Excision of suspicious small and medium CMN can be delayed until late childhood, because the risk for CMM increases in puberty. On the contrary, giant CMN should be removed as soon as possible due to the high risk for early aggressive CMM. However, as mentioned above, excision should be performed after the perinatal period when the risks from general anesthesia are diminished.

Surgical excision is the only acceptable method. Full-thickness skin graft, swing flaps, tissue expanders, or patient's skin grown in tissue culture may be required. Small- and medium-sized nevi (up to 5 cm in diameter) can be removed by an one-stage procedure with suturing of the wound, local plasty, or free-tissue skin graft. Blepharal and central facial lesions are best reconstructed with full-tissue skin grafting. Nevi

with a diameter >5 cm mandate a staged excision or removal at one stage with prior use of a tissue expander or pre-suturing. Giant nevi require staged treatment with the use of an intermediate-thickness skin graft.

Alternative and Experimental Therapies

Partial removal of superficial nevus cells by dermabrasion, laser therapy (Q-switched ruby, Q-switched alexandrite), curettage, or shave excision is less traumatic than excision surgery and produces an acceptable cosmetic result. Chemical peels, e.g., phenol, are an acceptable alternative method of therapy for those lesions that are too large for excision and primary closure or for lesions in which excision would result in unacceptable scars in areas such as the face. However, none of these techniques completely removes the risk for malignant transformation.

Halo Nevus

Definition and Epidemiology

Halo nevus (HN) is a melanocytic nevus surrounded by a depigmented zone or halo. The melanocytic nevus, which often undergoes spontaneous involution, may be a common acquired (dermal or compound), congenital, atypical, Spitz, or a blue nevus. According to a recent concept, HN should not be regarded as a distinct entity but as a halo phenomenon occurring in a wide variety of nevus types. HN have been erroneously confused with melanoma and have been the source of much anxiety among both clinicians and patients.

HN is seen in all races. No sexual predilection is reported. It most commonly affects adolescents and young adults (average age of onset is 15 years) with an estimated incidence of 1 % in individuals under 20 years of age. Family history is not unusual. Of the patients, 18–26 % have vitiligo. Furthermore, it may be a heralding manifestation of vitiligo.

HN are entirely benign lesions and of only cosmetic significance.

Basic Concepts of Pathogenesis

HN results from an immune response (both cellular and humoral) directed against either antigenically altered nevus cells undergoing dysplastic changes or nonspecifically altered nevus cells in response to various influences. The inflammatory infiltrate consists predominantly of T-lymphocytes with a cytotoxic (CD8) to helper (CD4) lymphocytes ratio of approximately 4:1 and scattered macrophages. The precipitating cause as well as the exact role of the lymphocytes remain unknown. Cytokines may act as mediators for the development of the white halo. Epidermal melanocytes in the halo component are completely absent, suggesting a similar pathogenetic mechanism with vitiligo. Immune mechanisms have been implicated also for the involution of the central nevus. A theory of direct cytotoxic effect of lymphocytes on melanocytes seems plausible. In advanced lesions, dermal macrophages containing portions of nevus cells were observed. Circulating antibodies to the cytoplasm of melanoma cells have been detected in patients with HN that disappeared after removal of the nevus. These antibodies are believed to result from the release of cytoplasmic proteins from damaged melanocytes.

Clinical Presetnation

HN is composed of a central macule or papule with uniform dark brown to pink color and regular well-defined border, encircled by a symmetrical, round or oval, sharply demarcated, white or hypopigmented rim. It is usually asymptomatic or slightly pruritic. HN are most often located on the trunk, especially on the back, but they can develop anywhere on the body. In 25–50 % of patients, multiple lesions are present.

The halo usually develops around preexisting melanocytic nevus within months. The course is variable. Only rarely HN remains unchanged. More often, the central nevus spontaneously regresses completely, followed by repigmentation of the white halo. This process lasts from months to years. In some cases, a depigmented

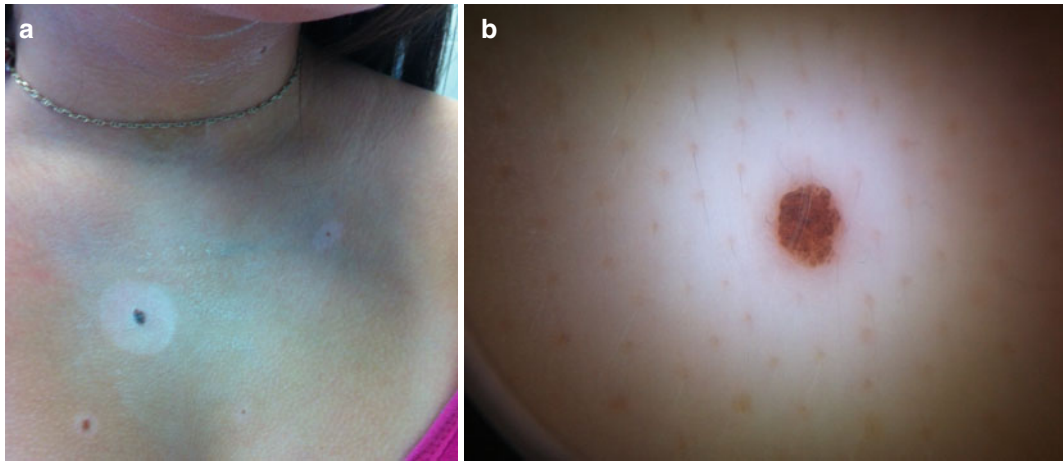

Fig. 65.4 Halo nevus. (**a**) Multiple common nevi on the trunk with a peripheral halo of depigmentation. (**b**) A small congenital nevus exhibiting a globular pattern surrounded by a *white* halo

macule remains, or in others, the halo repigments while the central nevus remains unchanged.

A depigmented halo may develop around a primary CMM. In older adults, the sudden appearance of multiple HN has been associated with the development of a primary CMM at another site (Fig. 65.4).

Diagnosis

Diagnosis of HN is easy on the basis of the distinctive clinical presentation. However, lesions that are not uniform in shape and color or are inconsistent with the patient's epidemiological profile or have a papular component are very important to be evaluated clinically and dermoscopically for malignancy, because a halo phenomenon can develop around a primary CMM. Family history and total skin examination for other HN, dysplastic nevi, vitiligo, or CMM are crucial. To exclude malignancy definitely, histological assessment may be necessary.

Dermoscopically, HN show a globular, homogenous, or, later, an unspecific global pattern. There are no specific local features. The characteristic confounding feature is the depigmentation of the peripheral skin.

The histology of HN varies depending on the age of the lesion. In most cases, a dense, somewhat band-like lymphocytic infiltrate is present in the papillary and often reticular dermis with nests of nevocytes located centrally. Macrophages may be seen within the infiltrate, although, surprisingly, there are less than would be expected in an inflamed melanocytic lesion. In more mature lesions, nevocytes may appear to be absent or decreased in number. The presence of halo clinically does not correlate with the degree of inflammation histologically. The most important lesion to differentiate from HN is melanoma.

Differential Diagnosis

Common acquired MN with halo must be differentiated from other pigmented nevi with halo:

- Spitz nevus.
- Blue nevus.
- Congenital melanocytic nevus.
- Dysplastic nevus.
- Malignant melanoma with surrounding leukoderma: primary CMM is usually solitary and most commonly affects adults; usually present for an extended period of time; the white zones represent areas of regression; the "halo" of a regressing melanoma is irregular in shape and variable in radial width; the central "nevus" is usually large with striking irregularity of color and structure.

Hypopigmented non-melanocytic lesions to be considered include:

- Dermatofibroma
- Seborrhoeic keratosis
- Basal cell carcinoma
- Flat warts
- Molluscum contagiosum
- Lichen planus
- Lichen sclerosus et atrophicus
- Psoriasis
- Sarcoidosis
- Vitiligo

General Principles of Treatment

HN with clinically and dermoscopically benign appearance does not require excision. The patient should be reassured and followed up periodically. The presence of a new "halo nevus" in an older adult (>40 years) or with a family history of CMM or dysplastic nevi (dysplastic nevus syndromes or multiple dysplastic nevi) should be regarded with a high index of suspicion for melanoma and may warrant performing a biopsy.

Nevus Spilus

Definition and Epidemiology

Nevus spilus (NS) is a slightly hyperpigmented macular lesion dotted with darker flat or raised spots.

It is usually acquired in childhood. An incidence of 2–3 % among Caucasians has been reported.

Basic Concepts of Pathogenesis

These are similar to that of CAMN. Ultraviolet radiation has no pathogenetic role. Segmental or zosteriform distribution suggests localized malformation.

Clinical Presentation

Oval or irregularly shaped, light brown, hairless macule (1–20 cm in diameter) containing scattered dark brown to black macules or papules (2–3 mm in diameter). Larger lesions may exhibit a lateral, segmental, or zosteriform distribution. NS persists indefinitely. CMM very rarely may arise in NS.

Diagnosis

The diagnosis is clinical. The macular pigmented lesion shows dermoscopical and histological features of lentigo simplex, while the spots are usually junctional or compound nevi or, rarely, dysplastic or Spitz nevi.

Differential Diagnosis

- Congenital melanocytic nevus
- Becker's nevus

Treatment

Risk of CMM development warrants periodic follow-up (with baseline photography), especially for congenital or large lesions. Changing clinical picture or atypical features must be assessed histologically. Complete surgical excision and closure with sutures is required.

Spitz Nevus

Definition and Epidemiology

Spitz nevus (SN) is a benign nodular melanocytic nevus with distinctive histopathological features that may be confused with CMM. Several attempts were made to establish objective criteria that would clearly delineate SN and melanomas. Even today, no set of criteria can be used to predict the clinical outcome of atypical Spitz tumors with absolute assurance. Perhaps SN and CMM exist along one continuum of disease.

SN are seen more frequently in fair-skinned individuals, but are not restricted to white patients. Estimated incidence rate of SN in

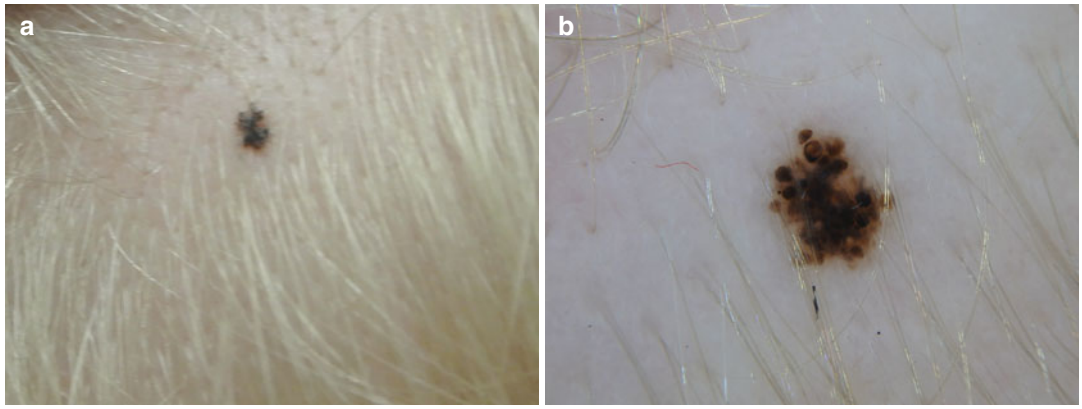

Fig. 65.5 Spitz nevus. (**a**) Small *brown* to *black* lesion on the scalp of a 3-year-old boy. (**b**) A pigmented Spitz nevus showing homogeneous *brown-black* pigmentation in the center of the lesion and multiple globules in the periphery

Australia is 1.4 cases per 100,000. It represents 1 % of all surgically excised melanocytic nevi in childhood. It is usually acquired. One-third of the patients are under 10 years of age, 36 % are between 10 and 20 years, and only 31 % are over 20 years. No familial distribution has been recognized. Both sexes are equally affected, or there is a slight female predominance.

These lesions are clinically benign. Atypical SN pose a minimal threat of mortality but have an increased risk of melanoma and a moderate risk of metastasis to regional nodes.

Basic Concepts of Pathogenesis

SN derives from cells originating from the neural crest. No pathogenetic associations have been documented. A SN can arise de novo or in association with an existing melanocytic nevus.

Clinical Presentation

SN presents as an asymptomatic, well-circumscribed, hairless, dome-shaped or flat, papule or nodule, 2 mm to 2 cm in diameter, varying in color from pink or orange red to tan or dark brown. The color is uniformly distributed. The surface is smooth or verrucous. It is most commonly located on the head and neck or the legs. There are rare cases with multiple or clustered SN.

Usually there is a history of sudden onset and rapid growth. After that it becomes static. The biological behavior of SN remains obscure. SN may evolve into conventional compound melanocytic nevus. Some undergo fibrosis, eventually resembling dermatofibromas. Very rarely SN may involute spontaneously. CMM may arise within SN, but this event is uncommon.

Malignant SN is an aggressive variant of SN that results in regional lymph node metastases (Figs. 65.5 and 65.6a).

Diagnosis

Clinical picture, young age, recent onset, and rapid growth suggest diagnosis.

Dermoscopy has significantly increased the diagnostic accuracy for SN, especially regarding the pigmented variant (Reed nevus). Nonpigmented SN displays an unspecific or homogenous global pattern, sometimes with some dotted vessels. Reed nevus typically (50 %) shows a starburst pattern (pigmented streaks symmetrically distributed at the periphery of the lesion) with central reticular blue-white structures (reticular depigmentation) or, less frequently, a regular and prominent pigment network. In 25 % of the cases, a regular globular pattern with brown to gray-blue pigmentation in the center, and often a characteristic peripheral rim of large brown globules is present. Brown to

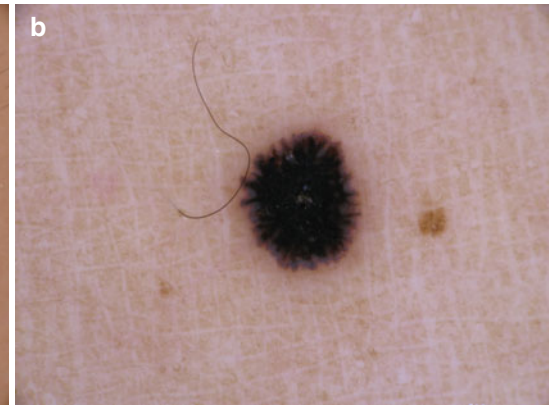

Fig. 65.6 (**a**) Spitz nevus (Courtesy of Professor Iris Zalaudek and Professor Giuseppe Argenziano). A *pink* nodule with regularly distributed dotted vessels and a reticular depigmentation. (**b**) Reed nevus (Courtesy of Professor Iris Zalaudek and Professor Giuseppe Argenziano). Jet-black structureless pigmentation in the center and radial streaks in the periphery ("starburst pattern")

gray-blue globules and dots may be detected. Another 25 % of cases may exhibit an atypical dermoscopic appearance characterized by an uneven distribution of colors and structures (irregular, diffuse, gray-blue pigmentation, pigment network, brown globules, black dots, hypopigmentation, irregular peripheral streaks). Remarkably, melanomas may rarely display either the starburst or the globular pattern seen in Reed nevi (Fig. 65.6b).

Histological confirmation is always necessary. The sine qua non histological feature is the presence of nests of admixed large spindle-shaped melanocytes and epithelioid cells extending from a hyperplastic and acanthotic epidermis into the reticular dermis in an inverted-wedge configuration. Striking symmetry, sharp lateral demarcation, absent (or rare) mitoses, absence of atypical mitoses, presence of eosinophilic and periodic acid-Schiff (PAS)-positive globules (Kamino bodies), and non-disruptive (single-file-like) infiltration of collagen are important features indicating the diagnosis of SN. Single-file melanocytes may also be observed in the reticular dermis located at the base of the lesion (dispersion). Atypical SN is characterized by prominent cellularity and increased mitotic activity. The greater the atypia, the more difficult the differentiation from CMM. Histopathologic differentiation from melanomas is equivocal in up to 8 % of case.

Immunohistochemistry and comparative genomic hybridization have proved helpful. SN stain diffusely with S100A6, demonstrate no deep Ki-67 positive cells, and show a gradient with HMB-45 staining. Melanomas show the opposite patterns.

Differential Diagnosis

Nonpigmented SN must be differentiated from:

- Pyogenic granuloma
- Hemangioma
- Verruca
- Molluscum contagiosum
- Dermatofibroma
- Mastocytoma
- Juvenile xanthogranuloma
- Dermal melanocytic nevus

Pigmented SN may be confused with:

- Dysplastic nevus
- Cutaneous malignant melanoma

In order to differentiate SN from CMM, excisional biopsy is warranted. Criteria that in concert strengthen the probability of SN diagnosis include a young patient, a well-demarcated and symmetrical lesion, maturation and dispersion of melanocytes at its base, and the presence of epithelial hyperplasia, but no criterion is absolutely reliable. Misdiagnosis of SN as melanomas and

vice versa is a possibility. In one study, 6.5 % of cases diagnosed clinically as melanomas were SN.

Treatment

Typical SN in children can be followed up. Atypical SN or lesions revealing the characteristic clinical and dermoscopic features of SN, when arising in adult patients and showing a history of recent change, should be excised.

Complete surgical excision (with margins of 0.5–1 cm for atypical variants) of the lesion and histopathologic evaluation is recommended, followed by re-excision of positive margins, if present. Incomplete excision often results in recurrence that should be also treated with re-excision. Periodic follow-up at 6–12-month intervals is advisable.

In a series of 12 cases with atypical SN, one-third of the patients showed nodal micrometastases suggesting a yet not understood metastatic potential. However, sentinel lymph node biopsy is not justified for surgical staging.

Blue Nevus

Definition and Epidemiology

Blue nevus (BN) is a benign, gray to dark blue, papular or nodular skin lesion, representing a localized proliferation of melanin-producing dermal melanocytes and characterized by spindled cytomorphology.

Although considered congenital, BN are uncommon at birth or in the first few years of life, usually appearing in childhood and adolescence. They are twice as common in women than in men. BN are most frequently seen in Asians populations with an estimated prevalence 3–5 % in adults. They are found in 1–2 % of white adults, and they are very rare in blacks. Most cases remain entirely benign. Rare cases of CMM have been reported arising in association with cellular blue nevi.

Basic Concepts of Pathogenesis

BN results from ectopic accumulation (in the dermis) of melanin-producing melanocytes, which have migrated from the neural crest during fetal life, but have failed to reach the epidermis. The optical phenomenon that accounts for clinical blueness is known as the Tyndall effect, i.e., the preferential absorption of longer wavelengths by the deep-seated brown pigment and the scattering by collagen bundles of shorter wavelengths (blue light), giving a bluish hue to such lesions.

On the basis of the variation of BN in different populations, a genetic predisposition has been suggested. However, familial cases are exceedingly rare. BN are not associated with chromosomal aberrations, and they show fewer *B-RAF* mutations compared with congenital and acquired nevi.

Clinical Presentation

The color varies from gray-blue to brown to bluish black depending on the degree of pigmentation. An amelanotic variant also exists. BN are usually relatively small and reasonably symmetric. Some may be large and nodular with high cellularity under the microscope. BN typically occur on the distal extremities or scalp, but they can occur at any body site. BN are often firm because of associated stromal sclerosis.

Three types of BN have been identified:

Common BN: small (0.5–1.0 cm), sharply circumscribed macule or dome-shaped papule or nodule, most commonly located on the dorsa of the hands or feet. Although usually solitary, it may be multiple or clustered. Malignant transformation does not occur in common BN.

Cellular BN: blue gray to black nodule, 1–3 cm or larger, with smooth or irregular surface. Sites of predilection include the buttocks, sacrococcygeal region, scalp, face, and feet. Malignant transformation can occur rarely.

Combined BN: nodular blue-brown to blue-black lesions with smooth surfaces. The face is the most common site. It represents an association of BN with overlying melanocytic nevus.

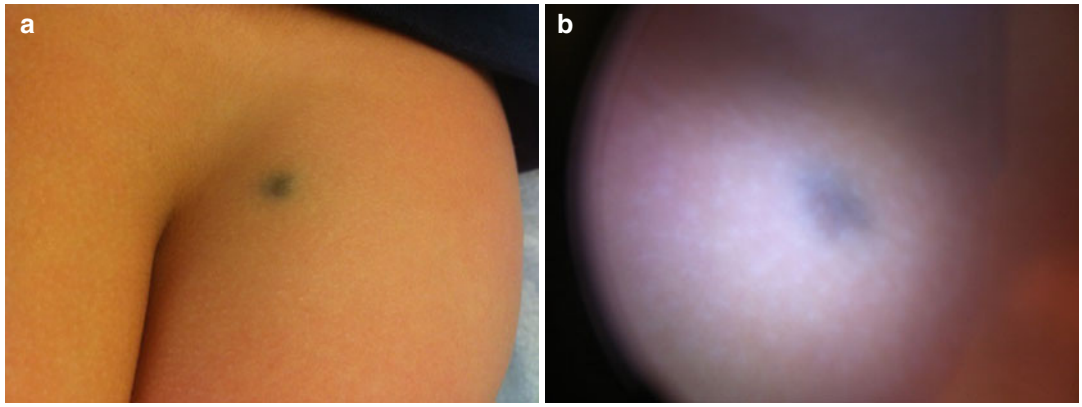

Fig. 65.7 Blue nevus. (**a**) A *bluish* nodule on the sacrococcygeal area of a 5-year-old boy. (**b**) Homogeneous and structureless deep *blue* pigmentation

There are occasional reports of BN in the vagina, cervix, prostate, spermatic cord, oral cavity, bronchus, and lymph nodes.

BN usually remains unchanged. Less often, it regresses, by flattening and fading in color, but still remaining symmetric. Malignant change in cellular blue nevi may be heralded by a sudden increase in size and, occasionally, ulceration (Fig. 65.7).

Diagnosis

Clinical findings along with dermoscopy suggest the diagnosis. Dermoscopically, BN is characterized by homogenous global pattern with complete absence of local features, sharp demarcation, and bluish color. Not uncommonly, diffuse hypopigmentation (increased collagen in the reticular dermis) can be observed in the fibrosing type of BN.

Histopathological examination confirms diagnosis. In common BN, a vaguely nodular collection of poorly melanized spindled melanocytes and deeply pigmented dendritic melanocytes within thickened collagen bundles is observed, as well as scattered melanophages. In cellular BN, medium-sized, spindled to oval melanocytes, tightly arranged in fascicles and nests, form a well-demarcated nodule with scattered melanophages in the reticular dermis, occasionally extending into the subcutaneous fat. Rare mitoses may be present, but significant cytologic atypia and areas of necrosis are absent.

Differential Diagnosis

The following skin conditions should be considered:

- Dermatofibroma
- Vascular lesions (sclerosing hemangioma, angiokeratoma, venous lake)
- Glomus tumor
- Apocrine hydrocystoma
- Pigmented basal cell carcinoma
- Pigmented spindle cell nevus
- Dysplastic nevus
- Primary or metastatic malignant melanoma
- Nevus of Ito, nevus of Ota
- Tattoo reactions

Treatment

Any BN smaller than 1 cm without atypical clinical features does not require excision. On the other hand, a new "blue nevus" in an adult, or a changing blue lesion, or a multinodular or plaque-like lesion warrants excisional biopsy and histological evaluation. For a solitary lesion, simple excision is usually curative. Complete prophylactic excision of cellular BN should be considered due to its malignant potential.

Common BN have been successfully treated with the Q-switched ruby laser. Dermal injection of riboflavin followed by exposure to near-ultraviolet/visible radiation (ribophototherapy) has been tried in BN recalcitrant to laser therapy.

Incomplete excision of a BN may be followed by recurrence. The latter is manifested by satellite lesions around the original excision site that are difficult to distinguish from malignant BN (malignant melanoma mimicking a benign melanocytic lesion).

Dysplastic Melanocytic Nevus

Definition and Epidemiology

Dysplastic melanocytic nevus (DMN) is an acquired melanocytic lesion with atypical clinical and histological features, compared to common acquired melanocytic nevi (CAMN). Clinical and histologic definitions for DMN are controversial and still evolving. The terms atypical moles and dysplastic nevi continue to be used interchangeably, regardless of clinical or histologic appearance. DMN occupies an intermediate position in the disease spectrum ranging from CAMN to malignant melanoma. The atypical mole and melanoma syndrome is defined as the presence of a large number (>50) of melanocytic nevi, some of which have atypical features. It is classified into familial atypical mole and melanoma (FAMM) syndrome and sporadic, depending on the presence or not of family history (one or more first degree relatives) of CMM.

The prevalence of DMN has been reported to be 5 % in the general white population in the USA and 5–10 % in Australia and New Zealand. DMN are found in 1.8–18.0 % of various populations. DMN are present in almost all patients with familial CMM and in 30–50 % of patients with sporadic CMM. The white race is predominantly affected, especially persons of northern European background (Celtic) with light-colored hair and freckles. DMN are rare in black, Asian, or Middle Eastern populations. There are no sex differences. Most DMN, especially those familial, appear during childhood and adolescence, sometimes by crises. Sporadic lesions may appear at any time in life (as late as the sixth decade). Atypical moles may also change or regress throughout adulthood. New or changing pigmented nevi are not uncommon in adults, but new or changing nevi in patients older than 50 years are more likely to be melanoma.

DMN is considered a potential precursor of CMM and a marker of persons at high risk for CMM. While most melanomas arise de novo, superficial spreading melanoma may arise from atypical moles. Patients with familial or sporadic atypical mole syndrome are at increased risk for CMM. Anatomical association with DMN has been observed in 8–36 % of patients with sporadic CMM, in about 70 % of patients with familial CMM and in >90 % of persons with familial atypical mole and melanoma syndrome. Among whites in the USA, the lifetime risk of developing CMM is approximately 0.6 %, or 1 in 150 individuals. In patients with DMN, the risk for CMM is significantly increased reaching 6 % or 10–15 %, when family history of CMM is present or not, respectively. For patients with FAMM, the overall lifetime risk of melanoma has been estimated to be 100 %. CMM risk increases with: increasing number of DMN, increasing atypia, and family history of DMN or CMM. CMM in DMN patients may arise either de novo (on normal skin) or within preexisting DMN, more often during the fourth decade of life.

Basic Concepts of Pathogenesis

Atypical moles can be inherited or sporadic. For familial DMN, an autosomal dominant mode of inheritance with fairly high penetrance has been recognized. A polygenic aetiology has been suggested. Germline mutations in three genes, *CDK2NA* and *CDK4*, mapped to 9p21 and 12q14, and *CMM1*, mapped to 1p, have been linked to a subset of hereditary melanomas and FAMM syndrome. In addition, somatic mutations in *PTEN*, *BRAF*, and *MCR1* (melanocortin-1 receptor) have been associated with melanoma. Other genomic events such as loss of heterozygosity

(LOH) for tumor suppressor genes are also responsible for the progression from atypical nevi to melanoma. Sun exposure, especially a pattern of acute and intermittent exposures, is considered as a precipitating factor for DMN development. However, DMN may occur in completely covered areas of the body. Ultraviolet light (UV-A and UV-B) has been proposed as both an initiator and a promoter in the transformation of melanocytes into atypical melanocytes or melanoma. A meta-analysis concluded that use of UV tanning beds before age 30 years increases the risk of melanoma by 75 %. Immunosuppression provides a favorable setting for DMN progression to malignancy. Endocrine, dietary, and environmental factors may also play a part.

Fig. 65.8 Atypical mole syndrome (AMS). A patient with sporadic atypical mole syndrome manifested by >20 dysplastic nevi and numerous common nevi

Clinical Presentation

Clinically, DMN are characterized by:

- Macular lesion with papular components.
- Asymmetry.
- Greatest diameter larger than CAMN, usually ranging between 5 and 15 mm.
- Irregular and ill-defined border.
- Flat, pebbled, or cobblestone surface with accentuation of skin markings by side-lighting.
- Irregular pigmentation pattern, including shades of brown, tan, flesh, pink, and brown black.
- Erythema may be present within or around the lesion (halo).
- Round, oval, or ellipsoid shape.
- Solitary or, more often, multiple, randomly dispersed lesions, usually one to ten in sporadic cases and up to hundreds, especially in familial cases (FAMM).
- Distribution: anywhere on the body, both exposed and covered areas. Most often occur on trunk (back, chest, breasts), arms, legs, dorsa of the hands and feet, buttocks, and scalp. Mucosae may be involved.
- No symptoms are present.

Unusual clinical subtypes include: fried egg compound DMN, bull's eye or targetoid variant, lentigo-like or seborrhoeic keratosis-like, erythematous, and simulant of melanoma variant.

Atypical moles may arise anytime during a patient's lifetime. Although most lesions remain stable or evolve into benign dermal MN, some may change over time, or new lesions may develop. DMN is one of the most important precursor lesions of CMM (Fig. 65.8).

Diagnosis

Clinical diagnosis may be assisted by dermoscopy. Imaging studies are not necessary. Differentiating atypical nevus from melanoma in situ and early invasive melanoma needs skills and experience. It is one of the most important and difficult tasks of dermoscopy.

