens obtained on different days should be routine. Eggs should be counted to estimate the intensity of infection and to monitor the response to therapy. Counts above 400 eggs per gram of feces or 10 mL of urine are considered heavy and

FIGURE 196.1 Shallow pond infested with *Biomphalaria*, the snail host of *Schistosoma mansoni* in Brazil.

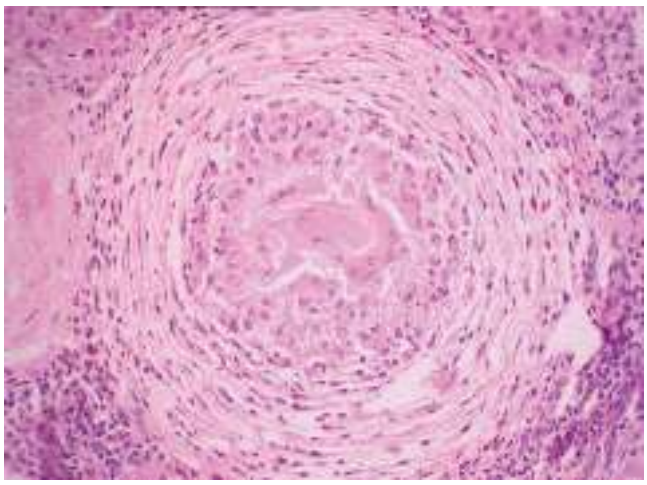

FIGURE 196.2 Granuloma around egg of *Schistosoma mansoni* that embolized to the liver and was trapped in a small branch of the portal vein.

are associated with higher rates of complications. Microscopic examination of snips of rectal mucosa obtained at proctoscopy may reveal eggs when stool examination is negative.

Serologic tests for antibodies to schistosomes are available at commercial laboratories in the United States and at the Centers for Disease Control and Prevention (CDC) in Atlanta. The CDC uses a sensitive and specific Falcon assay screening test/enzyme-linked immunosorbent assay (FAST-ELISA) for screening and a highly specific immunoblot for confirmation and species determination. These tests cannot distinguish active from past infections but are useful for the diagnosis of acute schistosomiasis before eggs are shed in the stool. Serologic tests should be used to screen previously unexposed travelers and expatriates; a positive serologic test is presumptive evidence of infection even if subsequent microscopy is negative.

Persons with confirmed infections due to the intestinal schistosomes should be evaluated with measurement of liver function tests and tests for chronic hepatitis B and C to rule out concomitant hepatocellular disease. Heavy infection or evidence of liver disease should prompt an ultrasound to document periportal fibrosis and signs of portal hypertension (Figure 196.5). Esophageal varices are visualized by barium swallow or endoscopy. Urinalysis, urine culture, and serum creatinine determination are indicated for persons with *S. haematobium* infection. Ultrasonography or other imaging studies detect complications such as hydronephrosis, polyps, stones, and carcinoma of the bladder.

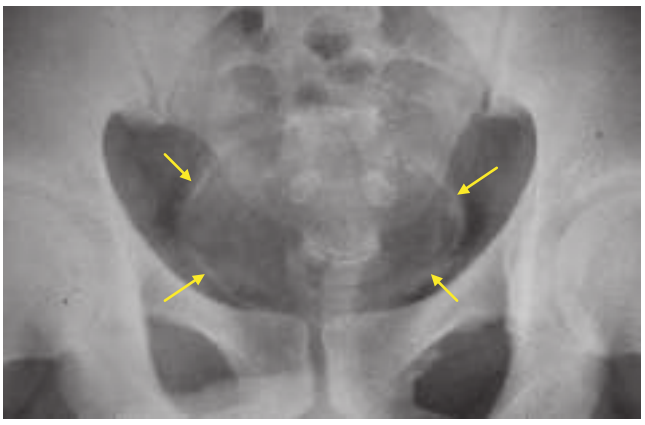

FIGURE 196.3 Plain radiograph of the pelvis showing calcification of the wall of the bladder and lower ureters (*arrows*).

Therapy

All persons with schistosomiasis should receive treatment. Eradication of infection is desirable because even a single pair of worms may deposit eggs in the central nervous system. In endemic areas where reinfection is inevitable, the goal is to reduce worm burdens to levels that are unlikely to produce disease. Successful treatment not only prevents complications but also may cause regression of polyps and fibrotic lesions. Fortunately, the treatment of choice, praziquantel, is safe and highly effective after one or a few oral doses (Table 196.2).

Praziquantel causes an influx of calcium ions across the tegument of the adult worm, leading to a tetanic contraction and vacuolization of the tegument that makes the parasite susceptible to immune destruction. Cure rates range from 65% to 95%, and in persons not cured, egg excretion is reduced by >90%. A few reports suggest that resistance to praziquantel may be developing. Adverse effects, which are usually mild and last less than 24 hours, may be caused by reactions to dying worms rather than drug toxicity. Patients occasionally report malaise, headache, dizziness, or abdominal discomfort. Nausea, vomiting, diarrhea, bloody stools, fever, and urticaria are uncommon. The World Health Organization has judged praziquantel safe for pregnant or lactating women. Persons with known or suspected cysticercosis should remain under observation during therapy because of the risk of seizures or other neurologic consequences of dying cysticerci. Praziquantel is metabolized in the liver, and the dosage need not be reduced because of renal insufficiency.

Severely ill persons with acute schistosomiasis should receive corticosteroids as well as praziquantel, although there is controversy about timing of anthelmintic therapy. Some experts recommend delaying praziquantel treatment because maturing schistosomes are less susceptible to praziquantel than are adult worms, corticosteroids lower serum levels of praziquantel, and acute illness may be exacerbated by reactions to killing of parasites. Because of the risk of ectopic infection, we favor administration of praziquantel shortly after administration of steroids. All patients should receive a second course of treatment 4 to 6 weeks after the first. Artemisinin derivatives have activity against immature parasites, but although they can be effective in preventing infection, their utility in the management of acute schistosomiasis is uncertain.

Because antischistosomal drugs may temporarily inhibit egg laying by adult worms, stool and urine should be examined 3 and 6 months after completion of therapy. Eosinophilia, hematuria, and other symptoms that persist beyond this time should prompt repeat parasitologic studies and evaluation for causes other than schistosomiasis. Serologic tests may remain positive for years after successful treatment and are of limited utility for the assessment of cure.

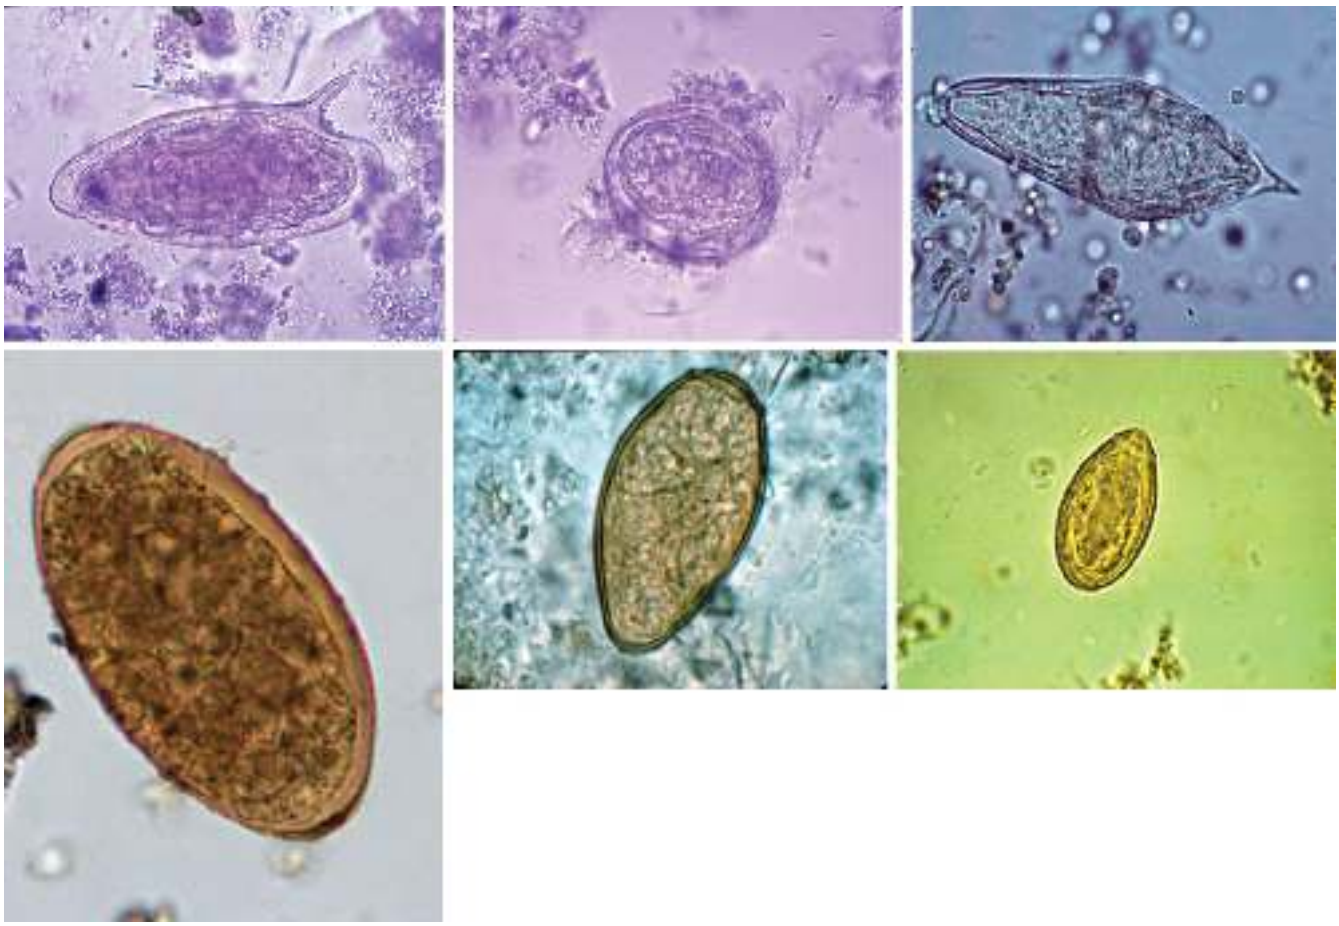

FIGURE 196.4 Trematode eggs. **Top row, left to right**: *Schistosoma mansoni, Schistosoma japonicum, Schistosoma haematobium*. **Bottom row, left to right**: *Fasciola hepatica, Paragonimus westermani, Clonorchis sinensis*.

Other trematode infections

More than 70 species of trematodes other than schistosomes infect 65 million or more persons worldwide. Most are parasites of wild and domestic animals. Human beings become infected by ingestion of metacercariae encysted in freshwater fish, crustacea, and plants, the second intermediate hosts.

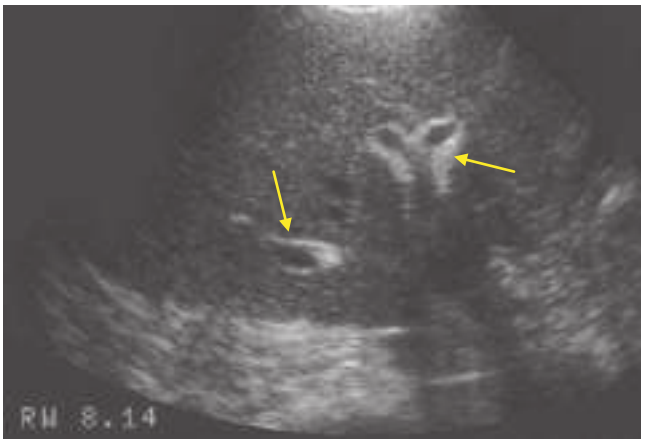

FIGURE 196.5 Ultrasound of the liver showing periportal fibrosis. Two portal tracts (one of the tracks is bifurcated) are surrounded with an area of increased echo (*arrows*).

Clonorchiasis and opisthorchiasis

The oriental liver flukes *Clonorchis sinensis*, *Opisthorchis viverrini*, and *Opisthorchis felineus* inhabit the biliary tree of persons who ingest infected carp and other freshwater fish without proper cooking. Most patients are asymptomatic, but eosinophilia is common. An acute illness resembling Katayama fever occasionally occurs 2 to 3 weeks after initial exposure. Persons with heavy infections for many years develop symptoms due to irritation and inflammation of biliary epithelium. Patients complain of right upper quadrant discomfort, anorexia, and weight loss. On physical examination the liver is palpable and firm. Cholangitis, pancreatitis, and cholangiocarcinoma are infrequent complications.

Diagnosis is made by finding eggs in the stool (Figure 196.4) or identifying adult worms during endoscopic retrograde cholangiopancreatography (ERCP) or surgery for complications. In symptomatic cases, ultrasonography or computed tomography (CT) demonstrates dilation and stricture of bile ducts, thickening

TABLE 196.2 **TREATMENT OF TREMATODE INFECTIONS**

Parasite	Drug of choice	Dosage
Schistosoma mansoni, S. haematobium, *S. intercalatum*, S. *guineensis*[a]	Praziquantel	40 mg/kg/d in 2 doses ×1 d
Schistosoma japonicum, S. mekongi	Praziquantel	60 mg/kg/d in 2 or 3 doses ×1 d
Clonorchis sinensis, Opisthorchis spp.	Praziquantel	75 mg/kg/d in 3 doses ×1 d
Fasciola hepatica, F. gigantica	Triclabendazole	10 mg/kg ×1 or 10 mg/kg × 2 doses 6 h apart
Paragonimus spp.	Praziquantel	75 mg/kg/d in 3 doses ×2 d
Fasciolopsis buski, Heterophyes heterophyes, Metagonimus yokogawai	Praziquantel	75 mg/kg/d in 3 doses ×1 d
Nanophyetus salmincola	Praziquantel	60 mg/kg/d in 3 doses ×1 d

[a] To increase the likelihood of a complete cure, praziquantel 60 mg/kg/day in 2 or 3 split doses can be given to persons with schistosomiasis who have left an endemic area. Many experts suggest that persons who acquired *S. mansoni* infection in Africa should also receive 60 mg/kg/day in 2 or 3 split doses.

of the gallbladder wall, and stones. A single course of praziquantel eradicates infection in more than 85% of cases (Table 196.2). An alternative is albendazole for 7 days.

Fascioliasis

Infection with the sheep liver fluke *Fasciola hepatica* and the closely related *Fasciola gigantica* results from ingestion of uncooked watercress or other aquatic vegetation from sheep- and cattle-raising parts of the world. After excysting in the duodenum, immature worms pass through the bowel wall and peritoneal cavity, invade the liver, and burrow through the parenchyma to the bile ducts. This migration provokes an acute syndrome of fever, nausea, tender hepatomegaly, eosinophilia, and urticaria lasting weeks to months. Aberrant migration causes nodules in the skin, painful inflammation of the intestinal wall, pleural effusion, or lesions in the lungs, brain, or elsewhere. Chronic fascioliasis is usually subclinical, but some persons have symptoms due to inflammation and obstruction of bile ducts.

Diagnosis is confirmed by demonstrating eggs in samples of stool, bile, or duodenal aspirates (Figure 196.4) or by recovering worms at surgery. Serologic tests are useful during acute infection because symptoms develop 1 to 2 months before eggs appear in the stool. Ultrasonography and ERCP may demonstrate adult worms and biliary pathology, and CT or magnetic resonance (MR) shows migratory hypodense lesions in the liver corresponding to necrosis along the path of larval migration.

Treatment of fascioliasis is with one or two doses of the veterinary drug triclabendazole which is available from Victoria Pharmacy in Zurich, Switzerland (Table 196.2). Given with food, treatment is successful in approximately 80% of cases, and a repeat course cures most of the remaining cases. The alternative, nitazoxanide, is less effective, and fascioliasis responds poorly to praziquantel.

Paragonimiasis

Infection with *Paragonimus westermani*, the oriental lung fluke, and, less commonly, other species of *Paragonimus*, follows ingestion of raw or poorly cooked freshwater crabs or crayfish. An acute phase with fever, abdominal and chest pain, cough, and eosinophilia corresponds to migration of immature parasites through the bowel wall, diaphragm, and pleura en route to the lungs. The inflammatory reaction to adults encapsulated in the lungs and the shedding of eggs into the bronchial tree are responsible for chronic symptoms. Patients complain of cough, rusty or golden sputum, hemoptysis, vague chest pains, and dyspnea on exertion. Radiographs of the chest show poorly defined infiltrates, cysts, nodules, cavities, calcified lesions, and pleural effusions that on aspiration are seen to contain eosinophils. The findings may suggest tuberculosis. Bronchiectasis, bacterial pneumonia, or empyema complicates heavy infections. Extrapulmonary migration of flukes causes migratory subcutaneous nodules, involvement of abdominal viscera, or focal lesions of the central nervous system. Cerebral paragonimiasis is characterized by headache, seizures, focal neurologic deficits, cerebrospinal fluid eosinophilia, and cystic lesions on radiographs and scans.

Paragonimiasis is diagnosed by identifying expectorated eggs in the sputum, swallowed eggs in the feces, or worms and eggs in biopsy specimens (Figure 196.4). Several examinations of stool and sputum may be necessary. Serologic tests, such as the immunoblot offered by the CDC, are useful for diagnosis of early, light, and extrapulmonary infections.

The treatment of choice for paragonimiasis is praziquantel or alternatively, triclabendazole (Table 196.2). Because the inflammatory reaction to dying worms may precipitate seizures or other neurologic complications, corticosteroids should be used simultaneously with praziquantel for cerebral paragonimiasis.

Intestinal fluke infections

Adult intestinal flukes live attached to the mucosa of the duodenum and jejunum, where they cause local inflammation and ulceration. Of the dozens of species that infect human beings, *Fasciolopsis buski*, the giant intestinal fluke, is the best known. Infection is acquired by eating uncooked aquatic plants, such as water caltrop, water chestnut, and watercress. Heavily infected persons develop hunger pains that suggest peptic ulcer, diarrhea with mucus, and in extreme cases, malabsorption, ascites, anasarca, and intestinal obstruction. Eosinophilia is common.

Other important intestinal flukes include *Heterophyes heterophyes* and *Metagonimus yokogawai*, both of which are acquired by ingestion of raw or undercooked freshwater fish. Symptoms caused by these parasites resemble those produced by *Fasciolopsis*,

but embolization of eggs that enter the circulation may cause severe myocarditis or cerebral hemorrhage. *Nanophyetus salmincola* is transmitted in the Northwest United States by ingestion of raw or undercooked salmon or trout. Manifestations include abdominal pain, watery diarrhea, and eosinophilia.

The diagnosis of all intestinal fluke infections is made by demonstrating eggs in the feces. Because the number of eggs excreted may be low, concentration techniques and repeated examinations are recommended. Praziquantel is the drug of choice (Table 196.2). Alternatives include triclabendazole and, for *Fasciolopsis* and *Heterophyes* infections, niclosamide.

Tapeworms (cestodes)

Zbigniew S. Pawlowski

Cestodes cause intestinal (e.g., taeniasis, hymenolepiasis) and/or tissue parasitoses (e.g., cysticercosis, echinococcosis). Most of intestinal tapeworm infections are meat-borne zoonoses, whereas tissue infections with larval cestodes are fecal-borne, acquired mainly through ingestion of the tapeworm eggs from human, dog, or fox feces.

Taenia saginata and *taenia asiatica* taeniasis

Taenia saginata, the beef tapeworm, sometimes >5m long, may live up to 30 years in the small intestine of humans, who are its only natural host. Humans are infected by ingestion of the cysticercus, a bladder worm <1 cm in diameter, present in raw or undercooked beef.

Taenia saginata infections can spread easily because of a high fecundity of the tapeworm (>500 000 eggs produced daily for years), wide and long-term contamination of the environment with eggs, bovine cysticercosis that may escape routine meat inspection when of a low intensity, and, finally, common consumption of raw beef. More than 10% of nomads are infected in East Africa; in Europe the annual incidence in urban populations is <0.1%; in the United States and Canada, *T. saginata* taeniasis is uncommon and observed mainly among migrants from Latin America.

Taenia saginata infection occurs mainly in well-nourished middle-aged individuals who are raw beef eaters. Complaints include vague abdominal pains, nausea, weight loss or gain, and some perianal discomfort caused by gravid proglottids (about six per day) crawling actively out of the anus. Sometimes, the patient passes a longer part of tapeworm strobila; in that case the expulsion of proglottids may stop for some weeks. The diagnosis is set up by questioning and macroscopic examination of expulsed tapeworm proglottids. *Taenia* eggs are found more often on anal swabs than in feces. Tests detecting parasite antigen in feces are highly sensitive and specific and may detect the infections even when proglottids or eggs are not expelled.

Treatment of *T. saginata* taeniasis with praziquantel or niclosamide is safe and effective in 95% and 80% of cases, respectively. Praziquantel is given orally in a single dose of 5 to 10 mg/kg an hour after a light breakfast. Niclosamide is preferred for children younger than 4 years and for pregnant women. Niclosamide (use only the original products, recently manufactured) should be chewed thoroughly on an empty stomach in a single dose of 2 g for adults, 1 g for children who weigh 10 to 35 kg, and 0.5 g for smaller children. For both drugs adverse effects, such as abdominal discomfort, headache, and dizziness, are rare and transient. Tapeworm is usually expelled in fragments within a few hours; the scolex, indicating elimination of the entire worm, is often difficult to find. Therefore, successful therapy can be confirmed only when no proglottids reappear within 4 months after treatment.

Taenia asiatica, described recently in several Asian countries, is a sister species of *T. saginata*, similar morphologically but a distinct species when examined by molecular techniques. Its life cycle is different; small cysticerci develop in liver and viscera of pigs and a range of wild animals. Humans become infected by eating raw viscera, especially liver, of the infected animals. The diagnosis and treatment are similar to *T. saginata*. *Taenia asiatica* and *T. saginata* do not produce cysticercosis in humans.

Taenia solium taeniasis and cysticercosis

Taenia solium (pork tapeworm) infection is common in Latin American countries, Central and South Africa, India, Indonesia, and China. Intestinal infection is acquired by eating undercooked pork containing cysticerci. Cysticercosis, a cystic larval form developing in the tissues, is acquired by ingesting *T. solium* eggs present in contaminated food or water or on hands spoiled with feces (autoinfections or family infections are not uncommon). Human cysticercosis may be common in endemic countries; sporadic cases of cysticercosis are diagnosed in humans in the United States and in Europe, having been acquired abroad or from immigrants infected with *T. solium* tapeworm.

The pork tapeworm is smaller than *T. saginata*, and its proglottids are usually expelled with feces, starting 2 months after ingestion of infected pork. Clinical symptoms and signs of taeniasis are not characteristic and are similar to *T. saginata* infection. The diagnosis is made by examination of the expelled proglottids or detecting the specific coproantigens. Finding *Taenia* eggs in feces can only confirm the diagnosis of taeniasis (*T. solium* eggs are morphologically indistinguishable from those of *T. saginata*). Proglottids and feces should be handled with care because *T. solium* eggs are infective for humans.

Treatment of *T. solium* taeniasis is mandatory as soon as possible, in both confirmed and suspected cases, due to a danger of spreading eggs causing cysticercosis in humans or pigs. Treatment of intestinal infection is the same as for *T. saginata* taeniasis; rarely, praziquantel may provoke symptoms in concomitant asymptomatic cysticercosis. Evaluation of treatment is by frequent fecal examination for *Taenia* eggs or coproantigens during the second and third months after anthelmintic therapy.

In cysticercosis, *T. solium* cysticerci may be localized in muscle and subcutaneous tissues (Figure 197.1A) without much symptomatology; the clinically important are mainly the cases of neurocysticercosis, ocular cysticercosis, and heart cysticercosis. Neurocysticercosis is suspected when epileptiform seizures (70% to 90% of cases), intracranial hypertension, or psychiatric disturbances occur, especially in adolescents or adults in endemic areas or having contact with a *T. solium* carrier (household infection is common). The most malignant forms of cysticercosis are at ventricular and basal cisternal parasite localizations. If subcutaneous nodules are present (which is uncommon, except in India), the final diagnosis

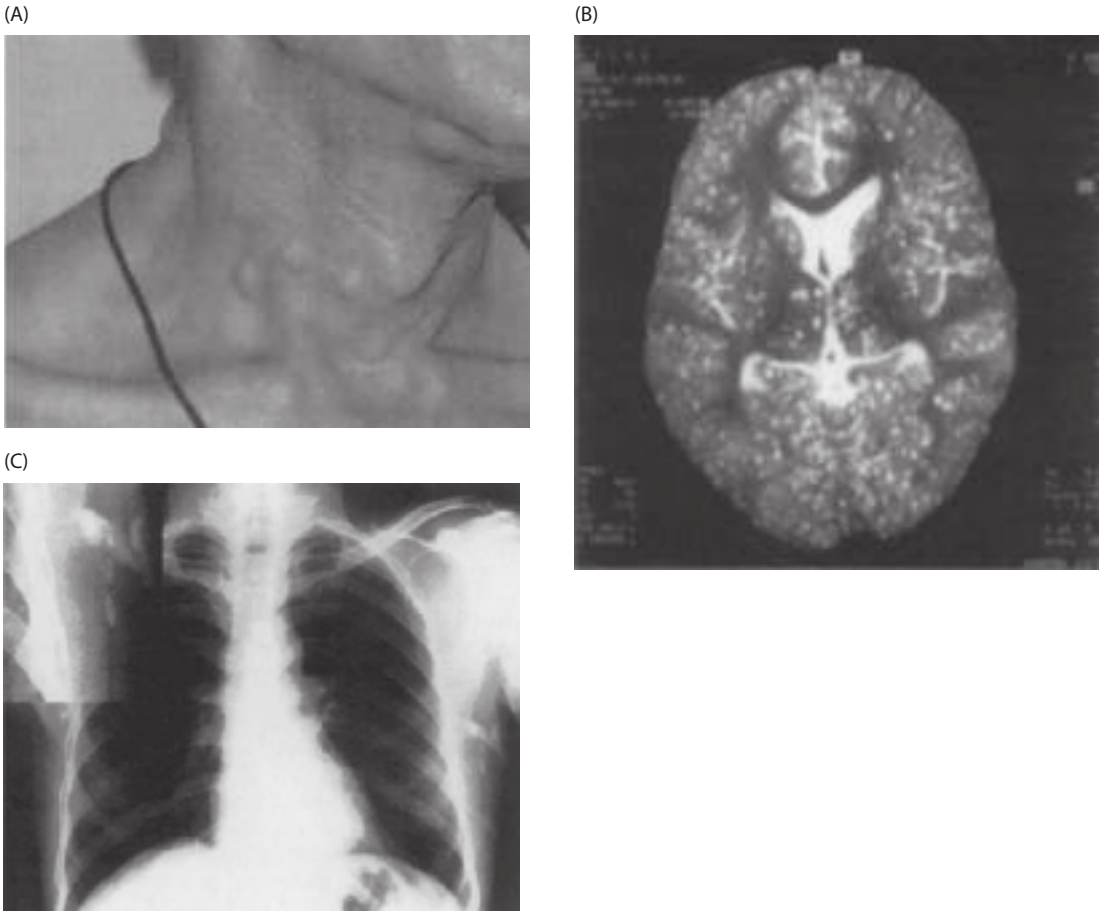

FIGURE 197.1 Cysticerci in subcutaneous location (A), on brain computed tomography (CT) showing innumerable cysticerci (starry-night appearance) (B), and calcifications in soft tissues (C). (Courtesy of Dr. S. K. Gaekwed.)

Bradley's *Neurology in Clinical Practice*, 4th edn. Butterworth-Heinemann; 2004.

can be made by biopsy demonstrating a scolex or typical structures of cysticercus wall. Most often, cysticerci are diagnosed by finding cysticercus-like structure(s) in the brain, spine, eye, or heart by computed axial tomography (CAT) or magnetic resonance imaging (MRI) scans (Figure 197.1B). In some cases the inflammatory reaction or edema and ventricular dilatation are present. In ocular cysticercosis the diagnosis can be made by ophthalmoscopy. Less often cysticercosis is suspected on the basis of ultrasound scanning and/or x-ray examination, particularly if calcifications are present (Figure 197.1C). Positive serologic tests, especially enzyme immunoassay (EIA) and enzyme-linked immunoelectrontransfer blot (EITB) assays, support the clinical diagnosis but cannot differentiate between active and past infections.

Neurocysticercosis is often asymptomatic; in such cases, indications for treatment must be considered carefully. Symptomatic cases can be active or inactive (calcified). Therapy can be via specific anthelmintic treatment, surgery, corticosteroids, or symptomatic treatment. The choice of treatment has to be individually tailored. Anthelmintic therapy with praziquantel or albendazole is indicated in active cysticercosis with several parenchymal cysts or with clinical signs of vasculitis, encephalitis, and arachnoiditis. Traditionally, praziquantel is given orally in a daily dose of 50 mg/kg for 14 days, but a shorter regimen with a higher dose has been proposed. Albendazole is given orally in a daily dose of 15 mg/kg for 8 days. For parenchymal brain cysticerci, the efficacy is about 60% for praziquantel and 85% for albendazole. Damage to cysticerci, caused by both drugs, may result in a local inflammatory reaction and edema, which necessitates a concomitant additional corticosteroid or antihistamine drug therapy.

Surgical extirpation is indicated for single parenchymal, intraventricular, spinal, and ocular cysticerci and with focal symptoms (e.g., cranial nerve dysfunction). A ventricular shunt is indicated in hydrocephalus. Corticosteroids and immunosuppressants may control vasculitis and encephalitis. Antiepileptic drugs are used mainly in inactive cysticercosis with granulomatous or calcified lesions. The global disability and mortality from neurocysticercosis are still considerable but its control measures are introduced only locally.

Hymenolepis nana infections

Hymenolepis nana, the dwarf tapeworm, 15 to 40 mm long, lives only up to 3 months in human small intestine. Some of the tapeworm eggs are expelled with feces and constitute a source of autoinfection or infection for other people. The other eggs hatch in the human intestine and develop within a month into cysticercoids in intestinal villi and later into the next generation of adult tapeworms in the same host.

Such a cycle facilitates spread of infection in close communities (day-care centers, schools, psychiatric institutions) as well as permits intensive infections of thousands of tapeworms, especially in malnourished or immunodeficient individuals. Usually a specific immunity develops and regulates the intensity and duration of infection, which occurs mainly in children and often clears spontaneously in adolescence. Hymenolepiasis is very common in regions with a hot, dry climate; it is rare in countries with appropriate sanitation.

Intensive infections may cause diarrhea, abdominal pains, and general symptoms such as weight loss, pallor, and weakness. Diagnosis is made by finding characteristic *H. nana* eggs in feces. Treatment with a single dose of praziquantel, 15 to 25 mg/kg, is highly effective; in intensive infections treatment must be repeated after 3 weeks. Niclosamide is much less effective and requires repeated courses of 7 days with the daily dose of 2 g for adult patients. Successful treatment has to be confirmed by negative fecal examination every 2 weeks for 2 months after therapy.

Other intestinal cestodes

Diphyllobothriasis, caused by *Diphyllobothrium latum*, *Diphyllobothrium dendriticum*, and *Diphyllobothrium pacificum*, still occurs around unpolluted large lakes in moderate climates (the Great Lakes in the United States and Canada and lakes in Finland and Switzerland) and along the Pacific Coast in South America. An uncommon clinical complication of diphyllobothriasis is vitamin B_{12} deficiency. Diagnosis is made by finding characteristic eggs during fecal examination. Treatment is a single dose of praziquantel, 15 to 25 mg/kg. Evaluation of successful therapy is by repeated fecal examination some months after.

Hymenolepis diminuta (rat tapeworm) and *Dipylidium caninum* (dog tapeworm) infections occur accidentally in humans and are usually nonintensive and asymptomatic. They are diagnosed by fecal examination and can be easily treated by a single dose of praziquantel, 15 mg/kg.

Spirometra spp., a tapeworm parasitizing a broad spectrum of amphibian hosts, reptiles, birds, and mammals, occur sporadically but worldwide. It causes sparganosis, larval worm infection, mainly in the subcutaneous tissue or in an orbit.

Cystic echinococcosis (hydatid disease)

Echinococcus granulosus is a tiny tapeworm living in the small intestine of some carnivores, mainly dogs. *Echinococcus granulosus* eggs, which are excreted in dog feces and contaminate an environment, are the source of cystic echinococcosis in various animals, mainly sheep or pigs, and sporadically in humans. Echinococcosis is still common in sheep-breeding regions in South America, Mediterranean countries, Middle East, Central Asia, and China. Small enzoonotic foci are found in Alaska, California, southern Utah, northern Arizona, and New Mexico. In Europe, sporadic cases of cystic echinococcosis are frequently caused by an *E. granulosus* strain, originating from pigs.

Echinococcus cysts develop mainly in the liver (about 65%) or lungs (25%), but they can invade any tissue, including the brain, kidney, spleen, heart, and bone. Clinical manifestations are diverse, depending on location, size, and number of the cysts as well as the complications resulting from cyst rupture and communication with biliary or bronchial systems or with adjacent body cavities. Bacterial

infection of the cysts and secondary peritoneal echinococcosis are not uncommon. Clinical diagnosis is confirmed mainly by imaging techniques (sonography, CT, MRI, positron emission tomography [PET], and/or x-ray examination. Classification of cystic echinococcosis in sonography is based on cyst morphology, considering also fertility and the content of the cyst; one can differentiate a cystic lesion (CL) stage, similarly to nonparasitic cysts, and C1 to C5 stages from young active cysts to old inactive cysts. Diagnosis can be confirmed by the serologic tests (sensitive enzyme-linked immunosorbent assay [ELISA], followed by more specific immunodiffusion or immunoblot tests). In some cases the clinical picture, imaging, and serology are not conclusive, and the final diagnosis is made by finding parasite hooks, protoscolices, or cyst wall fragments in sputum or in biopsy, surgical, or necropsy samples. In some specialized centers, cyst puncture with a fine needle guided by sonography and performed under the cover of albendazole is becoming widely used. Most commonly the differential diagnosis considers liver simple nonparasitic cysts.

The echinococcus cysts may be sterile or fertile (with protoscolices), simple or multiple, small or large (up to 20 cm in diameter), asymptomatic or symptomatic, active or inactive, complicated or noncomplicated. The choices of management are surgery, chemotherapy, PAIR (puncture, aspiration, injection of a cysticidal substance, and reaspiration), or observation without any intervention. Major indications for surgery are large, active, superficially located, and easy-to-rupture liver cysts and most of the brain, spinal, heart, and bone cysts. Surgery can be radical (removal of the whole intact cyst) or conservative (cystectomy and removal of the parasite but not the host pericyst). Surgery brings a risk of complications, such as anaphylactic shock or secondary echinococcosis and death (0.5% to 4%).

Chemotherapy is used more widely, mainly but not exclusively in inoperable cases. An important indication for chemotherapy before surgery or a puncture is prevention of secondary echinococcosis due to unintentional spillage of a cyst's contents. The drugs used are mebendazole, 40 to 50 mg/kg daily for at least 3 months, or albendazole, 10 to 15 mg/kg daily for at least 1 month. Sometimes repeated courses of treatment are necessary. Chemotherapy with both drugs brings a risk of embryotoxicity in early pregnancy. Careful clinical monitoring can prevent hepatotoxicity, neutropenia, and thrombocytopenia but not alopecia, which may occur.

PAIR is used in endemic regions with poor healthcare facilities. Unfortunately, no protoscolicide is both effective and safe; widely used now are 75% to 95% ethanol, 20% hypertonic sodium chloride solution, and 0.5% cetrimide. Formalin solution should no longer be used, as it can provoke sclerotic cholangitis.

Alveolar and polycystic echinococcosis

Echinococcus multilocularis tapeworms develop in the intestine of some carnivores, mainly foxes, but also dogs; the intermediate hosts are rodents such as voles, lemurs, and mice. Large natural enzoonotic foci of alveolar echinococcosis are in the Northern Hemisphere, especially the region of the Alps (France, Switzerland, Germany, Austria), Siberia, northern Japan, and Alaska. Humans are infected accidentally by *E. multilocularis* eggs present in fecally polluted natural environments (water, soil, berries) or on fox's skin or dog's hair.

Incidence of human alveolar echinococcosis varies between 0.02 and 0.18 per 100 000 inhabitants. However, a spread of *E. multilocularis* is observed in Europe westward (France), eastwards (Poland and Lithuania), northwards (Norway and Sweden), and southwards (northern Italy). In addition to its natural foci it spreads, together with foxes, in some urbanized areas.

Echinococcus multilocularis lesions, composed of clusters of tiny vesicles, usually begin in the liver, grow slowly over the years in a tumorlike pattern, and may metastasize to lungs and brain. Modern (PNM) classification of alveolar echinococcosis lesions in liver is based on the size of parasitic mass, involvement of the neighboring tissues, and distant metastases. The early clinical manifestations are usually vague; the advanced disease is invariably symptomatic due to liver lesions or lung or brain metastases. Diagnosis is based on imaging techniques and molecular and immunologic tests; the latter (e.g., Em2G11) are highly specific. The differential diagnosis is mainly with neoplasma conditions. Treatment is by radical surgical resection of liver lesions followed by at least 2 years of chemotherapy. Recurrent or nonresectable lesions require lifelong chemotherapy with mebendazole or albendazole, which are parasitostatic rather than parasitocidal. Nitrazoxanide and amphotericin B are now suggested as potential alternative additional or combined drugs. The treatment has to be performed in specialized centers because of various and frequently severe complications, which may need another surgery or in rare cases a liver transplantation.

Polycystic echinococcosis occurs in humans in Central and South America and is caused by *Echinococcus vogeli* and *Echinococcus oligartrus*, the parasites of wild mammals. The numerous small cystic lesions can be found in the liver, lungs, abdominal cavity, stomach, heart, and orbit. The clinical course is similar to alveolar echinococcosis. Polycystic echinococcosis frequently requires surgery and responds well to albendazole.

Toxoplasma

Roderick Go and Benjamin J. Luft

Toxoplasmosis, caused by the obligate intracellular parasite *Toxoplasma gondii,* is responsible for significant morbidity and mortality throughout the world. Although it has long been recognized as a serious congenital disease, it is only with the advent of acquired immunodeficiency syndrome (AIDS) and the increased use of immunosuppressive therapy that toxoplasmosis has reached epidemic proportions.

Humans are incidental hosts in the life cycle of *T. gondii*. Acute infection occurs via ingestion of meats or water contaminated with tissue cysts or tachyzoites or by handling cats, the definitive host. Once the human host develops an adequate immune response, tissue cysts are formed and a chronic or latent infection ensues. Antibodies against *T. gondii* will be present in serum for life. When a chronically infected person becomes immunocompromised, particularly with defects in cell-mediated immunity, devastating reactivation of the latent infection may occur.

Clinical manifestations and diagnosis

In the immunocompetent host, primary infection is often asymptomatic. Acute infection can mimic the symptoms of mononucleosis with a common manifestation of cervical or occipital lymphadenopathy. The lymph nodes usually are nontender, are nonsuppurative, and persist for less than 4 to 6 weeks. Infrequently, toxoplasmosis can lead to myocarditis, hepatitis, polymyositis, pneumonitis, and encephalitis.

Toxoplasmosis in the immunocompromised patient is most commonly manifested by toxoplasmic encephalitis (TE), usually alone but sometimes as part of a multiorgan infection. Isolated organ involvement without central nervous system (CNS) disease is uncommon. In the AIDS patient, TE usually develops when the CD4 lymphocyte count falls below 100/mm^3, although the risk of developing overt infection begins when CD4 counts fall below 200/mm^3. The clinical manifestations of TE are protean, including signs and symptoms of focal or generalized neurologic dysfunction or more commonly both, depending on the number, size, and location of the lesions. Cerebral edema, vasculitis, and hemorrhage, which can accompany active infection, also contribute to the disease process. Toxoplasmic encephalitis most commonly presents with a subacute onset of focal neurologic deficits with or without evidence of generalized cerebral dysfunction. Less often, seizures are the initial manifestation. Occasionally, signs and symptoms of generalized cerebral dysfunction dominate the presentation, and patients develop focal deficits as the infection progresses. The clinical presentation varies from an insidious process evolving over several weeks to a more acute or even fulminant course. Headaches may be focal or generalized and unremitting.

Serologic tests for diagnosis of toxoplasmosis in AIDS patients are useful only to identify human immunodeficiency virus (HIV)-infected individuals at risk for development of TE and as support for the diagnosis in AIDS patients with focal brain lesions. The Sabin–Feldman dye test is the accepted standard for measurement of immunoglobulin G (IgG) antibodies, which have been shown to be higher in AIDS patients with TE than in those without TE. The immunofluorescence assay (IFA), which is more commonly used, measures the same IgG antibodies as the dye test. Almost all AIDS patients with TE have detectable IgG. The absence of these antibodies strongly suggests another cause of the neurologic signs and symptoms.

The standard of care allows for the treatment of TE to be initiated on presumptive diagnosis when a typical neuroradiographic abnormality is noted on computed tomography (CT) or magnetic resonance imaging (MRI). MRI is more sensitive than CT in the demonstration of focal CNS lesions. The clinical diagnosis is a result of clinical and radiographic response to specific therapy because patients may have similar symptoms resulting from lesions of other causes, such as CNS lymphoma, progressive multifocal leukoencephalopathy, brain abscess, and focal lesions caused by other organisms, including *Cryptococcus neoformans, Aspergillus* spp., *Mycobacterium tuberculosis,* and *Nocardia* spp. The practice of presumptive therapy for patients who have not been receiving effective prophylaxis for *Toxoplasma* with a characteristic finding on CT or MRI and positive serology for *Toxoplasma* is widely accepted. With the use of these criteria, the predictive value has been estimated at 80%. However, for patients such as intravenous drug abusers in whom other CNS processes are more prevalent, the predictive value of a positive serology for *Toxoplasma* is reduced, and the widespread use of prophylaxis may further reduce it. Toxoplasmic encephalitis is predominantly intra-axial, so significant meningeal involvement is uncommon. Examination of cerebrospinal fluid (CSF) is used to exclude other diseases. Detection of *T. gondii* DNA by polymerase chain reaction (PCR) in CSF has demonstrated high specificity but variable sensitivity in establishing the diagnosis of TE in AIDS patients with focal lesions.

The lungs are the second most common site of infection in AIDS patients and in recipients of bone marrow transplants. The clinical manifestations of toxoplasma pneumonia are nonspecific, similar to those seen with *Pneumocystis jirovecii* (*carinii*) pneumonia (PCP). Most patients have fever, a nonproductive cough, dyspnea, and occasionally hemoptysis. However, the onset of disease tends to be faster than with PCP. The chest roentgenogram typically reveals bilateral interstitial infiltrates, although multiple nodular infiltrates, single nodules, isolated cavitary disease, lobar infiltrates, pleural effusions, and hilar adenopathy may occur. Pneumothorax complicating toxoplasmic pneumonia has been reported, as well as acute respiratory distress syndrome (ARDS). The diagnosis relies on a high index of suspicion and the demonstration of *T. gondii* from bronchoalveolar lavage (BAL) fluid or biopsy specimens, given the nonspecific nature of both clinical and radiologic manifestations in most cases.

Ocular toxoplasmosis is the most common retinal infection in the United States and is the second most common retinal infection in patients with AIDS after cytomegalovirus (CMV) retinitis. Patients usually present with decreased visual acuity and, less often, eye pain. Ocular toxoplasmosis may be the sole manifestation of infection or may accompany TE or disseminated disease. At times, in the immunocompromised host, ocular toxoplasmosis is a harbinger of TE. A CT scan of the head should be obtained to assess presence of concomitant TE. Fundoscopic findings are consistent with a necrotizing chorioretinitis. The lesions, which may be single or multiple and bilateral and are usually nonhemorrhagic, are yellow-white areas of retinal necrosis with ill-defined fluffy borders. They occur at the posterior pole and may be associated with a moderate to severe inflammatory response in the vitreous and anterior chamber. These characteristics help in the differential diagnosis with CMV retinitis. Fluorescein angiography may also be helpful. Dye leakage tends to occur along the edge of the lesions in toxoplasmosis and to be more prominent in the center of lesions in CMV retinitis. Ocular toxoplasmosis should be suspected in the AIDS patient who is seropositive for *T. gondii* and has changes in visual acuity with accompanying fundoscopic changes. A prompt response to specific therapy should also be expected. Definitive diagnosis has been made by demonstrating the organism in retinal biopsy specimens or isolation of *T. gondii* from vitreal fluid or PCR.

Therapy

Immunocompetent host

Most infections in immunocompetent hosts are asymptomatic and do not require therapy. Lymphadenopathy, the most common manifestation, is self-limited and usually resolves within 1 to 3 weeks. Treatment should be considered only if systemic symptoms are severe or long lasting or in the rare event of visceral involvement (encephalitis, myocarditis, pneumonitis). Acute infection as a result of laboratory accidents or transfusions may be severe and should be treated. The treatment regimen of choice consists of a combination of pyrimethamine (Daraprim) and sulfadiazine given for 2 to 4 weeks with folinic acid (leucovorin) (Table 198.1). In the event of pyrimethamine-induced hematologic toxicity, the dosage of folinic acid can be increased to 20 to 50 mg/day. For patients allergic to sulfa, clindamycin in combination with pyrimethamine and folinic acid has been used successfully (see Table 198.1).

For ocular toxoplasmosis, the drugs of choice are pyrimethamine and sulfadiazine or trisulfapyrimidine with folinic acid in the same dosages as described earlier. Therapy is given for 4 weeks and repeated as needed. Treatment is required to prevent relapse with the risk of progressive vision loss and other complications such as glaucoma. Adjunctive therapy with systemic corticosteroids (prednisone, 80 to 120 mg/day, or an equivalent) is indicated if the macula, optic nerve, or papillomacular bundle is involved.

Immunocompromised host

For TE, the combination of pyrimethamine, 200 mg loading dose in two divided doses followed by 50 to 75 mg/day orally, plus sulfadiazine, 4 to 6 g/day orally in four doses, remains the mainstay of treatment (see Table 198.1). Oral folinic acid is added to preclude the hematologic toxicities associated with antifolate agents. Acute therapy is recommended for at least 6 weeks. Longer treatment durations may be needed if there is extensive clinical and radiographic disease or the response is incomplete at 6 weeks. Patients who cannot tolerate sulfas can be given clindamycin in combination with pyrimethamine as described. Prophylactic use of anticonvulsants is not recommended. Corticosteroids should not be used routinely but are indicated if there is evidence of increased intracranial pressure. In one study, 70% of AIDS patients treated for TE had a quantifiable

TABLE 198.1 **DRUGS FOR TREATMENT OF TOXOPLASMIC ENCEPHALITIS AND EXTRANEURAL TOXOPLASMOSIS**

Antimicrobial	Mode of action	Metabolism	Adverse effects	Recommended dosage (immunocompromised)	Recommended dosage (immunocompetent)
Pyrimethamine (Daraprim) oral	Inhibits folic acid synthesis	Readily absorbed by gut; hepatic metabolism, lipid soluble	Cytopenias, rash, GI intolerance	Acute: loading dose 200 mg then 50–75 mg daily; with oral folinic acid (leucovorin) 10–20 mg/d Maintenance: 25–50 mg/day with oral folinic acid 10–25 mg/d	Loading dose 200 mg daily for 2 d, then 50–75 mg daily for 2–4 wk; with oral folinic acid 10–20 mg/d
plus					
Sulfadiazine[a] oral	Inhibits folic acid synthesis; acts synergistically and sequentially with pyrimethamine	Readily absorbed by the gut; penetrates blood–brain barrier; some hepatic metabolism	GI intolerance, rash (Stevens–Johnson syndrome), cytopenias, nephrolithiasis, crystalluria, interstitial nephritis, encephalopathy	Acute: 1–1.5 g q6h Maintenance: 500–1000 mg/day QID	1–1.5 g q6h, 2–4 wk
or					
Clindamycin[a] oral and IV	Unknown; possibly inhibition of plastid and/or mitochondrial protein synthesis	Readily absorbed by gut; excellent tissue penetration	GI intolerance, rash, pseudomembranous colitis	Acute: 600 mg q6h (up to IV 1200 mg q6h) Maintenance: 300–450 mg PO q6–8h	300 mg q6h, 4 wk, repeat as needed

Abbreviation: GI = gastrointestinal.
[a] Used in combination with pyrimethamine.
Adapted from Mofenson et al. *MMWR Recomm Rep*. 2004;53(RR–14):1.

clinical improvement by day 7 of therapy. Conversely, patients not responding to empiric therapy had evidence of progressive disease within the first 10 days. Ninety percent of patients had improvement on neuroradiographic studies within 6 weeks of starting therapy.

In immunocompromised hosts, maintenance therapy (secondary prophylaxis) should be initiated. The regimen is usually the same as that used for primary treatment but at half dose. Maintenance therapy should be continued for the life of the patient or until the underlying immunosuppression has resolved. In patients with AIDS, secondary prophylaxis can be discontinued if they have sustained CD4 counts greater than 200 cells/mm^3 for longer than 6 months.

The same chemotherapeutic regimens are used for extraneural toxoplasmosis; however, there are limited data available on the optimal length and outcome of treatment. As a rule, ocular toxoplasmosis responds favorably to therapy, and treatment of pulmonary infection has been reported to be successful in 50% to 77% of patients.

Intravenous trimethoprim–sulfamethoxazole (TMP–SMX, Bactrim, Septra), at 5 mg/kg/day trimethoprim component, has been used when oral therapy is contraindicated. Although TMP–SMX is available for oral use, response rates have been lower than standard regimens. Recently, trials have shown higher initial response rates when the dose was increased (trimethoprim, 6.6 to 10 mg/kg body weight per day).

The drugs described thus far are active only against the tachyzoite form of *T. gondii*. Surviving tissue cysts can reinitiate TE and other manifestations of reactivated latent disease if treatment is discontinued. Therefore it is necessary to give long-term suppressive therapy. Pyrimethamine, 25 to 50 mg/day, and sulfadiazine, 2 to 4 g/day orally in four doses, with 10 mg/day of oral folinic acid is recommended because of the low relapse rate associated with this combination. Clindamycin is used in cases of sulfa allergy. Atovaquone monotherapy at 750 mg two to four times a day may be considered in patients who are unable to tolerate pyrimethamine; however, this regimen has a 1-year relapse rate of 26%.

Primary chemoprophylaxis is a very attractive therapeutic option for patients known to be at risk for toxoplasmosis (i.e., those with CD4 counts less than 100 cells/mm^3 and seropositive for anti-*T. gondii* antibodies). Retrospective data suggest that TMP–SMX, one double-strength tablet per day orally, is efficacious. Neither dapsone nor pyrimethamine, when used as a single agent, is consistently effective. However, the combination of pyrimethamine, 50 mg/week, plus dapsone, 50 mg/day, plus folinic acid has been a useful alternative. In patients with a sulfa allergy, desensitization is also an option. Primary prophylaxis can be safely discontinued when the patient has sustained immune reconstitution with a CD4 count greater than 200 cells/mm^3 for 3 months.

Other drug regimens that have proven useful as initial and maintenance therapy (Table 198.2) include atovaquone (Mepron). An AIDS Clinical Trials Group (ACTG) trial evaluating the efficacy of atovaquone-containing regimens (either in combination with pyrimethamine or sulfadiazine) showed encouraging results, with 77% response to therapy. As salvage therapy, atovaquone alone induced initial clinical response in 50% of study patients. The response to

TABLE 198.2 **ALTERNATIVE TREATMENTS OF TOXOPLASMOSIS IN IMMUNOCOMPROMISED PATIENTS**

Antimicrobial	Mode of action	Metabolism	Adverse effects	Recommended dosages
Atovaquone (Mepron)[a] oral	Uncoupling electron biosynthesis; inhibition of de novo pyrimidine biosynthesis	Suspension has better bioavailability than old tablet formulation; improved absorption if taken with food, particularly fatty foods	Rash, elevated liver function tests	Acute: suspension 1500 mg q12h Maintenance: suspension 750 mg q6–12h
Azithromycin (Zithromax)[a] oral	Unknown; possibly inhibition of plastid and/or mitochondrial protein synthesis	Readily absorbed by gut; high intracellular levels	GI intolerance	Acute: 900–1200 mg/d Maintenance: same
Trimethoprim–sulfamethoxazole (TMP–SMX)[b] (Bactrim, Septra) oral or IV	Inhibits folic acid synthesis	Renal metabolism	Rash, Stevens–Johnson syndrome, bone marrow suppression, hepatotoxicity, increased serum creatinine	Acute: 5 mg/kg TMP and 25 mg/kg SMX IV or oral BID

Abbreviations: GI = gastrointestinal.

[b] Used in combination with pyrimethamine.

therapy with atovaquone has been directly correlated with serum drug levels achieved. The macrolide antibiotics azithromycin (Zithromax) and clarithromycin (Biaxin) in combination with pyrimethamine have limited utility as alternative agents.

Pregnancy

Women who acquire toxoplasmosis (primary infection) during pregnancy expose their fetuses to risk of infection. Infection of the fetus may result in stillbirth, spontaneous abortion, or birth of a symptomatic or an asymptomatic infant. Rarely, transmission has been reported in cases where the mother contracts acute toxoplasmosis 6 to 8 weeks before conception. Fetal infection is less common when the mother is treated during pregnancy. Early diagnosis, through serology, amniotic sampling for PCR, and fetal ultrasonography, is important in further management (antibiotics or therapeutic abortion).

Pyrimethamine plus a sulfonamide or spiramycin, a macrolide antibiotic available in western Europe, Mexico, and Canada and through the Food and Drug Administration of the United States, appears to decrease the incidence of congenital toxoplasmic infection when given to women who acquire *T. gondii* during pregnancy (Table 198.3). Pyrimethamine is teratogenic and should

TABLE 198.3 **DRUGS USED IN TREATMENT OF TOXOPLASMOSIS IN PREGNANT WOMEN**

In pregnant women infected during gestation	Medication	Dosage	Duration of therapy
First 18 wk of gestation or until term if fetus found not to be infected by amniocentesis at 18 wk	Spiramycin[a]	1 g every 8 h without food	Until fetal infection is documented or until it is excluded at 18 wk of gestation
If fetal infection confirmed, after wk 18 of gestation and in all women infected after wk 18	Pyrimethamine[b] plus	Loading dose: 50 mg each 12 h for 2 d; then beginning on day 3, 50 mg/d	Until term
	Sulfadiazine plus	Loading dose: 75 mg/kg; then beginning 50 mg/kg each 12 h (maximum 4 g/d) 10–20 mg daily	Until term
	Leucovorin (folinic acid)		During and for 1 wk after pyrimethamine therapy

[a] Spiramycin is not commercially available. Available only on request from the US Food and Drug Administration (telephone number: 301–443–5680), and then with approval by physician's request to Sanofi–Aventis (908–231–3365).
[b] Adjusted for megaloblastic anemia, granulocytopenia, or thrombocytopenia.
From Remington JS, McLeod R, Thulliez P, Desmonts G. Toxoplasmosis. In: Remington JS, Klein JO, Wilson CB, Baker CJ, eds. *Infectious Diseases of the Fetus and Newborn Infant*, 6th edn. Philadelphia, PA: Elsevier; 2006.

not be used until after the first trimester. There is no optimal medical therapy in the United States for treatment of women who become infected during the first trimester. However, sulfadiazine or trisulfapyrimidines should be used during the first trimester because sulfonamides alone have been shown to be effective in acute toxoplasmosis in animal models. If spiramycin can be obtained, pregnant women acutely infected in the first trimester may be treated until term with 30 to 50 mg/kg/day in three doses until fetal infection is confirmed or excluded. Treatment with spiramycin alone decreases the incidence of transmission but not the severity of established congenital infection. As spiramycin does not readily cross the placenta, treatment should be switched to pyrimethamine, sulfadiazine, and folinic acid in pregnant women with confirmed or a high possibility of fetal infection after the 18th week of gestation. If maternal or fetal infection is suspected or confirmed after the first trimester, pyrimethamine and sulfadiazine plus folinic acid should be used for treatment.

Pregnant women or women who are trying to become pregnant should be advised about risk factors for primary infection with toxoplasmosis. Education has been shown to be effective in decreasing the seroconversion rate during pregnancy. Women with cats should have someone else changing the litter box daily. They should avoid consuming undercooked meats, raw eggs, unpasteurized milk, or unfiltered water. All uncooked fruits and vegetables should be washed. Gloves should be used if they are working with soil, if they are preparing raw meat, or if they must change the cat litter box themselves. Proper hand hygiene should be practiced after working with soil, after handling the cat or the litter box, or after touching raw or undercooked meat.

Malaria

Jessica K. Fairley and Henry M. Wu

Malaria remains a life-threatening parasitic infection endemic throughout much of the world. It is estimated that in 2018 there were 228 million infections worldwide and 405,000 deaths due to malaria, with the majority of deaths among African children. In nonendemic countries, it is one of the most common causes of fever in returned travelers and recent immigrants, and several thousand people with malaria arrive in nonendemic countries yearly.

Malaria is a mosquito-borne protozoal infection caused by one of four human *Plasmodium* species (*P. falciparum*, *P. vivax*, *P. ovale*, and *P. malariae*) or by the monkey parasite, *P. knowlesi*, which has been increasingly described in parts of Southeast Asia. Malaria-endemic countries are shown in Figure 199.1. Given the risk of rapid progression to severe disease in nonimmune individuals, a high index of suspicion is critical when evaluating patients with febrile illness following travel to malarious areas, especially those endemic for *P. falciparum*. Proper treatment of malaria requires knowledge of the infecting species and where it was acquired since drug resistance patterns vary geographically. Widespread chloroquine-resistant *P. falciparum* (CRPF) malaria and emergence of resistance to other drugs have complicated treatment and prophylaxis.

Clinical aspects

Fever in a patient who has recently traveled to an area endemic for malaria should be considered a medical emergency. The minimum incubation period is generally considered to be 7 days after inoculation, and of greatest concern is the patient who has traveled to a *P. falciparum* endemic area within 2 months of presentation since an incubation period of 2 to 4 weeks is typical for falciparum malaria. Presentation several months to 1 year after departing an endemic region is also possible, particularly when infected with *P. vivax* or *P. ovale,* since infection with these species can result in a dormant liver stage. Patients with falciparum malaria can also present months after exposure because the use of prophylaxis or presence of semi-immunity can modify or delay the onset. For these reasons, febrile patients who have traveled to a malarious region in the preceding year should be ruled out for malaria regardless of prophylaxis history.

Malaria transmission occurs when a malaria-infected female *Anopheles* mosquito inoculates sporozoites into a human host. Initially, infected persons are asymptomatic as the sporozoites enter the bloodstream and travel to the liver where maturation occurs in hepatocytes. Malaria symptoms begin when merozoite forms are released into the bloodstream and the erythrocytic stage begins. In this stage, merozoites infect erythrocytes and replicate within them, resulting in rupture and further merozoite release. Symptom severity typically depends on the percentage of erythrocytes infected and the presence or absence of partial immunity due to previous infection.

Initial symptoms are nonspecific and include fever, chills, malaise, anorexia, headaches, and myalgias. Cough, abdominal pain, and diarrhea may also be present. The illness may resemble numerous other febrile syndromes including enteric fever, dengue fever, influenza, meningitis, and septicemia, so a high index of suspicion for malaria is critical even when an alternate diagnosis appears more likely. Although regular

periodicity of fever is classically described, this is unlikely early in the disease course and may not be seen at all, particularly with falciparum malaria.

Severe falciparum malaria is a multi–organ system disease. Infected erythrocytes adhere to vascular endothelium cells, resulting in sequestration, circulatory obstruction, and inflammation in the affected organ. Complications include severe anemia, jaundice, thrombocytopenia, hypoglycemia, pulmonary edema, acute respiratory distress syndrome (ARDS), renal failure, and disseminated intravascular coagulation (DIC). Seizures, impaired consciousness, and coma may result from hypoglycemia or suggest the presence of cerebral malaria. Even with treatment, the case fatality rate of severe malaria is 15% to 20%. Lactic acidosis suggests a worse prognosis. Nonimmune pregnant woman are at higher risk for severe disease, as well as preterm birth and fetal loss. Among travel-associated cases in nonendemic countries, patients >65 years have the worst outcomes. Though *P. vivax* typically causes uncomplicated malaria, severe *P. vivax* malaria can occur. However, since severe disease is most associated with falciparum malaria and mixed infection with multiple species is possible, severe disease in a patient diagnosed with nonfalciparum malaria should raise the possibility of coexisting falciparum malaria.

P. vivax and *P. ovale* infections can also result in a dormant hypnozoite liver stage which requires special consideration for treatment and prophylaxis. Patients carrying hypnozoites are asymptomatic until the infection reactivates and results in a relapsed infection.