According to their global dermoscopic pattern, DMN are classified into three types: reticular, globular, and homogeneous. Frequently a combination of two of these patterns can be observed. If all three patterns are present, a special attention is required because a multicomponent pattern is frequently found in early melanoma. The reticular type is the most common, and it is characterized by typical pigment

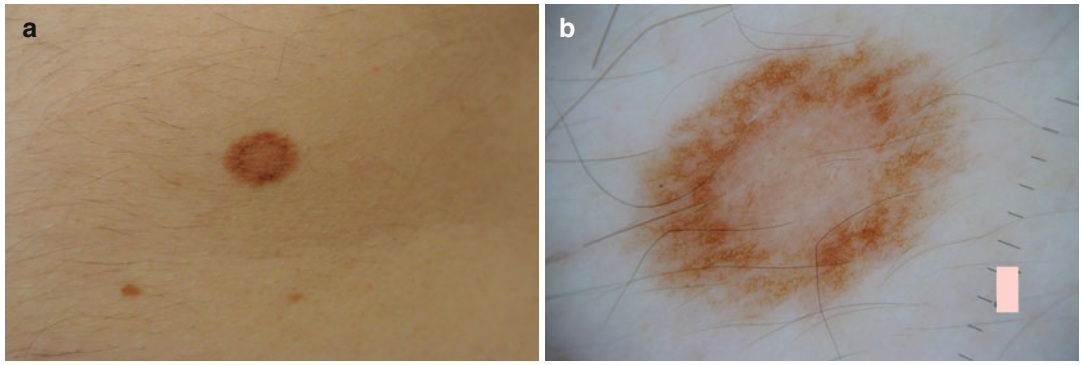

Fig. 65.9 Dysplastic nevus. (**a**, **b**) Dysplastic nevus with central hypopigmentation ("fried egg")

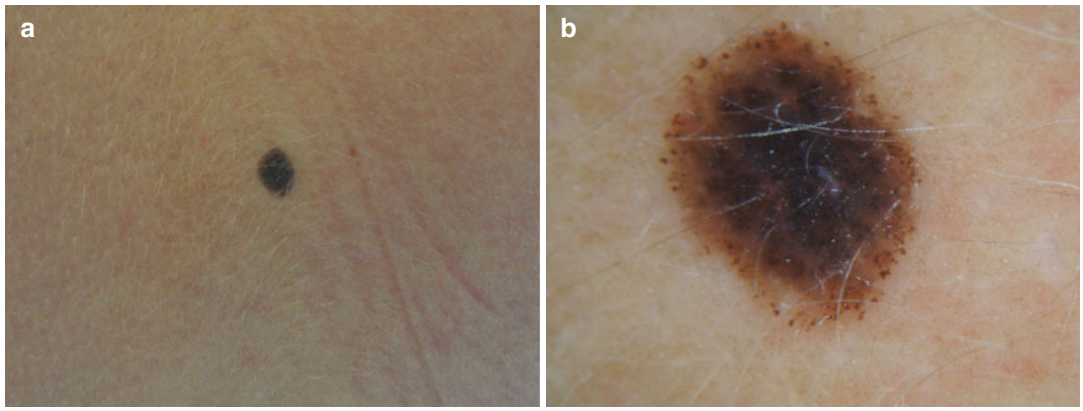

Fig. 65.10 Dysplastic nevus. (**a**, **b**) A growing dysplastic nevus with a homogeneously pigmented *dark brown* center and a peripheral rim of regular *brown* globules

network evenly distributed that fades in the periphery and possibly by atypical network. The globular type consists of numerous globules and dots of variable size and shape. The less frequent, homogeneous type exhibits a diffuse brown pigmentation with isolated reticular or globular areas. There are no specific local dermoscopic features. Additional local criteria include atypical network, streaks, blue-white structures, regression, and blotch. The vascular patterns commonly seen are comma or dotted vessels.

Based on variations in pigmentation, four dermoscopic subtypes can be distinguished: DMN with central hyperpigmentation (black nevus), DMN with central hypopigmentation ("fried egg" nevus), DMN with multifocal hyper-/hypopigmentation, and DMN with eccentric hyperpigmentation (of uppermost importance because this presentation overlaps with early melanoma) (Figs. 65.9, 65.10 and 65.11).

Histological examination is the gold standard to confirm diagnosis. Typical histopathologic features, which are superimposed on those of a typical junctional or compound nevus, include:

- An increased number of single melanocytes along the basal layer, with elongation of rete ridges.
- Extension of the junctional component beyond the last dermal nest to produce "shoulders."
- Cytologic atypia of melanocytes, usually confined to the shoulder region, with enlarged, hyperchromatic nuclei in the junctional component. Diffuse atypia is more worrisome.
- A horizontal arrangement of melanocytes that vary in shape from round to spindled.

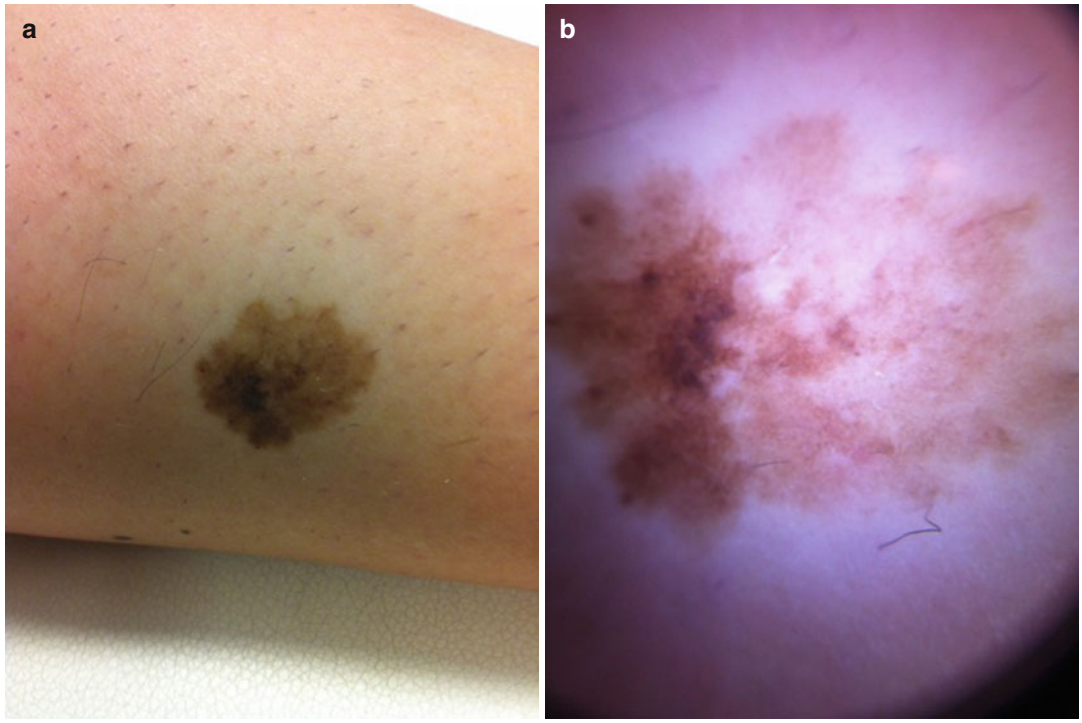

Fig. 65.11 Dysplastic nevus. (**a**, **b**) A dysplastic nevus appearing as an asymmetric multicolored patch with eccentric hypopigmentation and extensive regression. The differentiation from superficial spreading melanoma can be made only by histology

- A tendency for melanocytes to aggregate into variably sized nests, which fuse with adjacent rete ridges to produce bridging.
- Presence of lamellar and concentric dermal fibroplasia.
- Presence of a lymphocytic infiltrate (patchy or diffuse) in the superficial dermis.

It must be noted that some clinical atypical moles are normal histologically.

Differential Diagnosis

DMN must be differentiated from:
Melanocytic lesions:

- Common acquired nevi
- Small congenital MN
- Pigmented spindle cell nevus
- Nevus spilus
- Spitz nevus
- Blue nevus
- Solar lentigo
- Melanoma in situ and CMM (greater asymmetry, irregular margins with prominent notching, striking variations of color, including shades of red, gray, white, and blue black).

Non-melanocytic lesions:

- Pigmented actinic keratosis
- Seborrhoeic keratosis
- Solar lentigines
- Dermatofibroma
- Pigmented basal cell carcinoma

Treatment

Management depends on the number of DMN, history of CMM, and family history of DMN or CMM.

Patients with multiple DMN should be followed up periodically for life. Evaluation should include (a) total skin surface examination, (b) baseline and serial clinical color photography, (c) body charts that are

periodically updated, and (d) digital dermoscopic follow-up (mole mapping). Patients should be warned of the potential hazards of sun exposure and should be educated in methods of protecting themselves and their children. Sun avoidance and use of sunscreens of sun protective factor 30 or greater should be encouraged. Sunbathing and tanning parlors must be avoided. Blood relatives should also be examined for DMN and CMM and should be followed up regularly as well.

Clinically atypical nevi do not require excision as a routine procedure. Patients with few lesions must be followed up yearly or every 6 months if there is a family history of CMM. Patients with numerous lesions should be followed up every 6 months or every 3 months if there is personal or family history of CMM.

Recommended Therapies

As most melanomas develop de novo and because the risk for malignant transformation of any one atypical nevus is low, prophylactic removal of all atypical moles is not recommended. Lesions that require excision include:

- All lesions suspicious for CMM
- Changing lesions, i.e., increasing in size or changing in pigmentation, in shape, and/or in border
- Lesions that cannot be easily followed by self-examination (scalp, genitalia, upper back) or if the patient is unreliable for follow-up
- Lesions at special locations, such as palms, soles, or nail bed
- Based on dermoscopic criteria, lesions with multicomponent pattern or eccentric hyperpigmentation or atypical network

Complete surgical excision with narrow margin is the treatment of choice. Initial margins of 5 mm are sufficient. If the lesion is atypical or present in margins, excision with clear margins is necessary. If severe atypia is present, re-excision with 5–10-mm margins is recommended. Histological examination, preferably by specialists, to document diagnosis and to exclude malignancy, should always follow. If the suspicious mole is too large or is located in a cosmetically significant or functionally sensitive site, one or more incisional biopsies guided by dermoscopy may be considered. A wider excision may be indicated after histological examination.

Lasers, electrosurgery, cryotherapy, or other modalities resulting in physical destruction of the lesion should be avoided, because they do not permit histopathological examination of the lesion.

Management of Melanocytic Nevi at a Glance

Melanocytic nevi are benign lesions that only rarely require prophylactic excision. Unfortunately, as the golden standard for the diagnosis is histopathology, it is impossible to have a definite diagnosis for the enormous number of pigmented lesions under consideration during clinical practice. Therefore, it is of paramount importance to develop methods and practices for the in vivo evaluation of pigmented skin lesions. Clinical and dermoscopic examination and follow-up of melanocytic nevi is synonymous to the secondary prevention (early diagnosis) of malignant melanoma. When evaluating a pigmented lesion, the management decision may be excision, follow-up, or no action. When the clinical suspicion for a benign melanocytic lesion is verified by dermoscopy, no further action should be taken. Only for large or giant congenital melanocytic nevi (whenever possible) and Spitz nevi a prophylactic excision is warranted. When the clinical diagnosis does not coincide with the dermoscopic diagnosis; the lesion shows atypical features; there are some melanoma-specific dermoscopic criteria present (but not enough to establish a dermoscopic diagnosis of melanoma); a deviation in the natural history is noted; we are dealing with a new and/or changing lesion or a lesion that differs from the rest of the pigmented lesions of the same patient (“ugly duckling”), especially in high-risk patients; or the diagnosis is completely in doubt, excisional or incisional biopsy or short-term follow-up (3 months) should be considered. Nodular doubtful lesions should never be followed up. Single doubtful lesion should better be excised. Multiple suspicious lesions should be followed up by digital dermoscopy, either short term or long term.

On short-term digital follow-up (3 months), any dermoscopic change warrants excision. On long-term follow-up (6 months), lesions with substantial dermoscopic changes require excision. All persons should have a total skin examination yearly. Mole mapping with total body photography and digital dermoscopy should be reserved for high-risk individuals for melanoma development, i.e.:

- Personal or family history of melanoma
- Multiple dysplastic nevi or dysplastic nevus syndrome
- Large number of nevi, fair skin, light eye and hair color, and freckles
- History of sunburns in childhood and adolescence
- Excessive sun exposure and sun bed use
- Genetic syndromes (xeroderma pigmentosum, Gorlin syndrome, alphism)

In these persons clinical and dermoscopic examination should be performed every 3–6 months.

Future Perspectives

During the last decade, there have been many efforts to develop accurate and reliable techniques for the in vivo assessment of skin tumors in the context of early diagnosis of malignant melanoma. Most of these techniques are still under development. Most importantly, they are still very expensive and not user friendly. These diagnostic techniques include:

- Reflectance confocal microscopy
- Multispectral image analysis
- Optical coherence tomography
- High-resolution ultrasounds
- Magnetic resonance imaging
- Measurement of tumor oxygen status

Necrobiosis Lipoidica

66

Istvan Juhasz

Abbreviations

DM Diabetes mellitus
NBL Necrobiosis lipoidica

Key Points

- Necrobiosis lipoidica is of unknown etiology.
- It has a higher prevalence in diabetic patients, but the association between NBL and diabetes is debated.
- Microangiopathy and tissue hypoxia may play a leading role in the pathogenesis; ulceration and infection may contribute to persistence.
- Treatment is difficult, often resulting only in partial response and frequent relapses. Topically applied steroids or calcineurin inhibitors in combination with compression serve as baseline therapy, while various forms of phototherapy come as second line.
- New approaches emerge, such as photodynamic therapy and fractional laser therapy, local fumaric acid ester, intravenous immunoglobulin, and systemic targeted therapy with biologicals, but their effectiveness needs to be further evaluated.

Definition and Epidemiology

NBL presents as a mostly solitary, but not uncommonly multiple, chronic granulomatous infiltrative lesion of unknown etiology in the dermis of predominantly female patients. It has a higher prevalence in diabetic patients, but the association between NBL and DM is debated.

Basic Concepts of Pathogenesis

The most accepted theory attributes vascular changes often seen in NBL to microangiopathy due to proteoglycan deposition in vessel walls. This can be present in latent DM as well. Lower partial O_2 tension detected with laser Doppler imaging suggests hypoxia playing a role in the pathogenesis. Detection of spirochaetal microorganisms in lesional skin of NBL patients suggests an infectious etiology analogous to the evolution of morphea plaques (Eisendle et al. 2008). Familial cases both with and without

Fig. 66.1 Typical clinical presentation of necrobiosis lipoidica (NBL) with multiple infiltrated telangiectatic, opaque whitish plaques under shiny atrophic epithelium on both lower legs of a 52-year-old female patient

diabetes have been reported extensively drawing an attention to possible genetic predisposition. However, the comparison of HLA antigens between insulin-dependent diabetics with and without necrobiosis lipoidica revealed no significant differences (Soler and McConnachie 1983). Increased expression of the glioma-associated oncogene homologue (gli-1 oncogene) was found in necrobiosis lipoidica diabeticorum and other granulomatous skin disorders, like sarcoidosis (Macaron et al. 2005).

Clinical Presentation

Appearance of mostly single but sometimes multiple lesions with a predilection for the lower extremities of patients is typical for NBL (Fig. 66.1). Initially asymptomatic circumscribed papules are present, which may coalesce into yellowish-red waxy plaques with violaceous border (Fig. 66.2). These lesions are painless due to associated nerve damage. If painful, it is in most cases associated with ulceration which has a poor tendency to heal. The diagnosis of NBL can be set up in most cases based on the clinical picture, and in doubtful instances, biopsy is performed for histopathological examination. There are reports of carcinomatous transformation of NBL; these are most likely consequences of the premalignant status of the chronic ulceration itself.

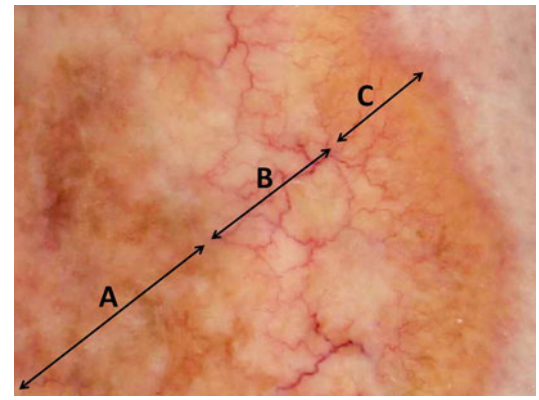

Fig. 66.2 Close-up photography of a NBL lesion showing its typical concentric (iris) structure (from *left* to *right*): *A* oldest sclerotic, slightly hyperpigmented portion, *B* intermediate atrophic part with dilated capillaries, and *C* infiltrated zone with peripheral interstitial inflammation

The association of NBL and diabetes is currently debated. There are reports on incidence of DM among NBL patients as high as 65 % and as low as 16 %. Incidence of NBL among diabetics is reported as 0.3 %, so this rather low association underlines the importance of possible other susceptibility factors in disease development. Proper determination of the association with comorbidities requires further prospective studies on large cohorts.

Differential Diagnosis

The sine qua non lesion for NBL is the waxy infiltrative plaque or plaques consisting of discolored dermis under atrophic epithelium. Granulomatous conditions, such as sarcoidosis, necrobiotic xanthogranuloma, and granuloma annulare (GA), are clinically similar lesions; therefore they need to be differentiated. These all may present with opaque discoloration, central atrophy, and telangiectasias. The dermatoscopy picture of NBL is characteristic with sharply focused, elongated serpentine telangiectasias typically located over a whitish, structureless background. This structure is different from GA and from other forms of granulomatous diseases. Histologically degenerated collagen is present in the dermis with an infiltrate of various inflammatory cells, lymphocytes, plasma cells, and histiocytes, together with multinucleated giant cells (Fig. 66.3). The most severe inflammatory signs are present in the lower part of the dermis and in the subcutis. Palisade-oriented inflammatory cells often form granulomas. Important differentiation item is the sclerotic transformation of the reticular dermis in NBL that is not seen in GA. On the contrary, deposits of acidic mucosubstances that cause bundles of collagen to separate in GA are not present in similar foci of palisaded histiocytes and degenerated collagen in NBL.

General Principles of Treatment

As with ailments that are difficult to treat, numerous therapeutic approaches have been applied, but none of them can be considered as gold standard. Avoidance of trauma to prevent ulceration of the lesion is an important factor, often requiring changes in previous lifestyle of individuals with NBL. Koebner phenomenon is frequently reported; therefore, surgical approaches are of limited importance. Dermal replacement is an interesting new approach whose practical value needs to be determined in the clinical setting.

Topical Treatments

Topically applied steroids as potent anti-inflammatory agents, usually in combination with compression therapy, are used most frequently, followed by topical calcineurin inhibitors. The rationale for the use of the latter might be their potential to inhibit gli-1 signaling besides

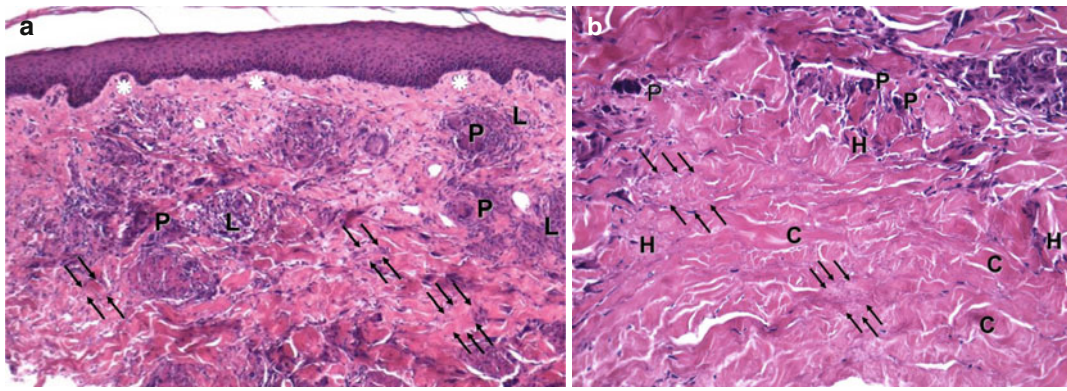

Fig. 66.3 (**a**) Cross-section of lesional skin at 100× magnification, H+E stain. Presence of relatively conserved epithelium with shallow rete ridges (*asterisk*). The dermis contains numerous foci of necrobiotic collagen (*arrows*) surrounded by granulomatous reaction. Marked perivascular focal lymphocytic infiltration is seen (*L*) with multinucleated giant cells (*P*). These initial changes mark the whole width of the dermis. (**b**) Deep layer of lesional skin at 200× magnification, H+E stain. The lower reticular dermal portion is loaded with cell-free degenerated collagen (*C*). The cellular components of the infiltrate are mainly lymphocytes (perivascular orientation), scattered with histiocytes (*H*) and polynucleated giant cells (*P*)

providing some sparing of the side effect profile of steroids. Diverse forms of phototherapy, mostly PUVA or high-dose UVA, emerge as second-line therapy. Popularity of photodynamic therapy and fractional laser therapy are increasing, although standardized guidelines are missing. Experimental use of local therapies such as fumaric acid esters or human recombinant platelet-derived growth factor (PDGF, becaplermin) needs to be further evaluated. Negative pressure wound therapy is an effective treatment option for slow-healing wounds, and it has shown benefit for the closure of ulcerative NBL lesions as well.

Systemic Treatments and Future Perspectives

Many systemic agents that are believed to influence metabolism, microcirculation, or inflammation of diseased tissues have been tried, resulting mostly in partial improvement or even occasional worsening (for review, see Reid et al.). Most therapeutic suggestions are based on reports of cases or small patient series however. Pentoxifylline with its anti-inflammatory, immunomodulatory, and positive rheological effects is a strong candidate for systemic treatment of NBL. There is also rationale for administration of aspirin alone or in combination, although it was tested as being ineffective in an early RCT. Treatment with immunosuppressants, such as cyclosporine or mycophenolate mofetil, results in temporary improvement with early relapse after cessation of therapy, but also long-term effectiveness is reported. Thiazolidinediones, a new class of oral antidiabetic drugs, act as potent agonists for peroxisome proliferator-activated receptor gamma (PPAR gamma), an important mediator of differentiation of adipocytes and lipid storage in adipose tissue. This therapy is reported to improve NBL in diabetics, most probably by its anti-TNF-α (alpha) effect. Marked improvement of lesions was also reported after administration of colchicine and antimalarial agents. Intravenous immunoglobulin (IVIG) therapy, possibly due to its immunoregulatory effect, has also been applied successfully. Resistance of the disease to conventional therapeutic approaches and the initial encouraging therapeutic success with anti-inflammatory biological therapies may justify the off-label use of this kind of therapy for NBL. Successful use of anti-TNF-α (alpha) therapy was reported with adalimumab, etanercept, and infliximab. Most of the publications describe the action as limited or temporary and suggest some form of maintenance therapy. None of the previously listed systemic agents have established protocols for optimal dose and duration of treatment. These therapeutic options should be assessed for efficacy and safety in the future preferably by randomized and controlled trials.

Nummular Eczema

67

Antonia Todorova, Harald Bruckbauer, and Johannes Ring

Key Points

- Nummular eczema is a noninfectious inflammatory dermatosis, characterized by severe pruritus and well-demarcated coin-shaped lesions.
- Aggravating factors as atopy, contact allergy, skin dryness, staphylococcal superinfection, dental infectious foci, viral infections, venous stasis, impaired liver function, and systemic medication may trigger the onset or a relapse of disease.
- Treatment is based on elimination of trigger factors in combination with topical and systemic anti-inflammatory and antimicrobial therapy.
- Topical treatment is performed according to stage of disease. Therapy of first choice during the acute stage (vesicles, erosion, exudation) is topical – rarely also systemic – corticosteroids in combination with desiccating, antiseptic solutions and wet bandages. In subacute and chronic eczema, topical corticosteroids as pastes and calcineurin inhibitors are recommended.
- Combination with phototherapy can be useful in disseminated or relapsing eczema.
- Systemic antimicrobial and anti-inflammatory therapy (antibiotics, corticosteroids) is indicated in severe cases or recurrent refractory eczema.
- Systemic antimicrobial treatment should be performed upon microbiological cultures with broad-spectrum antibiotics, effective against specific bacteria (*Staph. aureus*).
- Systemic corticosteroids are applied over 5–7 days in tapering dose.
- In single cases immunosuppressive therapy with other agents (ciclosporin, methotrexate) may be necessary to achieve remission.

Definition and Epidemiology

Nummular eczema is characterized through a chronic noninfectious inflammation of the epidermis and dermis and single or multiple

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_67, © Springer-Verlag Berlin Heidelberg 2015

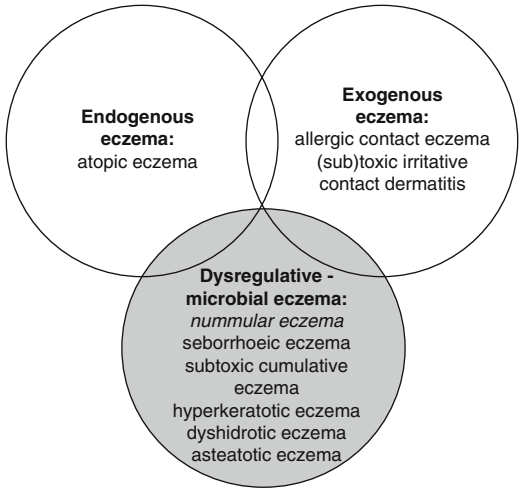

Fig. 67.1 Classification of eczema into three main groups (according to Hornstein)

Fig. 67.2 Nummular eczema and varicosis

coin-shaped, well-demarcated lesions. It undergoes the common eczema stages: initial stage with erythematous plaques and papules, alteration of the papules into itching and oozing vesicles, crust formation, and eventually healing.

Histological characteristics of nummular eczema are spongiosis, acanthosis, and parakeratosis with lymphocytic infiltration.

Hornstein's classification (Fig. 67.1) reveals three basic eczema groups: endogenous, exogenous, and dysregulative-microbial eczema with its subtype nummular eczema.

Epidemiological data indicate higher incidence of nummular eczema in male patients between 50 and 70 years; however single studies refer to female gender predominance (Jiamton et al. 2012).

Basic Concepts of Pathogenesis

The pathophysiology of nummular eczema has not been fully cleared yet. Multifactorial trigger in combination with epidermal barrier dysregulation is assumed to play a major role in the onset and maintenance of the disease. Among the common aggravation factors are atopy and dry skin. Recent studies report up to 50 % atopy in patients with nummular eczema. Contact sensitization to common allergens like metals, fragrance, rubber, and preservatives, but also sensitizations to bacterial antigens (*Staphylococcus spp*.) with subsequent T cell activation have been described as probable trigger. Bacterial (dental infections, sinusitis, tonsillitis, bronchitis, prostatitis) or viral infections (hepatitis) can represent an internal chronic activator of inflammation. Several case reports point out coincidence of nummular eczema and venous stasis (Fig. 67.2). Onset or exacerbation of eczema has been reported under medical treatment with gold preparations, isotretinoin, or antiviral combinations (ribavirin, interferon, telaprevir). Emotional stress, liver dysfunction, or extensive alcohol consumption had also been discussed to have negative impact on the course of disease. Recent study reports elevated tryptase in children with nummular eczema in absence of mastocytosis or atopic eczema.

As nummular eczema is a chronic disease, many authors relate to the significant impairment of quality of life in affected individuals.

Clinical Presentation

Common affected areas are the distal limbs (lower extremities > upper extremities; Figs. 67.2, 67.4 and 67.5).

In severe cases dissemination onto trunk, face, and neck can be found. Some authors suggest an

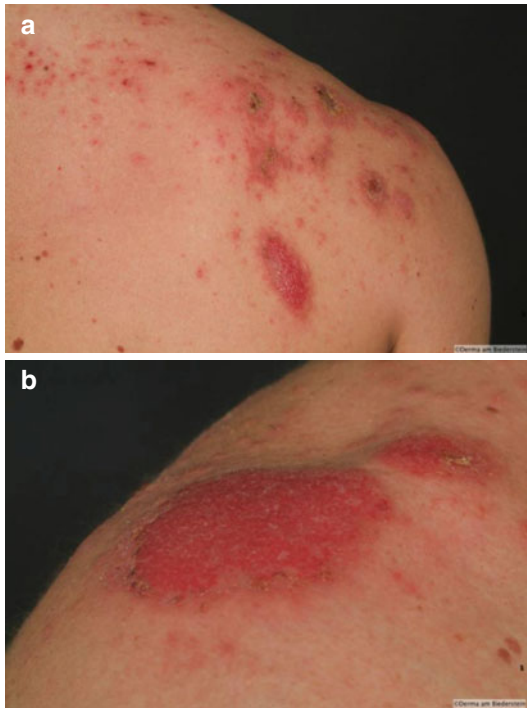

Fig. 67.3 Nummular lesion in acute stage. (**a**) Widespread eczema; (**b**) detailed image

Fig. 67.4 Nummular eczema in chronic stage

Fig. 67.5 Nummular eczema: well-demarcated lesion and skin exsiccation

association between the eczema location and an underlying xerosis cutis.

Based on the clinical appearance and duration of disease, nummular eczema can be classified as acute or subacute/chronic. During the acute phase occur erythematous plaques with diameter of 1–5 cm and distinct edges. Shortly upon onset papules, papulovesicles and vesicles develop on the surface of the plaques. Severe pruritus is characteristic for this stage. After the vesicles once erode (Fig. 67.3a and b), oozing, crusting, and scaling follow (Fig. 67.5).

Diagnosis

The diagnosis of nummular eczema is based on the typical clinical features of coin-shaped eczema with sharp demarcated edges and severe pruritus. To rule out differential diagnoses, a detailed history has to be taken. There are no specific laboratory markers available for nummular eczema. In some cases, trigger factors such as infection, atopy, and allergic contact sensitization can be determined.

Blood Tests

Blood tests are performed to detect underlying infectious diseases, atopy or allergies (Table 67.1).

Fig. 67.6 Nummular eczema under topical treatment

Table 67.1 Laboratory markers of underlying diseases

Blood test	Indication
Markers for bacterial infections	
• Leukocytosis	Bacterial infections
• Elevated erythrocyte sedimentation rate (ESR)	Bacterial infections
• Elevated anti-staphylolysin antibodies (ASTA)	Staphylococcal infections
• Elevated anti-streptolysin antibodies (ASO)	Streptococcal infections
• ReactiveTreponema-pallidum-Particle-Agglutination (TPPA) test	Syphilis
Markers for viral infections	
• Lymphopenia	Viral infection
• Monocytosis	Viral infection
• Hepatitis, HIV serology	Hepatitis A/B/C, HIV
Allergy diagnostics	
• Total-IgE, RAST, Prick test	Atopy/atopic eczema
• Patch test	Contact allergy

Histopathology

Skin biopsy from affected area shows acanthosis, hyperkeratosis (orthokeratosis and parakeratosis), and spongiosis with diffuse lymphocytic infiltration, eosinophils, and neutrophils. Spongiosis with vesiculation may be found in the early stages. Periodic acid–Schiff (PAS) stain is performed to rule out tinea infection.

Bacteriological Swabs

In cases of a superinfection, bacteriological swabs from the lesions can be useful to determine affecting bacteria and resistance spectrum.

Mycological Culture

Scales from affected area should be cultured to exclude tinea corporis.

Differential Diagnosis

Common relevant differential diagnoses are listed in Table 67.2.