Diagnosis

Prompt and accurate diagnosis is critical in malaria management. The diagnostic gold standard is examination of Giemsa-stained thick and thin blood smears. Thick smears are highly sensitive and can detect parasites in patients with low parasitemia levels that might be missed in thin smears. However, thin smears are best for speciation, quantification of parasites (i.e., percent of erythrocytes parasitized), and assessment of treatment response. If the initial blood smears are negative, they should be repeated at 12- to 24-hour intervals for a total of three sets before considering the disease ruled out. When expertise to prepare or examine thick smears is not immediately available, thin blood smears alone are better than none at all since a negative thin smear suggests a high parasitemia infection is unlikely. Wright's stain, which is typically used in clinical laboratories for peripheral blood smears, is not optimal for blood parasites; however, it can be helpful when Giemsa staining is unavailable.

A number of rapid diagnostic tests (RDTs) are available for malaria diagnosis when blood smears are not readily available. These tests rely on the detection of *Plasmodium* spp. antigens, including histidine-rich protein 2 (HRP2) and parasite lactate dehydrogenase. These tests can be highly sensitive and specific for falciparum malaria. However, test performance can vary widely among different kits, and false results can occur if instructions on use and storage are not strictly followed. Nonetheless, RDTs can be important in situations where microscopy is not feasible or timely.

Therapy

The increasing prevalence of drug-resistant plasmodia has complicated malaria treatment. In addition to widespread CRPF, mefloquine-resistant *P. falciparum* is endemic in several Southeast Asian countries, and strains of *P. vivax* resistant to drugs including chloroquine and primaquine have emerged. In contrast, drug resistance has not been described in *P. ovale* or *P. malariae*. When species identification is uncertain in a patient with malaria, clinicians should treat for the worst-case scenario (i.e., infection caused by CRPF). Malaria acquired while taking prophylaxis should not be treated with the same medication used for prophylaxis. Recommended drug regimens for treatment in the United States are listed in Table 199.1. Since effective malaria therapy requires consideration of the infecting species and local resistance patterns, clinicians are strongly advised to review current recommendations and seek diagnostic assistance when needed. Suspected or confirmed malaria should always be treated with the assistance of an infectious diseases or tropical medicine specialist when available. Updated country guides and detailed US treatment

recommendations are available from the US Centers for Disease Control and Prevention (CDC), either online (www.cdc.gov/malaria/index.html) or by phone through the CDC Malaria Hotline (1-770-488-7788 or 1-855-856-4713 toll free, weekdays 9 AM–5 PM; or 1-770-488-7100 for emergency consultation after hours).

Plasmodium malariae, Plasmodium knowlesi, and uncomplicated chloroquine-sensitive *P. falciparum* malaria

Chloroquine-sensitive *P. falciparum* malaria is confined to Central America north of the Panama Canal, Haiti, and the Dominican Republic. Chloroquine or hydroxychloroquine should be used to treat *P. falciparum* from these areas, as well as *P. malariae* and *P. knowlesi* infections from any part of the world.

Uncomplicated chloroquine-resistant *P. falciparum* malaria

With the exception of the regions just mentioned, CRPF is widespread. Artemisinin-based combination therapies (ACTs) are rapidly becoming the treatment of choice for CRPF. Artemisinin and its derivatives are well tolerated and lead to a rapid reduction in parasitemia and fever. Since monotherapy is associated with a high rate of recrudescence, the addition of a second agent is necessary. ACTs currently recommended by the World Health Organization (WHO) include artemether-lumefantrine, artesunate-amodiaquine, artesunate plus mefloquine, artesunate plus sulfadoxine-pyrimethamine, and dihydroartemisinin-piperaquine. Artemether-lumefantrine is approved in the United States for the oral treatment of uncomplicated falciparum malaria. Atovaquone-proguanil is another recommended and well-tolerated oral regimen for uncomplicated falciparum malaria. These regimens are effective against multidrug-resistant falciparum malaria acquired in Southeast Asia.

When artemether-lumefantrine and atovaquone-proguanil are not available or are contraindicated, oral quinine sulfate in combination with tetracycline, doxycycline, or clindamycin is an effective regimen, though longer and less well tolerated. Clindamycin is usually reserved for pregnant women and for young children (those <8 years old) in whom tetracycline derivatives are generally avoided. Patients taking quinine typically experience cinchonism,

Clinical severity/species	Resistance	Recommended treatments for adults[1]	Recommended pediatric treatments[1]
Severe malaria (usually *P. falciparum*)	All resistance profiles	**Artesunate IV,** 1 dose = 2.4 mg/kg 3 doses at 0, 12, and 24 hours If parasitemia >1%, continue for up to 6 more days qday When parasitemia, ≤1%, give a complete oral regimen as described in oral therapy	

Readers are strongly recommended to visit www.cdc.gov/malaria/diagnosis_treatment/index.html for further details, updated recommendations, and recommendations for pregnant women.
[1] Malaria acquired while taking prophylaxis should not be treated with the same medication used for prophylaxis.
[2] Infection acquired in Southeast Asia should be treated for 7 days with quinine/quinidine, and infections acquired in Africa and South America should be treated with 3 days of quinine/quinidine.
[3] Doxycycline and tetracycline are not indicated for children <8 years old.
[4] Treatment with mefloquine is not recommended for infections acquired in Southeast Asia due to *P. falciparum* resistance in this region. Due to high rates of neuropsychiatric side effects at treatment doses, mefloquine is only recommended when other options (i.e., atovaquone/progruanil, artemether-lumefantrine, quinine-based regimens) cannot be used.
[5] G6PD deficiency and pregnancy must be ruled out prior to primaquine use to eradicate hypnozoites in *P. vivax* and *P. ovale* infections. Expert consultation is recommended in patients with G6PD deficiency or in pregnant patients.
[6] *P. vivax* acquired in Papua New Guinea or Indonesia should be considered as potentially chloroquine-resistant and treated with alternative regimens. See www.cdc.gov/malaria/diagnosis_treatment/index.html for recommendations.
Adapted from: Centers for Disease Control and Prevention, 2020.

the reversible symptom complex that includes tinnitus, dizziness, headache, nausea, visual disturbances, and hearing loss. These side effects usually do not necessitate drug change. If oral medication is not tolerated, parenteral treatment is necessary (see parenteral regimens discussed later for severe malaria).

Mefloquine is also effective therapy for uncomplicated CRPF malaria, but it is not recommended for patients who might have multidrug-resistant infections acquired in Southeast Asia, particularly along the Thai–Myanmar (Burma) or Thai–Cambodian borders. Furthermore, concern for significant side effects generally restrict its use and make it an alternative regimen for uncomplicated malaria. Severe neuropsychiatric adverse reactions (psychosis, convulsions) are more likely to occur when the drug is used at treatment doses compared to prophylaxis dosing. Due to the QTc prolonging effects of mefloquine, an alternative regimen should be used in patients with a history of arrhythmia or other risk factors for prolonged QTc including medications.

The use of pyrimethamine-sulfadoxine (Fansidar) is no longer recommended due to widespread resistance to this regimen. Although halofantrine is widely used in malaria endemic areas, the CDC recommends against its use due to the risk of potentially fatal cardiac adverse events.

Plasmodium vivax malaria

The erythrocytic stage of *P. vivax* malaria is effectively treated with chloroquine or hydroxychloroquine. Eradication of hepatic hypnozoites requires treatment with primaquine or the newer tafenoquine. Primaquine is a potent oxidizing agent; therefore, glucose-6-phosphate dehydrogenase (G6PD) deficiency must be ruled out before primaquine therapy is initiated to avoid severe hemolysis.

Chloroquine-resistant *P. vivax* malaria was first described on the island of New Guinea in 1989, with subsequent spread across Indonesia. Since then, there are sporadic reports of declining chloroquine efficacy elsewhere in Southeast Asia, Africa, and the Amazon Basin of South America. Malaria caused by chloroquine-resistant *P. vivax* should be suspected when the illness recurs within 28 days after a patient has received standard therapy with chloroquine and primaquine. Due to the risk of chloroquine resistance, *P. vivax* malaria originating from Indonesia or Papua New Guinea should be treated with alternative regimens (Table 199.1). Notably, a recent Cochrane review concluded that some ACTs are as effective as chloroquine in treating the blood stage *P. vivax* infection, suggesting a potential strategy for simplifying empiric treatment for all forms of uncomplicated malaria where *P. falciparum* and *P. vivax* coexist. Though somewhat controversial, primaquine-resistant *P. vivax* malaria has been reported from the island of New Guinea, other parts of Southeast Asia, Somalia, and Colombia. When a relapse of *P. vivax* occurs more than 28 days after treatment with chloroquine and primaquine, primaquine resistance should be considered.

A newer agent, tafenoquine, can also be used for prevention of relapse in place of primaquine. However, it should only be given following chloroquine or hydroxychloroquine treatment (as opposed to other blood-stage treatments) and to those aged ≥16. Like primaquine, tafenoquine should not be given to those with G6PD deficiency or pregnant women.

Plasmodium ovale malaria

Malaria caused by *P. ovale,* found mostly in Africa, is managed in the same way as chloroquine-sensitive *P. vivax*. No drug-resistant strains of *P. ovale* have been documented.

Severe *P. falciparum* malaria

Even with appropriate treatment, the mortality rate of severe falciparum malaria ranges from 15% to 20%. Management comprises four main areas: clinical assessment, specific antimalarial treatment, adjunctive therapy, and supportive care. Severe falciparum malaria is typically defined by the presence of parasitemia of ≥5% or signs of major organ failure. Signs of major organ failure may include

impaired consciousness/coma, severe anemia, renal failure, ARDS, hypotension, DIC, spontaneous bleeding, acidosis, hemoglobinuria, jaundice, and repeated seizures.

Patients with severe malaria require parenteral therapy with artesunate, which was Food and Drug Administration (FDA) approved for the treatment of severe malaria in the United States in 2020. Quinidine is no longer recommended or available in the United States. Intravenous artesunate is safe and effective treatment, and it is a WHO-preferred treatment for severe falciparum malaria. If artesunate is not available commercially at their hospital, clinicians should contact the CDC Malaria Hotline to obtain artesunate dispensed through the CDC within 24 hours. Artesunate regimens require the addition of a second drug, as outlined in Table 199.1. The CDC recommends bridging with oral therapy while waiting for artesunate.

Supportive care is critical for the effective management of severe malaria. Blood glucose must be monitored closely as hypoglycemia is a common complication, especially in pregnant women and children, and it can contribute to impaired consciousness and seizure activity. Fluid balance should be corrected judiciously with the aim of avoiding fluid overload that increases the risk of ARDS. Exchange transfusion has historically been used as an adjunctive treatment for severe malaria, but a 2013 CDC analysis did not show a survival benefit and it is no longer recommended. Other important supportive measures include mechanical ventilation for ARDS and hemodialysis for renal failure. Ruling out coexisting infections such as meningitis and septicemia is important, and empiric antimicrobials might be indicated.

Prevention

Malaria prevention in travelers involves both prophylaxis and protective measures against mosquito bites. The primary goal of prophylaxis is to prevent *P. falciparum* infection in nonimmune travelers because almost all fatal cases are associated with illness caused by this species. Careful review of itineraries is important when advising travelers to assess whether they will enter malaria-endemic areas and the presence of any drug resistance. Risk can vary widely within a country. For example, when travel to Thailand is limited to the malaria-free cities of Bangkok and Phuket, prophylaxis is not needed, whereas travel to many rural areas in Thailand warrants prophylaxis against multidrug-resistant *P. falciparum*. Travel timing should also be considered, as some regimens require starting 1 to 2 weeks prior to departure, and the number of tablets prescribed will be determined by the duration of travel. Other considerations include medical contraindications to specific regimens, drug–drug interactions between prophylaxis drugs and the traveler's usual medications, and client preference. Client preference is often based on side-effect profile, convenience of the regimen, and cost. A general algorithm for determining an appropriate prophylactic regimen is shown in Figure 199.2. Since malaria distribution and resistance patterns can change, clinicians are strongly advised to review current country-specific recommendations, such as those provided by the CDC (www.cdc.gov/malaria/travelers), when advising travelers.

The various malaria prophylactic agents have different schedules, though all require starting prior to arrival in the malarious area and continuation after departure for a specified period (Table 199.2). Weekly chloroquine remains an excellent option for travel to the limited endemic areas without CRPF, although atovaquone-proguanil, doxycycline, and mefloquine are also options. For most areas with CRPF, prophylaxis with atovaquone-proguanil, doxycycline, and mefloquine are recommended. An exception exists for travel to areas in Southeast Asia with multidrug-resistant strains where atovaquone-proguanil and doxycycline are the only options.

Mefloquine prophylaxis has a weekly schedule and should be started 2 weeks prior to entering malaria risk areas. It is generally well tolerated by most travelers, though it can cause sleep disturbance, dizziness, and abnormal dreams. Mefloquine has been associated with rare but severe neurologic or neuropsychiatric side effects, including permanent vestibular toxicity, seizures, psychosis, anxiety, and depression. Its use is contraindicated in travelers with a history of active or recent major psychiatric or seizure disorder, and travelers prescribed mefloquine should be informed of potential adverse effects. Because the majority of adverse reactions to mefloquine occur with the first three doses, if possible it is prudent to commence the drug 4 weeks prior to departure to ascertain drug tolerance. Atovaquone-proguanil and doxycycline have daily schedules and can be started 1 to 2 days prior to arriving to the malaria risk area. Both drugs are usually well tolerated, but doxycycline can cause photosensitivity and gastrointestinal side effects such as nausea and esophagitis. Travelers taking doxycycline should be advised to take it with food and sufficient fluids, and it should not be taken at bedtime. Mefloquine and doxycycline need to be continued for 4 weeks after departing from the malaria risk area, while atovaquone-proguanil needs only to be continued for 7 days.

Prolonged exposure to malaria in areas intensely endemic for *P. vivax* or *P. ovale* (e.g., Central America, northwest Africa, South Asia, Oceania) warrants terminal prophylaxis or presumptive antirelapse therapy with primaquine to eradicate hypnozoites. As previously noted, G6PD deficiency should be ruled out before prescribing this drug, and it is contraindicated during pregnancy. Primaquine and tafenoquine are also recommended as an alternative for primary prophylaxis for short-term travelers to areas with primarily *P. vivax* malaria.

Prophylaxis options for pregnant women are limited to mefloquine in areas with CRPF and chloroquine in areas without CRPF. Unfortunately, there are no recommended prophylactic regimens at this time for pregnant women traveling to areas with multidrug-resistant *P. falciparum* in Southeast Asia. Long-term travelers (such as missionaries or overseas workers) and immigrants visiting their countries of origin pose additional challenges. These travelers often have itineraries and accommodations that are at higher risk

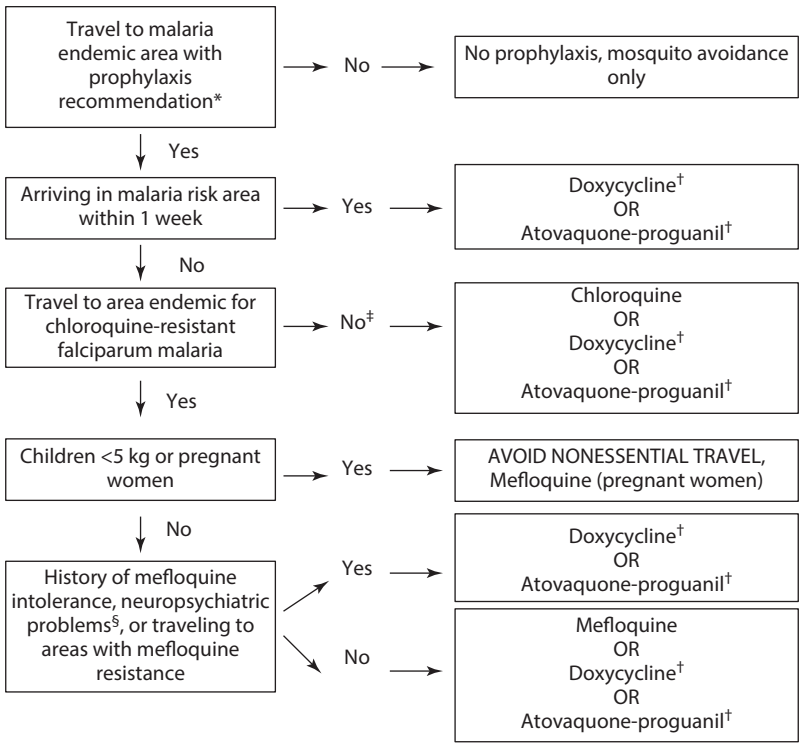

FIGURE 199.2 Algorithm for the prophylaxis of malaria. See Table 199.2 for dosages.

*Country-specific recommendations available at www.cdc.gov/malaria/travelers

† Contraindicated or not recommended in pregnancy.

‡ If traveling for short durations to an area with primary *P. vivax* malaria, primaquine primary prophylaxis is an option if glucose-6-phosphate deficiency and pregnancy are ruled out.

§ Seizures, psychosis, schizophrenia, generalized anxiety disorder, active or recent depression, other major psychiatric disorders.

for malaria than those of typical short-term travelers. Long-term travelers often adhere poorly to prophylaxis and mosquito-bite avoidance recommendations. Immigrants visiting friends and relatives in their country of origin often do not seek pre-travel advice and are often unaware that any malaria semi-immunity wanes quickly. Substandard or counterfeit drugs are also a common problem in developing countries, so travelers should be strongly cautioned against obtaining prophylaxis medications locally.

Because no prophylaxis regimen is 100% effective, all travelers to malarious regions need to be meticulous about personal protection measures. Furthermore, malarious areas are often endemic for other mosquito-transmitted infections, such as dengue fever. Insect repellents containing 30% to 50% of diethyltoluamide (DEET) are very effective. The CDC, American Academy of Pediatrics, and US Environmental Protection Agency have indicated that 30% DEET is safe for infants as young as 2 months of age. Other effective compounds used in repellents include picaridin, oil of lemon eucalyptus (OLE), PMD, and IR3535. Permethrin-impregnated protective clothing (long sleeves, pants) add further protection. Travelers should always follow product instructions carefully so these products are used safely and are reapplied at appropriate intervals. Since *Anopheles* mosquitoes typically bite between dusk and dawn, sleeping under permethrin-impregnated bed netting or in screened-in or air-conditioned rooms is important.

Because malaria prophylaxis recommendations often vary according to different authorities, travelers should be cautioned about potentially conflicting advice from fellow travelers and overseas healthcare providers. Also, travelers should be advised to seek medical attention immediately in the event of high fever during travel, as well as fevers that occur up to a year after travel. Acutely ill travelers should seek the best medical care available and follow local treatment recommendations. However, since malaria is often overdiagnosed in developing countries, travelers should be strongly cautioned against discontinuing their prophylaxis regimen if they are diagnosed with malaria.

TABLE 199.2 **MALARIA CHEMOPROPHYLAXIS REGIMENS**

Drug	Adult dose	Pediatric dose	Adverse effects
Chloroquine phosphate	300 mg base (= 500 mg salt) PO weekly, starting 1 wk before entering malarious area and continue for 4 wk after departing risk area	5 mg base/kg (= 8.3 mg salt/kg) PO weekly, starting 1 wk before entering malarious area and continue for 4 wk after departing risk area	Bitter taste, headache, pruritus, rash, blurry vision, reversible corneal opacity, partial alopecia. Rare: retinopathy, blood dyscrasias, nail discoloration, nerve deafness, myopathy. May exacerbate psoriasis
Hydroxychloroquine	310 mg base (= 400 mg salt) PO weekly, starting 1 wk before entering malarious area and continue for 4 wk after departing risk area	5 mg base/kg (= 6.5 mg salt/kg), maximum 310 mg base, PO weekly, starting 1 wk before entering malarious area and continue for 4 wk after departing risk area	As for chloroquine
Atovaquone–proguanil	250 mg atovaquone and 100 mg proguanil (1 adult tablet) PO daily, starting 1–2 d before entering malarious area and continue for 7 d after departing risk area	Weight-based daily dose starting 1–2 d before entering malarious area and continue for 7 d after departing risk area. Pediatric tablet contains 62.5 atovaquone and 25 mg proguanil: 5–8 kg: ½ ped tab PO daily >8–10 kg: 3/4 ped tab PO daily >10–20 kg: 1 ped tab PO daily >20–30 kg: 2 ped tab PO daily >30–40 kg: 3 ped tab PO daily >40 kg: see adult dosing	Nausea, abdominal pain, headache. May transiently increase transaminases. Rare: rash. Take with food. Do not use if creatinine clearance ≤30 mL/min. Not recommended for pregnant women, breastfeeding women, or children <5 kg
Doxycycline	100 mg PO daily, starting 1–2 d before entering malarious area and continue for 4 wk after departing risk area	≥8 years old: 2.2 mg/kg PO daily (maximum dose 100 mg/d), starting 1–2 d before entering malarious area and continue for 4 wk after departing risk area	Esophageal irritation, gastrointestinal upset, photosensitivity, candida vaginitis. Stains teeth of children aged ≤8 yr and fetuses. Contraindicated in pregnancy
Mefloquine	One 228 mg base tablet (= 250 mg salt) PO weekly, starting ≥2 wk before entering malarious area and continue for 4 wk after departing risk area	Weight-based daily dose starting ≥2 wk before entering malarious area and continue for 4 wk after departing risk area: ≤9 kg: 4.6 mg base/kg (= 5 mg salt/kg) PO weekly >9–19 kg: ¼ tablet PO weekly >19–30 kg: ½ tablet PO weekly >30–45 kg: 3/4 tablet PO weekly >45 kg: 1 tablet PO weekly One tablet contains 228 mg base (= 250 mg salt)	Dizziness, nausea, diarrhea, headache, nightmares, altered dreams, insomnia, mood changes. Rare: seizure, psychosis, permanent vestibular toxicity. Do not use if history of seizures, psychosis, schizophrenia, generalized anxiety disorder, active or recent depression, other major psychiatric disorders, or cardiac conduction abnormality present
Primaquine			
Terminal prophylaxis	30 mg base (52.6 mg salt) PO daily for 14 d	0.5 mg base/kg (0.8 mg salt/kg) PO daily for 14 d	G6PD deficiency should be ruled out prior to use to prevent hemolysis.
Primary prophylaxis (for short-duration travel to areas with primarily *P. vivax*)	30 mg base daily, starting 1–2 d before entering malarious area and continue for 7 d after departing risk area	0.5 mg base/kg (0.8 mg salt/kg) PO daily, starting 1–2 d before entering malarious area and continue for 7 d after departing risk area	Contraindicated in pregnancy and breastfeeding women (unless the breastfed infant has documented normal G6PD levels). Should be taken with food to prevent gastrointestinal upset
Tafenoquine			
Primary prophylaxis (for short-duration travel to areas with primarily *P. vivax*)	200 mg PO daily × 3 days 3 days prior to travel, then weekly while there and for 1 week after leaving malarious area	Not indicated in children <16 years old	Contraindicated in pregnancy, children under 16 years old and breastfeeding women (unless the breastfed infant has documented normal G6PD levels). Should be taken with food to prevent gastrointestinal upset

Babesiosis

Tempe K. Chen, Choukri Ben Mamoun, and Peter J. Krause

Babesiosis is an emerging zoonotic disease caused by intraerythrocytic protozoa of the Apicomplexa phylum and transmitted by hard-bodied ticks. The first well-documented case of human *Babesia* infection was reported in 1957, in a splenectomized resident of Yugoslavia. The patient died after an acute illness marked by anemia, fever, hemoglobinuria, and renal failure. Intraerythrocytic parasites were noted in his blood and tentatively identified as *Babesia divergens*. Since then, other *Babesia* spp. have been found to cause disease in humans, including *B. microti, B. duncani*, and *B. divergens*-like parasite in North America; *B. divergens, B. microti*, and *B. venatorum* in Europe; and *B. crassa*-like agent, *B. venatorum*, *B. microti,* KO-1, and XXB/HangZhou in Asia. *B. microti* is endemic in the United States and is responsible for most babesiosis cases worldwide, while *B. crassa*-like agent and *B. venatorum* are endemic in China. All other species cause sporadic disease. Although most babesiosis cases are vector-borne, transmission through blood transfusion, organ transplantation, and transplacentally also have been reported.

Epidemiology

More than 100 species in the genus *Babesia* infect a wide variety of wild and domestic animals. Humans are an uncommon and terminal host for *Babesia* spp., which depend on other species for their development and transmission. The most common cause for human babesiosis is *B. microti,* a *Babesia* of rodents. The primary reservoir for *B. microti* in North America is the white-footed mouse (*Peromyscus leucopus*). As many as two-thirds of *P. leucopus* have been found to be parasitemic in endemic areas. *Babesia* spp. are transmitted by hard-bodied ticks. The primary vector in eastern North America is *Ixodes scapularis* (also known as *Ixodes dammini*), which is the same tick that transmits *Anaplasma phagocytophilum,* the agent of human granulocytic anaplasmosis; *Borrelia burgdorferi* and *Borrelia miyonii,* etiologic agents of Lyme disease; *Borrelia miyamotoi* that causes relapsing fever; Powassan virus that causes Powassan encephalitis; and the *Ehrlichiosis muris euclairensis* agent that causes ehrlichiosis. Simultaneous human infection with two or more of these pathogens may occur due to transmission by coinfected ticks.

Each of the three active stages in the life cycle of *I. scapularis* (larva, nymph, and adult) requires a blood meal from a vertebrate host to mature to the next stage (Figure 200.1). The *Babesia* spp. ingested by one tick stage are transmitted to the next stage. The tick transmission cycle begins in late summer when newly hatched larvae ingest the parasite during a blood meal from an infected rodent and maintain the parasite to the nymphal stage. Nymphs transmit *Babesia* spp. to rodents in late spring and summer of the following year. Larvae, nymphs, and adults can feed on humans, but the nymph is the primary vector (Figure 200.2). All active tick stages also feed on the white-tailed deer (*Odocoileus virginianus*), which is an important host for the tick but is not a reservoir for *B. microti*. An increase in the deer population over the past few decades is thought to be a major factor in the emergence of *I. scapularis* and the resulting increase in human babesiosis cases.

FIGURE 200.2 *Ixodes scapularis* (also known as *Ixodes dammini*) ticks showing larval, nymphal, and adult stages.

Beginning in the 1990s, human babesiosis has been described with increasing frequency at sites in the northeastern and north-midwestern United States. Recent studies suggest that the endemic range continues to expand. In certain sites during years of high transmission, babesiosis may constitute a significant public health burden. For example, in one study of a highly endemic area in Rhode Island, approximately 9% of the population had serological evidence of previous *B. microti* infection compared with 11% of previous Lyme disease. Most human cases of babesiosis occur in the summer and in areas where the vector tick, rodents, and deer are in close proximity to humans. Rarely, babesiosis is acquired through transfusion of blood products (including whole blood, packed red cells, cryopreserved red cells, and platelets) or organ transplantation. Transplacental/perinatal transmission of babesiosis also has been described.

Pathogenesis

Our understanding of the pathogenesis of human babesiosis is incomplete and is primarily based on animal studies. Cytoadherence of *Babesia*-infected erythrocytes to vascular epithelium may diminish access of host immune factors to *Babesia*, at least in part by preventing transit of infected erythrocytes through the spleen where they are destroyed, thus preventing *Babesia* from completing their life cycle and invading other erythrocytes. Excessive cytoadherence may lead to erythrocyte sequestration and obstruction of microvasculature with subsequent tissue anoxia, as has been demonstrated in cattle infected by *B. bovis*. Similarly, production of host proinflammatory cytokines such as tumor necrosis factor (TNF) and interleukin (IL)-1 are thought to help destroy intracellular *Babesia*; however, excessive cytokine production associated with moderate to severe disease may account for the majority of clinical manifestations and complications. T cells, B cells, macrophages, neutrophils, antibody, and complement are important in clearing parasitemia but also may contribute to disease pathogenesis.

Clinical manifestations

The clinical severity of babesiosis ranges from subclinical infection to fulminating disease resulting in death. In clinically apparent cases, symptoms of babesiosis begin after an incubation period of 1 to 9 weeks from the beginning of tick feeding or 1 week to 6 months (usually 3 to 7 weeks) after transfusion. In most cases, there is a gradual onset of malaise and fatigue followed by intermittent temperatures as high as 40.9°C/105.6°F and one or more of the following symptoms: chills, sweats, headache, and myalgia. Less commonly noted are arthralgia, anorexia, nausea, vomiting, sore throat, abdominal pain, and/or weight loss, nonproductive cough, emotional lability, hyperesthesia, conjunctival injection, and photophobia. The findings on physical examination generally are minimal, often consisting only of fever. Splenomegaly, hepatomegaly, or both are noted occasionally. Slight pharyngeal erythema, jaundice, retinopathy with splinter hemorrhages, and retinal infarcts also have been reported. Rash is seldom noted, although ecchymoses and petechiae have been described in severe disease.

Symptoms usually persist for a few weeks to several months, with prolonged recovery of up to 18 months in severe cases. Parasitemia may continue even after a person feels well and may persist for >2 years without symptoms in immunocompetent patients or relapsing illness in immunocompromised patients. Although prolonged symptomatic disease or death may occur in immunocompromised hosts, complete recovery is the rule.

Patients at increased risk for more severe babesial disease include those with asplenia, malignancy, or concomitant HIV/AIDS infection; those at the extremes of age (neonates and the elderly); those with hemoglobinopathies; those with chronic heart, lung, liver, or hematologic disease; or those on immunosuppressive therapy. People infected through blood transfusion or organ donation, or who experience *B. divergens* infection also have more severe disease. Concurrent babesiosis and Lyme disease infection has been reported in 2% to 19% of patients experiencing Lyme disease and results in more severe illness than Lyme disease alone. Moderate to severe babesiosis may occur in children, but infection usually results in mild disease and is generally less debilitating than in adults. Numerous cases of neonatal babesiosis have been described, usually following transfusion with infected blood and sometimes resulting in severe illness. Symptoms and signs include lethargy, tachypnea, pallor, poor feeding, splenomegaly, hepatomegaly, jaundice, and generalized macular rash.

Complications

Severe babesiosis can occur, consisting of fulminant illness lasting about a week and ending in death or a prolonged convalescence. Although more common in immunocompromised hosts or those experiencing *B. divergens* infection, severe babesiosis can occur in otherwise healthy individuals who are infected with *B. microti*. In a retrospective study of 136 patients with *B. microti* infection from Long Island, New York, 7 patients (5%) died. The patients with fatal illness ranged in age from 60 to 82 years, and only 1 was known to be immunocompromised. Signs and symptoms in severe cases include high fever, severe hemolytic anemia, hemoglobinemia and hemoglobinuria, jaundice, ecchymoses, petechiae, congestive heart failure, pulmonary edema, renal failure, adult respiratory distress syndrome, and coma. Patients with malignancy (especially B-cell lymphoma), HIV/AIDS infection, and/or immunosuppressive therapy (especially rituximab) may experience a chronic form of babesiosis that is poorly responsive to multiple courses of standard antibabesial therapy.

Diagnosis

Babesiosis should be suspected in any patient with unexplained febrile illness who has recently lived or traveled in endemic regions during the months of May through September. There is often no recollection of a tick bite because the unengorged *I. scapularis* nymph is difficult to discern with the naked eye (~2 mm in length). Babesiosis also should be considered in any patient with unexplained febrile illness who has had a blood transfusion within the previous 6 months.

Laboratory findings reflect the invasion and subsequent lysis of erythrocytes by the parasite and the immune response to infection. They include moderate to severe hemolytic anemia, an elevated reticulocyte count, thrombocytopenia, an elevated erythrocyte sedimentation rate, elevated serum bilirubin and liver enzyme concentrations, elevated serum blood urea nitrogen and creatinine concentrations, and proteinuria. The leukocyte count is normal to decreased, with a "left shift." Atypical lymphocytes also may be noted on manual differential blood smear examination.

Specific diagnosis of babesiosis is made by microscopic demonstration of the organism using Giemsa-stained thin blood smears or amplification of *Babesia* DNA using polymerase chain reaction (PCR). Giemsa-stained *Babesia* parasites appear as round,

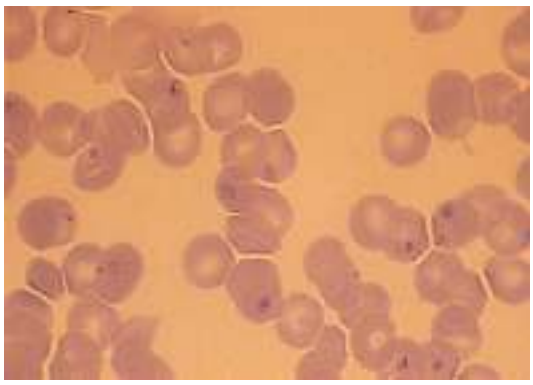

FIGURE 200.3 Ring forms of *Babesia microti* in human blood film (1,000×).

oval, or pear-shaped microorganisms with a blue cytoplasm and a red chromatin membrane (Figure 200.3). Multiple blood fields should be examined because only a few erythrocytes are infected in the early stage of the illness when most people seek medical attention. Fewer than 1% of erythrocytes may be parasitized initially and may escape detection. Parasitemia seldom exceeds 10% in normal hosts but may reach as high as 85% in people who are immunocompromised. Thick blood smears may be examined, but the organisms appear as simple chromatin dots that may be mistaken for stain precipitate or iron inclusion bodies. Accordingly, only someone with extensive experience in interpreting thick smears should perform this method. The ring form is most common and is very similar to the intraerythrocytic ring forms of *Plasmodium falciparum*. Although the presence of tetrad forms ("Maltese cross") is diagnostic, such elements are seldom encountered. Similarly, the absence of hemozoin (malarial pigment) is often considered to be generally diagnostic for the small blood stage parasites (piroplasms), but early ring stages of the plasmodia also lack pigment. Laboratory diagnosis of severe cases includes the presence of high parasitemia, erythrocytes infected by multiple parasites, and basket-shaped merozoites that are often extracellular.

Physicians also can confirm babesial infection by use of PCR, antigen capture assays, serologic testing, and small animal inoculation. The PCR assay is a sensitive and specific test for detection of babesia DNA, and real-time PCR provides an index of parasite number. Both immunoglobulin G (IgG) and immunoglobulin M (IgM) antibodies can be detected using an immunofluorescent assay (IFA) or enzyme-linked immunosorbent assay (ELISA). Antibody may be undetectable early in the course of disease, and the presence of antibody may reflect past rather than acute disease. Only a fourfold rise in antibody titer between acute and convalescent sera can confirm the diagnosis. During the acute phase of the illness, titers usually exceed 1:1024 but decline to 1:64 or less within 12 months. Thus, a *Babesia* IFA titer of ≥1:1024 usually signifies active or recent infection. A serological cutoff point of 1:64 generally is considered to be diagnostic of past or current infection. Although cross-reactions occur with different *Babesia* spp. and *Plasmodium* spp. with the IFA test, these titers are almost always low (≤1:16). The diagnosis of acute babesiosis is suspect in symptomatic patients whose serum contains antibody to *Babesia* but whose blood lacks identifiable babesial parasites on smear or babesial DNA by PCR. In sum, diagnosis is made by a combination of epidemiologic, clinical, and laboratory criteria.

For *B. divergens* babesiosis, specific antibodies do not become detectable until at least 1 week after onset of illness. Because this infection is rapidly fulminating, serological diagnosis is not practical in the diagnosis of acute infection, but serological conversion serves as an aid in retrospective diagnosis during convalescence. The high parasitemias that are present are easily detected by blood smear in the acute phase of infection. Infection by *B. duncani* may readily be detected by blood smear or PCR. This species may be cultivated in vitro. Unlike the IFA for *B. microti,* a higher cutoff value (>1:160) is required to impart specificity, for unknown reasons. In humans and in rodent models, tetrad forms are frequently seen in blood smears, but otherwise this agent is difficult to distinguish from *B. microti*.

Coinfection with the agents of Lyme disease (*B. burgdorferi*), human granulocytic anaplasmosis (*A. phagocytophilum*), or both may occur in patients experiencing babesiosis in areas where these pathogens are endemic. Babesiosis coinfection should be considered in Lyme disease patients who present with more severe initial symptoms than are commonly observed with Lyme disease alone or who do not respond to standard therapy.

Treatment

Early efforts to treat patients with babesiosis were unsuccessful, including use of the antimalarial drug chloroquine. The combination of clindamycin and quinine was the first effective antimicrobial therapy but is now an alternative to the treatment of choice, atovaquone and azithromycin. In the only prospective, randomized trial of antibabesial therapy in humans, the combination of atovaquone and azithromycin was compared with clindamycin and quinine for treatment of adults with non–life-threatening *B. microti* infection. The atovaquone and azithromycin combination was found to be as effective in clearing parasitemia and resolving symptoms as the clindamycin and quinine combination. Both drug combinations were given by mouth for 7 days. After 3 months, there was no microscopic evidence of *Babesia* or amplifiable *B. microti* DNA in either group. Significantly fewer adverse effects were associated with the atovaquone and azithromycin combination. Three-fourths of patients receiving clindamycin and quinine experienced adverse drug reactions, and one-third were forced to decrease the dose or discontinue the medication. Adverse effects of therapy included hearing loss, tinnitus, syncope, hypotension, and gastrointestinal symptoms (anorexia, vomiting, and diarrhea). In contrast, only 18% of subjects in the azithromycin and atovaquone group experienced symptoms consistent with adverse drug reaction, and only 1 (2%) subject required a decrease in dosage or discontinuation of medication. The primary conclusion of this study was that antibabesial therapy based on the atovaquone and azithromycin drug combination generally is superior to that based on clindamycin and quinine because efficacy is similar for the two antimicrobial combinations but the atovaquone and azithromycin regimen is much better tolerated than the clindamycin and quinine regimen. Physicians were encouraged to consider the use of atovaquone and

TABLE 200.1 **TREATMENT REGIMENS FOR BABESIOSIS PATIENTS**

Patient Category	Treatment Regimen	
	Adult doses	**Pediatric doses**
Ambulatory patients: mild to moderate disease [a]	**Preferred** Atovaquone 750 mg (with a fatty meal) orally Q12h plus azithromycin 500 mg orally on day 1, then 250 mg Q24h for 7 to 10 days. **Alternative** [c] Clindamycin 600 mg orally Q8h plus quinine sulfate 650 mg orally Q8h for 7 to 10 days.	**Preferred** [b] Atovaquone 20 mg/kg (up to 750 mg/dose) orally Q12h plus azithromycin 10 mg/kg (up to 500 mg/dose) orally on day 1, then 5 mg/kg (up to 250 mg/dose) Q24h for 7 to 10 days. **Alternative** [c] Clindamycin 7-10 mg/kg (up to 600 mg/dose) orally Q6h-8h plus quinine sulfate 8 mg/kg (up to 650 mg/dose) orally Q8h for 7 to 10 days.
Hospitalized patients: acute severe disease [d]	**Preferred** [c] Atovaquone 750 mg orally Q12h plus azithromycin 500 mg IV Q24h until symptoms abate, then convert to all oral therapy (see step-down therapy). **Alternative** [c] Clindamycin 600 mg IV Q6h plus quinine sulfate 650 mg orally Q8h until symptoms abate, then convert to all oral therapy (see step-down therapy). If infection relapses, consider one of the regimens listed in Table 3.	**Preferred** [f] Atovaquone 20 mg/kg (up to 750 mg/dose) orally Q12h plus azithromycin 10 mg/kg (up to 500 mg/dose) IV Q24h until symptoms abate, then convert to all oral therapy (see step-down therapy). **Alternative** [c] Clindamycin 7-10 mg/kg (up to 600 mg/dose) IV Q6h-8h plus quinine sulfate 8 mg/kg (up to 650 mg/dose) orally Q8h until symptoms abate, then convert to all oral therapy (see step-down therapy). If infection relapses, consider one of the regimens listed in Table 3.
Hospitalized patients: step-down therapy (transition to oral therapy)	**Preferred** Atovaquone 750 mg (with a fatty meal) orally Q12h plus azithromycin 250-500 mg orally Q24h. Treatment of acute disease plus step-down therapy typically lasts 7-10 days in total. A high dose of azithromycin (500-1000 mg) orally should be considered for immunocompromised patients. **Alternative** [c] Clindamycin 600 mg orally Q8h plus quinine sulfate 650 mg orally Q8h. Treatment of acute disease plus step-down therapy typically lasts 7-10 days in total.	**Preferred** Atovaquone 20 mg/kg (up to 750 mg/dose) orally Q12h plus azithromycin 5-10 mg/kg (up to 500 mg/dose) orally Q24h. Treatment of acute disease and step-down therapy typically last 7-10 days in total. **Alternative** [c] Clindamycin 7-10 mg/kg (up to 600 mg/dose) orally Q6h-8h plus quinine sulfate 8 mg/kg (up to 650 mg/dose) orally Q8h. Treatment of acute disease plus step-down therapy typically lasts 7-10 days in total.
Highly immunocompromised patients	Start with one of the regimens recommended for hospitalized patients: acute severe disease and follow with one of the step-down therapies but treat for at least 6 consecutive weeks, including 2 final weeks during which parasites are no longer detected on peripheral blood smear [3]. When oral azithromycin is used, a 500-1000 mg daily dose should be considered. If infection relapses, consider one of the regimens listed in Table 3.	

[a] These patients usually are immunocompetent, experience mild to moderate symptoms, have a parasitemia <4%, and do not require hospital admission.
[b] Azithromycin modestly increases the risk of pyloric stenosis for infants less than 6 weeks old [4].
[c] Clindamycin plus quinine is preferred when parasitemia and symptoms have failed to abate following initiation of atovaquone plus azithromycin. Some physicians have used parenteral quinidine instead of oral quinine; however, quinidine is no longer available in the United States. All quinine doses listed are for the sulfate salt, which is the only quinine salt available in the United States; 650 mg quinine sulfate is equivalent to 542 mg quinine base.
[d] Exchange transfusion should be considered for patients with high-grade parasitemia (>10%) or moderate to high-grade parasitemia and any one or more of the following: severe hemolytic anemia and/or severe pulmonary, renal, or hepatic compromise. Expert consultation with a transfusion services physician or hematologist in conjunction with an infectious diseases specialist is strongly advised.
[e] Azithromycin 1,000 mg given *orally*, in combination with other antibiotics, has been used successfully to clear *Babesia microti* infection in immunocompromised patients. Some physicians have used a one-time dose of azithromycin 1,000 mg *intravenously* for severe babesiosis. While this dose has been shown to be safe, there are no published reports of the use this 1000 mg dose for severe babesiosis [5]. If intravenous azithromycin 1,000 mg is given to an immunocompromised patient, subsequent doses should be reduced to 500 mg daily.
[f] This regimen has not yet been reported for the treatment of children with severe babesiosis.

azithromycin in adult patients experiencing non–life-threatening babesiosis and in others who could not tolerate clindamycin and quinine. Subsequent studies have shown that the atovaquone and azithromycin combination also is effective for patients experiencing life-threatening babesiosis. This combination is now recommended as first-line therapy for all babesiosis patients. The currently recommended dosing for atovaquone and azithromycin is shown in Table 200.1. Treatment usually is given for 7 to 10 days but may need to be extended for immunocompromised individuals. Higher doses and intravenous administration of azithromycin are also indicated for severe disease in these patients. Clindamycin and quinine is given to patients who do not respond to atovaquone and azithromycin because of the development of drug resistance or who experience untoward reaction to the drug combination. Dosing is listed in Table 200.1. This combination frequently produces untoward reactions, such as tinnitus, QT prolongation, allergic reaction, vertigo, and gastrointestinal upset. Treatment failures have been reported in patients with splenectomy, HIV-infected patients, and in those receiving concurrent corticosteroid therapy.

The combination of pentamidine (240 mg IV/d) and trimethoprim-sulfamethoxazole (3 g/d) was found to be moderately effective in clearing parasitemia and symptoms due to *B. divergens*. Potential adverse reactions to pentamidine that include pain at the site of injection, formation of sterile abscess, hyperglycemia or hypoglycemia, and nephrotoxicity limit the use of this combination.

Red blood cell exchange transfusion should be considered for babesiosis patients with high parasitemia (>10%), significant hemolysis, or renal or pulmonary compromise. Partial or complete exchange transfusion has been shown to rapidly decrease parasitemia by removing parasite-infected red blood cells from the circulation and correcting anemia. It also helps remove vasoactive elements such as pro-inflammatory cytokines and thromboplastic substances that may contribute to renal failure, disseminated intravascular coagulation, and other complications. Nonetheless, no prospective controlled trials have been carried out to confirm the efficacy of exchange transfusion in decreasing disease complications and death. Due to the risks associated with multiple blood exposures, these techniques should not be considered as routine therapy but only used for those severely ill with babesiosis.

Babesiosis patients should be monitored closely during therapy. In most cases, improvement will occur within 1 or 2 days after antiprotozoal therapy is begun. Symptoms generally resolve within 1 or 2 months after atovaquone and azithromycin or clindamycin and quinine therapy is completed. In severely ill patients, the hematocrit and percentage of erythrocytes parasitized should be monitored daily or every other day until the patient has improved and the parasitemia has decreased to less than 4%. Some patients may have persistence of low-grade parasitemia for months following antibiotic therapy.

Physicians should consider retreatment of patients with antibabesial therapy if patients show evidence of parasitemia in their blood for >3 months after initial therapy, especially if parasitemia is increasing. Physicians also should consider the possibility of coinfection with Lyme disease, human granulocytic anaplasmosis, or both in babesiosis patients who have a rash or experience persistent symptoms despite appropriate antibabesial therapy. Such patients may benefit from the addition of doxycycline therapy as neither clindamycin and quinine nor atovaquone and azithromycin has been shown to be effective for the treatment of Lyme disease or human granulocytic anaplasmosis.

Prevention

Prevention of babesiosis can be accomplished by avoiding *Babesia* endemic areas from May through September where ticks, deer, and mice are known to thrive. It is especially important for those at increased risk in endemic areas, such as asplenic individuals, to avoid tall grass and brush where ticks may abound. Use of clothing that covers the lower part of the body and that is sprayed or impregnated with diethyltoluamide (DEET), dimethyl phthalate, or permethrin (Permanone) is recommended for those who travel in the foliage of endemic areas. DEET has been shown to be more effective than other repellents against ticks, but the risk of adverse effects is greater. Thus, although DEET can help to prevent tick bites and is generally well tolerated when applied to the skin properly, care must be taken with repeated use of high-concentration products.

A search for ticks on people and pets should be carried out and the ticks removed using tweezers to grasp the mouthparts while carefully removing the tick. Prophylactic antibiotics after a tick bite to prevent babesiosis are not indicated. The effects of reduction of the tick, mouse, or deer populations in endemic areas on the incidence of human babesiosis have not been evaluated. Blood donors with a history of babesiosis or who test positive on blood donor screening for *Babesia* infection are excluded from donating blood to prevent transfusion-related cases. Effective vaccines have been developed to prevent *B. divergens* and *B. bovis* infections in cattle, but no vaccines are currently available for the prevention of human babesiosis.

Trypanosomes and leishmania

Anastacio de Sousa, Selma M. B. Jeronimo, and Richard Pearson

American trypanosomiasis (Chagas disease), human African trypanosomiasis (HAT, sleeping sickness), and leishmaniasis are caused by related protozoa of the family *Trypanosomatidae*, order Kinetoplastida (see Table 201.1). They have a unique mitochondrial structure, the kinetoplast; are transmitted in nature by insect vectors; and exist in multiple morphologic forms in their human hosts and insect vectors. They are important causes of morbidity and mortality in endemic areas of the world: Chagas disease in South and Central America, sleeping sickness in sub-Saharan Africa, and leishmaniasis in scattered areas on every continent except Antarctica. Although uncommon in industrial countries in North America and Europe, these diseases have been the source of increased attention in recent years. Infection with *Trypanosoma cruzi*, the cause of Chagas disease, is well-documented among Latin American immigrants to North America and Europe and poses a risk to them, children of infected mothers, and to recipients of donated blood or transplanted organs. Cases of African sleeping sickness have fallen to historic lows over the past two decades as a consequence of sustained control efforts, and the disease has been targeted for eradication by the World Health Organization (WHO). Cutaneous leishmaniasis is seen among tourists returning from endemic areas in Latin America and the Middle East as well as in military personnel who have served in Iraq, Afghanistan, and other endemic areas. Imported cases of visceral leishmaniasis to the United States in travelers or immigrants from the Indian subcontinent, East Africa, South America or southern Europe, some in association with HIV/AIDS, occur, but are rare. While canine visceral leishmaniasis has been reported in the United States among foxhounds and other dogs, linked to vertical transmission in female dogs that were infected in Europe, there have been no reports of leishmanial infection in persons exposed to them.

Despite several important recent advances, the treatment of Chagas disease, African trypanosomiasis, and leishmaniasis leaves much to be desired. Many of the drugs (Table 201.2) used for them are associated with frequent and potentially severe untoward effects, some require parenteral administration, and many must be administered over prolonged periods of time. Some of the drugs have been approved by the US Food and Drug Administration (FDA) for these diseases while others listed in Table 201.2 are investigational or used off-label. Several investigational drugs can be obtained from the US Centers for Disease Control and Prevention (CDC) Drug Service along with detailed information about administration and side effects; they are administered under Investigational New Drug (IND) protocols. The high cost of some of those medications and the lack of availability of others are important determinants in therapeutic decisions in impoverished endemic areas. Hopefully, more effective, less toxic approaches to chemotherapy and/or protective vaccines will become available in the future.

American trypanosomiasis (Chagas disease)

Chagas disease, caused by *T. cruzi*, is transmitted by triatomine (reduviid or kissing) bugs that reside in buildings in rural areas of Latin America and occasionally in contaminated juices or foods. *T. cruzi* infects a large number of animal species as well as humans. There are an estimated 6 to 7 million persons infected in the world. The parasite develops in the intestine of the triatomine bug and is passed in feces when it takes a

TABLE 201.1 **DISEASES CAUSED BY PROTOZOA OF THE FAMILY *TRYPANOSOMATIDAE***

Disease	Causative agent	Transmission	Vector	Reservoir
American trypanosomiasis (Chagas disease)	*Trypanosoma cruzi*	Americas	Triatomine (Reduviid) bugs; occasionally infected juices or foods	Multiple species of animals
African trypanosomiasis (sleeping sickness)	*Trypanosoma brucei gambiense*	West and Central Africa	Tsetse flies (*Glossina* species)	Humans, domestic animals (minor role)
	Trypanosoma brucei rhodesiense	East Africa		Large game animals
Leishmaniasis (visceral, cutaneous, disseminated, mucosal)	*Leishmania* species	Worldwide	Sand flies (*Phlebotomus* species in the America and *Lutzomyia* species elsewhere)	Rodents, canines (dogs, foxes), or humans depending on the *Leishmania* species

blood meal. The bite causes itching, and parasites may enter the skin through the imperceptible bite site when the person scratches. They may also be transferred to the conjunctiva, where they can enter in the absence of a lesion.

The invasion that follows can elicit a local inflammatory nodule or chagoma. When parasites invade through the conjunctiva, unilateral, painless, periorbital edema (Romaña's sign) may develop. After a period of local multiplication, trypomastigotes disseminate through the bloodstream, causing acute Chagas disease with fever, other constitutional symptoms, carditis, and, rarely, meningoencephalitis. Death can result, but the acute phase is often mild or asymptomatic. Symptoms usually resolve over 4 to 8 weeks as host immune responses develop. The indeterminate phase of infection follows in which persons are entirely asymptomatic but continue to harbor the parasite. Eventually, 20% to 30% of infected individuals progress to chronic Chagas disease with cardiac, esophageal, or large intestinal involvement. Progressive, disseminated Chagas disease with carditis and/or brain abscesses has been reported in a limited number of persons with AIDS, following transplants. or associated with other immunocompromising conditions. *T, cruzi* is present in the bloodstream and organs of persons throughout the period of infection. Transmission can occur through transfusion of contaminated blood or transplantation of contaminated organs. This has posed ongoing problems in endemic areas in Latin America and is of concern in North America and Europe related to immigration. Chagas disease can also be acquired through the gastrointestinal tract following ingestion of food or juices contaminated with *T, cruzi* released from the insect vector. Outbreaks have been reported in Brazil. Congenital transmission and accidental laboratory infections are well-documented.

The diagnosis of acute Chagas disease is frequently made by identifying the parasite microscopically in blood or body tissues (Figure 201.1) or by molecular probes for parasite DNA. Several serologic assays have been developed to detect antitrypanosomal antibodies in persons with indeterminate phase or chronic Chagas disease. The tests tend to be sensitive, but not always specific. They are routinely used in blood banks in endemic areas of Latin America. A screening test for anti-*T. cruzi* immunoglobulin G antibodies approved by the FDA is used to detect infected blood and organ donors in the United States. However, screening assays for anti-*T. cruzi* antibodies can cross-react with leishmanial and other antigens, and a second antibody test is done to confirm the diagnosis. Screening of potential blood and organ donors has brought to medical attention a number of infected immigrants now living in the United States, Canada and Europe.

The drugs of choice for the treatment of Chagas disease are benznidazole or nifurtimox. Both are now FDA approved. Benznidazole has been the mainstay of therapy in Latin American countries. Nifurtimox has been used in the United States. Untoward effects are common with both drugs and may necessitate premature discontinuation of therapy.

Nifurtimox (Bayer 2502, Lampit; Bayer) is typically given for 60 days (see Table 201.2 for dosage). The drug is better tolerated in children and adolescents than in adults; higher doses per kilogram of body weight are used in younger patients. Neurologic and gastrointestinal side effects are common. They include sleep disturbances, restlessness, tremor, memory loss, paresthesias, weakness, polyneuritis, and, rarely, seizures, as well as anorexia, nausea, vomiting, abdominal pain, and weight loss. Other, rare side effects include fever, pulmonary infiltrates, and effusions.

Benznidazole (Rochagan, Roche) is administered for a period of 60 days. Higher doses are used in children. Side effects are frequent and include gastrointestinal disturbances, psychiatric manifestations, dose-dependent neuropathy, and cutaneous hypersensitivity reactions. On rare occasions hepatitis or neutropenia develops.

Treatment is indicated for all cases of acute or reactivated Chagas disease and for indeterminate or congenital infection up to age 18 years. Treatment is also recommended for adults up to 50 years old with chronic infection who do not already have advanced cardiomyopathy. For those >50 years with chronic *T. cruzi* infection, the decision to treat is individualized, weighing the potential benefits and risks, based on the patient's age, clinical status, and preference.

Once the cardiac, esophageal, or large intestinal manifestations of advanced Chagas disease develop, neither drug appears to alter the outcome. Supportive therapy includes cardiotropic drugs for congestive heart failure and arrhythmias, pacemaker placement for heart block, and palliative endoscopic botulinum toxin injections or surgical procedures for esophageal disease or surgery for intestinal megadisease. Nifurtimox has been used to treat disseminated

TABLE 201.2 **TREATMENT OF TRYPANOSOMIASIS AND LEISHMANIASIS**

Drug of choice	Adult dosage	Pediatric dosage
American trypanosomiasis/Chagas disease (*Trypanosoma cruzi)*		
Benznidazole[a]	5–7 mg/kg/d in 2 divided doses × 60 d	2-12 yr: 5–8 mg/kg/d in 2 doses × 60 d ≥12 yr: same as adult x 60 d
Or Nifurtimox[a]	8–10 mg/kg/d in 3 doses × 60 d	Body Weight 2.5 kg to <40 kg: 10-20 mg/kg/d in 3 doses × 60 d Body Weight ≥ 40 kg 8-10 mg/kg/d in 3 doses for 60 d
East African sleeping sickness (*Trypanosoma brucei rhodesiense*)		
First (hemolymphatic) stage		
Suramin[a,b]	4-5 mg/kg (test dose) slowly IV, then 20 mg/kg IV (max 1 g) on days 1, 3, 7, 14, and 21	2 mg/kg (max 100 mg; test dose) slowly IV, then 10-15 mg/kg (max 1 g) IV on days 1,3,7,14, and 21
Second (central nervous system involvement) stage		
Melarsoprol[a,b,c]	2.2 mg/kg/d (max 180–200 mg/d) IV × 10 d	2.2 mg/kg/d (max 180–200 mg/d) IV× 10 d
West African sleeping sickness (*Trypanosoma brucei gambiense*)		
First (hemolymphatic) stage		
Pentamidine[d,e]	4 mg/kg/d IM or IV (over 2 hr) × 7 d	4 mg/kg/d IM or IV (over 2 hr) × 7d
Second (central nervous system involvement) stage Nifurtimox-eflornithine combination therapy (WHO) Nifurtimox[a,b,c] 15 mg/kg per day in 3 doses × 10 d *Plus* Eflornithine[a,f] 400 mg/kg/d IV in 2 doses × 7d Alternative Melarsoprol, dosed as per *T. brucei rhodesiense*		
Eflornithine[a,f]	400 mg/kg/d IV in 4 doses × 14 d	400 mg/kg/d IV in 4 doses × 14 d
Leishmaniasis (*Leishmania species*)		
Visceral[g]		
Liposomal amphotericin B[h,i]	3 mg/kg IV (d 1–5, 14, and 21)	3 mg/kg IV (d 1–5, 14, and 21)
Or Miltefosine[k]	50 mg PO TID × 28 d	≥12 yr and 30–44 kg: 50 mg PO BID × 28 d or ≥45 kg adult dose for 28 days
Alternatives: Sodium stibogluconate[a,b]	20 mg sb/kg/d IV or IM × 28 d[j]	20 mg sb/kg/d IV or IM × 28 d[j]
Or		
Meglumine antimoniate[a]	20 mg sb/kg/d IV or IM × 28 d[j]	20 mg sb/kg/d IV or IM × 28 d[j]
Or		
Amphotericin B deoxycholate[d]	0.5–1 mg/kg IV daily or every second day for total dose of 15–20 mg/kg	1 mg/kg IV daily or every second day for a total dose of 15–20 mg/kg
Cutaneous[l]		
Local therapy:	Cryotherapy (with liquid nitrogen) Thermotherapy (use of localized current field radiofrequency heat) Intralesional administration of Sb^V (not covered by CDC's protocol for Pentostam) Application of paromomycin (as an ointment containing 15% paromomycin; not commercially available in the United States)[m]	

(*continued*)

TABLE 201.2 **CONTINUED**

Drug of choice	Adult dosage	Pediatric dosage
Systemic therapy: Liposomal amphotericin B	3 mg/kg/d IV for 6–10 doses	3 mg/kg/d IV for 6–10 doses
Or Miltefosine,[n] dosed as for visceral leishmaniasis	20 mg sb/kg/d IV or IM × 20 d[h]	20 mg sb/kg/d IV or IM × 20 d[j]
Or Sodium stibogluconate [a,b]		
Or		
Meglumine antimoniate[a]	20 mg sb/kg/d IV or IM × 20 d[j]	20 mg sb/kg/d IV or IM × 20 d[j]
Or		
Amphotericin B deoxycholate [d]	0.5–1.0 mg/kg daily or every other day for a total dose of approx. 20 mg/kg	0.5–1.0 mg/kg daily; or every other day for a total dose of approx. 20 mg/kg
Or		
See text for fluconazole, pentamidine and fluconazole		
Mucosal[p]		
Liposomal amphotericin[d]	3 mg/kg/d for a total dose of 20-60 mg/kg	3 mg/k/d for a total dose of 20-60 mg/kg
Or Miltefosine[q]	50 mg PO TID × 28 d	≥12 yr and 30–44 kg: 50 mg PO BID × 28 d ≥45 kg: 50 mg PO TID × 28 d
Or Alternative Sodium stibogluconate[a,b]	20 mg sb/kg/d IV or IM × 28 d[j]	20 mg sb/kg/d IV or IM × 28 d[j]
Or		
Meglumine antimoniate[a]	20 mg sb/kg/d IV or IM × 28 d[j]	20 mg sb/kg/d IV or IM × 28 d[j]
Or		
Amphotericin B deoxycholate[d]	0.5–1 mg/kg IV daily or every second day for a total dose of 20-45 mg/kg	0.5–1 mg/kg IV daily or every second day for a total dose of 20-45 mg/kg

[a] Based on the recommendations of the Centers for Disease Control and Prevention, last reviewed April 8, 2021
[b] Available under an Investigational New Drug (IND) protocol from the CDC Drug Service, Centers for Disease Control and Prevention, Atlanta, GA Questions regarding treatment should be directed to Parasitic Diseases Inquiries (404-718-4745; e-mail chagas@cdc.gov).
[c] In frail patients, begin with as little as 18 mg and increase the dose progressively. Pretreatment with suramin has been advocated by some for debilitated patients. Corticosteroids have been used to prevent arsenical encephalopathy. Up to 20% of patients with *T. b. gambiense* fail to respond to melarsoprol.
[d] An approved drug, but considered investigational for this condition by the FDA.
[e] For treatment of *T. b. gambiense*, pentamidine and suramin have equal efficacy, but pentamidine is better tolerated.
[f] Eflornithine is effective for the treatment of *T. b. gambiense*, particularly in combination with nifurtimox, but not *T. b. rhodesiense*. See https://www.cdc.gov/parasites/sleepingsickness/health_professionals/index.html (last viewed April 13, 2021). Eflornithine is available in limited supply only from the World Health Organization (WHO) and the CDC. Flexinidazole is recommended by the WHO for treatment of first- and second-stage *T. b. gambiense* disease in endemic areas (WHO interim guidelines for the treatment of gambiense human African trypanosomiasis. August 2019), but it is not available or recommended for use in the US.
[g] Visceral infection is most commonly caused by *Leishmania donovani* and *L. infantum* (previously known as *L. chagasi* in Latin America). Treatment may vary based on symptoms, host immune status, species, and resistance pattern in the area where infection was acquired.
[h] Several lipid formulations of amphotericin B have been used for treatment of visceral leishmaniasis. Largely based on clinical trials in patients infected with *L. infantum*, the FDA approved liposomal amphotericin B (AmBisome) for treatment of visceral leishmaniasis. Amphotericin B lipid complex (Abelcet) and amphotericin B cholesteryl sulfate (Amphotec) are considered investigational.
[i] The FDA-approved dosage regimen for immunocompromised patients (e.g., HIV infected) is 4 mg/kg/d (d 1–5) and 4 mg/kg/d on d 10, 17, 24, 31, and 38. The relapse rate is high; maintenance therapy may be indicated, but there is no consensus as to dosage or duration.
[j] May be repeated or continued; a longer duration or higher dose may be needed for some patients treated with liposomal amphotericin.
[k] Gastrointestinal adverse effects are common, and the drug is contraindicated in pregnancy and breastfeeding. Resistance has been reported. Miltefosine is approved for *L. donovani* infection acquired in the Indian subcontinent.
[l] Cutaneous infection is most commonly due to the Old World species *L. major*, *L. tropica,* and *L. aethiopica* and New World species *L. mexicana*, *L. amazonensis, L. (Viannia) braziliensis, L. (Viannia) panamensis*, and others. The choice of treatment varies based on the location and characteristics of the lesion(s), host immune status, infecting *Leishmania* spp., and area of the world where infection was acquired. If lesions are small, few in number, cosmetically inconsequential, and not caused by *Leishmania* spp. associated with mucosal disease, they can be followed expectantly, particularly if there is evidence of self-healing, or the lesions may be treated locally. An oral or parenteral systemic option is used for the rest. The final choice depends on the infecting species or geographic location of acquisition and the relative toxicity of the treatment modality.
[m] Topical paromomycin should be used only in geographic regions where cutaneous leishmaniasis species have low potential for mucosal spread.
[n] Oral miltefosine is approved for the treatment of cutaneous and mucosal leishmaniasis due to *L. (V.) panamensis*, *L. (V.) braziliensis*, and *L. (V.) guyanensis*. See note k for adverse effects.
[o] Several azoles have been used with variable effects. Early reports suggested that fluconazole 200 mg/d for 6 weeks was effective in American military personnel with *L. major*, but failures have been reported with that dose when lesions are caused by other *Leishmania* spp. Fluconazole at higher doses, 8 mg/kg for 4–6 weeks, has been reported to be effective in the treatment of *L. (V.) braziliensis* in an observational study in Brazil.
[p] American mucosal leishmaniasis is most often due to *L. (V.) braziliensis*, but may be seen in persons infected with *L. (V.) panamensis, L. (V.) guyanensis,* and other species. The selection among treatment options is based on symptoms, host immune status, infecting *Leishmania* spp., and site where the infection was acquired.
Abbreviations: CDC = Centers for Disease Control and Prevention; FDA = Food and Drug Administration; IV = intravenously; IM = intramuscularly; sb = pentavalent antimony.

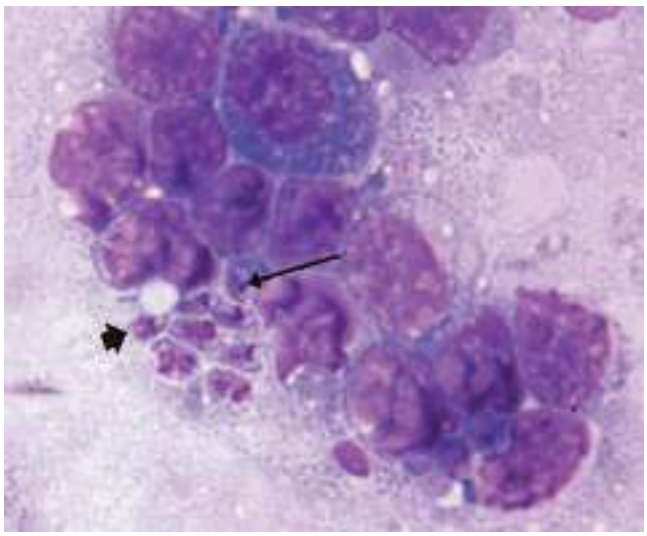

FIGURE 201.1 An imprint from a lymph node biopsy of a child with acute Chagas disease showing amastigotes (*arrowhead*), with large kinetoplast (*arrow*). Culture in LIT from the node and from whole blood grew *Trypanosoma cruzi*.

infection in persons who have undergone cardiac transplantation for chagasic cardiomyopathy in the United States.

Human African trypanosomiasis

HAT (sleeping sickness) is caused by *Trypanosoma brucei gambiense*, which is endemic in West and Central Africa, and *T. brucei rhodesiense* in East Africa. Uganda is the only country where both exist. The African trypanosomes are transmitted by tsetse flies, which are found only in rural areas of sub-Saharan Africa. Humans are the primary reservoir of *T. b. gambiense*, whereas *T. b. rhodesiense* is found in large game animals and sometimes domestic cattle. There has been a dramatic (≥95%) decrease in reported cases of African trypanosomiasis since 1999. There were only 977 reported cases in 2018, although the actual number was likely higher due to underreporting. Transplacental transmission and transmission through contaminated blood or transplanted organs can occur, but are uncommon. *T. b. gambiense* (West African trypanosomiasis) accounts for approximately 98% of cases of HAT worldwide, but it is rarely encountered in industrialized countries. In the United States, there is on average one case of HAT per year; most cases are due to American tourists returning with *T. b. rhodesiense* (East African trypanosomiasis). An indurated chancre may develop at the site of parasite inoculation. It is more likely to occur in *T. b. rhodesiense* than *T. b. gambiense* infection and in expatriates than in residents of endemic areas.

The first (hemolymphatic) stage of *T. b. gambiense* infection is characterized by recurrent bouts of fever, headaches, edema of the face, myalgias, arthralgias, other constitutional symptoms, rash in some patients, and lymphadenopathy. Swollen posterior cervical nodes are known as *Winterbottom's sign*. Trypanosomes may be seen in the blood or aspirates of lymph nodes. After a period of several weeks to months the second stage begins when they invade the central nervous system, producing meningoencephalitis. Symptoms and findings include headaches, which may be severe; loss of concentration; personality changes; memory loss; seizures; difficulty walking; increased sleep; and eventually obtundation, coma, wasting, and death.

In *T. b. rhodesiense* infection, systemic symptoms develop a few days to several weeks after the tsetse fly bites. A chancre may be present at the bite site. Fever, headache, severe fatigue, irritability, lymphadenopathy, myalgias, and arthralgias follow. Invasion of the central nervous system can occur early during infection resulting in death within several weeks or months if treatment is not initiated. The courses may be indistinguishable, but *T. b. rhodesiense* infection is usually more acute and severe, and lymphadenopathy is not as prominent as it is with *T. b. gambiense* infection.

All cases of HAT must be treated. Given the complexity of the regimens and toxicity of the drugs, consultation with experts at the CDC or elsewhere is recommended. Persons with first-stage HAT (hemolymphatic disease) due to *T. b. gambiense* are treated with pentamidine isethionate, which is administered parenterally (Table 201.2). Those with first-stage *T. b. rhodesiense* HAT are treated with suramin. Pentamidine and suramin are of comparable efficacy for *T. b. gambiense*, but pentamidine is less toxic.

Pentamidine isethionate is administered daily, intramuscularly (IM) or intravenously (IV). If infused too rapidly, IV pentamidine can produce hypotension and shock. Gastrointestinal disturbances, pain at the injection site when the drug is given IM, liver enzyme abnormalities, and nephrotoxicity are other side effects. Some patients develop life-threatening hypoglycemia due to pancreatic β cell injury and insulin release; insulin-dependent diabetes may follow. Rare side effects include acute pancreatitis, hyperkalemia, anaphylaxis, and ventricular arrhythmias.

Toxicity is frequent with suramin and includes gastrointestinal disturbances such as nausea and vomiting; neurologic side effects such as photophobia, hyperesthesias, and peripheral neuropathy; and urticaria and pruritus. Administration of the drug is occasionally associated with shock, renal toxicity, optic atrophy, or blood dyscrasias. Severe reactions can occur in persons who are coinfected with *Onchocerca volvulus*. A test dose of suramin is given IV prior to the administration of treatment doses because of rare, but potentially severe hypersensitivity reactions.

Eflornithine, which has been called the "resurrection drug," is used for second-stage (central nervous system) disease caused by *T. b. gambiense*. It is given IV. It can be used as monotherapy (Table 201.2), but the combination of eflornithine plus nifurtimox (see the section on Chagas disease) has higher cure rates and a lower risk of mortality. Unfortunately, supplies of eflornithine are limited worldwide, and while effective, it is not used for first-stage disease. Eflornithine-based regimens are not effective for *T. b. rhodesiense* infection.

Melarsoprol (*Arsobal*, Rhone-Poulenc Rorer) is the only effective drug for persons with second-stage HAT (central nervous system involvement) due to *T. b. rhodesiense* (see Table 201.2). It can also be used for second-stage *T. b. gambiense* infection if eflornithine is not available, but it is far more toxic than eflornithine-based regimens. Melarsoprol is administered IV. Untoward effects are common. In

addition to encephalopathy, which occurs in as many as 18% of recipients and is fatal in 3% to 10%, treatment is frequently associated with nausea, vomiting, abdominal pain, peripheral neuropathy, hypertension, allergic reactions, and, rarely, shock. Administration of prednisolone, 1 to 2 mg/kg/d, may reduce the severity of arsenical encephalopathy and the risk of death by approximately half. A number of dosage regimens have been studied. Lower doses of melarsoprol have been used in cachectic patients.

Finally, flexinidazole is recommended by the WHO for treatment of first- and second-stage *T. b. gambiense* disease in endemic areas, but it is neither available nor recommended for use in the US. New therapeutic approaches are needed.

Leishmaniasis (cutaneous, mucosal, disseminated, and visceral)

Leishmaniasis refers to the spectrum of disease caused by 20 *Leishmania* spp. that infect humans and other vertebrate hosts. The three major clinical syndromes include cutaneous, mucosal, and visceral leishmaniasis, but a variety of other presentations, including post–kala-azar dermal leishmaniasis, disseminated cutaneous leishmaniasis, diffuse cutaneous leishmaniasis, and viscerotropic leishmaniasis, have been described. *Leishmania* spp. are transmitted by sand flies in nature. In many areas of the world, leishmaniasis is a zoonosis with dogs, other canines, or rodents serving as reservoirs, and humans become infected when they venture into endemic habitats. An outbreak of canine visceral leishmaniasis has been reported in the United States among foxhounds and some other dogs. Infection seems to occur by dog-to-dog or in utero transmission. There have been no human cases. In some sites such as India, humans are the only reservoir of visceral leishmaniasis. The manifestations of disease depend on interactions between the infecting *Leishmania* sp. and the genetically determined cell-mediated immune responses of its human host (Figures 201.2–201.9).

In persons with cutaneous leishmaniasis, parasites multiply in macrophages at the site of inoculation in the skin and in draining lymph nodes. The morphology of the resulting lesion is variable. Often, a nodule develops, expands, and then ulcerates over a course of weeks. Lesions may be single or multiple. Some have a "pizza-like" appearance with a raised, erythematous, outer border, a central area of red granulation tissue, and a yellowish or brown overlying crust. Others are "volcano-like" or flat and plaque-like. Lesions can persist for months to years but eventually heal, leaving a burn-like scar as evidence of disease. In mucosal leishmaniasis due to *L. (Viannia) braziliensis* and related species in Latin America, mucosal lesions of the nose, oral pharynx, and occasionally adjacent sites develop months to years after the initial skin lesion has healed. Disseminated leishmaniasis due to *L. braziliensis* or *L. amazonensis* infection is associated with 10 to several hundred papules, nodules, or ulcerative skin lesions.

The majority of persons infected with *L. donovani* or *L. infantum* (formerly known as *L. chagasi* in Latin America), are asymptomatic, despite parasitemia in some instances, and have spontaneously resolving infections. In the subset of persons who develop progressive visceral leishmaniasis, known as *kala-azar*, parasites

FIGURE 201.2 (A and B) Brazilian child with advanced visceral leishmaniasis and massive hepatosplenomegaly.

disseminate throughout the reticuloendothelial system. They are found within macrophages in the liver, spleen, bone marrow, lymph nodes, and occasionally other organs. Patients with advanced visceral leishmaniasi typically present with massive splenomegaly,

hepatomegaly, fever, weight loss, constitutional symptoms, and hypergammaglobulinemia. Visceral leishmaniasis emerged in Spain, southern France, and Italy, and later in Brazil, India, Ethiopia, and elsewhere as an opportunistic infection in persons with AIDS. Persons with concurrent visceral leishmaniasis and AIDS may present in the classical manner, but atypical presentations are common. Splenomegaly may be absent, and gastrointestinal and pleuropulmonary involvement are often seen.

The diagnosis of cutaneous or visceral leishmaniasis is suggested by a history of exposure in an endemic region and the clinical findings. It is confirmed by identifying *Leishmania* amastigotes by smear, culture, or molecular tests for DNA, in blood, bone marrow, splenic aspirates, lymph nodes, or other tissue from patients with visceral leishmaniasis or in biopsies of skin or mucosal lesions from those with cutaneous or mucosal leishmaniasis. Anti-leishmanial antibodies are usually present in high titer in persons with visceral leishmaniasis, but may be absent in persons with AIDS. Several assays are available to measure antibodies; an enzyme-linked immunosorbent assay using a recombinant 39-kDa kinesin-like antigen is sensitive and specific for visceral leishmaniasis. Serology is not diagnostic in cutaneous leishmaniasis, as antileishmanial antibodies are variably present and at low titer. The leishmanin (Montenegro) skin test (Figure 201.10) is not approved or available in the United States and has been discontinued in most countries. It is negative in patients with visceral leishmaniasis, but it usually becomes positive after successful treatment. The test is typically positive in persons with cutaneous and mucosal leishmaniasis. Interferon-release assays are under development.

Liposomal amphotericin B (AmBisome, Fugisawa) and miltefosine are approved in the United States for treatment of visceral leishmaniasis. Liposomal amphotericin B is highly effective and the drug of choice in industrialized countries. Its cost and availability have limited its use in some impoverished endemic areas. Other lipid-associated compounds have also been reported to be effective, but they have been less well studied. Amphotericin B deoxycholate is an alternative, but it is more toxic than liposomal amphotericin B.

The emergence of pentavalent antimony resistance in India and adjacent countries and the desire for an oral regimen stimulated the search for new drugs. Miltefosine, a phosphocholine analog that is administered orally, is now FDA-approved for the treatment of visceral leishmaniasis due to *L. donovani* acquired in India and adjacent areas; for cutaneous leishmaniasis due to *L. braziliensis, L. guyanensis,* and *L. panamensis*; and for mucosal leishmaniasis due to *L. braziliensis*. Gastrointestinal side effects are common, but have not prevented the completion of therapy in most patients. Transient elevations of liver enzymes and creatinine have been noted. Miltefosine is embryotoxic and contraindicated during pregnancy and breastfeeding. Women in the reproductive age range must be provided effective birth control. Resistance has been reported.

Sodium sibogluconate (Pentostam) and meglumine antimoniate (Glucantime), both pentavalent antimony compounds, have been used for decades to treat leishmaniasis. Pentostam is available through the CDC Drug Service in the United States. These drugs are dosed on the basis of their pentavalent antimony content; Pentostam contains 100 mg of pentavalent antimony/mL and Glucantime contains 85 mg/mL. Side effects increase with age and include gastrointestinal symptoms, pancreatitis, myalgias, headache, malaise, and cardiac toxicity including sudden death in older people and those receiving higher than recommended doses. Antimony resistance and treatment failures are now common in the Indian subcontinent and some other regions. In areas where pentavalent antimony resistance has not emerged, either Glucantime or Pentostam remain an alternative for the treatment of visceral leishmaniasis.

Relapses of visceral leishmaniasis may occur after treatment with any of the drugs just discussed. Relapses are usually observed within 6 months

FIGURE 201.10 Positive Montenegro test (leishmanin skin test), 50 mm, with central necrosis, in a patient with mucosal leishmaniasis.

of the completion of therapy. Persons who relapse can be treated with a second course of the same drug or an alternative regimen. Liposomal amphotericin B is the treatment of choice in persons with AIDS. Relapses are more common after treatment with other drugs. It is important to optimize antiretroviral therapy. Suppressive anti-leishmanial therapy has also been used in people with AIDS or other severe, immune compromising conditions and more than one relapse, but there have been no controlled trials to ascertain the optimal drug or regimen.

Persons with visceral leishmaniasis in the developing world can be severely wasted when they present, and they can die from secondary bacterial or viral infections. Attention should focus on addressing their nutritional needs as well as treating concurrent bacterial or viral infections with appropriate antimicrobial drugs.

Cutaneous leishmaniasis typically has a self-resolving course. If lesions are small, few in number, cosmetically inconsequential, and not caused by *Leishmania* spp. associated with mucosal disease, they can be followed expectantly, particularly when there is evidence of self-healing. When that is not the case, lesions can be treated topically, provided the infecting *Leishmania* species is not associated with mucosal disease, or systemically. The choice of treatment depends on the infecting *Leishmania* species; the number, location, and size of the skin lesions; and the availability of the therapeutic modality.

Options for local treatment include thermal therapy, cryotherapy for very small lesions, or topical application of paromomycin (15%) in an effective vehicle. Intralesional injections with Pentostam are used for uncomplicated lesions of Old World leishmaniasis in Europe and Asia, but Pentostam is currently available only for systemic administration in the United States.

When skin lesions are large, multiple, cosmetically significant, or caused by *L.* (*V.*) *braziliensis* or related New World species associated with mucosal leishmaniasis, systemic treatment is used. The only oral drug approved by the FDA for treatment of cutaneous leishmaniasis is miltefosine, specifically for *L. braziliensis, L. guyanensis,* and *L. panamensis* infections. Historically, either Pentostam or Glucantime, 20 mg of pentavalent antimony/kg/d, for 20 days was used, but both drugs are associated with substantial toxicity. Oral fluconazole has been effective in some settings, but not all. Fluconazole, 200 mg/d for 6 weeks, was associated with a high response rate in persons with cutaneous leishmaniasis due to *L. major*, but *L. major* infections often heal spontaneously in a matter of weeks to months without treatment. In an observational study in northeastern Brazil, persons with cutaneous leishmaniasis due to *L. braziliensis* responded to high-dose, prolonged fluconazole (8 mg/kg/d for 4–6 weeks) therapy.

Liposomal amphotericin B, or alternatively amphotericin deoxycholate, can be effective in the treatment of cutaneous leishmaniasis, but both are costly and potentially toxic. Pentamidine has activity against *Leishmania* spp., but its side effects, which include severe, life-threatening hypoglycemia and later diabetes mellitus, preclude its use for uncomplicated cutaneous leishmaniasis. Whatever the therapy, cutaneous lesions respond slowly and often take weeks to epithelialize. An atrophic, burn-like scar is often left as evidence of disease.

Persons with mucosal leishmaniasis can be treated initially with liposomal amphotericin B or miltefosine. The latter is FDA approved for treatment of mucosal disease due to *L. braziliensis.* Alternatives include Pentostam or Glucantime, alone or in combination with pentoxifylline in areas where pentavalent antimony resistance is rare; or amphotericin B deoxycholate. Treatment failures and relapses are not unusual in patients with mucosal disease. Plastic surgical repairs should be delayed for 12 months after treatment to ensure clinical cure, Grafts may be lost if relapses occur in the months following surgery.

Intestinal protozoa

M. Paul Kelly

Intestinal protozoal infection produces substantial morbidity and mortality in people of all ages, particularly in tropical and subtropical parts of the world. Amebiasis, giardiasis, cryptosporidiosis, and those infections associated with AIDS are important problems for health in many parts of the world, but some protozoa found in the human digestive system do not cause disease. Vaccines are not yet available for protection against these infections, and many are difficult to treat. The intestinal protozoa that produce important human infections are summarized in Table 202.1. There are differences between protozoa in their impact in patients with AIDS: cryptosporidiosis is an AIDS-defining infection, but neither the incidence nor the severity of amebiasis or giardiasis are affected by HIV.

Entamoeba histolytica

Entamoeba histolytica causes dysentery, chronic colonic amebiasis, and hepatic amebiasis. The last topic is dealt with in Chapter 203, "Extraintestinal amoebic infection." Amebic dysentery is a syndrome of bloody diarrhea caused by invasion of the colonic wall by trophozoites of *E. histolytica*. It is common in many parts of the world, especially West and southern Africa, Central America, and south Asia. In the United States, 3,000 to 4,000 cases are reported each year. There is now consensus that the species formerly recognized as *E. histolytica* in fact comprises two species: *E. histolytica* and *Entamoeba dispar*. The first is the pathogenic protozoan long associated with human invasive disease and with hepatic amebiasis, and the latter is a morphologically identical nonpathogenic protozoan first recognized as the nonpathogenic zymodeme of *E. histolytica*. The latter does not require treatment, but it cannot be differentiated from *E. histolytica* morphologically. Diagnosis of invasive amebiasis is achieved by the identification of hematophagous trophozoites in very fresh stool smears or in colonic biopsies; the latter may also show typical flask-shaped ulcerations. Serologic testing using an immunofluorescent antibody test is now an important contribution to the diagnosis of a seriously ill patient, particularly in distinguishing colonic dilation resulting from amebiasis from that caused by ulcerative colitis. Serology does not distinguish between *E. histolytica* and *E. dispar*. Diagnosis using the polymerase chain reaction (PCR), which detects specific DNA sequences of genetic material, is increasingly available, and it does allow species identification.

Treatment of invasive amebiasis is shown in Table 202.2. Treatment can be divided into two stages: (1) eradication of tissue forms with metronidazole, tinidazole, or nitazoxanide and (2) eradication of luminal carriage with diloxanide furoate. Dehydroemetine and iodoquinol, used formerly for the treatment of amebiasis, are toxic and no longer used.

Intestinal amebiasis may be complicated by acute toxic colitis, presenting in a similar manner to the dilation of acute severe ulcerative colitis. The patient will be febrile and unwell, sometimes with signs of peritoneal irritation, and a plain abdominal radiograph will indicate dilation. Intravenous fluids must be given, the patient kept NPO, and metronidazole and a broad-spectrum antibiotic given intravenously. Worsening dilation of the colon or perforation will necessitate surgery, but, in the event of perforation, the

Stramenopile		*Blastocystis hominis*

outcome is poor. If treatment with metronidazole is started early in patients with severe amebic colitis, medical management should nearly always suffice, but surgery should not be delayed if perforation is impending.

Chronic amebiasis may be difficult to distinguish from intestinal tuberculosis or Crohn's disease but responds to metronidazole and diloxanide as discussed. Surgery is sometimes necessary because stricturing may persist.

Giardia lamblia

Giardia lamblia infection, first recognized by Van Leeuwenhoek in 1681, is a cause of acute and persistent diarrhea and possibly malnutrition in children in many tropical and subtropical countries. It is also a well-recognized cause of travelers' diarrhea. In many cases it is self-limiting, but the course may be prolonged in immunoglobulin deficiencies. Asymptomatic infection is common. Diagnosis is by stool microscopy, although when this is negative and the clinical suspicion is strong, trophozoites may be detected in small intestinal fluid and mucosal biopsy specimens obtained by endoscopy (Figure 202.1). Fecal *Giardia* antigen enzyme-linked immunosorbent assays (ELISA) and PCR are now increasingly used in many routine diagnostic laboratories.

Several drugs are now available for the treatment of giardiasis but none is regarded as safe in pregnancy, and treatment failures are not uncommon, requiring a second and sometimes a third course of therapy. Five classes of chemotherapy are available (Table 202.3): nitroimidazoles (metronidazole and tinidazole), benzimidazoles (albendazole, secnidazole), nitazoxanide, nitrofurans (furazolidone), and paromomycin, which is the treatment of choice in pregnancy because it is not absorbed. If single agents fail repeatedly, combination therapy may be tried, but there are few controlled data to guide drug choice, dose, or duration.

Balantidium coli

Balantidium coli infection manifests as a severe, sometimes life-threatening colitis indistinguishable from amebic dysentery. It is uncommon but occurs in Central and South America, Iran, Papua New Guinea, and the Philippines, usually in communities that live in

TABLE 202.2 **DRUG TREATMENT OF AMEBIASIS**

		Adult dosage	Child dosage
Tissue infection			
First choice	Metronidazole[a]	750 mg TID for 10 d	50 mg/kg/d for 10 d[b]
	Tinidazole[a]	2 g/d for 3 d	60 mg/kg/d for 3 d
Second choice	Nitazoxanide	500 mg BID for 3 d	Age 2–3 years: 100 mg BID; age 4–11 years: 200 mg BID for 3 d
	Paromomycin	30 mg/kg/d for 10 d[b]	30 mg/kg/d for 10 d[b]
Luminal carriage			
First choice	Diloxanide furoate	500 mg TID for 10 d	20 mg/kg/d for 10 d[b]
Second choice	Paromomycin	30 mg/kg/d for 10 d[b]	30 mg/kg/d for 10 d[b]

[a] Must be followed by eradication of luminal carriage.
[b] In three doses.

close proximity to pigs, which are an important reservoir. Diagnosis is made by identification of the large trophozoites in feces or in rectal biopsies. Treatment is with tetracycline, 500 mg four times daily for 10 days (Table 202.4). Metronidazole and paromomycin are alternatives.

Cryptosporidiosis

Infection with *Cryptosporidium parvum* or *C. hominis* is likely to present as acute, self-limiting watery diarrhea in children or in travelers or as a waterborne epidemic. Most episodes require no specific therapy, but attention to fluid and electrolyte balance is important. Cryptosporidiosis is associated with persistent diarrhea, even in apparently immunocompetent children, and, in HIV-infected individuals, it often persists until death. Cryptosporidiosis is also common in malnourished children in the tropics, irrespective of HIV infection. In patients with HIV-related diarrhea, cryptosporidiosis can be found in 10% to 30% of cases in industrialized countries and 10% to 40% of cases in tropical populations. However, since the introduction of highly active antiretroviral therapy (ART) with multidrug regimens, this infection is much less frequent in those regions where ART programs have been scaled up. It remains a significant clinical challenge in patients in the tropics, where patients often present with advanced AIDS or compliance is often poor. Diagnosis is usually made by microscopy of fecal smears using a modified Ziehl–Neelsen stain, which reveals the red-staining 5-μm oocysts(Figure 202.2), but ELISA and PCR tests are being adopted.

Although many drugs have been tried, only two have been shown to have any value in controlled trials: paromomycin and nitazoxanide. Hyperimmune bovine colostrum is a form of passive immunotherapy but is not in clinical use. Paromomycin (30 mg/kg/d in three doses) has been found to be of very limited efficacy. Nitazoxanide (1 g BID for 14 days) has been demonstrated to be effective in children and adults without AIDS in randomized controlled trials. Uncontrolled data from the US compassionate use program indicate that prolonged courses of 500 to 1,500 mg nitazoxanide twice daily can be useful, but meta-analyses do not confirm this. There is still an urgent need for drugs that are effective in the severely immunocompromised host, and new drugs are in development. Interestingly, there is direct evidence that cryptosporidiosis can be prevented by simple measures: intensive hand washing reduced diarrheal disease, including cryptosporidiosis, in American AIDS patients, but to the author's knowledge this finding has not been replicated in a tropical setting.

Cystoisospora belli

Cystoisospora belli is uncommon in industrialized countries but may be found in up to 40% of patients with AIDS-related diarrhea in Africa. In HIV-infected individuals it causes a clinical syndrome of persistent diarrhea and wasting, which is indistinguishable from that attributed to other intracellular enteropathogenic protozoa (cryptosporidiosis, microsporidiosis). There were reports of isosporiasis before HIV infection appeared. Diagnosis rests on the identification in fecal smears of elongated, large sporocysts, which appear red with the modified Ziehl–Neelsen stain.

Trimethoprim-sulfamethoxazole (TMP-SMX) has been reported to be effective at a dosage of 160/800 mg four times daily for 10 days. In patients with AIDS, this needs to be followed with the same drug in a dose of 160/800 mg three times weekly indefinitely as prophylaxis against recurrence. Otherwise, recurrence is seen in 50% of patients with HIV infection at 2 months. An alternative drug is sulfadoxine-pyrimethamine (500/25 mg weekly) as

TABLE 202.3 **DRUG TREATMENT OF GIARDIASIS**

Drug	Adult dosage	Child dosage	Efficacy
Metronidazole	500 mg TID for 3 d	5 mg/kg TID for 10 d (maximum 750 mg/d)	>90%
Tinidazole	2 g single dose	75 mg/kg single dose	>90%
Albendazole	400 mg/d for 5 d		>85%
Nitazoxanide	100–200 mg 2× daily		85%
Furazolidone	100 mg QID for 10 d	2 mg/kg TID for 10 d	>80%
Paromomycin	500 mg 3× daily for 5–10 d		

TABLE 202.4 **TREATMENT OF CILIOPHORA, COCCIDIA, AND MICROSPORIDIA**

Organism	Drug regimen
Ciliophora	
Balantidium coli	Tetracycline, 500 mg QID for 10 d
Coccidia	
Cryptosporidium parvum	Nitazoxanide, 500 mg 2× daily for 3 d
Cystoisospora belli	Trimethoprim–sulfamethoxazole, 1 DS tab PO QID for 10 d; Prophylaxis: 1 DS tab 3×/week (or once daily to aid compliance)
Sarcocystis species	As for *C. belli*
Cyclospora cayetanensis	Trimethoprim-sulfamethoxazole, 1 DS tab PO BID for 7 d
Microsporidia	
Enterocytozoon bieneusi	Fumagillin, 60 mg daily for 14 d
Encephalitozoon intestinalis	Albendazole, 400 mg BID for 14 d
Blastocystis hominis	
	The status of this organism as a pathogen is still the subject of controversy, so it is uncertain whether it requires treatment. It is our practice to attempt eradication with metronidazole, 750 mg TID for 10 d, when there are gastrointestinal symptoms and no other cause is apparent

secondary prophylaxis. Patients intolerant of sulfonamides could be given diclazuril, but only anecdotal evidence of its efficacy is available. In the author's experience it does not respond to nitazoxanide.

Sarcocystis species

Sarcocystis infection, which may give rise to a persistent diarrhea, is treated in the same way as *C. belli*. This infection is very uncommon.

Dientamoeba fragilis

Most infections with *Dientamoeba fragilis* are asymptomatic and do not require treatment. When required, treatment is as for amebiasis.

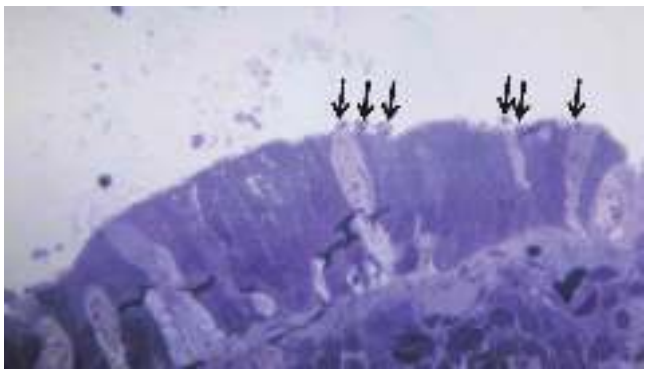

FIGURE 202.2 *Cryptosporidium* sp. trophozoites in small intestinal mucosa of an AIDS patient (semi-thin section stained with toluidine blue).

Cyclospora cayetanensis

Cyclospora cayetanensis causes travelers' diarrhea (especially in travelers to South America and Nepal) and foodborne outbreaks. In fecal smears, the oocysts resemble those of *C. parvum* in taking up carbol fuchsin in the modified Ziehl–Neelsen stain, but the oocysts are larger than *C. parvum* at 8 to 10 μm and they autofluoresce. Eradication is achieved using TMP-SMX (160/800 mg BID) for 7 days. If infection persists, then TMP-SMX should be continued for a further 3 to 5 days. In patients who are intolerant of TMP-SMX, ciprofloxacin can be used but it is less effective.

Microsporidia

Two microsporidia are pathogenic in the human gastrointestinal tract: *Enterocytozoon bieneusi* and *Encephalitozoon intestinalis* (formerly known as *Septata intestinalis*). These organisms have recently been reclassified and are actually fungi, but we consider them here because their clinical manifestations are so similar to intracellular protozoal infections such as cryptosporidiosis and isosporiasis. They are intracellular parasites that generally infect severely immunocompromised individuals. The most common manifestation is a persistent diarrhea associated with weight loss, but a syndrome of sclerosing cholangitis is also described. Diagnosis relies on detection of the parasite in duodenal biopsies obtained at endoscopy (Figure 202.3) or on the finding of the spores in the feces using a variety of stains. *E. intestinalis* may cause a disseminated infection with renal spore excretion.

Treatment of *E. intestinalis* infection is with albendazole, 400 mg twice daily for 1 month, but maintenance treatment may be

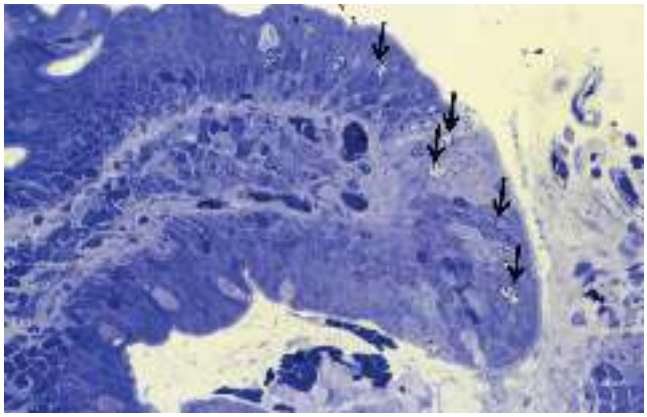

FIGURE 202.3 *Encephalitozoon intestinalis* in a small intestinal biopsy of an AIDS patient (semi-thin section stained with toluidine blue).

needed if relapse occurs following the cessation of therapy, although eradication may be achieved in some patients. *E. bieneusi* infection responds much less well, but fumagillin, 60 mg/d for 14 days, results in symptomatic improvement and parasite clearance in some patients. Fumagillin is toxic.

Extraintestinal amebic infection

Rosa Andrade

Extraintestinal manifestations of invasive amebic disease are less common than amebic colitis, where amebic liver abscesses (ALA) are the most frequent manifestation. ALA arises from hematogenous dissemination of intestinal amebic trophozoites presumably through the portal circulation, and they may present months to years after an episode of amebic colitis.

Other extra-abdominal manifestations, such as thoracic and brain amebiasis, are frequently associated with the direct dissemination of trophozoites from an ALA. They are diagnosed clinically and supported with relevant epidemiologic risks and serologic, antigen-based, or molecular testing. Untreated extraintestinal manifestations are usually fatal. However, outcomes have improved since the introduction of nitroimidazoles, such as metronidazole, as the mainstay treatment for invasive amebiasis.

Amebic liver abscess

Entamoeba histolytica infections are mostly asymptomatic. Only 4% to 10% of infections become symptomatic over the course of a year. An ALA can complicate invasive amebic colitis in approximately 5% of cases. Travelers to the endemic countries are at risk for developing amebiasis and liver disease. Longer stays are associated with increased risk. Of travelers who develop an ALA after leaving an endemic area, 95% do so within 5 months; however, they can occur anywhere from 4 days to 20 years after leaving the endemic area. Therefore, a detailed travel history is essential to assist with the diagnosis.

Adult men are 7 to 10 times more likely to have ALA (often between the ages of 20 and 40) than women. However, this difference is not observed in children. Notably, men who have sex with men are an at-risk population, given their overall increased risk for intestinal amebiasis. Testosterone may explain this increased susceptibility to ALA in men as observed in a mice model of *E. histolytica* infection. In this model, testosterone inhibited the release of interferon-γ from natural killer T cells, which are critical for the control of ALA. Additionally, people with cell-mediated immune defects including chronic steroid users, pregnant women, alcoholics, the malnourished, and those with malignancies may also be at increased risk of invasive amebiasis.

The clinical presentation of ALA is characterized by fever and right upper quadrant pain as the most frequent complaints and the most consistent findings on examination (Table 203.1).

The duration of disease influences the symptoms, as patients with symptoms for >2 weeks tend to be afebrile and have weight loss and more focal abdominal pain. The classic finding of point tenderness in the right upper quadrant or intercostal tenderness has been frequently noted in earlier literature but is likely neither sensitive nor specific.

Young patients with an ALA are more likely than older patients to present in the acute phase with prominent symptoms of <10 days duration. Older patients from endemic areas are more likely to have a subacute course lasting 6 months, with weight loss and hepatomegaly.

Most ALA are solitary lesions, and approximately 80% are found in the right lobe of the liver, thus explaining the location of the pain. The pain may also occur in the epigastrium, right lower chest, or the

TABLE 203.1 **CLINICAL FINDINGS FOR PATIENTS WITH AMEBIC LIVER ABSCESS**

Clinical findings	%
Fever	85–90
Right upper quadrant pain	84–90
Hepatomegaly	30–50
Weight loss	33–50
Diarrhea	20–33
Cough	10–30
WBC count >12,000/μL	80
Elevated level of alkaline phosphatase	70

WBC, white blood cell.
From Petri and Singh. Diagnosis and management of amebiasis. *Clin Infect Dis*. 1999; 29:1117–1125.

right shoulder tip (referred pain). Left-sided abdominal pain, corresponding to an abscess in the left lobe of the liver, is less common. Localized swelling or generalized hepatomegaly may be noted on exam depending on the size and location of the abscess or abscesses. Abscesses high in the right lobe of the liver may not result in hepatomegaly but, if of significant size, can lead to elevation of the right hemidiaphragm, which is evident on a chest radiograph.

Laboratory findings in a patient with amebic liver disease include leukocytosis (white blood cell [WBC] count >12 000/mm^3), an elevated alkaline phosphatase, and, occasionally, elevated transaminases. It is uncommon to see an elevated bilirubin, and thus jaundice in a febrile patient with right upper quadrant pain should point the clinician toward another diagnosis. A mild degree of anemia (anemia of chronic disease) is present in many cases, particularly with symptoms for >2 weeks. Peripheral eosinophilia is rare and should suggest an alternative parasitic infection such as echinococcosis and hepatic fascioliasis (liver fluke).

Diagnosis

Most cases of extraintestinal amebiasis occur in the absence of active amebic colitis. Their diagnosis relies in a combination of appropriate clinical symptoms, epidemiologic risk factors, characteristic imaging findings, positive serologic, antigen detection, or molecular testing.

Serologic testing for antibodies to *E. histolytica* is >80% sensitive in disease of >1 week duration and nearly 99% sensitive in recovering patients. A negative test essentially rules out the diagnosis except in early infection (≤1 week). It is important to use an enzyme immunoassay (EIA) or agar gel dilution to test serology as an indirect hemagglutination often remains positive for years at high titer, and residents of an endemic region may have positive antibodies to *E. histolytica* that do not represent acute disease. Serum antigen detection tests for the *E. histolytica* Gal/GalNAc lectin gave a positive result in >95% of patients with ALA in a study of Bangladeshi patients before treatment, comparing favorably to currently available serum antibody tests. Importantly, after treatment with metronidazole, circulating antigen levels were rarely detected (15%), making the test potentially useful for the diagnosis of acute disease in endemic countries. Molecular diagnosis using polymerase chain reaction (PCR) assays are highly sensitive and specific for ALA. They are currently part of multiplex PCR assays for multiple enteric pathogens, but this test remains expensive and depends on skilled laboratory personnel.

Diagnostic aspiration of an ALA is seldom needed. However, it is indicated to rule out a pyogenic liver abscess or in those at high risk for abscess rupture. Patients at high risk of abscess rupture have an abscess cavity with a diameter >5 cm or one located in the left lobe, which could rupture into the pericardium. The classic amebic pus resembles "anchovy paste" or "chocolate sauce" which refers to the thick, acellular, proteinaceous debris consisting of necrotic hepatocytes and a few polymorphonuclear cells obtained by successful aspiration. Amebic trophozoites are magenta-colored by periodic acid-Schiff staining, making them easy to visualize, but finding trophozoites in an aspirate only occurs in 20% to 30% of cases, with a higher yield from the edge of the abscess.

Several imaging modalities that detect a space-occupying lesion in the liver support the diagnosis of ALA in the presence of a positive amebic serology. Imaging frequently demonstrates a single round or oval, homogeneous, hypoechoic lesion. Low-attenuation lesions with septations or an observable fluid level or debris may also be seen (see Figures 203.1 and 203.2). Chest radiographs in approximately 50% of patients with ALA demonstrate an elevated right hemidiaphragm or other abnormality such as discoid atelectasis. Ultrasonography, computer tomography (CT)scanning, and magnetic resonance imaging (MRI) are all quite sensitive, but none are specific because they cannot distinguish an ALA from a pyogenic abscess.

The differential diagnosis of ALA includes pyogenic abscess; hepatocellular carcinoma, especially with necrosis; and echinococcal cyst. On imaging, the differential can often be narrowed to pyogenic abscess versus amebic liver abscess, with the clinical and radiographic findings being largely indistinguishable. Some epidemiologic differences may help to increase the likelihood of pyogenic liver abscess: age >50 years old, no sex predominance, underlying diabetes mellitus, biliary disease, and lack of travel to an endemic country. Nevertheless, these clues do not rule out amebic liver abscess, especially in a patient living in an endemic region.

Treatment

Nitroimidazoles, such as metronidazole and tinidazole, are the mainstay of treatment for invasive amebiasis worldwide due to their effectiveness in affected tissue. Metronidazole is effective in a dose of 750 mg three times daily for 7 to 10 days for adults, and 35 to 50 mg/kg/d in three doses for 7 to 10 days for children (Table 203.2).

Metronidazole is generally well-tolerated, but the disulfiram-like reaction to alcohol is important to mention to patients. Minor side effects such as nausea, vomiting, anorexia, and a metallic taste

FIGURE 203.1 Contrast CT scan image of an amebic liver abscess. The abscess appears as a hypoattenuating mass within the right lobe of the liver with an irregular, multiseptated rim with a thin rim of surrounding edema.

occur more frequently than rare neurologic adverse effects such as vertigo, seizures, and encephalopathy. The drug should be discontinued if these latter effects or, rarely, neutropenia occur. Long-term use of metronidazole is also known to cause peripheral neuropathy.

FIGURE 203.2 Ultrasound of the same amebic liver abscess as Figure 203.1

However, the short duration of amebiasis treatment precludes this adverse event.

Tinidazole, a newer nitroimidazole compound, is also effective for the treatment of ALA. It has a longer half-life and is better tolerated, allowing for a shorter treatment course. The recommended dose of tinidazole for amebic liver abscess is 2 g/d for 3 to 5 days in adults and 50 mg/kg/d for 3 to 5 days in children.

The nitroimidazoles remain >90% effective treating amebic liver abscess, and no clinical cases of metronidazole-resistant amebiasis have been documented to date. Treatment with these agents typically results in defervescence, decreased abdominal pain, and normalization of the WBC count within 3 days.

Ultrasonographic or CT-guided aspiration of amebic liver abscesses is typically reserved for patients not responding to 3 to 5 days of medical therapy with persistent fever or pain, imminent rupture of an abscess >5 cm, or a left lobe abscess that may rupture into the pericardium.

All treatment regimens with a tissue amebicide should be followed by treatment with a luminal amebicide to eliminate intestinal carriage of the organism that could lead to relapse if not treated.

In the United States, treatment for 7 days with paromomycin, a nonabsorbable aminoglycoside, is the preferred luminal amebicide. It is safe in pregnancy, has minimal gastrointestinal side effects, and ototoxicity and nephrotoxicity rarely occur. Diloxanide furoate is also effective and well-tolerated and has few side effects but is not commercially available in the United States. Iodoquinol is likewise effective but has some serious side effects such as optic neuritis and peripheral neuropathy and requires a 20-day course. Nitazoxanide, a 5-nitrothiazolyl derivative, is active against *E. histolytica in vitro* and *in vivo* as suggested in a double-blind, placebo-controlled trial; however, it has not been directly compared to the standard luminal amebicides already mentioned.

The usual response to medical therapy of an ALA is a rapid resolution of fever and pain. There is no reason for follow-up ultrasound early in the course as lesions may enlarge acutely, but they ultimately resolve entirely within a year. Serology by EIA typically reverts to negative within 6 months.

Amebic extra-abdominal invasive disease

Pulmonary amebiasis

Other extra-abdominal manifestations such as thoracic and brain involvement are frequently associated with direct dissemination from an amebic liver abscess. The amebic intrathoracic disease is the leading extra-abdominal manifestation that occurs in approximately 10% of ALA patients. Depending on the ALA location, amebic intrathoracic disease can present as empyema, bronco-hepatic fistulas, or extension of pleuropulmonary abscesses into the pericardium. This latter presentation has a 15% to 20% mortality after the ALA ruptures through the diaphragm.

Pulmonary amebiasis may develop as a serous, sympathetic effusion in the right pleural cavity due to a right-sided liver abscess.

TABLE 203.2 **DRUG TREATMENT OF AMEBIC LIVER ABSCESS**[a]

Drug of choice	Adult dose	Pediatric dose	Side effects
Metronidazole	750 mg IV/PO TID × 7–10 d	35–50 mg/kg/d in 3 doses × 7–10 d	Common: nausea, vomiting, metallic taste Occasional: peripheral neuropathy, vertigo, seizures, encephalopathy Disulfiram effect: nausea, vomiting with alcohol ingestion
Tinidazole[b]	2 g IV/PO qd × 5 d	60 mg/kg/d (maximum 2 g) × 5 d	Similar side effect profile as metronidazole: better tolerated with less nausea and vomiting

[a] All treatments should be followed by luminal amebicidal agent, described in text and detailed in Chapter 202, "Intestinal protozoa."
[b] Used only as alternative to metronidazole.

Rupture of a liver abscess into the chest cavity can lead to empyema, producing signs such as cough, dyspnea, and pleuritic chest pain. Thoracentesis will reveal the classic anchovy paste fluid described in ALA aspirations. Classically, patients who develop bronchopleural fistula will expectorate the contents of the liver abscess. Although unpleasant, before the availability of amebicidal agents, this occurrence was deemed a good prognostic sign, as it was an effective means of draining the abscess. In addition, hematogenous spread of amebic trophozoites can rarely cause disease in the lung parenchyma, leading to consolidation and sometimes lung abscess. Treatment of pleuropulmonary disease involves using a tissue amebicide, such as metronidazole, and, in the case of empyema, drainage with a chest tube. Amebic pneumonia and lung abscesses from hematogenous spread are successfully treated with metronidazole alone.

Amebic pericarditis

The second most common intrathoracic manifestation of invasive amebiasis is pericarditis (1–3% of patients with ALA), which has a 40% mortality. It is the most serious complication of a left-lobe ALA which ruptures into the pericardium leading to pericarditis and, potentially, cardiac tamponade. A left-lobe liver abscess threatening the pericardial sac may cause irritation and a serous effusion. The rapidity of the amebic pus leakage into the pericardial sac determines both the signs and symptoms that develop. A slow leak gives more insidious symptoms of gradually increasing shortness of breath, unmitigated fever, and patient deterioration. In contrast, a rapid rupture into the pericardium may cause cardiac tamponade and the associated chest pain, tachypnea, pulsus paradoxus, elevated neck veins, and hypotension.

The evaluation of amebic pericarditis begins with establishing the diagnosis of invasive amebic infection with positive serologic testing in a patient with left-lobe liver abscess and a compatible epidemiologic history. An electrocardiogram will show evidence of pericarditis, and chest radiography demonstrates an elevated and immobile left diaphragm. Confirming the diagnosis is only definitively accomplished by aspiration of the pericardium, which, along with effective tissue amebicides, is the treatment of choice. A concomitant large liver abscess should also be aspirated and repeat aspirations performed if needed to eliminate the risk of further pericardial accumulation. Fibrous constriction is unusual after the just described treatment, and surgical treatment is unnecessary in most cases.

Amebic peritonitis

In about 2% of patients with ALA, intraperitoneal abscess and peritonitis complicate the case. The associated physical exam findings of an acute abdomen are usually present. Compared to amebic peritonitis due to perforation of the colon from amebic colitis, patients with ruptured liver abscesses and peritonitis have better outcomes because there is not concomitant colonic bacterial flora contaminating the peritoneum. Treatment of amebic peritonitis due to liver abscess rupture requires metronidazole and therapeutic paracentesis to drain infected collections.

Amebic brain abscess

Approximately 0.66% to 4.7% of patients with ALA may develop an amebic brain abscess. Untreated, an amebic brain abscess has a high mortality rate (90%). Amebic brain abscesses have been described in the frontal, parietal, temporal, and occipital lobes and the cerebellum. Typically, a patient with an amebic brain abscess can present with unspecific symptoms: headache, vomiting, and altered mental status. Signs of amebic brain abscess included most commonly meningeal signs, facial nerve (VII) palsy, motor paralysis, and seizure. Most patients had abnormal cerebrospinal fluid, although there was no distinctive or characteristic abnormality. CT scanning of the head often reveals multiple space-occupying lesions, which may be circumscribed areas of low-attenuation without a clear rim or enhancement early in the course of disease. Treatment involves a prolonged course of metronidazole, which has good central nervous system penetration, and possibly surgical drainage depending on the size of the lesion(s) and severity of the symptoms.

Other manifestations of invasive amebic disease

Amebic splenic abscesses, resulting from the hematogenous spread of amebic trophozoites, can be visualized with ultrasound or CT scan and treated medically with metronidazole. Splenectomy is occasionally required.

Urinary tract amebiasis, manifesting as perinephric abscesses, is again due to the hematogenous spread of amebic trophozoites and is treated with metronidazole. Genital amebiasis is more common in women than men, with vaginitis, vulvovaginal amebiasis, cervicitis, and salpingitis all having been reported. These cases may be sexually transmitted; consequently, ulcerative penile lesions in a sexual partner should be evaluated for possible amebiasis. Invasive carcinoma of the penis and carcinoma of the cervix are often initially suspected because the clinical appearance of amebic ulcerative lesions mimics those of these malignancies. An epidemiologic study in Japan found a link between genital amebiasis and men who have sex with men engaging in anal sex with partners with amebic colitis. The treatment for these manifestations of the disease is again with metronidazole, and sexual partners should always be treated as well. Finally, cases of cutaneous amebiasis, presenting as painful ulcers in both children and adults, have also been described in the literature. These presentations are often, but not always, associated with intestinal amebiasis and respond to metronidazole.

Section 25

Antimicrobial therapy: General considerations

Principles of antibiotic therapy

John S. Czachor

Over the past three to four decades, there has been a disturbing trend of antibiotic resistance among a wide variety of pathogens that are causing serious disease in patients residing in the community, in long-term care facilities, and in hospitals. The lines of acquisition, however, have begun to blur with increasingly less separation between nosocomial and community settings. Multidrug resistance has become an everyday occurrence, so much so that both the US Centers for Disease Control and Prevention (CDC) and the World Health Organization (WHO) have instituted antibiotic risk notifications and grading systems ranking the severity of various threats to our health (https://www.cdc.gov/drugresistance/biggest_threats.html https://www.who.int/news-room/detail/27-02-2017-who-publishes-list-of-bacteria-for-which-new-antibiotics-are-urgently-needed). Antibiotic drug-resistant microorganisms are now a global problem, made worse by the ease of travel and transmission of these microbes. The advent of medical tourism adds an unintended complication to this scenario as well.

The pharmaceutical industry has responded to this grave concern, although there has been an overall decline in the number of new antibiotics introduced compared to the past decade. A number of compelling reasons have been given for this situation, including fewer pharmaceutical companies, the costly vetting/research process of bringing a drug to market, the perceived lower profitability of antimicrobial agents, and the relative delayed initial use of a new product. In any instance, the need for newer and more effective antibiotics has become essential for the future, and there does seem to be an uptick in the numbers of agents approved for use. New classes of antimicrobial agents—and finding different uses for recognized antibiotics, such as aerosolized amikacin—have augmented our choices.

Another event that has merited attention is the continuously evolving novel indications for antibiotics for both infectious and noninfectious disorders. The newer macrolides have anti-inflammatory properties that allow them to be used, for example, in cystic fibrosis. The use of ampicillin combined with ceftriaxone is now the benchmark to treat infective endocarditis caused by *Enterococcus faecalis* infections with high-level resistance to aminoglycosides. Finally, there are a number of antimicrobial compounds that are prescribed for nonbacterial dermatologic conditions, such as dapsone for dermatitis herpetiformis.

When selecting an antibiotic, the clinician must reflect on a variety of issues. Some of the more common factors that merit consideration include the patient's drug allergy history, the relative safety of the medication, the potential of the antibiotic to cause a significant drug–drug interaction, the mechanism of the drug's elimination from the body, the agent's historical "track record" in the therapy of the specific infection being treated, the route of administration of the antibiotic, and, finally, the cost of the medication. With oral administration of antibiotics there are the additional concerns of patient compliance and adequate drug absorption.

Pharmacokinetics and pharmacodynamics

The term "pharmacokinetics" refers to the disposition of an antibiotic throughout the human body. This encompasses such principles as absorption, bioavailability, distribution, protein binding, metabolism, and

elimination. "Pharmacodynamics" refines the concept of pharmacokinetics by describing the interaction between the concentration of the antibiotic at the site of the infection over time and its subsequent effect on the infection itself. Pharmacodynamics is useful for establishing optimum dosing regimens. The absorption of most oral antibiotics occurs by passive diffusion in the small intestine. Some antibiotics, including vancomycin, aminoglycosides, and aztreonam, are not adequately absorbed when given orally. On occasion, this can be advantageous. Oral neomycin can be prescribed as a preoperative preparation prior to large bowel surgery or in the treatment of hepatic encephalopathy, whereas the poorly absorbed oral vancomycin and fidaxomicin are used for the therapy of *Clostridium difficile*-related colitis. Other drugs, such as cefpodoxime proxetil and cefuroxime axetil, are administered as prodrugs to facilitate absorption. Food interferes with the absorption of some antimicrobials (e.g., penicillin, ampicillin, cephalexin, tetracycline, and azithromycin).

A fundamental tenet of antimicrobial activity is that it must achieve therapeutic concentrations at the tissue source of the infection. Multiple factors influence the distribution of antibiotics from plasma to these sites: the nature of the capillary bed (those fenestrated by small pores vs. those unfenestrated capillaries of the brain, leptomeninges, and vitreous humor), the agent's lipid solubility and degree of protein binding (as only unbound drug is antibacterially active and capable of diffusing across capillaries), and the presence of active transport pumps (located in the choroid plexus of the brain, retina, kidneys, and biliary ducts).

Antibacterial agents are eliminated from the body through hepatic and biliary excretion (ceftriaxone and piperacillin), hepatic metabolism (clindamycin, chloramphenicol, metronidazole, erythromycin, sulfonamides, some tetracyclines, isoniazid, rifampin, linezolid), and predominantly renal excretion (most penicillins and cephalosporins, imipenem, aminoglycosides, nitrofurantoin, most tetracyclines, vancomycin, trimethoprim-sulfamethoxazole [TMP-SMX], daptomycin). It is essential that the clinician be aware of renal compromise from congestive heart failure, hypertension, diabetes, medication, and physiologic alteration with age because this will mandate a dosage reduction for those compounds predominantly eliminated by renal excretion. The estimated glomerular filtration rate (GFR; using the Cockroft–Gault equation or the Modification of Diet in Renal Disease [MDRD] equation) has traditionally been used to help determine appropriate drug doses for antimicrobials eliminated primarily by renal excretion when the measured creatinine clearance is not available. A newer formula, the Chronic Kidney Disease Epidemiology Collaboration (CKD-EPI), may be the best to estimate GFR.

Concentration-dependent antimicrobial agents function such that optimal bacterial killing occurs while the concentration of the antibiotic is above the minimum inhibitory concentration (MIC) of the organism. The aminoglycosides are one example of this type and are usually administered as once-daily dosing (unless prescribed for synergistic purposes), taking advantage of the observation that the ratio of the maximum peak drug concentration to organism MIC (8 to 12) correlates with clinical response. Other concentration-dependent antimicrobials include fluoroquinolones, daptomycin, and metronidazole. Alternatively, those compounds that are concentration-independent or time-dependent measure their success by the percentage of time the drug concentration exceeds the MIC of an organism. Drugs in this class include vancomycin, clindamycin, the macrolides, and the β-lactam group. There may be some benefit for continuous intravenous administration of the β-lactam antibiotics, thereby maintaining sustained drug levels above the MIC of the pathogen, particularly in the severely ill or immunocompromised patient.

The postantibiotic effect (PAE) is another pharmacodynamic concept that may impact antimicrobial choice. This refers to the persistent suppression of bacterial regrowth following limited exposure to an antibiotic and can be considered the time it takes for the organism to recover from this exposure. Classically, drugs that affect protein synthesis or nucleic acid synthesis, such as the fluoroquinolones, aminoglycosides, tetracyclines, macrolides, chloramphenicol, and rifampin, have significant PAEs against gram-negative organisms, although the only β-lactam antibiotics that share this property are the carbapenems.

Selection of therapy

Table 204.1 delineates some of the more important host and drug features that influence antibiotic selection. Additional concerns

TABLE 204.1 **SELECTION OF THERAPY**

Host factor	Special antibiotic concern
Drug allergy	Safety record
Site of infection	Success record
Pregnancy	Most likely organism(s) and susceptibility
Epidemiologic information	
Renal function	Bactericidal/bacteriostatic
Recent antibiotic exposure	Penetration into privileged sites (CNS, endocardium)
Infection acquisition (community/ECF/hospital)	Potential to cause major untoward event
Concomitant medication

- -Febrile, severely neutropenic host
- -Polymicrobic infection
- -Life-threatening infection with inapparent source

relate to adherence to the therapeutic regimen and cost of the medication. Antibiotics that can be administered infrequently lend themselves to out-of-hospital administration. Daptomycin, ertapenem, telavancin, and ceftriaxone can usually be infused as infrequently as once a day. Both dalbavancin and oritavancin have prolonged half-lives which offer unique one-time dosing. The development of newer oral antimicrobial agents that can be given as infrequently as once or twice per day achieves enhanced compliance. Compounds such as the fluoroquinolones, metronidazole, and linezolid/tedizolid have excellent absorption, resulting in high serum levels without the need for intravenous administration. Some medications, although still available, including chloramphenicol and erythromycin estolate, are infrequently prescribed, having fallen out of favor due to adverse effects, unfavorable pharmacokinetics and/or pharmacodynamics, or a limited spectrum of activity.

Antibiotic combinations are sometimes used to manage selected infections (Box 204.1). There are potential disadvantages, however, to the administration of antibiotic combinations, such as increased untoward events, heightened costs, and superinfection.

Practice guidelines and antibiotic stewardship

In the past, with few exceptions, choosing an antibiotic has been left to the whims of clinicians. Seldom has the optimal duration of antibacterial treatment been defined by evidence-based medicine. Practice guidelines have emerged in response to questions regarding the quality, consistency, and expense of medical care. Guidelines are generally created based on the best available scientific evidence melded with expert opinion and cohesively assembled in a usable format for practitioners. Selected medical societies and organizations, as well as easily accessible websites, have become the repositories for the recommended information. Access to these guidelines has helped to transform how medicine is practiced today. Guidelines for various infectious conditions already exist, whereas others are being created and refined.

Just as important as the guidelines has been the recognition of the need for optimal, cost-effective, and rational use of antibiotics. Stewardship has evolved from guidelines to encompass antimicrobial utilization for all conditions and can be found in hospitals, long-term care facilities, long-term acute care facilities, ambulatory surgical centers, dialysis centers, and other medical settings. Institutions employing stewardship are coordinating interventions, often in conjunction with pharmacy assistance, to promote appropriate antibiotic selection as well as their proper dose, duration, and route of administration. Benefits of antibiotic stewardship include improved clinical outcomes, reduced medical costs, fewer toxic and adverse effects, and decreased selection of antibiotic-resistant microorganisms.