Table 67.2 Differential diagnoses of nummular eczema

Name of disease	Clinical features
Psoriasis with nummular pattern	Family history of disease, no vesicles, no/discrete pruritus
Parapsoriasis	No vesicles, typical distribution pattern in Langer's lines
Atopic eczema with nummular pattern	Susceptibility for atopic diseases, manifestation in childhood, chronic eczema (lichenification)
Prurigo with nummular lesions	Prurigo nodules
Sulzberger–Garbe exudative discoid and lichenoid chronic dermatosis	Polymorph clinical appearance, diffuse, nummular and lichenoid pattern of lesions, genital affection (penis, scrotum)
Allergic contact eczema	Distinct trigger +/– positive patch test
Tinea corporis	Positive direct detection or culture, pets
Impetigo contagiosa	Positive bacterial analysis for streptococci or staphylococci, contagious
Leprosy	No pruritus, dysesthesia
Mycosis fungoides	Persisting lesions in same location, no vesicles, different histology

Table 67.3 Stage adequate treatment of nummular eczema

Clinical stage	Clinical characteristics	Treatment	General measures
Acute nummular eczema	Vesicles, exudation, erosion, crusts	In severe and extended cases: systemic therapy with steroids (0.5–1.0 mg/kg prednisone) for about one week in tapering dose	Treatment of underlying disease Antipruritic therapy with antihistamines Psychosomatic counselling Avoid worsening factors
		In super infected eczema: systemic antibiotic therapy (e.g., cephalosporins)	
		Topical exsiccating, antiseptic and anti-inflammatory treatment: dyes (Sol. pyocatnini, Sol. castellani), glucocorticoid cream (O/W) in combination with wet dressings (clioquinol or KMnO solutions)	
Subacute nummular eczema	Erythema, edema, papules, Seropapules, scales	Mild exsiccation: dyes, glucocorticoid cream (O/W) with wet dressing, zinc oil, soft paste, lotion (powder in water) on nonexudative lesions	
Chronic nummular eczema	Dry scaling, psoriasiform scaling, lichenification papules	Glucocorticoid cream or ointment, Occlusive soft paste lipophilic ointment, Tars (Ichthyol- tumenol-LCD – Pix lithanthracis) 3–5 % in soft paste or ointment	Ultraviolet B phototherapy Oil bath
	Hyperkeratotic lesions	Keratolytic ointments (urea 10 % or salicylic acid 5 %)	

General Principles of Treatment

Causative and symptomatic treatment should be performed according to clinical manifestations (stage of disease) (Table 67.3).

Triggering factors as infections, dry skin, and contact with sensitizing substances need to be eliminated and avoided. Venous stasis should be treated. Medications, considered as trigger, should be withdrawn or substituted.

In patients with xerosis cutis, sufficient basis therapy is essential. In case of systemic infections, causative systemic antibiotic or antiviral therapy has to be applied. Symptomatic treatment is based on anti-inflammatory, anti-eczematous, and immunomodulation approaches.

Topical corticosteroids (TCS) with diverse potency and formulation have been established as first-line therapy in every stage of disease. Immunosuppressive and immunomodulatory therapy with topical calcineurin inhibitors (TCI) can be applied for long-term treatment with similar anti-inflammatory efficacy. Combination therapies as TCS with antiseptics and astringents (for acute stadium) or with keratolytic ointments (chronic eczema) have shown good outcome.

In disseminated lesions, UV phototherapy (UVA and UVB) is used along with topical corticosteroids or tar preparations for its anti-inflammatory, immunosuppressive, and antipruritic effect.

In severe and resistant cases, systemic corticosteroid treatment in combination with antibiotics should be applied.

In severe pruritus, systemic antipruritic treatment with antihistamines is recommended; however the efficacy in patients with nummular eczema can be limited.

Psychosomatic counseling, relaxation techniques, or acupuncture can be beneficial as supportive approaches to minimize emotional stress.

Topical Treatments

Topical Corticosteroids (TCS)

Topical corticosteroids are used in the treatment of eczema lesions for their anti-inflammatory and immunosuppressive effects. According to their potency, there are four groups of TCS (group I: low potency to group IV: very potent), although

clinical effect can depend on formulation, duration of treatment, extent of the treated area, and stage of disease. Mostly once daily application is recommended.

In acute eczema corticoid cream (O/W) in combination with topical antiseptics and astringent dyes ensures faster exsiccation. In severe cases wet dressings applied over the treated area increase the penetration of the active agents and thereby contribute to accelerate healing. Limited treatment duration has to be considered with this approach, due to higher rate of side effects and possibility of systemic resorption of the corticosteroids.

Lipophilic corticosteroid ointments and creams are appropriate in chronic eczema for higher penetration.

In short-term treatment regiments, TCS have low rate of side effects. Most common are skin atrophy, hypertrichosis, and steroid acne or acute contact dermatitis due to preservative agents. To avoid possible side effects, mild TCS are applied once daily at the beginning of treatment (up to 14 days), potent TCS over 3–5 days with subsequent dose tapering (lower TCS potency or extension of application interval). In stable disease proactive therapy with once/twice weekly application of a low potent TCS can be offered in chronic recidivant cases as relapse prophylaxis.

Topical Calcineurin Inhibitors (TCI)

Tacrolimus (0.03 % and 0.1 %) ointment and pimecrolimus 1 % cream are immunomodulatory agents with suppressive activity on T cells. As an alternative nonsteroid topical treatment, these agents became an essential part of the eczema therapy during the last years. They are mostly applied in mild to moderate eczema and can be used in delicate skin areas such as the face, genital region, and intertrigines. Recent studies have shown that a long-term treatment on a daily basis over several months is well tolerated in children and adults. Most common side effects are burning or itching on the application side; in atopic patients skin infections (herpes simplex, molluscum contagiosum) can occur and have to be treated with temporary discontinuation of the TCI therapy. Sun protection and skin disinfection on the application sites are recommended during use of TCI.

Topical Antiseptics (TAS) and Astringents

Topical antiseptics have antimicrobial effect and help to reduce bacterial contamination in affected areas. Due to the compromised skin barrier in eczema lesions, the use of clioquinol, potassium permanganate (KMnO4), and diverse astringent solutions is recommended (Table 67.4) rather than alcoholic solutions (irritation).

This topical treatment is favored because of its broad antimicrobial spectrum and low risk of bacterial resistance.

Contact dermatitis can develop after sensitization; persistent skin and clothes coloration are seen in contact areas upon application.

Topical Antibiotics (TAB)

Due to the risk of emerging bacterial resistance, the use of topical antibiotics for nummular eczema is not recommended.

Tar Preparations

Tar mixtures cause antimicrobial, antipruritic, and photosensitizing effect. The last finds application in the therapy of chronic resistant eczema in combination with UVB phototherapy. Possible side effects are phototoxicity and long-term high risk of skin cancer. To minimize carcinogenic risk, the use of tar mixtures has been limited over the last years.

Table 67.4 Topical antiseptics and astringents for nummular eczema

Solution %	Coloration
Clioquinol	Yellow
KMnO4 aq. Sol.	Pink
Solutio pyoctanini (Gentian violet aqueous 1 %)	Ink blue
Solutio castellani aq.	Magenta
Eosin aq. solution 1 %	Red

Supportive Approaches and Treatment Regiments

Wet Wrap Dressings

Wet wrap dressing is a technique of topical treatment during the acute stage of eczema with vesicles, erosions, and exudation. Oozing lesions are creamed with corticosteroid cream and dressed with wet bandages for 20 min. This causes enhanced penetration of the cream with more potent effect and faster drying of the vesicles. Dressings can be applied once daily; mostly up to 3 days are sufficient to exsiccate the lesions. Caution is needed because of the higher penetration of corticosteroids with possible systemic side effects.

Proactive Treatment

Use of TCS or TCI in previously affected areas (once/twice weekly) to avoid exacerbation after clinical improvement.

Topical Treatments at a Glance

- *Acute nummular eczema*:
  Exsiccating agents with anti-inflammatory and antiseptic properties
  Wet dressings
  Glucocorticosteroid lotions and solutions in tapering dose
  Topical calcineurin inhibitors in delicate areas and for prolonged treatment
  (Phototherapy)
- *Subacute and chronic eczema*
  Lipophilic TCS ointments in tapering dose
  Topical calcineurin inhibitors
  Keratolysis in hyperkeratotic lesions with salicylic acid 3–5 % or urea 10 %
  Intensive basis therapy (lipophilic lotions and creams)
  Tar preparations in combination with UVB phototherapy
  UVA1 phototherapy

Systemic Treatments

Systemic treatment is indicated in severe cases with disseminated eczema lesions, superinfection, or in relapsing cases.

Systemic Antibiotics (SAB)

As in nummular eczema a sensitization to staphylococcal superantigens has been assumed as a trigger and *Staph. aureus* superinfection is common in eczema lesions, antibiotic treatment is mostly performed with anti-staphylococcal agents (penicillins, cephalosporins, lincosamides).

Beta-lactamase-resistant penicillins are recommended after performing an antibiogram. Possible adverse effects are intolerance reactions like allergic exanthema or urticaria. Another challenge is the increasing bacterial resistance to penicillins.

Cephalosporins and carbapenems are well tolerable and effective treatment alternative. A significant side effect of clindamycin is pseudomembranous colitis. In cases of acute onset of diarrhea, clindamycin should be withdrawn.

Due to the wide spread resistance to tetracyclines and macrolides, these are no longer recommended in the therapy of *Staph. aureus*.

Systemic antibiotic treatment is performed over 5–7 days; in case of an underlying infection (tonsillitis, urethritis, bronchitis), specific antimicrobial therapy is recommended.

Systemic Corticosteroids (SCS)

Systemic corticosteroids are indicated in severe cases of acute eczema with widespread affection of the body and extremities and in chronic recurrent eczema.

Daily administration of 0.5–1.0 mg/kg prednisolone equivalent is recommended for up to 7 days in tapering dose.

Side effects on the skin such as atrophy, telangiectasia, striae distensae, purpura, and hypertrichosis or systemic side effects as Cushing, osteoporosis, and suppression of the pituitary–adrenal-axis occur usually after long-term treatment but have to be reconsidered and monitored.

Contraindications represent severe systemic infections, peptic ulcer disease, psychiatric

disorders, glaucoma, hypertension, and osteoporosis. These should be ruled out.

Antihistamines (AH)

Antihistamines are indicated as supportive treatment in patients with severe pruritus. Parenteral application is more effective than oral administration. First-generation antihistamines have pronounced antipruritic effect, also causing sedation and fatigue. AH are generally well tolerated. Caution is indicated in patients with impaired renal function, cardiac diseases, or concomitant medication such as antidepressants. AH are mostly part of a combination therapy with local and systemic corticosteroids.

Ciclosporin (CyA)

Ciclosporin is a T cell immunosuppressive drug with broad application in the transplantation medicine and in the field of dermatology in refractory atopic eczema, psoriasis, pemphigus, and other autoimmune diseases. For severe nummular eczema in atopic patients, ciclosporin treatment can be reconsidered to achieve remission. Possible side effects are hypertension, impairment of the renal and liver function, hypertrichosis, gingival hyperplasia, and infections. Regular laboratory checkup (blood cell count, hepatic and renal function parameter, ESR, CRP) and blood pressure should be monitored every 4–6 weeks during the long-term treatment. Based on the potential epithelial carcinogen effect, ciclosporin should not be combined with phototherapy, and the duration of treatment should be limited (up to 1 year).

Methotrexate (MTX)

Methotrexate represents a cytostatic agent with immunosuppressive and antiproliferative effect, based on suppression of the folic acid synthesis. In autoimmune disorders, psoriasis, and rheumatic diseases, it has already found broad application. Recently, successful and well-tolerated treatment of refractory nummular eczema in children with MTX has been reported (Roberts et al.). Limitations of use are pregnancy and lactation, hepatic and renal diseases, bone marrow suppression, or systemic infections. Regular checkup of blood cell count, liver and renal function, as well as contraception are required. Men should be aware of potential impairment of spermiogenesis. Semen cryopreservation should be discussed with male patient before initiating therapy. In cases of cough and dyspnea under treatment, pulmonar toxicity and alveolitis should be ruled out.

Phototherapy (PT)

Phototherapy is used for its immunomodulatory and anti-inflammatory effects as whole body irradiation alone (UVA; 320–400 nm) or in combination with photosensitizing substances (psoralen UVA/PUVA) or with tar preparations (UVB; 280–320 nm). According to irradiation type and minimal erythema doses (MED) of the patient, procedures are performed three to five times per week over 3–4 weeks. Purpose of treatment is to maintain discrete erythema in order to achieve therapeutic effect. Depending on the individual skin reaction, UVB irradiation doses are increased on a daily basis with 15–30 %, beginning with the 80 % of the personal MED (25–70 mJ/cm^2). PUVA therapy starts usually with initial dose 0.5–1.0 J/cm^2.

Phototherapy should only be performed in patients without increased photosensitivity. Medications causing phototoxicity (diuretics, tetracyclines, quinolones, herbs) should be withdrawn over the treatment duration. Patients should wear protective glasses and cover face and genitalia during irradiation. Other side effects are acute dermatitis (overexposure), skin aging, and higher long-term risk for skin cancer (Fig. 67.7).

Systemic Treatment at a Glance

- Systemic treatment should be applied in severe and recurrent eczema.
- Therapy of first choice is systemic corticosteroids in combination with broad-spectrum antibiotics.
- Combination with phototherapy is effective in disseminated eczema.
- Systemic immunosuppressive agents as CyA and MTX can be considered in refractory cases to achieve remission. Immunosuppressive therapy should be performed over limited duration under regular laboratory checkups.

Fig. 67.7 Nummular eczema improved after UVB phototherapy

Complementary Treatments

Psychosomatic Counseling

As in many cases with chronic recurrent disease, significant impairment of quality of life has been reported in patients with nummular eczema. Severe pruritus seems to have essential impact on the limitations in patient's daily activities and social interactions. Psychological and psychosomatic techniques as behavioral therapy and autogenic training have shown significant supportive effect in controlling the itch–scratch behavior and eventually in improvement of the skin condition.

Prognosis

Nummular eczema is a chronic disease with relapsing and refractory course.

Onychomycosis

68

Dimitris Rigopoulos and Stamatis Gregoriou

Key Points

- Onychomycosis is the most common nail disorder and has a severe impact on health-related quality of life.
- Onychomycosis is caused by dermatophytes, yeasts, and non-dermatophyte molds and is more common in immunosuppressed and patients with nail trauma.
- There are five major clinical presentations of onychomycosis: distal and lateral subungual onychomycosis (DLSO), proximal subungual onychomycosis (PSO), superficial white onychomycosis (SWO), endonyx, and total dystrophic onychomycosis (TDO).
- Topical treatment is recommended for restricted disease. The most effective agents are 8 % ciclopirox and 5 % amorolfine nail lacquers.
- Systemic treatment is recommended in extensive disease. Terbinafine is more effective in dermatophyte infections.
- Treatment through the use of devices includes lasers and photodynamic therapy, but more evidence-based data are needed to obtain strong recommendation.
- Chemical or surgical nail avulsion should not be used as monotherapy but rather in combination with topical or systemic treatment.
- Treatment of choice should be individualized and should take into account the type of fungi isolated through direct microscopy and culture, the age of the patient, and concomitant use of other systemic medications.

Definition

Onychomycosis is the most common nail disorder. Even though some consider it just a cosmetic problem, hand nail onychomycosis may lead to pain, discomfort, and impaired tactile functions, while toenail dystrophy can impair walking and exercise. Onychomycosis has significant impact in health-related quality of life with both emotional and social function affected in patients with onychomycosis (Belyayeva et al. 2013).

Epidemiology

Onychomycosis affects up to 6 % of the population and represents 20–40 % of all nail disorders (Baran et al. 2006). Onychomycosis is more common in aged populations and patients with HIV infection

DOI 10.1007/978-3-662-45139-7_68, © Springer-Verlag Berlin Heidelberg 2015

or under immunosuppressive therapy. Activities predisposing to onychomycosis include sports participation, swimming in swimming pools, and occlusive footwear. Toe nails are more frequently affected than fingernails probably due to slower growth rate. Other predisposing factors include nail trauma, peripheral vascular disease, smoking, and psoriasis (Sehgal et al. 2010). Epidemiology of fungi causing onychomycosis varies according to geography. Dermatophytes are the most frequently implicated causative agents in onychomycosis (approximately 90 % in toenail and 50 % in fingernail). *Trichophyton rubrum* (*T. rubrum*) is the most common causative agent followed by *T. mentagrophytes*. Nondermatophyte molds (NDM) mainly affect toenails and occasionally fingernails and include *Scytalidium dimidiatum* and *Scytalidium hyalinum*, *Scopulariopsis brevicaulis*, *Aspergillus* species, *Onychocola canadensis*, and *Acremonium* species (Singal and Khanna 2011). Molds are considered pathogens when the following criteria are fulfilled:

1. Nail features consistent with onychomycosis
2. Positive direct microscopy
3. Failure to isolate a dermatophyte in the culture
4. Growth of more than five colonies of the same mold in at least two consecutive nail samplings (Tosti et al. 2000)

Yeasts can be either contaminants or pathogens in fingernail infections. *Candida albicans* accounts for 70 % of cases, while *C. parapsilosis*, *C. tropicalis*, and *C. krusei* can also be isolated. Chronic exposure to moisture and chemicals, as seen in laundry workers, house and office cleaners, food handlers, cooks, dishwashers, bartenders, chefs, fishmongers, confectioners, nurses, and swimmers, contributes to chronic paronychia accompanied by *Candida* onychomycosis (Rigopoulos et al. 2008).

Clinical Presentation

There are five major clinical presentations of onychomycosis:

- Distal and lateral subungual onychomycosis (DLSO)
- Proximal subungual onychomycosis (PSO)
- Superficial white onychomycosis (SWO)
- Endonyx
- Total dystrophic onychomycosis (TDO)

DLSO is the commonest clinical variant affecting both fingernails and toenails. The fungus enters via the distal subungual and lateral nail groove and spreads proximally. Clinically, there is onycholysis and subungual hyperkeratosis.

PSO is uncommon and often associated with immunosuppression. It affects both fingernails and toenails. The fungus first invades the proximal nail fold, migrates to the underlying matrix, and then spreads distally under the nail plate. Clinically, there is subungual hyperkeratosis, transverse leukonychia, and proximal onycholysis and eventually destruction of the proximal nail plate.

SWO affects mostly toenails. Clinically, small opaque white spots of leukonychia are present on the dorsal nail plates. Baran et al. have proposed a classification of SWO as classical SWO, dual invasion of the nail plate, superficial and ventral, and the pseudo-SWO with deep fungal invasion of the nail plate (Baran et al. 2004).

In endonyx onychomycosis the infection starts from the free edge, and the fungus penetrates the distal nail keratin of the nail plate where it forms milky white patches without subungual hyperkeratosis or onycholysis (Figs. 68.1 and 68.2).

In TDO there is total destruction of the nail plate where the nail crumbles and disappears leaving a thickened abnormal nail bed.

Candida may cause onycholysis with distal subungual hyperkeratosis with a yellowish gray mass that lifts off the nail plate.

Fig. 68.1 Dermatophytoma

Fig. 68.2 Endonyx

Diagnosis

Identification of the pathogen before initiating treatment is important in order to select the appropriate therapeutic agent.

Samples should be obtained from affected nails. The patient should have discontinued topical and systemic antifungal drugs for an appropriate duration (Table 68.1). The nail should be thoroughly cleaned with alcohol, the onycholytic nail plate should be clipped, and then scrapings should be obtained from the nail bed. Subsequently, direct microscopy of the specimen in 10–30 % KOH should be performed. The nail is examined for fungal hyphae, spore, or yeast forms. Culture confirms the diagnosis and identifies the fungus. Specimens should be sent for culture even when direct microscopy is negative. Different media are used to grow different fungal species. Colonies of most dermatophytes are usually completely differentiated in 2 weeks. Absence of growth after 3–6 weeks should be considered as negative. False-negative results may be attributed to inappropriate nail sampling (Singal and Khanna 2011).

Table 68.1 Time needed to discontinue medication in order to obtain a nail sample for a credible direct microscopy and culture

Drug	
Topical agent	4 weeks
Itraconazole	9 months
Terbinafine	8 weeks
Fluconazole	1 week

Histopathology may be necessary when direct microscopy and culture are repeatedly negative in patients with clinical signs of onychomycosis. Nail plate clippings are stained with periodic acid-Schiff (PAS) staining to evaluate the presence or absence of fungi.

Other less frequently used tests to diagnose onychomycosis include immunohistochemistry and dual flow cytometry especially for identifying mixed infections and for quantification of fungal load in the nail. DNA-based methods such as PCR-RFLP assays have been used recently for detecting fungi (Bontems et al. 2009). The role of scanning electron microscopy and confocal microscopy at present is primarily for research.

General Principles of Treatment

Treatment options for onychomycosis include topical agents, systemic agents, chemical or surgical nail avulsion, and devices such as lasers and photodynamic therapy.

Topical Treatments

Topical agents are the mainstay of onychomycosis treatment. A recent study with 1,447 patients with onychomycosis showed that 89.1 % were prescribed a topical agent either as monotherapy or in addition to other treatment (Di Chiacchio et al. 2013). The 2005 consensus on treatment guidelines for onychomycosis suggests topical treatment if:

A. Nail surface involvement is less than 50 %
B. Number of nails involved are less than 5
C. Nail matrix is not affected
D. There is a contraindication for systemic treatment

In addition topical treatment can be used as adjuvant to systemic treatment and nail avulsion or as prophylaxis after systemic treatment. Immunosuppressed patients or patients with nail thickness more than 2 mm should be considered for systemic treatment regardless of other factors (Lecha and Effendy 2005).

Permeation of nail plate by water-soluble or lipophilic vehicles is poor. Nail plate shows a radically different biochemistry from the skin consisting of 15 % water and less than 5 % lipids (van de Kerkhof et al. 2005). Bovine hoofs often used as in vitro models for evaluating nail permeation have been reported to have 14-fold more permeation when compared to human nails (Monti et al. 2011). An ideal topical agent should be able to exhibit prolonged presence on the nail plate after application and increased concentration on the nail plate after evaporation of the vehicle. Treatment outcomes are also dependent on compliance which is known to be compromised for prolonged therapies. A study on compliance of patients using topical agents for onychomycosis reported an overall compliance of 23.9 %. Successful treatment was observed in 63 % of patients with adequate compliance; on the other hand only 2 % of patients with poor response achieved complete remission of onychomycosis (Zhou et al. 2011).

Ciclopirox 8 % Lacquer

Ciclopirox is a synthetic hydroxypyridone antifungal agent. Glucuronidation is the main metabolic pathway of ciclopirox; therefore, it does not normally interact with drugs metabolized via the cytochrome P450. Ciclopirox does not interfere with ergosterol biosynthesis. It chelates trivalent cations, inhibits metal-dependent enzymes that are responsible for degradation of toxic metabolites in the fungal cells, and targets metabolic and energy-producing processes in microbial cells. Ciclopirox is a broad-spectrum antimicrobial that includes dermatophytes, yeasts, and non-dermatophyte molds. It is also effective against some Gram-positive and Gram-negative bacteria including resistant strains of *Staphylococcus aureus*. After evaporation of volatile solvents in the lacquer, the concentration of ciclopirox in the remaining lacquer film reaches approximately 35 %, providing a high concentration gradient for penetration into the nail. It achieves fungicidal concentrations inside the nail plate for most pathogens. Although ciclopirox readily penetrates nails, very low levels of ciclopirox are recoverable systemically, even after chronic use. This unique and multilevel mechanism of action provides a very low potential for the development of resistance in pathogenic fungi, with cases of resistance rarely reported (Subissi et al. 2010). Mycological cure rates after daily application for 48 weeks (negative culture and negative light microscopy) have been reported to range between 29 % and 85.7 %, while complete cure rate (clinical cure plus mycological cure) has been reported to range between 5.5 % and 8.5 %. The most common adverse event is the appearance of mild erythema in 5 % of the treated population (Gupta et al. 2000).

Amorolfine 5 % Lacquer

Amorolfine is a structurally unique, topically active antifungal agent that belongs to morpholines. It inhibits ergosterol biosynthesis, modifies fungal cellular membrane permeation, and inhibits fungal metabolic pathways. It possesses both fungistatic and fungicidal activity in vitro. Its spectrum of in vitro activity includes dermatophyte, dimorphic, some dematiaceous and filamentous fungi, and some yeasts. The amorolfine concentration in the nail plate following application of 5 % nail lacquer is 25 %. In clinical trials, application of amorolfine 5 % nail lacquer once or twice weekly for up to 6 months produced mycological and clinical cure in approximately 40–55 % of patients with mild onychomycosis 3 months after cessation of therapy (Banerjee et al. 2011).

Tioconazole 28 % Nail Solution

Tioconazole is an imidazole antifungal agent. Percutaneous absorption of tioconazole is negligible suggesting it is unlikely to produce systemic side effects. It has been shown to have a broad spectrum of activity in vitro against dermatophytes and yeasts, as well as against some chlamydia, trichomonads, and Gram-positive

bacteria. It inhibits ergosterol synthesis and additionally has a toxic effect on fungal cellular membrane (Sobue and Sekiguchi 2004). Complete cure rates after twice daily application of tioconazole 28 % nail solution for 48 weeks has been reported to be 22 % (Hay et al. 1985).

Miconazole 2 % Tincture

There are scarce data in medical literature about the efficacy of miconazole 2 % tincture on the treatment of onychomycosis. The tincture leaves a brownish hue on the nail after multiple applications. A study reported 13 dropouts out of 23 patients using miconazole treatment. At least partial response was observed in 80 % after application for 32 weeks (Bentley-Phillips 1982).

Nail Avulsion

Nail avulsion can be performed either surgically or chemically. Application of urea 40 % formulation followed by ketoconazole, oxiconazole, or bifonazole cream results in 50–75 % mycological cure after 12 weeks (Grover et al. 2007; Tsuboi et al. 1998). Removal of the nail by itself has poor or no result in mycological cure (Malay et al. 2009). Compliance of therapy after nail avulsion could be compromised as all studies report a 50 % dropout rate.

Topical Agents for Prophylaxis

Topical application of amorolfine for 52 weeks after complete nail cure has been reported to decrease recurrence to 29.2 % compared to 50 % among those not using prophylactic application after 3 years (Sigurgeirsson et al. 2010).

Systemic Treatments

A clinician should always evaluate efficacy, safety, and cost when deciding on systemic treatment options for onychomycosis. Oral therapy is recommended in:

1. Moderate to severe onychomycosis
2. Multiple nail involved
3. Immunocompromised patients
4. Matrix involvement
5. Failure of previously used topical therapies

Oral antifungals used to treat onychomycosis include griseofulvin; azoles including ketoconazole, itraconazole, and fluconazole; and the allylamine terbinafine. Azoles inhibit ergosterol synthesis and increase fungal cell membrane permeability by reducing the activity of various enzymes. Ketoconazole is rarely used nowadays because of risk of severe hepatic side effects. Griseofulvin takes a long time to achieve therapeutical concentration in the nail and persists for just 2 weeks after stopping therapy. Consequently administration is prolonged (4–9 months for fingernails and 10–18 months for toenails,) and results in poor compliance. Mycological cure rates are low making griseofulvin the least preferred agent. The adult dose is 500 mg to 1 g daily to be administered after a fatty meal (Roberts et al. 2003).

Itraconazole

Itraconazole is a triazole with spectrum against dermatophytes, *Candida*, and NDM. It is highly lipophilic and bioavailability is increased if received after food intake. Itraconazole gets into the nail through both matrix and nail bed 7 days after starting therapy and remains for up to 6–9 months post-treatment. It achieves high concentrations even in subungual hyperkeratosis (567 ng/g). Itraconazole classical regimen is a dose of 200 mg once daily for 3 months. A pulse regimen with 200 mg twice daily for a week every month with two such pulses for fingernail onychomycosis and three for toenail disease has been reported to be as effective as the continuous (Gupta and Ryder 2003). Drug interaction may potentially occur because of binding of itraconazole to cytochrome P450 3A4 system in the liver. Common adverse reactions include headache and gastrointestinal adverse events. Less common adverse events include asymptomatic liver function abnormalities and hepatitis. Monitoring for hepatic functions is recommended only in patients with preexisting liver disorders or concomitant uptake of hepatotoxic drugs. It is contraindicated in patients with congestive cardiac failure due to increased risk of negative ino-

tropic effects and in patients receiving H1 and H2 inhibitors because it increases the risk for arrhythmia (Singal and Khanna 2011). Itraconazole is not approved for children less than 12 years old.

Fluconazole

Fluconazole does not have an on-label use in the treatment of onychomycosis. However, it is highly effective against both *Candida* and dermatophytes. It has been detected in nails within 7 days after initial dose and remains for 3–6 months after treatment. Weekly administration is sufficient and uptake should not necessarily be associated with meals. Dosage in published studies varies between 150 and 450 mg per week for 5–12 months. The common adverse effects include headache, skin rash, gastrointestinal complaints, insomnia, and palpitations. Fluconazole inhibits both CYP3A4 and CYP2C9, and close monitoring is required when prescribing drugs metabolized by these enzymes. Simultaneous use of fluconazole and terfenadine or cisapride is contraindicated (Singal and Khanna 2011).

Terbinafine

Terbinafine is an allylamine. It inhibits fungal squalene epoxidase, resulting in accumulation of squalene, dysfunction of fungal cell membrane, and death of the fungal cell. In vitro terbinafine is fungicidal against dermatophytes, NDM (*Aspergillus fumigatus* and *Scopulariopsis brevicaulis*), and *C. parapsilosis* and fungistatic against *C. albicans*. Terbinafine is well absorbed orally with >70 % bioavailability. It is detectable in the nail 7–21 days after initial dose and up to 9 months after treatment. Approved continuous treatment consists of 250 mg daily for 6 weeks for fingernail and 12 weeks for toenail onychomycosis. Pulse regimens of terbinafine have also been used with success in the treatment of onychomycosis. Gupta et al. employed two courses of terbinafine (250 mg daily for 4 weeks) alternating with 4 weeks interval without terbinafine and found it to be as effective as continuous terbinafine and more efficacious than pulse itraconazole for treatment of toe nail onychomycosis (Gupta et al. 2009). Common adverse reactions with terbinafine include gastrointestinal symptoms, skin rash, pruritus, urticaria, asymptomatic liver enzyme abnormalities, and taste disturbances. Severe adverse drug reactions are infrequent and include agranulocytosis, hepatitis, acute generalized exanthematous pustulosis, and lupus erythematosus. Terbinafine is metabolized by cytochrome P450 enzymes, and therefore, concentration is decreased by rifampicin and increased by cimetidine. It decreases cyclosporin levels and inhibits the cytochrome P450 enzyme CYP2D6 responsible for metabolism of tricyclic antidepressants, beta-blockers, selective serotonin reuptake inhibitors, and monoamine oxidase inhibitors type B (Singal and Khanna 2011).

Head on Comparative Studies

The LION study demonstrated superiority of the continuous terbinafine regimen over intermittent itraconazole regimen in both mycological and clinical cure and lower risk of recurrence (Sigurgeirsson et al. 1999). A meta-analysis of randomized controlled trials by Gupta et al. reported mycological cure rates of 73–79 % for terbinafine, 56–70 % for itraconazole pulse, and 54–64 % for pulse itraconazole regimens. The corresponding values for clinical response were as follows: terbinafine 61–71 %, pulse itraconazole 59–81 %, and continuous itraconazole 65–75 % (Gupta et al. 2004).