Antibiotics and the human microbiome

Recently, we have begun to unravel the mystery and the science behind the human microbiome. Our own innate microorganisms help us in so many ways, and yet, with antibiotic use, we alter their function and composition. This change in these microbes, known as *dysbiosis*, has far-reaching effects beyond the immediate concerns of antibiotic-associated diarrhea, *Clostridium difficile* colitis, and establishing a reservoir for antibiotic resistance. In fact, the effects of antibiotic therapy on the microbes within the gut may persist for a longer time than previously appreciated, perhaps even months to years. Increased susceptibility to infections; a link to atopic, inflammatory, and autoimmune diseases; and effects on the regulation of host metabolism, energy homeostasis, and adiposity, all have been associated with dysbiosis. The role of dysbiosis affecting chronic inflammation is being delineated as well. *Probiotics* have been seen by many as a restorative option once antibiotics have been prescribed. It is unclear, however, which preparation and/or composition of probiotic provides the best replenishment for the gut microbiota. A greater understanding and appreciation of the effects of antibiotics on the human microbiome is essential knowledge if we are to use antibiotics appropriately and wisely.

Special populations

The pregnant patient, the lactating patient, and those of reproductive potential

Physiologic changes in the urinary tract and complications of parturition predispose the pregnant woman to urinary tract infections as well as chorioamnionitis and endometritis. Antibiotic selection for the pregnant woman must take into consideration the potential for drug-induced toxicities for both the woman and her developing fetus. Antibiotics were traditionally classified based on animal studies and epidemiologic data often generated from pregnant women who were exposed to antibacterial agents because of clinical need. The antibiotics were then assigned a letter from A to D or X to quantify their relative risk. On the horizon, however, is

the soon to be introduced regulation from the US Food and Drug Administration (FDA) that fundamentally changes how we address pregnancy and antimicrobial concerns. Referred to as the Pregnancy and Lactation Labeling Rule (PLLR), the intent is to provide prescribers clear and in-depth information on the risks and benefits of a drug administered either during pregnancy or lactation. Gone is the old alphabet system, which will be replaced by risk summary information from the manufacturer regarding the specific antibiotic's effects on pregnancy, lactation, and potential untoward effects on females and males of reproductive potential. For further information, visit https://www.fda.gov/downloads/Drugs/GuidanceComplianceRegulatoryInformation/Guidances/UCM425398.pdf.

The elderly patient

A number of factors distinguish the administration of antibiotics in elderly patients: concern about compliance with the medication because of poor memory, impaired vision, diminished hearing, or difficulty in opening child-resistant containers; the decrease of renal function with normal aging and the need to make appropriate dosage adjustment of medications to prevent antibiotic-related toxicities; the potential for drug–drug interactions because many geriatric patients take numerous medications daily; and the presence of concomitant medical disorders that can adversely influence antibiotic distribution and penetration. Elderly patients appear to experience adverse drug reactions from antibacterial compounds more frequently than do younger patients. Older patients with comorbid conditions often may be excluded from clinical trials, and therefore evidence coming from these studies may only be partly applicable to this particular group. As the elderly are more frequently admitted to the hospital, many times with an infection, antibiotic use follows. With many preexisting medications in place, the risk of potentially dangerous pharmacological interactions involving antimicrobial agents is among the most frequent and undesirable consequences of polypharmacy in older persons.

Antibiotic use in continuous renal replacement therapy

For critically ill patients with infection, acute renal insufficiency often develops. Acute renal failure is associated with increased morbidity and mortality in patients with sepsis. Continuous renal replacement therapy (CRRT), an alternative to traditional hemodialysis and better tolerated by hemodynamically unstable patients, decreases the incidence of adverse biomarkers. Appropriate dosing of antimicrobial agents for patients receiving CRRT remains poorly defined as the pharmacokinetics of drug removal in critically ill patients undergoing CRRT is complex. Those antibiotics with low protein-binding capacity and/or poor tissue penetration have enhanced removal. Mechanical or operational factors associated with CRRT play a role in antibiotic therapy in these patients as well, and increasing the blood flow or dialysate flow rate of CRRT may increase drug clearance. However, recent consensus is that using the CRRT modality, whether it be convective or diffusive, does not affect patient infectious outcomes. A more important variable is the effluent flow rate, which, when kept within the Kidney Disease: Improving Global Outcomes (KDIGO) guidelines, results in a target goal attainment of antibiotic levels. Tables 204.2 and 204.3 list antibiotic dose alterations for patients with CRRT.

TABLE 204.2 **DRUGS NOT REQUIRING DOSAGE ALTERATION DURING CONTINUOUS RENAL REPLACEMENT THERAPIES**

Aztreonam	Linezolid
Azithromycin	Meropenem
Cefepime	Metronidazole
Ceftriaxone	Moxifloxacin
Clindamycin	Oxacillin
Doxycycline	Quinupristin-dalfopristin
Imipenem	Rifampin

Route of administration

Antibiotics are administered intravenously when the patient has systemic perfusion issues (septic shock, hypotension), has bacterial infection at a unique or protected site (e.g., leptomeninges, endocardium, a deep neck infection, epiglottitis, endophthalmitis, myopericarditis, mediastinitis, septic thrombophlebitis), has an infection that is imminently life-endangering (e.g., meningococcemia, Rocky Mountain spotted fever, plague, bacteremia), has an infection that precludes oral administration because of nausea/vomiting or impaired function of the gastrointestinal tract (peritonitis, appendicitis, ascending cholangitis, pancreatic abscess), or has an infection that cannot be managed with an oral compound. Traditionally, physicians have prescribed an intravenous antibiotic simply because

TABLE 204.3 **DRUGS REQUIRING DOSAGE ALTERATION DURING CONTINUOUS RENAL REPLACEMENT THERAPIES (CRRT)**[a]

Amikacin	Penicillin
Ampicillin/sulbactam	Piperacillin
Cefazolin	Piperacillin-tazobactam
Ciprofloxacin	Ticarcillin-clavulanate
Daptomycin	Tobramycin
Gentamicin	TMP-SMX
Levofloxacin	Vancomycin

[a] Dose reduction as compared to normal renal function.

a patient was admitted to the hospital. However, the decision to hospitalize a patient does not automatically dictate that the antibacterial therapy must be administered intravenously. Unless one of the indications previously listed is present, some serious infections can be successfully managed by oral antibiotics.

Adverse reactions

Antibiotic-induced untoward events are a concern not only because they result in host injury but also because these adverse events interrupt and complicate treatment, thereby requiring the administration of alternative and often more expensive and potentially toxic medication. Antibiotic-induced untoward events can also serve as a source of medical litigation.

Adverse events attributed to antibiotics are usually caused by three mechanisms: exaggerated response to the known pharmacologic effects of the drug, immunologic reactions to the drug or its metabolites, and toxic effects of the medication or its metabolites. Many of the antibiotic-related adverse events are initiated by an extension of the drug's normal pharmacology, and these events are often avoided by appropriate dosage adjustment.

In addition to the direct influence of the antibiotic, host factors such as genetic constitution, integrity of drug elimination mechanisms, and concomitant medical disorders can affect the frequency and severity of antibiotic-induced untoward events. For example, with HIV-infected patients, TMP-SMX causes more non–dose-related gastrointestinal intolerance, fever, and altered liver function, while ampicillin-induced rash is more common in those patients with infectious mononucleosis.

Antibiotic allergy

Antibiotic-induced allergic reactions are immunologically mediated and most commonly involve the skin, presenting as pruritus, a maculopapular eruption, or urticaria. More significant antibiotic-induced allergic reactions include erythema multiforme major (Stevens–Johnson syndrome), toxic epidermal necrolysis, exfoliative dermatitis, angioedema, and anaphylaxis. Antibiotic-induced allergic reactions are not confined to the skin: bone marrow suppression of all three cell lines, pulmonary hypersensitivity reactions, renal and liver manifestations, and muscle involvement have been routinely documented.

Among the most feared allergic reactions to penicillins and cephalosporins are angioedema and anaphylaxis. These events are usually attributed to drug-specific immunoglobulin E (IgE) antibodies from prior drug administration, but these serious untoward events can also result from direct release of mast-cell mediators following the first dose of antibiotic. Vancomycin and fluoroquinolones can also cause direct mast cell release in the absence of drug-specific IgE antibodies. Skin testing has been very accurate in identifying penicillin-related IgE antibodies and for determining the risk for patients experiencing an immediate reaction (see Chapter 210, "Hypersensitivity to antibiotics").

There is room for discussion regarding penicillin allergy. Frequently, patients are unaware of the exact manifestation of this problem. Perhaps it occurred as a child, and there is nobody to historically confirm the allergy, nor is there allergy testing as an option to verify the allergy. Many times, the patient cannot recall the untoward effect. The question for the clinician is whether a β-lactam class drug may be safely administered. Studies addressing this concern have consistently shown that true penicillin allergy is uncommon based on allergy testing, but the conundrum presented is what to do if no such testing is available? The percentage of cross-reactivity to other -lactam antibiotics has been slowly reduced over time. For cephalosporins, rates of cross-reactivity are approximately 1% to 2%, and the risk lessens as the compounds go from first-generation to fourth-generation. Although structurally similar to the β-lactam antibiotics, aztreonam can be safely administered to patients who have experienced an anaphylactic reaction following the administration of a member of the penicillin family. In the past, it was considered potentially harmful to administer a carbapenem to patients with a history of immediate hypersensitivity to penicillin, though recent investigations and experience suggest that the allergic crossover is approximately 1%. There always remain useful desensitization protocols for those who are in dire need of penicillin or β-lactam class antibiotics but who have immediate hypersensitivity reactions. It is noteworthy to remember, however, that any drug desensitization can be complicated by severe allergic reactions.

Drug monitoring

Monitoring the adequacy of antibiotic treatment involves the physician critically assessing the patient's response on a regular basis, as determined by the resolution of both the systemic and local inflammatory response and, in part, measured by results obtained from laboratory studies, microbiology data, and radiologic exams. In general, antibiotic concentrations in blood are not routinely measured. Aminoglycoside antibiotics are an exception, however, because serum concentrations of these compounds are performed to ostensibly reduce the risk of nephrotoxicity and ototoxicity and ensure appropriate therapeutic levels. Better outcomes for treating patients with gram-negative bacteremia are noted if peak levels of gentamicin and tobramycin exceed 5 μg/mL, and peak amikacin concentrations exceed 20 μg/mL. Avoiding elevated aminoglycoside levels may result in decreased ototoxic and nephrotoxic effects. Serial audiometric testing to assess ototoxicity should be considered for those patients receiving long-term administration of aminoglycosides and vancomycin. Some practitioners also measure vancomycin troughs to assist their choice of dosage interval and drug amount, and appropriate levels may reduce the incidence of ototoxicity. Some antifungals agents, in particular the azole class, often require serum level monitoring to ensure optimum concentrations of the drug for good outcomes.

Outpatient parenteral antibiotic therapy

Outpatient parenteral antibiotic therapy (OPAT) is designed either to avoid hospitalization or to continue treatment initiated in the hospital and provide therapy that is therapeutically equivalent to the inpatient setting while enhancing the patient's quality of life and achieving significant cost savings. The decision to initiate OPAT is influenced by the availability of an adequate oral treatment; the patient's clinical status and acceptance of this form of treatment; the home environment and support systems; the option for an infusion center or advanced treatment area; the potential for treatment plan compliance; the availability of competent, professional follow-up; and reimbursement status. OPAT has been a safe and effective form of treatment for patients with a wide array of infectious diseases, and antibiotics such as ceftriaxone, vancomycin, daptomycin, ertapenem, and aminoglycosides lend themselves to OPAT because these compounds can be administered infrequently. The advent of dalbavancin and oritavancin has expanded the dosing options available to practitioners because of their unique half-lives allowing for extended intervals between doses. In addition to antibiotic-related adverse events, outpatient intravenous antibiotic infusion poses the risk of vascular access–related complications, such as venous thrombosis, and catheter-related bloodstream infections.

Switch (step-down) therapy

The availability of numerous safe and effective oral antimicrobials that are well absorbed and can be administered infrequently provides the opportunity for *switch* or *step-down therapy*. This approach, available to the patient who has stabilized and appears to be "turning the corner," as manifested by resolution of fever with improved appetite and strength as well as the reduction of the signs and symptoms caused by the infection, has been successfully used to treat patients with the most commonly identified community-acquired infections. Switch therapy frees the patient from the inconvenience, discomfort, and risks of intravenous access; results in considerable cost savings; and permits earlier hospital discharge. Switch therapy requires patient compliance with the medication and adequate intestinal absorption of the antimicrobial, coupled with the appropriate follow-up from the clinician.

A similar concept to step-down is to "streamline" or narrow the spectrum of activity of the antibiotic once susceptibility testing is completed. Often this can be one intravenously administered medication switching to another parenteral drug or possibly to an oral antibiotic. This is a common practice within the realm of antibiotic stewardship. Rapid testing for resistance markers or genes may result in a shorter time of broad-spectrum antibiotic treatment and perhaps reduce the potential for side effects, drug interactions, and effects on the microbiome.

Antibacterial prophylaxis

Appropriately administered antibiotic prophylaxis is the standard of care for patients who undergo selective surgical procedures. The ideal prescribed agent should cause minimal untoward events, not select for virulent organisms, achieve adequate local tissue levels, be relatively inexpensive, demonstrate inhibitory activity for the bacteria anticipated to cause postoperative infection, and should be infused (usually 30–60 minutes before the surgery begins) so that therapeutic concentrations are present prior to the initial operative incision (see Chapter 112, "Surgical prophylaxis").

In addition to their indication for the prevention of postoperative infections, antibacterial agents have been effective for the prevention (primary/secondary) of several nonsurgical disorders, including repetitive cellulitis, rheumatic fever, syphilis, traveler's diarrhea, tuberculosis, invasive meningococcal disease, pertussis, diphtheria, plague, and recurrent cystitis in women. Although no definite studies have confirmed that antibiotic prophylaxis provides protection against the development of endocarditis during bacteremia-producing procedures, it is currently recommended that patients with certain cardiac conditions receive antibiotic prophylaxis when subjected to selective dental, respiratory tract, gastrointestinal tract, and genitourinary tract bacteremia-producing procedures (see Chapter 111, "Nonsurgical antimicrobial prophylaxis" and Chapter 37, "Endocarditis").

Antimicrobial failure

When a patient is not responding to antimicrobial therapy, there is a temptation to administer an alternative compound with an extended spectrum of activity. This approach is often valid, particularly for the seriously ill patient. It is essential, however, for the clinician to establish an accurate diagnosis because noninfectious disorders often masquerade as infection. For example, hypersensitivity to an insect bite, acute gout, a fixed drug reaction, skin manifestations of Lyme disease, necrotizing fasciitis, and anaerobic myonecrosis can initially resemble traditional bacterial cellulitis; Charcot joint in the diabetic simulates osteomyelitis; pulmonary infarction, lung cancer, acute respiratory distress syndrome, aspiration of gastric contents, drug-induced pneumonitis, and congestive heart failure can imitate an infectious pneumonia; and vasculitis can resemble endocarditis. There should be consideration given to those factors that have the potential to impede successful antibiotic treatment (obstruction, necrotic tissue, undrained abscess, or an infected prosthetic device), the possibility of a polymicrobic infection, the development of drug resistance or a superinfection, or infection in a "privileged site," such as meningitis, endocarditis, or chronic bacterial prostatitis, disorders that require antimicrobials with unique penetration properties.

The clinician should also consider drug compliance and adequacy of drug dosage and recognize that selective infections, such as bacterial endocarditis, bacterial meningitis, and life-threatening

infections in granulocytopenic hosts, require a bactericidal antibiotic. An additional factor that can impact antibiotic treatment for patients is the recognition that numerous patients self-prescribe antibiotics prior to their first encounter with physicians. This practice can alter the anticipated microbiologic pathogens, the manifestations of the infection, and the clinical response of the infection.

In addition to antibiotics, survival of seriously ill, hospitalized infected patients often requires early institution of adjunctive treatments. Therapies that merit consideration include vigorous fluid administration, cardiovascular support with a vasopressor or an inotropic agent, oxygen delivery via lung-protective ventilation, and aggressive renal replacement therapy including CRRT.

Inappropriate administration

There are no convincing scientific data to support the administration of antibiotics to otherwise healthy patients who experience rhinitis and nonbacterial pharyngitis, laryngitis, acute bronchitis, or acute sinusitis. These infections are predominantly self-limited viral disorders. Antibiotic administration to these patients will serve only to add to healthcare-related costs, promote the spread of antibiotic-resistant organisms, and place patients at risk of adverse drug reactions. Additional disorders for which antibiotics are not indicated include witnessed aspiration pneumonitis, colonized noninfected wounds, and asymptomatic bacteriuria, unless the latter condition is identified in a pregnant woman or those about to undergo an invasive genitourinary procedure.

Antibiotic therapy is not appropriate treatment for the patient with persistent unexplained fever. These patients merit a thorough evaluation consisting of a comprehensive medical history and physical examination complemented with the judicious application of laboratory and radiographic studies. Empiric administration of an antibiotic to the patient with protracted fever may serve to obscure and/or delay the correct diagnosis and result in untoward drug-induced events.

When making decisions regarding the administration of antibiotics, clinicians should be guided by accurate susceptibility data for those clinically significant isolates recovered from appropriately collected specimens, as well as expert consultation and evidence-based medicine as published in accepted practice guidelines.

Antibacterial agents

Richard R. Watkins

The modern antibiotic era began with the discoveries of penicillin by Fleming in 1928 and sulfonamides by Domagk in 1932.Since then, more than a dozen different classes of antibacterial agents have been developed for use in humans. This chapter describes the various antibacterial agents, emphasizing their mechanisms of action, clinical indications, and mechanisms of bacterial resistance (Box 205.1).

Penicillins and monobactams

The core structure of the penicillins consists of a thiazolidine ring attached to a β-lactam ring and an R-group side chain. The thiazolidine–β-lactam ring provides antibacterial activity, while the side chain determines the antimicrobial spectrum and pharmacologic characteristics. Penicillins are bactericidal agents that inhibit penicillin-binding proteins (PBPs), which are involved in the synthesis of peptidoglycan. PBPs vary in their concentrations among bacteria and in their binding affinity for β-lactam antibiotics. This largely explains why β-lactam antibiotics differ in their efficacy and antibacterial spectrum. One type of PBP is β-lactamase, which hydrolyzes and inactivates the β-lactam ring. The penicillins may be conveniently grouped into the following classes: natural penicillins, penicillinase-resistant penicillins, aminopenicillins, and extended-spectrum penicillins. In addition, some of the penicillins have been combined with β-lactamase inhibitors including clavulanic acid, sulbactam, and tazobactam, which widen their antibacterial spectrum of activity.

The natural penicillins, penicillin G and penicillin V, are so named because they can be purified directly from cultures of the mold *Penicillium*. Penicillin G is unstable in acid and inactivated by gastric contents. It is administered by intramuscular, subcutaneous, intrathecal, or intravenous (IV) injection. Benzathine penicillin G, the treatment for primary, secondary, and latent syphilis, is slowly absorbed from tissue after intramuscular injection and detectable in serum for up to 30 days. However, levels are inadequate for treating neurosyphilis and IV formulations should be used. Most bacteria have developed resistance to the natural penicillins. Those that remain susceptible include *Streptococcus pyogenes*, viridans group streptococci, some enterococci, some *Streptococcus pneumoniae*, *Listeria monocytogenes*, *Neisseria meningitidis*, some *Haemophilus influenzae*, *Clostridium* (except *Clostridioides difficile*), *Actinomyces israelii*, and *Leptospira*. Penicillin V is only available for oral use and treats most of the same organisms as penicillin G, although it is less active against *Haemophilus* and *Neisseria*. Nafcillin, a penicillinase-resistant penicillin, is active against methicillin-sensitive *Staphylococcus aureus* (MSSA), penicillin-susceptible strains of *S. pneumoniae*, and most anaerobic gram-positive cocci. Importantly, nafcillin does not treat enterococcus and *Listeria*. Oral formulations of penicillinase-resistant penicillins include dicloxacillin (which is frequently used for skin and soft tissue infections [SSTIs]) and cloxacillin. The aminopenicillins, ampicillin and amoxicillin, have improved activity against enterococci compared to penicillin G. Amoxicillin is better orally absorbed than ampicillin, while the latter is effective in treating meningitis due to *L. monocytogenes*, *N. meningitidis*, and group B streptococci. Ampicillin has been combined with the β-lactamase inhibitor sulbactam and is often given for mixed bacterial infections, such as intra-abdominal infections and obstetric and gynecologic infections. Amoxicillin-clavulanate is an oral formulation that is also given when multiple organisms

Chloramphenicol
Nitrofurantoin
Fosfomycin
Topicals

need to be treated, such as animal or human bite wounds. The extended-spectrum penicillins include piperacillin, ticarcillin, and carbenicillin. Piperacillin is almost always given in combination with the β-lactamase inhibitor tazobactam. It has a wide range of activity including streptococci, anaerobes, enterococci, many Enterobacterales as well as *Pseudomonas aeruginosa*. Piperacillin-tazobactam is utilized for many serious infections including hospital-acquired pneumonia, neutropenic fever, polymicrobial SSTIs, intra-abdominal infections, complicated urinary tract infections (UTIs), and often empirically for sepsis. Of note, use of piperacillin-tazobactam has been identified as a risk factor for *Candida glabrata* and *Candida krusei* fungemia. Ticarcillin-clavulanate is another parenteral broad-spectrum agent with similar indications as piperacillin-tazobactam, although less active against enterococci.

Monobactams consist of a single β-lactam ring with side chains. Currently the only commercially available monobactam is aztreonam. Monobactams are active exclusively against gram-negative aerobic bacteria. Aztreonam is not absorbed from the gastrointestinal tract and is usually given by the IV route. It is the only β-lactam that can be given to patients with allergies to penicillin or other β-lactam antibiotics since there is no cross-reactivity between them. An inhaled formulation of aztreonam has been developed for chronic use in cystic fibrosis patients with endobronchial *P. aeruginosa* infection. The combination of aztreonam and the non–β-lactam β-lactamase inhibitor avibactam is in late stage development for antibiotic-resistant infections.

Bacteria employ a number of resistance mechanisms against the penicillins and monobactams. The most common is the production of β-lactamase, which covalently reacts with and lyses the β-lactam ring. Four different classes of β-lactamases have been identified, designated A through D. Other mechanisms include efflux pumps which push penicillin out across the bacterial outer membrane, porins which do not allow passage of penicillins into the cytoplasm, and production of low-affinity PBPs.

Cephalosporins

The second major group of β-lactams, cephalosporins, are widely used in clinical practice. Currently there are >20 cephalosporins available worldwide. They are composed of a β-lactam ring fused to a six-member dihydrothiazine ring. This structure bestows more intrinsic resistance against β-lactamases compared to the five-member ring of penicillin. Cephalosporins are commonly classified according to generation, with agents in each generation having a similar antibacterial spectrum of activity. Successive generations gain activity against aerobic gram-negative bacteria. Enterococci are intrinsically resistant to cephalosporins, although the methicillin-resistant *S. aureus* (MRSA)-active cephalosporins have lower minimum inhibitory concentrations (MICs) against ampicillin-sensitive strains. The mechanism of action of cephalosporins is similar to other β-lactam agents, namely binding to and inhibiting PBPs, which in turn prevents peptidoglycan synthesis. Cephalosporins are bactericidal drugs and cause persistent suppression of bacterial growth for several hours, called the *post-antibiotic effect* (PAE), in gram-positive bacteria, but not in gram-negative organisms. Their rapidity of bacterial killing is determined by the amount of time that the drug concentration exceeds the MIC, with maximal killing at four times the MIC.

The first-generation cephalosporins include cefazolin, cefadroxil, and cephalexin, with the first administered parenterally and the latter two orally. Cefazolin is commonly used for infections caused by MSSA and streptococci, such as SSTIs, endocarditis from susceptible strains, and surgical prophylaxis for foreign-body insertion and other clean and clean-contaminated surgical procedures with a high risk for infection. The oral first-generation agents have good oral bioavailability and are effective for many SSTIs. They are often used to transition to oral therapy after parenteral cefazolin or in the outpatient setting. They are not active against *H. influenzae* or *Moraxella catarrhalis* and should not be used for respiratory infections. Second-generation cephalosporins are divided into two groups, the true cephalosporins (cefuroxime) and the cephamycins (cefoxitin and cefotetan). Cefuroxime was frequently used in the past for respiratory tract infections, but its poor activity against penicillin-resistant *S. pneumoniae* has now limited its effectiveness. The cephamycins have good activity against aerobic gram-negative and anaerobic organisms and are first-line agents for intra-abdominal, gynecologic, and mixed skin infections. The parenteral third-generation cephalosporins (ceftriaxone, cefotaxime, ceftazidime, and ceftizoxime) have a number of important clinical indications. Ceftriaxone and cefotaxime are active against penicillin-resistant pneumococcus and are recommended for treatment of community-acquired pneumonia (CAP; when combined with azithromycin) and meningitis. Ceftriaxone is the drug of choice for gonococcal infections and is combined with

doxycycline to treat pelvic inflammatory disease. Both ceftriaxone and cefotaxime are active against *Borrelia burgdorferi* and are effective for neurologic Lyme disease. Also, these agents have good activity against Enterobacteriales, although caution should be used with monotherapy against *Citrobacter*, *Serratia*, and *Enterobacter* species as they can develop inducible resistance through chromosomal β-lactamase production. Ceftazidime has good activity against *P. aeruginosa* but limited activity against *S. aureus*. Ceftazidime-avibactam has further coverage against resistant gram-negative bacilli including ceftazidime-resistant strains, and *Acinetobacter baumannii*. Several oral third-generation cephalosporins are available (cefpodoxime, cefixime, cefdinir, and cefditoren) and are commonly prescribed for respiratory infections, sinusitis, and otitis media. Currently the only available fourth-generation cephalosporin in the United States is cefepime. This drug has an enhanced spectrum of activity against gram-negative organisms including those with reduced sensitivity to third-generation drugs. Cefepime is recommended as monotherapy for patients with neutropenic fever, although it is often combined with an aminoglycoside. Ceftaroline and ceftobiprole are advanced-generation cephalosporins with broad gram-positive and gram-negative in vitro activity and comparable efficacy to vancomycin against MRSA. They are also active against ampicillin-sensitive enterococci but not against *P. aeruginosa* or *Acinetobacter* spp. Ceftaroline has been approved in the United States to treat CAP and SSTIs, including those caused by MRSA and MSSA. Ceftolozane-tazobactam is another advanced cephalosporin-β-lactamase inhibitor combination primarily used to treat antibiotic-resistant *P. aeruginosa*. Finally, cefiderocol is indicated for complicated urinary tract infections due to multidrug-resistant gram-negative bacteria, including *Pseudomonas aeruginosa*, when no other options are available.

Carbapenems

Among the most broad-spectrum antibiotics, carbapenems are often reserved for serious infections. There are four available agents in this class: ertapenem, meropenem, imipenem, and doripenem. Also, the combinations of meropenem-vaborbactam and imipenem-cilastatin-relebactam have been recently approved. Their chemical structure is slightly different from other β-lactams in that the sulfur is replaced by a methylene group and the ring contains a double bond. Imipenem is a substrate for the kidney enzyme dehydropeptidase-1. It is coadministered with cilastin, a dehydropeptidase-1 inhibitor. Carbapenems have a similar mechanism of action (i.e., binding to high-molecular-weight PBPs) and are not hydrolyzed by most penicillinases. All have excellent activity against many gram-positive cocci. Penicillin-susceptible *Enterococcus faecalis* is susceptible to imipenem with MICs of ≤2 μg/mL but resistant to the other carbapenems. *Enterococcus faecium* is resistant to all carbapenems, as are methicillin-resistant staphylococci. *Neisseria* spp., *Haemophilus* spp., and Enterobacteriales are all highly susceptible to carbapenems, including strains that produce extended-spectrum β-lactamases (ESBLs). Doripenem is the most active against *P. aeruginosa*, while ertapenem is inactive. Ertapenem also has poor activity against *Acinetobacter*. *Stenotrophomonas maltophilia* and *Burkholderia cepacia* are intrinsically resistant to all four carbapenems. As a class, carbapenems are highly active against anaerobic bacteria. The addition of the cyclic boronic acid inhibitor vaborbactam extends the spectrum of meropenem to include some carbapenem-resistant organisms. Relebactam, a class A/C β-lactamase inhibitor, can restore activity against imipenem-cilastatin–resistant organisms, including some carbapenem-resistant *Klebsiella* and *P. aeruginosa*.

Because of their activity against many gram-positive, gram-negative, and anaerobic bacteria, carbapenems treat a wide range of infections. Moreover, they are often a good choice for patients who have recently received other antibiotics or for empiric coverage of sepsis. From an antibiotic stewardship perspective, carbapenems are advantageous since they can replace multiple antibiotics with one drug. For instance, ertapenem, with its long half-life that permits once-daily dosing, is often given to treat polymicrobial infections. However, the convenience of carbapenems must be carefully balanced against the potential for the emergence of resistance. Adverse events are similar to other β-lactams, although as a class there is an increased risk for seizures, particularly with imipenem.

Resistance to carbapenems usually occurs through overproduction of efflux pumps, altering PBPs, diminished outer membrane permeability, or production of β-lactamases. Several species of Enterobacteriales carry the plasmid-borne carbapenemases KPC-1, KPC-2, and KPC-3, which are capable of degrading carbapenems. *P. aeruginosa* also has a distinct efflux pump that is capable of removing numerous antibiotics, including meropenem, doripenem, and ertapenem but not imipenem. The carbapenemase New Delhi metallo-β-lactamase-1 (NDM-1) has spread worldwide. It is a class B carbapenemase (also called a metallolactamase) that requires zinc at its active site.

Aminoglycosides

The first aminoglycoside to be produced was streptomycin in 1944. It was followed by neomycin, then gentamicin, tobramycin, and amikacin. In 2018, plazomicin was approved for adults with complicated UTIs and limited or no alternative treatment options. Aminoglycosides are bactericidal agents that exhibit concentration-dependent killing. They bind to the 30S subunit of the prokaryotic ribosome, preventing protein synthesis from mRNA. This occurs through penetration of the bacterial cytoplasmic membrane by an oxygen-dependent active transport mechanism. Because of this action, aminoglycosides work poorly in anaerobic environments such as abscesses. These agents demonstrate a significant PAE, which increases with the peak serum concentration. Aminoglycosides are rarely used as single agents and are usually combined with another antimicrobial, such as a β-lactam or vancomycin. This helps prevent the emergence of resistance and gains the benefit of synergy. In cases of endocarditis, gentamicin should be administered using multiple daily dosing. However, for other types of infections there are several advantages of once-daily administration over multiple daily dosing. Animal studies have shown a lower rate of drug-related toxicities as well as a more robust PAE with once-daily dosing. Studies in humans

have also demonstrated that once-daily dosing is efficacious, causes less nephrotoxicity, and is more cost-effective compared to multiple daily dosing regimens. The toxicities of aminoglycosides are well established and include nephrotoxicity (incidence 5–10%), ototoxicity, vestibular toxicity, and neuromuscular blockade. Therefore, these agents should be used cautiously in patients with myasthenia gravis, electrolyte abnormalities such as hypocalcemia and hypomagnesemia, or with concurrent drugs that interfere with neuromuscular transmission, such as calcium channel blockers. Renal failure associated with aminoglycosides is usually reversible and often resolves once the drug is discontinued. Ototoxicity is more likely to be permanent.

Among their clinical indications, aminoglycosides have in vitro activity against strains of MSSA, although resistance can develop quickly unless used in combination with another active drug. Gentamicin is active against species of *Enterococcus*, but tobramycin and amikacin are not. Pneumococci and all other streptococci are resistant to aminoglycosides, as are anaerobic bacteria. Certain aminoglycosides have activity against mycobacteria; for instance, streptomycin inhibits *Mycobacteria tuberculosis* and amikacin inhibits *Mycobacteria avium-intracellulare*. Most species of Enterobacteriales, *P. aeruginosa*, *Serratia*, and *Acinetobacter* are susceptible to plazomicin, amikacin, gentamicin, and tobramycin but resistance rates vary between institutions. Notably, plazomicin has potent in vitro activity against carbapenem-resistant *A. baumannii*. *Stenotrophomonas maltophilia* and *Burkholderia cepacia* are resistant to aminoglycosides. Streptomycin is effective therapy for *Yersinia pestis* and *Francisella tularensis*, and gentamicin plus doxycycline is used to treat brucellosis.

Overall, the prevalence of bacterial resistance to the aminoglycosides remains low. There are three main mechanisms for resistance to these agents: (1) point mutations in 16S ribosomal RNA, (2) efflux pumps that prevent accumulation of the drug, and (3) bacterial enzymes that modify the drug to bind poorly to ribosomes. Enterococci are intrinsically resistant due to their facultative anaerobic metabolism. ESBLs are carried on plasmids that also carry resistance genes for aminoglycosides.

Quinolones

The first quinolone, nalidixic acid, was generated as a by-product during the production of chloroquine. Investigators discovered it had activity against certain gram-negative bacteria. Modifications of the compound, including the addition of fluorine, led to further quinolones with aerobic gram-positive, additional aerobic gram-negative, and some anaerobic activity. Quinolones available for human use include ciprofloxacin, levofloxacin, ofloxacin, moxifloxacin, gemifloxacin, and most recently delafloxacin. They are rapidly bactericidal agents that stop bacterial DNA synthesis by inhibiting two enzymes, topoisomerase IV and DNA gyrases. Like aminoglycosides, quinolones cause PAE against gram-negative bacilli, lasting approximately 2 to 6 hours. The bioavailability of quinolones is high (close to 100%), making for an easy transition from the IV to oral route. They have a high distribution in tissues including lung, bile, prostate, and stool. Except for moxifloxacin, concentrations in the kidney and urine are high. Although bone concentration is less than serum, quinolones have been successfully used to treat osteomyelitis and prosthetic joint infections, especially when combined with rifampin in the latter. The clinical uses for quinolones are presented in Table 205.1. Common toxicities associated with this class include gastrointestinal upset, dizziness, delirium (especially in the elderly), and rashes, while prolongation of the QT interval, arrhythmias, and tendonitis are rare but potentially serious. They should not be given with dairy products or metals like aluminum, calcium, or magnesium as these can reduce absorption of the drugs. Likewise, caution should be used in patients concurrently on warfarin, with close monitoring of prothrombin times because an increased risk of bleeding has been reported.

Bacterial resistance to quinolones occurs mainly from spontaneous mutations in genes that code for DNA gyrase or topoisomerase IV. Less commonly, resistance mutations occur in genes that encode membrane porin channels, leading to reduced diffusion as well as overexpression of efflux pumps. Studies have shown an increased risk for the development of resistance while on therapy in *P. aeruginosa* and *S. aureus*.

Tetracyclines

Originally derived from soil microorganisms, tetracyclines have broad-spectrum activity against gram-positive and gram-negative bacteria, intracellular bacteria, and some parasites. They are bacteriostatic agents, have anti-inflammatory properties, and inhibit protein synthesis by binding to the 30S subunit of the bacterial ribosome. Currently available drugs in this class include doxycycline, minocycline, and tetracycline, while saracycline is a narrow spectrum tetracycline derivative. A similar class is the glycylcyclines, which are derivatives of minocycline and have a modified side chain at position 9. These include tigecycline and eravacycline. The recently approved drug omadacycline belongs to the aminomethylcycline subclass of tetracycline. Both doxycycline and minocycline have high bioavailability, while the bioavailability of tetracycline is reduced when taken with food. Like quinolones, their absorption is decreased by multivalent cations like calcium and magnesium. The routes of elimination differ between the agents, with tetracycline cleared through the urine, doxycycline through the feces, minocycline through the liver, and tigecycline through the biliary/fecal route and, to a lesser extent, the urine. Toxicities are uncommon and include gastrointestinal upset, esophageal ulcers, rashes, and photosensitivity reactions. Minocycline can cause vertigo, more often in women. Tetracyclines should be avoided in pregnant women and children <8 years because of teeth staining. Patients should be encouraged to take oral tetracyclines with a full glass of water and remain upright for at least 30 minutes to decrease the risk for esophageal irritation.

Tetracyclines have a multitude of clinical uses. Doxycycline is included in the Infectious Diseases Society of America guidelines for the management of CAP for monotherapy in outpatients and in combination with a β-lactam for inpatients. Given recent reports associating arrhythmias with macrolides and quinolones,

TABLE 205.1 CHARACTERISTICS OF QUINOLONES

Drug	Principle route of metabolism	Common clinical indications and uses
Ciprofloxacin	Renal	UTIs, prostatitis, atypical pneumonia, HAP, travelers' diarrhea, gastroenteritis, peritonitis prophylaxis with cirrhosis, chronic osteomyelitis; excellent activity against gram negatives including *P. aeruginosa*
Levofloxacin	Renal	AECOPD, CAP, HAP, *P. aeruginosa* infections
Moxifloxacin	Hepatic	Aspiration pneumonia, AECOPD, CAP, abdominal infections, mixed anaerobic infections
Ofloxacin	Renal	UTIs, prostatitis, travelers' diarrhea
Gemifloxacin	Renal	AECOPD, CAP
Delafloxacin	Renal	ABSSSI, CAP

Abbreviations: UTI = urinary tract infection; CAP = community-acquired pneumonia; HAP = hospital-acquired pneumonia; AECOPD = acute exacerbations of chronic obstructive pulmonary disease; ABSSSI = acute bacterial skin and skin structure infections.

doxycycline seems to be a safe and effective alternative. It is often used to treat mild MRSA SSTIs. Moreover, doxycycline has been associated with a lower risk for *C. difficile* infection than other antibiotics. Tetracyclines are first-line therapy for Lyme disease, Rocky Mountain spotted fever, Q fever, cat scratch disease, anaplasmosis, ehrlichiosis, bartonellosis, brucellosis, pelvic ulcer disease, and in combination therapy for *Helicobacter pylori*. They also serve as alternative therapy for several conditions when patients are allergic or otherwise intolerant to first-line agents, including syphilis, leptospirosis, and Whipple's disease. Saracycline is a narrow-spectrum agent approved for moderate to severe acne vulgaris. Tigecycline is a broad-spectrum antibiotic with activity against MRSA, vancomycin-resistant enterococci (VRE), and many gram-negative bacilli including multidrug-resistant strains of *Acinetobacter*. However, it does not treat "the three P's" *Pseudomonas*, *Proteus*, and *Providencia*, or *Morganella*. Tigecycline is indicated to treat intra-abdominal infections, CAP, and SSTIs. Approximately 25% of patients develop nausea, which may necessitate discontinuation of therapy. Eravacycline is usually reserved for antibiotic-resistant infections. It has activity against some carbapenem-resistant organisms, ESBL-producing organisms, and *A. baumannii*, but it lacks activity versus *P. aeruginosa*. Eravacycline also treats MRSA and VRE. Omadacycline has activity against a broad range of gram-positive and select gram-negative pathogens and is approved to treat CAP and SSTIs.

Tetracycline resistance occurs mainly by acquisition of exogenous genes for efflux pumps and ribosomal protection proteins. Tigecycline has a higher affinity for ribosomes and can overcome ribosomal protection proteins, although it remains susceptible to multidrug-resistance pumps.

Macrolides

The macrolide group of antibiotics includes erythromycin, azithromycin, clarithromycin, and fidaxomicin. The first three drugs are used to treat a wide range of infections, while fidaxomicin is only used to treat *C. difficile* (Table 205.2). In addition to their primary indications, macrolides are often used as alternative agents for several conditions, such as Lyme disease in pregnancy and streptococcal pharyngitis in penicillin-allergic patients.

The first macrolide to be discovered, erythromycin, previously had good activity against many gram-positive organisms, but resistance has decreased its clinical efficacy. Erythromycin still maintains excellent activity against *Bordetella pertussis* and atypical respiratory pathogens. It is also used as a prokinetic agent for gastroparesis. However, gastrointestinal side effects and frequent dosing limit its use. Azithromycin has been the most commonly prescribed antibiotic in the United States for adults in recent years. It is better tolerated than erythromycin and, for many of its indications, is taken once a day for a 5-day course. Unfortunately, azithromycin has been associated with an increased risk of cardiovascular death, estimated at 47 additional cardiovascular deaths per 1 million courses.

All macrolides exhibit anti-inflammatory and immunomodulatory properties. Evidence suggests they are beneficial in certain chronic noninfectious illnesses such as cystic fibrosis and bronchiectasis. Their role in cardiovascular disease is controversial and requires further clarification.

Resistance to erythromycin, azithromycin, and clarithromycin is mediated through efflux pumps, mutations in genes for 50S ribosomal proteins, and enzymatic inactivation by phosphotransferases. A single strain of *C. difficile* with an elevated fidaxomicin MIC taken from a cured patient was found to have a single mutation in the β subunit of the RNA polymerase.

Pleuromutilins

Lefamulin is the first pleuromutilin to be used systemically in humans. Its mechanism of action is the inhibition of protein synthesis by preventing the binding of tRNA for peptide transfer. Lefamulin is approved for the treatment of CAP in adults and is available in both oral and IV formulations. It has potent in vitro activity against both typical and atypical CABP pathogens, as well as viridans streptococci, *Enterococcus faecium*, and MRSA. Lefamulin is also being investigated for acute bacterial skin and soft tissue

TABLE 205.2 **CHARACTERISTICS OF MACROLIDES**

Drug	Mechanism of action	Common clinical uses	Adverse reactions
Erythromycin	Binds bacterial 50S ribosome and inhibits RNA-dependent protein synthesis	*Bordetella pertussis* Atypical respiratory pathogens Prokinetic agent for gastroparesis	Nausea, vomiting, rashes, ototoxicity (high doses), QT prolongation
Azithromycin	Binds bacterial 50S ribosome and inhibits RNA-dependent protein synthesis	Pharyngitis Bacterial sinusitis CAP Otitis media MAC treatment and prophylaxis NGU Q fever SSTIs	Diarrhea, nausea, abdominal pain, cholestatic hepatitis, arrhythmias
Clarithromycin	Binds bacterial 50S ribosome and inhibits RNA-dependent protein synthesis	Pharyngitis Bacterial sinusitis CAP Otitis media *H. pylori* MAC and other mycobacterial infections (except MTb) Q fever SSTIs	Diarrhea, nausea, abdominal pain, arrhythmias
Fidaxomicin	Inhibits bacterial RNA polymerase	*C. difficile* infection; lower relapse rate compared to vancomycin except with NAP1/B1/027 strain	Nausea, vomiting, abdominal pain, gastrointestinal hemorrhage

Abbreviations: CAP = community-acquired pneumonia; MAC = *Mycobacterium avium* complex; MTb = *Mycobacterium tuberculosis*; NGU = nongonococcal urethritis; SSTIs = skin and soft-tissue infections.

infections. The most common side effects observed in clinical trials were infusion reactions and diarrhea. Patients with liver or kidney injury prescribed lefamulin are at increased risk of QT prolongation. Lefamulin should be avoided in patients with QT prolongation at baseline, who have a known ventricular arrhythmia, are taking class IA or IIIA antiarrhythmic drugs, or are taking other drugs that are known to cause QT prolongation.

Glycopeptides, lipopeptides, and streptogramins

Vancomycin, derived from the word "vanquish," was the first glycopeptide introduced for clinical use. The other glycopeptide is teicoplanin, which is available in Europe and Asia but not the United States. Glycopeptides are bactericidal agents that inhibit cell wall synthesis in dividing bacteria by binding to precursors of the peptidoglycan chain. Vancomycin has activity against most strains of staphylococci (including MRSA), streptococci, and enterococcus. Most strains of *L. monocytogenes* are susceptible although some with high MICs have been reported. *Leuconostoc*, *Lactobacillus*, and *Pediococcus* are intrinsically resistant. Vancomycin is used for many serious infections including meningitis, endocarditis, MRSA pneumonia, cellulitis, osteomyelitis, and gram-positive bacteremia. Oral vancomycin, which is not systemically absorbed, is used to treat moderate to severe *C. difficile* infections and recurrences. Adverse reactions to the drug are uncommon and include infusion-related reactions such as rash (red man syndrome), neutropenia, thrombocytopenia, ototoxicity, and nephrotoxicity. Resistance in enterococci is mediated by the *van* genes, which are found mostly in *E. faecalis* and can be transmitted to other bacteria such as staphylococci. It is increasingly common for strains of *S. aureus* to exhibit rising MICs to vancomycin (so-called *MIC creep*). Indeed, high rates of clinical failure with vancomycin have been observed with MRSA bacteremia when the vancomycin MIC is ≥2 μg/mL.

Telavancin is a semisynthetic lipoglycopeptide derived from vancomycin. It has a bactericidal concentration-dependent method of killing and a dual mechanism of action, inhibiting cell wall synthesis and disrupting membrane integrity. Telavancin exhibits potent in vitro activity against many gram-positive organisms, including staphylococcus, streptococcus, both vancomycin-susceptible and -resistant enterococcus, and gram-positive anaerobes. In the United States, telavancin is approved for the treatment of patients with complicated SSTIs. Women of childbearing age should have a pregnancy

test prior to starting telavancin because of possible teratogenicity. Dalbavancin is another lipoglycopeptide with broad gram-positive activity that is approved for SSTIs. It has a long half-life and is given once weekly for two doses. The semisynthetic glycopeptide ortivancin is similar to dalbavancin in terms of spectrum of activity and clinical indications. It is given as a single 1,200 mg dose administered IV over 3 hours.

The lipopeptide daptomycin is a rapidly acting, bactericidal agent that forms calcium-dependent ion channels in the cytoplasmic membrane of gram-positive organisms, causing loss of intracellular potassium and cell death. Daptomycin has a similar spectrum of activity as vancomycin and can be used to treat SSTIs, *S. aureus* bloodstream infections and right-sided endocarditis, osteomyelitis, and septic arthritis. Pulmonary surfactant inactivates daptomycin, and it should not be used for pneumonia. It is usually well-tolerated but reversible myopathy can occur. Therefore, monitoring of creatine phosphokinase (CPK) should be done weekly and concurrent statin therapy should be avoided. Resistance to daptomycin has been associated with MRSA strains with decreased susceptibility to vancomycin. Many bacteria with elevated daptomycin MICs demonstrate phenotypic changes in their cell membranes.

The streptogramins consist of two different macrocyclic compounds that each bind to the 50S subunit of the bacterial ribosome, inhibiting protein synthesis. Currently quinupristin-dalfopristin is the only streptogramin available in the United States. It is active against most gram-positive organisms (except *E. faecalis*) and a few gram-negatives including *Neisseria gonorrhoeae*, *N. meningitidis*, *M. catarrhalis*, and *H. influenzae*. Resistance occurs through conformational changes in the 50S subunit, enzymatic inactivation, and production of efflux pumps. The clinical use of quinupristin-dalfopristin has been limited by its frequent side effects (arthralgias, myalgias, hyperbilirubinemia), many drug interactions, and because it needs to be administered through a central line due to frequent thrombophlebitis and pain when given peripherally.

Oxazolidinones

Linezolid is the first of the oxazolidinones, a completely synthetic class of antibacterial agents with broad gram-positive activity. Unlike vancomycin, daptomycin, and quinupristin–dalfopristin, linezolid is available in both IV and oral formulations. It is a bacteriostatic agent that inhibits protein synthesis by binding to 23S rRNA in the catalytic site of the 50S ribosome. It is approved for the following indications: (1) VRE infections, including bacteremia; (2) nosocomial pneumonia caused by MSSA, MRSA, and *Streptococcus pneumoniae*; (3) complicated SSTIs, including diabetic foot infections without concurrent osteomyelitis caused by MSSA, MRSA, *Streptococcus pyogenes*, or *Streptococcus agalactiae*; (4) uncomplicated SSTIs caused by MSSA or *S. pyogenes*; and (5) CAP caused by MSSA or *S. pneumoniae*. Adverse events are uncommon and usually mild, including headache, nausea, and diarrhea. More serious ones can also occur, usually if linezolid is given for >28 days. These include anemia, thrombocytopenia, lactic acidosis, optic neuritis, and peripheral neuropathy. It is therefore recommended that a weekly CBC be done while on therapy. Linezolid can cause serotonin syndrome when taken concurrently with selective serotonin reuptake inhibitors (SSRIs) and should be avoided. Resistance to linezolid has been observed in strains of MRSA and VRE with mutations in the 23S ribosomal RNA domain V region and is usually associated with prior exposure to the drug. Once-daily tedizolid has fewer drug–drug interactions than linezolid and is approved to treat complicated SSTIs.

Sulfonamides

The first class of antibacterials in clinical use, sulfonamides are still widely prescribed. There are two agents currently available: trimethoprim-sulfamethoxazole (TMP-SMX) and dapsone. They are bacteriostatic and inhibit folic acid synthesis, thus stopping bacterial growth. Trimethoprim is a dihydrofolate reductase inhibitor that potentiates the activity of sulfonamides but also has antibacterial properties itself. Sulfonamides have broad in vitro activity against many gram-positive and gram-negative bacteria. TMP-SMX is most often used to treat UTIs, including pyelonephritis, cystitis, and prostatitis. It can also be given as prophylaxis for patients with recurrent UTIs. Furthermore, TMP-SMX is effective for treating SSTIs due to community-associated MRSA, with >90% of strains currently susceptible. It is first-line therapy for patients with *Pneumocystis jirovecii* pneumonia (PCP), as well as PCP prophylaxis. IV TMP-SMX is often used in severe cases. Dapsone is the treatment of choice for leprosy and for PCP prophylaxis in patients intolerant of TMP-SMX. Hemolytic anemia can occur on dapsone especially in individuals with glucose-6-phosphate dehydrogenase (G6PD) deficiency, so a G6PD level should be obtained before therapy is started. Adverse reactions associated with TMP-SMX include rashes (rarely Stevens–Johnson syndrome), fever, gastrointestinal upset, hepatitis, cytopenias, and hyperkalemia.

Because of long-standing usage (>70 years), widespread resistance to the sulfonamides has developed. It is mediated by overproduction of para-aminobenzoic acid (PABA) or structural changes in dihydropteroate synthetase, or by plasmids that code for the production of drug-resistant enzymes or decreased bacterial cell wall permeability.

Metronidazole and clindamycin

Developed in the 1950s, metronidazole is commonly used for parasitic and anaerobic infections. It is bactericidal and acts by interfering with electron transport proteins via reduction of its nitro group, leading to free radical formation and cell death. Oral metronidazole is well absorbed and serum levels are comparable to IV therapy. Metronidazole is active against nearly all gram-negative anaerobic bacteria, including *Bacteroides fragilis*; gram-positive anaerobes such as *C. difficile* and *H. pylori*; and parasites such as *Giardia*, *Entamoeba*, and *Trichomonas vaginalis*. Clinically it is used to treat a variety of anaerobic infections such

as brain abscesses, bacteremia, endocarditis, bacterial vaginosis, bone and joint infections, and infections of the head and neck. Oral metronidazole is effective against mild *C. difficile* infection, but recurrences are common (approximately 25%) and oral vancomycin is now recommended as first-line treatment. Of note, it should not be used as a single agent in treating lung abscesses because of the frequent presence of aerobic gram-positive cocci, against which it lacks activity. Adverse reactions associated with metronidazole include gastrointestinal upset, rashes, neutropenia, and neurologic complaints such as headache, dizziness, and peripheral neuropathy. Alcohol should be avoided as it can lead to a disulfiram-like reaction. Resistance is rare and results from a decreased capacity of the electron transport chain to reduce the nitro group of metronidazole. Certain strains of *H. pylori* acquire resistance from mutational inactivation of the *rdxA* gene.

Clindamycin is a chemical modification of lincomycin, the original member of the lincosamide group. Similar to the macrolides, clindamycin binds to the 50S subunit of the bacterial ribosome and inhibits protein synthesis. It has in vitro activity against many aerobic gram-positive bacteria, including staphylococci and streptococci, and anaerobes, although resistance is becoming more common. In particular, approximately 25% of clinical strains of *B. fragilis* are resistant to the drug. Clindamycin is used to treat lung abscesses, intra-abdominal and gynecologic infections, and gas gangrene from *Clostridium perfringens*. Topical formulations are effective for acne vulgaris and vaginal ones for bacterial vaginosis. It has good activity against MSSA but less so with MRSA. A D test should be done on strains of MRSA or *S. pyogenes* resistant to erythromycin; a positive D test indicates resistance to clindamycin will also occur. It can also be given as an adjunctive agent to bind toxins produced by *S. pyogenes* and *S. aureus*. Finally, clindamycin can serve as an alternative to penicillin or macrolides for most indications for patients with drug allergies. The major toxicity associated with clindamycin is *C. difficile* infection, which is not infrequent and now limits its clinical usage. Resistance to the drug occurs mainly through 50S ribosomal modification and enzymatic inactivation.

Rifamycins

A versatile class of drugs, the rifamycins have many indications but are usually used in combination with other antibiotics. There are four drugs currently available: rifampin, rifabutin, rifapentine, and rifaximin. Rifamycins act by inhibiting the β-subunit of bacterial RNA polymerase. They are potent inducers of the cytochrome P450 system. This leads to many drug interactions including HIV medications, warfarin, cardiovascular drugs such as β-blockers and statins, and immunosuppressive agents such as tacrolimus and glucocorticoids. Rifamycins are also associated with many adverse reactions. They cause an orange-red discoloration of tears and other secretions. Gastrointestinal symptoms such as nausea, vomiting, and diarrhea are common, while rashes, hepatitis, cytopenias, uveitis, and a lupus-like syndrome can also occur.

There are different clinical indications for each of the rifamycins. Rifampin is the oldest and most commonly used. It can be given as an alternative to isoniazid for treatment of latent tuberculosis, as one of the four drugs to treat active tuberculosis, in combination with dapsone for leprosy, as monotherapy for prophylaxis against meningococcal disease, or in combination therapy for prosthetic valve endocarditis or osteomyelitis (especially with foreign bodies) from *Staphylococcus*. Furthermore, rifampin can be used to eradicate MRSA colonization along with another drug such as doxycycline. Rifabutin and rifapentine are mainly used to treat mycobacterial infections. Rifaximin is poorly absorbed and is indicated for travelers' diarrhea. Moreover, it is sometimes used for recurrent or refractory *C. difficile* infection, usually for 2 weeks after finishing a standard course of oral vancomycin. Rifaximin is also effective for treating and preventing hepatic encephalopathy.

Resistance to rifamycins occurs mainly through single-step mutations in the gene that codes for RNA polymerase. Because this process occurs rapidly, rifamycins are not used to treat infections by themselves, except for the few indications jus noted.

Polymyxins

First discovered in the 1940s, polymyxins were used to treat serious gram-negative infections until around 1980, when safer agents with less nephrotoxicity became available. They have reemerged in recent years, often as agents of last resort, due to the ongoing spread of multidrug-resistant bacteria. The two drugs in this class currently available are polymyxin B and colistin. They are rapidly bactericidal and act like a detergent by punching holes in the bacterial cell membrane. Polymyxins have broad activity against aerobic gram-negative bacteria, including most strains of *P. aeruginosa* and *A. baumannii*. However, *Proteus*, *Serratia*, *Providencia*, *Burkholderia*, *Moraxella*, *Vibrio*, *Morganella*, *Helicobacter*, and *Edwardsiella* are resistant. Colistin is often used parenterally to treat serious multidrug-resistant gram-negative bacterial infections such as ventilator-associated pneumonia. Aerosolized colistin is also available and mainly given to treat colonization or infection of the bronchial system in patients with cystic fibrosis. A dose-related nephrotoxicity is a common side effect and is usually reversible with discontinuation of the drug. Also, neurologic side effects can occur, such as paresthesias, peripheral neuropathy, and muscle weakness. Resistance to polymyxins develops through modification of lipopolysaccharides on the bacterial cell wall.

Miscellaneous agents

Chloramphenicol is rarely used in North America and Europe, although an inexpensive oral formulation is widely available in underdeveloped countries. It has excellent activity against aerobic gram-positive and gram-negative bacteria, anaerobes (including *Clostridium* and *B. fragilis*), and atypical bacteria. However, serious toxicities limit its clinical utility. The most common is reversible

bone marrow suppression. Development of aplastic anemia from chloramphenicol is rarer but can be irreversible. Because of these, it should only be used for serious, life-threatening infections (e.g., bacterial meningitis) when alternative drugs are contraindicated.

Nitrofurantoin is an oral agent used to treat and prevent UTIs. It is bactericidal and acts by inhibiting translation and pyruvate metabolism. More than 90% of *Escherichia coli* and *Citrobacter* strains are susceptible, and it has excellent activity against group B streptococci, *Staphylococcus saphrophyticus*, and enterococci including VRE. However, most other strains of Enterobacteriales are resistant. For uncomplicated cystitis, a 10-day course of therapy is usually given because shorter courses have been associated with suboptimal cure rates. Daily nitrofurantoin (100 mg) is effective therapy for both young and postmenopausal women with asymptomatic and symptomatic bacteriuria. Toxicities include gastrointestinal symptoms, pulmonary reactions including fibrosis, hepatitis, hemolytic anemia, and peripheral neuropathy. Patients on long-term prophylaxis should be monitored for these conditions.

Fosfomycin is another oral agent for lower UTIs whose usage has been increasing in recent years because of bacterial resistance to other agents. It is bactericidal and inhibits cell wall synthesis through inactivation of the bacterial enzyme MurA. Resistance occurs through mutations in the bacterial membrane transporter for the drug. Fosfomycin has broad-spectrum antibacterial activity. Among susceptible pathogens are *E. coli* (including ESBL-producing strains), *Citrobacter*, *Proteus*, and *Enterococcus* (including VRE). Rates of susceptibility vary in *Klebsiella* and *Enterobacter*, while strains of *Pseudomonas* are often resistant. Fosfomycin is given as a one time mega-dose that is formulated as a powder and dissolved in a glass of water. It can also be given as a prophylactic agent for recurrent UTIs once every 10 days.

Topicals

Topical antibiotics are important agents for both treating and preventing infections of the skin, as well as to eradicate chronic carriage of MRSA. The two most common agents used for this purpose are povidone-iodine and chlorhexidine, with the latter becoming more widely available and popular in recent years.

Available topical antibacterials include silver sulfadiazine, which is mainly used as a burn wound dressing. Activated silver has broad-spectrum antimicrobial activity and some anti-inflammatory properties. Silver sulfadiazine decreases colonization of wounds but there is no clear evidence that it treats infections or improves wound healing. Bacitracin is active against many gram-positive bacteria including staphylococci, streptococci, and clostridia. It is effective for treating impetigo but may also lead to slower wound healing. Mupirocin is another agent with in vitro activity against gram-positive organisms, especially MRSA. It is used to treat impetigo, folliculitis, and infected wounds and ulcers, and to decolonize the nares in patients colonized with *S. aureus*. Unfortunately, the development of mupirocin resistance in MRSA is becoming increasingly common. Neomycin is an aminoglycoside with activity against both gram-positive and gram-negative organisms including *S. aureus*, *S. pyogenes*, *E. coli*, *Proteus*, and *Serratia* while *P. aeruginosa* is usually resistant. It can cause contact sensitivity and resistance may develop. Neomycin is not recommended for patients with decreased renal function as it can be systemically absorbed, leading to ototoxicity. Polymyxin B is bactericidal against several aerobic gram-negative organisms including *P. aeruginosa* but not species of *Proteus*, *Serratia*, and *Providencia*. It is often used in combination with another agent such as bacitracin. Fusidic acid is another topical with only gram-positive activity. It gets good tissue penetration and is useful for treating boils. Retapamulin has in vitro activity against staphylococci (including MRSA) and streptococci and exhibits a potent post-antibiotic effect lasting 3 to 4 hours. It is indicated for treating impetigo in adults and children.

Future directions

The spread of antibiotic-resistant bacteria is a major challenge for public health in the twenty-first century. Indeed, some experts believe we will soon enter a post-antibiotic era. To forestall this dire prediction, judicious usage of antibiotics is necessary, along with prudent infection control methods that reduce the spread of multidrug-resistant pathogens. Developing new antibiotics is a priority that should be actively supported by the pharmaceutical industry, professional societies, and government agencies.

Principles and practice of antimicrobial stewardship

Cheston B. Cunha

Introduction

The primary goal of antimicrobial stewardship is to optimize antibiotic use while using cost-effective interventions to minimize antibiotic resistance and control *Clostridium difficile* infection. Before the formal creation of antimicrobial stewardship programs (ASPs), infectious disease (ID) clinicians acted as the antibiotic stewards in hospitals. More recently, the US Centers for Disease Control and Prevention (CDC) has mandated ASPs for all US hospitals and more emphasis has been placed on mitigating the damage of suboptimal antibiotic use.

Principles of antimicrobial stewardship programs

The CDC has determined seven core measures that all ASPs should follow. The hospital must designate a single ID clinician who will direct the hospital's ASP efforts. To be effective, the ID clinician leader must possess the requisite interpersonal, diplomatic, and leadership skills that form the basis for the enthusiastic support of the medical staff. The ID clinician leader should have special expertise in various aspects of antimicrobial therapy (i.e., pharmacokinetics, resistance, pharmacoeconomics, and *C. difficile*). Most successful ASPs interventions focus on seven key areas where antimicrobial use can be optimized (Table 206.1). If these problem areas are the focus of ASPs, unnecessary and suboptimal antimicrobial use will be reduced and benefit for patients and institutions will be maximized.

To create and maintain an effective hospital-wide ASP, the ASP team leader needs full and ongoing financial support for the ASP from the hospital administration. Support includes a staff of ID/AS trained clinical pharmacists (PharmDs) who are a vital component of ASPs. There must be a sufficient number of PharmDs for the size of the hospital to ensure the effectiveness of the ASP. The ID team leader and PharmDs need committed IT support to effectively accomplish daily stewardship activities and larger stewardship projects. These key activities include a daily prospective audit with feedback to clinicians, data collection to track and monitor antibiotic use, resistance, and *C. difficile* infections, as well as ASP cost-savings to the institution.

Just as important, the success of an ASP depends on the understanding and support of medical staff. The medical staff needs to understand the principles of antibiotic therapy put forth in ASP initiatives if they are to accept and support ASP recommendations for the benefit of patients and the hospital.

Most physicians need relevant, targeted antibiotic education to understand optimal versus adequate antimicrobial therapy (i.e., pharmokinetics [PK]-/pharmodynamic [PD]- based dosing; see Table 206.2), IV versus PO administration, dosing adjustments in renal/hepatic insufficiency, factors in tissue penetration, shortest duration of therapy for cure, antibiotic resistance potential, and antibiotic *C. difficile* potential. Antibiotic myths and misconceptions abound. All too often, antibiotic

TABLE 206.1 ANTIMICROBIAL STEWARDSHIP PRINCIPLES AND PRACTICE: BEYOND THE GUIDELINES

Monotherapy vs. combination therapy

- Monotherapy is preferred whenever possible to cover the most likely pathogen or cultured pathogen clinically relevant to the site of infection.
- Combination therapy should be avoided if possible. Always try to preferentially use monotherapy.
- Monotherapy is usually less expensive than combination therapy and has less potential for adverse effects and drug–drug interactions.
- Combination therapy is often used for potential synergy (rarely occurs and, if used, must be based on microbiology laboratory synergy studies), to increase spectrum (preferable to use monotherapy with same spectrum), or to prevent resistance (except for TB, ineffective in most cases).

Narrow vs. broad-spectrum therapy

- Narrow vs. broad spectrum doesn't prevent resistance; for example, in treating *E. coli* urosepsis, switching from a carbapenem (broad-spectrum) to ampicillin (narrow-spectrum) may actually increase resistance potential.
- Narrow- vs. broad-spectrum is not always clinically superior to well-chosen broad-spectrum therapy, such as switching from ceftriaxone (broad-spectrum) to penicillin (narrow-spectrum in treating *S. pneumoniae* has no clinical rationale or clinical advantage and has no effect on controlling resistance.
- Antibiotic resistance is not related to spectrum narrowness or broadness; for example, levofloxacin has a broad spectrum but low resistance potential whereas ampicillin has a narrow spectrum but high resistance potential.

Colonization vs. infection

- Treat infection, not colonization.
- Provide empiric coverage primarily directed against the most probable pathogens causing the infection at the body site.
- Avoid "covering" multiple organisms cultured (pathogens and nonpathogens) at the body site cultured.
- Colonization of respiratory secretions, wounds, or urine with "water" (*S. maltophilia, B. cepacia, P. aeruginosa*) or skin organisms (MSSA, MRSA, CoNS, VSE, VRE) is the rule.

Antibiotic resistance

- The best way to control resistance is a selectively restricted formulary; restricted only to "high resistance potential' antibiotics, such as imipenem (not meropenem or ertapenem), ceftazidime (not other third- or fourth-generation), gentamicin/tobramycin (not amikacin).
- Some antibiotics may be restricted for other reasons; for example, excessive vancomycin (IV not PO) use predisposes to VRE emergence, and vancomycin may cause cell wall thickening in *S. aureus* resulting in permeability-related resistance (to vancomycin and other antibiotics; e.g., daptomycin).
- Overrestriction of antibiotics may impair timely effective therapy and does not, per se, decrease resistance.
- Preferentially select antibiotics (all other things being equal) with a "low resistance potential." Avoid, if possible, "high resistance potential" antibiotics, such as macrolides (for respiratory infections), TMP-SMX (for UTIs).
- Since resistance is, in part, concentration-dependent, subtherapeutic or low antibiotic tissue concentrations (all other things being equal) predispose to resistance.
- Suboptimal dosing or usual dosing with inadequate tissue penetration, such as into the body fluids or undrained abscesses (source control is key) predisposes to resistance.

C. difficile diarrhea/colitis

- Preferentially select antibiotics (all other things being equal) with low *C. difficile* potential.
- Predisposing factors to *C. difficile* include relatively few antibiotics (e.g., clindamycin, β-lactams, ciprofloxacin).
- Most antibiotics have little/no *C. difficile* potential (e.g., aminoglycosides, aztreonam, macrolides, TMP-SMX, colistin, polymyxin B, daptomycin, Q/D, doxycycline, minocycline, tigecycline, vancomycin, linezolid).
- Some antibiotics are protective against *C. difficile* (e.g., doxycycline, tigecycline).
- Always consider non-antibiotic factors that may predispose to *C. difficile* (e.g., cancer chemotherapy, anti-depressants, statins, PPIs).
- Also consider person-to-person spread or acquisition for the environment.

PO and IV to PO switch antibiotic therapy

- Wherever possible, treat with entirely oral antibiotic therapy instead of IV therapy.
- Switch from IV to PO antibiotic therapy after clinical defervescence (usually <72 h).
- Early IV to PO switch therapy eliminates phlebitis and IV line-associated infections.

TABLE 206.1 **CONTINUED**

Pharmacoeconomic considerations
The least expensive therapy is usually not the best therapy.
The least expensive antibiotic (acquisition cost) may, in fact, be expensive (re: total cost) when considering the cost implications to the institution of dosing frequency, *C. difficile* potential, resistance potential, and degree of activity against the known or likely pathogen, and the cost of potential therapeutic failure vis-à-vis ↑ length of stay (LOS) and medicolegally.
Stewardship savings are best achieved by decreasing duration of antibiotic therapy and by treating entirely with oral antibiotic therapy or early IV to PO switch therapy.

CoNS, coagulase-negative staphylococci; MRSA, methicillin-resistant *Staphylococcus aureus*; MSSA, methicillin-susceptible *Staphylococcus aureus*; PPI, proton pump inhibitor; Q/D, daily dose; TMP-SMX, trimethoprim-sulfamethoxazole; UTI, urinary tract infection; VRE, vancomycin-resistant *Enterococcus*; VSE, vancomycin-susceptible *Enterococcus*.

therapy is regarded as a cure and is an immediate response for all febrile disorders. In these cases, multiple antimicrobials are often prescribed in an attempt to "cover the patient." Polypharmacy is nearly always unnecessary and increases costs and adverse events potential.

The most successful ASPs rely on a multidisciplinary approach that includes the critical support of the microbiology laboratory, infection control, and hospital epidemiology.

Colonization versus infection

One of the most frequently encountered problems for clinicians is to differentiate *colonization* from actual *infection*. When an organism is recovered from a culture site (e.g., urine cultures in asymptomatic individuals, superficial wound cultures, etc.), most clinicians feel compelled to treat the organism. Often, the more resistant the organism, the stronger the urge to treat it. Colonization, with very few

TABLE 206.2 **PHARMACOKINETIC/PHARMACODYNAMIC (PK/PD) CONSIDERATIONS**

Antibiotics		**Optimal dosing strategies**
Concentration-dependent antibiotics (C_{max}:MIC)		
Quinolones Aminoglycosides Vancomycin (if MIC >1 μg/mL use 2 g (IV) q12h)	Doxycycline Tigecycline Polymyxin B Colistin	Use highest effective dose without toxicity
Time-dependent antibiotics (T > MIC)		
Penicillins: Maintain concentrations > MIC for ≥60% of the dosing interval β-lactams: Maintain concentrations > MIC for ≥75% of the dosing interval Carbapenems: Maintain concentrations > MIC for ≥ 0% of the dosing interval		Use high doses (which increase serum concentrations which also increases T > MIC for more of the dosing interval)

MIC, minimum inhibitory concentration.

exceptions, should not be treated. Because colonization may be difficult to eradicate, multiple, prolonged courses of antimicrobials are frequently given to patients; this results in no benefit to patients and increased costs to the healthcare system while increasing local resistance and *C. difficile* rates.

Antibiotic resistance

The majority of resistance in hospitals comes from the community (e.g., nursing homes/chronic care facilities) and the food supply (antibiotics are commonly used in the food supply). Hospital-acquired resistance is still a concern, and, to minimize the risk of this, hospitals should preferentially select formularies with "low resistance potential" antibiotics. There are many misconceptions about resistance (i.e., resistance is class-related or is related to volume or duration of use). Rather than considering overall antimicrobial "tonnage" as a risk for generating resistance, the potential of individual antimicrobials should be taken into account. Antibiotics may be considered as having a "low or high resistance" potential. The "low resistance potential" antibiotics (e.g., doxycycline) induce little or no resistance independent of volume or duration of use, whereas "high resistance potential" antibiotics (e.g., ceftazidime) may induce resistance even with limited use. Obviously, if high resistance potential drugs are used in large volume, the likelihood of worsening resistance in a hospital/community increases dramatically. Within each antibiotic class are low and high resistance potential antibiotics; for example among third-generation cephalosporins, ceftazidime has a high resistance potential while ceftriaxone has a low resistance potential, thus showing that resistance is not related, per se, to antibiotic class (see Tables 206.3 and 206.4).

C. difficile diarrhea

C. difficile diarrhea (CDD) is an area that ASPs must also impact. Unnecessary antimicrobial administration can lead to increased rates of CDD in an institution. Also, it is not well appreciated that antibiotics have different *C. difficile* potentials (i.e., high risk for CDD vs. low risk). While it is often difficult to determine the precise CDD risk of an antimicrobial, clindamycin and the β-lactams (excluding ceftriaxone) are the most frequent antibiotic causes of CDD. Most other antibiotics have low *C. difficile* potential (e.g., macrolides, tetracyclines, aztreonam, aminoglycosides, trimethoprim-sulfamethoxazole [TMP-SMX]). Some antibiotics are actually protective against *C. difficile* (e.g., doxycycline, tigecycline). *C. difficile*-protective drugs (e.g., the tetracyclines) should be favored by formularies to minimize CDD. In selecting an antibiotic, clinicians must consider *C. difficile* potential as well as resistance potential.

TABLE 206.3 **ANTIBIOTIC RESISTANCE POTENTIAL**

High resistance potential antibiotics

Clinical and pharmacoeconomic benefits

Optimal antibiotic therapy is based on the aforementioned principles, but other ASP interventions also benefit the patient and the hospital (i.e., IV to PO switch therapy and PO therapy). The advantages of IV to PO switch/PO therapy include decreased drug costs (PO antibiotics cost less, at any given dose, than their IV equivalents) as well as decreasing the incidence of phlebitis (shorter duration of IV lines). IV to PO switch programs increase patient satisfaction (shorter IV days and earlier discharge) and decreases hospital length of stay, which is a significant cost savings to hospitals. Well-chosen PO therapy is increasingly becoming the standard for multiple infections. There has been increasing data supporting the use of PO therapy over IV which should give clinicians and ASPs increasing confidence in the many benefits of IV to PO and PO therapy.

Practice of antimicrobial stewardship programs

While the problems faced by and the general approach to these problems is similar among all ASPs, specific programs must differ among hospitals. Depending on the hospital size, location (rural, suburban, urban), teaching versus community focus, staff antibiotic prescribing habits, presence or absence of full-time ID clinicians, resistance patterns, etc., the individual priorities and strategies of each ASP must vary. What is a successful ASP intervention in one hospital may be ineffective in another. The ASP ID team leader and clinical ID-trained PharmD staff must tailor ASP interventions to the hospital's unique set of antibiotic use–related concerns. The success of ASPs relies on determining the most effective strategy for a specific antibiotic-related problem at a specific institution. The effectiveness of various ASP interventions is assessed and modified based on the findings of effective audit

and feedback. Audit with feedback identifies effective/ineffective interventions and may suggest modifications or entirely new and innovative approaches.

Antifungal therapy

Dimitrios Farmakiotis and Ralph Rogers

Introduction

The patient population at risk for invasive fungal infections is rapidly growing. This is the result of more effective treatments for hematologic malignancies, which lead to prolonged periods of neutropenia, but also newly recognized syndromes associated with the use of novel therapies, such as a variety of fungal infections in patients receiving tyrosine kinase inhibitors (ibrutinib) or endemic mycoses (histoplasmosis) associated with tumor necrosis factor (TNF-α) inhibitors. Invasive fungal infections are also increasingly recognized in immunocompetent or "immunomodulated" individuals, such as the outbreak of *Cryptococcus gatii* infections in Northwestern United States and British Columbia, chronic cavitary and semi-invasive aspergillosis in patients with chronic obstructive pulmonary disease (COPD), and post-influenza and ICU-related aspergillosis. Recent advances in our understanding of fungal pathogenesis and the development of potent, relatively nontoxic antifungal agents have led to significantly improved outcomes and even cure of severe fungal infections that were almost uniformly fatal three decades ago. Therefore, knowledge of clinical mycology and antifungal treatment basics is paramount across different specialties other than infectious diseases, such as oncology-hematology, rheumatology, transplantation medicine, and critical care. Figure 207.1 provides an overview of fungal pathogens for the clinician, and Table 207.1 summarizes the spectra, pharmacokinetics, and main toxicities of the most commonly used antifungal drugs. Figure 207.2 provides and algorithm for the empiric treatment of fungal infections. This chapter focuses on the three main classes of antifungal agents used in clinical practice: polyenes (amphotericin B formulations), echinocandins, and (tri)azoles.

Amphotericin B

Amphotericin B is the main antifungal in the class of polyenes and was the first antifungal agent discovered that was effective for the treatment of systemic fungal diseases. It probably has the broadest spectrum, is highly cidal, and remains the primary antifungal agent in clinical use today for many severe or recalcitrant fungal infections. The original formulation of amphotericin B deoxycholate (AmBD, Fungizone, 1959) has several associated dose-limiting toxicities, and three alternate lipid-associated formulations have since been developed: amphotericin B lipid complex (ABLC, Abelcet, 1995), amphotericin B colloidal dispersion (ABCD, Amphotec, 1996), and liposomal amphotericin B (L-AmB, Ambisome, 1997), which are less toxic, but adverse effects still pose frequent limitations in their use compared to other classes of antifungals. The predominant formulations in clinical use today (AmBD and L-AmB) will be the main focus of this section.

History, mechanism, adverse effects

Amphotericin B (AmB) was first described in 1956 after its isolation from a Streptomycete (*Streptomyces nodosus*) found in a soil sample obtained from the Orinoco River region of Venezuela. Its name reflects

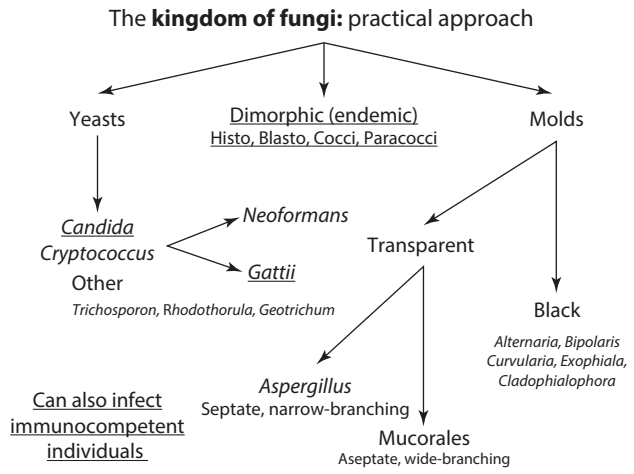

FIGURE 207.1 An overview of fungal pathogens.

its amphipathic nature (having both a hydrophobic and hydrophilic group) and being the second of two new antimicrobials isolated from this sample (with amphotericin A having less antifungal activity). AmB is highly insoluble in water and so was originally formulated with sodium deoxycholate (AmBD) to form a colloid and allow for intravenous infusion. In an effort to reduce nephrotoxicity, three lipid-associated formulations were developed: ABLC, which consists of AmB complexed with two lipids in a large ribbon-like structure; ABCD, which consists of AmB bound to cholesteryl sulfate in a much smaller disc-like structure; and L-AmB, which consists of small unilamellar liposomes each containing AmB. These lipid formulations have demonstrated a decrease in nephrotoxicity as compared with AmBD while maintaining similar clinical efficacy but are in general more expensive.

Although amphotericin B has been used clinically for decades, there is not yet a firm understanding of its mechanism of action. The drug is thought to act on the cell membrane, as might be expected given its amphipathic structure. However, various studies show disparate, but not necessarily mutually exclusive, mechanisms of action. One hypothesis, the "barrel-stave" model, suggests that AmB self-assembles into channel-like structures (or nanopores) that span the lipid bilayer and allow for ionic permeability and subsequent cell death. This long-standing model is supported by studies demonstrating that these transmembrane channels tend to be more stable in the presence of ergosterol rather than cholesterol, providing an explanation for the relatively increased action of amphotericin B

[5]High-dose, not recommended in general as monotherapy for aspergillosis.

against fungal cells as compared to bacterial or human cells. Another hypothesis, the "sterol-sponge" model, suggests that binding of ergosterol by AmB and subsequent ergosterol sequestration are sufficient to promote fungal cell death independent of membrane permeabilization given the dependence of multiple critical aspects of fungal physiology on the presence of ergosterol. Further research into the specific mechanisms of AmB on-target and off-target actions is ongoing in an effort to further understand the mechanism(s) of clinical resistance as well as to aid in the potential development of less toxic derivatives.

Adverse effects of AmB (and the subsequent development of effective and less toxic antifungal agents; namely, azoles and echinocandins) have contributed to this agent no longer being used as first-line therapy for many fungal infections. One of the most frequent and most severe dose-related effects of AmB is nephrotoxicity, with early studies showing an incidence as high as 83%. This effect is manifested clinically by azotemia, renal tubular acidosis, and electrolyte abnormalities (hypokalemia, hypomagnesemia) and, not uncommonly, can progress to acute renal failure. The toxicity is thought to be due to formation of membrane pores in tubular cells by AmB with ensuing tubular cell injury, compounded by decreased renal blood flow (and subsequent decrease in glomerular filtration rate), via activation of the tubuloglomerular feedback system. Some studies have shown that salt loading prior to AmB infusion can help minimize nephrotoxicity, perhaps by ameliorating the tubuloglomerular feedback response. Similarly, use of the lipid-associated formulations is also associated with decreased incidence of nephrotoxicity due to the decreased distribution of the drug to the kidneys. One large randomized study showed a decrease in the incidence of nephrotoxicity from 34% to 19% with the use of L-AmB as compared to AmBD.

Infusion-related adverse effects are also relatively common, with distinct syndromes associated with both AmBD and L-AmB. AmBD infusions are commonly followed within 1 to 3 hours by fever, chills/rigors, headache, muscle aches, and nausea; this syndrome is thought to be due to induction of pro-inflammatory cytokines by AmB. In contrast, L-AmB infusions are occasionally associated with a syndrome of chest pain, dyspnea, hypoxia, abdominal pain, flushing, and urticaria, all starting within minutes of initiating an infusion; this syndrome is thought to be due to a "pseudo-allergic" complement-mediated reaction to the liposomal moiety rather than related to AmB itself. AmBD infusion reactions are often ameliorated by premedication with an anti-inflammatory agent or by slowing the infusion rate, whereas L-AmB infusion reactions can often be ameliorated by an antihistamine and are often less severe or absent with subsequent doses. Premedication with nonsteroidal anti-inflammatory drugs (NSAIDs), corticosteroids, or meperidine, and, according to some investigators using a different lipid formulation of AmB (ABLC vs. L-AmB) might also help. ABCD has a similar or higher rate of these infusion reactions than AmBD and is no longer manufactured or distributed. One other potential adverse effect of AmB is hypoproliferative anemia; hepatotoxicity is rare.

Pharmacology, drug interactions

Amphotericin B is poorly absorbed after oral administration and thus is generally given intravenously. After an infusion of AmBD, the AmB moiety dissociates and thereafter remains highly bound (>90%) to lipoproteins when circulating in plasma, though the majority of AmB is distributed widely to tissues (including the kidneys). There is no significant metabolism of AmB, and most of the drug is eventually excreted unchanged in urine and feces, albeit very slowly (terminal $t_{1/2} \approx 5$ days). In contrast, after an infusion of L-AmB, the liposomes are largely sequestered in the plasma compartment but are also eventually excreted unchanged in urine and feces, with a terminal $t_{1/2}$ of approximately 6 days. A standard dose of L-AmB (3–6 mg/kg/d) achieves a much higher peak plasma concentration than a standard dose of AmBD (0.3–1.5 mg/kg/d) due both to the higher dose given (and tolerated) as well as to the distribution of the drug. However, by virtue of being associated with a liposome rather than simply being bound to a lipoprotein, there is

overall decreased exposure of the renal tubules to "free" AmB with L-AmB as compared to AmBD; thus, even with a higher plasma concentration of L-AmB, there is less nephrotoxicity.

There are no renal or hepatic dosing adjustments for any formulations of AmB given the lack of renal or hepatic metabolism or significant contributions to drug clearance. AmBD distributes to most tissues, although the concentration of AmB at some sites is much lower than that of plasma given the limited diffusion potential of a lipoprotein-bound drug. L-AmB is largely sequestered in the plasma compartment but similarly is thought to be available at most sites of infection due to inflammatory changes allowing for local extravasation of liposomes. Neither AmBD nor any of the lipid-associated formulations have any significant interactions with other medications, though care should be taken to avoid simultaneous administration with other nephrotoxic or hypokalemia-inducing agents.

Therapeutic use, clinical resistance

Amphotericin B is active against a broad array of fungal pathogens; additionally, it is used clinically as an alternative agent for the treatment of leishmaniasis, a protozoal disease. It is active against almost all *Candida* (except *C. lusitaniae* strains) and *Aspergillus* spp. (except *A. terreus* strains), as well as *Cryptococcus* spp., the dimorphic/endemic fungi, and many non-*Aspergillus* hyaline (transparent or pale) molds including the Mucorales. AmB is also active against some (but not all) dematiaceous (dark brown or black) molds (e.g., *Alternaria*, *Bipolaris*, *Exophiala* spp.), the etiologic agents of phaeohyphomycosis or chromoblastomycosis. The formulations of AmB can generally be used interchangeably for most infections without regards to efficacy, with the exception of genitourinary infections which are thought to be more appropriately treated with AmBD rather than L-AmB given the reduced excretion of the latter in urine. Local instillation (intraperitoneal, intrathecal, intravitreal, bladder irrigation, or through nephrostomy tube) of AmB is occasionally necessary for severe or recalcitrant infections. While alternate classes of effective antifungal agents (i.e., azoles and echinocandins) have replaced AmB as first-line antifungal therapy for many infections due to their decreased toxicity, AmB remains an effective treatment option for many infections and, not uncommonly, is the only antifungal agent available with clinical activity against some more atypical or resistant fungal pathogens.

A more approachable assessment of the breadth of activity of AmB involves examining fungal pathogens encountered clinically which are less susceptible or frankly resistant to AmB. Resistance to AmB among *Candida* spp. is generally rare, but an elevated minimum inhibitory concentration (MIC) and/or a clinically resistant phenotype is not uncommonly seen in *C. lusitaniae* and the emerging pathogen *C. auris* (as well as the closely related but less commonly encountered *C. haemulonii*). Resistance is thought to be most often due to a mutation in an enzyme involved in the ergosterol biosynthesis pathway (e.g., ERG2, ERG3, ERG5, ERG6, or ERG11) which results in decreased production of ergosterol and thus decreased susceptibility to AmB. In general, these mutations also lead to decreased virulence and/or decreased susceptibility to external stressors, which is thought to have prevented the emergence of widespread clinical AmB resistance in most *Candida* spp. It is unclear why AmB resistance is more common in the *Candida* species mentioned earlier, although some reports have demonstrated a relationship between AmB resistance and phenotypic switching in *C. lusitaniae* (perhaps allowing for the expression of an intrinsically resistant phenotype in the presence of AmB) as well as demonstrated some preliminary evidence of alternate mechanisms of AmB resistance in *C. auris*. Resistance to AmB among *Aspergillus* spp. is also generally rare but does occur in *A. terreus*. Rather than a decrease in ergosterol content of the fungal cell membrane as observed with some *Candida* spp., resistance to AmB in *A. terreus* is thought to be primarily due to an increased intrinsic stress response capability. Recent reports have highlighted a troubling trend of increasing AmB resistance in other common *Aspergillus* spp., including *A. fumigatus*.

Data describing resistance to AmB for other fungal pathogens is much sparser. Notably, in vitro antifungal susceptibility testing is limited in its ability to predict clinical outcomes, with many other factors playing roles that are perhaps more relevant when considering atypical fungal infections in immunocompromised hosts (e.g., virulence of pathogen, clinical syndrome, host immune status). Many *Fusarium* spp. (especially *F. solani* complex) demonstrate elevated MICs to AmB, although there are no formal interpretive clinical breakpoints, no clear mechanism of resistance has been uncovered, and there is no clear correlation between elevated MIC and clinical failure. In some guidelines, voriconazole rather than L-AmB is the first-line agent recommended for treatment of fusariosis. *Scedosporium* spp. (including teleomorphic forms previously named *Pseudallescheria* spp.) and the now renamed *Lomentospora prolificans* also demonstrate elevated MICs to AmB. Similarly to *Fusarium* spp., no clear mechanism of resistance to AmB has been identified for *Scedosporium* spp., although the clinical relevance of an elevated MIC is a bit more straightforward given the generally poor clinical outcomes of this infection despite AmB treatment. Voriconazole rather than AmB again remains the first-line agent recommended for the treatment of scedosporiosis, especially infections with *S. apiospermum* (*S. prolificans* is notorious for multidrug resistance), although surgical debridement is often the mainstay of therapy if possible, given the lack of clinical efficacy for many antifungals. Treatment of scedosporiosis with combinations of antifungal agents, often including AmB and terbinafine, is also relatively common practice.

Echinocandins

Three echinocandin antifungal agents are currently available for clinical use: caspofungin (Cancidas, 2001), micafungin (Mycamine, 2005), and anidulafungin (Eraxis, 2006). Two other glucan synthase inhibitors are in development (rezafungin and ibrexafungerp, see further discussion in the "Novel Antifungals" section of this chapter). Echinocandins are the antifungal agents of choice for invasive candidiasis, not only because of their superior cidality against *Candida* and clinical efficacy but also due to their tolerability and minimal interactions with other medications.

History, mechanism, adverse effects

The first echinocandin compound described was a lipopeptide with anti-yeast activity isolated from an *Aspergillus* strain (*A. nidulans var. echinulatus*, now *A. spinulosporus*) in 1974. This early compound and its derivatives proved too toxic for clinical use, but a similar group of compounds was eventually isolated from another ascomycete (*Zalerion arboricola*) in 1992, which subsequently gave rise to the echinocandin agents currently in use. Given the origin of these echinocandin precursors, the limited clinical efficacy against *Aspergillus* (see later discussion) found within this class of antifungal agents is not altogether surprising.

Echinocandins act by inhibiting (1,3)-β-D-glucan synthase (GS), the enzyme responsible for the synthesis of (1,3)-β-D-glucan (BDG), a major component of the fungal cell wall. Additional components of the fungal cell wall include various other glucans, mannans (including galactomannan), and chitin. Cell wall components vary among disparate fungal species (e.g., *Candida albicans*: 30–39% BDG, 43–53% [1,6]-β-D-glucan, 2–6% chitin; *Aspergillus fumigatus*: 20–35% BDG, 20–25% galactomannan, 7–15% chitin); moreover, the relative abundance of each component can vary in response to environmental stimuli (e.g., antifungal exposure). For fungal species in which BDG is a predominant component of the cell wall, such as *Candida* spp., the decreased production of BDG after exposure to an echinocandin results in a weak and osmotically fragile fungal cell wall, leading to fungal cell lysis. For some other fungal species in which BDG is present but in relatively lower abundance, particularly in molds such as *Aspergillus* spp., the inhibition of BDG production by an echinocandin causes lysis of the cell wall at rapidly growing hyphal tips but in general does not halt the overall growth of the fungal organism. Opposite to mold-active triazoles, echinocandins are fungicidal against *Candida* and fungistatic against *Aspergillus*.

All of the echinocandins are generally well-tolerated. Notably, there are no mammalian homologues for GS, thus no expected on-target adverse effects. Beyond mild to moderate generalized symptoms such as headache or gastrointestinal discomfort primarily reported in clinical trials, hepatotoxicity is the one adverse effect noted most frequently with clinical echinocandin use, though the reported prevalence of this complication varies (3.8–37%) and likely depends at least in part on an individual's preceding level of hepatic dysfunction. Although caspofungin and micafungin both undergo hepatic metabolism while anidulafungin does not, aside from a potential impact on dosing regimens, these differences in metabolism have not been shown to impact the relative frequency of hepatotoxicity between different echinocandins. Hypokalemia has been reported sporadically, but its association with echinocandin administration is not well-established.

Pharmacology, drug interactions

Echinocandins are only available for parenteral use given their large molecular weight and poor absorption when administered orally. All are highly protein-bound, which results in relatively long half-lives and allows for once-daily dosing. Their large molecular weight, protein-bound status, and minimal lipophilicity all contribute to poor penetration into tissue compartments without fenestrated capillaries (e.g., brain/CSF, eye, prostate). Importantly, since none of these agents undergoes appreciable renal excretion, there is minimal active drug found in urine. Echinocandins do not undergo renal metabolism, so no dose adjustments are necessary for renal insufficiency. Caspofungin and micafungin both undergo hepatic metabolism to form inactive metabolites which are eventually excreted via urine and feces, though only caspofungin has an indicated dose reduction for hepatic dysfunction. Anidulafungin does not undergo hepatic metabolism and is instead primarily degraded in the plasma to an inactive form which is eventually excreted primarily in the feces. Preliminary data suggest that optimal dosing of echinocandins in obese individuals may necessitate a dose increase. Higher doses are also recommended by some experts against aspergillosis and in serious *Candida* infections, such as endocarditis.

Drug interactions with echinocandins are relatively rare. None of these agents is primarily metabolized by cytochrome P450 (CYP) enzymes, so they are neither affected by nor affect other CYP inducers, inhibitors, or competitors. Decreased concentrations of caspofungin have been found when coadministered with rifampin, thought to be due to increased hepatic uptake (rather than metabolism) of caspofungin via the OATP1B1 transporter due to the induction of OATP1B1 by rifampin. Other studies have demonstrated that cyclosporin may increase caspofungin levels, that caspofungin may decrease tacrolimus levels, and that micafungin may increase sirolimus and itraconazole levels, all via unknown mechanisms. However, these drug–drug interactions are not considered nearly as clinically significant as those with most azoles.

Therapeutic use, clinical resistance

The echinocandins are primarily active against *Candida* spp. and are recommended for use as first-line therapy for the treatment of invasive candidiasis. They are active against the majority of *Candida* spp. and are used to treat *Candida* infections at all anatomic sites with the exception of brain/central nervous system (CNS), eye, urine, and prostate. They are also effective for treatment of febrile neutropenia and antifungal prophylaxis in neutropenic patients. The echinocandins also have some fungistatic activity against *Aspergillus* spp. and can be used for salvage therapy (alone or in combination with other classes of antifungal agents) for selected and sometimes refractory cases of invasive aspergillosis. They are active against the mycelial forms of dimorphic fungi (e.g., *Blastomyces dermatitidis*, *Coccidioides immitis*, *Histoplasma capsulatum*) but are much less active against their yeast-like forms and thus are generally not used clinically to treat infections due to these pathogens. Echinocandins lack activity against *Cryptococcus* spp. The *Mucorales* and other non-*Aspergillus* non-dematiaceous molds are generally not susceptible to echinocandins.

Most data regarding mechanisms of echinocandin resistance have been derived from work with *Candida* spp. In contrast to the azoles, for which intrinsic resistance (due at least in some part to many years of agricultural azole herbicide use) is relatively common, intrinsic echinocandin resistance in *Candida* spp. is rare. Instead, echinocandin resistance is generally associated with repeated or prolonged exposure to these agents. The development of clinical resistance is closely linked to the acquisition of a mutation in an FKS

gene (FKS1 or FKS2). These genes encode catalytic subunits of GS, the target of echinocandins, and mutations in certain hotspot areas lead to decreased echinocandin susceptibility. Beyond a target gene mutation, no other common resistance mechanisms have been found; notably, echinocandins are not substrates for multidrug transporters. However, some cellular stress responses, such as an increase in chitin synthesis, are also thought to contribute to resistance by promoting echinocandin tolerance and allowing time for the development of FKS mutations.

Globally, echinocandin resistance is relatively rare among common *Candida* spp. including *C. albicans* (0–0.2%), *C. parapsilosis* (0–0.5%), *C. tropicalis* (0–1.3%), and *C. krusei* (0%). Resistance is more common in *C. glabrata* (0.8–2.5%), and especially so when measured at some centers with many immunocompromised patients and prevalent echinocandin use (10–22%). Echinocandin resistance in *C. glabrata* is often also associated with concurrent fluconazole resistance (up to 36% in one study). The increased rate of echinocandin (and azole) resistance in *C. glabrata* is thought to be at least in part due to alterations in a DNA mismatch repair gene (MSH2) allowing for the more rapid emergence of escape mutations in this organism ("mutator phenotypes"). Uncommon *Candida* spp. clinical isolates demonstrate varying echinocandin resistance patterns, with one cross-sectional study demonstrating rates of MIC greater than the epidemiologic cutoff values (ECV) as follows: *C. lusitaniae*: 6/55 (11%), *C. dubliniensis*: 0/50 (0%), *C. guilliermondii*: 1/19 (5.3%), *C. kefyr*: 1/16 (6.3%). Interpretation of these elevated MICs is limited by the lack of published clinical breakpoints due to the rare isolation and decreased virulence of some of these organisms. *C. auris*, an emerging pathogen associated with nosocomial infections, typically has intrinsic fluconazole resistance and not uncommonly also has acquired pan-azole resistance and/or amphotericin B resistance. It is worrisome that some of these isolates have also shown relatively high rates of echinocandin resistance (2–7%), leaving limited options for effective antifungal therapy, which makes the emergence of multidrug-resistant (MDR) *C. auris* a public health emergency.

Triazoles

Triazoles were the second major class of systemic antifungal agents developed (after amphotericin B). There are five agents currently in clinical use: fluconazole (Diflucan, 1990), and the mold-active triazoles: itraconazole (Sporanox, 2001), voriconazole (Vfend, 2003), posaconazole (Noxafil, 2006), and isavuconazole (Cresemba, 2015). Triazoles are first-line therapy for many infections due to *Aspergillus* spp. given their fungicidal activity against this pathogen, but they have been supplanted from first-line therapy for invasive candidiasis by the echinocandins given that triazoles are fungistatic against *Candida* spp. and the increasing prevalence of triazole-resistant *Candida* clinical isolates.

History, mechanism, adverse effects

The synthetically derived imidazoles (e.g., clotrimazole, miconazole) have been used for the treatment of superficial fungal infections since 1969, but their use for systemic mycoses is restricted by their limited efficacy and systemic toxicity. Ketoconazole, a triazole (produced by N-substitution of the imidazole ring) developed in 1978, was the first orally active broad-spectrum antifungal agent available for clinical use. Similarly to imidazoles, its use as a systemic antifungal has fallen out of favor due to toxicities not present in later triazole derivatives. Fluconazole (FLC), a miconazole derivative, and itraconazole (ITC), a ketoconazole derivative, were subsequently developed and remain the "first-generation" triazoles in clinical use today. Further modifications of FLC and ITC produced the "second-generation" triazoles, voriconazole (VCZ) and posaconazole (PCZ), respectively. Most recently introduced into clinical use is the "third-generation" triazole isavuconazole (ISA), which has a structure most similar to FLC and VCZ. VCZ, PCZ and ISA are often referred to as the "newer" triazoles because of extended spectrum and favorable pharmacokinetics.

Triazole antifungal agents act by inhibiting the biosynthesis of ergosterol, an integral component of the fungal cell membrane. More specifically, they act by inhibition of lanosterol 14α-demethylase (encoded by genes ERG11 in *Candida* or CYP51 in *Aspergillus*), a key enzyme involved in the conversion of lanosterol to ergosterol in fungi, and the conversion of lanosterol to cholesterol in humans. Inhibition of this enzyme leads to a decrease in available ergosterol and, more importantly, the production of toxic metabolites by alternate metabolic pathways. Thus, triazole administration results in growth arrest and a fungistatic effect seen across most of the fungal kingdom, especially yeasts. However, in some mold (specifically many *Aspergillus*) species, there is also a subsequent fungicidal effect of some triazoles due to an ensuing period of overexuberant fungal cell wall biosynthesis without any corresponding development of hyphal protrusions; this leads to fungal cell wall stress, rupture, and, finally, fungal death.

The major adverse effect associated with the use of all triazoles is hepatotoxicity, which often manifests as asymptomatic elevation in liver function tests but in rare cases can also progress to acute liver failure. Each of the triazole agents has a differing incidence of associated hepatoxicity, with a relatively low incidence for FLC and a relatively higher incidence for VCZ. This hepatoxicity is thought to be dose-dependent (at least with VCZ), and thus the incidence of toxicity is also affected by several pharmacokinetic parameters. Alopecia is also relatively common with extended triazole therapy (including at least FLC and VCZ), and QTc prolongation (FLC, ITC, VCZ, PCZ) or shortening (ISA) have also been described. The adverse-effect profile of VCZ is somewhat unique. Early side effects include relatively common reports of visual disturbances (often transient as a result of early retina stimulation with the first doses), but also frank hallucinations and peripheral neuropathy. Long-term adverse effects associated with prolonged VCZ use are painful periostitis (due to fluoride accumulation, a component of VCZ formulations, often manifesting as isolated elevation of alkaline phosphatase levels) and development of cutaneous malignancies associated with VCZ skin phototoxicity, especially in vulnerable patient populations with additional risk factors, such as organ transplant recipients on calcineurin inhibitors and stem cell transplant recipients with graft-versus-host disease.

Pharmacology, drug interactions

The "short-tailed" triazoles (FLC, VCZ, ISA) all have excellent bioavailability (>90%), though VCZ is best absorbed on an empty stomach, whereas absorption of the "long-tailed" triazoles (ITC, PCZ) is less straightforward. ITC is well absorbed after a full fatty meal, is also best absorbed at low gastric pH, but notably has only 54% relative bioavailability with an empty stomach. Furthermore, ITC solution has 133% relative bioavailability as compared to ITC capsules. PCZ is formulated as an oral suspension as well as delayed-release tablets. The PCZ oral suspension has similar characteristics as ITC, with bioavailability maximized by administration with a high-fat meal and low gastric pH, but otherwise has relatively lower and unpredictable absorption. In contrast, absorption of the PCZ delayed-release tablet is unaffected by food intake and gastric acidity, providing uniformly adequate drug levels. FLC, VCZ, PCZ, and ISA are all also available in parenteral formulations; both VCZ and PCZ parenteral formulations contain cyclodextrin so their use is limited in patients with renal insufficiency. ISA is given as isavuconazonium sulfate (the water-soluble prodrug of isavuconazole) in both the oral and parenteral formulations, which rapidly disassociates to release the active drug soon after administration. It also has excellent absorption that is not affected by food intake or gastric acidity.

ITC, VCZ, PCZ, and ISA are highly protein-bound (99%, 58%, 98%, and 99%, respectively) and have extensive tissue distribution, whereas FLC is minimally protein-bound (12%) and has a distribution that approximates total body water. FLC does not undergo significant metabolism but is instead primarily excreted unchanged in the urine; it therefore requires dosage adjustments for renal impairment (but not for hepatic impairment) and is also the only triazole reliably effective for *Candida* urinary tract infections. In contrast, ITC, VCZ, and ISA undergo extensive hepatic metabolism (ITC and ISA via CYP3A4, VCZ via CYP2C19), with inactive metabolites of each excreted in urine or feces. PCZ undergoes limited hepatic metabolism via UGT1A rather than via a CYP enzyme and is primarily excreted unchanged in the feces. ITC and VCZ have recommended dosage adjustments for hepatic impairment whereas PCZ and ISA do not. All triazoles have generally good penetration into most tissues; however, given its relatively small size, low lipophilicity, and low affinity for plasma proteins, FLC has superior penetration to aqueous compartments such as the cerebrospinal fluid (CSF), eye, and urine. VCZ also has some CSF penetration (50%) given its relatively lower affinity for plasma proteins as compared to some of the other triazoles, but is almost absent (<5%) from the urinary compartment. ITC, PCZ, and ISA each have suboptimal (compared to VRC) CSF and very poor urine penetration. All of the triazoles have long terminal half-lives allowing either once- or twice-daily dosing.

Therapeutic drug monitoring (TDM) is recommended for VCZ given its narrow therapeutic window and metabolism by CYP2C19, an enzyme with several relatively common genetic polymorphisms which can widely vary the rate of VCZ metabolism. TDM has also been recommended for ITC and PCZ (especially the oral suspension) given the variable oral absorption of these agents; it is unclear if TDM is necessary for the PCZ delayed-release tablets or ISA given the uniformly adequate drug levels found with these formulations. However, PCZ or ISA levels can be measured and the authors of this chapter have found them useful in selected cases, such as patients with absorption issues or concerns for toxicity or significant drug–drug interactions (e.g., induced catabolism of ISA by phenobarbital).

The triazoles are notorious for interacting with other medications, due primarily to interactions with CYP enzymes, leading to increased levels of other drugs metabolized by these enzymes (e.g., warfarin, NSAIDs, angiotensin receptor blockers [ARBs] for 2C9; proton pump inhibitors [PPIs], selective serotonin reuptake inhibitors [SSRIs], methadone for 2C19; and statins, amiodarone, cyclosporine, tacrolimus, and sirolimus for 3A4). Moreover, ITC and ISA are metabolized via CYP3A4 and VCZ is metabolized via CYP2C19, therefore inducers (e.g., rifampin or some antiepileptics) or inhibitors (e.g., clopidogrel or some protease inhibitors) of these CYP enzymes act to decrease or increase, respectively, the levels of these three triazoles. While some drug–drug interactions are predictable (e.g., the reliably increased cyclosporine, tacrolimus, and sirolimus levels encountered with triazole use), given the multitude of potential interactions it is wise to always carefully address drug interactions when using triazoles. For tacrolimus and sirolimus, usually a 50% and 66% dose reduction with FLC or VRC/PCZ coadministration is recommended, depending on pre-administration levels and goal.

Therapeutic use, clinical resistance

FLC is active against most yeasts, including many *Candida* spp. and *Cryptococcus* spp., but is generally not active against molds. ITC is used clinically for the treatment of the dimorphic fungi and has anti-*Aspergillus* activity. VCZ is active against most yeasts (including some FLC-resistant *Candida* spp., such as *C. krusei* that is intrinsically resistant to FLC). VCZ is considered the first-line antifungal agent for infections due to *Aspergillus* spp. (including the often AmB-resistant *A. terreus*) and can also be used for the treatment of other hyaline and dematiaceous molds including *Fusarium* spp. and *Scedosporium apiospermum*. PCZ and ISA have additional activity against *Mucorales* spp. FLC is the only triazole agent used for the treatment of urinary tract infections given the limited renal excretion of the other agents. FLC and VCZ are the two triazole agents used most often for treatment of fungal infections in the CNS given their relatively increased CSF penetration as compared to the other triazoles. Posaconazole is also used for antifungal prophylaxis during induction chemotherapy for acute myeloid leukemia and in hematopoietic stem cell transplant recipients with graft-versus-host disease.

There is an ongoing trend of increased resistance to triazole agents, due both to increased rates of triazole use in humans for prophylaxis and treatment as well as to the widespread use of biosimilar fungicides in veterinary and agricultural practice. Resistance to triazoles can be either intrinsic or acquired and is generally due to target modification, increased target production,

or antifungal efflux. In *Candida* spp., intrinsic FLC resistance due to an ERG11 modification is seen consistently in both *C. krusei* and *C. auris*. Acquired pan-triazole resistance, not uncommon in *C. glabrata* and *C. auris*, can develop as a result of a distinct ERG11 modification or via a gain of function mutation in a regulatory gene resulting in overexpression of ERG11 (too much target) or of a CDR efflux pump (not enough antifungal). These mutations are thought to be more common in *C. glabrata* than in other *Candida* spp due to its haploid genome, and, possibly, an intrinsic mutation in MSH2 (a DNA repair gene). In *Aspergillus* spp., intrinsic FLC resistance is ubiquitous due to a polymorphism of CYP51 (as compared to the ERG11 homolog in *Candida* spp). Intrinsic resistance to multiple triazole agents is associated with *A. fumigatus* isolates which have the TR34-L98H or TR46-Y121F/T289A genotypes (representing paired mutations in the CYP51 promoter as well as the CYP51 gene) and are thought to have developed due to selective pressure from ongoing environmental fungicide use. *A. fumigatus* resistance to triazoles is an important emerging concern of clinical significance in Europe, less so in the United States. Acquired triazole resistance is most often associated with prolonged triazole treatment and is usually due to one of many known resistance-conferring single-point mutations in CYP51. Less is known about resistance mechanisms in other *Aspergillus* spp. and in other molds.

Other antifungal agents

Nystatin

Similar to amphotericin B, nystatin is a polyene with similar mechanism of action. However, its use is limited to topical application for skin infections (nystatin powder) and oropharyngeal candidiasis (nystatin oral suspension, "swish and spit or swallow"). Some centers use it as antifungal prophylaxis in a high-risk (transplant) patients, although fluconazole is superior, to avoid CYP-mediated drug–drug interactions, especially with calcineurin or mTOR inhibitors (see earlier discussion).

Flucytosine (5FC)

Flucytosine is metabolized to 5-fluro-uracil (5FU), acting then as an antimetabolite that inhibits fungal DNA synthesis. As such, the genetic barrier to development of resistance is very low, and monotherapy is only recommended for uncomplicated urinary tract infections from susceptible *Candida* strains. However, it is useful in combination therapy, its combination with AmB being the standard of care for the initial ("induction") treatment of serious cryptococcal infections, including cryptococcal meningitis. The combination of AmB+5FC is also recommended for the management of some serious *Candida* infections, such as endocarditis. TDM of 5FC levels can have a role in dose adjustments if prolonged administration is required. The main adverse events associated with 5FC are myelosuppression (especially hypoproliferative anemia) and hepatotoxicity. 5FC needs to be renally adjusted.

Terbinafine

Similar to azoles, terbinafine, an allylamine, acts on the fungal cell wall, disrupting ergosterol synthesis by inhibition of a different enzyme, squalene monooxygenase (2,3-epoxidase). It is highly lipophilic and therefore accumulates in the skin, nails, and fatty tissues. Its main indication as monotherapy is onychomycosis. Clinicians also use it in combination regimens against difficult to treat and potentially resistant mold infections such as fusariosis and scedosporiosis. It can cause hepatotoxicity.

Antifungals under development

The antifungal armamentarium has rapidly expanded over the past few decades at an unprecedented rate, and many new molecules are currently being investigated with promising results. Nikkomycin Z (VFS-1) targets the synthesis of the cell wall component, chitin, and has activity against *Coccidioides immitis* and *Blastomyces dermatitidis* alone and against *Candida* spp., *C. neoformans*, and *A. fumigatus* in combination with azoles. T-2307 is an aromatic diamidine with some structural similarities to pentamidine, which acts on the mitochondrial membrane, and it has potent activity against *Candida* spp., including *Candida* strains that are resistant to other antifungals, *C. neoformans* and *A. fumigatus*.

Rezafungin (also known as biafungin or CD101) is a long-acting echinocandin that is administered weekly. Despite its long half-life, it achieves high serum concentrations for long periods of time and has not been shown in preliminary studies to select resistant strains more than existent echinocandins. Ibrexafungerp (SCY-078) is an oral β-D-glucan inhibitor that also seems to have in vitro activity against some resistant *Candida* strains, including isolates with decreased susceptibility to echinocandins. Olorofim (F901318) is an orotomide that targets dihydroorotate dehydrogenase (DHODH) in the de novo pyrimidine biosynthesis pathway. It lacks anti-*Candida* activity, but is effective against *Aspergillus* spp. and, potentially, other molds. A detailed review of novel compounds with potential antifungal action is beyond the scope of this chapter and has been included in other recent comprehensive publications.

Antiviral therapy

Rajeev Shah and Cheston B. Cunha

Successful antiviral therapy continues to be one of many challenges facing the healthcare provider today. All viruses parasitize host cell enzymes and structures to varying degrees. Designing or discovering drugs that specifically target viral enzymes without affecting host cell machinery is difficult. This is crucial because a lack of specificity increases the risk of toxicity. Additionally, many viruses establish a latent infection in the host, during which time they are essentially quiescent. Elimination of latent viruses from the host has not been possible to date. Some of the most serious viral infections today stem from the reactivation of latent viruses during periods of impaired cell-mediated immunity. Additionally, an ongoing challenge in antiviral therapy is the development of drug resistance due to viral mutagenicity.

The availability of antiviral agents has significantly reduced the incidence of morbidity and mortality. Most of the currently available antiviral agents target the virus by exploiting differences between the viral and host replication processes. Many viruses have their own specific DNA polymerases, which are more susceptible to inhibition by specific drugs than are the cellular DNA replication enzymes. Consequently, many antiviral agents are nucleoside or nucleotide analogs that inhibit these enzymes and cause chain termination when incorporated into replicating genetic material. In addition, some of these compounds accumulate preferentially in virus-infected cells or are activated by virus-encoded enzymes, increasing their specificity. Nevertheless, similar to antibacterial agents, most antiviral agents remain far from being a panacea due to dose-related toxicities and potential for development of resistance.

This chapter reviews the clinical utility, pharmacokinetics, adverse effects, and drug–drug interactions of antiviral agents for the treatment of herpes simplex virus (HSV), varicella-zoster virus (VZV), influenza, hepatitis B virus (HBV), hepatitis C virus (HCV), cytomegalovirus (CMV), respiratory syncytial virus (RSV), and coronavirus disease 2019 (COVID-19) (Table 208.1). Antiretrovirals associated with the treatment of human immunodeficiency virus (HIV) are discussed in Chapter 98, "HIV infection: antiretroviral therapy."

Herpes simplex virus: Systemic therapies

Acyclovir

Acyclovir, a guanine derivative, has in vitro activity against several viruses, but in clinical practice it is used primarily for the treatment and prevention of HSV-1, HSV-2, and VZV. Acyclovir is preferentially taken up by HSV-infected cells and is phosphorylated by viral thymidine kinase, which is necessary for conversion to the active triphosphate form. It competitively inhibits viral DNA polymerase and causes DNA chain termination when incorporated into replicating DNA.

Oral acyclovir may be used for primary episodes of genital herpes to reduce the time of viral shedding and time to healing at a dose of 200 mg five times per day or 400 mg three times daily for 7 to 10 days. The latter regimen is preferred for patients with HIV and may be preferred for patients with poor adherence due to decreased frequency of administration. It can also be used for treatment of recurrent episodes

TABLE 208.1 **ANTIVIRAL DRUGS APPROVED BY THE US FOOD AND DRUG ADMINISTRATION (FDA)**

HSV/VZV	Influenza	HBV	HCV	CMV	RSV	COVID-19
Acyclovir	Oseltamivir	Lamivudine	Ledipasvir/sofosbuvir	Ganciclovir	Palivizumab	Remdesivir
Valacyclovir	Peramivir	Entecavir	Sofosbuvir/velpatasvir	Valganciclovir		
Famciclovir	Zanamivir	Tenofovir	Elbasvir/grazoprevir	Cidofovir		
Docosanol	Baloxavir	Adefovir	Sofosbuvir/velpatasvir / voxilaprevir	Foscarnet		
Penciclovir	Amantadine	Telbivudine	Glecaprevir/pibrentasivir	L4etermovir		
Trifluridine	Rimantadine	Peginterferon- α2a	Ombitasvir/paritaprevir/ ritonavir/dasabuvir			
			Daclatasvir			
			Ribavirin			

Abbreviations: CMV = cytomegalovirus, COVID-19 = coronavirus disease 2019, HBV = hepatitis B virus, HCV = hepatitis C virus, HSV = herpes simplex virus, RSV = respiratory syncytial virus, VZV = varicella-zoster virus.

with several dosing regimens such as 400 mg orally three times daily for 5 days, 800 mg orally twice daily for 5 days, or 800 mg orally three times daily for 2 days. Duration of therapy for initial episodes and recurrences may be extended if there is insufficient clinical improvement. All regimens for recurrence should be initiated within 24 hours of lesion development or prodrome onset. Last, acyclovir can be used as chronic suppressive therapy to decrease the incidence of recurrent genital HSV at a dose of 400 mg orally twice daily. Chronic suppressive therapy should be evaluated annually to reassess the need for suppression as incidence of recurrence decreases over time. Antiviral therapy improves time to healing and duration of symptoms but does not completely eradicate latent virus. Dosing of oral acyclovir for herpes labialis is similar.

Acyclovir is available in two topical forms. A topical ointment demonstrated mild benefit for initial genital HSV episode, but failed to show a benefit for recurrent episodes. A topical acyclovir cream is applied 5 times a day for 4 days for primary herpes labialis, but its impact on the natural course of the infection is limited to a decrease in median duration of symptoms by only 0.5 days. For these reasons, topical therapies are not recommended. For the severe mucosal and cutaneous lesions most commonly seen in patients with immunodeficiencies, hospital admission and acyclovir 5 mg/kg intravenously (IV) every 8 hours is warranted.

IV acyclovir reduces mortality in HSV encephalitis and should be used at high dosages (10 mg/kg IV q8h) for 14 to 21 days. It is typically dosed based on ideal body weight; however, some data suggest that ideal body weight dosing in patients with a body mass index (BMI) >40 kg/m^2 may lead to lower serum concentrations and drug exposure. Adjusted body weight may be more appropriate in patients with BMIs of >40 kg/m^2 if there is not significant clinical improvement when dosing based on ideal body weight.

Acyclovir is also active against VZV, but treatment of VZV infections requires higher dosages than treatment of uncomplicated HSV infections because acyclovir undergoes less efficient activation to the triphosphate form by VZV thymidine kinases. Acyclovir, 800 mg five times daily for 7 to 10 days, should be used in patients with herpes zoster (shingles) to prevent dissemination and to shorten the time to healing. In immunocompromised patients, localized infection can be treated with the same oral dosing of acyclovir just mentioned. However, if there is severe, disseminated, or complicated disease, 10 mg/kg IV every 8 hours is indicated. Therapy duration is approximately 7 days, but may need to be extended pending clinical course. Oral agents such as acyclovir or valacyclovir may be used as stepdown therapy to complete the course. Unfortunately acyclovir therapy does not convincingly alter the subsequent development of complications such as postherpetic neuralgia (PHN). VZV can also present with ophthalmologic involvement and can cause acute retinal necrosis, both of which require prompt medical evaluation and treatment. Acyclovir ophthalmic ointment is commercially available and indicated for HSV-related keratitis.

Acyclovir 800 mg orally five times daily for 5 to 7 days is effective in the treatment of primary varicella or chickenpox, shortening the duration and severity of illness when begun within 24 hours after the onset of rash. The recommended dose for the treatment of immunocompromised patients with an uncomplicated infection is the same as the preceding, but for severe, disseminated, or complicated infection 10 mg/kg IV every 8 hours for 7 to 10 days is appropriate.

Acyclovir is also indicated for mucocutaneous HSV prophylaxis in solid organ and bone marrow transplant recipients who are not already receiving prophylaxis against CMV. Acyclovir 400 to 800 mg orally twice daily is recommended for 30 days in solid organ transplant and at least until resolution of neutropenia in bone marrow transplant patients. The incidence of acyclovir resistance in HSV and VZV is low in the general population but should be considered in patients who fail to respond to therapy. Resistance is mediated by changes in viral thymidine kinase or DNA polymerase and is most commonly seen in immunocompromised patients. For cases of acyclovir-resistant HSV, consider use of topical cidofovir 1% gel, trifluridine 1% solution, foscarnet 1% solution, or imiquimod 5% cream for mucocutaneous cases and IV foscarnet or cidofovir for more severe cases. Topical cidofovir, trifluridine, and foscarnet are not commercially available in the United States and

must be compounded. In the case of acyclovir-resistant VZV, use IV foscarnet or cidofovir.

Pharmacokinetics

Acyclovir has poor water solubility and hence poor oral bioavailability (10–20%) but good tissue distribution. The low oral bioavailability is unaffected by administration with food and necessitates frequent administration, which is partly resolved by using either the IV formulation or the prodrug valacyclovir. The serum half-life is 2.5 to 3 hours, depending on renal function. Acyclovir is predominantly excreted as unchanged drug in the urine, and dose adjustment is necessary in patients with impaired renal function. Dose adjustments begin at a creatinine clearance (CrCl) of <25 mL/min/1.73 m^2 and 50 mL/min/1.73 m^2 for oral and IV acyclovir, respectively. Acyclovir is safe for use in pregnant and breastfeeding women with active or a history of HSV infection.

Adverse effects

Central nervous system adverse effects range from confusion to seizures and coma, especially in the settings of renal insufficiency, underlying altered mental status, and advanced age. Renal failure may occur from acyclovir precipitation in the renal tubules. Therefore, when administering high IV doses, it is important to ensure adequate hydration of the patient. Common adverse effects of oral acyclovir include nausea and vomiting (2.7%), diarrhea (2.4%), and malaise (11.5%).

Drug interactions

Acyclovir is primarily excreted in the urine as unchanged drug (60–90%), but a small portion is metabolized by cytochrome P450 1A2 (CYP1A2). As a result, concomitant therapy with medications that inhibit CYP1A2, decrease renal function, or compete for renal transporter may lead to increased acyclovir exposure. For example, coadministration of acyclovir with theophylline, aminoglycosides, or probenecid may increase acyclovir exposure although dose adjustment is usually not necessary because of the wide therapeutic index of oral acyclovir. Consider dose adjustment of IV acyclovir in patients who are at higher risk for toxicity (e.g., elderly, poor renal function at baseline).

Valacyclovir

Valacyclovir is metabolized to acyclovir after oral administration, and oral bioavailability of the active form is 55%.Valacyclovir is indicated for primary (1 g BID for 7–10 days) and recurrent (500 mg BID for 3 days or 1 g once daily for 5 days) genital HSV. Treatment of recurrent episodes is ideally initiated within 24 hours of lesion development or prodrome onset. The efficacy of valacyclovir for genital HSV is similar to that of acyclovir, but the improved bioavailability reduces the number of administrations required per day. There is no IV formulation of valacyclovir; for severe, complicated, or disseminated infections IV acyclovir may be used initially. The dose of valacyclovir for suppression of HSV is 500 mg or 1 g once daily. For patients with HIV (PWH), 500 mg twice daily is recommended. The need for suppression should be reassessed annually as incidence of recurrence decreases over time. Herpes labialis can be treated with 2 g twice daily for 1 day; however, a longer treatment duration of 1 g twice daily for 5 to 10 days is required for PWH. Treatment duration may need to be extended pending clinical improvement. Early initiation of treatment has shown to reduce the mean duration of symptoms by 1 day. Antiviral therapy does not completely eradicate HSV or influence incidence of recurrent episodes.

In terms of treatment of VZV (both shingles and primary varicella infection) a higher dose of 1 g three times daily for 7 days is indicated, but therapy may be extended until there are no new lesions and lesions have crusted. Data demonstrate in a reduction in duration of VZV symptoms by one day with valacyclovir therapy when compared to placebo. Valacyclovir 500 mg twice daily can also be used for prophylaxis in solid organ and bone marrow transplant patients to prevent reactivation of HSV in patients not receiving anti-CMV therapy. If there is concern for valacyclovir-resistant VZV or HSV, please refer to the acyclovir section for management. When treating VZV meningitis/encephalitis, a higher dose of 2 g every 6 hours should be used.

Pharmacokinetics

Valacyclovir is readily absorbed from the GI tract after oral intake and is almost completely converted to acyclovir and L-valine via first-pass intestinal and hepatic metabolism. Acyclovir is then primarily excreted in the urine (89%). The half-life of active acyclovir is 2.5 to 3 hours but can be prolonged in renal impairment. Dose adjustments of valacyclovir begin at CrCl of 50 mL/min and 30 mL/min for herpes zoster/labialis and genital HSV, respectively. No hepatic dose adjustments are required. Acyclovir remains the drug of choice in pregnancy as it is the most well studied, but valacyclovir may be an alternative if there are concerns for acyclovir intolerance or pill burden.

Adverse effects

The major toxicities are similar to those of acyclovir including confusion, seizures, and altered mental status. Common adverse reactions were similar to acyclovir and include headache (14%), dizziness (2%), and nausea (6%).