Device Treatment

Device treatment seeks to address some of the unmet needs of onychomycosis therapy such as high rates of relapse, drug adverse events, and fungal resistance. Currently there are four categories of device-based treatments: laser devices, photodynamic therapy, iontophoresis, and ultrasound.

Lasers

Fungi are heat sensitive above 55 °C, so absorption of laser energy is likely to result in fungicidal effects. However, heating dermal tissue to temperatures above 40 °C results in pain and necrosis; therefore, the laser energy format must either be pulsed to allow the dissipation of heat by the tissue through its superior thermal conduction or

delivered at a moderate energetic level to prevent tissue damage (Gupta and Simpson 2012).

Long-pulse Nd:YAG lasers have been used to treat the nail in a spiral pattern with 30–40 J/cm2 energy fluence with a spot size of 4 mm and a pulse duration of 35 ms. Treatment was repeated after 2 min. Participants received two treatments per session with a 2 min interval, four sessions at 1 week intervals, and they were followed after therapy from 12 to 30+ months. A completely clear nail plate was achieved by 93.5 % of participants (Kozarev and Vizintin 2010). Flashlamp pumped short pulse Nd:YAG 1,064 nm lasers have also been reported to be effective in the treatment of onychomycosis. Treatment protocol used was four sessions, at 1 week intervals with a pulse length of 0.3 ms, an energy fluence of 13 J/cm2, and a repetition rate of 6 Hz. Follow-up mycological culture was negative in 95 % of patients (Gupta and Simpson 2012). Q-switched lasers emit the highest peak power per pulse of all the Nd:YAG lasers. They have also been reported to have efficacy in the treatment of onychomycosis(Gupta and Simpson 2012). The diode lasers that are currently under investigation for onychomycosis operate at near-infrared wavelengths. Studies have shown that 870 and 930 nm wavelength treatment comprised of 4 min of dual wavelength therapy, followed by 2 min of 930 nm treatment showed an 85 % improvement of infection in 26 toes treated at 180 days (Landsman et al. 2010). However, more evidence-based data is needed.

Photodynamic Therapy

5-Aminolevulinic acid (ALA) and methyl aminolevulinate (MAL) are precursors of heme. They cause a buildup of protoporphyrin IX (PpIX) that, in the presence of the correct spectrum of light, generates reactive oxygen species that initiate apoptosis. Case reports and two case series have reported controversial results regarding efficacy in the treatment of onychomycosis. The protocols developed for these studies indicate that the nail plate should be pretreated with urea ointment to soften the nail plate prior to application of the photosensitizer. Treatment length has been reported to be 3–5 h for each session with an irradiation source of 570–670 nm at 36–100 J/cm2 repeated for one to three sessions (Watanabe et al. 2008; Piraccini et al. 2008; Sotiriou et al. 2010; Gilaberte et al. 2011).

Iontophoresis

There are two iontophoresis devices currently in clinical trials. Iontophoresis has been reported to increase the amount of terbinafine accumulated in the nail plate. The nail plate then acts as a reservoir of terbinafine that is then released into the nail bed and matrix over 60–70 days. Mycological cure after three sessions of iontophoresis with terbinafine has been reported to reach 84 % (Amichai et al. 2010).

Special Populations

Children

Prevalence of onychomycosis in children is extremely low, possibly because of faster nail growth. Griseofulvin has an on-label use in children in a dosage of 10 mg/kg daily. Terbinafine is approved for use in children above 4 years of age. However, terbinafine, fluconazole, and itraconazole have been used safely with favorable outcome in children aged 2 years and above (Gupta et al. 1998).

Elderly

Treatment of onychomycosis in the elderly may include no therapy, mechanical or chemical debridement, topical and oral agents, or combination of these modalities. Debridement is more used more frequently than in younger patients because nail dystrophy is more common because of high prevalence of arthritis problems. Systemic treatment should be used with caution because the risk for drug interactions is increased due to multiple medications received.

Pregnancy and Lactation

Terbinafine is category B drug while itraconazole and fluconazole are in pregnancy category C. Use of all these drugs should be avoided in pregnancy. All oral antifungals are excreted in breast milk and therefore contraindicated in lactating mothers.

Future Options

Oxaboroles include tavaborole and benzoxaborole and have shown good efficacy against *Trichophyton rubrum* and *Trichophyton mentagrophytes* and excellent penetration of the nail plate (Alley et al. 2007). A lacquer employing 10 % eficonazole used once daily for 48 weeks has shown 15–18 % complete cure in patients with onychomycosis (Elewski et al. 2013). A solution of amphotericin B applied for 12 months resulted in 100 % mycological cure in eight patients with NDM (Lurati et al. 2011). Considerable resources have been allocated in the development of new permeation enhancers such transfersomes that release terbinafine and nanoemulsions (Sigurgeirsson and Ghannoum 2012). Systemic treatment with posaconazole has been reported to be as effective as treatment with terbinafine in patients with onychomycosis (Elewski et al. 2012). There are only case reports about the systemic use of voriconazole in the treatment of onychomycosis (Spriet et al. 2012).

Key Points

- Pemphigus foliaceus and pemphigus erythematosus are autoimmune diseases of the skin associated with an autoantibody response directed against desmoglein-1, a component of desmosomes in human epidermis.
- Their incidences greatly vary in different countries and continents. In South America and North Africa, endemic forms of pemphigus foliaceus exist, the prevalence of which is relatively high.
- Clinical presentation is characterized by development of fragile bullae, which rapidly rupture, resulting in erosions, crusting, and scaling. Lesions may remain either localized to the seborrheic areas of the face, scalp, back, and chest or generalize.
- In patients affected by pemphigus erythematosus and the sporadic form of pemphigus foliaceus, drug triggering should always be considered and excluded.
- Management of pemphigus foliaceus does not greatly differ from that of pemphigus vulgaris. Systemic corticosteroids

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_69, © Springer-Verlag Berlin Heidelberg 2015

represent the mainstay of therapy and are usually combined with an immunosuppressive adjuvant. Dapsone and, in treatment-resistant cases, rituximab may be employed with substantial benefit.

Definition and Epidemiology

Pemphigus foliaceus (PF) is a chronic autoimmune blistering disease of the skin, characterized by autoantibodies against a structural component of the epidermal desmosome, desmoglein 1 (Dsg1). Binding of anti-Dsg1 antibodies to the antigen results in subcorneal split formation, dissociation of keratinocytes with loss of cell-cell adhesion (acantholysis) in the superficial epidermis and, clinically, flaccid bullae. The sporadic form of PF most commonly starts in adulthood, with equal distribution in both sexes. Its incidence is low, with 0.1–1/million new cases per year. In contrast, there is an endemic form of PF, which is relatively common in distinct subtropical areas of Brazil and Colombia, where the prevalence of the disease is up to 3–5 %. PF affects predominantly young women with painful erosions (*fogo selvagem*, Portuguese for *wild fire*). Further endemic forms exist in Northern Africa (e.g., Tunisia, Mali, Egypt). Pemphigus erythematosus (PE; syn. Senear-Usher syndrome) is a localized form of PF with lesions typically developing on the face and the upper trunk and back (Figs. 69.1 and 69.2).

Fig. 69.1 Pemphigus foliaceus, localized disease. The presence of isolated erythematous, scaling lesions on the trunk. Superficial fragile blisters occur leaving eroded areas. Insert with close-up view of some lesions

Fig. 69.2 Pemphigus foliaceus, localized disease with the presence of isolated erythematous and scaling lesions on the scalp, ear, and neck. Based on these features mimicking seborrheic eczema, the condition is also called seborrheic pemphigus

Basic Concepts of Pathogenesis

Pemphigus diseases are autoimmune in nature. The exact mechanisms leading the human immune system to react against normal skin components are far from being understood in detail. In PF, IgG antibodies (abs) against Dsg1 are formed (with involvement of both B and T cells), circulate in the bloodstream, and bind to their target skin antigen. The direct pathogenicity of these antibodies has been shown convincingly in vitro and in vivo. Even as monovalent cloned single-chain variable fragments, these abs can cause loss of cell-cell adhesion in the superficial epidermis where Dsg1 is highly and specifically expressed.

Interestingly, B cells from individuals without PF can potentially produce nonpathogenic antibodies against the precursor protein of Dsg1 (preDsg1), and ELISA screening of individuals from endemic areas frequently detects serum anti-preDsg1 IgG (which is not found in cohorts of US-American or Japanese individuals). As suggested by this geographical clustering of cases, the transition from nonpathogenic to pathogenic IgG abs, which finally bind the mature Dsg1 protein, might be triggered by environmental factors. In case of Brazilian *fogo selvagem*, anti-Dsg1-specific PF sera have been described to cross-react with a sand fly salivary antigen, implying a precipitating role for this vector.

When PE was first described by Senear and Usher in 1926, they suggested that the presentation with a lupus-like rash or seborrheic dermatitis was a combination of pemphigus and cutaneous lupus erythematosus. This hypothesis has been abandoned, as, in most cases, serum antinuclear abs are absent in PE and patients do not meet the American College of Rheumatology (ACR) criteria for systemic lupus erythematosus. In lieu thereof, the "lupus-band" phenomenon in PE patients may be apportioned to UV irradiation-induced basement membrane zone deposition of complexes of Dsg1 ectodomains and Dsg1-specific IgG abs, thus somehow resembling lupus bands found in patients with various cutaneous forms of lupus erythematosus.

Clinical Presentation

In contrast to pemphigus vulgaris, in PF there is only skin involvement, without mucosal lesions, although very rarely transitions from PF to pemphigus vulgaris and vice versa have been described (Figs. 69.3 and 69.4).

Whereas endemic PF also occurs in children and adolescents, sporadic PF frequently occurs in middle age. The seborrheic areas of the face, scalp, back, and chest are preferentially affected in both forms. Because of the localization of acantholysis in the upper epidermis, the resulting blisters are very fragile and rapidly rupture. The Nikolsky sign may be positive. In the course of disease, hyperkeratotic, crusting "puff pastry–like," psoriasiform, or seborrheic scales develop. Erosions heal without scarring but typically result in postinflammatory hyperpigmentations. In some cases, the extensive exfoliation may resemble erythroderma, a complication commonly seen in *fogo selvagem*. All erosions are subject to possible bacterial (and viral) superinfection, with rarely sepsis.

Fig. 69.3 Pemphigus foliaceus, extensive disease with widespread erythema, erosions, crusts, and scaling of the gluteal region

Fig. 69.4 Pemphigus foliaceus, extensive disease with erythrodermic involvement. Widespread erythematous psoriasiform lesions in a young woman living in North Africa

Clinical features of PE on the face, back, and trunk may closely resemble those of cutaneous lupus erythematosus with erythema and scaling. As most patients with PE do not meet the ACR criteria for systemic lupus erythematosus, PE should clearly be separated from the few cases in which PF coincide with cutaneous lupus erythematosus.

Drug-Induced Pemphigus Erythematous and Pemphigus Foliaceus

Association of disease onset with certain drugs is well recognized and should be actively excluded in all patients with PE and PF. Two groups of medication related to the occurrence of pemphigus have been identified, sulfur-containing drugs (thiol drugs) and drugs not containing sulfur. Penicillamine and captopril, both drugs that contain a thiol group, are the most frequently reported triggers. Among the other group, non-sulfhydryl angiotensin-converting enzyme inhibitors, pyrazolone derivatives, penicillin, and rifampicin have been frequently described. Thiol compounds have been particularly implicated in PF triggering. In these cases, pemphigus disease can remit spontaneously in up to 50 %, after drug withdrawal.

Diagnosis and Differential Diagnosis

Following the in 2013 validated European Guidelines for diagnosis and treatment of pemphigus, four criteria have to be considered to confirm the diagnosis (Hertl et al. 2013):

1. Clinical presentation (see above).
2. Histopathology: For histopathology a 4 mm punch biopsy should be taken of a fresh small vesicle or one third of the peripheral portion of a blister and two thirds perilesional skin. In PF, acantholysis at the granular layer is expected leading to subcorneal splitting.
3. Direct immunofluorescence (IF) microscopy of a perilesional skin biopsy: For this purpose, a skin biopsy of perilesional skin is taken and analyzed for IgG and/or C3 deposits in the epidermis. In PE, "lupus-band-like" deposits may be noted along the cutaneous basement membrane, in particular in sun-exposed areas.
4. Serological detection of serum antibodies that label, by indirect IF microscopy, the cytoplasmic cell membrane of typically used substrates such as monkey or guinea pig esophagus and anti-Dsg1 abs by ELISA: The pattern of indirect IF microscopy on monkey esophagus is expected to be reticular and "fishnet like." For ELISA, two commercial systems are available to test for anti-Dsg1 antibodies (Euroimmun, Lübeck, Germany; MBL, Nagoya, Japan). In general, ELISA values correlate well with the extent and activity of the disease.

Differential diagnoses of PF and PE include:

- Pemphigus vulgaris (mucosal lesions always present; histopathology with suprabasal "tombstone-like" acantholysis, ELISA for Dsg3-specific abs positive)
- Drug-triggered bullous eruptions (negative direct IF microscopy, negative Dsg1 ELISA)
- IgA pemphigus (intraepidermal neutrophilic dermatosis and subcorneal pustular dermatosis, IgA reactivity with desmocollin occasionally found)
- Bullous impetigo (microbiology) and staphylococcal scalded skin syndrome (negative IF microscopy/ELISA studies)
- Neutrophilic dermatoses (negative IF microscopy/ELISA studies)
- Cutaneous lupus erythematosus (histopathology, direct IF microscopy, ACR criteria)
- Other acantholytic dermatoses (Hailey-Hailey disease, Darier's disease, Grover's disease, here negative IF microscopy/ELISA studies)

General Principles of Treatment

Therapy aims at induction and maintenance of remission in patients, with reduction of pathologic autoantibodies, and prevention of further blistering, erosion of skin, or other complications (bacterial and viral infections).

Given the rarity of PF and PE, data from large, randomized controlled clinical trials (RCTs) are sparse, and the recent publication of *consensus statements* with common definitions and end points will help to conduct future studies.

However, the mainstay of therapy is general immunosuppression with corticosteroids (CS), and the use of adjuvant immunosuppressants has been shown to exert a steroid-sparing effect that is highly desirable in long-term CS administration. Treatments for pemphigus vulgaris and PF do not differ, except for the point that PF and PE are generally thought to be better responsive to therapy, although no comparative data are available.

Corticosteroid doses are generally being calculated with prednisone as reference; low doses equal to <7.5 mg/day of prednisone equivalent, 7.5–30 mg/day (or: 0.5 mg/kg/day) correspond to medium, and 30–100 mg/day (or: >0.5 mg/kg/day) to high doses. Pulsed therapy relates to >250 mg/day of prednisone equivalent for a few days.

Prior to initiation of CS and additional immunosuppressive therapy, serological tests for the following entities are indicated: complete blood count, blood electrolytes, creatinine, liver enzymes, and fasting serum glucose (complemented by an oral glucose tolerance test, where applicable). Depending on the treatment considered and on the individual patient situation, the authors recommend the following additional investigations: tuberculin skin test and/or interferon-gamma release assay (to prevent reactivation of latent or chronic TB), chest X-ray, serologies for HIV, hepatitis B and C, testing for serum IgA deficiency (if IVIg is considered), thiopurine methyltransferase (TPMT) activity (if azathioprine is considered), G6PD serum activity (if dapsone is considered), beta-HCG (to exclude pregnancy in females of childbearing age), bone density scan (prior to CS treatment, especially in postmenopausal women), and ocular examination (to exclude glaucoma or cataract).

First-Line Treatment as Recommended by the 2013 European Guideline and Overview of Selected Studies

Especially in initial control of newly diagnosed cases, CS represents the first-line choice of treatment (Table 69.1).

CS dosing in PF is largely empirical. The 2013 European S2 Guideline for diagnosis and treatment of pemphigus (Hertl et al. 2013) recommends initial systemic CS therapy at 0.5–1.5 mg/kg/day. If initial control is not reached within 2 weeks, a higher prednisone dose is advised.

Table 69.1 Algorithm for treatment of pemphigus

	Remarks
First line	
Corticosteroids (1.0–1.5 mg/kg/day initial dose; tapering by 25 % dose reduction every 2 weeks (more extended <20 mg day^{-1}))	Dose is given as prednisone equivalent; optimal dose not validated
Second line	(*In refractory disease, in addition to first-line therapy*)
Azathioprine (1–2.5 mg/kg/day), mycophenolates (2 g day^{-1}), or cyclophosphamide (500–750 mg i.v. as bolus or 50 mg/day p.o.)	Steroid-sparing effects are demonstrated for all immunosuppressants listed
Third line	(*In refractory disease, or in case of contraindications to immunosuppressive agents*)
Rituximab (2 × 1 g i.v. (2 weeks apart) or 4 × 375 mg m^{-2} (each 1 week apart)), IVIg (2 g/kg/month), immunoadsorption (on 3–4 consecutive days with 3–4-week intervals), dapsone (100 mg/day or up to 1.5 mg/kg/day), methotrexate (10–20 mg/week)	

Adapted from the 2013 European Guidelines, (Hertl et al. 2013)

As high-dose CS therapy did not differ from medium-dose usage (with regard to time to remission and relapse rates) in a prospective study with 22 pemphigus patients by Ratnam et al. (1990), moderate and individually adjusted CS use is advocated to prevent potentially severe side effects as hyperglycemia, osteoporosis, or iatrogenic Cushing's syndrome. When no new lesions appear and old ones begin to heal, CS are tapered by 25 % of the initial dose and, every 2 weeks, by another 25 % (with extended tapering at doses <20 mg/day). Nevertheless, there is little data supporting such a tapering regimen, which should be

always adjusted to the clinical context, response to therapy, clinical tolerance, and existing comorbidities. If lesions reappear during tapering of oral CS therapy, the dose should be increased again (and a change in adjuvant immunosuppression may be considered).

First-Line Adjuvants

Systemic CS are generally combined with an immunosuppressive adjuvant, although both the molecule of first choice and the best time for its introduction remain unclear (i.e., as early as possible vs. treatment-resistant cases or when contraindications to corticosteroid therapy exist). Following the 2013 European Guideline, first-line adjuvants are azathioprine (AZA) at doses of 1–3 mg kg/day and mycophenolate mofetil (MMF; 2 g/day) or mycophenolic acid (MPA; 1,440 mg day^{-1}).

In a large 4-arm RCT with 120 patients by Chams-Davatchi et al. (2007), the steroid-sparing effect of AZA has been shown to be superior to that of MMF. Beissert et al. (2006) compared two combination therapy protocols (CS plus AZA, both at 2 mg/kg/day, vs. CS plus MMF, at dosages of 2 mg kg/day and 2 g/day) and could not find differences regarding the clinical end points. In an intention-to-treat analysis, this study suggested that AZA had lower effectiveness than MMF in induction of disease control. In another RCT, Beissert et al. (2010) compared two protocols (CS [1–2 mg/kg/day] plus MMF [2–3 g/day] vs. CS [1–2 mg/kg/day] plus placebo). These authors were unable to demonstrate superiority of the combined regimen compared to CS alone as primary end point. As secondary end points, patients with adjuvant MMF appeared to have a shorter time to response and a more sustained duration of response. Nevertheless, the high dropout rate (>20 %), the side effects profile in the MMF group, and costs of MMF make any conclusion difficult. The most important side effects and peculiarities of the compounds discussed here are summarized in Table 69.2.

Second-Line Adjuvants

Options compliant with the 2013 guidelines are anti-CD20 monoclonal antibody (i.e., rituximab), intravenous immunoglobulins (IVIg), immunoadsorption, cyclophosphamide, methotrexate, and dapsone.

- Rituximab (RTX) is a chimeric IgG1 anti-CD20 monoclonal antibody that specifically binds the human CD20 antigen, expressed on the majority of B cells, except for early B-cell progenitors and plasma cells. RTX is usually given as either four weekly infusions of 375 mg m^{-2} (lymphoma protocol) or as two 1 g infusions, separated by 2 weeks (rheumatoid arthritis protocol). It is indicated in patients who remain dependent on more than 10 mg CS per day (combined with an immunosuppressive adjuvant). This treatment can be repeated with a single infusion of 1,000 mg (or even 500 mg) in case of clinical relapse and as early as 6 months after initial administration. So far, no RCT on RTX therapy in pemphigus has been published. Two uncontrolled prospective studies by Ahmed et al. (2006) and Joly et al. (2007) demonstrated initially high response rates: clinical remission after RTX administration (and, in one study, concomitant IVIg) was noted in 81–86 % of patients, which was, however, not sustained in every patient. In a recent retrospective study with 47 patients by Leshem et al. (2013), remission rates were 76 % after one cycle and 91 % after a second cycle. At a median follow-up time of 8 months, 22 % of patients experienced a relapse, and additional cycles led to remission in 75 % of those individuals. Of note, a retrospective study by Lunardon et al. (2012) underlined a higher efficacy in those patients treated earlier in the course of disease. A meta-analysis of 20 PF patients reported severe adverse events in only one (5 %) patient who developed a bacterial sepsis in contrast to severe adverse events (two of them fatal) in 14 (14 %) of 103 PV patients.

Table 69.2 Side effects of first- and second-line drugs in therapy of pemphigus, as mentioned in the text

Compound	Dosing	Peculiarities	Potential side effects
Corticosteroids, CS	1.0–1.5 mg/kg/day initial dose (prednisone equivalent)	Adjust dose to disease activity; combination with CS-sparing immunosuppressants often indicated	Hyperglycemia, osteoporosis, weight gain, Cushing's syndrome, fluid retention, immunosuppression, glaucoma, cataract, increased blood pressure, thinning of skin, mood changes
Azathioprine	1–2.5 mg/kg/day	Slow onset of efficacy; frequent controls of blood counts necessary; adjust dose to TPMT activity	Myelosuppression (usually manifested as neutropenia), nausea, immunosuppression, hepatotoxicity, increased risk for nonmelanoma skin cancers or lymphoma
Mycophenolates	2 g/day	Differences of bioactive MPA serum levels between patients; side effects profile more favorable compared to AZA but higher costs	Nausea, vomiting, reversible hematological adverse effects as leukopenia, thrombocytopenia; immunosuppression; rare cases of PML
Rituximab	2 × 1 g i.v. (2 weeks apart) or 4 × 375 mg m^{-2} (each 1 week apart)	Remarkable effect in treatment-resistant cases. Reinfusion may be necessary upon relapse; immunogenic potential of compound	Severe infections, deep venous thrombosis, sepsis, urticaria, arthralgia, anemia
Intravenous immunoglobulins	2 g/kg/month	May be cost-effective, although expensive; should be given in combination with other immunosuppressants; alternative for pregnant pemphigus patients	Infusion reaction (chills, pyrexia, tachycardia), aseptic meningitis, migraine, headache, renal insufficiency
Immunoadsorption	On 3–4 consecutive days with 3–4-week intervals	Fast removal of pathogenic serum antibodies; adsorption over 3–4 consecutive days; adjuvant treatment	Hypotension, bradycardia, sepsis (in particular with central venous line)
Cyclophosphamide	500–750 mg i.v. (as bolus) or 50 mg/day	Formation of metabolites, e.g., acrolein (needs to be antagonized with Mesna); prophylaxis of *Pneumocystis* (*carinii*) *jiroveci* pneumonia	Hematologic, gastrointestinal, pulmonary toxicities; risk of secondary malignancies after prolonged exposure (i.e., >20 g cumulative dose); gonadal toxicity and infertility after cumulative doses of >5 g
Methotrexate	10–20 mg/week	Anti-inflammatory properties	Myelosuppression, hepatic toxicity, pulmonary fibrosis
Dapsone	50–100 mg per day or up to 1.5 mg/kg/day	Anti-inflammatory properties; regular laboratory work-up with complete blood cell counts and liver enzymes required	Methemoglobinemia, hemolysis, agranulocytosis, very rare: hypersensitivity syndrome ("dapsone syndrome") with fever, rash, eosinophilia involvement of internal organs

- High-dose IVIg are clinically effective in pemphigus, as shown by a RCT in 61 Japanese patients. In this study, patients with PV and PF who did not respond to prednisolone doses of >20 mg day over at least 7 days received, over 5 consecutive days, a single cycle of 200 or 400 mg/kg/day or placebo. Lowering of disease activity and serum levels of anti-Dsg

antibodies in a dose-dependent manner was observed. The 2013 European Guidelines recommend combination of IVIg (2 g/kg/cycle^{-1}; applied monthly over 2–5 days) with systemic CS and immunosuppressive adjuvants, as IVIg alone may not lead to long-term suppression of autoantibody synthesis. Its favorable properties also render IVIg a very safe therapeutic alternative in pregnant pemphigus patients.

- Immunoadsorption (IA) allows for fast removal of circulating antibodies and is recommended as an option in patients who have not sufficiently responded to first-line treatment. Performed on 3 consecutive days, IA is capable of lowering anti-Dsg serum IgG by 95 % compared to initial measurements, and by combining IA with standard immunosuppressive therapy, reductions of about 90 % were maintained after 12 months (Schmidt et al. (2009)). Combination of IA with standard immunosuppressive therapy and the anti-CD20 monoclonal antibody RTX is reported with 80–96 % of patients in complete remission after 6–9 months of protocol treatment, and with 91 % overall complete remission rate after a mean follow-up of 33 months (Behzad et al. (2012), Kasperkiewicz et al. (2012a, b)). By this combination therapy, patients benefit from both the rapid reduction of serum autoantibody levels by IA and the excellent long-term effects of RTX.
- Cyclophosphamide (CYC) is an alkylating agent resulting in reduced lymphocyte counts, affecting both T and B cells. It shows the capacity to spare steroids, an effect, which was less attenuated that that of AZA and superior to that of MMF (Chams-Davatchi et al. (2007)). Oral administration at doses of 1–2 mg/kg/day may result in significant cumulative doses, and CYC-sparing pulsed monthly i.v. protocols were applied in pemphigus (Sethy et al. (2009)). Given the severe side effects (Table 69.2), safer therapeutic approaches such as rituximab, IVIg, and IA are currently replacing CYC in Europe and Northern America.
- Methotrexate (MTX) is a folic acid antagonist with antitumorigenic properties (at high concentrations) and anti-inflammatory properties (at low doses). Retrospective studies suggest clinical improvement at doses of 10–50 mg/week and a beneficial effect in control of less severe cases of pemphigus.
- Dapsone is a long-established sulfone derivative with both antibiotic and anti-inflammatory effects. In one placebo-controlled, randomized study in a small series of pemphigus vulgaris patients, Werth et al. (2008) investigated the efficacy of adjunct dapsone: the outcome was defined as the ability of tapering CS to at least 7.5 mg/day within 1 year of reaching the maximum dose of 200 mg/day dapsone, and, although not statistically significant, the trend favored the dapsone-treated group (8/11 patients reached the primary outcome measure, with no adverse effects, vs. 3/10 patients receiving placebo). The European Guideline recommends, if considered, 100 mg/day or doses up to 1.5 mg/kg/day.

Additional Supportive Treatments and Precautions

Besides systemic pharmacologic therapy, additional topical and external therapies have a place and are beneficial in management of the disease. According to the European Guideline, these measures include:

- Intralesional CS injections for isolated lesions of the skin (triamcinolone acetonide)
- Topical treatment of lesions with potent CS (clobetasol propionate) or calcineurin inhibitors
- Antiseptic baths
- Covering of erosive lesions with low-adhesive wound dressings or local emollients
- Analgesics

Prolonged CS therapy and immunosuppression require additional measures of precaution, including:

- Prophylaxis of osteoporosis (bone density scans, vitamin D and calcium supplementation)
- Ophthalmologic controls
- Use of antifungals, antivirals, and/or antibiotics, when clinically indicated

- Prevention of gastric/duodenal ulcers (H2-blockers, proton-pump inhibitors)
- Antithrombotic prophylaxis, when appropriate
- Vaccinations against seasonal influenza, tetanus, and pneumococcus (although the protection may be questionable during immunosuppressive therapy)
- Support from psychologists and physiotherapists
- Use of sunscreens and avoidance of bright sunlight

Follow-Up and Discontinuation of Therapy

Due to the potential side effects from therapy and the chronic course of disease, patients should be monitored closely, not for disease control only, but for tolerance to treatment and side effects. Based on the evolution of disease, serological monitoring by Dsg1-ELISA and/or IIF should be performed regularly. After discontinuation of systemic CS in patients with complete remission, adjuvant immunosuppression can also be reduced over 6–12 months. The discontinuation of therapy is primarily based on the clinical presentation with complete absence of active cutaneous lesions over several months. In these cases, negative or low ELISA-Dsg1 values or negative direct IF microscopy findings are useful markers to support discontinuation of therapy, but prospective studies are needed to assess their exact role in guiding management.

and Luca Borradori

Abbreviations

CS	Corticosteroids
Dsg	Desmoglein
IF	Immunofluorescence
Pveg	Pemphigus vegetans

Key Points

- Pemphigus vegetans is a rare variant of pemphigus vulgaris that is predominantly associated with autoantibodies directed against desmogleins.
- Historically, two forms have been differentiated, the Hallopeau type and the Neumann variant. Nevertheless, there are overlaps between these two forms and with pemphigus vulgaris.
- Treatment options are essentially based on the guidelines proposed for pemphigus as well as case reports.

Definition and Epidemiology

Pemphigus vegetans (Pveg) is a rare (<5 %) variant of pemphigus vulgaris clinically characterized by chronic vegetating erosions. These affect primarily the intertriginous areas. Historically, two forms were described, the Hallopeau type and the Neumann type. Although clinical features may be distinctive, overlaps between these two types and with pemphigus vulgaris exist. It is therefore questionable to consider Pveg as a distinct entity but rather a clinical phenotype observed within the pemphigus vulgaris spectrum (Figs. 70.1, 70.2 and 70.3).

Fig. 70.2 Pemphigus vegetans, Hallopeau type. Grouped pustular lesions on the palm

Due to the rarity of Pveg, there is only little insight in the mechanisms responsible for the peculiar presentation and evolution of Pveg.

Fig. 70.3 Pemphigus vegetans, Hallopeau type. Perioral pustular lesions with involvement of the lips

Basic Concepts of Pathogenesis

Desmoglein 3 (Dsg3) has been found to be the main and preferential target antigen of Pveg, although a number of patients have anti-Dsg1 and, more rarely, anti-desmocollin 1 or 3 antibodies. It is likely that a different pathogenicity of the autoantibodies (specificity for distinct antigenic sites within the Dsg3 ectodomain, distinct IgG subclass profile) plays a role in the peculiar clinical presentation of affected patients. Other genetic and environmental factors may also be relevant. In case of the pustular Hallopeau form, the presence of distinct HLA loci also found in pustular psoriasis may contribute to the clinical picture. In some patients, intake of angiotensin-converting enzyme inhibitors, penicillamine, or other drugs was described as trigger.

Clinical Presentation

The Neumann type of Pveg was first described in 1886. It begins with extensive blistering and characteristically shows a tendency to heal

with papillomatous vegetations. The Hallopeau type, described in 1889, is rather associated with pustules having a grouped or annular distribution that subsequently develop into vegetating and eroded lesions with an unpleasant odor and without frank blister formation. The Nikolsky sign may be positive. Lesions can be restricted to a single site in the initial phase of the disease and then become multifocal. Although most lesions are typically located in intertriginous spaces (groins, axillae, intergluteal folds, etc.), any area of the integument can be affected. Involvement of the scalp, soles, genitalia, and nails has been described. Involvement of the lips, oral commissure, and oral mucosa also is possible. Oral lesions are usually few in number, rarely vegetating, and usually resemble those found in pemphigus vulgaris. Food intake may be disturbed by significant pain from oral lesions, and rarely, esophageal involvement leads to weight loss. In some cases, a presentation of Pveg is observed during the course and treatment of other forms of pemphigus, an observation arguing against the idea of Pveg being a separate entity. According to a retrospective study by Zaraa et al. (2011) including 17 patients, the Neumann subtype occurred in about two-thirds and the Hallopeau form in one-third of patients. In one patient, both clinical variants coexisted (simultaneously or serially). There is some controversy if the Hallopeau variant really has a more favorable course than the Neumann subtype, as often reported, since no large case series with follow-up are available.

Diagnosis and Differential Diagnosis

To confirm the clinical diagnosis suspected on clinical grounds of the aforesaid, the following investigations are essential: (1) lesional histopathology, (2) direct immunofluorescence (IF) microscopy of perilesional skin, and (3) serological detection of anti-epithelial cell-surface antibodies by indirect IF microscopy (using monkey esophagus or guinea pig esophagus as substrate) and Dsg3 ELISA. The number of circulating eosinophils may be increased in some patients.

- Lesional histopathology typically shows suprabasal intraepidermal acantholysis, papillomatosis, and/or eosinophilic abscesses. The formation of intraepidermal microabscesses and eosinophilic infiltration helps differentiate Pveg from pemphigus vulgaris.
- Direct IF microscopy findings, however, are indistinguishable from those in classical pemphigus vulgaris and reveal deposition of IgG/C3 at the intercellular space of keratinocytes. Labeling of IgA, isolated or combined with IgG/C3, is rarely observed.
- Circulating autoantibodies against Dsg3 are frequently detectable by commercially available ELISAs. In occasional cases, autoantibodies against Dsg1, desmocollins, and periplakin have also been detected.

Knowledge of the peculiar clinical presentation of Pveg is essential to consider the diagnosis, carry out the appropriate immunopathological and immunoserological studies, and start appropriate management of affected patients.

Differential diagnoses of Pveg include:

- IgA pemphigus
- Neutrophilic dermatoses (negative IF microscopy studies)
- Halogenoderma (intake of halogen-containing drugs, negative IF microscopy studies)
- Pyodermatitis-pyostomatitis vegetans (negative IF microscopy studies, presence of chronic inflammatory gastrointestinal diseases—ulcerative colitis, Crohn's disease)
- Acrodermatitis continua suppurativa Hallopeau (variant of pustular psoriasis; negative IF microscopy)
- Keratoderma blenorrhagicum of Reiter's syndrome (negative IF microscopy)
- Paraneoplastic pemphigus (association with lymphoproliferative disorders distinct

immunopathological profile with anti-plakin antibodies)
- Tinea capitis with kerion formation (positive mycology)
- Hailey-Hailey disease (negative IF microscopy, family history)

General Principles of Treatment

Given the rarity of Pveg, data from randomized controlled clinical trials are not available. As treatment regimens for Pveg do not differ significantly from those for pemphigus vulgaris (and pemphigus foliaceus), we refer to the corresponding chapters (see Chapter 71) and to the 2013 European Guidelines on treatment of pemphigus for more detailed information.

The overall aim of therapy is to induce remission from disease, to improve quality of life of affected patients, and to avoid complications related to both the skin disease and the introduced therapy.

Generally, systemic corticosteroids (CS) are the mainstay of therapy and should be combined with immunosuppressants (e.g., azathioprine, mycophenolates) in refractory cases. Due to the vegetating and verrucous lesions and their peculiar distribution in flexural areas, the use of topical medications in addition to systemic therapy has a more important role in controlling lesions compared to pemphigus vulgaris, and in IgA-related cases the use of dapsone may be beneficial. Here, we provide a short overview of anecdotic treatment regimens successfully used in Pveg patients:

- Dapsone, a sulfone derivative, may result in an excellent response (check first for G6PD serum activity and ensure laboratory follow-up).
- Single patients have been treated by combination of CS and etretinate (10–50 mg/day). The latter molecule has now been replaced by acitretin (a metabolite of etretinate).
- Extracorporeal photopheresis has successfully been used in a patient with recalcitrant Pveg who had severe side effects from long-term treatment with CS and azathioprine (Kaiser et al. (2007)).
- Combination therapy of CsA (300 mg/day) with CS induced full remission within 3 weeks in one report.
- In a case of Pveg with esophageal involvement, the combination of minocycline (100 mg/day) and nicotinamide was reported as successful (Sawai et al. (1995)).
- Etanercept, an inhibitor of TNF-α, has been used in a recalcitrant case of Pveg: Blistering was controlled by combining etanercept, CS, and azathioprine (Lin et al. (2005)).

Additional Supportive Treatments and Precautions

Besides systemic therapy, additional topical and external therapies are beneficial in the management of the disease, including intralesional CS injections, topical treatment of lesions with very potent CS, antiseptic baths, low-adhesive wound dressings, and analgesics. The use of skin grafting or laser vaporization seems questionable (Motomura et al. (2009)).

Follow-Up and Discontinuation of Therapy

Due to the potential side effects from CS therapy and immunosuppression and the chronic course of the disease, patients should be monitored closely. Discontinuation of therapy is primarily based on the clinical presentation with absence of lesions under minimal therapy (prednisolone equivalent at or below 10 mg/day) over several months. Negative direct IF microscopy studies and serum anti-Dsg3 ELISA reactivity may represent valuable prognostic markers.

IVIg	Intravenous immunoglobulin
LFT	Liver functions tests
MMF	Mycophenolate mofetil
MTX	Methotrexate
PV	Pemphigus vulgaris
RA	Rheumatoid arthritis
TPMT	Thiopurine methyltransferase

Key Points

- Pemphigus vulgaris (PV) is a potentially life-threatening blistering disorder due to autoantibody formation against a plethora of epithelial antigens (including both adhesion and nonadhesion molecules) characteristic of epidermis and other stratified squamous epithelia.
- Genetic predisposition, based on a complex polygenic basis ("the soil"), though essential, is not by itself sufficient to initiate the autoimmune mechanism. The intervention of many and various inducing or triggering environmental factors ("the seed") seems to be crucial to set off the disease.
- The clinician, who plans the therapy, cannot overlook the frequent association of PV with other preexisting or coexisting conditions (diabetes, hypertension, peptic ulcer, autoimmune diseases, and neoplasms), as well as the existence of wide clinical variations of the disease.
- Due to the lack of standard criteria of care, the management of PV cannot be based on large-scale randomized controlled trials, but is hinged more on expert opinion rather than on empirical evidence. For all these reasons, to indicate a standard treatment tailored to all

forms of PV and to each patient's needs is a utopian task.
- Of note, the growing interest towards PV genetics and, in particular, a more complete knowledge of its complex polygenic basis may lead to the development of a genetic-based tailored therapy in the next future.
- In this chapter, therapeutic guidelines for cases of PV of average severity, along with grades of recommendation and levels of evidence that are associated to the proposed treatments, are indicated. Supportive measures, precautions, and suggestions for PV patients are also outlined.

Definition and Epidemiology

Pemphigus (from the Greek πέμφιξ-ίγος that means blister) vulgaris (from the Latin for common) (PV) is the most frequent and representative form of a group of mucocutaneous diseases (autoimmune pemphigus) characterized by intraepithelial blister formation.

PV is a potentially life-threatening blistering disorder sustained by autoantibody formation against a plethora of epithelial antigens including both adhesion and nonadhesion molecules characteristic of the epidermis and other stratified squamous epithelia. Its incidence is estimated at one to five cases per one million inhabitants per year but is much higher in some Ashkenazi Jewish populations and in Eastern countries, such as India, Malaysia, China, and Japan. The mean age at onset ranges from 40 to 60 years, although several cases have been reported in childhood, adolescence, and old age. PV shows equal or quite equal frequencies among males and females in the Northern countries (North America, UK, France) as well as Malaysia and India, while a female predominance (range M/F: 1/1.1–1/2.25) is reported in Mediterranean areas and at temperate latitude (Italy, Israel). Sex gender may play a role due to its influence on the immune system disclosed at many levels, such as sex chromosomes, hormonal makeup (sex steroids and prolactin), childbearing potential, pregnancy, sociological characteristics, and finally psychological makeup.

The existence of a complex polygenic basis, involving both HLA loci and non-HLA ones (desmoglein 3, immunoglobulin heavy chain constant region, tyrosine phosphatase N22 genes), seems to be established. To date, the association between HLA class II genes (DR4, DR14, DQ1, and DQ3) and PV is the strongest one. Recent molecular gene subtyping studies have revealed a significant increase of DRB1*0402, DRB1*1401, DRB1*1404, DRB1*1454, DQB1*0503, and DQB1*0302. Furthermore, some findings focus on the HLA class I A (A3, A10, A26, B15, B35, B38, B44, and B60) and HLA class I B (HLA-E*0103) antigens.

Basic Concepts of Pathogenesis

According to the recent "apoptolysis (apoptosis-acantholysis) theory," PV would be the consequence of simultaneous, synergistic, and cumulative effects of a constellation of autoantibodies targeting several keratinocyte cell membrane antigens, so disrupting the epidermis integrity through steric, immunological, and biochemical events ("multiple hit theory").

Cell-cell dishesion is depicted as a multistep mechanism initiating with the autoantibody binding to keratinocyte membrane and subsequent activation of the apoptotic machinery; continuing with basal cell shrinkage (early acantholysis) and internalization of extra-desmosomal desmogleins; and ending up with complete cell-cell detachment, formation of suprabasal clefts (advanced acantholysis), rounding up with apoptotic death of isolated parabasal keratinocytes (Tzanck cells), and "tombstoning" of the surviving basal cells.

Originally, desmogleins 1 and 3 (Dsg1 and Dsg3), both combined with plakoglobin, and belonging to the cadherin supergene family, have been representing the necessary and sufficient

targets of pemphigus antibodies, usually known as intercellular antibodies ("compensation theory" by Amagai and Stanley). In the last years, other autoantibodies directed towards non-Dsg antigens (desmocollins, plakoglobin, FcεRIα, annexins, PERP (a tetraspan membrane protein implicated in apoptosis and adhesion), and acetylcholine (Ach) receptors) have been found in PV sera. The presence of autoantibodies towards Ach receptors (nicotinic, muscarinic, the mixed muscarinic and nicotinic α9-AchR, and pemphaxin) outlines the involvement of a possible impairment in the keratinocyte acetylcholine axis, which plays a pivotal role in regulating proliferation, cell adhesion, motility, and desmosomal cell contact.

Genetic factors alone are essential but not enough to initiate the autoimmune response. Factors able to facilitate PV in genetically predisposed individuals are many and various. Most of them are exogenous and directly originating from the environment (e.g., drug intake, viral infections, physical agents, contact allergens, diet); however, also endogenous factors, such as emotional stress and hormonal imbalance, can be taken into account.

Fig. 71.1 Oral pemphigus

Fig. 71.2 Pemphigus vulgaris on the trunk

Clinical Presentation

The primary lesion is a flaccid bulla containing a serous fluid and occurring on apparently normal skin or mucosa (cold bulla). The duration of this bulla is ephemeral, particularly in mucous membranes, due to the fragility of the roof; their tearing produces serum-weeping erosions that reepithelialize gradually.

In nearly two-thirds of cases, PV begins in the oral mucosa, where the disease can remain confined for several months (oral pemphigus) (Fig. 71.1). Intact bullae are quite an uncommon finding in the mouth, where poorly healing erosions represent the hallmark lesions. They are typically painful, in particular to the contact with sour or salty foods and drinks. Salivation becomes abundant with frequent bloody streaks. It is almost constant a characteristic "fetor" of the mouth. With their spreading, the lesions then affect the epiglottis, pharynx, and larynx, not infrequently causing odynophagia and dysphonia. Lips are often covered by bloody crusts, which constantly detach and reappear.

Subsequently, PV affects the skin with a certain predilection for the trunk, intertriginous areas (axillae, submammary, umbilical, and inguinal regions), as well as the scalp (Fig. 71.2). The size of bullae can vary from a lentil to an egg; the content, initially serous and clear, becomes purulent or serohematic after a few days and characteristically does not fill the cavity, giving a typical flaccid appearance to the lesion. Some of the bullae wilt, so resulting into squamous crusts; others break, so evolving in serum-weeping erosions that heal slowly without scarring sequelae. In the most severe forms, oral and skin manifestations are associated to lesions affecting other mucous membranes (esophageal,

genital, urethral, anal, and less often conjunctival) and sometimes keratinized appendages (areas of alopecia, onychomadesis). If a treatment is not started, the disease becomes generalized (new crops of bullae appear everywhere, more and more areas of skin present eroded and crusted): there is a progressive loss of serum, blood proteins, and electrolytes, which, together with the considerable difficulty in eating and frequent opportunistic infections of the eroded areas, seriously compromises the overall condition of the patient, leading to death in 2–3 years. The use of systemic glucocorticoids and immunosuppressive drugs has completely modified the natural course and dramatically improved the prognosis of the disease. Currently, mortality from PV is low, but deaths from treatment complications are not a rare event.

Diagnosis

PV diagnosis is generally based on typical clinical findings (including Nikolski signs), histopathological as well as immunohistochemical examinations, and finally laboratory tests. Nikolski sign I is evoked when a lateral pressure is applied to the edge of a blister or to normal-appearing skin, with resultant enlargement of the preexisting bulla or formation of a new bulla. Peripheral extension of a bulla can also be obtained by exerting a direct pressure onto it (Nikolski sign II or Asboe-Hansen sign). Despite being significant, both these clinical signs lack an absolute diagnostic value. In our experience, Tzanck test is a useful diagnostic tool although it is not required by some experts as a key diagnostic finding: by scraping the floor of a skin or oral lesion of recent onset, typical acantholytic cells may be observed under light microscopy. Biopsy, performed on recent bulla including a small margin of healthy tissue, shows the presence of suprabasal cavities. Histological diagnosis should be confirmed by immunofluorescence. Direct immunofluorescence (DIF), performed on perilesional intact skin/mucosa or uninvolved skin, shows the deposition of intercellular antibodies and often C3 in the epidermis. Indirect immunofluorescence (IIF) on monkey esophageal epithelium both detects and determines pemphigus antibodies titers. Despite being less sensitive than DIF, IIF is more common in clinical practice, especially when biopsy is difficult to perform (uncooperative patients). Enzyme-linked immunosorbent assay (ELISA) is available for direct measurement of anti-Dsg3 and anti-Dsg1 serum antibodies, thus superseding IIF due to its higher sensitivity and specificity (particularly useful in detecting anti-Dsg3 in IIF negative PV patients). ELISA has shown a significant association between anti-Dsg1 as well as anti-Dsg3 titers and disease localization: mucosal dominant PV has a strong correlation with anti-Dsg3 positivity, while mucocutaneous PV type has high titers of both anti-Dsg1 and anti-Dsg3. However, the link between these titers and PV activity (severity, relapse) as well as response to treatment is still a controversial topic. Some authors claim that antibodies titers do not correlate with disease activity and therapeutic response, while others claim that anti-Dsg3 and anti-Dsg1 titers are reliable indicators of disease activity and severity, treatment status, and clinical course. In fact, both anti-Dsg1 and anti-Dsg3 titers (particularly the former compared with the latter) have been found to be significantly reduced after treatment and achievement of clinical remission. A strong association has recently been demonstrated between salivary anti-Dsg1 antibodies and mucosal severity of PV. When the diagnosis remains uncertain, immunoprecipitation and immunoblotting studies on serum are needed. In conclusion, expert opinion rather than empirical evidence still has a pivotal role in PV diagnosis, due to the lack of large-scale controlled trials, which can explain wide variations among diagnostic techniques. Although the desire of establishing common diagnostic criteria, through epidemiological studies, has been emerging, this goal is still far.

Differential Diagnosis

Recurrent aphthous stomatitis, Behcet's disease, erosive lichen planus, Stevens-Johnson syndrome, or cicatricial pemphigoid may simulate oral pemphigus: however, in all these conditions,

Tzanck test is always negative. Widespread skin erosions may evoke the diagnosis of bullous pemphigoid, glucagonoma syndrome, and epidermolysis bullosa: the findings of acantholytic cells (pathognomonic of pemphigus), of intercellular antibodies by immunofluorescence, and anti-Dsg 3 antibodies by ELISA (both hallmarks of PV), remove any doubt. In particular circumstances (e.g., suspicion of paraneoplastic pemphigus), immunoprecipitation or immunoblotting may help to establish the diagnosis.

General Principles of Treatment

The initial aim of treatment in PV is to halt blister formation, promote healing of blisters and erosions, and determine the minimal dose of medication necessary to control the disease, while the ultimate aim should be drug withdrawal.

Since the introduction of systemic corticosteroids (CS), in the 1950s, and immunosuppressive agents, in the 1960s, the prognosis of the disease has been dramatically improving.

However, mortality, although decreased, still remains at a relatively high level (12 %): in most cases, death is not related to PV itself but to the complications of long-term therapy. Along with treatment adverse effects, the clinician, who plans the therapy, cannot overlook the frequent association with other preexisting or coexisting conditions (diabetes, hypertension, peptic ulcer, autoimmune diseases, and neoplasms), as well as the existence of wide clinical variations of PV and the lack of standard criteria of care based upon large-scale randomized controlled trials. As a result, PV treatment has been hinged solely on expert opinion rather than on empirical evidence. For all these reasons, to indicate a standard treatment tailored to all forms of PV and to each patient's needs is a utopian task. Of note, the growing interest towards PV genetics and, in particular, a more complete knowledge of its complex polygenic basis may in the next future lead to the development of a genetic-based tailored therapy.

Therapeutic guidelines for cases of average severity, along with associated grades of recommendation and levels of evidence (Table 71.1), are given here. Supportive measures, precautions, and suggestions for PV patients are also outlined.

General Therapeutic Guidelines

The combination of CS and immunosuppressive drugs (used as adjuvant medications for their steroid-sparing effect) is the cornerstone of management in PV. As a rule, the impact of the initial treatment determines the therapeutic outcome. For this reason, we recommend a full steroid dosage even in less severe cases, although some Associations of Dermatologists suggest patients with mild disease should receive an initial prednisone or prednisolone dosage of 40–60 mg/day, while patients with severe disease a dosage of 60–100 mg/day.

There are two schedules of using this combination therapy depending on the disease severity: conventional therapy (orally given), in mild to moderate cases of PV, which uses continuous high dosage, and pulse therapy (intravenously given) in severe life-threatening or recalcitrant PV cases, that instead administers intermittent exceedingly high doses.

Concerning CS, it is worth noting that, in addition to their well-known immunosuppressive and anti-inflammatory activities, these drugs also exert a typical action in PV regulating adhesion and viability of keratinocytes, through a combination of genomic and nongenomic pathways. They upregulate the expression of several genes and block the post-transcriptional phosphorylation of some adhesion molecules, so interfering with the pathogenic mechanisms carried out by PV antibodies.

The immunosuppressive drug used in conventional therapy is usually azathioprine, claimed to be the most effective steroid-sparing agent: in the early stages, it is used in combination with oral CS to induce PV remission and then alone to maintain the achieved clinical remission after CS withdrawal. When contraindicated, it can be replaced by other drugs (oral cyclophosphamide,

Table 71.1 Grades of recommendation and levels of evidence associated to most of the treatments for PV discussed in the text

Drug or treatment	Strength of recommendation	Quality of evidence
Oral corticosteroids	A	II-iii
Azathioprine	B	II-iii
Oral cyclophosphamide	B	III
Mycophenolate mofetil	B	III
Methotrexate	C	III
Chlorambucil	C	IV
Cyclosporine	C	I
Dapsone	C	IV
Pulsed corticosteroids	C	IV
Pulsed cyclophosphamide and corticosteroids	B	II-iii
IVIg	B	III
Gold	B/C	III
Tetracyclines and nicotinamide	C	IV
Plasmapheresis	C	I
Immunoadsorption	Unreported	Unreported
Grades of recommendation		
A. There is good evidence to support the use of the procedure		
B. There is fair evidence to support the use of the procedure		
C. There is poor evidence to support the use of the procedure		
D. There is fair evidence to support the rejection of the use of the procedure		
E. There is good evidence to support the rejection of the use of the procedure		
Levels of evidence		
I: Evidence obtained from at least one properly designed, randomized controlled trial		
II–i: Evidence obtained from well-designed controlled trials without randomization		
II–ii: Evidence obtained from well-designed cohort or case-control analytic studies, preferably from more than one center or research group		
II–iii: Evidence obtained from multiple time series with or without the medical intervention. Dramatic results in uncontrolled experiments (such as the introduction of penicillin treatment in the 1940s) could also be regarded as this type of evidence		
III: Opinions of respected authorities based on clinical experience, descriptive studies, or reports of expert committees		
IV: Evidence inadequate owing to problems of methodology (e.g., sample size, or length or comprehensiveness of follow-up or conflicts of evidence)		

cyclosporine, mycophenolate mofetil, methotrexate, chlorambucil, and others).

The adjuvant drug used in pulse therapy is cyclophosphamide, first in combination with intravenous CS, and then alone.

Although PV is largely managed with systemic therapy, supplementary topical treatment may be of additional benefit: this is aimed at preventing local infections and stimulating reepithelialization of eroded areas.

Conventional Therapy

In our experience, associated *deflazacort* and *azathioprine* offer the best therapeutical results and the fewest side effects, except for the patients who carry a double low-activity allele for thiopurine methyltransferase (TPMT), being at risk of myelosuppression when long treated with azathioprine. The effect of azathioprine is exerted by active 6-thioguanine nucleotide metabolites,

I Attack treatment for 4 weeks

- Deflazacort 120 mg daily
- Azathioprine 100 mg daily

IIa Alternate day decrease in steroid dosage

Days	1	2	3	4	39	40
Deflazacort (mg)	120	114	120	108	120	0
Azathioprine		100 mg daily			100 mg daily	

IIb Weekly decrease in steroid dosage

Weeks	I							II							VI						
Days	1	2	3	4	5	6	7	1	2	3	4	5	6	7	1	2	3	4	5	6	7
Deflazacort (mg)	120	0	120	0	120	0	120	105	0	105	0	105	0	105	45	0	45	0	45	0	45
Azathioprine							100 mg daily								100 mg daily						

III Maintenance treatment: spacing steroid administration

- Deflazacort 45 mg every other day for 2 months
  45 mg every third day for 2 months
  45 mg on Tuesday and Friday for 2 months
  45 mg weekly for 6 months to 2 years
- Azathioprine 100 mg daily

Fig. 71.3 Stages of conventional corticosteroid-immunosuppressive therapy for PV

generated by hypoxanthine guanine phosphoribosyltransferase (HPRT) once 6-mercaptopurine (6-MP) crosses cell membranes. These metabolites compete with their endogenous counterparts in several biochemical pathways (nucleotides are precursors of RNA and DNA as well as carriers of energy and second messengers). As a result, azathioprine has both immunosuppressive and cytotoxic properties.

The schedule of conventional treatment is organized in four stages (Fig. 71.3).

Front-Line Treatment

Therapy starts with an attack steroid dosage of about 2 mg/kg/day deflazacort (120–150 mg/die) and 1.5 mg/kg/day azathioprine (100 mg/die) until all active lesions disappear, which on average requires 4 weeks.

Decreasing Steroid Dosage on Alternate Days

The only steroid dosage is lowered by 6 mg on alternate days progressively down to zero: this requires at least 6–7 weeks. On the other days, the initial dose of deflazacort (120–150 mg/die) remains unchanged. Azathioprine dosage is not modified.

At the end of this period, esophagoscopic monitoring and ELISA test for anti-Dsg1-Ab should be performed, and the patient's condition should be carefully assessed.

Decreasing Steroid Dosage Weekly

If the therapeutical response is good, the alternate-day administration of deflazacort will be lowered by 15 mg weekly until it reaches

45 mg, while it seems wise not to reduce azathioprine dose in the mean time. Should mucosal lesions still persist or the antibody titer rise, the alternate-day full-dose deflazacort cannot be lowered, while the daily dose of azathioprine can be increased to 150 or 200 mg, until signs of active PV disappear. Only after that deflazacort decreasing can be accomplished as indicated above.

As a result, the duration of this last schedule strictly depends on the course of the disease.

Once 45 mg dosage is reached, deflazacort is continued for alternate days for 2 months.

Maintenance Treatment: Distancing Steroid Dosage

After the 2 months of deflazacort 45 mg on alternate days, its dosage is gradually spaced out to every third day (for a further 2 months), twice a week (for another 2 months), and subsequently once a week for a variable period (6 months to 2 years). The concomitant daily dose of azathioprine is maintained at 100 mg. There are no absolute criteria for when treatment can be stopped.

In most cases, if remission lasts 2 years, the weekly administration of deflazacort at 45 mg can be discontinued, thus giving the patient only azathioprine at an unmodified dosage (usually 100 mg/day) for another year. Then, even the azathioprine treatment may be stopped.

In case of relapses, the high-dosed combination may be taken into account, although less severe forms may reasonably be treated with immunosuppressive drugs alone.

Side Effects of CS and Azathioprine

The early unavoidable adverse effects of CS include enhanced appetite, changes in blood glucose levels and serum electrolytes, fluid and salt retention resulting in weight gain, neuropsychiatric disorders (emotional lability, insomnia, irritability, anxiety, depression, euphoria, hyperactivity, and manic episodes), infections, and transient hematological abnormalities. Delayed drawbacks include cushingoid appearance, hypothalamic-pituitary-adrenal suppression, hyperlipidemias, atherosclerosis, cardiovascular events, cataracts, growth retardation, osteoporosis, osteonecrosis, myopathy, muscle cramps, weakness, and skin bruising and thinning. Furthermore, CS treatment may aggravate concomitant acne vulgaris, diabetes mellitus, hypertension, and peptic ulcer disease.

As to azathioprine, nausea and myelosuppression are related to TPMT activity, while hepatotoxicity, hypersensitivity reactions, rash, pancreatitis, and increased susceptibility to infections are unrelated to TPMT status. Patients who are homozygotes for the low-activity allele encoding TPMT are at risk for severe myelosuppression if treated long term, due to the lack of its metabolism ability. Therefore, before starting the treatment, TPMT measurement should be performed in all patients prescribed azathioprine for dermatological conditions. As this enzymatic assay is not easy to perform, the evaluation of azathioprine toxicity is carried out through periodic monitoring of the full blood count (FBC) and liver functions tests (LFT), with a weekly frequency for the first 4 weeks or until maintenance dose is achieved. In the maintenance period, the monitoring frequency can be reduced to once every 3 months for the duration of therapy. A more frequent evaluation of FBC and LFT is advised in patients with hepatic or renal impairment, in the elderly, and in those treated with high doses of azathioprine.

Immunosuppressive Drugs Replacing Azathioprine

When contraindicated, azathioprine can be replaced by other immunosuppressants that proved to be effective in controlling PV patients if added to the basic steroid treatment (steroid-sparing agents).

Oral *cyclophosphamide* (1–3 mg/kg daily in two or three divided doses) can be an alternative to azathioprine if secondary infertility is not a concern. Long-term use of oral cyclophosphamide may cause sterilization with azoospermia

(this explains why this drug should be avoided in young patients), hematological abnormalities (lowering in platelets and leukocytes), hair loss, gastrointestinal disturbance, raised transaminases, potential risk of hemorrhagic cystitis, and carcinoma of the bladder.

Mycophenolate mofetil (MMF) at a daily dosage of 2–2.5 g, given in two divided doses with CS, is a relatively new drug in PV treatment, to be considered in recalcitrant cases or when azathioprine or cyclophosphamide are unsuitable. MMF is believed to have a favorable safety profile compared with other immunosuppressive drugs (including azathioprine) because of its selective inhibitory action on inosine monophosphate dehydrogenase affecting "de novo" purine synthesis of mainly T and B lymphocytes. Compared with azathioprine, despite having an inferior steroid-sparing activity, MMF is more effective in inducing disease control. MMF should be preferred to azathioprine not only in the homozygotes for the low-activity allele for TPMT (see above) but also when treating PV patients with a coexistent herpetic infection, since the former markedly potentiates the antiherpes virus activities of acyclovir, ganciclovir, and penciclovir, while the latter can undermine the host's antiviral defenses. Although MMF has a better safety profile, it may evoke the same adverse effects associated to immunosuppressive drugs (gastrointestinal disturbances, hematologic alterations, and increased risk of opportunistic infections): their incidence is relatively lower if compared to that reported with other immunosuppressive agents. MMF has been used with good results even in monotherapy. As experience increases, it may supersede other agents as the immunosuppressant of choice due to its efficacy and more favorable safety profile.

Methotrexate (2.5 mg every 12 h × 3 doses each week) (MTX) can be considered as adjuvant treatment if more established drugs cannot be used. Methotrexate has been recently reevaluated after early reports of high mortality and morbidity rates. Its drawbacks include myelosuppression, hepatotoxicity, and pneumonitis.

Oral *chlorambucil* (4–6 mg once daily) is another adjuvant drug that can be considered when more established options cannot be used. To date, there are still limited data to support its administration.

Cyclosporine (5 mg/kg daily) in association with CS offers no advantage over treatment with CS alone in PV patients. Thus, on the basis of the current evidence, it cannot be recommended as an adjuvant drug.

Dapsone (50–200 mg daily) has been suggested as a steroid-sparing agent in the maintenance phase of PV treatment or as a first-line agent. However, little evidence to recommend the use of dapsone in PV is available. The untoward effects occurring with high/protracted doses of this drug include methemoglobinemia and hemolytic anemia, which often force the reduction of the dosage or the discontinuation of dapsone. Glucose-6-phospate dehydrogenase deficiency (G6PD) is an absolute contraindication to its administration. A combination of CS and dapsone may be used in childhood PV to avoid severe effects of immunosuppressants in the growing age.