Drug interactions

As valacyclovir is a prodrug of acyclovir, the drug interaction profile is similar. Please see acyclovir section on drug–drug interactions.

Famciclovir

Famciclovir is an inactive prodrug of penciclovir, which has a spectrum of activity similar to that of acyclovir. After oral administration, famciclovir is rapidly metabolized to penciclovir, which is then triphosphorylated by viral thymidine kinase and has a mechanism of action similar to acyclovir. Famciclovir's bioavailability is 77%, which

is considerably higher than that of acyclovir, and consequently it has less frequent administration. It is also indicated for the treatment of initial (250 mg TID for 7–10 days), recurrence (1 g BID for 1 day, 125 mg BID for 5 days, or 500 mg once followed by 250 mg BID for 2 days) and also for suppression of recurrent genital HSV (250 mg q12h). For PWH, genital HSV initial episodes, recurrences, and suppression requires 500 mg twice daily. Treatment duration in PWH is 7 to 10 days and 5 to 10 days for initial episodes and recurrences, respectively. Treatment of recurrent genital HSV should begin within 24 hours of symptom or prodrome onset. The need for suppressive therapy should be reassessed annually as incidence of recurrence decreases over time. It is also used for recurrent herpes labialis in immunocompetent patients (1,500 mg as a single dose at the first sign of recurrence) and PWH (500 mg BID for 5–10 days). Longer durations of therapy may be required pending clinical course. Antiviral therapy does not completely eradicate HSV or influence incidence of recurrent episodes. No IV formulation is available, and, for severe, complicated, or disseminated infections use IV acyclovir.

Famciclovir is approved for treatment of herpes zoster in immunocompetent and immunocompromised populations (500 mg TID for 7 days) and provides similar clinical benefit to acyclovir. Duration of therapy may need to be extended if there is insufficient clinical response after 7 days. One study found a decreased duration of PHN when comparing famciclovir to placebo, but no significant difference was found when it was studied against acyclovir. Famciclovir can be used as step-down therapy after IV acyclovir in severe cases to complete the treatment course. If there is concern for famciclovir-resistant VZV or HSV, please refer to the acyclovir section for management.

Pharmacokinetics

Famciclovir is a prodrug that is converted via aldehyde oxidase into active penciclovir upon administration. Administration of famciclovir with food decreases penciclovir maximal concentration and increases its time to peak penciclovir concentration; however, total drug exposure remains the same. Penciclovir is primarily excreted renally as unchanged drug (73%). The serum half-life is 2.5 to 3 hours, but the intracellular half-life is 10 to 20 times longer. Dose adjustment is necessary in patients with reduced renal function and begins at a CrCl of 60 mL/min for most indications, but no hepatic dose adjustments are necessary. Acyclovir remains the drug of choice in pregnancy as it is the most well-studied, but famciclovir may be an alternative if there are concerns for acyclovir intolerance or pill burden.

Adverse effects

Common adverse effects include headache (8.5–39%), nausea (2.2–12.5%), diarrhea (1.2–9%) and vomiting (0.7–4.8%).

Drug interactions

Probenecid may lead to increased famciclovir serum concentrations through competition for renal transporters used for elimination. Famciclovir is not a CYP3A4 substrate.

Herpes simplex virus: Topical therapies

Docosanol

Docosanol is a saturated fatty alcohol that reduces the duration of cold sores associated with HSV by approximately 1 day in clinical studies. Its mechanism of action is prevention of HSV entry into the host cell through inhibition of viral fusion. Docosanol 10% is available without a prescription in the United States and is applied topically to the cold sore five times a day at the first sign of infection for up to 10 days. The most commonly reported side effects include headache and local skin irritation.

Penciclovir

Penciclovir is another nucleoside analog with mechanism of action and spectrum of activity similar to that of acyclovir. It is available only as a topical preparation at a concentration of 1% for recurrent herpes labialis. Famciclovir is an oral prodrug of penciclovir. In clinical trials, topical penciclovir shortened the duration of symptoms by 0.5 days if applied within 1 hour of the beginning of symptoms and again every 2 hours while awake for 4 days. Thus the combination of its unimpressive clinical performance and cumbersome dosing have decreased its use in clinical practice.

Trifluridine

Trifluridine 1% is a fluorinated thymidine analog that interferes with DNA synthesis and is used topically for the treatment of HSV keratitis or for acyclovir-resistant mucocutaneous HSV. Trifluridine may cause local irritation and palpebral edema when used for HSV keratitis.

Influenza therapies

Oseltamivir

Oseltamivir phosphate was approved in 1999 as the first oral neuraminidase inhibitor. Inhibition of influenza's neuraminidase prevents release of newly formed virus and infection of surrounding cells. It was originally approved for the treatment of uncomplicated influenza. Initial clinical trials demonstrated a 1.3-day shorter time to improvement when compared to placebo. However, it is now also recommended for severe or complicated cases in the outpatient and hospital setting. Clinical efficacy is greatest when initiating therapy within 48 hours of illness onset, but oseltamivir has shown some benefit in hospitalized patients with illness onset of 4 to 5 days prior to administration. The dose for treatment of influenza is 75 mg orally twice daily for 5 days, but extended duration may be necessary in hospitalized patients with severe and prolonged illness. Oseltamivir can also be used for prophylaxis of influenza at a dose of 75 mg orally once daily for 10 days started within 48 hours of exposure. A longer duration of prophylaxis can be used in institutional or hospital settings, such as continuing therapy for 7 days

after last known exposure. Cross-resistance with other neuraminidase inhibitors can occur.

Pharmacokinetics

Oseltamivir is well absorbed by the GI tract with an oral bioavailability of at least 75%. Oral oseltamivir is well absorbed in critically ill patients, and data demonstrate serum concentrations similar to those in ambulatory patients. It is converted to the carboxylate salt by hepatic esterases, but there is no metabolism by CYP enzymes. Volume of distribution ranges from 23 to 26 liters, and it has low plasma protein binding. Oseltamivir carboxylate is eliminated in the urine by both glomerular filtration and tubular secretion, and so renal dose adjustments are required at CrCl of 60 mL/min. No hepatic dose adjustment is required. Oseltamivir is the preferred agent for the treatment of influenza in pregnant women.

Drug interactions

Oseltamivir may reduce the efficacy of the live attenuated influenza vaccine, and the vaccine should not be administered 2 weeks before or 48 hours after administration. Inactivated influenza vaccine may be administered at any time.

Adverse effects

Associated adverse events include vomiting (9%), nausea (10%), abdominal pain (2%), and dizziness (2%). Serious but rare adverse effects are serious skin hypersensitivity reactions and neuropsychiatric events.

Peramivir

Peramivir was approved in 2015 as a single-dose IV neuraminidase inhibitor for the treatment of acute uncomplicated influenza. Inhibition of influenza's neuraminidase prevents release of newly formed virus and infection of surrounding cells. In clinical trials for acute uncomplicated influenza, single-dose peramivir demonstrated a shorter time to recover by 21 hours when compared to placebo. Of note, the vast majority of patients (99%) enrolled in this study had influenza A; there were an insufficient number of patients with influenza B. It failed to show a benefit as a single dose in serious influenza requiring hospitalization. However, data are conflicting on the efficacy of multiple-dose peramivir in hospitalized patients. The dose is 600 mg intravenously once and should be initiated within 48 hours of symptom onset. Clinical utility in the outpatient setting is limited by route of administration. Cross-resistance with other neuraminidase inhibitors has been seen. Peramivir does not undergo metabolism and is predominantly eliminated via the kidneys (90%) with a half-life of 20 hours. Renal dose adjustment is required for patients with CrCl of <50 mL/min. Safety and efficacy in pregnancy and lactation has not been established. Serious but rare adverse effects include serious skin hypersensitivity and neuropsychiatric events. Other adverse effects in clinical studies were diarrhea (8%), increases in creatine phosphokinase (>6 times the upper limit of normal) (4%), and elevations in alanine aminotransferase (ALT; >2.5 times the upper limit of normal) (3%). Peramivir may reduce the efficacy of the live attenuated influenza vaccine, and the vaccine should not be administered 2 weeks before or 48 hours after administration. Inactivated influenza vaccine may be administered at any time.

Zanamivir

Zanamivir is an inhaled neuraminidase inhibitor that is indicated for the treatment of influenza A and influenza B in patients who have been symptomatic for no longer than 48 hours. Inhibition of influenza's neuraminidase prevents release of newly formed virus and infection of surrounding cells. The clinical benefit seen of zanamivir in clinical studies was a decrease in median time to symptom improvement by approximately 24 hours. Zanamivir is dosed as two inhalations (10 mg) every 12 hours for 5 days for the treatment of influenza. It is also indicated for the prophylaxis of influenza. The dosing for prophylaxis is lower at two inhalations (10 mg) once daily. A duration of 10 days is recommended for prophylaxis of household contacts, and a longer duration can be used for community or institutional outbreaks. There is a significant risk of bronchospasm in patients with underlying respiratory conditions such as asthma and chronic obstructive pulmonary disease. Consequently, the clinical utility of zanamivir is limited because it cannot be used in those patient populations at one of the highest risks of complications from influenza. In addition, post-marketing reports of neuropsychiatric events such as delirium have been reported. Common adverse effects include diarrhea (3%), nausea (3%), and headaches (2%). A small percentage of zanamivir is systemically absorbed, but no dose adjustments are required for renal or hepatic impairment. Safety and efficacy in pregnancy and lactation has not been established. Coadministration with the live attenuated influenza vaccine may decrease effectiveness of the vaccine; the vaccine should not be administered 2 weeks before or 48 hours after administration. Inactivated influenza vaccine may be administered at any time.

Baloxavir

Baloxavir is a polymerase acidic endonuclease inhibitor indicated for the treatment of acute uncomplicated influenza. Inhibition of the endonuclease prevents viral gene transcription which decreases viral replication. It was approved in 2018 for adults and pediatric patients >12 years as a first in class agent with a novel mechanism of action. For patients weighing <80 kg, a single dose of 40 mg is a sufficient treatment course. Patient weighing ≥80 kg or more should receive 80 mg as a single dose. Therapy should be initiated within 48 hours of symptom onset. Baloxavir retains activity against neuraminidase-resistant strains of influenza; cross-resistance is not expected because the mechanism of action is different. Initial clinical trials demonstrated a 28-hour decrease in time to alleviation of symptoms when compared to placebo; however, no difference was noted in comparison to oseltamivir. Results were similar in studies of hospitalized patients. Baloxavir is highly protein bound, undergoes metabolism by UGT1A1 and CYP3A4, and has a long half-life of 79 hours. There are no recommendations for dosing in CrCl of <50 mL/min, but only 15% of the dose is eliminated in

the urine. No hepatic dose adjustment is required. Safety and efficacy in pregnancy and lactation has not been established. Baloxavir can be administered without regard to food, but should not be administered with polyvalent cations due to chelation and subsequent reduction drug exposure. It may also decrease the effectiveness of the live attenuated influenza vaccine. The incidence of adverse effects were low with diarrhea (3%), bronchitis (2%), and nausea (1%) being the most common.

Amantadine and rimantadine

Amantadine is used to treat Parkinson's disease and as an antiviral agent that prevents uncoating of influenza A virus by inhibiting the M2 channel protein. Rimantadine is a structural analog of amantadine with the mechanism of action. They do not have activity against influenza B. Widespread resistance exists to these agents among circulating influenza A strains. It is therefore no longer recommended for prevention or treatment.

Hepatitis B therapies

Lamivudine

Lamivudine is a cytosine analog most commonly used as part of antiretroviral regimens for treatment of HIV. Incorporation of monophosphorylated lamivudine into replicating HBV causes chain termination, and the triphosphorylated form inhibits HBV DNA polymerase. The dose for treatment of HBV is 100 mg/d and has been shown to result in serologic conversion, virologic response, and histologic improvement. Of note, this dose is lower than the 300 mg/d dose recommended for HIV. Although lamivudine has demonstrated clinical benefit, monotherapy for both HIV and HBV is not recommended as treatment emergent resistance will occur. Therefore, lamivudine is no longer first-line therapy in many national guidelines. The preferred regimen for HBV/HIV coinfection is lamivudine or emtricitabine (another cytosine analog) in combination with tenofovir disoproxil fumarate (TDF) or tenofovir alafenamide (TAF). Screening for HIV coinfection should occur prior to initiation of lamivudine as monotherapy of occult HIV results in rapid appearance of lamivudine-resistant HIV. If a patient has a history of HBV lamivudine resistance, the preferred therapy is tenofovir monotherapy or tenofovir in combination with lamivudine (or emtricitabine).

Pharmacokinetics

Lamivudine is rapidly absorbed after oral intake, but administration with food decreases maximal concentration. The majority of lamivudine is eliminated unchanged in the urine, and dose adjustment is recommended at CrCl of <50 mL/min. The mean elimination half-life is typically between 5 and 7 hours but may be longer in patients with renal impairment. No hepatic dose adjustment is required, and lamivudine is safe for use in pregnancy.

Adverse effects

Lamivudine is well-tolerated in general. Serious adverse events are rare, but include lactic acidosis, hepatic steatosis, pancreatitis, and exacerbation of HBV after discontinuation. Common adverse effects include malaise and fatigue (24%), nausea and vomiting (15%), and headache (21%).

Drug interactions

Because lamivudine is mainly eliminated by active organic cationic secretion into the urine as unchanged drug, the possibility exists of interactions with other drugs eliminated by a similar mechanism. However, no clinically relevant interactions are known that would require dose adjustments. Lamivudine and emtricitabine are both cytosine analogs with similar activity; they should not be used in combination.

Entecavir

Entecavir is a guanosine analog that works by inhibiting HBV DNA polymerase. For the treatment of chronic HBV patients with compensated liver disease who are nucleoside-treatment naïve, the dosing is 0.5 mg orally once daily. Although tenofovir is preferred in the setting of lamivudine failure or in lamivudine and/or telbivudine resistance, entecavir 1 mg orally once daily can be used. The higher dosing of 1 mg/d is also recommended for patients with decompensated liver disease. In the case of entecavir resistance, it is recommended to add tenofovir or change to emtricitabine-tenofovir. Like lamivudine, HIV resistance may emerge in chronic hepatitis B patients treated with entecavir but with unrecognized or untreated HIV infection. If entecavir therapy is required in a patient with HIV, ensure that the patient is on a fully suppressive HIV regimen to prevent development of resistance.

Pharmacokinetics

Entecavir has a bioavailability of 100% following oral administration under fasted conditions. Patients should be counseled to take entecavir 2 hours prior or 2 hours after a meal. Food delays absorption and decreases maximal concentration and overall drug exposure by 44% to 46% and 18% and 20%, respectively. It is predominantly eliminated by the kidney as unchanged drug and undergoes glomerular filtration and tubular secretion. It requires renal dose adjustment beginning at CrCls of <50 mL/min.

Adverse effects

Commonly reported side effects include headaches (2–4%), fatigue (1–3%), dizziness (< 1%), and gastrointestinal (GI) symptoms (1%). Severe acute exacerbations of hepatitis have occurred when treatment has been discontinued.

Drug interactions

Entecavir may be potentiated by drugs that decrease renal function or compete for active tubular secretion.

Tenofovir

Tenofovir is an adenosine analog that competitively inhibits HBV DNA polymerase. There are two different formulations of tenofovir: tenofovir disoproxil fumarate (TDF) and tenofovir alafenamide (TAF). TDF was originally approved in the United States in 2001 for the treatment of HIV-1 in combination with other agents and later gained approval for the treatment of chronic hepatitis B in 2008. After oral administration, serum TDF is converted into tenofovir through hydrolysis and is intracellularly activated to its disphophate form. The dose of TDF for the treatment of HIV and HBV is 300 mg once daily; however, it must be adjusted for renal impairment. Long-term use of TDF is associated with nephrotoxicity and decreases in bone mineral density leading to osteopenia/osteoporosis. To overcome these adverse effects, TAF was developed and marketed for HIV in 2015 (as a part of the combination tablet elvitegravir-cobicistat-emtricitabine-tenofovir alafenamide) and for chronic hepatitis B in 2016. TAF's enhanced safety profile is due to primarily intracellular conversion of TAF to tenofovir. As a result, there is a 90% decrease in systemic tenofovir exposure. The dose of TAF for treatment of chronic hepatitis B is 25 mg once daily; however, the dose is reduced to 10 mg if given as a fixed-dose combination with boosting agents for the treatment of HIV. Similar to TDF, TAF is renally eliminated. Patient with progressively worsening renal function on tenofovir-based therapies should be switched to an alternative agent such as entecavir if there are no contraindications.

Both TDF and TAF are currently first-line agents in many national guidelines and preferred if there is coinfection with HIV (in combination with a cytosine analog). They are well-tolerated overall and have a high genetic barrier to resistance for HBV. Key monitoring parameters include renal function and bone mineral density. TAF is preferred over TDF in patients with poor baseline renal function or osteopenia/osteoporosis. Given that both formulations of tenofovir are indicated for the treatment of HIV, baseline HIV testing should be performed prior to initiation to prevent monotherapy of HIV infection.

Pharmacokinetics

Following oral intake, both TDF and TAF are converted to their active forms through hydrolysis and phosphorylation, as described previously. Food increases absorption of both TDF and TAF by 65% and 15%, respectively. TDF can be administered without regard to food; however, TAF should be administered with food. Tenofovir is renally excreted by both glomerular filtration and tubular secretion. The half-life of TDF is 17 hours, but only 0.5 hours for TAF. The dosing interval should be adjusted in patients with CrCl of <50 mL/min for TDF; TAF is not recommended in patients with a CrCl of <15 mL/min. There are no dose adjustments for hepatic impairment, but TAF is not recommended in Child Pugh Class B or C. TDF is safe for use in pregnancy; however, there are limited data with TAF.

Adverse effects

The most common adverse effects associated with long-term use are decreases in renal function and loss of bone mineral density. Other adverse effects of TDF in patients with HBV include nausea (20%), vomiting (13%), and dizziness (13%). Clinical data in PWH show improvement in renal function and bone mineral density when switching therapy from TDF to TAF. Fanconi's syndrome, a rare but serious adverse effect, is associated with both TDF and TAF. An exacerbation of HBV can occur when treatment is discontinued.

Drug interactions

Tenofovir may potentiate or be potentiated by drugs that decrease renal function or compete for active tubular secretion. TAF is a substrate of P-glycoprotein (P-gp) and is contraindicated with strong inducers of P-gp, such as rifampin, phenytoin, and carbamazepine. However, pharmacokinetic data demonstrate that TDF can be used safely without dose adjustment with strong P-gp inducers such as rifampin.

Adefovir

Adefovir dipivoxil is an adenosine analog that inhibits both HIV reverse transcriptase and HBV DNA polymerase. It is converted into its active disphosphate form by cellular kinases, which competitively inhibits HBV DNA polymerase and causes chain termination if incorporated into replicating DNA. It was initially developed as a nucleotide reverse transcriptase inhibitor for the treatment of HIV; however, the dose of 60 mg once daily was associated with significant nephrotoxicity. It was then developed for the treatment of chronic hepatitis B infection at a lower dose of 10 mg once daily. Renal dose adjustment is required beginning at a CrCl of 50 mL/min. HIV testing should be obtained prior to initiation because adefovir does have activity against HIV, and resistance may develop if there is unrecognized coinfection with HIV. Adverse effects include nephrotoxicity and exacerbations if HBV is discontinued. Adefovir is no longer a preferred agent in several national guidelines for the treatment of HBV because it has been shown to be inferior to both entecavir and tenofovir.

Telbivudine

Telbivudine is a thymidine analog with activity against HBV DNA polymerase. Its mechanism of action also involves activation through intracellular triphosphorylation and causes chain termination if incorporated into replicating DNA. It is indicated for the treatment of chronic hepatitis B infection in adult patients at a dosage of 600 mg once daily. It has a low genetic barrier to resistance, and long-term monotherapy is associated with the resistance and virologic breakthrough. Cross-resistance may occur in patients who have developed resistance to lamivudine. For these reasons, it is no longer a first-line agent in many national guidelines. This agent undergoes renal

elimination and requires dose adjustment at CrCls of <50 mL/min. Telbivudine is well-tolerated overall but can cause elevations in serum creatinine kinase, peripheral neuropathy, and exacerbations of HBV if discontinued.

Peginterferon-α2a

Interferons are naturally occurring glycoproteins with antiviral and immunomodulatory activities. They were the mainstay of treatment for a number of viral infections; however, in current practice, they have been replaced by agents with an improved safety and/or efficacy profile. For example, interferon-based therapies for the treatment of HCV have almost been completely supplanted by use of direct-acting antiviral (DAA) therapies. DAAs can be administered orally, have fewer adverse effects, and vastly outperform interferon in terms of efficacy. One of the last remaining indications for interferon therapy is in the treatment of HBV infection.

Peginterferon-α2a is administered as 180 μg subcutaneously once weekly for 48 weeks in the treatment of HBV. The main advantage of peginterferon-α2a over nucleotide analogues is that there is a finite duration of therapy. Duration of nucleotide therapy is unclear and often indefinite as discontinuation risks virologic relapse and decompensation. The exact mechanism of action against HBV is not clear. Treatment with peginterferon-α2a yields sustained seroconversion of HBV Be antigen in 20% to 31% of cases. HBV genotypes A and B are most responsive to interferon therapy compared to other genotypes. There is a warning for worsening neuropsychiatric, autoimmune, ischemic, and infectious disorders, and close monitoring is suggested. Other major toxicities commonly observed are depression (18%), flu-like symptoms (14%), fever (37–54%), myalgias (37%), fatigue (56%), and alopecia (18–23%). The long half-life of 50 to 160 hours allows for weekly dosing. Liver function tests should be monitored closely, and the dose may need to be decreased if ALT increases to greater than five times the upper limit of normal. It should not be used in patients with autoimmune hepatitis or hepatic decompensation (Child Pugh Class B or C). Dose adjustments are also required if patients develop myelosuppression, depression, or CrCl of <30 mL/min.

Hepatitis C therapies: Single-tablet regimens

Ledipasvir/Sofosbuvir

Ledipasvir/sofosbuvir (LDV/SOF) was approved in the United States in 2014 as the first single-tablet regimen for the treatment of HCV genotype 1 and later received approval for genotypes 4 through 6. LDV inhibits the NS5A protein, and the active metabolite of SOF inhibits the NS5B RNA-dependent RNA polymerase and causes chain termination. Inhibition of both of these essential enzymes halts HCV viral replication. This regimen is coformulated with LDV 90 mg and SOF 400 mg and administered orally once daily without regard to food. The duration of therapy is dependent on patient factors such as treatment history, HIV status, HCV genotype, baseline HCV viral load, and cirrhosis status. Therapy can be as short as 8 weeks for patients mono-infected with HCV who are treatment-naïve with genotype 1, non-cirrhotic, and have a baseline HCV viral load of <6 million IU/mL. Most patients receive 12 weeks of therapy, but for those with decompensated cirrhosis, the addition of ribavirin for 12 weeks or extension to 24 weeks of therapy is required.

Pharmacokinetics

Both agents are rapidly absorbed from the GI tract. LDV requires an acidic environment for absorption, and acid suppressive therapy may reduce absorption. Administration with food increases SOF exposure by twofold but does not affect its maximal concentration or exposure of the active metabolite. Food has no effect on the absorption of LDV. Plasma protein binding of ledipasvir is 99.8% and 65% for sofosbuvir. After absorption, SOF is hepatically activated into its triphosphate form known as GS-461203. This compound is then further metabolized to the inactive GS-331007, which is eliminated through the urine. Although sofosbuvir is ultimately eliminated renally, no renal dose adjustment is required as clinical data have demonstrated the safety of the 400 mg dose of sofosbuvir in patients with chronic kidney disease and end-stage renal disease on hemodialysis. LDV is eliminated unchanged primarily through the biliary tract, with a half-life of 47 hours. The safety and efficacy of LDV/SOF in pregnancy and lactation has not yet been established.

Adverse effects

The combination of ledipasvir/sofosbuvir is well tolerated overall, especially in combination with interferon-based therapies. The most common adverse effects noted in clinical trials of patients with compensated liver disease were fatigue (13–18%), headache (11–17%), nausea (6–9%), and diarrhea (3–7%). Rarely, reactivation of HBV leading to fulminant hepatitis, hepatic failure, and death has been reported in patients coinfected with HBV who were not currently receiving HBV therapy. Therefore, it is important to screen for HBV exposure and coinfection prior to initiation of HCV therapy and manage as clinically indicated.

Drug interactions

Coadministration of SOF-containing regimens with amiodarone may lead to severe symptomatic bradycardia and is not recommended. The mechanism of this interaction is unknown. Acid-suppressive therapies reduce absorption of LDV and should be reassessed prior to initiation of LDV/SOF. A maximum dose of omeprazole 20 mg once daily is recommended and should be administered simultaneously with LDV/SOF under fasted conditions to avoid decreased absorption. The maximal dose of famotidine is 40 mg twice daily and must be administered simultaneously with LDV/SOF and/or 12 hours apart.

Both agents are substrates of P-gp and breast cancer resistance protein (BRCP). Drug exposures may be significantly increased or decreased by inhibitors or inducers of these transporters. For

example, LDV/SOF is not recommended with strong P-gp inducers such as rifampin, phenytoin, and carbamazepine. However, LDV/SOF is the only single-tablet regimen that can be given with efavirenz-based antiretroviral therapy. Renal function must be monitored closely with concomitant TDF therapy as drug exposure of TDF increases by 98% when administered with LDV/SOF. No clinically significant interaction is seen with TAF.

In addition to being a substrate, LDV is also an inhibitor of P-gp and BRCP. Therefore, administration with other P-gp and BRCP substrates may lead to supratherapeutic serum concentrations and drug exposure. The clinical relevance of this interaction is seen when examining the effects of coadministration with HMG-CoA reductase inhibitors, such as rosuvastatin. The combination of LDV/SOF and rosuvastatin is not recommended as there is an increased risk of HMG-CoA reductase inhibitors adverse effects such as myalgia, myopathy, and rhabdomyolysis.

Sofosbuvir/Velpatasvir

In 2016, the US Food and Drug Administration (FDA) approved sofosbuvir/velpatasvir (SOF/VEL) 400/100 mg once daily for the treatment of HCV genotypes 1 through 6. Velpatasavir is an NS5A inhibitor, and sofosbuvir is an inhibitor of the NS5B RNA-dependent RNA polymerase as discussed previously. The coformulated tablet is dosed as one tablet once daily without regard to food. Treatment duration is typically 12 weeks for patients without cirrhosis or compensated cirrhosis. It is important to screen for baseline resistance-associated substitutions (RAS) in genotype 3 for treatment-naïve patients with compensated cirrhosis and for peginterferon/ribavirin-experienced patients without cirrhosis. If the Y93H RAS is detected in these populations, the addition of ribavirin is indicated. In patients with decompensated cirrhosis, duration is 12 weeks in conjunction with ribavirin or 24 weeks without ribavirin.

Pharmacokinetics

Velpatasvir achieves its maximal concentration 3 hours after administration, and food increases absorption of velpatasvir by 21% to 34% depending on the fat and caloric content of the meal. Like ledipasvir, velpatasvir is also highly protein-bound. Metabolism of velpatasvir occurs via CYP2B6, CYP2C8, and CYP3A4. Elimination is via the biliary tract, with a half-life of approximately 15 hours. For a discussion of SOF pharmacokinetics, please see the pharmacokinetics section of LDV/SOF. No renal dose adjustment is required of either SOF or VEL. The safety and efficacy of SOF/VEL in pregnancy and lactation has not yet been established.

Adverse effects

Data from phase 3 clinical trials show that the combination of SOF/VEL is well-tolerated. The most common adverse effects in patients with compensated liver disease were headache (22%) and fatigue (15%). Less common adverse effects included nausea (9%), asthenia (5%), and insomnia (5%). Rarely, reactivation of HBV leading to fulminant hepatitis, hepatic failure, and death can occur after initiation of SOF/VEL. Patients should be screened for HBV exposure and coinfection at baseline and managed appropriately as clinically indicated.

Drug interactions

Because this regimen contains SOF, it should not be coadministered with amiodarone as there is a significant risk of severe symptomatic bradycardia. Acid-suppressive medications decrease absorption of velpatasvir and should be avoided if possible. If acid-suppressive therapy is required, omeprazole at a dose of no greater than 20 mg once daily can be administered 4 hours after ingestion of VEL/SOF with a meal. This administration strategy does not significantly affect treatment outcome. Of note, these administration requirements are more complex than that of LDV/SOF, and so LDV/SOF may be preferred if a patient with genotype 1 or 4 to 6 requires proton pump inhibitor therapy. A similar interaction with famotidine is also present. Up to 40 mg of famotidine twice daily can be administered simultaneously with and/or 12 hours after VEL/SOF to mitigate the drug–drug interaction.

VEL is a substrate of P-gp and BRCP, organic anion transporter 1B1 (OATP1B1), and OATP1B3. Unlike ledipasvir, velpatasvir undergoes hepatic metabolism by CYP2B6, CYP2C8, and CYP3A4. Strong inducers or inhibitors of these transporters or enzymes will reduce or increase serum concentrations and drug exposure of VEL, respectively. The classic CYP and P-gp inducers such as rifampin, phenytoin, and carbamazepine are contraindicated with this regimen. SOF/VEL is not compatible with efavirenz-based antiretroviral therapy.

VEL is also an inhibitor P-gp, BRCP, OATP1B1, OATP1B3, and OATP2B1. Substrates of these transporters may have increased serum concentrations if coadministered. SOF/VEL also increases exposure to TDF by 30% to 80%, so close monitoring of renal function is necessary if TDF is a part the patient's HIV or HBV regimen. Consider alternative HIV or HBV therapy with TAF. A significant drug–drug interaction is present with HMG-CoA reductase inhibitors atorvastatin and rosuvastatin. SOF/VEL increases the maximal concentration of rosuvastatin by 2.61-fold and the area under the curve by 2.69-fold. No more than 10 mg of rosuvastatin should be used with SOF/VEL therapy.

Elbasvir/Grazoprevir

Elbasvir/grazoprevir (EBR/GZR) is a single-tablet regimen which combines EBR, an NS5A inhibitor, with GZR, an NS3/4A protease inhibitor. The NS3/4A protease is responsible for proteolytic cleavage of HCV polyproteins, and inhibition halts viral replication. It was initially approved in the United States in 2016, for the treatment of HCV genotypes 1 and 4. For patients with genotype 1a, the most common genotype in the United States, RAS testing is required. If genotype 1a RAS are detected, the addition of ribavirin and extended duration to 16 weeks are required or an alternative regimen should be selected. A single coformulated tablet of EBR/

GZR 50/100 mg is given orally once daily for 12 weeks without regard to food.

Pharmacokinetics

Times to peak concentrations for GZR and EBR are 2 and 3 hours, respectively. A high-fat, high-calorie meal decreases EBR exposure by 11% and increases GZR exposure by 1.5-fold; however, these changes are not clinically significant, and the regimen can be administered without regard to food. Both agents are highly protein-bound and have long half-lives of between 24 and 31 hours. Metabolism occurs hepatically, primarily through CYP3A4, and elimination is through the biliary tract. Therefore, no renal dose adjustments are required. EBR/GZR can be used safely in patient with cirrhosis but is contraindicated in patients with a history of or active decompensated cirrhosis. The safety and efficacy of EBR/GZR in pregnancy and lactation has not yet been established.

Adverse effects

In clinical studies leading to EBR/GZR approval, adverse effects were minimal and incidence was low. The most common adverse effects were fatigue (11%) and headache (10%) in patients receiving EBR/GRZ alone. Rarely, reactivation of HBV leading to fulminant hepatitis, hepatic failure, and death has been reported in patients coinfected with HBV who were not currently receiving HBV therapy. Therefore, it is important to screen for HBV exposure and coinfection prior to initiation of HCV therapy and manage as clinically indicated.

Drug interactions

There is no black box warning regarding use of EBR/GZR with amiodarone as there is with sofosbuvir-containing regimens. However, GZR is an inhibitor of CYP3A4 and may increase drug exposure of amiodarone, leading to bradycardia. Combination therapy of EBR/GZR and amiodarone therapy is not recommended unless the patient can be monitored very closely for signs and symptoms of bradycardia. Acid-suppressive therapies such as omeprazole and famotidine do not significantly impact absorption of EBR/GZR. Therefore, EBR/GZR is considered an agent of choice when a patient requires acid-suppressive therapies.

EBR and GZR are substrates of CYP3A4 and P-gp. Additionally, GZR is affected by OATP1B1/3. EBR/GRZ is contraindicated with strong inducers of CYP3A4 and P-gp such as rifampin, phenytoin, and carbamazepine. In addition, EBR/GRZ has clinically significant interactions with antiretroviral therapy as well; it should not be coadministered with efavirenz (CYP3A4 inducer) and HIV protease inhibitors like darunavir because they are strong CYP3A4 inhibitors. Antiretroviral therapy should be modified or another DAA should be selected in this scenario.

Although EBR and GZR are P-gp substrates, data demonstrate they are minimally affected by intestinal P-gp and therefore have minimal effect on other P-gp substrates such as digoxin. A pharmacokinetic study demonstrated no significant difference in digoxin drug exposure when administered with EBR/GZR. For this reason, consider use of EBR/GZR in patients who require concomitant therapy with narrow therapeutic index P-gp substrates. As with other DAAs, drug–drug interactions are present with HMG-CoA reductase inhibitors. A maximum dose of 20 mg of atorvastatin should not be exceeded while on EBR/GZR therapy as the latter can increase atorvastatin drug exposure by 94%.

Sofosbuvir/Velpatasvir/Voxileprevir

Sofosbuvir/velpatasvir/voxilaprevir 400/100/100 mg (SOF/VEL/VOX) is a pangenotypic regimen initially approved in 2017, primarily for the treatment of patients who had failed a previous NS5A-containing regimen. SOF/VEL/VOX can also be used for patients who failed a non-NS5A sofosbuvir-containing regimen in genotypes 1a and 3. It contains an agent from each class of the DAA group: SOF (NS5B inhibitor), VEL (NS5A inhibitor), VOX (NS3/4A protease inhibitor). Dosing consists of one tablet orally daily administered with food for 12 weeks. SOF/VEL/VOX can even be used as retreatment in patient who previously failed SOF/VEL/VOX. In this scenario, the addition of ribavirin and extension to 24 weeks is recommended on the basis of expert opinion.

Pharmacokinetics

The pharmacokinetics of SOF/VEL have been discussed previously (see SOF/VEL section). Administration with food increases absorption of VOX by 112% to 435% relative to fasted conditions. It is also highly protein-bound, and metabolism occurs via CYP3A4. Elimination is biliary with a half-life of 33 hours. The safety and efficacy of SOF/VEL/VOX in pregnancy and lactation has not yet been established. No renal dose adjustment is required. SOF/VEL/VOX is contraindicated in patients with a history of or active decompensated liver disease.

Adverse effects

Treatment discontinuations due to adverse effects were rare in clinical trials. Common adverse effects included headache (21–23%), fatigue (17–19%), and diarrhea (10–13%). Rarely, reactivation of HBV leading to fulminant hepatitis, hepatic failure, and death has been reported in patients coinfected with HBV who were not currently receiving HBV therapy. Therefore, it is important to screen for HBV exposure and coinfection prior to initiation of HCV therapy and manage as clinically indicated.

Drug interactions

Drug interactions with amiodarone and acid-suppressive therapies of SOF and VEL have been previously discussed. SOF/VEL/VOX is primarily metabolized by CYP3A4 and contraindicated with strong CYP3A4 and P-gp inducers such as rifampin, phenytoin, and carbamazepine. Additionally, HIV protease inhibitors such as darunavir and atazanavir should not be coadministered with VOX. Cyclosporine significantly increases the serum concentration of VOX. HMG-CoA reductase inhibitor interactions exist with SOF/VEL/VOX. Rosuvastatin and pitavastatin are not recommended, and the lowest effective dose of atorvastatin is suggested by the

prescribing information. No more than pravastatin 40 mg can be used with SOF/VEL/VOX.

Hepatitis C therapies: Multi-tablet regimens

Glecaprevir/Pibrentasvir

Glecaprevir/pibrentasvir (GLE/PIB) is a combination of an NS5A inhibitor and an NS3/4A protease inhibitor. It was approved in 2017 by the FDA for HCV genotypes 1 through 6 as 100/40 mg tablets administered as three tablets (total 300/120 mg) orally once daily with food. Duration of therapy is typically 8 weeks for uncomplicated patients, but some patients may require 12 or 16 weeks. The longer durations of 12 weeks is reserved for those who are coinfected with HIV and have cirrhosis or those who are treatment-experienced with pegylated interferon and ribavirin for genotypes 1, 2, and 4 through 6 and have cirrhosis. Interferon- and ribavirin treatment-experienced patients with genotype 3 require 16 weeks of GLE/PIB.

Pharmacokinetics

Both agents of this regimen have a time to maximal concentration of 5 hours after administration. As mentioned earlier, this regimen requires food for absorption. Food increases systemic exposure by 83% to 163% and 40% to 53% for GLE and PIB, respectively. Similar to other regimens, GLE and PIB are highly protein-bound. GLE undergoes metabolism by CYP3A, but PIB does not undergo metabolism. Elimination occurs through the biliary tract with a half-life of 6 hours for GLE and 13 hours for PIB. Use of GLE/PIB in patients with a history of or active decompensated cirrhosis is contraindicated. The safety and efficacy of GLE/PIB in pregnancy and lactation has not yet been established.

Adverse effects

In approval studies, GLE/PIB was very well tolerated, and common adverse effects included headache (13%), fatigue (11%), and nausea (8%). Rarely, reactivation of HBV leading to fulminant hepatitis, hepatic failure, and death has been reported in patients coinfected with HBV who were not currently receiving HBV therapy. Therefore, it is important to screen for HBV exposure and coinfection prior to initiation of HCV therapy and manage as clinically indicated.

Drug interactions

Absorption of glecaprevir is affected by proton pump inhibitors such as omeprazole. Omeprazole 20 mg once daily reduced glecaprevir exposure by 29%. A higher dose of omeprazole 40 mg further decreased glecaprevir drug exposure by 51%. However, product labeling does not recommend dosage adjustment with omeprazole as long as dosage does not exceed 40 mg once daily. Pibrentasvir absorption and drug exposure is not affected by omeprazole. Coadministration of GLE/PIB with famotidine has not been studied.

GLE and PIB are affected by transporters P-gp, BRCP, and OATP1B1/3. Consequently, strong inhibitors or inducers of these transporters will significantly increase or decrease GLE/PIB exposure, respectively. They are also weak inhibitors of CYP3A, CYP1A2, and uridine glucuronosyltransferase 1A1 (UGT1A1). Drug exposure of amiodarone may be increased by GLE/PIB, and close monitoring is recommended. GLE/PIB is contraindicated with HIV protease inhibitors (strong CYP3A4 inhibitors) and the non-nucleoside reverse transcriptase inhibitor efavirenz (CYP3A4 inducer). Other strong inducers such as rifampin, phenytoin, and carbamazepine are also contraindicated. A unique interaction exists between GLE/PIB and ethinyl estradiol; coadministration may increase the risk of ALT elevations. This interaction is not seen with progestin-only contraceptives such as norethindrone. GLE/PIB can also significantly increase exposure of HMG-CoA reductase inhibitors. For example, they increase atorvastatin exposure by 8.3-fold, increasing the risk of myalgia, myopathy, and rhabdomyolysis. Coadministration with atorvastatin is not recommended; select an alternative agent or consider withholding atorvastatin while on GLE/PIB therapy.

Ombitasvir, paritaprevir, ritonavir, and dasabuvir

The regimen of coformulated ombitasvir, paritaprevir, and ritonavir copackaged with dasabuvir achieved FDA approved in 2014. Ombitasvir is an NS5A inhibitor, paritaprevir is an NS3/4A protease inhibitor, and dasabuvir is an NS5B inhibitor. Ritonavir is not active against HCV, but is used to increase the serum concentrations and drug exposure of paritaprevir, similar to its current role in treatment of HIV. Two tablets of the coformulated ombitasvir, paritaprevir, and ritonavir 12.5/75/50 mg are taken once daily in the morning. The dasabuvir is administered as its own tablet as 250 mg twice daily with food. The regimen is indicated for treatment of genotype 1b in patients without cirrhosis. Ribavirin must be added for patients with genotype 1b with cirrhosis and for treatment of genotype 1a. Treatment duration is either 12 or 24 weeks. This regimen contains ritonavir, which also has activity against HIV. It is important to screen for HIV prior to initiation or ensure that the patient coinfected with HIV is on a suppressive regimen to avoid the selection for HIV protease inhibitor resistance mutations.

Food increases absorption of all components of this regimen, and therefore it should not be administered on an empty stomach. Ombitasvir, paritaprevir, ritonavir, and dasabuvir are not recommended in moderate hepatic impairment (Child-Pugh B) and contraindicated in severe hepatic impairment (Child-Pugh C). No renal dose adjustments are required. Safety and efficacy in pregnancy and lactation have not been established. There are numerous drug–drug interactions with CYP3A substrates, strong CYP3A/2C8 inducers, and strong CYP2C8 inhibitors. Examples include amiodarone, rifampin, efavirenz, rilpivirine, ethinyl estradiol, fluticasone nasal spray, HIV protease inhibitors, and HMG-CoA reductase inhibitors. Adverse effects include nausea (8%), pruritus (7%), and insomnia (5%). Incidence of adverse effects is higher when coadministered with ribavirin, as expected. A rare but serious side effect is increases in ALT (1%); ALT should be monitored

during the first 4 weeks of treatment. Patients on ethinyl estradiol are at higher risk of this side effect, and, as a result, ethinyl estradiol products are contraindicated. HBV reactivation can occur; screen for HBV at baseline and manage as clinically indicated. Please see the ribavirin section for ribavirin specific information.

Daclatasvir

Daclatasvir is an NS5A inhibitor that was originally approved in 2015. It is indicated for the treatment of HCV genotypes 1 and 3 in combination with sofosbuvir and/or ribavirin. Patients with genotype 1 and compensated liver disease receive daclatasvir 60 mg with sofosbuvir 400 mg once daily. Ribavirin is added for decompensated liver diseases or patients who are post liver transplant. RAS testing for genotype 1a in patients with cirrhosis is recommended because certain mutations (M28, Q30, L31, Y93) are associated with decreased efficacy. In genotype 3, patients without cirrhosis are eligible for daclatasvir and sofosbuvir given for 12 weeks. However, patients with any degree of cirrhosis or those posttransplantation require the addition of ribavirin. Treatment duration is 12 weeks.

Daclatasvir can be administered without regard to food, and metabolism occurs primarily via CYP3A4. Elimination is biliary; no changes in dosing are indicated for renal impairment. Safety and efficacy in pregnancy and lactation have not been established. Dose adjustment is required when administered with strong CYP3A4 inhibitors (reduce dose to 30 mg once daily) and moderate CYP3A4 inducers (increase dose to 90 mg once daily). Daclatasvir is contraindicated with strong CYP3A4 inducers such as rifampin, phenytoin, and carbamazepine. It also may increase serum concentrations of HMG-CoA reductase inhibitors, digoxin, and amiodarone. Rarely, reactivation of HBV leading to fulminant hepatitis, hepatic failure, and death has been reported in patients coinfected with HBV who were not currently receiving HBV therapy. Therefore, it is important to screen for HBV exposure and coinfection prior to initiation of HCV therapy and manage as clinically indicated. Please see the ribavirin section for ribavirin-specific information.

Ribavirin

Ribavirin is a synthetic guanosine analog with numerous proposed mechanisms of action including inhibition of viral RNA synthesis and immunomodulatory effects. Ribavirin has a broad spectrum of activity against RNA viruses, including HCV, RSV, and viral hemorrhagic fevers.

A major use for ribavirin is as combination therapy with against HCV; monotherapy is not effective. Oral ribavirin was initially combined with injected interferon-α and has been shown to produce a sustained virologic response when used either as initial therapy or after relapse in patients previously treated with interferon-α alone. In current practice, ribavirin is typically added to DAA regimens such as LDV/SOF, SOF/VEL, EBR/GZR, and GLE/PIB to improve sustained virologic response in patients with decompensated cirrhosis, genotype 1 or 3, or prior treatment failures. For patients <75 kg, 1,000 mg in two divided doses with food is recommended. In patients weighing ≥75 kg, 1,200 mg in two divided doses with food is recommended. Duration of therapy ranges from 12 to 24 weeks depending on patient-specific factors.

Ribavirin is administered as an aerosol via a specialized nebulizer for confirmed, severe, lower respiratory RSV infection. It is approved for use in infants and children, and used off-label in immunosuppressed adult populations. The mechanism of action against RSV is not completely understood; however, ribavirin has demonstrated in vitro activity against RSV. The FDA-approved dose is 6 g administered over 12 to 18 hours per day. Intermittent aerosolization strategies have also been investigated and used in practice. Ribavirin has also been used for treatment of Lassa fever and Hantaviruses.

Pharmacokinetics

Ribavirin is rapidly absorbed after oral administration, but bioavailability varies based on formulation. It undergoes hepatic metabolism, and its half-life is very long (up to 300 hours at steady state). Dose adjustment begins at CrCl <50 mL/min. Refer to a formulations-specific monograph for further information as pharmacokinetics are formulation-specific. It is contraindicated in pregnancy. Aerosolized ribavirin is absorbed systemically with a plasma half-life of 9.5 hours.

Adverse effects

Ribavirin is teratogenic and embryotoxic and so use in pregnancy is contraindicated. Patient counseling, discussion of contraception options, and close monitoring of women of childbearing potential on ribavirin therapy is recommended. The risk of teratogenicity persists for up to 6 months after completion of ribavirin therapy. Similar precautions should be observed if the male partner is being treated.

Hematologic side effects are common and principally consist of hemolytic anemia, but leukopenia and thrombocytopenia are possible as well. The recommendations for dosage adjustment and discontinuation vary depending on whether the patient has known cardiac disease. If the affected cell line recovers, ribavirin can be reinitiated at a lower dose. Ribavirin by aerosolization may worsen respiratory status, cause bronchospasm, or lead to worsening ventilation.

Drug interactions

It is not recommended to coadminister ribavirin with zidovudine due to increased risk of anemia. Concomitant therapy with azathioprine may lead to increased concentrations of azathioprine's active metabolite and lead to enhanced immunosuppression.

Cytomegalovirus therapies

Ganciclovir and valganciclovir

Ganciclovir, a guanine derivative, is a major antiviral agent used primarily for the treatment of CMV, but it also has activity against acyclovir-resistant HSV and VZV. It is the active form of the oral

prodrug valganciclovir. After preferential cellular uptake in CMV-infected cells, ganciclovir undergoes monophosphorylation via the CMV UL97 kinase. It is subsequently triphosphorylated to its active form by cellular kinases, and ganciclovir trisphosphate competitively inhibits viral DNA polymerase and decreases the rate of DNA chain elongation.

In patients with HIV, valganciclovir and ganciclovir are used primarily in AIDS-associated CMV retinitis. Patients with CD4 counts of <50 cells/mm^3 are at highest risk of CMV disease. Efficacy in patients with AIDS is clearly established because treatment with anti-CMV therapy reduces involvement of the contralateral eye, prevents visceral organ involvement, and improves mortality. Preferred therapy for treatment of sight-threatening retinitis begins with an induction phase of valganciclovir 900 mg orally twice daily for 14 to 21 days in combination with intravitreal ganciclovir or foscarnet. After induction therapy, chronic maintenance therapy continues with valganciclovir 900 mg orally once daily. IV ganciclovir can be used as an alternative for induction and maintenance in patients with impaired oral absorption at a dose of 5 mg/kg IV every 12 hours and 5 mg/kg IV every 24 hours, respectively. Therapy can be discontinued after 3 to 6 months with inactive lesions and CD4 count of >100 cells/mm^3 for 3 to 6 months in response to antiretroviral therapy. Chronic maintenance therapy should be re-introduced if CD4 count falls below 100 cells/mm^3. An intravitreal ganciclovir implant for the treatment of CMV retinitis was available, but has since been discontinued in the United States. A ganciclovir ophthalmic solution is commercially available for treatment of HSV keratitis. Fortunately, the incidence of CMV retinitis has significantly decreased since the development and optimization of antiretroviral therapy. Both agents can also be used for the treatment of invasive CMV colitis and pneumonitis with ganciclovir 5 mg/kg IV every 12 hours or valganciclovir 900 mg orally every 12 hours. Duration of therapy in these syndromes varies depending on patient-specific factors, clinical course, and severity of illness.

Ganciclovir and valganciclovir are used to prevent CMV disease in bone marrow transplant patients. They are either used as prophylaxis or preemptive therapy. Prophylactic therapy is typically reserved for high-risk patients. Preemptive therapy consists of closing monitoring of CMV DNA and initiating therapy if CMV DNA increases significantly. Preemptive therapy uses doses of ganciclovir and valganciclovir similar to those for induction of CMV retinitis. Duration is typically 2 weeks, but may be extended to include maintenance therapy if viremia persists. Maintenance dosing is similar to that for CMV retinitis. The duration of maintenance therapy depends on the intensity of immunosuppression and should be given for at least 100 days after the transplant. In solid organ transplant, a similar approach of either prophylactic or preemptive therapy exists. Duration of therapy varies based on organ transplanted and institutional protocols.

Resistance to ganciclovir and valganciclovir can develop and should be considered in patients who fail to respond to therapy or develop breakthrough viremia. Resistance is typically mediated by changes in the UL97 kinase, which is responsible for the first step in the activation of ganciclovir to ganciclovir triphosphate. Additionally mutations in UL54 gene, which is responsible for encoding the CMV DNA polymerase, can also confer resistance to ganciclovir. Foscarnet and cidofovir maintain activity in strains with UL97-mediated resistance, but cross-resistance can occur with UL54 mutations.

Pharmacokinetics

Similar to oral acyclovir and valacyclovir, oral ganciclovir has poor bioavailability and has been primarily replaced by valganciclovir. Valganciclovir should be administered with food due to 30% lower bioavailability if taken on an empty stomach. After oral administration, valganciclovir is rapidly converted to ganciclovir by hepatic and intestinal esterases. There is minimal plasma protein binding. Ganciclovir is excreted renally as unchanged drug. Dose reductions begin at CrCls of <70 mL/min and 60 mL/min for ganciclovir and valganciclovir, respectively. Half-life ranges from 4 to 6 hours in different populations and is prolonged in patients with renal impairment. No hepatic dose adjustments are required. Both agents carry a warning for birth defects based on animal data, and use in pregnant women should depend on risks and benefits of use.

Adverse effects and drug interactions

The major toxicity of ganciclovir is hematologic and can involve all cell lines, but most commonly causes neutropenia and thrombocytopenia. Incidence varies based on patient population but can be as high as 42% to 58% in bone marrow transplant patients. Neutropenia is typically reversible upon discontinuation. Risk of hematologic toxicity is compounded by use of other agents that affect blood counts such as chemotherapeutic agents, trimethoprim-sulfamethoxazole, dapsone, and zidovudine. Increases in serum creatinine have also been reported, and concomitant nephrotoxins such as amphotericin B and cyclosporine should be prescribed with caution. Probenecid increases ganciclovir drug exposure by 53%.

Cidofovir

Cidofovir is a cytosine analogue with activity against numerous viruses, including adenoviruses, HSV, VZV, and CMV. Cidofovir was designed to minimize the resistance that develops in response to nucleoside analogs that require phosphorylation by viral enzymes, such as acyclovir and ganciclovir. Although cidofovir must be diphosphorylated to become active, it does not require phosphorylation by viral kinases as it bypasses the UL97 kinase. Rather, cidofovir is activated by cellular enzymes alone. Cidofovir is more active against herpesvirus DNA polymerases than cellular DNA polymerases and thus has selective antiviral activity.

Cidofovir is used as an alternative to ganciclovir/valganciclovir for the treatment of CMV retinitis in patients with HIV. Cidofovir has been effective in delaying the progression of CMV retinitis in AIDS patients, including those who have failed ganciclovir or foscarnet therapy. It can also be used topically or systemically for patients with acyclovir-resistant HSV or VZV. Successful treatment of serious adenovirus infections with cidofovir in immunocompromised patients has been reported. Last, it has shown efficacy in BK

virus–associated hemorrhagic cystitis at lower doses or administered intravesicularly.

Ganciclovir-resistant strains of CMV, which carry mutations in the UL97 phosphokinase gene, generally remain susceptible to cidofovir. Cidofovir may be considered in patients failing ganciclovir or those who have developed resistance. However, other ganciclovir-resistant mutants, especially those carrying mutations in the DNA polymerase gene (UL54) may be cross-resistant to cidofovir. CMV strains resistant to ganciclovir, foscarnet, and cidofovir have also been described. Induction therapy with cidofovir is initiated at a dosage of 5 mg/kg once weekly for 2 weeks, followed by the same dose once every 2 weeks as maintenance therapy.

Cidofovir is highly nephrotoxic, which often limits its use in clinical practice. Nephrotoxicity is mediated by high concentrations of cidofovir in the renal tubules. Infrequent dosing due to its long half-life and administration with probenecid, which prevents rapid secretion of the drug by the renal tubules, both attenuate nephrotoxicity. Probenecid is administered as follows: 2 g 3 hours before infusion and 1 g at 2 and 8 hours after infusion. Baseline renal function should be assessed prior to use. A CrCl of <55 mL/min, a serum creatinine of >1.5 mg/dL, or 2+ proteinuria is a contraindication to its use. IV saline prehydration with 1 L of normal saline immediately before cidofovir infusion is mandatory to prevent nephrotoxicity. If possible, an additional liter of saline should be administered with and after cidofovir over a 1- to 3-hour period. In addition, great care should be taken to monitor renal function with both urine and serum measurements, and the importance of taking the probenecid should be emphasized.

Pharmacokinetics

Approximately 70% to 85% of cidofovir is eliminated unchanged by the kidneys. Its plasma half-life is approximately 2.5 hours, but it has a long-lasting antiviral effect due to the long intracellular half-life of the disphophorylated form. There are no hepatic dose adjustments, and cidofovir should not be used in pregnant women unless benefits outweigh risks to the fetus.

Adverse effects

As described previously, the major toxicity of cidofovir is its nephrotoxicity. Cases of Fanconi's syndrome with cidofovir have been reported. Neutropenia has occurred in approximately 20% of cidofovir recipients in clinical trials. Cidofovir requires administration with probenecid, and the adverse effects of probenecid should also be considered.

Drug interactions

The most important drug interactions are those with other nephrotoxic medications. Caution should be exercised with concomitant therapy with nephrotoxins such as vancomycin, aminoglycosides, NSAIDs, and amphotericin B. Probenecid decreases cidofovir clearance through inhibition of renal transporters, but overall attenuates nephrotoxicity by decreasing the rate of renal tubule exposure to cidofovir. Probenecid has the potential to increase systemic concentrations of other drugs such as β-lactams and other anti-HSV agents such as valacyclovir.

Foscarnet

Foscarnet (phosphonoformic acid) binds to pyrophosphate binding sites on CMV DNA polymerase. It does not require phosphorylation, unlike ganciclovir and cidofovir. At therapeutic concentrations, foscarnet does not bind to human DNA polymerases. Foscarnet can be used as alternative therapy to ganciclovir/valganciclovir for treatment of CMV retinitis, treatment of ganciclovir-resistant or cidofovir-resistant CMV, and acyclovir-resistant VZV and HSV. It retains activity in CMV strains with mutations in the UL97 gene, but cross-resistance can occur through mutations in UL54. Induction treatment is given at 60 mg/kg IV every 8 hours for 2 to 3 weeks, followed by maintenance therapy at 90 mg/kg once daily.

Pharmacokinetics

Foscarnet is administered intravenously only and excreted renally. Its half-life is variable and highly dependent on renal function, which is invariably impaired by foscarnet. Thus, close monitoring of renal function with appropriate dosage adjustment is recommended. No hepatic dose adjustment is required, and foscarnet should be avoided in pregnancy unless benefits outweigh risks.

Adverse effects

The major toxicities of foscarnet are impairment of renal function (27%), anemia (33%), and electrolyte abnormalities. Hypocalcemia (15–30%), hypophosphatemia (8–26%), hyperphosphatemia (6%), hypomagnesemia (15–30%), and hypokalemia (16–48%) may occur. Careful assessment of baseline renal function and electrolytes status is required prior to initiation. Aggressive electrolyte monitoring and repletion is recommended.

Drug interactions

Adverse effects of foscarnet may be potentiated with agents with similar toxicity profiles. If possible, avoid concomitant nephrotoxins such as vancomycin and aminoglycosides. Amphotericin B also causes electrolyte derangements, and these effects may be compounded with concomitant foscarnet.

Letermovir

Letermovir was approved as a first-in-class agent in the United States in 2017, as a CMV DNA terminase complex inhibitor for the prophylaxis of CMV in CMV-seropositive allogeneic stem cell transplant patients. Inhibition of this complex prevents cleavage to produce individual viral units. It is dosed as 480 mg orally or intravenously once daily beginning between day 0 and 28 posttransplant and continued through day 100. Approval trials demonstrated letermovir had significantly lower failure rates at week 24 when compared to placebo. Given its unique mechanism of action in inhibiting the DNA terminase complex consisting of UL51, UL56,

and UL89, cross-resistance with other agents is not anticipated. Although not FDA-approved for treatment of CMV, cases of successful treatment of CMV have been reported in the literature and additional studies for treatment are under way. Letermovir-associated resistance mutations have been observed in clinical trials.

Pharmacokinetics

Letermovir is rapidly absorbed and can be administered with or without food. The bioavailability in the target population is 35%, but is increased to 85% if coadministered with cyclosporine. It is highly plasma protein-bound and undergoes metabolism through UGT1A1/1A3. Elimination is primarily as unchanged drug through the hepatobiliary system, with a half-life of 12 hours. Use of letermovir is not recommended in patients with a CrCl of <10 mL/min or with severe hepatic impairment (Child Pugh Class C). There are insufficient data for use in pregnancy and lactation.

Adverse effects

Common adverse events seen in clinical trials included nausea (27%), diarrhea (26%), and vomiting (19%); however, the incidence of adverse effects leading to discontinuation were similar between groups. Nausea was the most common adverse effect that led to discontinuation. Hematologic toxicities were common, but incidence was similar to the placebo group.

Drug interactions

There are numerous drug–drug interactions with letermovir. Letermovir is a substrate of CYP2D6, CYP3A4, P-gp, and OATP1B1/1B3, as well as a moderate inhibitor of CYP3A4. A significant interaction exists with cyclosporine, where the dose of letermovir must be halved to 240 mg once daily. Cyclosporine concentrations should be monitored closely when initiating letermovir. It also has the potential to increase drug exposure of amiodarone, tacrolimus, pimozide, and HMG-CoA reductase inhibitors among others.

Coronavirus disease 2019 therapy

Remdesivir

Remdesivir was initially developed as antiviral agent for the treatment of Ebola, but it failed to provide a significant benefit. Remdesivir is an adenosine analog that undergoes triphosphorylation to inhibit viral RNA-dependent RNA polymerase. During the coronavirus disease 2019 (COVID-19) pandemic, remdesivir was found to have in vitro activity against the causative pathogen SARS-CoV-2. Data regarding efficacy of remdesivir are currently evolving. The dose is 200 mg IV once on day 1 followed by 100 mg IV once daily for patients weighing >40 kg. For patients <40 kg, 5 mg/kg IV on day 1 followed by 2.5 mg/kg IV once daily is indicated. Optimal duration of therapy is unclear. The most common adverse effect is liver toxicity, and close monitoring of hepatic function is prudent. The IV formulation contains sulfobutylether-β-cyclodextrin, which has been associated with nephrotoxicity. Due to the pressing need for antiviral therapy, drug–drug interaction studies were forgone and so there are limited data on this subject.

Probiotics: an update

Varsha Gupta and Ritu Garg

Nobel laureate Elie Metchnikoff, in the early 1900s, proposed that the long life of Bulgarian peasants resulted from their consumption of fermented milk products. The term "probiotic" was first used in 1965, by Lilly and Stillwell, to describe substances secreted by one organism which stimulate the growth of another. In 2002, Marteau et al. defined them as "microbial preparations or components of microbial cells that have a beneficial effect on health and well- being."

Humans live in close association with vast numbers of microorganisms present on the skin, in the mouth, and in the gastrointestinal (GI) tract. The GI tract harbors a rich flora of >500 different bacterial species, some of which have important health functions that include stimulating the immune system, protecting the host from invading bacteria and viruses, and aiding digestion.

The use of antibiotics, immunosuppressive therapy, and irradiation, as well as other means of treatment, may cause alterations in the composition and actions of these gut flora. Therefore, the introduction of beneficial bacterial species into the GI tract may be a very attractive option to reestablish microbial equilibrium and prevent disease.

The term "probiotics" was derived from the Greek meaning "for life." The Food and Agriculture Organization/World Health Organization (FAO/WHO) later defined probiotic as "live microorganisms," which, when administered in adequate amounts, confer a health benefit on the host.