Pulse Therapy

Pulse therapy entails the periodic intravenous (IV) administration of massive doses of CS (dexamethasone or methylprednisolone) and of the immunosuppressive drug (megadoses or boluses), interspersed by the oral assumption of low doses of the immunosuppressant only. This schedule may be considered in patients with very severe forms of PV and with high antibody titers, particularly if unresponsive to high oral doses.

On the first day, *dexamethasone* (100 mg) or, alternatively, *methylprednisolone* (500 mg) is associated with *cyclophosphamide* (500 mg) and dissolved in 500 mL of 5 % glucose solution given by slow IV drip (1–2 h); on the second and third day, 100 mg dexamethasone (or, alternatively, 500 mg methylprednisolone) alone (without cyclophosphamide) is administered again by IV drip; from the fourth to the 14th day, only 50 mg/day of cyclophosphamide is given orally. Subsequently, the previous cycle is resumed. The interval between boluses, initially 2 weeks, is then increased to 4 weeks

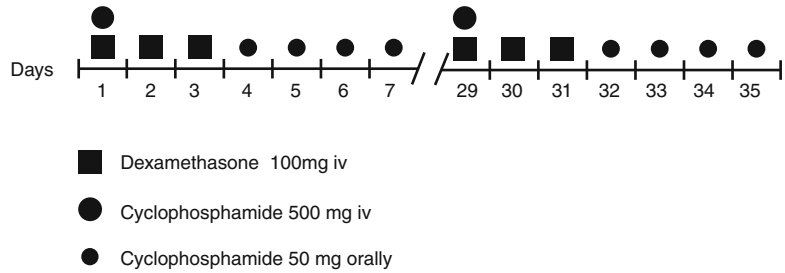

Fig. 71.4 Pulse therapy: IV megadoses of corticosteroid and immunosuppressive drugs are given over a short time (3 days and 1 day, respectively) every fourth week; in between these pulses, a low-dosed immunosuppressive treatment is given orally

until clinical remission (Fig. 71.4). Once this aim is achieved, the treatment is usually continued for 4–6 months. The number of pulses required to induce disease remission ranges from 6 to 30 weeks. After the pulses interruption, oral 50 mg cyclophosphamide is continued alone for at least 1 year as maintenance management, if there are no relapses. A variant of the classical pulse therapy (50 mg/kg/day of cyclophosphamide alone per 4 days) has been successfully used in recalcitrant patients (Hayag et al. 2000).

Side effects of pulse therapy encompass rare mild acute events (nausea, facial flushing, mood change, sleep disturbance) and severe drawbacks (aseptic osteonecrosis, seizures, cardiac arrhythmias, and even sudden death), which are more frequent among patients with concomitant risk factors. Paradoxically, long-term treatment with oral cyclophosphamide may cause several drawbacks (see above) which are more common than those reported with IV high-dosed administration of the same drug.

Biologic Agents

They include essentially IVIg and rituximab. The use of TNF-α antagonists (infliximab, etanercept) in PV has been emerging in the recent years, and therefore it still belongs to innovative nonconventional therapies.

Intravenous Immunoglobulin (IVIg) Therapy

IVIg is a purified blood product deriving from the plasma of between 1,000 and 15,000 healthy donors, containing IgG antibodies directed against pathogens, foreign antigens, and even self-antigens. It has demonstrated to be an effective, although expensive, treatment exerting its action through several postulated mechanisms. In PV, it may directly neutralize circulating antibodies (mimicking anti-idiotypic mechanism) and indirectly slow down their production through immunomodulatory effects. Repeated courses of IVIg could be considered as an adjuvant maintenance agent for recalcitrant PV become unresponsive to conventional regimens (CS and immunosuppressive drugs), or when high doses of CS are relatively contraindicated (diabetes, gastrointestinal diseases, osteoporosis, infections, or immunodeficiency). In addition, in view of report of a faster action in some cases, it could be used to help the induction of immediate remission in patients with severe recalcitrant PV, if necessary associated with slower-acting drugs.

Patients are given a daily dose of 400–600 mg/kg of IgG for three to five consecutive days. The infusion is administered slowly over 4–5 h. The cycles are initially spaced 2–3 weeks apart; thereafter, the interval is increased to 4 weeks, and the treatment is continued until the disease is successfully controlled. Past studies suggested that the efficacy of IVIg for PV treatment involved multiple cycles. However, recent studies demon-

strate that a single cycle may be sufficient to suppress disease activity.

To date, IVIg is one of the safest agents available: the incidence of long-term adverse effects requiring medical treatment has been reported to be relatively low with IVIg therapy compared with other treatments. Potential common early complications reported include chills, dyspnea, tachycardia, hypertension, muscle pains, abdominal pain, pyrexia, nausea, and headache. These drawbacks are self-limited and generally respond to slowing the infusion. Moreover, they may be prevented by premedication with oral diphenhydramine and acetaminophen. Rare side effects reported include anaphylaxis, increased creatinine and transaminases, hepatic dysfunction, hepatic encephalopathy, hematological alterations (lowering in white blood cell, red blood cell, and platelets count), bleeding tendency (particularly in the digestive tract), hypoalbuminemia, and aseptic meningitis (incidence ranging from 11 to 17 %). Of note, there is a theoretical risk of blood-borne virus infections.

Conversely, local or systemic infections facilitated by conventional immunosuppressants may be better controlled by IVIg. This firmly supports the recent use of this therapy in association with rituximab: in this schedule, IVIg role is more than a prophylaxis due to its both synergistic and immunomodulatory effects.

Other benefits of IVIg therapy include a corticosteroid-sparing effect, the possible use as monotherapy and, in addition to controlling PV, the ability to induce sustained clinical remission.

On the other hand, further multicenter trials, with large groups of patients, are needed, and some practical considerations along with the high cost may be a deterrent to IVIg use. However, the cost of treating present and future adverse effects of long-term therapy with high-dose systemic CS and immunosuppressive agents would also be high, and probably comparable.

Rituximab

In PV patients who do not enter into remission despite the use of high-dose steroid therapy and immunosuppressive treatments, a chimeric IgG1 monoclonal anti-CD 20 antibody, rituximab, has been recently employed as adjuvant with promising results. According to the latest findings, rituximab may be the first-choice treatment in PV due to some characteristics: a good safety and tolerability profile as well as a positive and long-lasting response in patients after a single course. Altogether these elements make rituximab a therapy that is potentially able to modify the natural history of PV.

This antibody targets the B cell differentiation antigen CD 20, a membrane protein that participates in B cell activation and proliferation. By eliminating CD 20+ B cells (essentially through complement and antibody dependent cytotoxicity) in their evolutive stages (pre-B cells, immature B cells, mature B cells, and immature plasma cells), rituximab affects both the humoral- and cell-mediated responses in patients with PV because of the close interaction between B and T cells: circulating B cells are reduced so preventing their maturation into antibody-producing plasma cells. Rituximab is administered intravenously at a dosage of 375 mg/m^2 by slow infusion (4–6 h) once weekly for 4 weeks per course, with a premedication of oral paracetamol (500 mg) and chlorpheniramine maleate (10 mg).

The clinical response usually occurs only after several weeks. In most of the cases, clinical improvement goes parallel to the serum decrease of autoantibodies measured by indirect immunofluorescence. Conversely, in some patients, it was not accompanied by a simultaneous decrease of antidesmoglein titers. Once control of the disease has been achieved, low doses of steroids and immunosuppressants can suffice for the subsequent management. Rituximab is able to induce a prolonged clinical remission after a single course of four treatments.

In previously reported cases, a variety of immunosuppressive drugs were used as adjuvant therapy after rituximab administration with a frequent complicated course due to the onset of systemic infections. Recent studies using no drugs or only steroids after rituximab administration showed an uncomplicated follow-up as well as long-lasting clinical remission. Thus, we may assume that, after rituximab administration, the use of an immunosuppressant other than a steroid

does not result in much difference in the rate of response, period of remission, or incidence of relapses, but it is responsible for higher risk of systemic infections.

Side effects of rituximab include infusion-related toxicity (fever and chills), generally occurring only during the first infusion, serious infections, deep venous thrombosis, long-term hypogammaglobulinemia, and neutropenia.

Particularly, some researchers believe that the use of rituximab in severe PV does not increase significantly the infection rates, but only the addition of immunosuppressive drugs other than steroids could increase this risk: sepsis from *Pseudomonas aeruginosa* and *Staphylococcus aureus*, hip arthritis caused by *Pseudomonas aeruginosa*, a community-acquired pneumonia, and pneumonia from *Pneumocystis carinii* have been reported in PV.

Being rituximab a chimeric murine-human molecule, there are some concerns about the long-term adverse effects of infusion of a foreign protein. A prior sensitivity to murine proteins has to be ruled out before administering this drug. As rituximab is very expensive, its use should be limited to selected patients with treatment-resistant or life-threatening disease.

Rituximab and IVIg

This association has been used in PV patients who had inadequate responses to long-term, high-dose CS plus at least three or more immunosuppressants, or a minimal response to IVIg, or who experienced acute relapses whenever intervals between IVIg infusions were increased, or finally who experienced a failure of immunosuppressive drugs used in combination with IVIg therapy. The proposed schedule includes two cycles of rituximab (375 mg/m^2 of body surface area) once weekly for 3 weeks and IVIg (2 g /kg) administered in the fourth week, then followed by a single monthly infusion of rituximab and IVIg for 4 consecutive months (consolidation therapy). Along with a dramatic clinical response, patients treated with this combination have not shown the side effects generally associated with rituximab.

Second-Line Treatments

Numerous side effects of a prolonged administration of CS and immunosuppressive drugs have spurred on a continued search for other therapies that might be used alone as sole systemic alternative treatment, or in combination with a low-dose conventional cure, as an adjuvant management.

The use of *gold salts*, which have long been used in the treatment of rheumatoid arthritis (RA) and lupus erythematosus, has waned with the introduction of other immunosuppressive agents. The mechanism of action is probably linked with the T-mediated immunosuppressive properties of gold salts. Intramuscular injections of either gold sodium thiomalate or aurothioglucose are given once weekly, in single doses of 50 mg to a total dose of 1 g. The treatment can be continued with fortnightly doses to 2 g, then monthly doses up to 3 g. Adverse side effects, such as pruritus, allergic reactions, nausea, renal toxicity, and bone marrow suppression, are frequent, up to 42 % of cases. Auranofin is an oral preparation (3 mg twice daily) that seems to be less toxic but also less effective. As a rule, we do not favor the use of gold compounds in patients with PV because of the reported onset of pemphigus lesions in patients treated with chrysotherapy for RA.

The association of oral *tetracycline* (2 g/day) or *minocycline* (200 mg/day) with *nicotinamide* (1.5 g/day), jointly with topical steroids, has proven to be a beneficial adjunct to the conventional treatments, allowing a reduction in steroid or immunosuppressive doses required to maintain remission. It has been used in some cases of PV in order to protect the patient, for a certain period, from untoward effects that occurred with the conventional treatment. On the whole, tetracycline-nicotinamide association exhibits a good safety profile (reversible minocycline-induced hyperpigmentation is a possible mucocutaneous side effect), and it may be helpful in mild forms of the disease. Even if the mechanism of action of tetracyclines remains obscure, though presumably based on anti-inflammatory properties, it is likely that nicotinamide, being a cholin-

ergic agonist, can act as a protective factor against acantholysis by interfering with acetylcholine receptor-reactive autoantibodies.

Topical Treatment

In PV, topical treatment is considered supplementary to the systemic therapy and aimed primarily at preventing infections and stimulating reepithelialization of the abraded areas. Intact bullae should be incised, and the resulting erosions should be treated with *spray*, *lotions*, or *creams containing CS* and *antibiotics* or *nonirritant antiseptics* (potassium permanganate, chlorhexidine).

Oral lesions, often stubbornly resistant to systemic therapy, are treated with *potent topical CS* (clobetasol propionate) in a special *adhesive paste*, which keeps the drug in place longer. For gums and hard palate mucosa, the local therapeutic activity of topical steroids can be enhanced by an *occlusive dressing of acrylic trays*. This method can achieve a prolonged remission phase in about half of the patients adopting it (stabilized oral PV with few lesions), without needing systemic therapy. Under these circumstances, similar results and benefits have been reported with *intralesional injections of triamcinolone acetonide* diluted to 10 mg/mL. Finally, to alleviate the pain that hampers food intake, *anesthetic nebulizers* (benzocaine) are used immediately before meals. In case of extensive erosive lesions on nasal, laryngeal, and upper respiratory tract mucosae, it may be useful nebulizing *steroid aerosols* with appropriate masks thrice a day.

Innovative topical treatments include *epidermal growth factor* (10 μg/g), *nicotinamide* gel 4 %, and *pimecrolimus* 1 % cream. The topical treatment with a *proteomics-derived desmoglein peptide* (Dsg349-60REWVKFAKPCRE) appears promising because it halted disease progression and persistently decreased desmoglein-reactive antibody titer, without adverse effects, in a patient with severe PV (Angelini et al. 2006; Ruocco et al. 2013).

Interventional Treatments

They include plasmapheresis and its derivative immunoadsorption.

Plasmapheresis

In 1978, our group introduced the technique of plasma exchanges for problem cases of PV as a logical consequence of the proven pathogenicity of pemphigus autoantibodies. The rationale of this method was removing harmful antibodies from the patient's circulation, although the effectiveness of the intervention showed to be temporary. It was soon clear that, being the antibody level in the circulation regulated by a feedback mechanism, a massive antibody depletion triggers a burst of new antibody production ("rebound" to the antibody "vacuum"). Thus, if every plasma exchange is followed by short cycles ("pulses") of conventional treatment with high doses of steroids and immunosuppressants (in particular cyclophosphamide), the therapeutic effect is increased and stabilized, as these "pulses" target B cells during their peak of autoantibody synthesis thus destroying them.

The regimen is scheduled with daily large-volume (60 mL/kg) plasma exchanges on days 1, 2, 3, and 7, intravenous *prednisolone* (2 mg/kg/day) and *cyclophosphamide* (12 mg/kg/day) on days 4, 5, and 6 during the first week (Fig. 71.5). The number of cycles necessary to achieve clinical control may vary from 3 to 12 over a period between 2 weeks and 10 months. The interval between two cycles is generally fixed at 4 weeks, but in most cases the treatment protocol is determined by the clinical severity of the disease and by patients' response to treatment following each cycle. The steroid dosage is gradually reduced to zero within 11 months, while oral cyclophosphamide (100–150 mg/day) is given for 6 months and then tapered to 50 mg/day for a further 4 months.

Plasmapheresis cannot be recommended as a routine treatment option in newly presenting

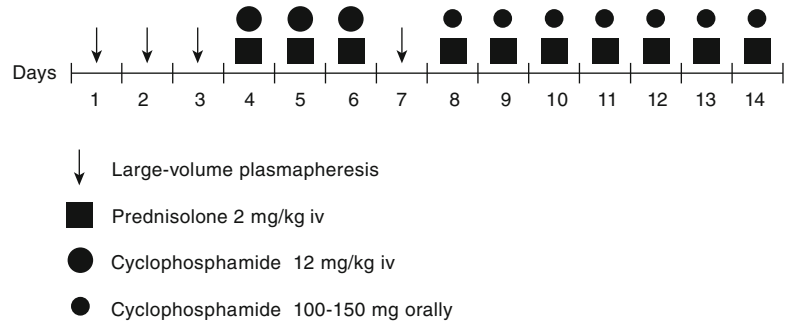

Fig. 71.5 Synchronization of plasmapheresis and pulse corticosteroid-immunosuppressive therapy: the pharmacological treatment is given soon after the antibody depletion caused by plasma exchanges to best hinder the "rebound" antibody production

patients with PV, while it caters for patients who are not responding to standard therapy, life-threatening cases of PV, and whenever the conventional therapy is contraindicated. This is the case of severe flare-ups of PV in pregnancy, which specifically call for plasmapheresis (plus CS and without cyclophosphamide), because this interventional treatment reduces the risk of intrauterine or neonatal pemphigus and obviates the serious side effects that conventional immunosuppressive therapy may cause to the fetus.

Plasmapheresis complications can be divided into minor ones (chills, fever, allergic reactions, transient hypotension) and major ones, which include fluid and electrolyte imbalance (rarely resulting in pulmonary edema or shock), depletion of platelets and other clotting factors with consequent bleeding diathesis, and systemic infections (pneumonia).

Working better than cyclophosphamide to prevent the risk of opportunistic infections due to its prophylaxis effect, high-dose IVIg infusion may be administered instead of cyclophosphamide to face the "rebound" antibody burst. Thus, IVIg use partly compensates the global immunosuppression induced by repeated plasma exchanges.

Plasmapheresis should always be conducted in immunohematology centers by a specialized staff.

Immunoadsorption

The main side effect of plasma exchange is removing a wide range of protective immunoglobulins, albumin, and clotting factors along with the pathogenic pemphigus antibodies. To overcome this drawback, one of us (V. R.) in the far 1984 theorized the possibility of selectively trapping the pathogenic autoantibodies out of the body by means of filtering membranes rich in sulfhydryls (-SH groups), thereby returning protective antibodies and plasma components to the patient. Unfortunately, technical problems, linked with difficulty in preventing air oxidation of -SH groups to disulfide bonds (S-S), stopped the fulfillment of the project. The original idea was accomplished 10 years later by Amagai et al. with the extracorporeal immunoadsorption (IA) of desmoglein-reactive autoantibodies using the extracellular domain of baculovirus-produced desmoglein 3. Interestingly, the molecular structure of desmoglein 3 is rich in -SH groups, which denotes the correct rationale of the original idea. Subsequently, different IA devices (protein A immunoadsorption columns, a tryptophan-linked polyvinyl alcohol gel adsorber) have been used. High-affinity reusable systems are preferably employed, but, in selected patients, IA with single-use systems can be chosen. The usual protocol entails one treatment cycle of four IA procedures on consecutive days. Further cycles with free intervals of 3–4 weeks are carried out depending on disease activity until clinical improvement is obtained. IA is a significant improvement over plasmapheresis also because it does not require reconstitution with fresh frozen plasma or human albumin; moreover, infections and allergic reactions are

less frequent. The clinical results can be rapidly observed: progressive reepithelialization of mucous and skin lesions is usually paralleled by an average of 50–70 % decrease in desmoglein-reactive autoantibodies titers. The incidence of adverse events (deep venous thrombosis, hypotension, bradycardia) is relatively low. However, despite undergoing a rapid remission, the disease usually recurs once the treatment is discontinued.

On the whole, extracorporeal IA is a candidate treatment of choice for patients with severe, life-threatening pemphigus and high levels of pathogenic autoantibodies, a circumstance where the immediate clinical response required is hard to achieve with the pharmacological therapy alone. Recently, due to the high incidence of relapses when the treatment is stopped, IA has also been associated to rituximab in a new treatment protocol. The aim is to combine the rapid remission induced by IA with the favorable positive longer-term effects of rituximab therapy. In fact, IA acts more rapidly than rituximab, but achieves a shorter disease remission than the latter when treatment is discontinued. This new protocol has been well tolerated.

Innovative Therapies

TNF-α antagonists (*infliximab* and *etanercept*) have also been used in PV, showing good results probably due to the role TNF-α exerts in the acantholytic process.

Cholinergic drug employment, ensuing from the recent acquirement on the role of keratinocyte acetylcholine axis imbalance in PV pathogenesis, has also been considered. The first cholinergic drug used was *pyridostigmine bromide* (Mestinon), an acetylcholinesterase inhibitor that also exerts an underrated direct nicotinergic action. As to muscarinic agonists, the topical application of *pilocarpine* gel 4 % showed a significantly higher reepithelialization index compared with placebo. Pilocarpine exerts its action by binding to M1 receptor, which is specifically targeted by PV antibodies, thus blocking the phosphorylation they induce.

Intravenous *desmoglein 3 peptides* have been used to suppress the production of anti-Dsg3 antibodies through inactivation or deletion of disease-associated CD4+ T cells.

A clinical trial is currently underway on *sirolimus*, which is an inhibitor of the *m*ammalian *T*arget *O*f *R*apamycin (mTOR), a serine/threonine protein kinase that regulates cell growth, proliferation, survival, protein synthesis, and transcription and that is overexpressed in keratinocytes exposed to PV antibodies.

Behavioral and Dietary Suggestions

Patients suffering from PV should avoid the abuse and indiscriminate use of drugs, even during the remission phase or if clinically healed, because of the risk for a drug-induced relapse of the disease. In particular, the medications often implicated in inducing or triggering PV (e.g., thiol drugs, phenol drugs, angiotensin-converting enzyme inhibitors, nonsteroidal anti-inflammatory drugs, vaccines, interferons, and other cytokines) should be forbidden or limited as much as possible. When needed, the drug suspected of favoring PV can be replaced by others with similar therapeutic action but of a different category and with no inducing potential. Even the use of contraceptives and progestogens calls for caution in patients with PV. Women with PV should be informed that pregnancy may reactivate the disease due to a physiological steroid hormone imbalance.

Exposure to the sun and other ultraviolet sources requires special caution because of the risk for photoinduced relapses. The same can be said for intensive and prolonged emotional stress, which may interfere with the immune system.

Patients with PV should be advised to have a balanced diet and to avoid foods spiced with garlic, onion, and leek as these culinary plants, belonging to the genus *Allium*, contain thiol allyl compounds with a proven acantholytic potential. Patients should also be warned against the ingestion of very hot foods and beverages because of the possible acantholytic effect that excessive

heat may exert on oral and esophageal mucosae. Milk is among the foods to recommend, because of its high protein content, its easy intake even in the presence of painful oral erosions, and its high level of an oxidative enzyme (sulfhydryl oxidase) that has the potential to neutralize the acantholytic effect of thiol allyl derivatives found in the vegetarian diet.

Finally, even if it seems contrary to good sense, cigarette smoking is not contraindicated in patients with PV because nicotine can attenuate the acantholytic effect of pemphigus pathogenic autoantibodies both directly due to a cholinergic agonism and indirectly by inducing T cell-mediated immunosuppression.

Drug-Induced Pemphigus

72

Olga Golberg and Karen Elizabeth Harman

Abbreviations

HLA	Human leukocyte antigen
IL-1	Interleukin-1
TNF-α	Tumour necrosis factor alpha

Key Points

- Drug-induced pemphigus is a rare variant of pemphigus.
- Multiple drugs are reported to induce pemphigus, most commonly thiol drugs. The mechanisms include autoantibody formation and direct acantholysis.
- The diagnosis requires an accurate drug history, a skin or mucosal biopsy for histology and direct immunofluorescence and may be supplemented by serological tests including indirect immunofluorescence and enzyme-linked immunosorbent assay.
- The clinical, histological and immunopathological features of drug-induced pemphigus are similar to those of idiopathic disease, and there may be a long latent period between starting a drug trigger and disease onset, making the diagnosis challenging.
- Patients in whom the disease persists after removal of the drug require treatment with systemic corticosteroids and/or immunosuppressive therapy, as for idiopathic pemphigus.

Definition and Epidemiology

Pemphigus comprises a group of autoimmune bullous diseases characterized by acantholysis (loss of adhesion between keratinocytes) that results in the formation of intraepithelial blisters in skin and mucous membranes. Drug-induced pemphigus (DIP) is a rare but well-established type of pemphigus, which was first recognized in the 1950s. Epidemiological data on DIP is very limited. It is estimated that approximately 10 % of cases of pemphigus are drug related. DIP affects all races and both sexes and can occur at any age. A number of reports from Israel may suggest an increased incidence of the condition in Ashkenazi Jews (Brenner et al. 1998).

Basic Concepts of Pathogenesis

While in the past most cases of DIP were associated with penicillamine, a variety of other drugs have been implicated in recent decades (see Table 72.1). Some of these drugs are thought to induce pemphigus via the same immunological mechanisms that are found in idiopathic pemphigus. Other drugs are postulated to cause acantholysis directly, through biochemical processes. A combination of both mechanisms may be involved in many cases of DIP. Pemphigus-inducing drugs can be broadly divided in two categories: thiol and non-thiol drugs.

Thiol drugs contain a sulfhydryl group (-SH) in their chemical structure and are the commonest cause of DIP. Examples of thiol drugs include penicillamine and captopril. About 7 % of patients treated with penicillamine for at least 6 months develop pemphigus. The sulfhydryl groups have been speculated to interact with desmogleins, enhancing their antigenicity and leading to autoantibody production. Thiol drugs have also been shown to induce acantholysis in vitro without antibody formation. The potential mechanisms for thiol-induced direct acantholysis include inhibition of enzymes of keratinocyte aggregation, disruption of cell adhesion by thiol–cysteine bonds and activation of proteolytic enzymes such as plasminogen activators.

Non-thiol drugs associated with pemphigus include penicillins, cephalosporins and ACE inhibitors other than captopril. Additional drugs have been recently reported to induce pemphigus, for instance, angiotensin II receptor blockers, anticonvulsants and glibenclamide. Some non-thiol drugs, such as penicillins and piroxicam, have sulphur in their chemical structure, which may be metabolized in vivo to form thiols. These are termed masked thiols, and their mechanism of acantholysis may be similar to thiol drugs. Other non-thiol drugs contain phenol groups, for example, levodopa and rifampicin. Phenol drugs have been postulated to induce acantholysis by causing release of cytokines (TNF-α, IL-1) from keratinocytes, which participate in the regulation and synthesis of complement and proteases. An active amide group is also found in the structure of many non-thiol drugs, and its role in the pathogenesis of DIP has been questioned.

Table 72.1 Drugs implicated in pemphigus

	Non-thiol drugs		
Thiol (SH) drugs	Phenol drugs	Pyrazolone derivatives	Miscellaneous drugs

[a]Both thiol and phenol drugs

[b]Drugs containing sulphur in their molecules (masked thiols)

Non-thiol drugs are more likely to induce pemphigus via immunological mechanisms. Studies have shown the presence of antibodies to pemphigus antigens, desmoglein 3 (Dsg3) and desmoglein 1 (Dsg1), in most cases of thiol- and non-thiol-induced pemphigus. However, 4–5 % of rheumatoid arthritis patients treated with thiol compounds produce antibodies to non-conformational epitopes of Dsg1 or Dsg3 without developing pemphigus, suggesting that such antibodies alone are not sufficient to induce acantholysis (Yamamoto et al. 2010).

Patients with DIP have been found to carry the same susceptibility alleles HLA-DR4 that are thought to predispose to idiopathic pemphigus vulgaris (PV). Therefore, perhaps drugs are capable of triggering pemphigus in genetically susceptible individuals.

Clinical Presentation

DIP usually begins a few weeks to several months after initiation of an offending agent, although the onset of pemphigus after 6 years of anticonvulsant therapy has been described (Tang and Zhang 2012). The latency period may be much shorter on repeat exposure to the culprit drug. The clinical features of DIP are similar to idiopathic disease although pruritus is more common. Pemphigus foliaceus (PF) is the most common pattern of DIP, observed in up to 70 % of thiol-induced cases. It is characterized by multiple, superficial, fragile blisters over the seborrhoeic areas of the body, which easily rupture, evolving into erythematous, crusted and scaly erosions and plaques. The scalp, face and upper trunk are the common sites of involvement. Skin lesions may coalesce to cover large areas of the body and occasionally progress to an exfoliative erythroderma. The cutaneous lesions are often associated with itching and burning. The mucous membranes are typically spared. DIP may also present as pemphigus erythematosus (PE), which is a variant of PF localized to the malar region of the face and sometimes associated with the laboratory features of systemic lupus erythematosus.

Pemphigus induced by non-thiol drugs tends to manifest as PV. Most patients develop mucosal lesions, with painful erosions of the oral cavity being the commonest presenting feature. Other mucous membranes can be affected, in particular the conjunctiva, oesophagus and genitalia. Cutaneous involvement manifests with flaccid blisters, which soon rupture, producing painful erosions that tend to ooze and bleed. The Nikolsky sign can usually be elicited.

The prognosis seems to be more favourable in DIP caused by thiol drugs. Withdrawal of the drug results in remission in up to 50 % of thiol-induced cases of pemphigus compared with only 15 % of patients with pemphigus induced by non-thiols. This observation led some authors to term thiol- and non-thiol-related disease "drug-induced" and "drug-triggered" pemphigus, respectively. In patients who do not remit upon drug withdrawal, the course and prognosis of DIP is similar to that of idiopathic pemphigus.

Diagnosis

The diagnosis of DIP is challenging because it resembles idiopathic pemphigus, cannot conclusively be distinguished with investigations, and the latency between drug initiation and disease onset may be long. Furthermore, disease may persist despite cessation of the suspected agent. In most published reports, the diagnosis of DIP was based on the history, resolution of disease after withdrawal of the drug (with or without treatment) and recurrence/worsening of pemphigus after re-exposure to the same or similar drug. Some authors have also noticed a poor response to standard systemic treatment before stopping the culprit agent. A thorough drug history is therefore crucial for the diagnosis of DIP and should be obtained in all cases of pemphigus. The patient's medications should be cross checked against a list of those drugs reported to induce pemphigus (Table 72.1), and any potential triggers should be stopped, taking into account that there may be a prolonged latency period between starting the drug and the onset of pemphigus.

In addition to a clinical assessment, the diagnosis of DIP always requires laboratory investigations. These must include a lesional skin or mucosal biopsy for histopathology and a biopsy of perilesional skin or mucosa for direct immunofluorescence (DIF). The histological findings in DIP are identical to those in idiopathic disease and correlate with the clinical variant of pemphigus. In drug-induced PF, superficial intraepidermal cleavage is found, with acantholysis beneath the stratum corneum or within the granular layer. In drug-induced PV, there is a suprabasal acantholysis and retention of basal keratinocytes along the basement membrane, known as a "row of tombstones". Other findings in DIP include a mixed inflammatory infiltrate in the dermis, with possible eosinophil predominance, and eosinophilic spongiosis. DIF demonstrates intercellular epidermal deposition of IgG, with or without C3, in up to 90 % of patients with DIP.

Serological studies, indirect immunofluorescence (IIF) and enzyme-linked immunosorbent assay (ELISA), are often used to further support the diagnosis of pemphigus. IIF detects circulating antibodies to PF or PV antigens (Dsg1 and Dsg3, respectively), or both, in about 70 % of patients with DIP and usually at low titre. DIF and IIF are negative in some patients, particularly in thiol-induced cases. ELISA is a very sensitive and specific test for the diagnosis of pemphigus and may be useful when IF studies are negative. In a small series of DIP, ELISA was positive for Dsg1 or Dsg3 in all six patients, while DIF and IIF were negative in one and two patients, respectively.