Bacterial products, in the absence of viable organisms, may have similar effects on signaling pathways and barrier functions. These bacterial products are broadly characterized as *postbiotics* and can be defined as nonviable bacterial products or metabolic by-products from probiotic microorganisms that have biologic activity in the host. Generally, postbiotics include bacterial metabolic by-products, such as bacteriocin, organic acids, ethanol, diacetyl, acetaldehydes, and hydrogen peroxide; it has been also found that certain heat-killed probiotics can also retain important bacterial structures that may exert biological activity in the host. Research shows that these metabolic products have a broad inhibitory property toward pathogenic microbes and therefore can be used as an alternative to antibiotics. Because these are nonviable bacterial products or metabolic by-products from probiotics, postbiotics are nontoxic, nonpathogenic, and resistant to hydrolysis by mammalian enzymes. In some instances, postbiotics can also enhance barrier function against species like *Saccharomyces boulardii*, and they have been shown to improve angiogenesis in vitro and in vivo in epithelial cells by activation of $\alpha 2\beta 1$ integrin collagen receptors.

A *prebiotic* is a nondigestible food ingredient that confers benefits on the host by selectively stimulating the growth and/or activity of one bacterium species or a group of bacteria species in the colon and thus improving host health. Prebiotics are dietary carbohydrates that escape digestion in the upper GI tract and alter the bacterial composition of the gut by changing the type of substrate provided to the existing microbial population in the gut; these carbohydrates include fructo oligosaccharides, gluco oligosaccharides, and inulin.

Both probiotics and prebiotics are together called as *synbiotics*. They improve the survival of bacteria in the GI tract and thus enhance their effect. The synergistic benefits are more efficiently promoted when both probiotics and prebiotics work together in the living system.

The characteristics of an ideal probiotic preparation include:

- High cell viability, thus resistant to low pH and acids
- The ability to persist in the intestine, even if the probiotic strain cannot colonize the gut
- Adhesive to the gut epithelium so that it can cancel the flushing effects of peristalsis
- Able to interact or send signals to immune cells associated with the gut and influence local metabolic activity
- Of human origin
- Nonpathogenic, nontoxic, free of serious side effects
- Resistant to processing and be present in the product in adequate numbers of viable cells to confer a health benefit

Numerous microorganisms are used as probiotics. The following lists those microbes being used in probiotic preparations.

- Lactobacillus: *L. acidophilus, L. casei, L. fermentum, L. gasseri, L. johnsonii, L. lactis, L. paracasei, L. plantarum, L. reuteri, L. rhamnosus GG, L. salivarius, L. bulgaricus, L. sporogenes, L. delbrueckii, L. brevis, L. cellobiosus, L. helveticus, L. crispatus, L. delbrueckii subsp. lactis, L. salivarius subsp. salicinius.*
- Bifidobacterium: *B. bifidum, B. breve, B. lactis, B. longum, B. infantis, B. thermophilum, B. animalis, B. adolescentis*
- Streptococcus: *S. thermophilus, S. salivarius, S. lactis, S. cremoris, S. intermedius*
- Saccharomyces: *S. boulardii, S. cerevisiae*
- Others: *Bacillus cereus, Escherichia coli, Enterococcus faecalis, Enterococcus faecium, Propionibacterium, Bacteroides uniformis, Peptostreptococcus, Leuconostoc, Pediococcus, Akkermansia, Aspergillus niger, Aspergillus oryzae, Candida pintolopesii.*

Sources of probiotics are shown in Figure 209.1.

Mechanism of action

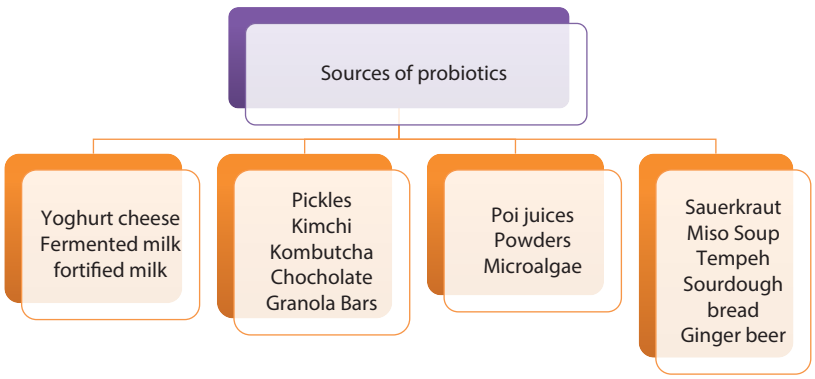
The beneficial actions of intestinal microflora, also referred to as "colonization resistance" or the "barrier effect," is an important mechanism used by the indigenous (autochthonous) gut bacteria to maintain their presence and confer niche protection against freshly ingested microorganisms, including pathogens. Probiotics are also known to demonstrate promising results by adding to the gut flora's unique ability to compete with pathogenic microbiota for adhesion to the gut and improve their colonization. Probiotics also stimulate, modulate, and regulate the host's immune response by initiating the activation of specific genes within localized host cells. They even modulate GI hormone release and regulate brain behavior through bidirectional neuronal signaling as part of the gut–brain axis. Probiotics also play a significant role in inducing intestinal angiogenesis by vascular endothelial growth factor receptor (VEGFR) signaling that, in turn, regulates the acute and chronic inflammation in intestinal mucosal tissue caused by the progression of inflammatory bowel disease (IBD). Because probiotics have physiological functions that contribute to the health of the host environment by regulating microbes they are also helpful in combating overweight and obesity.

Clinical significance of probiotics and potential applications

The use of probiotics for clinical health benefits is a fascinating area of research because probiotics have been shown to be effective in varied clinical conditions ranging from infantile diarrhea, necrotizing enterocolitis (NE), antibiotic-associated diarrhea, relapsing *Clostridium difficile* colitis, *Helicobacter pylori* infections, and inflammatory bowel disease to cancer, female urogenital infections, and surgical infections.

necrotizing enterocolitis

NE is one devastating intestinal disorder that a preterm infant may face in a neonatal intensive care unit (NICU). Low-birthweight preterm infants delivered by caesarean section often require intensive care and are breastfed only after several days. The normal process by which microorganisms such as lactobacilli are ingested via vaginal birth and propagated by the mother's milk does not take place in these infants. A human trial with 2.5×10^8 colony-forming units (CFUs) of live *Lactobacillus acidophilus* and 2.5×10^8 CFU of live *Bifidobacterium infantis* given to 1,237 newborns in Colombia resulted in a 60% reduction in NE and overall mortality.



Diarrhea

Probiotics can prevent or ameliorate diarrhea through their effects on the immune system. Moreover, probiotics might prevent infection because they compete with pathogenic viruses or bacteria for binding sites on epithelial cells. Anti-pathogenic activity is regarded as one of the most beneficial effects of probiotics because, unlike classic antibiotics, disturbance or alteration in the composition of the complex population of the gut microbiota is inhibited. Probiotics might also inhibit the growth of pathogenic bacteria by producing *bacteriocin*, which is mostly involved in increasing the membrane permeability of target cells, which leads to the depolarization of the membrane potential and, ultimately, cell death.

The use of probiotics reduces the duration of diarrhea, although the size of the effect varied considerably between studies. Probiotics have preventive as well as curative effects on several types of diarrhea of different etiologies. There is ample evidence that probiotics reduce the duration and severity of rotavirus diarrhea, antibiotic-associated diarrhea, radiation-induced diarrhea, and traveler's diarrhea.

Helicobacter pylori infection

H. pylori is a major cause of chronic gastritis and peptic ulcers and is a risk factor for gastric malignancies. Antibiotics directed toward *H. pylori* eradication are 90% effective. However, these treatments are expensive and can cause side effects as well as with antibiotic resistance. Probiotic treatment can reduce the side effects associated with *H. pylori* therapy.

Constipation

In adults, data suggest a favorable effect of treatment with *Bifidobacterium lactis* DN-173 010, *Lactobacillus casei* Shirota, and *E. coli* Nissle 1917 on the frequency of defecation and stool consistency.

Lactose intolerance

Lactose intolerance results from insufficient activity in the lactose-cleaving enzyme lactase (β-galactosidase) in the small intestine. The health effect associated with the consumption of fermented milk products is an enhancement of lactose digestion and avoidance of intolerance symptoms in lactose malabsorbers. Yogurt commonly made from *Lactobacillus bulgaricus* and *Streptococcus salivarius subsp. thermophilus* is usually effective.

Inflammatory bowel disease

IBD classically includes ulcerative colitis, Crohn's disease, and chronic pouchitis, representing different patterns of chronic inflammation within the GI tract. Research has shown that an imbalance in the gut microbiota plays an important pathophysiological role in the regulation of IBD. It is also understood that the disorder could possibly be altered by supplementation with probiotics, prebiotics, and both. IBD has been associated with impaired production of short-chain fatty acids (SCFAs), particularly acetate, butyrate, and propionate. Moreover, these SCFAs are known to play a key role in maintaining colonic homeostasis. They also possess anti-inflammatory effects and improve the propulsive colonic function. Therefore, supplementation with indigestible carbohydrates and fiber (prebiotic) alone or in combination with probiotics to increase the production of SCFAs could be a useful therapeutic approach. Presently, progress in the field is mostly concerned with developing genetically engineered probiotic bacterial strains that are able to produce and discharge immunomodulators such as interleukin-10 or lipoteichoic acids that can impact the host immune system and restore the level of protective commensal bacterial species.

Urogenital tract infections

According to the US Centers for Disease Control and Prevention (CDC), >1 billion women around the world suffer from non–sexually transmitted urogenital infections, such as bacterial vaginosis (BV), urinary tract infection (UTI), and several other yeast infections. Sexually transmitted diseases (STDs) are also a significant cause of morbidity worldwide. The two most commonly documented bacterial STIs in some developed countries are *Gonorrhoea* and *Chlamydia*, which are caused by *Neisseria gonorrhoeae* and *Chlamydia trachomatis,* respectively. As the pathogenic organisms responsible for these conditions are concurrently becoming resistant to existing medications, it may be that instead of developing new medicines, our present focus should be on developing new live supplements, like nonpathogenic microbes that act against these pathogens. There is an association between abnormal vaginal microbial flora and an increased incidence of UTI. There are about 50 different species of microorganisms inhabiting the vagina that are regarded as the main regulators of the vaginal micro-environment. Imbalance in the microbial composition greatly influences the health of the vaginal microenvironment, potentially leading to the compromised states of BV and UTI. These compromised states can be restored by balancing the number of *Lactobacillus* spp. present via supplementation with probiotics.

Cancers

Cancer is a dreadful disease affecting peoples all over the globe. More than 70% of the global cancer deaths are from the Asian, African, and American continents. Currently, many new drugs with powerful therapeutic properties have been discovered, but tolerance to their burden of side effect has been a major limitation to effective treatment. Natural sources that confer anticarcinogenic effects, such as probiotics, have been receiving prime focus in recent years. In vitro studies have demonstrated that probiotic strains *Lactobacillus fermentum* NCIMB-5221 and -8829 are highly potent in suppressing colorectal cancer cells and promoting normal epithelial colon cell growth through the production of SCFAs (ferulic acid). This ability was also compared with other probiotics, namely *L. acidophilus* ATCC 314 and *L. rhamnosus* ATCC 51303, both of which were previously characterized as having tumorigenic activity. And, two other probiotic strains, *L. acidophilus* LA102 and *L. casei* LC232, have also been found to show pronounced cytotoxic activities, with in vitro anti-proliferative activity against two colorectal

cancer cell lines (Caco-2 and HRT-18). Although probiotics could play a significant role in neutralizing cancer, research is limited only to in vitro tests. Hence, the anti-cancer potential of probiotics must be proved in in vivo models and then proceed toward animal and clinical trials.

Allergy

The increasing prevalence of allergic diseases caused by immune disorders is a serious economic and social burden worldwide. Recently, the beneficial role of probiotics in the prevention and management of allergic diseases has advanced the understanding of their cause and prevention. In vitro studies of certain probiotics, such as *Lactobacillus plantarum* L67, have shown the potential of these substances to prevent allergy-associated disorders through the production of interleukin-12 and interferon-γ in their host. In another study, *L. plantarum* 06CC2 significantly alleviated allergic symptoms and reduced the levels of total immunoglobulin E, ovalbumin-specific immunoglobulin E, and histamine in the sera of ovalbumin-sensitized mice. In the spleen cells of mice, *L. plantarum* 06CC2 is known to significantly enhance the secretions of interferon- γ and interleukin-4, which are responsible for alleviating allergic symptoms. Further work may be helpful in evaluating the anti-allergic activity of probiotics and their mode of action.

Serum cholesterol

Large dietary intake of yogurt was found to lower dietary cholesterolemia, and the findings suggested that yogurt contains a factor that inhibits the synthesis of cholesterol from acetate.

Diabetes

According to the International Diabetes Federation (IDF) of Southeast Asia, 425 million people have diabetes worldwide, including 78 million people in the Southeast Asian region. The management of this disorder includes multiple medications although there is no definitive cure for diabetes. Based on large-scale 16 S rRNA gene sequencing, quantitative real-time polymerase chain reaction (PCR), and fluorescent in situ hybridization, a connection between the composition of the intestinal microbiota and metabolic diseases like obesity and diabetes has been postulated by Larsen et al. Gram-negative Bacteroidetes and the gram-positive Firmicutes are two specific bacterial phyla that dominant the gut microenvironment. More specifically, patients with type 2 diabetes have significantly reduced numbers of Firmicutes species, and, as the Bacteroidetes/Firmicutes ratio increases, this positively correlates with plasma glucose concentration. A similar pattern has been implicated in the development of autoimmune diseases such as type 1 diabetes. Management of type 2 diabetes by modulating gut hormones, such as gastric inhibitory polypeptide and glucagon-like peptide-1, via probiotic and prebiotic interventions is another convincing strategy. Hormones play a role in glucose homeostasis so that improving the gut microbiome could result in neutralizing this disorder caused by peripheral insulin resistance or failure of β cells to produce insulin. Current research is focused on generating new prebiotics, such as arabinoxylane and arabinoxylane oligosaccharides, which show promising results in neutralizing metabolic disorders because both carbohydrates have been linked to adiposity reduction.

Obesity

Weight loss is facilitated by thermogenic and lipolytic responses through stimulating the sympathetic nervous system. Probiotic strains of *Lactobacillus gasseri* BNR17 have been shown to possess properties that inhibit the increases in adipocyte tissue that are the main source of leptin and adiponectin and thereby limit leptin secretion. Other probiotic microbes such as *L. casei, Lactobacillus acidophilus,* and *Bifidobacterium longum* have also been reported to have hypocholesterolemic effects.

Oral medicine and dentistry

Particular species of *Lactobacillus* and *Bifidobacterium* may exert beneficial effects in the oral cavity by inhibiting carcinogenic streptococci and various species of *Candida. Lactobacillus reuteri* was efficacious in reducing both gingivitis and plaque in patients with moderate to severe gingivitis.

Brain and central nervous system

In recent years, many studies have been devoted to elucidating the influence of gut microbiota on the central nervous system (CNS). The "microbiota-gut-brain axis" is an interactive, bidirectional communication established by the exchange of regulatory signals between the GI tract and the CNS. The effect of probiotics on the CNS has been mainly studied in clinical trials, where it has been evident that gut microbiota influence human brain development function. In children with autism spectrum disorder, a daily dose of *L. plantarum* WCFS1 ($4.5X10^{10}$ CFU/d) led to an improvement in their school records and attitude toward food. In a randomized trial involving healthy volunteers, there was reduced psychological distress when participants were treated with oral administration of *Lactobacillus helveticus* R0052 and *B. longum* R0175. Another clinical trial showed a decrease in anxiety symptoms by administration of *L. casei strain Shirota* to patients suffering from chronic fatigue syndrome, and reduced anxiety was thought to be due to improved bowel function. Human intestine–derived strains of *L. brevis* DPC6108 and *Bifidobacterium dentium* were reported to produce large amounts of γ-aminobutyric acid, a brain neurotransmitter that helps humans to suppress anxiety and depression. Oral intake of *L. acidophilus* has been shown to assist people in regulating their mood in respect to rewards and addictive behavior.

Bones

Several studies in humans have shown positive effects of nondigestible oligosaccharides (NDO) on mineral absorption and metabolism and on bone composition and architecture. Synbiotics (i.e., a combination of probiotics and prebiotics) can induce additional effects. Proposed future applications include the treatment of

rheumatoid arthritis, prevention of ethanol-induced liver disease, and prevention or treatment of graft-versus-host disease.

Next-generation probiotics

Probiotics are thought to improve the microbiotic balance in the host, prevent disturbances, and decrease the risk of pathogen colonization. They have been referred to as "functional foods" or "beneficial bacteria," and they have been considered for the prevention and treatment of *C. difficile*–associated diarrhea. Furthermore, findings from randomized control trials (RCTs) and meta-analyses suggest that there is moderate evidence for the ability of probiotics to prevent primary *C. difficile* infection (CDI) in those people at risk, but there is not enough evidence to suggest that probiotics can prevent secondary CDI (recurrent CDI; rCDI). There are still some evidence gaps for the use of probiotics in the prevention of CDI concerning the interaction between specific classes of antibiotics with the probiotics used on CDI risk, the bacterial taxa that provides the best efficacy in the prevention of CDI, and the use of probiotics in immunocompromised or critically ill patients.

Overall, classical probiotics show limited effects on the human gut microbiota, thus the need for a better selection and formulation of bacterial strains. Results from previous studies show promising outcomes in the treatment or prevention of diverse metabolic and inflammatory diseases by specific bacteria. Those probiotics encompass species different from *Lactobacillus* and *Bifidobacterium*. The FAO definition of probiotics is broad, allowing flexibility in terms of the phylogenetic origin of probiotics. Information generated from previous studies assisted in the selection of next-generation probiotics, which include members from *Clostridium* clusters IV, XIVa and XVIII; *F. prausnitzii*; *Akkermansia muciniphila*; *Bacteroides uniformis*; *Bacteroides fragilis*; and *Eubacterium hallii*. These next-generation probiotics were evaluated in preclinical trials and yielded positive outcomes for inflammatory and metabolic disorders. In addition, new techniques are required for the development of new probiotic products containing strains of human origin. These strains must come from the major groups of the intestinal microbiota and must be safe and proved to have potential beneficial effects.

Fecal microbiota transplant therapy

Fecal microbiota transplant (FMT) or fecal bacteriotherapy is an alternative strategy successfully used for the treatment of CDI. FMT can resolve both CDI and rCDI with a success rate of 90% when further antibiotic treatments fail. Given the success of FMT, it is now being considered as potential treatment for disorders such as ulcerative colitis, IBS, and metabolic syndrome. The complexity of the fecal sample can be the key factor behind the positive shift in microbiota composition generated by FMT. Thus, diversity of the donor microbiome may be crucial. Indeed, some patients do not respond to FMT, probably because only specific bacterial phylotypes can be therapeutic when effectively transferred. Adverse effects after FMT include nausea, vomiting, fever, abdominal pain, and diarrhea. The uncharacterized nature of FMT may result in undetected or unmonitored risk factors such as viruses, pathogens, or even allergens being passed to the FMT recipient, causing disease. To overcome this problem, Petrof et al. (2013) developed a synthetic bacterial cocktail with characterized nature. The authors of the study suggested that using a synthetic stool substitute may be an effective method to replace the use of FMT for treating rCDI, and thus, the concept of "RePOOPulating" the gut microbiome was coined. In addition, patient safety can be guaranteed because the bacterial mixture can be rendered pathogen- and virus-free. These data suggest that a multispecies community such as that in the RePOOPulate study can be more effective than single-strain probiotics or mixed cultures of probiotic species. This may be because the RePOOPulate community preserves its structure and thus successfully colonized a new environment. Moreover, RePOOPulate consisted of a more phylogenetically diverse community including strains with beneficial health effects that can be candidates for next-generation probiotics.

Safety

To establish safety guidelines for probiotic organisms, the FAO and the WHO recommended that probiotic strains should be characterized through a series of tests to determine, at a minimum, antibiotic resistance patterns, metabolic activity, toxin production, hemolytic activity, infectivity in immunocompromised animal models, side effects, and adverse incidents in consumers.

Conclusion

The evidence suggests that probiotics have a considerable role to play in the prevention and treatment of certain conditions related to the GI and urogenital tracts, and the contribution of probiotics in preventing and treatment of diabetes, obesity, and cancer is an exciting and rapidly advancing research ground. For that reason, current research focus is on evaluating new strains of probiotics and their applicability in biomedical/clinical research, thus paving a new direction for exploration and exploitation of probiotics aimed at improving human health.

Hypersensitivity to antibiotics

Santiago Alvarez-Arango and N. Franklin Adkinson, Jr.

Adverse drug reactions (ADRs) are usefully separated into type A reactions (predictable from known pharmacologic properties and largely dose related), which make up 85% to 90% of all ADRs, and type B reactions (unpredictable and restricted to a vulnerable subpopulation). Type B reactions comprise 10% to 15% and include *immunologic drug reactions, drug intolerance* (e.g., tinnitus after single aspirin tablet), and *idiosyncratic reactions*, some of which are pseudoallergies (e.g., aspirin-induced reactions, vancomycin-induced red man syndrome).

ADRs can be subdivided based on time of appearance of symptoms (e.g., immediate vs. delayed ADRs), mode of action of the drugs, or on immunologic mechanism. Immune mechanisms are thought to be involved in 6% to 10% of all ADRs. Allergenic drugs can induce the entire spectrum of immunopathologic reactions, which are clinically indistinguishable from reactions elicited by foreign macromolecules (Table 210.1). *Gell and Coombs type I reactions* are caused by drug/antigen-specific immunoglobulin E (IgE) that binds to high-affinity Fc-IgE receptors on mast cells and basophils. Cross-linking of these receptors leads to the release of vasoactive mediators such as histamine and cysteinyl leukotrienes. Typical syndromes include urticaria, anaphylaxis, rhinitis, and bronchoconstriction, which can occur immediately in a previously sensitized individual. *Type II cytolytic reactions* are generally confined to rapidly haptenating drugs such as penicillins and are based on immunoglobulin G (IgG)-mediated cytotoxic mechanisms, resulting mainly in blood cell cytopenias. *Type III reactions* are immune complex–mediated and may involve complement activation and stimulation of Fc-α receptor-activated inflammatory cells. Drug-specific immune complexes result from high-dose, prolonged therapy and may produce drug fever, a classic serum sickness syndrome, and various forms of cutaneous vasculitis. *Type IV reactions* are mediated by T lymphocytes and cause "delayed hypersensitivity reactions," the most typical examples being delayed maculopapular exanthem and contact dermatitis from topically applied drugs. Many drug-induced hypersensitivity reactions such as bullous, pustular, and some morbilliform skin eruptions that are presumed to have an immune etiology did not seem to fit into the older Gell and Coombs classification. Recent studies of T-cell subsets and functions in the pathogenesis of delayed-onset immune reactions have suggested subcategories of type IV reactions, as shown in Table 210.1.

However, some drug reactions resemble allergic syndromes but are not immunologic in origin. These nonimmune hypersensitivity reactions are also known as "pseudoallergic reactions." Most pseudoallergic reactions mimic type 1 IgE-mediated reactions such as urticaria, angioedema, bronchospasm, and anaphylaxis (Table 210.2). In such cases, basophils and mast cells are activated by nonimmune mechanisms, and vasoactive mediators are released.

In this chapter, we review type B ADRs to antibiotics with a focus on current concepts in the diagnosis and management of allergies to β-lactam antibiotics, the prototype of immunologic drug allergies. Moreover, we address the current issue regarding overdiagnosis of β-lactam allergy and its impact on clinical practice and healthcare utilization. Last, we also address the management of multiple antibiotic sensitivity syndromes.

TABLE 210.1 **FEATURES OF IMMUNOPATHOLOGIC REACTIONS TO ANTIBIOTICS AND MANAGEMENT STRATEGIES**

Reaction category	Clinical manifestation	common examples for antibiotics	Timing for sensitization with the first use of the drug	Onset after re-exposure to the drug	Skin tests	In vitro tests	Readministration of the drug (DPT/ desensitization)
Type I (IgE)	Urticaria, angioedema, rhinitis, bronchospasm, anaphylaxis	B-lactam antibiotics Sulfamethoxazole	Required: 1–2 wk	Usually within 1 h (rarely after hours)	Immediate (wheal/ flare)[a] Intradermal tests	RAST (serum IgE) Serum mast cell tryptase level Basophil activation	Desensitization if skin test þ
Type II (IgG and complement)	Hemolytic anemia, drug-induced nephritis, thrombocytopenia, Neutropenia	Penicillins Cephalosporins Sulfonamides	Required: 1–2 wk	Many days or weeks	None	Complete blood count Coombs tests	Cautious DPT
Type III (IgG immune complexes)	Serum sickness, fever, vasculitis	Penicillins Cephalosporins Sulfonamides Streptomycin	Required: 10–21 d	Usually days to weeks	None	ESR CRP Immune complex Serum complement levels	Cautious DPT
Type IVa (Th1 lymphocytes)	Allergic contact dermatitis	Penicillins Neomycin Bactrim	Required: 1–3 wk	8–120 h	Patch tests Intradermal tests (delayed response at 48–72 h)	Lymphocyte transformation tests	Likely contraindicated
Type IVb (Th2 lymphocytes)	Maculopapular eruptions	Penicillins, especially diaminopenicillins like amoxicillin and ampicillin Sulfonamides	Required: 4–14 d		Patch tests Intradermal tests (delayed response at 48–72 h)	Lymphocyte transformation tests[b]	DPT useful
Type IVc cytotoxic lymph. (perforin/ granzyme B)	Contact dermatitis, maculopapular and bullous exanthema, hepatitis, SJS, TEN	Sulfonamides Penicillins Macrolides	Required: 1–2 wk		Patch tests Intradermal tests (delayed response at 48–72 h)	Lymphocyte transformation tests[b]	Contraindicated (for bullous exanthem and SJS/TEN)

Abbreviations: CRP = C-reactive protein, ESR = erythrocyte sedimentation rate.

TABLE 210.2 **FEATURES OF NONIMMUNE HYPERSENSITIVITY REACTIONS TO ANTIBIOTICS AND MANAGEMENT STRATEGIES**

Reaction category	Clinical manifestation	common examples for antibiotics	Timing for sensitization with the first use of the drug	Onset after re-exposure to the drug	Skin tests	In vitro tests	Readministration of the drug (DPT/ desensitization)
Nonimmunologic	Urticaria, angioedema, rhinitis, erythema bronchospasm	Vancomycin (red man syndrome)	Not required Reaction may occur with first dose	Within minutes, infusion rate dependent	None	None	Slow infusion Use premedication

Abbrevations: DPT = drug provocation tests; ESR = erythrocyte sedimentation rate; CRP = C-reactive protein; RAST ¼ radioallergosorbent test; IgE = immunoglobulin E; IgG = immunoglobulin G; SJS = Stevens–Johnson syndrome; TEN = toxic epidermal necrolysis.
[a] Only validated for penicillin skin testing, which has high negative predictive value. Positivity may be helpful with certain antibiotics; however, negative skin tests do not exclude the diagnosis for many immediate reactions to antibiotics.
[b] Clinically, false positivity may occur.
According to Gell and Coombs, as modified.

Epidemiology of antibiotic allergy

β-Lactams and sulfonamides are the most prevalent causes of antibiotic hypersensitivity. In a cross-sectional survey of a general population from Porto, Portugal, history of hypersensitivity to penicillin and other β-lactam antibiotics was found in 4.5% of adults. In the United States, in recent large healthcare insurance database studies, history of hypersensitivity to penicillin was recorded in about 10% of patients. Data from developing countries are limited but suggest that penicillin allergy is the most commonly reported antibiotic allergy. History of hypersensitivity to sulfonamides has been reported to occur in 2% to 4% of populations but is increased among AIDS patients to 40% to 80%. Immunologic reactions to the newer classes of antibiotics are often rare and poorly documented. The perceived relative risk of immunologic drug reactions with commonly used antibiotics is given in Table 210.3.

Burden of antibiotic allergy

β-Lactams are among the most commonly prescribed antibiotics for the treatment of many types of bacterial infections. However, recent data show a significant decrease in β-lactam prescriptions, in part due to a rising prevalence of histories of allergy, which can exceed 30% in intensive care environments. Emergence of bacterial resistance as well as the introduction of newer antibiotics have also contributed to this trend. Penicillin allergy is reported by 10% of the US population, which is equivalent to >32.7 million people. Prescriptions of quinolones and macrolides as alternative antibiotics for common infections have been increasing, as has the use of vancomycin in patients with histories of penicillin allergy. Yet only 10% to 15% of the subjects with a history of acute, IgE-dependent penicillin reactions have a currently positive penicillin type I skin tests. Unevaluated histories of antibiotic allergies may lead to the substitution of often less effective or more toxic—and more expensive—alternative drugs, which can result in high medical and economic burdens on healthcare. Studies from the United States, Europe, and Australia have shown that penicillin-allergic patients have higher antibiotic costs, longer hospital stays, and are more likely to receive a broader spectrum antibiotic such as cephalosporins, macrolides, and quinolones, leading to increased frequency of drug-resistant microbes. In addition, hospitalizations with registration of penicillin allergy are associated with increased length of stay, economic costs, and frequency of infections by drug-resistant agents. At the Mayo Clinic, prophylactic vancomycin use in patients with a history of penicillin or cephalosporin allergy undergoing elective orthopedic surgery was substantially reduced by targeted allergy consultation and penicillin allergy skin testing. Similar benefits are likely to occur in patients with histories of other antibiotic allergies who are appropriately evaluated before alternative antibiotics are selected.

Clinical features

The presentation of antibiotic allergies is similar to known hypersensitivity reactions, and the clinical features are variable depending on the type and severity of the reaction and the organ systems affected (Table 210.1 and Table 210.2). Many factors, such as the immunologic profile of the antibiotic; treatment factors, including dosage, administration route, and frequency; host factors such as immune status and comorbidities; and the inflammatory milieu in which antibiotics are used, can influence the frequency and characteristics of hypersensitivity reactions.

The skin is the most common organ involved in antibiotic reactions, and it is involved in up to 90% of anaphylactic episodes. Maculopapular eruptions (MPEs), urticaria, and pruritus are the most common presentations that typically occur after hours, days, or even weeks of antibiotic exposure but can also be part of an acute allergic reaction. Immunologic drug reactions require a sensitization period, whereas a nonimmunologic mast cell release can occur on first exposure in susceptible patients (e.g., vancomycin-induced red man syndrome).

TABLE 210.3 **RELATIVE RISKS OF IMMUNOLOGIC REACTIONS TO COMMONLY USED ANTIBIOTICS**

Risk of inducing an immunologic reaction[a]	Antibiotic (or its class)
Common (>2%)	Penicillins
	Antimicrobial sulfonamides
	Nitrofurantoin
Intermediate (0.1–2%)	Bacitracin
	Cephalosporins
	Penems
	Itraconazole
	Quinolones
	Minocycline
Rare (0.1%)	Monobactam (aztreonam)
	Aminoglycosides
	Amphotericin B
	Chloramphenicol
	Clindamycin
	Fluconazole
	Griseofulvin
	Ketoconazole
	Macrolide antibiotics
	Vancomycin
	Tetracyclines
	Polymyxin
	Metronidazole
	Linezolid
	Daptomycin

[a] Among patients receiving multiple courses of therapy.

Antibiotics can also cause severe but rare exfoliative skin syndromes such as toxic epidermal necrolysis (TEN) and Stevens–Johnson syndrome (SJS). Other targeted organ manifestations, such as interstitial pneumonitis and immune cytopenias, are rare. Life-threatening reactions such as anaphylaxis are also rare. However, fatalities in Australia due to anaphylaxis during a 9-year study period revealed an increase of approximately 150% in drug-induced anaphylaxis admissions and an increase of approximately 300% in drug-induced anaphylaxis deaths. Although β-lactams are the most common antibiotic class inducing anaphylaxis, IgE antibody responses have also been documented for sulfonamides; those now in use are given in Table 210.4.

Clinical assessment

Drug allergy syndromes are recognized by the constellation of signs and symptoms identified with a particular mechanism of immunopathology (Table 210.1 and Table 210.2). Appropriate diagnosis of these cases depends largely on careful history taking, with attention to prior drug experience and the chronology of the reaction, supplemented by compatible physical and laboratory findings and knowledge of drug allergenicity profiles (Table 210.3). For atypical or discordant reactions, skepticism is appropriate to avoid labeling the patient as "drug allergic" incorrectly.

Step 1: Initial evaluation

History-taking

A detailed history is essential for the initial evaluation of patients with suspected drug allergies. The history guides a decision about performing further diagnostic testing and other evaluation strategies. It is also possible to make a reasonable decision about the risks of reintroducing the suspected drug by using historical detail. Medical records that describe previous reactions and treatment can be very helpful, especially in patients with vague histories or altered mental status. Occasionally, information provided by a relative or friend who witnessed the event can also be very helpful in differential diagnosis. Nevertheless, it is crucial to document in detail a witnessed drug allergy reaction and update medical records and allergy labels to accurately reflect the signs and symptoms as well as the timing of a suspected antibiotic allergy.

The clinical history of suspected drug allergy should be focused on both medication-related and patient-related factors. The medication(s) implicated, clinical features of the reaction(s), and the previous exposure and reaction to each drug and related compounds, as well as patient comorbid disorders, should be recorded. For example, patients with chronic urticaria often attribute cutaneous reactions to drugs and foods. Similarly, symptoms of chest tightness or pain, dyspnea, and tachycardia after use of a drug can be a sign of underlying cardiovascular disease. Other patient comorbidities include the high frequency of amoxicillin-induced morbilliform rashes in patients with mononucleosis and frequent trimethoprim-sulfamethoxazole reactions in AIDS patients. Another example is that patients with cystic fibrosis have a higher risk for immune reactions to antibiotics, probably because of frequent reexposure.

History-taking provides information helpful in assessing the likelihood of immune mediation. Immunologic reactions require a sensitization period, so putatively allergic patients should have a history of prior use of either the drug itself or a structurally related compound. For first drug exposure, an immunologic reaction may be seen after 3 to 10 days, which can be sufficient for primary sensitization. Reexposure will lead to a Type I reaction, which classically begins within 1 hour of the first administered dose.

Nonimmunologic reactions do not require sensitization, and reactions may be seen even after the first dose. Pseudoallergic reactions can often be distinguished from IgE-mediated reactions with similar clinical manifestations by reliable histories of previous drug use. Based on clinical features and the chronology of the reaction, conclusions can be drawn about whether a reaction is immunologically mediated (Table 210.1). However, in certain situations, immunologic and nonimmunologic reactions may be clinically indistinguishable.

TABLE 210.4 **CLINICAL FEATURES OF HYPERSENSITIVITY REACTIONS**

Antibiotic	Common	Less common/rare
β-lactams	Urticaria, MPE	Exfoliative dermatitis, TEN, SJS, serum sickness syndrome, vasculitis, cytopenias, anaphylaxis, nephritis
Sulfonamide	Fixed drug eruption HIV(+): delayed MPE + fever, urticaria, angioedema	Erythema multiforme, SJS, TEN Anaphylactic reactions
Quinolones	Urticaria, FDE, photoallergic reactions	Acute interstitial nephritis, acute hepatitis, serum sickness, SJS, TEN, MPE, acute pancreatitis, anemia; thrombocytopenia
Macrolides	Urticaria, angioedema, FDE, and MPE	TEN, vasculitis
Vancomycin	"Red man syndrome," lineary IgA bullous dermatosis	MPE, FDE, vasculitis, thrombocytopenia, erythema multiforme, and urticaria anaphylaxis

Abbrevations: FDE = fixed drug eruptions; MPE = maculopapular eruption; TEN = toxic epidermal necrolysis; SJS = Stevens–Johnson syndrome; IgA = immunoglobulin A; HIV = human immunodeficiency virus.

Physical examination

Direct observation of patients undergoing presumed drug reactions can be useful for both differential diagnosis and objective assessment of severity, which can often be exaggerated in retrospective patient accounts. A complete physical examination is desirable because many organ systems have the potential for involvement. For skin reactions occurring with drug use, a detailed dermatologic examination is often helpful. Viral exanthems are easily confused with maculopapular drug eruptions. Fever and coryza or pharyngitis can help to identify the former.

Step 2: Decision about application of further diagnostic testing

History alone is often not sufficient for establishing current drug sensitivity. Only 10% to 15% of subjects with a convincing history of IgE-dependent penicillin allergy will be positive by validated skin testing, indicating a very low diagnostic accuracy of history alone for current sensitivity. Data with other drugs are similar, suggesting that sensitivity may wane with time. Approximately 80% of patients with IgE-mediated penicillin allergy have lost the sensitivity by skin testing after 10 years. Thus, patients with recent reactions are more likely to be allergic than are patients with remote reactions.

Drug provocation tests that are the gold standard for the diagnosis of current drug allergy have a similarly low positivity rate in patients with a history of drug allergy. These data indicate that diagnosis of current sensitivity based on history alone is often not advisable. Further diagnostic tests for definite diagnosis may be needed. Unfortunately, many in vivo and in vitro diagnostic tests for allergy have shown limited value in the diagnosis of allergy to haptenic (small molecular weight) drugs.

Although skin testing provides valuable information for the diagnosis of immediate reactions to penicillins and in some cases to other β-lactams, the validity of skin tests with other antibiotics is limited because the antigenic determinants are not adequately known. In vitro tests for drug-specific IgE to antibiotics are of limited value because they are less sensitive than intradermal tests. A positive result, however, is usually reliable and corresponds to skin test results. If there is no contraindication, drug provocation testing with the offending drug is the most reliable test for diagnosis of current antibiotic hypersensitivity for many haptenic drug allergies. Because such testing carries some risk for the patient, its use is usually restricted to cases where alternative antibiotics are unacceptable or there are multiple antibiotic sensitivities. A stepwise approach to the diagnosis of antibiotic allergy is given in Figure 210.1. Diagnostic testing can be pursued based on likely immunopathology as given in Table 210.1 and Table 210.2.

Evaluation of immediate-type sensitivities

Skin testing for β-lactam antibiotics

Intradermal skin testing with a 15- to 20-minute readout of wheal and flare has been validated for detecting drug-specific IgE antibodies to penicillins and other β-lactam antibiotics. A major determinant analog (*penicilloyl-polylysine*) and minor determinants (*benzylpenicilloate, benzylpenilloate*, and *benzylpenicillin* isomers of penicillin) are used for skin test evaluation for IgE-dependent penicillin allergy. IgE antibodies to minor determinants are clinically associated with anaphylactic reactions and can predict the risk of more severe reactions. IgE antibodies to the major penicilloyl determinant correlate loosely with risk for urticarial reactions.

Testing is undertaken with two or more reagents, usually penicilloyl-polylysine (Pre-Pen) antigen and either penicillin alone (10,000 IU/mL) or a mixture of minor antigens, including at least benzylpenicillin and benzylpenicilloate (10 mM each). Of these minor determinants, only benzylpenicillin is available commercially in the United States. Skin prick testing with full-strength reagents is done first, and, if these tests are negative at 15 minutes, they are followed by intracutaneous testing, raising an initial bleb of 2 to 3 mm. A wheal diameter of least 3 mm greater than negative control is considered positive. In some centers, elective testing is followed by the administration of one to three doses of oral penicillin and a period of observation to confirm that the drug is tolerated. For

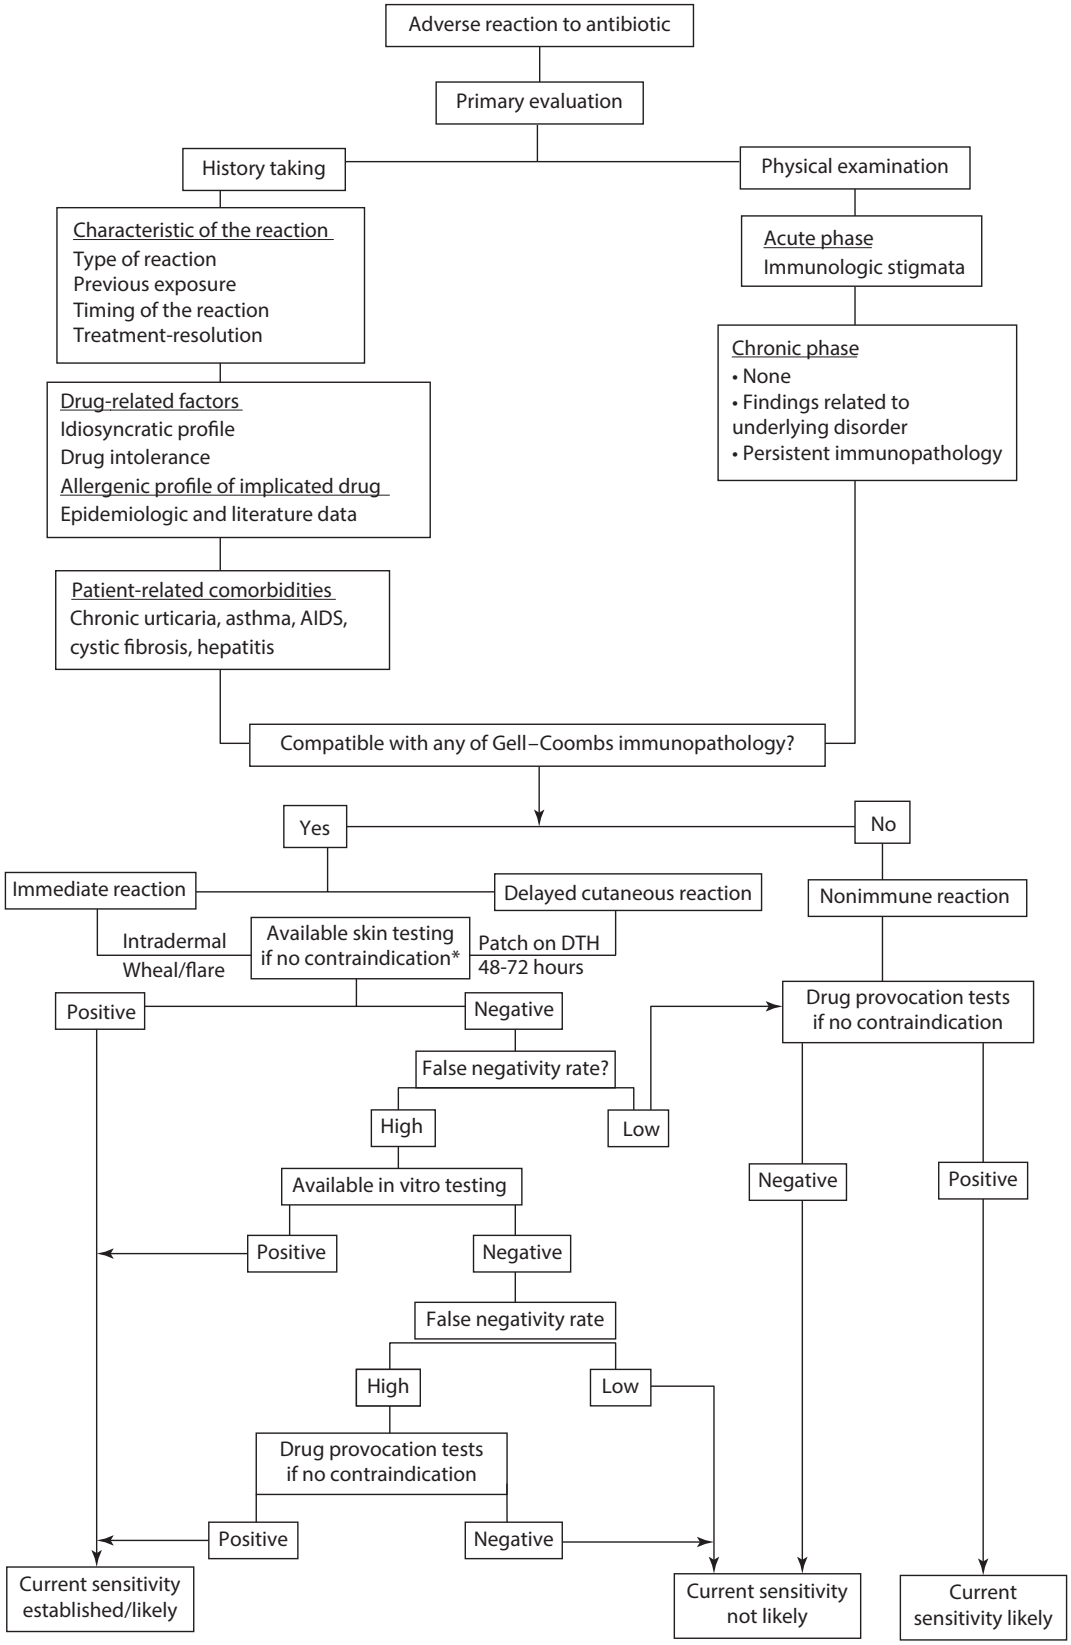

FIGURE 210.1 A diagnostic algorithm for evaluation of putative immunologic reactions to antibiotics. *Contraindications for skin immunoglobulin E testing are extensive skin lesion, recent antihistamine use, and history of serious immediate systemic reaction with allergen exposure. AIDS, acquired immunodeficiency syndrome; DTH, delayed-type hypersensitivity.

hospitalized patients with serious infection, a rapid dose escalation of the intravenous antibiotic of choice is judiciously employed. Late-occurring maculopapular rashes are not easily predictable by skin testing and oral challenge and may occur at a frequency of 3% to 10% for penicillin antibiotics.

Falsely negative penicillin skin testing for IgE is rare, and all reports are of mild, self-limited, and/or transient reactions. About 85% to 90% of patients with histories compatible with IgE-dependent reactions will have currently negative penicillin testing, allowing a large majority of such patients to be retreated safely. Despite this substantial diagnostic power, it has been difficult to maintain persistent commercial sources for these reagents in the United States and Europe. Some academic centers have produced the reagents for their own use, but concerns persist about access to these orphan drug products.

Recent studies show promising results with cephalosporin skin tests. Concentrations of 2 to 3 mg/mL of a parenteral cephalosporin preparation are reported to be usually nonirritating, but each cephalosporin requires concurrent evaluation for its irritant potential in nonallergic subjects. Although a positive cephalosporin skin test implies the presence of drug-specific IgE antibodies, a negative test does not exclude immediate hypersensitivity.

Commercial cephalosporin skin test reagents are not currently available in the United States. Positive intradermal skin tests have been reported for imipenem and other β-lactams, but validated skin testing protocols have not been developed.

In vitro tests

Specific IgE tests have been established for a wide variety of immediate-type drug allergies. Only with penicillin allergy have in vitro test results been systematically compared with skin tests. The consistent finding has been diagnostic sensitivity for penicilloyl-IgE by radioallergosorbent test (RAST) of 65% to 85% compared with penicilloyl-polylysine skin tests and 32% to 50% compared with a combination of skin testing and challenge. Minor determinant penicillin IgE antibodies are not reliably detected by available immunoassays. In recent years, flow cytometry has been increasingly used in the diagnosis of allergy. Assessment of basophil activation by means of increase in surface markers such as CD63 and CD203c have been investigated in penicillin allergy. However, the sensitivity of the basophil activation test has been highly variable, and, in the case of β-lactam antibiotics, sensitivity ranged from 44% to 63% when compared with a diagnosis confirmed by skin testing. As with unvalidated skin tests, a clearly positive result is of greater clinical value than a negative result, thus in vitro basophil activation tests remain investigational.

Evaluation of nonimmediate reactions

Skin testing

European studies suggest that both patch tests and intradermal tests with delayed cutaneous readouts (at 48 and 72 hours) are useful in evaluating non-immediate reactions to aminopenicillins and certain β-lactams and that both can reliably predict the results of rechallenge. Additional studies are required to confirm and extend these results to other drug allergies and to define more precisely the clinical correlation and predictive value for retreatment.

Other tests

Drug-specific T lymphocytes, which are involved in some cutaneous hypersensitivity reactions, may be detected with the use of in vitro lymphocyte transformation tests, which are utilized in Europe but not approved for diagnostic use in the United States. However, sensitization may be found after recent treatment even in the absence of any clinical reactivity, and positive test results have been demonstrated after both immediate and delayed antibiotic-induced reactions caused by β-lactam antibiotics, sulfonamides, and quinolones. Cytokine detection assays are also available to evaluate delayed-type hypersensitivity drug reactions but are still investigational.

Use of drug provocation tests

Definitive diagnosis of drug allergy involves provocation testing as the last step, during which gradually increasing doses of the offending drug are given. Provocation testing may be necessary to accurately identify the responsible agent when multiple drugs are given simultaneously and a reaction occurs. It is particularly important not to incorrectly label a patient allergic to a β-lactam antibiotic because it leads to the use of more-expensive and less-effective drugs and may result in adverse consequences, including but not limited to, a longer length of hospital stay and increased risk of infection.

Studies indicate that only a small minority of history-positive subjects have positive drug challenges. Drug provocation tests should be considered only after evaluating the risk–benefit ratio for an individual patient and should be performed by experienced personnel in an appropriate environment. Informed consent of the patient should be obtained prior to the procedure.

Management of antibiotic allergy

Alternatives for drug-allergic patients

Three alternative approaches are available to provide acceptable pharmacotherapy for infection in antibiotic-allergic patients (Figure 210.2). The physician may choose to use an unrelated antibiotic, or a potentially cross-reactive alternative, or to readminister the implicated antibiotic after an induction of a drug tolerance procedure, also commonly known as *drug desensitization*. A structurally unrelated antibiotic is usually chosen if the tradeoffs of safety, efficacy, and cost are acceptable. If there is no acceptable alternative to the offending drug class, a potentially cross-reacting member of the same antibiotic family may be administered using rapid dose escalation under careful

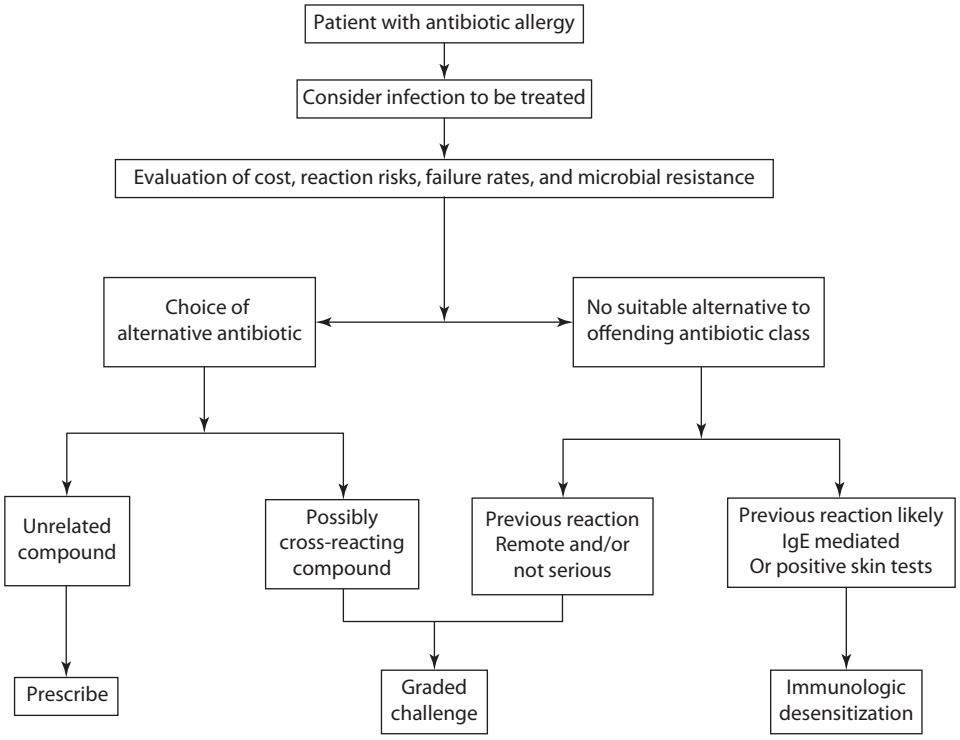

FIGURE 210.2 An approach to treating patients with antibiotic allergy.

observation. If a reaction occurs during graded challenge, then an induction of drug tolerance protocol is warranted. Classical induction of drug tolerance is applied only for IgE-dependent allergy in patients with demonstrable or presumed IgE antibody responses. Induction of drug challenge protocols have been used for non–IgE-mediated reactions; however, neither the effectiveness of the procedure nor a clear mechanism of action has been demonstrated. The procedure aims to induce a temporary state of drug tolerance.

Induction of drug tolerance procedures usually start at 1/10,000 of the full dose with a 2- to 2.5-fold dose increment every 30 to 60 minutes. The procedure entails risk of acute allergic reactions, which occur in mild form in 30% to 80% of penicillin-allergic patients undergoing desensitization. Reactions are generally confined to local and mild systemic reactions during the procedure and, occasionally, late-occurring reactions during therapy, including urticaria or serum sickness and hemolytic anemia if prolonged high-dose therapy is used. The protocol should usually be performed in a hospital setting where experienced personnel and emergency treatment are available. Induction of drug tolerance is an active and reversible process dependent on the continuous presence of the drug. After drug discontinuation, the tolerized state dissipates over days to weeks, and the induction of tolerance procedure would need to be repeated for subsequent treatment courses. Both oral and parenteral routes can be used to initiate drug tolerance, and both appear equally effective in inducing clinical tolerance. The oral approach is arguably safer, although not always feasible.

A variety of protocols have been used for reintroducing β-lactams, trimethoprim-sulfamethoxazole, vancomycin, and other antimicrobials. Table 210.4 shows an illustrative published protocol for penicillin.

Management of β-lactam allergy

β-Lactam antibiotics are the most commonly prescribed class of antibiotics and the most frequent cause of antibiotic allergy. It is the only group of antibiotics for which skin tests have been validated. This group includes penicillins, cephalosporins, carbapenems, and monobactams, all of which share a β-lactam ring but otherwise vary in nuclear structure and side chains.

If skin testing reagents are available, then therapy may be dispensed according to the results of skin tests. When reagents or consultants are not available, an approach is outlined in Figure 210.3. Patients with histories of a reaction to a β-lactam class other than penicillin should first be skin tested with the benzylpenicillin reagents and, if negative, with the diluted β-lactam chosen for use. Yet multiple studies have shown that most patients with penicillin IgE responses can be safely treated with third- and fourth-generation cephalosporins, carbapenems, and monobactams.

Cross-reactivity among β-lactam antibiotics

Cross-reactivity within the penicillin class is virtually complete. A patient who is allergic to any penicillin is likely to react to all penicillins. However, some data suggest that there are patients who are selectively allergic to amoxicillin or ampicillin while tolerating other penicillins. Immunologic cross-reactivity between cephalosporins and penicillins is readily demonstrated in vitro

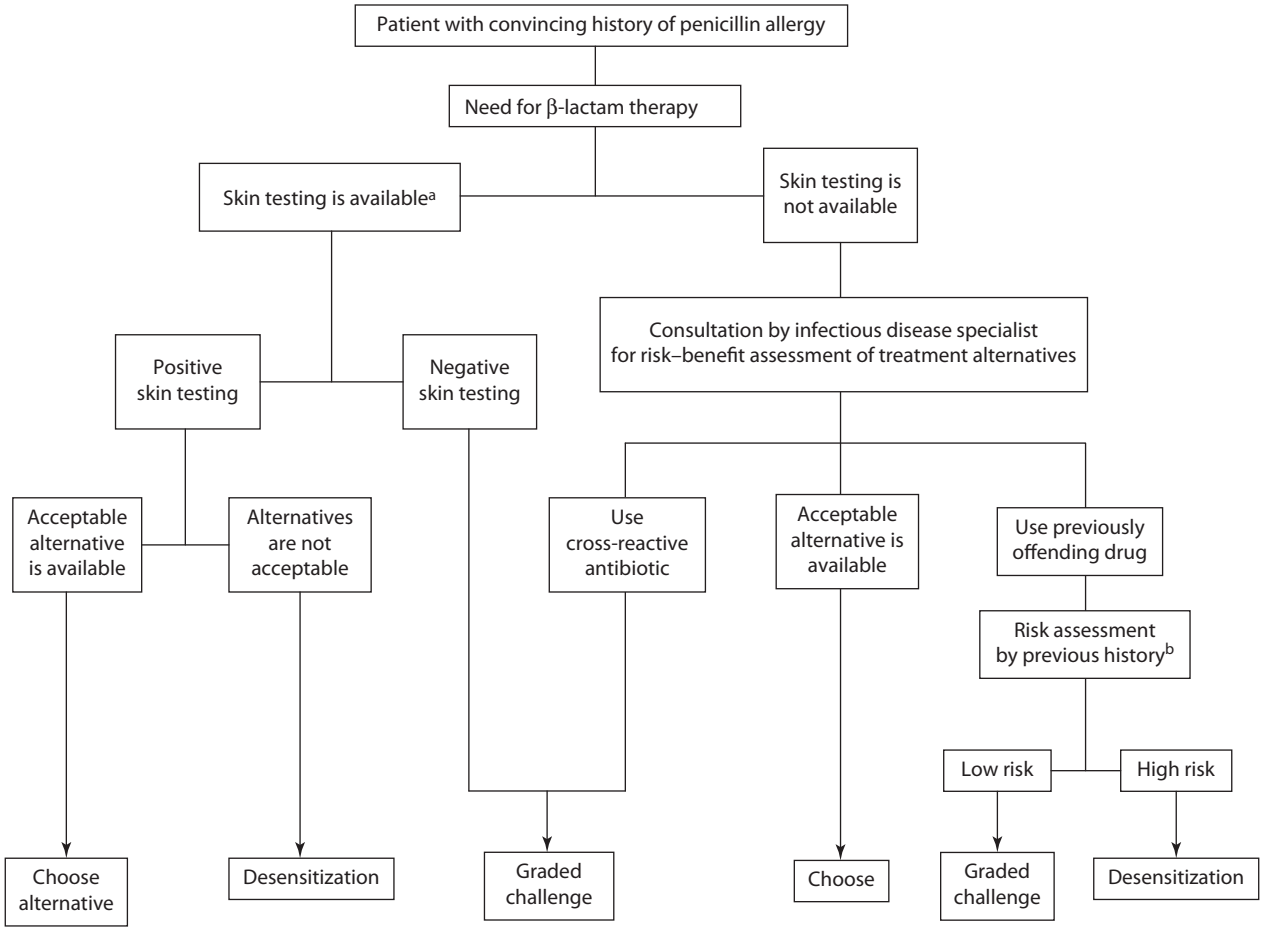

FIGURE 210.3 Diagnostic evaluation of patients with histories of penicillin allergy. (A) Intradermal skin tests should include penicilloyl-polylysine (Pre-Pen) as a major determinant analog, plus one or more minor determinants (especially benzylpenicillin, benzylpenicilloate); the previously offending antibiotic if known and/or the currently desired antibiotic choice may be usefully included, especially in evaluating non-penicillin β-lactams. (B) Risk assessment by previous history: *High risk*: Histories of bronchospasm, angioedema, hypotension, shock that occurred within 30 minutes of penicillin administration in the last year. *Low risk*: History of isolated urticaria or maculopapular rash occurring after days of treatment remotely (>5 years in the past).

and by skin testing, yet multiple studies have shown that most patients with penicillin IgE responses can be safely treated with cephalosporins, especially those of the third and fourth generations. Still, penicillin allergy conveys an odds ratio of 4.8 for acute reactions to first-generation cephalosporin in a meta-analysis, and in one series, a majority of cases of fatal anaphylactic reactions to cephalosporins involved penicillin-allergic patients. Because of this, administration of cephalosporins to penicillin-allergic patients should be undertaken cautiously, especially for patients with previous life-threatening reactions to β-lactam antibiotics of any class.

Penicillin-allergic patients can be given the monobactam aztreonam with little risk because clinically significant cross-reactivity between penicillin and monobactams has not been demonstrated. In contrast, cross-reactions between aztreonam and ceftazidime have been reported, presumably due to identical side chains. The carbapenem antibiotics (imipenem, meropenem, and ertapenem) will induce positive skin tests in about half of penicillin-allergic patients. However, a clinical report from Europe found that 100% of 110 patients with positive penicillin skin tests tolerated imipenem. A more recent study found a cross-reactivity rate of 0.8% between penicillin and imipenem in 124 children. These data suggest that cautious cross-treatment may be reasonably attempted.

Sulfonamide antimicrobials (sulfamethoxazole, sulfadiazine, sulfisoxazole, and sulfacetamide) are extensively cross-reactive and also cross-react with dapsone. Sulfonamide antimicrobial agents differ from other sulfonamide-containing medications by having an aromatic amine group at the N4 position and a substituted ring at the N1 position that are not found in non-antibiotic sulfonamide-containing drugs. Patients allergic to sulfonamide antibiotics tolerate thiazide diuretics, oral hypoglycemic agents, and other SO_2-containing drugs and vice versa.

Other antibiotics

Immunologic reactions to quinolones and macrolides are very rare. These antibiotics mostly evoke maculopapular eruptions and occasionally urticaria and angioedema (Table 210.4). As there are no validated skin or in vitro tests, drug provocation tests are the only available diagnostic methods for these classes of antibiotics.

TABLE 210.5 **PARENTERAL DESENSITIZATION PROTOCOL**

Infection number	Benzylpenicillin concentration (U/mL)	Volume/route (mL)

19	Continuous IV infusion (1,000,000 U/h)	

Doses are administered at 20-minute intervals. Observe skin wheal and flare response to intradermal doses.
Abbreviations: ID = intradermal; SC = subcutaneous; IM = intramuscular; IV = intravenous.
Adapted from Wesis ME, Adkinson NF. Immediate hypersensitivity reactions to penicillin and related antibiotics. *Clinical Allergy*. 1988;18:515–540.

Vancomycin is associated with two main types of hypersensitivity reactions; namely, a nonallergic hypersensitivity reaction (pseudoallergic reaction) known as "red man syndrome" and anaphylaxis. Skin testing with vancomycin at concentrations of 1 μg/mL or lower is presumptive for the presence of IgE antibodies that can be elicited by multiple courses of therapy.

Topical antibiotics such as bacitracin and neomycin usually cause delayed-type skin reactions. Although immediate-type reactions are rarely reported, repeated usage of bacitracin has been associated with near fatal anaphylaxis in a few cases. Hypersensitivity reactions to metronidazole are infrequently reported. Fixed drug eruptions and delayed-type skin reactions are the most common clinical presentations.

The general approach to antibiotic allergy, as depicted in Figure 210.1, is also useful for management of adverse reactions to non–β-lactam antibiotics.

Multiple antibiotic allergy syndromes

Some patients show a marked propensity to react to several chemically unrelated antibiotics and sometimes to non-antibiotic drugs. This condition has been termed the multiple drug allergy syndrome (MDAS). In most cases, MDAS presents clinically as acute urticaria +/− angioedema after ingestion of multiple doses of offending drugs. However, other variants including non-urticarial rashes, including SJS, anaphylaxis, serum sickness-like reactions, and immune cytopenias, have also been described. Mechanisms underlying multiple drug reactivity are still unclear. Published studies have suggested a high propensity to MDAS among patients with a history of allergy to β-lactams or any other antimicrobial drug. Whether MDAS results from a facilitated ability to make immune responses to drug haptens or an increased vulnerability to drug-induced immunopathology has yet to be determined. Some cases of MDAS are "pseudoallergic" and reflect classically conditioned responses that can readily be misinterpreted as anaphylaxis.

Clinical management of MDAS is similar to that in patients with single antibiotic allergy. Avoidance of unnecessary use of drugs should be the first step. Preferential use of low-risk antibiotics such as macrolides and quinolones may be helpful. With testing (e.g., validated skin or in vitro tests) or full allergy consultations, readministration of previously implicated drugs, especially β-lactams, can be justified.

Conclusion

Patients relating a history of immune or nonimmune reactions to antibiotics are not rare in medical practice. Because history alone has low diagnostic value, it is desirable that the history-positive patient should be evaluated by diagnostic tests when validated or by drug provocation tests when the index of suspicion is low. Although alternative antimicrobials can often be identified, they can have higher costs and treatment failures or greater toxicity. For the truly drug-allergic patient, management approaches include cautious administration of cross-reactive antimicrobials from the same class or drug desensitization. When approached systematically, almost all antibiotic-sensitive patients can be safely and effectively treated.

Fidaxomicin	Dificid	200 mg PO q12h	≥6 months: 16 mg/kg/dose PO q12h (max 200 mg/dose)	Unchanged	Usual
Fosfomycin	Monurol	Oral: 3 g once or q2–3d; IV: 12–24 g/d divided q6–8h	Oral: <12 years: 2 g once; IV: <10 kg: 200–300 mg/kg/d divided q6h; 10–40 kg: 200–400 mg/kg/d divided q6–8h; >40 kg 12–24 g/d divided q6–8h	Unchanged	IV: Usual
Gatifloxacin	Zymaxid, Zymar	400 mg PO/IV q24h	[b]	None	Usual

adjustment for reduced CrCl		Dosing in dialysis		Major toxicity
10–50	≤10	HD	PD	
Usual	Usual	[b]	[b]	Blood dyscrasias, dermatologic reactions (toxic erythema multiforme), hyperbilirubinemia, hepatitis, peripheral neuropathy, headache, GI irritation, infectious mono-like syndrome
q24–48h	q48h	q48h, pHD on HD days	q48h	Eosinophilic pneumonia, myopathy, rhabdomyolysis, peripheral neuropathy, GI disturbance, increased creatine phosphokinase, insomnia, headache
oral:450 mg q12h; IV: 200 mg q12h	N.R.	N.R.	q12h	GI disturbance, dizziness, headache, tremors, confusion, QT prolongation, aortic aneurysm, dysglycemia, photosensitivity, tendon rupture/tendinitis, peripheral neuropathy, seizures, psychiatric reactions
Usual	Usual	Usual	Usual	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting
250 mg q8h	250 mg q12h	250–500 mg q24h	[b]	Anaphylaxis, hypersensitivity, GI disturbance, seizures, headache
Usual	Usual	Usual	Usual	GI disturbance, photosensitivity reactions, hepatic toxicity, esophageal ulcers
Usual	Usual	Usual	Usual	abnormal LFTs, photosensitivity reactions
CrCl ≤30: 500 mg q24h	CrCl ≤30: 500 mg q24h	500 mg q24h, give supplemented dose of 150 mg pHD	[b]	Thrombocytopenia, increased LFTs, allergic reactions; seizures, GI disturbance
Usual	Usual	Usual	Usual	GI disturbance; rare: allergic reactions, hepatic dysfunction, hearing loss
Usual	Usual	Usual	Usual	Cholestatic hepatitis, hearing loss or tinnitus, GI disturbance, hypersensitivity reactions
Usual	Usual	Usual	Usual	GI disturbance; rare: allergic reactions, hepatic dysfunction
Usual	Usual	Usual	Usual	GI disturbance; rare: allergic reactions, hepatic dysfunction, hearing loss
Usual	Usual	Usual	Usual	Nausea, vomiting, hypersensitivity reaction, fever
20–70% of dose q8–12h	20% of dose q12–24h	2 g pHD	[b]	Electrolyte abnormalities, hepatic abnormalities, headache, GI disturbance, vaginitis
400 mg ×1 then 50% q24h	[b]	[b]	[b]	Hyperglycemia, hypoglycemia, QT prolongation, tendon rupture

(*continued*)

TABLE 211.1 CONTINUED

Name		Usual dose		Change in absorption with food	Adult dose interval
Generic	Brand	Adult[a,c]	Pediatric[a,d]		>50
Gentamicin[e]	Garamycin	IV: 3–5 mg/kg/d divided q8h or 5–7 mg/kg IV q24h; IT: 4–8 mg/d	2–2.5 mg/kg IV q8h or 4.5–7.5 m/kg IV q24h	n.a.	Usual
Grepafloxacin		400–600 mg q24h	[b]	No change	Usual
Imipenem-cilastatin	Primaxin	500 mg IV q6h or 1 g IV q8h	60–100 mg/kg/d IV divided q6h	n.a.	Usual
Imipenem-cilastatin-relebactam	Recarbrio	1.25 g IV q6h	[b]	n.a.	CrCl 60–89: 1 g q6h
Kanamycin[e]	Kantrex	15 mg/kg/d divided IV q8–12h	15 mg/kg/d divided IV q8–12h (newborn: 0–7 d, 15–20 mg/kg/d q12h; 1–4 wk, 15 mg/kg/d q8–12h)	n.a.	Usual
Lefamulin	Xenleta	Oral: 600 mg q12h; IV: 150 mg IV q12h	[b]	Decreased	Usual
Levofloxacin	Levaquin	250–750 mg PO/IV q24h	N.R.	Unchanged	Usual
Lincomycin	Lincocin	600 mg–1 g IV q8–12h	10–20 mg/kg/d IV divided q8–12	n.a.	q8–12h
Linezolid	Zyvox	600 mg PO/IV q12h	<12 years: 10 mg/kg/dose IV/PO q8h; ≥12 years: 600 mg IV/PO q12h	Unchanged	Usual
Lomefloxacin	Maxaquin, Uniquin, Okacyn	400 mg PO q24h	N.R.	Decrease	Usual
Loracarbef	Lorabid	400 mg PO q12h	15–30 mg/kg/d PO divided q12h	Decreased	Usual
Meropenem	Merrem	500 mg - 2 g IV q8h	20–40 mg/kg/dose IV q8h	n.a.	Usual
Meropenem-vaborbactam	Vabomere	4 g IV q8h	[b]	n.a.	Usual
Metronidazole	Flagyl	Oral: 250 mg–1 g q6–12h; IV: 500–1 g q6–12h	Oral: 15–50 mg/kg/d divided q8h; IV: 22.5–40 mg/kg/d divided q6–8h	Unchanged	Usual
Mezlocillin		3–4 g IV q4–6h	50 mg/kg IV q4–6h	n.a.	Usual
Minocycline	Minocin, Dynacin	200 mg IV/PO once, then 100 mg IV/PO q12h	4 mg/kg (max 200 mg) IV/PO once, then 2 mg/kg/dose q12h (max 100 mg)	Unchanged	Usual

adjustment for reduced CrCl		Dosing in dialysis		Major toxicity
10–50	≤10	HD	PD	
q12–48h	>48 h	1–2 mg/kg q48–72h	1 mg/2 L dialysate removed	Renal toxicity, vestibular and auditory toxicity, CNS reactions, neuromuscular blockade (rare)
Usual	Usual	Usual	Usual	Phototoxicity, QT prolongation, tendon rupture
200–300 mg q6h or 500 mg q8–12h	N.R.	250–500 mg pHD then q12h	[b]	Fever, rash, nausea, vomiting, diarrhea, seizures (rare)
CrCl 30–59 L 750 mg q6h; CrCl 15–29: 500 mg q6h	N.R.	500 mg IV q6h	N.R.	Fever, headache, diarrhea, vomiting, increased liver enzymes, seizures (rare)
q12–48h	>48 h	4–5 mg/kg pHD	3.75 mg/kg/d	Cranial nerve VIII and renal damage
Usual	Usual	Usual	Usual	QT prolongation, hypokalemia, GI disturbance, increased liver enzymes, headache, insomnia
250 mg q24h or 500 mg q48h	250–500 mg q48h	250–500 mg q48h	250–500 mg q48h	GI disturbance, dizziness, headache, tremors, confusion, QT prolongation, aortic aneurysm, dysglycemia, photosensitivity, tendon rupture/tendinitis, peripheral neuropathy, seizures, psychiatric reactions
q8–12h	q8–12h	[b]	[b]	Diarrhea, including pseudomembranous colitis
Usual	Usual	Usual	Usual	Myelosuppression (primarily thrombocytopenia), lactic acidosis, peripheral neuropathy, optic neuropathy, serotonin syndrome
0.2 g q24h	0.2 g q24h	0.4 g load, then 0.2 g q24h	[b]	Nausea, vomiting, dizziness, headache, tremors, confusion, photosensitivity
200 mg q24h	200 mg q72h	400 mg pHD	[b]	Allergic reactions, GI disturbance
q12h	500 mg–1 g q24h	500 mg–1 g q24h	500 mg–1 g q24h	Seizures, rash, headache, GI disturbance
2 g q8–12h	1 g q12h	[b]	[b]	Thrombocytopenia, seizures, headache, diarrhea
q6–12h	q6–12h	q6–12h	q6–12h	Headache, nausea, vaginitis, metallic taste, GI disturbance
CrCl 10–30: 1.5–3 g q6–8h	1.5–2 g q8h	3–4 g pHD then q12h	3 g q12h	Hypokalemia
Usual	Usual	Usual	Usual	GI disturbance, photosensitivity, hepatic toxicity, esophageal ulcers, vestibular toxicity; tooth discoloration

(*continued*)

TABLE 211.1 CONTINUED

Name		Usual dose		Change in absorption with food	Adult dose interval
Generic	Brand	Adult[a,c]	Pediatric[a,d]		>50
Moxifloxacin	Avelox	400 mg PO/IV q24h	N.R.	Unchanged	Usual
Nafcillin	Nallpen, Unipen	1–2 g IV q4h	Birth–7 days: 75 mg/kg/d IV divided q8–12h; 8–28 days: 100–150 mg/kg/d IV divided q6–8h; >28 days: 200 mg/kg/d IV divided q6h	n.a.	Usual
Neomycin	Neo-tabs	4–12 g/d PO divided q4–6h	–	Unchanged	[b]
Netilmicin[c]		4–6 mg/kg/d IV/IM divided q8–24h	0–1 week: 3 mg/kg IV/IM q12h; >1 week 2.5 mg/kg IV/IM q8h	n.a.	q8–12h
Nitrofurantoin macrocrystals	Furadantin, Macrodantin	50–100 mg PO q6h;	5–7 mg/kg/d PO divided q6h	Increased	Usual
Nitrofurantoin monohydrate/macrocrystals	Macrobid	100 mg PO q12h	Adolescents: 100 mg PO q12h	Increased	Usual
Norfloxacin	Noroxin	400 mg PO q12h	N.R.	Decreased	Usual
Ofloxacin	Floxin	200 mg PO q12h or 400 mg PO q24h	N.R.	Unchanged	Usual
Omadacycline	Nuzyra	Oral: 450 mg q24h on days 1 and 2, then 300 mg q24h; IV: 200 mg once, then 100 mg q24h	[b]	Decreased	Usual
Oritavancin	Orbactive	1.2 g IV once	[b]	n.a.	CrCl ≥30: Usual
Oxacillin	Bactocil	1–3 g IV q4–6h	100–200 mg/kg/d IV divided q4–6h (max 12 g/d)	n.a.	Usual
Penicillin V	Pen–VeeK, Pen–V	125–500 mg PO q6–8h	25–75 mg/kg/d PO divided q6h (max 2 g/d)	Decreased	Usual

adjustment for reduced CrCl		Dosing in dialysis		Major toxicity
10–50	≤10	HD	PD	
Usual	Usual	Usual	Usual	GI disturbance, dizziness, headache, tremors, confusion, QT prolongation, aortic aneurysm, dysglycemia, photosensitivity, tendon rupture/tendinitis, peripheral neuropathy, seizures, psychiatric reactions
Usual	Usual	Usual	Usual	Allergic reactions (rare: anaphylactic), diarrhea, bone marrow suppression agranulocytosis, interstitial nephritis, hypokalemia
[b]	[b]	[b]	[b]	Cranial nerve VIII and renal damage
q12–48h	>48 h	2 mg/kg pHD	[b]	Renal toxicity, vestibular and auditory toxicity, CNS reactions, neuromuscular blockade (rare)
Avoid CrCl <30	N.R.	N.R.	N.R.	Headache, increased serum phosphate, increased LFT, decreased hemoglobin, eosinophilia
Avoid CrCl <30	N.R.	N.R.	N.R.	Headache, increased serum phosphate, increased LFT, decreased hemoglobin, eosinophilia
CrCl ≤30: q24h	q24h	[b]	[b]	GI disturbance, dizziness, headache, tremors, confusion, QT prolongation, aortic aneurysm, dysglycemia, photosensitivity, tendon rupture/tendinitis, peripheral neuropathy, seizures, psychiatric reactions
q24h	100–200 mg q24h	100–200 mg pHD	200 mg q24h	GI disturbance, dizziness, headache, tremors, confusion, QT prolongation, aortic aneurysm, dysglycemia, photosensitivity, tendon rupture/tendinitis, peripheral neuropathy, seizures, psychiatric reactions, visual disturbance
Usual	Usual	Usual	Usual	GI disturbance, headache, hypertension, insomnia, increased LFT
[b]	[b]	[b]	[b]	GI disturbance, headache, increased LFT
Usual	Usual	Usual	Usual	Allergic reactions (rare: anaphylactic), diarrhea, acute interstitial nephritis, acute renal tubular disease
Usual	Usual	Usual	[b]	Allergic reactions (rare: anaphylactic), melanoglossia, GI disturbance, oral candidiasis

(*continued*)

TABLE 211.1 CONTINUED

Name		Usual dose		Change in absorption with food	Adult dose interval
Generic	Brand	Adult[a,c]	Pediatric[a,d]		>50
Penicillin G benzathine	Bicillin L-A	1.2–2.4 million units IM once	≤27 kg: 600,000 units IM once; >27 kg: 1.2 million units IM once	n.a.	Usual
Penicillin G	various	2–4 million U IV q4–6h	25,000–90,000 U/kg/d divided q4–8h PO 25,000–400,000 U/kg/d divided IV q4–6h (neonate: 0–7 d, 50,000–150,000 U/kg/d q8–12h; 1–4 wk, 75,000–200,000 U/kg/d q6–8h)	Decreased	Usual
Piperacillin		6–18 g/d IV divided q6–12h	≥12 years: refer to adult dosing	n.a.	Usual
Piperacillin–tazobactam	Zosyn	3.375–4.5 g IV q6–8h	≥2 months: 240–300 mg piperacillin/kg/d divided q6–8h (max 16 g/d)	n.a.	Usual
Plazomicin[j]	Zemdri	15 mg/kg IV q24h	[b]	n.a.	CrCl 30-<60:10 mg/kg q24h
Polymyxin B	Aerosporin, Neosporin	Loading dose: 2–2.5 mg/kg (20,000–25,000 IU/kg); Maintenance dose: 1.25–1.5 mg/kg (12,500–15,000 IU/kg) IV q12h; infused over 1 h	2.5–4 mg/kg/d (25,000–40,000 IU/kg/d) IV divided q4–6h	n.a.	Usual
Procaine penicillin G	Wycillin	600,000–2.4 million units IM q12–24h	50,000 units/kg/d IM divided q12–24h	n.a.	Usual
Quinupristin–dalfopristin	Synercid	7.5 mg/kg IV q8h	[b]	n.a.	Usual
Rifaximin	Xifaxan	200–400 mg PO TID	100–550 mg PO q6–8h, dosing specific to indication and age	Unchanged	[b]
Sparfloxacin		400 mg PO once, then 200 mg PO q24h	[b]	Unchanged	Usual
Spectinomycin	Spectam, Trobicin	2 g IM x1 dose	[b]	n.a.	Usual
Streptomycin[e]		7.5–15 mg/kg IV/IM q12–24h	15–40 mg/kg/d IV/IM divided q6–12h (max 2 g/d)	n.a.	Usual
Sulfadiazine	Microsulfon	500 mg–1.5 g PO q6h	120–150 mg/kg/d PO divided q4–6h (max 6 g/d)	Unchanged	[b]

adjustment for reduced CrCl		Dosing in dialysis		Major toxicity
10–50	≤10	HD	PD	
Usual	Usual	Usual	Usual	Allergic reactions (rare: anaphylactic), GI disturbance, Jarisch-Herxheimer reaction
1–2 million U IV q4h	1 million U IV q8h	500,000 U	[b]	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting
3–4 g q8h	3–4 g q12h	1 g pHD, then 2 g IV q8h	[b]	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting; platelet dysfunction with high doses
2.25–3.375 g q6h or 4.5 g q8h	2.25 g q6–8h or 4.5 g q12h	4.5 g q12h or 2.25 g q8h	4.5 g q12h or 2.25 g q8h	Allergic reactions (rare: anaphylactic), GI disturbance
CrCl 15-<30: 10 mg/kg q48h	[b]	[b]	[b]	Nephrotoxicity, ototoxicity
Usual	Usual	Usual	[b]	Nephrotoxicity, flushing, neurotoxicity: ataxia, blurred vision, drowsiness, irritability, numbness of extremities, oral paresthesia, dizziness
Usual	Usual	[b]	[b]	Allergic reactions (rare: anaphylactic), diarrhea, nausea, vomiting
Usual	Usual	[b]	[b]	Pain at infusion site, thrombophlebitis, arthralgia, myalgia, hyperbilirubinemia
[b]	[b]	[b]	[b]	Peripheral edema, dizziness, fatigue, ascites, nausea, headache, depression, pruritus, skin rash, GI disturbance, anemia, muscle spasm, arthralgia, fever
400 mg once, then 200 mg q48h	400 mg once, then 200 mg q48h	[b]	[b]	Photosensitivity, diarrhea, nausea, headaches, cardiac arrhythmias in patients taking antiarrhythmic drugs
Usual	Usual	[b]	[b]	Pain at injection site, nausea, allergic reactions
q24–72h	q72–96h	50% of dose pHD on HD days	[b]	Cranial nerve VIII damage, paresthesias, rash, fever, nephrotoxicity, neuromuscular blockade, optic neuritis, ototoxicity
[b]	[b]	[b]	[b]	GI disturbance, rash, pruritus, bone marrow suppression, serum sickness, drug fever, crystalluria, photosensitivity, hepatitis

(*continued*)

TABLE 211.1 CONTINUED

Name		Usual dose		Change in absorption with food	Adult dose interval
Generic	Brand	Adult[a,c]	Pediatric[a,d]		>50
Sulfisoxazole	Pediazole	Oral: 0.5–1 g PO q6h: IV: 25 mg/kg IV q6h	120–150 mg/kg/d divided PO q4–6h	Decreased	Usual
Tedizolid	Sivextro	200 mg IV/PO q24h	≥12 years: 200 mg IV/PO q24h	Unchanged	Usual
Teichoplanin	various	0.2–0.4 g IV q24h	10 mg/kg IV q24h	n.a.	Usual
Telavancin	Vibativ	10 mg/kg IV q24h	[b]	n.a.	Usual
Telithromycin	Ketek	800 mg PO q24h	[b]	Unchanged	Usual
Tetracycline	Achromycin	250–500 mg PO q6h	6.25–12.5 mg/kg/dose PO q6h (max 3 g/d)	Decreased	Usual
Ticarcillin	Ticar	3 g IV q6h	≥3 months: <60 kg, 50 mg/kg IV q4–6h (max 3 g/dose); ≥60 kg: 3 g IV q4–6h	n.a.	Usual
Ticarcillin–clavulanate potassium[l]	Timentin	3.1 g IV q4–6h	200–300 mg ticarcillin/kg/d IV divided q4–6h	n.a.	Usual
Tigecycline[o]	Tygacil	Package insert: 100 mg IV once, then 50 mg q12h; High dose therapy (for serious systemic infections) dosing: loading dose 200–400 mg IV once, then maintenance dose of 100–200 (50% of load) mg IV q24h	8–11 years: 1.2–2 mg/kg/dose IV q12h (max 50 mg/dose); ≥12–17 years: 1.5 mg/kg/dose IV once (max 100 mg/dose), then 1 mg/kg/dose q12h (max 50 mg/dose)	n.a.	Usual
Tinidazole	Tindamax	1–2 g PO q24h	≥3 years: 50 mg/kg/dose PO q24h (max 2 g/dose)	Unchanged	Usual
Tobramycin[c]	Nebcin	IV: 3–5 mg/kg/d divided q8h or 5–7 mg/kg IV q24h; IT: 5–20 mg/d	3–6 mg/kg/d divided IV q8h (newborn: 0–7 d, ≤4 mg/kg/d q12h; 1–4 wk, 3–5 mg/kg/d q8h)	n.a.	Usual
Trimethoprim–sulfamethoxazole[m]	Bactrim, Septra	Oral: 1–2 DS PO q8–12h; IV: 8–20 mg/kg/d divided q6–12h	≥2 months: 6–12 mg TMP/kg/d IV/PO divided q6–12h (max 160 mg TMP/dose)	Unchanged	Usual
Trimethoprim	Proloprim	100 mg PO q12h	≥6 months–11 years: 2–5 mg/kg/dose PO q12h	Unchanged	Usual

adjustment for reduced CrCl		Dosing in dialysis		Major toxicity
10–50	≤10	HD	PD	
q8–12h	q12–24h	[b]	[b]	Rash, photosensitivity, drug fever
Usual	Usual	Usual	Usual	GI disturbance, thrombocytopenia, optic neuropathy
q48h	q72h	[b]	[b]	Ototoxicity
CrCl 30–50: 7.5 mg/kg q24h; CrCl 10–30: 10 mg/kg q48h	[b]	[b]	[b]	Nephrotoxicity, QT prolongation, metallic taste, GI disturbance
CrCl <30: 600 mg q24h	CrCl <30: 600 mg q24hk	600 mg q24h, dose pHD on HD days	[b]	GI disturbance, headache, dizziness, thrombocytopenia, increased LFTs, reversible diplopia (females <40 years)
Use doxycycline	Use doxycycline	Use doxycycline	[b]	GI disturbance, photosensitivity, hepatic toxicity, esophageal ulcers, candidiasis (thrush and vaginitis)
2 g q8h	2 g q12h	3 g pHD; then 2 g q12h	3 g q12h	Allergic reactions (rare: anaphylactic), GI disturbance, Jarisch-Herxheimer reaction (with syphilis or other spirochetal infections), increased LFTs
q6–8h	2 g q12h	3.1 g pHD; then 2 g q12h	3.1 g q12h	Allergic reactions (rare: anaphylactic), GI disturbance, Jarisch-Herxheimer reaction (with syphilis or other spirochetal infections), increased LFTs
Usual	Usual	Usual	Usual	GI disturbance (nausea/vomiting), increased LFTs, electrolyte abnormalities.
Usual	Usual	Administer pHD on HD days	[b]	Metallic taste, GI disturbance
q12–48h	>48 h	1–2 mg/kg q48–72h	1 mg/2 L dialysate removed	Renal toxicity, vestibular and auditory toxicity, CNS reactions, neuromuscular blockade (rare)
CrCl 15–30: 50% of usual dose; Oral: q12–24h; IV: q6–24h	CrCl <15: 25% of usual dose; Oral: q12–24h; IV: 24–48h	Follow dosing for CrCl <15: administer pHD on HD days	CrCl <15: 25% of usual dose; q24–48h	GI disturbance (dose dependent), rash, pseudoelevation in serum creatinine, reversible hyperkalemia (dose dependent), bone marrow suppression
q12–18h	q24h	q24h	q24–48h	GI disturbance, reversible hyperkalemia (dose dependent), bone marrow suppression

(*continued*)

TABLE 211.1 **CONTINUED**

Name		Usual dose		Change in absorption with food	Adult dose interval
Generic	**Brand**	**Adult**[a,c]	**Pediatric**[a,d]		**>50**
Trovafloxacin	Bactocil	300 mg IV load; 200 mg IV/PO q24h	[b]	Unchanged	Usual
Vancomycin	Vancocin	Oral: 125 mg q6h (*C. difficile* infection) or 500 mg q6h (fulminant *C. difficile* infection); IV: 15–20 mg/kg IV q8h	40 mg/kg/d divided PO q6–8h 40 mg/kg/d divided IV q6–12h (newborn: 0–7 d, 15 mg/kg load, then 10 mg/kg q12h; 1–4 wk, 10 mg/kg q8h)	Not absorbed	CrCl >90: q8h, CrCl 60–89: q12h

[a] Dosing weight, actual body weight (kg) unless indicated otherwise
[b] Insufficient information available to make a recommendation.
[c] Specific dosing is dependent on indication
[d] Pediatric dosing may be specific to age, weight (kg), and/or indication
[e] In underweight (less than IBW), ABW is used. In normal-weight, IBW is used. In overweight patients (ABW >20% ideal weight), AdjBW is used. Aminoglycoside dosing may be
[f] Dosing based on amoxicillin component; formulations are not interchangeable
[g] Dosing based on ampicillin component
[h] Dosing based on ceftazidime component
[i] Use AdjBW to estimate CrCl; CBA= colistin base activity; CMS= colistin methanesulfonate
[j] Use ABW in non-obese patients, for patients with ABW > IBW by ≥25% use AdjBW
[k] CrCl <30 ute and concomitant hepatic impairment: 400 mg once daily
[l] Dosing based on Ticarcillin component
[m] Weight-based dosing recommendations are based on the TMP component. Each double-strength tablet contains TMP 160 mg and SMX 800 mg. Each single-strength tablet

Abbreviations: q = every; h = hour; IV= intravenous; PO = by mouth; IM = intramuscular; IT = intrathecal; CrCl = creatinine clearance (); HD = hemodialysis; PD = peritoneal body weight (kg); AdjBW = adjusted body weight (kg); TBW= total body weight (kg); IR = immediate release; XR = extended release; pHD =post-hemodialysis; n.a.=not

adjustment for reduced CrCl		Dosing in dialysis		Major toxicity
10–50	≤10	HD	PD	
Usual	Usual	Usual	Usual	Hepatotoxicity, including severe liver failure, dizziness, nausea, headache, photosensitivity, insomnia
CrCl 30–59: q24h	CrCl <30: dose by vancomycin level	Dose by level	Dose by level	Red-man syndrome, nephrotoxicity, thrombocytopenia, ototoxicity, Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS), IgA dermatitis

modified after obtaining serum levels.

contains TMP 80 mg and SMX 400 mg. CrCl <15, HD, PD - avoid if possible

dialysis; CNS = central nervous system; GI =gastrointestinal; TEN = toxic epidermal necrolysis; p = post; LFTs = liver function tests; IBW= ideal body weight (kg); ABW = actual applicable; AST =aspartate aminotransferase; ALT =alanine aminotransferase; N.R.=not recommended; TMP= trimethoprim; SMX=sulfamethoxazole

TABLE 211.2

Name		Usual dose		Change in absorption with food
Generic	**Brand**	**Adult[a,c]**	**Pediatric[a,d]**	
Bedaquiline	Sirturo	Weeks 1–2: 400 mg PO q24h Weeks 3–24: 200 mg 3 times weekly	≥5 years: 15 to <30 kg: Weeks 1–2: 200 mg PO q24h Weeks 3–24: 100 mg 3 times weekly ≥30 kg: use adult dosing	Increased
Capreomycin	Capastat	15 mg/kg IV/IM q24h or 25 mg/kg IV/IM 3 times weekly	<15 years: ≤40 kg: 15–20 mg/kg IV/IM q24h or 25 mg/kg/dose 2 times weekly (max 1 g/dose) >40 kg or ≥15 years: use adult dosing	N.A.
Clofazimine		100 mg PO q24h	[b]	Increased
Cycloserine	Seromycin	10–50 mg/kg/d (max 1 g/d) PO, divided q12–24h	15–20 mg/kg/d (max 1 g/d) PO, divided q12–24h	Unchanged
Ethambutol[e]	Myambutol	15–25 mg/kg (max 1.6 g) PO q24h	15–25 mg/kg PO q24h	Unchanged

INH + RIF + PZA	Rifater	6 tablets PO q24h	[b]	Decreased
INH + RIF	Rifamate	2 capsules PO q24h	[b]	Decreased
Isoniazid		300 mg PO q24h or 900 mg PO 1–3 times weekly	<15 years and ≤40 kg: 10–15 mg/kg/dose (max 300 mg/dose) PO q24h; >40 kg or ≥15 years: use adult dosing	Decreased
Para-amino salicylic acid		150 mg/kg q6–12h	150–360 mg/kg/d divided q6–8h	Decreased
Pyrazinamide	Tebrazid	25 mg/kg (max 2 g) PO q24h	35 mg/kg/dose (max 2 g) PO q24h	Unchanged
Rifabutin (ansamycin)	Mycobutin	300 mg PO q24h	10–20 mg/kg/d (max 300 mg/d) PO q24h or 3 times weekly	Unchanged
Rifampin	Rifadin, Rimactane	600 mg IV/PO q24h	10–20 mg/kg/d IV/PO max 600 mg/d); divided q12–24h	Decreased
Rifapentine	Priftin	Active TB: 600 mg PO 2 times weekly for 2 months, then 600 mg once weekly for 4 months; Latent TB: 600–900 mg PO once weekly	≥12 years: use adult dosing	Increased
Streptomycin[f]		15 mg/kg IV/IM q24h or 25 mg/kg IV/IM 3 times weekly	15–40 mg/kg/d IV/IM q24h (max 1 g/dose)	N.A.

[a] Dosing weight, actual body weight (kg) unless indicated otherwise.
[b] Insufficient information available to make a recommendation.
[c] Specific dosing is dependent on indication.
[d] Pediatric dosing may be specific to age, weight (kg), and/or indication.
[e] Use lean body weight.
[f] In underweight (less than IBW), ABW is used. In normal weight, IBW is used. In overweight patients (ABW >20% ideal weight), AdjBW is used. Aminoglycoside dosing may be
CNS, central nervous system; CrCl, creatinine clearance mL/min; GI, gastrointestinal; HD, hemodialysis; INH, isoniazid; IT, intrathecal; N.A., not applicable; N.R., not

Adult dose reduced interval adjustment CrCl for			Dosing in dialysis		Major toxicity
>50	10–50	≤10	HD	PD	
Usual	Usual	Use with caution	[b]	[b]	QT prolongation, increased LFTs, hepatotoxicity, headache, arthralgia, rash, hyperuricemia, peripheral neuropathy, anemia, otovestibular toxicity
q24h	7.5 mg/kg q24–48h	7.5 mg/kg 2×/wk	15 mg/kg/dose 2–3 times weekly	[b]	Nephrotoxicity, ototoxicity, electrolyte abnormalities, pain at injection site
q24h	q24h	q24h	Use with caution	Use with Caution	Hyperpigmentation, ichthyosis, dry eyes, GI disturbance
q12h	250 mg q24h	N.R.	500 mg 3 times weekly	[b]	Anxiety, depression, confusion, hallucinations, headache, peripheral neuropathy (associated with peaks >35 mcg/mL), seizure (dose dependent)
q24h	q24–36h	q48h	15 mg/kg/d pHD	q48h	Optic neuritis, allergic reactions, GI disturbance, acute gout
q12h	CrCl ≥30: q12h	CrCl <30: 250–500 mg/d	CrCl <30: 250–500 mg/d	[b]	GI disturbance, liver toxicity, CNS disturbance, yellow staining of eyes or skin, dizziness, ototoxicity, Goiter, gynecomastia, hypoglycemia, hypothyroidism, menstrual disease, pellagra
q24h	q24h	[b]	[b]	[b]	As with individual drugs
q24h	q24h	[b]	[b]	[b]	As with individual drugs
q24h	q24h	150 mg q24h in slow acetylators	5 mg/kg pHD	Daily dose pPD	Peripheral neuropathy, liver toxicity (possibly fatal), glossitis, GI disturbance, fever
[b]	[b]	[b]	[b]	[b]	GI disturbance
q24h	q24h	CrCl <30: 25–35 mg/kg/dose 3 times weekly	[b]	[b]	Arthralgia, hyperuricemia, liver toxicity, GI disturbance, rash, gouty arthritis
q24h	q24h	CrCl <30: 150 mg q24h	[b]	[b]	Uveitis, orange discoloration of urine, sweat, tears; liver toxicity, GI disturbance, myalgia, arthralgia
q24h	q24h	300 mg q24h	300–600 mg q24h	300–600 mg q24h	Orange discoloration of urine, sweat, tears; liver toxicity, GI disturbance, flu-like syndrome
[b]	[b]	[b]	[b]	[b]	Similar to rifampin
q24h	q24–72h	q72–96h	50% of dose pHD on HD days	[b]	Cranial nerve VIII damage, paresthesias, rash, fever, nephrotoxicity, neuromuscular blockade, optic neuritis, ototoxicity

modified after obtaining serum levels.
recommended; PD, peritoneal dialysis; pHD, post hemodialysis; pPD, post peritoneal dialysis.; PZA, pyrazinamide; RIF, rifampin.

TABLE 211.3

Name		Usual dose		Change in absorption with food
Generic	**Brand**	**Adult[a,c]**	**Pediatric[a,d]**	
Amphotericin B (conventional)	Fungizone	0.25–1 mg/kg IV q24h	0.25–1 mg/kg IV q24–48h	N.A.
Amphotericin B lipid complex	Abelcet	5 mg/kg IV q24h	5 mg/kg IV q24h	N.A.
Amphotericin B liposomal	AmBisome	3–5 mg/kg IV q24h	3–5 mg/kg IV q24h	N.A.
Amphotericin B cholesteryl sulfate complex		3–4 mg/kg q24h	3–4 mg/kg q24h	N.A.
Anidulafungin	Eraxis	200 mg IV once, then 100 mg IV q24h	N.A.	N.A.
Caspofungin	Cancidas	75 mg IV once, then 50 mg IV q12h	≥3 months to <18 years:70 mg IV once, then 50 mg IV q24h	N.A.
Clotrimazole	Mycelex	10 mg PO 3–5 times daily	≥3 years: 10 mg PO 5 time daily	Unchanged
Fluconazole	Diflucan	150–800 mg IV/PO q24h	6 to 12 mg/kg/dose IV/PO, followed by 3 to 12 mg/kg/dose IV/PO q24h	Unchanged
Flucytosine	Ancobon	25 mg/kg PO q6h	25 mg/kg PO q6h	Decreased
Griseofulvin	Grisactin, Grifulvin, Fulvicin	500 mg–1 g PO q24h	>2 years: 15 mg/kg PO q24h	Increased
Isavuconazonium Sulfate	Cresemba	IV/PO Load: 372 mg q8h for 6 doses; Maintenance: 372 mg q24h; start 12–24 h last loading dose	[b]	Unchanged
Itraconazole[e]	Sporanox	200 mg PO q12–24h; can load 200 mg PO q8h for 3 days	2.5–5 mg/kg/dose (max 200 mg) PO q8h for 3 days, then 5–10 mg/kg/dose (max 400 mg) PO q12–24h	Capsule: Increased; Solution: Decreased
Ketoconazole	Nizoral	200–400 mg PO q24h	≥2 years: 3.3–6.6 mg/kg PO q24h (max 400 mg/d)	Increased
Micafungin	Mycamine	100–150 mg IV q24h	≤40 kg: 2–6 mg/kg IV q24h	N.A.
Miconazole		50 mg PO q24h	[b]	N.A.
Nystatin	Mycostatin	400,000–600,000 units q6h	200,000–600,000 units q6h	Not absorbed
Posaconazole[e]	Noxafil	Delayed release tablet or IV: 300 mg q12h x 2 doses, then 300 mg q24h; Oral suspension: 200 mg q6h	Oral Suspension: 200–300 mg q8h	Increased
Voriconazole[e]	Vfend	Oral: 200 mg PO q12h; IV: 6 mg/kg q12h for 2 doses, then 4 mg/kg q12h	2–<15 years: Oral suspension: 9 mg/kg q12h (max 350 mg/dose); IV: 6–9 mg/kg q12h for 2 doses, then 3–8 mg/kg q12h	Oral: Decreased; IV: N.A.

[a] Dosing weight, actual body weight (kg) unless indicated otherwise.
[b] Insufficient information available to make a recommendation.
[c] Specific dosing is dependent on indication.
[d] Pediatric dosing may be specific to age, weight (kg), and/or indication.
[e] Formulations are not interchangeable.
CrCl, creatinine clearance mL/min; GI, gastrointestinal; HD, hemodialysis; N.A., not applicable; PD, peritoneal dialysis; pHD, post hemodialysis; SLE, systemic lupus erythematosus.

Adult dose interval adjustment for reduced CrCl			Dosing in dialysis		Major toxicity
>50	10–50	≤10	HD	PD

Usual	[b]	[b]	[b]	[b]	Fever, chills, nausea with infusion, renal insufficiency (less than amphotericin B conventional), anemia, hypokalemia, hypomagnesemia, flushing, hypertension
Usual	[b]	[b]	[b]	[b]	Fever, chills, nausea with infusion, renal insufficiency (less than amphotericin B conventional), anemia, hypokalemia, hypomagnesemia, flushing, hypertension
Usual	[b]	[b]	[b]	[b]	Fever, chills, nausea with infusion, renal insufficiency (less than amphotericin B conventional), anemia, hypokalemia, hypomagnesemia, flushing, hypertension
Usual	Usual	Usual	Usual	Usual	Infusion site reaction, hypokalemia, hypomagnesemia, GI disturbance, drug fever
Usual	Usual	Usual	Usual	Usual	Infusion site reaction, hypokalemia, hypomagnesemia, GI disturbance, drug fever
Usual	Usual	Usual	Usual	Usual	Elevated LFTs, nausea, taste disturbance
q24h	50% dose q24h	50% dose q24h	Usual dose 3 times weekly pHD on HD days	50% dose q24h	Headache, GI upset, hepatitis, elevated LFTs
q6h	q12–24h	q48h	q48–72h	[b]	Bone marrow suppression, hypoglycemia, hypokalemia, agranulocytosis, elevated LFTs
Usual	Usual	Usual	[b]	[b]	GI disturbance, allergic and photosensitivity reactions, blood dyscrasias, liver toxicity, exacerbation of SLE and leprosy
Usual	Usual	Usual	Usual	Usual	Peripheral edema, headache, fatigue, insomnia, hypokalemia, GI disturbance, elevated LFTs, dyspnea
Usual	Usual	Usual	Usual	Usual	Nausea, rash, headache, edema, hypokalemia, hepatotoxicity
Usual	Usual	Usual	Usual	Usual	Nausea, vomiting, gynecomastia, decreased testosterone synthesis, rash, hepatotoxicity, adrenal insufficiency
Usual	Usual	Usual	Usual	[b]	Thrombophlebitis, GI disturbance, abnormal LFTs, fever, rash, hyperkalemia, hypoglycemia, headache
Usual	Usual	Usual	Usual	Usual	Headache, GI disturbance
Usual	Usual	Usual	Usual	Usual	GI disturbance
Usual	Usual	Usual	[b]	[b]	GI disturbance, headache, hypokalemia, prolonged QT interval, hepatotoxicity
Usual	Usual; PO preferred due to accumulation of cyclodextrin	Usual; PO preferred due to accumulation of cyclodextrin	[b]	[b]	Photopsia, hepatotoxicity, CNS neurotoxicity (hallucinations), alopecia, and photosensitivity associated with later squamous cell carcinoma and melanoma (with prolonged use)

TABLE 211.4

Name		Usual dose		
Generic	**Brand**	**Adult**	**Child**	**Change in absorption with food**
Abacavir	Ziagen	0.3 g PO q12h	8 mg/kg PO q12h	Unchanged
Abacavir/ lamivudine	Epzicom	1 daily	[b]	Unchanged
Acyclovir	Zovirax	0.2–0.8 g PO 2–5×/d 5–12 mg/kg IV q8h	0.2 g 5×/d (HSV) PO 20 mg/kg PO q6h, max 800 mg q6h (VZV) 25–50 mg/kg/d IV q8h	Unchanged
Amantadine	Symmetrel	0.1 g PO q12h	2.2–4.4 mg/kg PO q12h	No data
Amprenavir		1.2 g PO q12h	[b]	Decreased with high-fat meal
Atazanavir	Reyataz	300–400 mg PO qd	[b]	Increased
Boceprevir	Victrelis	800 mg PO TID	[b]	Increased
Cidofovir	Vistide	5 mg/kg IV qwk ×2 wk, then 5 mg/kg q2wk	[b]	n/a
Darunavir	Prezista	600 mg PO BID with 100 mg PO ritonavir	[b]	Increased
Didanosine	Videx	0.167–0.2 g PO q12h	0.143–0.248 mg/m2 divided PO q12h	Decreased
Efavirenz	Sustiva	0.6 g PO qhs	[b]	Unchanged
Emtricitabine	Emtriva	200 mg PO qd	6 mg/kg PO sol qd (3 mo–17 yr)	Unchanged
Enfuvirtide	Fuzeon	90 mg SC BID	2 mg/kg SC BID	n/a
Entecavir	Baraclude	0.5–1 mg PO qd	>16 yr, 0.5–1 mg PO qd	Decreased
Etravirine	Intelence	200 mg PO BID	>6 yr, based on weight	Increased
Famciclovir	Famvir	0.125 g PO q12h (HSV) 0.5 g PO q8h (VZV)	[b]	Unchanged
Fosamprenavir	Lexiva	700–1,400 mg PO BID	[b]	Unchanged
Foscarnet	Foscavir	60 mg/kg IV q8h ×14–21 d; then 90 mg/kg/d	[b]	n/a
Ganciclovir	Cytovene	5 mg/kg IV q12h ×14–21 d; then 5 mg/kg/d	5 mg/kg IV q12h	IV: n/a
Indinavir	Crixivan	800 mg PO q8h	[b]	Decreased
Lamivudine	Epivir	150 mg PO q12h	4 mg/kg PO q12h	Unchanged

	Dose interval adjustment for reduced CrCl			Supplemental dose in dialysis

C	q4h	q6h	q6–12h	100 mg pHD	100 mg q6–12h	Anemia, granulocytopenia, headache, nausea, insomnia, nail pigment changes

human studies no risk; C = animal studies show toxicity, human studies inadequate but benefit may exceed risk; D = evidence of human risk, benefit may outweigh risk; X = fetal

CPK, creatine phosphokinase; CrCl, creatinine clearance mL/min; GI, gastrointestinal; HD, hemodialysis; HSV, herpes simplex virus; LFT, liver function test; N.A., not

TABLE 211.5

Name		Usual dose		Change in absorption with food
Generic	**Brand**	**Adult**[a,c]	**Pediatric**[a,d]	
Albendazole	Albenza	400 mg PO q12–24h	>2 years: 400 mg PO q12–24h	Increased
Artemether–lumefantrine	Coartem	400 mg PO, repeat in 8 h then twice daily for 48 h	Weight-based, see full prescribing information	Increased
Artemisinine		10 mg/kg/d ×5 d	Same as adult	[b]
Atovaquone	Mepron	750 mg PO q12h	1–3 months: 30 mg/kg PO q24h; 4–24 months: 45 mg/kg PO q24h; >24 months: 30 mg/kg PO q24h; (max: 1,500 mg/d)	Increased
Benznidazole[e]		5–7 mg/kg/d PO divided q12h (max 300 mg/d)	5–8 mg/kg PO q12h	Unchanged
Bithionol[f]	Bitin	30–50 mg/kg on alternate days ×10–15 d	Same as adult	[b]
Chloroquine phosphate	Aralen phosphate	1 g (600 mg base) PO on day 1, followed by 500 mg (300 mg base) 6h, 24h, and 48h following first dose	16.6 mg/kg chloroquine phosphate (max dose: 1 g) PO; followed by 8.3 mg/kg chloroquine phosphate (max: 500 mg/dose) PO at 6h, 24h, and 48h following first dose	Unchanged
Dehydroemetine[f]		1 mg/kg/d (max 60 mg/d) IM for 4–6 days	1 mg/kg/d IM for max of 5 days	n.a
Diethyl carbamazine[f]	Hetrazan	Day 1: 50 mg PO Day 2: 50 mg PO q8h Day 3: 100 mg PO q8h Days 4–14: 6 mg/kg/d divided q8h	Day 1: 1 mg/kg PO Day 2: 1 mg/kg PO q8h Day 3: 1–2 mg/kg PO q8h Days 4–21: 2 mg/kg PO q8h	Increased
Diloxanide furoate[e]	Furamide	500 mg PO q8h for 10 days	[b]	[b]
Eflornithine[e]	Ornidyl	400 mg/kg/d IV divided QID × 14 d, then 300 mg/kg/d PO ×3–4 wk	[b]	[b]
Furazolidone	Furoxone	100 mg PO q6h for 7–10 days	1.25–1.5 mg/kg PO q6h for 5–10 days	[b]
Halofantrine	Halfan	500 mg PO q6h for 3 doses, repeat in 1 wk	<37 kg: 8 mg/kg q6h for 3 doses; repeat in 1 week; ≥37 kg: use adult dosing	Increased
Hydroxychloroquine sulfate salt	Plaquenil	800 mg once, followed by 400 mg at 6h, 24h, and 48h following first dose (total dose: 2 g)	12.9 mg/kg hydroxychloroquine (max dose: 800 mg); followed by 6.5 mg/kg at 6h, 24h, and 48h following first dose; (max: 400 mg/dose)	Increased

Dose interval adjustment for reduced CrCl			Dosing in dialysis		
>50	10–50	≤10	HD	PD	Major toxicity
Usual	Usual	Usual	Usual	[b]	Diarrhea, abdominal discomfort, elevated AST, ALT and bone marrow suppression, alopecia with high dose
Usual	Usual	[b]	[b]	[b]	Headache, anorexia, fever, QT prolongation
Usual	[b]	[b]	[b]	[b]	Transient heart block, elevated AST and ALT, neutropenia, decreased reticulocyte count, abdominal pain, diarrhea, fever
Usual	Usual	Usual	Usual	Usual	Rash, GI disturbance, fever, headache, insomnia, myalgia, flu-like symptoms
[b]	[b]	[b]	[b]	[b]	Peripheral neuropathy, rash, bone marrow suppression, weight loss, GI disturbance
[b]	[b]	[b]	[b]	[b]	Hypotension, wheezing, angioedema, rash, hyperthermia, diarrhea, anorexia, nausea, vomiting, dizziness, headache
Usual	Usual	No Adjustment with Short-term Use	No Adjustment with Short-term Use	No Adjustment with Short-term Use	Blurred vision (retinopathy with prolonged use), GI effects, pruritus, hemolysis in patients with G6PD deficiency, hypoglycemia,
[b]	[b]	[b]	[b]	[b]	Arrhythmias, precordial pain, pain at injection site, muscle weakness, GI disturbance, neuropathy, heart failure, headache
Usual	[b]	[b]	[b]	[b]	Headache, malaise, arthralgia, nausea, vomiting, anorexia, pruritus, fever, hypotension, lymphadenitis, encephalopathy
[b]	[b]	[b]	[b]	[b]	Flatulence
Usual	[b]	[b]	[b]	[b]	Anemia, thrombocytopenia, leukopenia, nausea, vomiting, diarrhea, transient hearing loss
[b]	[b]	[b]	[b]	[b]	GI disturbance, yellow-brown discoloration of urine, rash, fever, headache, hemolysis in patients with G6PD deficiency
Usual	[b]	[b]	[b]	[b]	Abdominal pain, vomiting, diarrhea, headache, pruritus, rash
Usual	[b]	[b]	[b]	[b]	Blurred vision, GI disturbance, pruritus, rash, headache, QTc prolongation, abnormal LFTs, cardiomyopathy (rare), hypoglycemia, bone marrow suppression, neuromuscular effects (long-term use)

(*continued*)

TABLE 211.5 CONTINUED

Name		Usual dose		Change in absorption with food
Generic	Brand	Adult[a,c]	Pediatric[a,d]	
Iodoquinol	Yodoxin, Diquinol	650 mg PO q8h	40 mg/kg/d PO divided q8h	Unchanged
Ivermectin	Stromectol	150–200 mcg/kg/dose PO	≥15 kg: 150–200 mcg/kg/dose PO	Decreased
Mebendazole	Vermox	100–200 mg PO q12h	Same as adults	Unchanged
Mefloquine	Lariam	750 mg PO once, followed by 500 mg PO 6–12 hrs after first dose	15 mg/kg PO once (maximum: 750 mg/dose) followed by 10 mg/kg PO 6–12 hrs after first dose	Increased
Meglumine antimonate[e]	Glucantine	20 mg/kg IV ×2 d (850 mg/d limit)	[b]	n.a
Melarsoprol B[f]	Mel B, Arsobal	2.2 mg/kg/d IV for 10 days	2.2 mg/kg/d IV for 10 days	n.a
Niclosamide	Niclocide	2 g PO q24h	50 mg/kg PO q24h	N.A.
Nifurtimox[f]	Lampit	8–15 mg/kg/d PO divided q6–8h	1–10 years: 15–20 mg/kg/d PO; 11–16 years: 12.5–15 mg/kg/d PO; ≥17 years: 8–10 mg/kg/d PO divided q6–8h	[b]
Niridazole[e]	Ambilhar	[b]	[b]	[b]
Oxamniquine[e]	Vansil	15 mg/kg PO q12–24h once	10–15 mg/kg/dose PO q12h	Increased
Paromomycin	Humatin	25–35 mg/kg/d PO divided q8h	25 to 35 mg/kg/d PO divided q6–12h	Unchanged
Pentamidine	Pentam, Nebupent	3–4 mg/kg IV q24h	3–4 mg/kg IV q24h	n/a
Piperazine citrate[e]	Antepar	2–3.5 g/d PO for 2–7 days	75 mg/kg/d (max: 3.5 g) PO for 2 days	[b]
Praziquantel	Biltricide	40–75 mg/kg/d PO divided q8–12h	25 mg/kg PO q8h	Increased
Primaquine phosphate		30 mg (base) PO q24h	0.5 mg/kg (base) PO q24h	Unchanged
Proguanil HCl/atovaquone	Malarone	400/1,000 mg PO q24h (treatment)	31.25/12.5 mg–1,000/400 mg PO q24h (depending on weight) (treatment)	Increased
Pyrantel pamoate	Antiminth, Pin-X	11 mg base/kg (max 1 g/d) PO once	≥2 years: 11 mg/kg/d PO once	Unchanged

Dose interval adjustment for reduced CrCl			Dosing in dialysis		
>50	10–50	≤10	HD	PD	Major toxicity
Usual	[b]	[b]	[b]	[b]	Optic neuritis, peripheral neuropathy, GI disturbance, skin eruptions, vertigo, fever, chills
Usual	[b]	[b]	[b]	[b]	Mazzotti reaction, fever, lymphadenitis, arthralgia
Usual	[b]	[b]	[b]	[b]	Diarrhea, nausea, vomiting, abdominal pain, fever, headache, neutropenia, thrombocytopenia, hepatitis
Usual	Usual	Usual	Usual	[b]	Vertigo, nightmares, insomnia, GI disturbance, sinus bradycardia, visual disturbance
Usual	[b]	[b]	[b]	[b]	Bradycardia, hypotension, rashes, facial edema, injection site pain, pancreatitis, leukopenia, nephrotoxicity
Usual	[b]	[b]	[b]	[b]	Encephalopathy, phlebitis, peripheral neuropathy, Jarisch-Herxheimer-like reaction, hepatic dysfunction, hypertension, arthralgia, GI disturbance, fever, hemolysis in patients with G6PD deficiency
Usual	Usual	Usual	Usual	Usual	Nausea, abdominal discomfort, diarrhea, drowsiness, dizziness, headache
Usual	[b]	[b]	[b]	[b]	GI disturbance, weight loss, restlessness, insomnia, paresthesias, seizures, rash, neutropenia, hepatitis, hemolysis in patients with G6PD deficiency
Usual	[b]	[b]	[b]	[b]	Seizures, hallucinations
Usual	[b]	[b]	[b]	[b]	Dizziness, drowsiness, headache, nausea, vomiting, abdominal pain, orange-red discoloration of urine, fever, hepatitis, EEG changes, hallucinations
Usual	Usual	Usual, Monitor for ototoxicity	Usual, Monitor for ototoxicity	Usual, Monitor for ototoxicity	GI disturbance, rash, headaches, vertigo, nephrotoxicity, ototoxicity
Usual	Usual	4 mg/kg q48h	[b]	[b]	Nephrotoxicity, hypotension, sterile abscess with IM injection, hypoglycemia or hyperglycemia, nausea, vomiting, abdominal pain, pancreatitis, hypocalcemia, cough and bronchospasm with inhalation, QTc prolongation, bone marrow suppression, increased LFTs
Usual	N.R.	N.R.	[b]	[b]	GI disturbance, headache, dizziness, rash, hemolytic anemia, ataxia
Usual	Usual	Usual	Usual	[b]	Malaise, bitter taste, headache, dizziness, sedation, GI disturbance, fever, sweating, fatigue, pruritus, rash
Usual	Usual	Usual	[b]	[b]	Hemolytic anemia in patients with G6PD deficiency (must screen prior to start), methemoglobinemia, leukopenia, neutropenia, GI disturbance, blurred vision, pruritus
Usual	CrCl ≤30 mL/min N.R.	N.R.	N.R.	N.R.	Pruritus, GI Disturbance, increased LFTs, hepatitis, asthenia, headache, neutropenia, pancytopenia
Usual	[b]	[b]	[b]	[b]	GI disturbance, dizziness, drowsiness, headache

(*continued*)

TABLE 211.5 CONTINUED

Name		Usual dose		Change in absorption with food
Generic	Brand	Adult[a,c]	Pediatric[a,d]	
Pyrimethamine	Daraprim	25–75 mg PO q24h	1–2 mg/kg PO q24h (max 50 mg/d)	[b]
Pyrimethamine/sulfadoxine	Fansidar	2–3 tablets PO once	>2years: 5–10 kg: ½ tab PO once 11–20 kg: 1 tab PO once 21–30 kg:1½ tabs PO once 31–45 kg: 2 tabs PO once >45 kg: 3 tablets PO once	[b]
Quinacrine Hcl[e]	Atabrine	100 mg PO q8h	2 mg/kg (max dose: 100 mg) PO q8h for 5 days	[b]
Quinidine gluconate	Quinaglute	6.25 mg base/kg IV over 1–2 hrs, then 0.0125 mg base/kg/min	Same as adult	Increased
Quinine sulfate	Legatrin Quinamm	650 mg PO q6–8h	10 mg/kg PO q8h	Increased
Spiramycin[e]	Rovamycine	1 g (3 million units) PO q8h	[b]	Unchanged
Stibogluconate	Pentostam	20 mg/kg IV q24h	20 mg/kg IV q24h	n.a
Suramin[f]	Germanin	1 g IV qwk ×5 wk (100-mg test dose)	[b]	n/a
Thiabendazole	Mintezol	50 mg/kg/d PO divided q12–24h	25 mg/kg (max 1.5 g) PO q12h	[b]
Trimetrexate	Neutrexin	45 mg/m2/d with leucovorin 20 mg/m2 q6h; continue leucovorin at least 72 h after last dose	[b]	n/a

[a] Dosing weight, actual body weight (kg) unless indicated otherwise.
[b] Insufficient information available to make a recommendation.
[c] Specific dosing is dependent on indication.
[d] Pediatric dosing may be specific to age, weight (kg), and/or indication.
[e] Not available in the United States.
[f] Available from the Centers for Disease Control and Prevention drug service.
ALT, alanine aminotransferase; AST, aspartate aminotransferase; CrCl, creatinine clearance mL/min; G6PD, glucose-6-phosphate dehydrogenase; GI, gastrointestinal; HD, he-

Dose interval adjustment for reduced CrCl			Dosing in dialysis		
>50	10–50	≤10	HD	PD	Major toxicity
Usual	Usual	Usual	Usual	[b]	Reversible bone marrow suppression with high doses, megaloblastic anemia, folate deficiency, erythema multiforme, Stevens-Johnson Syndrome, toxic epidermal necrolysis, GI disturbance, headache, dizziness
Usual	[b]	[b]	[b]	[b]	Folic acid deficiency (leading to megaloblastic anemia and pancytopenia, hemolytic anemia, leukopenia, thrombocytopenia), elevated LFTs, GI disturbance, headache, dizziness, insomnia, Stevens-Johnson Syndrome, toxic epidermal necrolysis, interstitial nephritis, crystalluria, hypersensitivity pneumonitis, jaundice, hepatitis, polyneuritis, atrophic glossitis
Usual	[b]	[b]	[b]	[b]	Bitter taste, dizziness, headache, GI disturbance, yellow discoloration of skin/urine (dose dependent), acute psychosis, restlessness, insomnia, rash
Usual	Usual	Usual loading dose, reduce maintenance by 50–75% on 3rd day	[b]	[b]	Cardiac toxicity (close monitoring required), tachycardia, QTc prolongation, flattening t-wave, ventricular arrhythmias, hypoglycemia, hypotension, hemolytic anemia (G6PD deficiency), tinnitus, thrombocytopenia, elevated LFTs, rash, torsades de pointes
Usual	Usual	650 mg q24h	[b]	[b]	Cardiac toxicity, flushing, pruritus, rash, fever, tinnitus, headache, nausea, thrombocytopenia, hemolysis in patients with G6PD deficiency, hypoglycemia, hepatitis
Usual	[b]	[b]	[b]	[b]	QT interval prolongation, vasculitis, rash, diarrhea, increased LFTs, leukopenia, thrombocytopenia, cholestatic hepatitis, dizziness, dry mouth
Usual	[b]	[b]	[b]	[b]	Abdominal pain, nausea, vomiting, malaise, headache, elevated AST and ALT, nephrotoxicity, myalgia, arthralgia, fever, rash, cough, prolonged QTc
Usual	[b]	[b]	[b]	[b]	Nausea, vomiting, shock, loss of consciousness, death during administration; fever, rash, exfoliative dermatitis, paresthesia, photophobia, renal insufficiency, diarrhea
Usual	[b]	[b]	[b]	[b]	GI disturbance, asthenia, disorientation, vertigo, drowsiness, rash, headache, leukopenia, olfactory disturbance, hepatotoxicity, Stevens-Johnson syndrome, toxic epidermal necrolysis
Usual	[b]	[b]	[b]	[b]	Neutropenia (must be given with leucovorin); rash; elevated AST and ALT; reversible peripheral neuropathy

modialysis; LFT, liver function tests; N.A., not approved; N.R., not recommended; PD, peritoneal dialysis.

New Drugs

Artesunate Anti-malarial