Unfortunately, the distinction between drug-induced and idiopathic pemphigus is not possible based on the histological features, nor routine immunopathology. However, novel tests have been proposed as adjuncts in the diagnosis of DIP. One study has shown differences in the pattern of immunostaining with the monoclonal antibody 32-2B which binds desmogleins 1 and 3 (Maruani et al. 2008). A normal pattern of immunostaining with 32-2B demonstrated a 70 % sensitivity and 84 % specificity for the diagnosis of DIP. In comparison, 84 % of idiopathic pemphigus cases showed a patchy pattern of immunostaining with 32-2B. The normal pattern of immunostaining in DIP was also associated with a better prognosis. Another potential diagnostic tool is the in vitro interferon-gamma release test, performed by culturing lymphocytes of PV patients with and without suspected drugs and considered positive if interferon-gamma secretion is at least 30 % higher from lymphocytes cultured with the drug compared with those cultured in medium alone (Goldberg et al. 2008). This assay was positive in 10 out of 14 patients with suspected DIP and may be useful for identifying culprit drugs in pemphigus patients. However, neither 32-2B immunostaining nor the interferon release assays are widely available and at present represent research tools rather than routine diagnostic tests.

Differential Diagnosis

The histopathology and immunopathology usually readily distinguishes pemphigus from other diseases but the differential diagnosis of DIP includes:

- All other forms of pemphigus
- Mucous membrane pemphigoid
- Bullous pemphigoid
- Linear IgA disease
- Subcorneal pustular dermatosis
- Erythema multiforme and Stevens–Johnson syndrome
- Bullous impetigo and staphylococcal scalded skin syndrome (in children)
- Lupus erythematosus (subacute, bullous or systemic)
- Severe seborrhoeic dermatitis (for drug-induced PF)
- Hailey–Hailey disease
- Other causes of mucosal ulceration

General Principles of Treatment

The first and crucial step in the treatment of DIP is to identify and stop the offending drug. If the patient is taking any implicated drug, consider stopping it even if there has been a delay between drug initiation and disease onset. This may result

in remission in many, but not all, patients and reduced disease severity in others. A rapid decline in circulating anti-desmoglein antibodies, associated with clinical improvement, has been observed after withdrawal of the offending drug (Nagao et al. 2005).

Patients in whom the disease persists after cessation of the implicated agent require therapy with systemic corticosteroids (CS) and/or immunosuppressants as for idiopathic pemphigus. Appropriate skin care is also an important part of management.

CS are the mainstay of treatment and the dosing regimens are similar to those used for idiopathic pemphigus. The most common approach is to initiate prednisolone with doses ranging from 0.5 mg/kg/day for mild disease to 1–1.5 mg/kg/day for more severe cases. If the clinical response is insufficient after 1 week, the dose could be increased up to 2–2.5 mg/kg. Once the disease activity is under control, tapering of CS should begin, with the aim of reaching the lowest dose needed for remission maintenance. One approach is to reduce the dose of prednisolone by 5–10 mg/day weekly and more slowly below the dose of 20 mg/day.

In severe DIP or if doses greater than 100 mg/day of prednisolone are required for disease control, pulsed intravenous CS should be considered. Intravenous methylprednisolone 250–1,000 mg or equivalent doses of dexamethasone are given on one to five consecutive days and can be repeated.

Adjuvant drugs are commonly prescribed in conjunction with CS in order to allow tapering of steroids to reduce their risks. Azathioprine is the most common immunosuppressive drug used for pemphigus, and its steroid-sparing effect in PV treatment has been supported by clinical trials (Chams-Davatchi et al. 2007). The dose of azathioprine is 1–3 mg/kg per day, but patients with low levels of thiopurine methyltransferase (TPMT) should receive reduced doses, e.g. 0.5 mg/kg.

Mycophenolate mofetil (MMF) may be useful in the treatment of DIP and has a more favourable side effect profile. The typical dose is 2 g per day (taken in two divided doses), prescribed in addition to systemic CS. In recent trials, MMF failed to show a significant steroid-sparing effect in pemphigus but was associated with a longer remission (Ioannides et al. 2012).

Methotrexate, ciclosporin and dapsone have also been utilized as adjuvants for the treatment of pemphigus, but there is little evidence to support their use in DIP.

For refractory disease and patients who cannot tolerate the first-line regimens, therapeutic options include cyclophosphamide, intravenous immunoglobulin (IVIG), rituximab, immunoadsorption and plasmapheresis.

Cyclophosphamide is usually prescribed as an adjuvant to CS and its dosing schedules vary. A well-established treatment regimen consists of monthly intravenous pulses of dexamethasone (100 mg for 3 days) and cyclophosphamide (500 mg on day 2), followed by oral cyclophosphamide 50 mg daily in between the pulsed therapy. Another approach is to combine conventional daily oral CS with monthly intravenous cyclophosphamide pulses (15 mg/kg).

IVIG is commonly given at a dose of 2 g/kg/cycle over two to four consecutive days, with cycles repeated every 4–6 weeks. A high dose of IVIG (400 mg/kg/day for 5 days) administered in a single cycle has proven to be safe and efficient for steroid-resistant pemphigus.

Rituximab, a monoclonal antibody against CD20 on B-lymphocytes, has shown efficacy in paraneoplastic pemphigus and severe PV and PF. Two dosage schedules are used: the lymphoma schedule of 375 mg/m^2 intravenously once weekly for 4 weeks and the rheumatoid arthritis schedule of 1 g IV given on two occasions, 2 weeks apart. Lower doses of rituximab (e.g. two 500 mg infusions 2 weeks apart) may also be effective.

Immunoadsorption works by removing circulating IgG antibodies and is typically administered as an adjuvant to immunosuppressive therapy (3–4 day cycles repeated every 3–4 weeks). In comparison, plasmapheresis non-selectively removes plasma proteins from the circulation and is more widely available.

Combination therapy with rituximab, IVIG, immunoadsorption and immunosuppressants has been tried but requires further evaluation.

The response to treatment is assessed clinically and characterized by cessation of new blisters and healing of old lesions. ELISA titres for anti-desmoglein antibodies may assist clinical assessment as they sometimes correlate with disease activity.

Key Points

- Paraneoplastic pemphigus (PNP) or paraneoplastic autoimmune multiorgan syndrome (PAMS) is a rare autoimmune blistering disease associated with neoplasia, most commonly lymphoproliferative disorders.
- The pathogenesis of PNP is not fully understood. Multiple antibodies, mainly directed against proteins of the plakin family, are detected in the sera of patients with this disease. Antibodies to periplakin and envoplakin are strongly associated with PNP.
- Clinical manifestations include severe oral ulceration and a polymorphous cutaneous eruption. Pulmonary disease consistent with bronchiolitis obliterans may occur and is often fatal.
- Diagnosis is based on clinical, histopathological and immunological findings. Immunological investigations, including indirect immunofluorescence on rat bladder, ELISA, immunoblotting and immunoprecipitation, have high sensitivity and specificity for the diagnosis of PNP.
- Treatment includes systemic corticosteroids, rituximab and other immunosuppressive therapies. The response to treatment and prognosis in PNP is generally poor.

Definition and Epidemiology

Paraneoplastic pemphigus (PNP) is a life-threatening autoimmune blistering disease associated with neoplasia, most commonly lymphoproliferative disorders. An alternative term for PNP, which has been increasingly used in the literature, is paraneoplastic autoimmune multiorgan syndrome (PAMS). The latter term reflects the diversity of the cutaneous manifestations and

systemic involvement that may occur in this disorder. The incidence and prevalence of PNP are unknown, but it is a rare disease. Anhalt et al. first described PNP in 1990, and by 2011, over 450 cases had been reported in the literature (Czernik et al. 2011). PNP occurs worldwide and affects both sexes, with possible male predominance. The disorder can occur at any age but appears to be most common in the 45–70 years age group.

Basic Concepts of Pathogenesis

PNP is associated with a variety of neoplasms, both malignant and, less commonly, benign. Lymphoproliferative disorders account for the vast majority of PNP cases. The most frequently associated neoplasms are non-Hodgkin lymphoma (40 %), chronic lymphocytic leuchemia (CLL) (18–30 %) and Castleman's disease (10–18 %), followed by carcinoma (9 %), thymoma (6 %), sarcoma (6 %) and Waldenström's macroglobulinaemia (1 %). Monoclonal gammopathy and malignant melanoma each account for fewer than 1 % of cases (Kaplan et al. 2004). Castleman's disease is the leading cause of PNP in children, and it has been reported with a higher frequency in Chinese patients. The most common non-haematological malignancy associated with PNP is carcinoma, with an increasing variety of adenocarcinomas and squamous cell carcinomas reported in the recent years (Webster et al. 2013). Sarcomas are less commonly implicated and include leiomyosarcoma and follicular dendritic cell sarcoma.

PNP is an autoimmune disorder induced by an underlying neoplastic process. The pathogenesis of PNP is not entirely understood, but thought to involve both humoral and cell-mediated immune mechanisms. The humoral response is characterized by production of antibodies mainly directed against intracellular proteins of the plakin family, which are essential components of desmosomes and play a key role in epidermal cell adhesion. Antibodies directed against two of these proteins, periplakin and envoplakin, are the most characteristic of PNP, and their detection is a highly sensitive and specific laboratory feature of the disease. Other commonly associated antibodies include those to desmoplakins I and II, bullous pemphigoid antigen 1 (BPAG1), plectin and a recently identified alpha-2-macroglobulin-like-1 antigen (A2ML1). Desmoglein 3 and 1 (Dsg 3, 1) antibodies are present in some cases, and antibodies to desmocollins, laminin-332 and plakophilin-3 have also been reported (Yashiro et al. 2013). In addition to circulating autoantibodies and tissue-bound antibodies in skin and mucous membranes, deposits of autoantibodies have been found in many internal organs of the affected patients. The role of most antibodies in the pathogenesis of PNP is uncertain, but those to periplakin and envoplakin may be pathogenic. The mechanism by which neoplasms induce antibodies to plakins and other antigens is unknown. Proposed mechanisms include dysregulation of the immune system, cross-reactivity between tumour and epidermal antigens and epitope spreading (increased exposure of multiple antigens to the immune system, as a result of tissue injury). The latter theory may explain the variety of antibodies found in PNP.

There is growing evidence that cell-mediated immunity is involved in the pathophysiology of PNP. Apoptosis of keratinocytes, mediated by cytotoxic T-lymphocytes, along with an increased local production of interferon-γ (IFN-γ) and TNF-α, has been demonstrated in PNP (Billet et al. 2006). In addition, CD8+ cytotoxic T-lymphocytes, CD56+ natural killer cells and CD68 + monocytes/macrophages have been found at the dermal–epidermal junction of affected patients. These inflammatory infiltrates are similar to the ones present in other diseases characterized by cell-mediated cytotoxic reactions, such as erythema multiforme and lichen planus. Therefore, it is possible that lichenoid variants of PNP predominantly involve cellular immunity, whereas vesiculobullous eruptions are mainly mediated by humoral responses.

Clinical Presentation

Approximately two-thirds of patients are known to have neoplasia at the time of onset of PNP. All PNP patients develop mucosal erosions, with

severe, painful stomatitis being the most constant feature and the first manifestation of the disease in about 45 % of patients. The oral erosions are typically widespread, involving the tongue (particularly lateral borders), oropharynx and vermilion border of the lips. The erosions tend to appear more necrotic than those observed in pemphigus vulgaris (PV). Multiple other mucosal surfaces can be affected, including the conjunctiva, larynx, anogenital region and gastrointestinal tract.

The cutaneous involvement in PNP is characterized by polymorphous eruptions that significantly overlap with other dermatological diseases. The spectrum of cutaneous lesions includes vesicles and bullae, which may be flaccid or tense, erythematous/violaceous scaly papules and plaques, targetoid lesions and erosions. Based on the morphology and histological findings, five clinical variants of PNP have been described: pemphigus-like, bullous pemphigoid-like, lichen planus-like, graft-versus-host-disease (GVHD)-like and erythema multiforme-like. Pustules and vegetative lesions can occur, and a combination of various lesion types is often present in PNP patients. Involvement of the palms, soles and periungual skin is common, unlike PV in which it is rare. Extensive epidermal detachment, resembling toxic epidermal necrolysis (TEN), has also been described. Pulmonary involvement is increasingly recognized in PNP and manifests with a bronchiolitis obliterans-like disease. It is thought to occur in about 30–40 % of patients. Clinically it is characterized by dyspnoea in the presence of a relatively normal chest X-ray and an obstructive pattern on pulmonary function testing. High-resolution CT may demonstrate features of bronchiolitis obliterans, such as expiratory air trapping and bronchial wall thickening. The pulmonary disease is usually progressive and often leads to fatal respiratory failure. The mechanisms of respiratory involvement in PNP are not fully understood, but it has been shown that respiratory epithelial cells express the plakin proteins which are recognized by PNP antibodies, and their reactivity against pulmonary epithelial antigens may cause sloughing of epithelial cells with subsequent obstruction of small airways. In addition, T-cell-mediated cytotoxicity appears to play an important role in pulmonary disease.

The prognosis in PNP is poor, with mortality rates approaching 90 %. However, a recent study of 53 patients showed a 5-year survival rate of 38 %, suggesting that better outcomes may be possible (Leger et al. 2012). The main causes of death include sepsis, multiorgan failure, respiratory failure due to bronchiolitis obliterans and progression of an underlying malignancy. Erythema multiforme-like eruptions and keratinocyte necrosis have been shown to be predictors of fatal outcome. The prognosis is better in PNP associated with Castleman's disease and thymoma, after resection of the tumours.

Diagnosis

The diagnosis of PNP is based on the combination of clinical and laboratory findings. There are no generally accepted diagnostic criteria, but the following mandatory criteria have been suggested: severe stomatitis, positive indirect immunofluorescence (IIF) on rat/monkey bladder epithelium, positive direct immunofluorescence (DIF) if negative IIF, detection of antibodies against envoplakin or periplakin and a concurrent neoplasm.

The laboratory tests used in PNP include histopathology, DIF and serological studies. The most common histopathological findings are suprabasal acantholysis, lichenoid interface dermatitis and keratinocyte necrosis. However, the histological features in PNP are not diagnostic as they are highly variable and may overlap with many other conditions.

DIF findings in PNP include epithelial intercellular and/or basement membrane zone (BMZ) IgG and/or C3. Combined intercellular and BMZ binding is unusual and should prompt suspicion about PNP. The sensitivity of DIF for PNP ranges from 41 to 79 %. IIF labelling of rat bladder epithelium has a high sensitivity and specificity for PNP of up to 86 and 99 %, respectively (Joly et al. 2000). IIF performed on rat bladder epithelium is positive exclusively in PNP, whereas IIF on monkey oesophagus detects antibodies in both

PV and PNP. Enzyme-linked immunosorbent assay (ELISA) for circulating antibodies against envoplakin and periplakin has a high diagnostic accuracy in PNP, with a sensitivity and specificity around 80 and 96 %, respectively (Probst et al. 2009). Immunoblotting and immunoprecipitation are additional serological tests for the diagnosis of PNP. They detect antibodies directed to periplakin (190 kD), envoplakin and desmoplakin II (210 kD double band), desmoplakin I (250 kD), BPAG1 (230 kD), plectin (>400 kD), A2ML1 antigen (170 kD) and other proteins found in PNP. Immunoblotting and immunoprecipitation are highly sensitive specific tests, but their availability may be limited.

Once the diagnosis of PNP is established, evaluation for an underlying malignancy is necessary.

Differential Diagnosis

- Oral mucositis due to chemotherapy and other causes of severe oral ulceration
- Pemphigus (vulgaris, drug-induced)
- Bullous pemphigoid and other autoimmune blistering disorders
- Mucous membrane pemphigoid
- Drug eruptions
- Lichen planus
- GVHD
- Erythema multiforme
- Stevens–Johnson syndrome and TEN

General Principles of Treatment

Treatment of PNP requires close collaboration between oncology, dermatology and respiratory physicians. Response to treatment in PNP is variable and generally poor. The cutaneous lesions are more responsive to therapy than the stomatitis, which is often refractory. Treatment of an underlying malignancy may be beneficial, but PNP commonly progresses despite controlling the neoplastic disease. In cases associated with thymoma and Castleman's disease, complete tumour resection sometimes results in remission of PNP. Supportive measures and adequate analgesia play an essential role in the management of PNP. In terms of specific treatment, this is similar to that of PV both in terms of the drugs used and doses. Systemic corticosteroids (typically prednisolone 1 mg/kg/day) are usually the first-line therapy for patients with PNP. Pulsed intravenous steroids (e.g. methylprednisolone 500–1,000 mg on 1–5 consecutive days) can also be used as initial therapy. Prednisolone is slowly tapered over months and often combined with other immunosuppressive agents, such as azathioprine, ciclosporin, mycophenolate mofetil and cyclophosphamide (→see Pemphigus chapter). Due to the rarity of PNP, there is insufficient evidence to date to support any particular treatment modality or therapeutic regime. In case reports and small case series, the following doses of immunosuppressive agents have been used, alongside steroids: azathioprine 100 mg/day, ciclosporin 5–7 mg/kg/day and mycophenolate mofetil 1–2 g/day. Several treatment regimens have been described for cyclophosphamide, for instance, cyclophosphamide 500 mg intravenously on days 1–3 every 3 weeks with dexamethasone 100 mg intravenously at 3-week intervals (Frew and Murrell 2011). Rituximab, a monoclonal antibody against CD20, expressed on B-lymphocytes, has shown efficacy for PNP in case reports, albeit inconsistently (Frew and Murrell 2011). The main dosage schedule used is 375 mg/m^2 intravenously once weekly for 4 weeks with (or without) subsequent doses at the intervals of several weeks to months. Alemtuzumab, a monoclonal antibody to CD52, expressed on T- and B-lymphocytes, has recently been reported to be effective in PNP associated with CLL. Other therapeutic options, such as plasmapheresis and intravenous immunoglobulin (e.g. 2 g/kg/cycle over 2–4 consecutive days, with cycles repeated every 4–6 weeks), have been used as adjuncts to immunosuppressive therapy.

Treatment should continue until disease control is achieved (as defined by the absence of new and healing of existing cutaneous and mucosal lesions), lack of efficacy is apparent or serious side effects occur. Careful monitoring and close liaison with oncologists are essential when using

immunosuppressive therapy in the context of an underlying malignancy. A particular caution should be taken in the setting of an undiagnosed neoplasm, as empirical immunosuppression in such circumstances can be detrimental.

Pityriasis Lichenoides Acuta

74

Andrea Andreassi and Lucio Andreassi

Pityriasis Lichenoides Acuta (PLEVA)

Key Points

- PLEVA includes a wide spectrum of clinical situations, ranging from cases with modest expressions to forms with high fever, malaise, intense myalgias, and multiple ulcero-necrotic lesions.
- In most cases, PLEVA is a self-healing process that resolves in a few months. Sometimes, the disease changes to pityriasis lichenoides chronica and may persist for years.
- The course of febrile ulcero-necrotic variant can last from 1 month to 2 years with recurrent acute episodes. Some cases can have a fatal outcome.
- The therapeutic strategy must be adapted to cope with the characteristics of clinical presentation.
- In cases with fever, an antibiotic treatment is always useful. In children, erythromycin is the antibiotic of choice, whereas tetracycline is preferable in adults.
- In cases without fever with moderate cutaneous lesions, in addition to topical treatment with steroid creams, it may be appropriate to start immediately the phototherapy. In adults, NB-UVB or PUVA may be preferable.
- In highly febrile patients with severe general condition and multiple ulcero-necrotic lesions, in addition to an antibiotic, it is advisable to administer a systemic steroid or methotrexate. Systemic steroids are suitable for adults and children, whereas methotrexate should be reserved for adult patients.
- Once an attenuation of clinical severity is obtained, it may be appropriate to begin a phototherapy session following the above criteria.

Definition

Pityriasis lichenoides et varioliformis acuta (PLEVA), or acute guttate parapsoriasis, or Mucha-Habermann disease, is the acute form of a papulosquamous cutaneous disorder, whose chronic form is also known as pityriasis lichenoides chronica (PLC) or chronic guttate parapsoriasis. A rare severe ulcero-necrotic form, which is a febrile variant of PLEVA, is also known. Lymphomatoid papulosis, formerly considered

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_74, © Springer-Verlag Berlin Heidelberg 2015

as a possible persistent variant of PLEVA, is now classified as a primary cutaneous CD30(+) lymphoproliferative disorder, but the description of PLEVA variant, characterized in the conspicuous CD30 component, suggests the existence of intermediate forms between the classical PLEVA and lymphomatoid papulosis.

Epidemiology

The incidence and prevalence of PLEVA are unknown. Racial predisposition or special geographical frequency has not been reported. The disease has been observed mainly in adolescents and in young adults, less frequently in infancy, and rarely in old age.

Basic Concepts of Pathogenesis

Pityriasis lichenoides acuta is a disease of unknown etiology. It is debated if it is an inflammatory reaction triggered by various infectious agents, or an immune complex-mediated vasculitis, or a genuine lymphoproliferative process that is part of the cutaneous T-cell lymphoproliferative spectrum, possibly related to lymphomatoid papulosis. Attempts to isolate bacterial or viral agents have given controversial results, but the hypothesis of a reaction to an infective organism is largely accepted. The elevated incidence in young patients and the self-limited course support such a hypothesis. Pathogens that have been supposed to cause PLEVA include adenoviruses, Epstein-Barr virus, *Toxoplasma gondii*, parvovirus B19, as well as gram-positive cocci.

Clinical Presentation

The lesions of PLEVA usually appear on the anterior trunk and flexor surfaces of the extremities (Figs. 74.1 and 74.2). The onset is sudden with reddish-brown macules and edematous pink papules that undergo central vesiculation and hemorrhagic necrosis. Occasionally, headache, malaise, and fever may precede or accompany the onset of the disease. Lesions tend to be more numerous on the proximal than the distal parts of the extremities. The face, scalp, and palmoplantar surface are usually spared, but in some cases, the lesions may involve the entire body surface. In most cases, PLEVA is a self-healing process that resolves in a few months. Sometimes, however, the disease changes to pityriasis lichenoides chronica and may persist for years with a course characterized by remissions and exacerbations.

The febrile ulcero-necrotic Mucha-Habermann disease is characterized by necrotic cutaneous ulcerations associated with systemic manifestations. The disease begins with high fever, asthenia, malaise, intense myalgias, neuropsychiatric alterations, and multiple cutaneous lesions. Older lesions progress to large painful ulcers with central necrosis and raised borders. The course of febrile ulcero-necrotic variant can last from 1 month to 2 years with recurrent acute episodes. Some cases can have a fatal outcome.

Diagnosis and Differential Diagnosis

PLEVA histopathology has several aspects similar to PLC, confirming that the two clinical features, as well as their variants, belong to a common clinicopathological spectrum. In early stages, the most typical histological changes are represented by focal necrosis, occasional vesicles, and vacuolization of the basal layer. In advanced stages, the epidermis can be invaded by a dense infiltrate, while the necrotic phenomena are more pronounced and may involve the entire epidermis. A lymphohistiocytic infiltrate is present in the dermis with a predominantly perivascular arrangement and extends from the dermoepidermal junction until the reticular dermis. The vessels are dilated, sometimes occluded, and often surrounded or invaded by inflammatory cells with possible leukocytoclasis.

A number of laboratory abnormalities have been shown in patients with PLEVA, but they are not significant for the diagnosis. Immunofluorescence techniques have shown

Fig. 74.1 PLEVA in a 6-year-old child

Fig. 74.2 PLEVA in a 52-year-old woman

slight vascular deposits of IgM and C3 in most lesions. Perivascular deposits of fibrin have been observed in early lesions; more extensive perivascular and interstitial deposits of fibrin have been detected in advanced lesions.

Clinical differential diagnosis of PLEVA includes conditions reported in Table 74.1.

Table 74.1 Conditions which must be clinically differentiated from PLEVA

Disease	Main clinical features
Pityriasis lichenoides chronica	Discrete papules and macules with micaceous scales
Lymphomatoid papulosis	Erythematous papules, rapidly evolving into red-brown, or hemorrhagic, or vesicular, or pustular, or necrotic lesions; occasional noduloulcerative lesions; in later phase, possible large plaques or nodules showing slow regression
Varicella	Small, erythematous macules on the scalp, face, and trunk, rapidly progressing into papules, vesicles, pustules with subsequent central umbilication and crust formation
Guttate psoriasis	Monomorphic lesions completely covered with stratified scales; bright underlying erythema; Auspitz's sign positive
Gianotti-Crosti disease	Lack of necrosis; acral distribution of the lesions
Erythema multiforme	Involvement of mucous membranes; target lesions

General Principles of Treatment

Most patients with PLEVA are in good general health and symptom-free except low-grade fever and mild pruritus. For these subjects, considering that the disease is often a self-healing process, treatment is not always necessary. A couple of weeks are usually sufficient to determine whether the disease may be a self-limiting condition without treatment. In any case, therapy is required in more severe forms, particularly in febrile patients with ulcero-necrotic nodules and plaques, evolving in ulcerated lesions.

Since the clinical evidence suggests that an infectious agent may be involved in the pathogenesis of PLEVA, an antibiotic treatment is recommended at least at the onset of the disease.

The patient's age is another important criterion to be considered in defining the therapeutic strategy. In fact, although PLEVA displays similar characteristics in adults and children, the latter cannot benefit by all available therapeutic procedures.

Topical Treatments

Steroid creams are largely used in the treatment of PLEVA, but there are no controlled studies demonstrating their effectiveness. Topical tacrolimus, a calcineurin inhibitor, mostly used in the treatment of atopic dermatitis, has been reported to work in some patients. Topical creams, with antiseptics or antibiotics, may be necessary in the forms with ulcerated lesions.

Systemic Treatments

Antihistamines are the most common and safe treatment and can be used both in adults and in children. They may relieve pruritus but have little influence on the course of the disease.

Antibiotics are largely used in the treatment of PLEVA, especially in the febrile forms. *Tetracycline* is mainly used in adults, whereas *erythromycin* is the first-line drug in childhood.

In a study of 15 children (11 suffering from PLEVA and 4 from PLC) treated with 200 mg of erythromycin 3 or 4 times a day, 2 PCL patients and 11 PLEVA patients had remission (Truhan et al. 1986). In another study including 22 children (72 % suffering from PLEVA and the remainder from PLC), erythromycin was administered to 8 subjects with moderate results (Romani et al. 1998). In a retrospective review of 124 patients, erythromycin was the initial treatment option in 79.7 % of patients. Andrea Andreassi observed a response to erythromycin in 66.6 % of patients with a median response time of 2 months; of those, 61 % cleared completely (Ersoy-Evans et al. 2007). More recently, a retrospective study on 24 children (15 affected by PCL, 6 from PLEVA, and 3 from PLEVA-PLC overlap) showed that oral erythromycin, at a dosage of 30–50 mg/kg/day in three to four divided dosages for 1–4 months, is an effective and well-tolerated therapeutic option (Hapa et al. 2012).

Patients with PLEVA are responsive to tetracycline given at the initial dose of 2 g daily for 2–4 weeks, followed by treatment of 1 g daily. According to our experience, minocycline and doxycycline at a dosage of 100 mg daily can be alternative options. Since tetracyclines are effective even if no infection signs are evident, a possible inhibition of neutrophil chemotaxis is hypothesized.

Corticosteroids have been reported fully effective in sporadic cases. In our experience, they are able to reduce the intensity of the disease. A short treatment with prednisolone at 0.5 mg/kg daily induces the regression of general symptoms, permitting other treatments to be performed, particularly phototherapy in patients with severe clinical lesions.

Methotrexate is effective in patients with PLEVA and in some cases it has been administered in association with corticosteroids. In one of the first studies, six patients with PLC were treated with methotrexate at doses ranging from 7.5 to 20 mg/week, with good final results. In subsequent studies, the use of methotrexate was extended to PLEVA with good results, but its potential side effects, as well as the tendency of the disease to recur after treatment, suggest restricting the use of this drug only to selected patients.

Other systemic drugs for the treatment of PLEVA include dapsone, cyclosporine, and high-dose immunoglobulins. All showed good efficacy, but the number of cases is small and does not allow a reliable assessment.

Phototherapy

UV treatment has been widely used with varying success both in patients with PLEVA and in those with PLC. It has been used as simple solar exposure, psoralen plus ultraviolet A (PUVA), UVA or UVA1 without psoralen, UVA/B, and UVB narrowband. All these procedures, except PUVA, can be used in adults and in children; however, some clarifications are necessary.

Treatment with UVB is performed two or three times a week, starting with doses of 20–40 mJ/cm^2 in relation to skin type. Twenty to thirty sessions are usually required to get the clearance of the lesions. UVA/B therapy is performed with modalities similar to those used for UVB alone. Narrowband UVB therapy with TL01 lamps provides further advantages. In a study performed on 31 patients (23 PLEVA, 8 PLC) treated with NB-UVB phototherapy, a complete response was observed in 15 out of 23 PLEVA patients (65.2 %) with a mean cumulative dose of 23 J/cm^2 after a mean number of 43.4 exposures (Aydogan et al. 2008). Particularly interesting are the results obtained with the UVA1 radiation, between 340 and 400 nm. In a study carried out on eight patients (three with PLEVA and five with PLC), each subject received 60 J/cm^2 UVA1 daily until remission. UVA1 therapy was an effective and well-tolerated treatment for PLEVA and PLC. The therapeutic activity seems to be related to direct effects on cutaneous inflammatory infiltrates because the lesions in unexposed cutaneous areas did not respond (Calzavara-Pinton et al. 2002). In a recent study, 15 subjects suffering from pityriasis lichenoides were divided in two groups, respectively, treated with PUVA or NB-UVB. As the difference between the two groups was insignificant, it was concluded that both options are acceptable for treating this disorder (Farnaghi et al. 2011).

The regression of PLEVA after UV radiation is not always permanent. Possible recurrences can be treated with further UV treatments. How UV radiation works in the treatment of PLEVA is not known. A possible hypothesis is that UV radiation inhibits the release of some inflammation mediators and therefore is able to interfere with lymphocyte infiltrate.

Practical Suggestions at Glance

Before starting the treatment of a patient suffering from PLEVA, it is necessary to accurately assess the case to be treated. This is because PLEVA includes a wide spectrum of clinical situations, ranging from cases with modest expressions to forms with high fever, asthenia, malaise, intense myalgias, neuropsychiatric alterations, and multiple ulcero-necrotic lesions. The therapeutic strategy must be adapted to cope with the characteristics of clinical presentation (Table 74.2).

Table 74.2 Treatment levels depending on the severity of disease

Severity of disease	Step-by-step treatment
Moderate and sporadic lesions, without fever	Topical steroids, possible phototherapy
Intense and disseminated lesions, with moderate fever	1. An antibiotic treatment is always useful: erythromycin in children, tetracycline in adults
	2. Phototherapy may begin when patients become afebrile
Highly febrile patients with severe general condition and multiple ulcero-necrotic lesions	1. In addition to an antibiotic, it is advisable to administer a systemic steroid (children and adults) or methotrexate (only adults)
	2. Phototherapy can be performed when patients are in good general condition

Several modalities of phototherapy are available: in *adults* NB-UVB or PUVA may be preferable. In *children*, the most suitable options are UVA or UVA/B or UVA1

In cases without fever with moderate cutaneous lesions, in addition to topical treatment with steroid creams, it may be appropriate to start immediately the phototherapy. In adults, NB-UVB or PUVA may be preferable.

In cases with fever, an antibiotic treatment is always useful. In children, erythromycin is the antibiotic of choice, whereas tetracycline is preferable in adults. Once the fever has disappeared, it is appropriate to begin phototherapy following the above indications.

In highly febrile patients with severe general condition and multiple ulcero-necrotic lesions, in addition to an antibiotic, it is advisable to administer a systemic steroid or methotrexate. Systemic steroids are suitable for adults and children, whereas methotrexate should be reserved for adult patients. Once an attenuation of clinical severity is obtained, it may be appropriate to begin a phototherapy session following the above criteria. Large ulcerations, typical of the febrile ulcero-necrotic variant, require local wound care. Infected lesions may be treated with topical antibiotic.

Pityriasis Lichenoides Chronica

75

Paloma Borregón and Agustín España

Key Points

- Pityriasis lichenoides (PL) represents a unique group of inflammatory and acquired skin disorders that include pityriasis lichenoides et varioliformis acuta (PLEVA or Mucha-Habermann disease) and pityriasis lichenoides chronica (PLC).
- PLEVA and PLC are two ends of a disease spectrum. The prevalence, incidence and risk factors of PL in the general population are still unclear.
- PLC is distinguished by gradually developing, small, dim, erythematous-to-brown flattened maculopapules with fine centrally attached shiny scales. These crops of lesions are usually scattered across the trunk and proximal extremities and fade with minor hypo-/hyperpigmentation in the absence of scarring. PLC histopathology shows superficial perivascular interface dermatitis.
- PLC must be differentiated mainly from parapsoriasis, guttate psoriasis and lichen planus.
- There are no diagnostic or therapeutic guidelines for PLC.
- Topical corticosteroids, phototherapy and oral tetracycline or erythromycin are the most recommended treatments.

Definition

Pityriasis lichenoides (PL) is an uncommon, acquired skin condition. It represents a unique group of inflammatory skin disorders that include pityriasis lichenoides et varioliformis acuta (PLEVA or Mucha-Habermann disease) and pityriasis lichenoides chronica (PLC). PLEVA and PLC are two ends of a disease spectrum.

History

PL was first described between 1894 and 1925. Neisser and Jadassohn described what would now be considered the acute and chronic forms, respectively. In 1899, Juliusberg described pityriasis lichenoides in a chronic form and thus coined the term pityriasis lichenoides chronica (PLC).

In 1902, Brocq described pityriasis lichenoides as a form of parapsoriasis under the category of parapsoriasis en gouttes. This classification lasted for several years, and it was not until 1926 that PL was first distinguished on clinical grounds as an entity separate from parapsoriasis.

Mucha separated the acute form of pityriasis lichenoides from PLC in 1916. But it was in 1925 when this acute form was given the name pityriasis lichenoides et varioliformis acuta (PLEVA) by Habermann.

Epidemiology

The prevalence, incidence and risk factors of PL in the general population are still unclear. Some investigators estimate the incidence to be around 1 in 2,000 people. Neither an ethnic nor a geographic predisposition has been reported. However, PL does maintain a slight male predisposition and tends to present in late childhood and early adulthood.

Basic Concepts of Pathogenesis

The aetiology of PL is unknown. There are three major pathogenic theories: an inflammatory reaction triggered by infectious agents or drugs, an inflammatory response secondary to a T-cell dyscrasia and an immune complex-mediated hypersensitivity vasculitis. Both PLEVA and PLC contain lesion T-cell infiltrates, with a general predominance of CD8+ cells in PLEVA and CD4+ cells in PLC. Both types of lesions can exhibit dominant T-cell clonality, easily seen in PLEVA, where the infiltrate is denser. This clonality indicates that PL is a T-cell lymphoproliferative disorder like lymphomatoid papulosis and some forms of T-cell cutaneous hyperplasia. This concept may help to explain the occasional association of PL with other lymphoproliferative disorders such as cutaneous T-cell lymphoma, Hodgkin's disease and other lymphomas.

Clinical Presentation

The most common and subtle form of PL is PLC, which presents sequentially or concomitantly and, eventually, may overtake PLEVA. PLC is distinguished by gradually developing, small, dim, erythematous-to-brown flattened maculopapules with fine centrally attached shiny scales (Figs. 75.1 and 75.2). These crops of lesions are usually scattered across the trunk and proximal extremities and fade with minor hypo-/hyperpigmentation in the absence of scarring. Palms, soles, face and scalp can be also affected. This rash may resolve in months or wax and wane for years with extended lengths of remission. Irregular erythema and superficial ulcerations on the oral mucosa and palate have been reported. In dark-skinned people, PLC may rarely present with widespread hypopigmentation rather than the typical papular morphology, especially common in children.

PLC generally manifests a more indolent course than PLEVA. The distribution of PLC lesions may predict its prognosis; a generalized rash may last months but peripheral lesions can take years to resolve.

The diagnosis of PLC is made by clinical evaluation of the skin and a biopsy with histopathologic examination as a confirmatory tool.

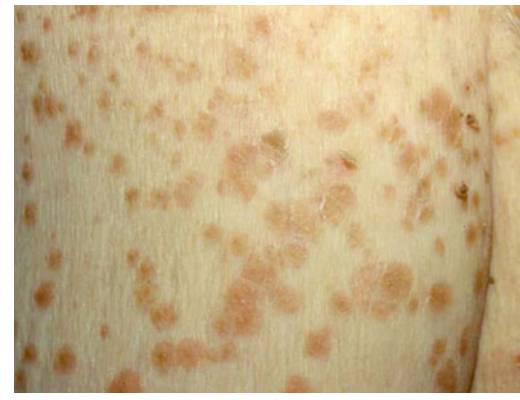

Fig. 75.1 Old patient with diffuse scaly papules and plaques

Fig. 75.2 Pityriasis lichenoides chronica in a 14-year-old boy: red scaly papules on the trunk

Diagnosis

PLC histopathology shows superficial perivascular interface dermatitis. The principal microscopic features are parakeratosis and mild lymphocytic infiltrate accompanied by focal keratinocyte necrosis and mild erythrocyte extravasation. They are similar changes to that observed in PLEVA but milder. While some observers allow occasional atypical lymphocytes, others regard this as a sign of lymphomatoid papulosis.

Immunohistochemical studies have shown that T cells predominate in both the dermal and epidermal inflammatory infiltrates. Most studies indicate that CD4+ T cells predominate in PLC. Admixed in the infiltrate are variable numbers of macrophages and CD1a + epidermal dendritic cells (Langerhans or indeterminate cells).

Differential Diagnosis

The differential diagnosis of the PLC is extensive and encompasses guttate psoriasis, lichen planus, papular eczematous dermatitis, tinea versicolor, Gianotti-Crosti syndrome, pityriasis rosea, drug or viral exanthemas (varicella), generalized arthropod bite reaction, erythema multiforme, cutaneous small vessel vasculitis, secondary syphilis, papulonecrotic tuberculid, polymorphous light reaction, generalized folliculitis, dermatitis herpetiformis, toxic epidermal necrolysis, graft-versus-host disease and mycosis fungoides. PLC must be differentiated mainly from parapsoriasis, guttate psoriasis and lichen planus. A thorough history and clinical, pathologic and laboratory examinations are strongly recommended to distinguish PL from other diagnoses.

An important skin entity to recognize and isolate from PLC is lymphomatoid papulosis, which is very similar clinically so that a biopsy is mandatory to make differential diagnosis by histopathology. The presence of atypical lymphocytes and CD30 positivity for most of these cells are seen in lymphomatoid papulosis but not in PL.

General Principles of Treatment

There are no diagnostic or therapeutic guidelines for PLC. Dozens of different treatments are advocated for this disorder. PLC can regress spontaneously, and due to the low frequency of the disease, its unknown aetiology and the unpredictability of its course, it is difficult to evaluate the effectiveness of the recommended therapies.

Phototherapy

For some authors, phototherapy is by far the most successful therapy and is the first-line therapy for PLC. It is used for a variety of modalities (e.g. UVB, narrowband UVB, psoralen plus UVA and

UVA) and is well tolerated. The total amount of energy used has varied from 10 to 370.5 J/cm^2. Ultraviolet light therapy, especially UVB, has even shown therapeutic value and safety in the paediatric population. Recurrences after cessation of therapy or after long periods of remission are not uncommon, although complete clearing has also been documented.

Topical Treatments

Topical corticosteroids are a good option for PLC, though no studies have specifically compared the efficacy of such agents with that of either placebo or other treatments. However, concerns about their side-effect profile have led to the increased utilization of nonsteroidal topical immune-modulating therapies. Topical tacrolimus has been reported to work in some patients with PLC, both 0.03 % ointment and 0.1 % ointment twice daily, probably because of its anti-inflammatory ability to affect T cells. Topical coal tar preparations could be also helpful.

Systemic Treatments

Oral agents most often used for treatment of PLC include antibiotics and methotrexate. The most common antibiotics include tetracycline and erythromycin.

If a foreign antigen is the suspected trigger (as drug or infectious agent), cessation of the implicated drug or anti-pathogen therapy must be the treatment used. Oral *tetracycline and erythromycin* are used for their anti-inflammatory rather than antibiotic effect, with erythromycin favoured in children younger than 12 years of age (to avoid possible adverse effects in dentition). Especially in the treatment of children, a long-term (4–8 weeks) high-dose treatment with erythromycin (30–50 mg/kg per day) can be effective. For adults, tetracyclines in high doses of about 2 g/day for at least 4 weeks have shown favourable results. Depending on the response, the dosage can be tapered over the course of several months to minimize the risk of relapses.

Antihistamines may be helpful in cases with significant pruritus.

Methotrexate is an effective treatment in some patients with severe forms of PLC in dosages of 7.5–20 mg/week. Recommended initial test dose of 5–10 mg/week can be gradually increased by 2.5–5 mg/week. Reduction of the dose can lead to recurrence. It is not recommended in children. Laboratory control of the treatment is essential. Before it, renal, hepatic and bone marrow function have to be monitored.

Systemic corticosteroids (e.g. prednisone 0.5–1.0 mg/kg of body weight per day with a slow taper) should be considered in PL cases with concurrent and chronic constitutional symptoms such as fever, arthritis and myalgias (more frequent in PLEVA).

Cyclosporine can be considered an alternative in refractory cases. The initial dose is 5 mg/kg per day over a period of about 6–8 weeks. Once the response is achieved, the dose should be slowly tapered. Blood pressure and renal function must be monitored every 2–4 weeks.

Pityriasis Rosea

76

Milos Nikolic

Key Points

- Pityriasis rosea (PR) is a common, acute, or subacute self-limited papulosquamous skin disease.
- Approximately 1–2 % of new dermatological patients are affected by PR.
- PR affects mainly children, adolescents, and young adults.
- PR usually remits within 3–6 weeks.
- Viral etiology of PR is probable.
- Asymptomatic and mild cases may be left untreated.
- If itch is important, topical corticosteroids are indicated.
- Phototherapy (UVB or UVA_1) may be useful in the treatment.
- High-dose oral acyclovir, if introduced early in the course of PR, may reduce the disease duration.

Definition and Epidemiology

Pityriasis rosea is a very common papulosquamous skin disease. Most frequently, PR is mild, with an acute or subacute course, usually lasting 3–6 weeks. In some cases, the eruption may disappear in 1 week, but in rare cases PR may persist even 5 months or longer. The recurrence rate of PR is only 2 %.

Basic Concepts of Pathogenesis

The etiology of PR remains unelucidated. Many clinical and epidemiological characteristics suggest an infective agent as the etiologic factor. True epidemics have not been documented, but family outbreaks have been reported. Seasonal variations have been found: in Europe and North America, most cases have been diagnosed in winter months. The course of PR includes herald patch/patches as sites of inoculation, disseminated lesions that appear after a certain period, mild constitutional symptoms, self-limited course, and relatively rare relapses are the characteristics compatible with an infectious disease. Worsening of the eruption that may appear in patients treated with systemic corticosteroids is also an argument that favors infective etiology.

Investigations of many microorganisms as possible causative agents in PR were fruitless for many years. Recently, systemic active infection with human herpes viruses 6 (HHV-6) and/or 7

M. Nikolic
Department of Dermatovenereology, Faculty of Medicine, University of Belgrade, Belgrade, Serbia
e-mail: milos_nikolic@yahoo.com

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_76, © Springer-Verlag Berlin Heidelberg 2015

(HHV-7) has been implicated in PR pathogenesis. HHV-8 has also been found as a possible etiologic agent of PR. Unfortunately, not all authors have been able to confirm the causative role of these viruses in PR.

Clinical Presentation

PR has been reported in all races and equally affects males and females. It may occur at any age, but most patients are between 10 and 35 years old. In temperate climate zones, the incidence is highest in winter and lowest in summer months. The prevalence of PR in the United States has been estimated to be 0.13 % in men and 0.14 % in women.

Prodromal symptoms are uncommon, and the first manifestation is the herald patch, present (or at least noticed) in 70–80 % of patients. Herald patch is usually a solitary, oval, erythematous, and scaly plaque, measuring 2–6 cm in diameter. Within 2–3 days to 2 weeks, smaller, erythematous (Fig. 76.3), round to oval macules and/or slightly infiltrated plaques with crinkly surface and a rim of fine scale (collarette scale – free at the center of the lesion and attached at the periphery), measuring 1–3 cm in diameter, appear in crops on the trunk and proximal extremities. The long axes of the lesions are oriented along the skin tension lines, running parallel to the ribs, forming the classical "Christmas-tree-like pattern." The face, hands, and feet are usually spared. Especially in children, these areas may be involved. New lesions continue to appear over a few weeks, persist for a few weeks, and then gradually resolve over another few weeks. The entire course of PR usually lasts 3–6 weeks. Most frequently, the lesions are asymptomatic, but mild to severe itch may be present. In some cases, the lesions may persist up to 3 months and very rarely more than 5–6 months. Upon resolution of the inflammatory lesions, residual hyper- or hypopigmented macules, lasting for another several weeks to months, may be found.

There are several clinical variants of PR, and the variants may be as frequent as the "classical" cases. The herald patch may be absent, or there may be more than one herald patch. In children, the lesions are often papular or purpuric. Vesicular (Fig. 76.2) or bullous lesions may be seen. Inverse PR affects predominantly skinfolds (Fig. 76.3). Urticarial lesions are rarely reported. In patients with darker skin, the lesions may have lichenoid aspect. The extent of the eruption in PR may be variable – in some patients the lesions are very numerous and disseminated, and in other cases, there may be only several lesions. Oral, palmar, or plantar lesions are rare but described in the literature.

The recurrence rate is low; approximately 2 % of patients will have a second attack, while multiple recurrences are even rarer.

Diagnosis

There are no specific laboratory tests that could help in the diagnosis. Biopsy is relatively rarely performed in routine practice, and most frequently, it is not necessary for the diagnosis. The histopathological characteristics are not diagnostic but may be suggestive. In the epidermis, spongiosis, vesicles, and focal parakeratosis are usually present. Also, exocytosis of mononuclear cells into the epidermis is frequently seen. In the upper dermis, edema and mild perivascular mononuclear cell infiltrate can be present, sometimes with extravasation of red blood cells (Figs. 76.1, 76.2, and 76.3).

Differential Diagnosis

The differential diagnosis includes secondary syphilis, viral exanthems, guttate psoriasis, seborrheic dermatitis, pityriasis lichenoides ("guttate parapsoriasis"), small plaque parapsoriasis, disseminated nummular eczema, PR-like drug eruptions (induced by captopril, gold salts, ketotifen, barbiturates, metronidazole, isotretinoin, lamotrigine, adalimumab, rituximab, etc.), and disseminated tinea corporis. Herald patch(es) may mimic psoriasis, tinea corporis, or nummular eczema.

Fig. 76.2 One of the atypical variants of PR: disseminated, somewhere annular oval plaques with edge papulovesicles

Fig. 76.3 Inverse PR in darkly pigmented skin (Courtesy of Dr. V. Petronic-Rosic, University of Chicago, Chicago, IL, USA)

General Principles of Treatment

The patients should be reassured about the nature and the benign course of the disease. Many patients, especially those with mild and asymptomatic disease, will not need any treatment.

Topical Treatments

If any treatment is necessary, most patients will benefit from mid-potency topical corticosteroids, applied twice a day. This approach will alleviate the itch and will hasten the regression of individual lesions. Pruritus can be also controlled using the topical antipruritics such as calamine lotion and lotions with menthol, camphor, or pramoxine. In disseminated forms, UVB phototherapy (both broadband and narrowband) may be helpful. Also, UVA_1 phototherapy (30 J/cm^2, three times weekly, for 3 weeks) has been found effective in the treatment of PR. In summer months, cautious exposure to sunshine can also be recommended. Phototherapy of PR may increase the risk of post-inflammatory hyperpigmentation.

Topical Treatments at a Glance

- Patients with itch will benefit from topical mid-potency corticosteroids.
- Patients with disseminated PR may be treated with UVB or UVA_1.

Systemic Treatments

If a patient with disseminated PR is seen early in the disease (first 7–10 days), oral acyclovir (based on the concept that HHV-6 and HHV-7 are causative agents) can significantly shorten the disease duration. Acyclovir tablets, 800 mg, should be given five times daily, for 7 days (the mean time for skin clearance in the acyclovir group was 18.5 days and in the placebo group, 37.9 days).

In some studies, oral erythromycin (given for its anti-inflammatory and immunomodulating effects) was successfully used in the treatment of PR: 1 g in four equally divided doses for 2 weeks in adults and 25–40 mg/kg in four divided doses in children. In some subsequent studies, erythromycin and azithromycin turned out to be ineffective in the treatment of PR.

Oral corticosteroids have been given for disseminated forms of PR, but in some cases this treatment even provoked a worsening of the eruption.

Patients with pruritus might benefit from oral H1 antihistamines.

Systemic Treatments at a Glance

- For patients diagnosed early, oral high-dose acyclovir may be given for 7 days.
- Oral erythromycin can be given for 14 days.

Overview of Pityriasis Rosea Treatment at a Glance

- For cases with limited number of lesions, topical mid-potency corticosteroid, twice a day.
- If disseminated PR is diagnosed early, oral high-dose acyclovir can be given for 7 days.
- If a patient with disseminated PR is diagnosed with a delay, UVB or UVA1 phototherapy can be recommended.

Pityriasis Rubra Pilaris

77

Andrej Petrov and Vesna Pljakoska

Key Points

- Pityriasis rubra pilaris (PRP) is a chronic papulosquamous disorder of keratinization. The etiology is unknown. PRP shows similarities with psoriasis, but it is a distinct disease.
- According to Griffiths, there are six types of PRP. It appears in adults but also in a juvenile form. It typically affects extensor parts of the body, starting usually from the face. Typical lesion is hyperkeratotic papule. Spearing islands of the non-affected skin are a pathognomonic sign. After some time, salmon-like discoloration of the skin occurs. Palmoplantar keratoderma is almost always present.
- Histology is not confirmatory.
- PRP should be distinguished from psoriasis and other papulosquamous disorders.
- Treatment is topical or systemic. Retinoids are first-line treatment. Biologics are a new class of available medications for the treatment of PRP, basically used with success in psoriasis.

Definition and Epidemiology

Pityriasis rubra pilaris (PRP) is a chronic, inflammatory, papulosquamous disorder of keratinization with unknown etiology, characterized with affection of the body and palmoplantar ("sandal") affection. It appears both in hereditary and in acquired form. The first description of PRP is described by Claudius Tarral who, in 1835, published a case report in Rayer's *A Theoretical and Practical Treatise on the Diseases of the Skin* of a patient he had seen 7 years earlier. Tarral did not recognize the dermatosis as a distinct entity, and it was listed under the title of "general psoriasis."

It affects both sex male and female equally without sexual predilection. The highest incidence is in the first and sixth decade. Incidence is around 1:5,000. There may be racial variation as the incidence of classical PRP was reported to be closer to 1 in 50,000 in India.

The etiology is unknown. There are some similarities with psoriasis, but it is a distinct disease, which is more of a disorder of keratinization than an inflammatory disease. There are some clinical and histological evidence as well about vitamin A deficiency. Infective etiology and familial distribution are also suggested. PRP could appear also after drug therapy and the influence of some triggering factors, such as severe infection, especially in juvenile form. Simultaneously PRP may appear with other immunological disorders, like rheumatoid

Table 77.1 Classification of pityriasis rubra pilaris. Griffiths' six types of PRP

Type	% of cases	Distribution	Prognosis
I. Classical adult	55	Generalized	Most clear in 3 years
II. Atypical adult	5	Generalized	Chronic
III. Classical juvenile	10	Generalized	Most clear in 1 year
IV. Circumscribed juvenile	25	Focal	Uncertain
V. Atypical juvenile	5	Generalized	Chronic

From Albert and Mackool (1999) modified

arthritis, and some malignancies like leukemia or Sezary syndrome, which indicates association with immunosuppression.

6. HIV related. Symmetrical, pruritic eruption composed of erythematous papules is associated with late-onset acne conglobata.

Classification

According to Griffiths there are six types of PRP (Table 77.1) and the classical adult type is the most common, and it has the best prognosis. Remission is appearing after several years. Type 2 PRP is the atypical adult form with a tendency to become chronic. The type 3 classical inherited variant seems to have also good prognosis. Type 6 is described recently in which PRP is associated with HIV and this type has a poor prognosis.

1. Classical adult. Commonest type (50 % of cases). Spreads caudally. The patient is usually erythrodermic with diffuse thickening of the palms and soles. Ectropion often is present.
2. Atypical adult. Long duration. Involves a more ichthyosiform pattern in association with hair loss and areas of eczematous changes.
3. Classical juvenile. Similar to type 1 but affects children in the first decade.
4. Circumscribed juvenile. Affects children, with sharply demarcated areas of follicular hyperkeratosis and erythema on the knees and elbows. Usually does not progress.
5. Atypical juvenile. Appears in the first few years of life and is chronic. Characterized by follicular hyperkeratosis, whereas erythema is not a prominent feature. The skin on the hands and feet can appear scleroderma-like.

Clinical Presentation

Clinical picture is the basis for establishing the diagnosis of PRP.

Classical disease begins on the face, with scaling and erythema, and on lateral parts of the neck and trunk. Also, the disease may appear on extensor surface of the extremities and especially on the back of the first and second phalange. PRP is starting with small plaque lesions which spread all over the body. Typical lesion is follicular hyperkeratotic papule. Spearing "islands" of not affected skin are a pathognomonic sign. In 20 % of the patients, mild pruritus and burning sensation are present. Also Koebner phenomenon may appear like in psoriasis. After some time orange-red "salmon-like" discoloration of the skin is present. This is the hallmark for PRP.

Palms and soles are almost always involved, often showing an orange color. Palmoplantar waxy keratoderma appears after some period, with typical side spreading, producing the so-called sandal pattern. Changes of the nails, thickened nails with a distal discoloration, and subungual hyperkeratosis are often present, but pitting of the nail and dystrophy like in psoriasis do not exist.

Erythroderma can occur after 2–3 months. Erythroderma is a very serious development of the disease and should be monitored carefully. However, usually PRP remains static and disappears after 12 months. Mild pruritus is present.

Histology

Histopathological examination is showing hyperkeratosis, acanthosis, and parakeratosis, both horizontal and vertical, and superficial perivascular lymphocytic infiltrate. There is prominent follicular plugging with dense keratotic material. Histopathological findings are not pathognomonic; they can exclude other papulosquamous diseases.

Differential Diagnosis

PRP has to be distinguished from psoriasis (which is sometimes very difficult) and other papulosquamous disorders in adults and atopic dermatitis in childhood. Other reasons of erythroderma should be excluded. Cutaneous T-cell lymphoma and drug skin reactions should be taken in consideration.

There is no diagnostic laboratory test to confirm PRP. Distinguishing clinical features of PRP include islands of normal, non-affected skin, follicular keratotic plugs, and orange-red discoloration of affected skin.

General Principles of Treatment

Because of the variable clinical course and low incidence, assessment of the treatment modalities is difficult. Treatment modalities should include topical application of medications and systemic therapy.

Topical Treatments

Emollients are effective treatments for pityriasis rubra pilaris. Conservative approach is advised in juvenile cases. Keratolytics, like salicylic acid and tar, are important in the treatment. Calcipotriol can also be effective in children. Urea is very helpful. Topical corticosteroids are not very effective. All irritating factors should be avoided. Palmoplantar keratoderma is difficult to treat. Keratolytics and corticosteroids under occlusion are advised. Calcipotriene should be considered. Tazarotene is also available in the treatment of PRP.

Systemic Treatments

Oral synthetic retinoids are currently the treatment of choice for PRP and have largely replaced vitamin A therapy. Oral retinoids are the first choice in the treatment of widespread disease. Acitretin 0.5–1 mg/kg (in adults) or isotretinoin 0.5–2 mg/kg is advised. Duration of treatment is from 3 to 6 months. The main disadvantage of retinoids is teratogenesis in females. Appropriate contraceptive measures are mandatory and pregnancy is absolutely contraindicated during treatment with acitretin and for 2–3 years after discontinuation of acitretin and during treatment with isotretinoin and for 1 month after discontinuation of isotretinoin. So, oral acitretin is not indicated for the treatment of women of reproductive potential.

Methotrexate is an alternative agent for refractory PRP. Methotrexate is a second line of treatment given orally 15–25 mg/weekly.

Use of cyclosporine in the treatment of pityriasis rubra pilaris is still controversial.

UV-light treatment uses the ultraviolet light spectrum of 290–400 nm to treat a variety of skin diseases. It can be used alone or in combination with other medications applied directly to the skin or taken orally. PUVA, Re-PUVA, is also applied in PRP with less success than in psoriasis vulgaris. UVB therapy used in psoriasis vulgaris could have negative influence and aggravate pityriasis rubra pilaris.

Oral antihistamines can be successful to decrease itching.

Oral megadoses of vitamin seem to be not so effective.

Biologics are new classes of medications that target immune system responses. The beneficial use of biologics in psoriasis is evidence based and tumor necrosis factor alpha (TNF-α) has a central role in psoriasis. There are some data emphasizing that blockade of tumor necrosis factor alpha with antagonists of TNF-α also could

have positive effects in PRP. They are administered by subcutaneous injection (adalimumab, ustekinumab, etanercept) or by intravenous infusion (infliximab).

In case of erythroderma, intensive supportive therapy is imperative.

Polymorphic Light Eruption

78

Robert S. Dawe

Key Points

- Polymorphic light eruption is a common condition characterised by a recurrent abnormal reaction to sunlight (or artificial source ultraviolet radiation) that occurs with a delay following exposure and heals without scarring.
- There are several morphological variants (papular, 'pinpoint papular', vesicular, papular with vesicles, plaque, erythema multiforme-like, insect bite-like, haemorrhagic and even 'sine eruptione' [typical time course but no visible eruption]), hence the term 'polymorphic'.
- In those who are only affected a few times each year, such as on holidays, first-line photoprotection measures, if necessary supplemented by occasional use of prophylactic topical or systemic corticosteroids, can be enough.
- For those more severely affected, one of the second-line phototherapy approaches is indicated.
- For those who remain severely affected, third-line systemic immunosuppression is rarely necessary.

R.S. Dawe
Photobiology Unit, Department of Dermatology, Ninewells Hospital and Medical School, DD1 9SY, Dundee, Scotland, UK
e-mail: r.s.dawe@dundee.ac.uk

Definition and Epidemiology

This is a recurrent abnormal reaction to sunlight (or artificial source ultraviolet radiation) that occurs with a delay following exposure and heals without scarring. There are several morphological variants (papular, 'pinpoint papular', vesicular, papular with vesicles, plaque, erythema multiforme-like, insect bite-like, haemorrhagic and even 'sine eruptione' [typical time course but no visible eruption]), hence the term 'polymorphic'. In many parts of the world, polymorphic light eruption (PLE) is the commonest cause of abnormal cutaneous photosensitivity. This condition is also sometimes termed polymorphous light eruption (PMLE), although the term PMLE has historically been used to include what are now recognised to be distinct conditions such as actinic prurigo (Addo and Frain-Bell 1984). Juvenile springtime eruption is considered by some to be a variant of PLE. 'Spring and summer eruption of the elbows' (Molina-Ruiz et al. 2013), 'benign summer light eruption' (Guarrera et al. 2011) and Taiwanese 'solar dermatitis' (Chen and Lee 2013) probably are variants of PLE.

PLE is common, affecting as many as 10–20 % of some populations (Rhodes et al. 2010). As such there is a broad range of severity. At least amongst those severely enough affected to attend tertiary referral dermatology services, the effects on quality of life can be pronounced. The diagnosis is usually straightforward and based on history taking. It typically starts before the age of 30

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_78, © Springer-Verlag Berlin Heidelberg 2015

years old and is more common amongst females than men. Investigations to look for alternative and relevant concomitant diagnoses (such as solar urticaria or photoallergy) are rarely required. Management is through advice on photoprotection measures (behavioural, environmental, clothing and topical sunscreen), prophylactic topical or systemic corticosteroid therapy if only problematic a few times each year (such as during annual holidays) and, when more severe, prophylactic phototherapy. Systemic immunosuppressive therapy is rarely required.

Basic Concepts of Pathogenesis

The mechanism behind PLE is probably a delayed-type hypersensitivity response to an ultraviolet-induced photoallergen. There is some evidence that PLE is associated with reduced ultraviolet suppression of the induction phase of delayed hypersensitivity responses than in those without PLE (Palmer et al. 2005). This may be a factor predisposing some people to development of the presumed autosensitisation of PLE. This could fit with the fact that people with PLE appear less prone to skin cancers and that this might not simply be due to sunlight avoidance measures alone (Lembo et al. 2008). Possibly those who show better recognition of skin antigens after ultraviolet exposure are better protected against skin cancers but more prone to PLE.

Diagnosis

Once PLE has been diagnosed (usually on history alone), sometimes with investigations in case of concomitant problems such as sunscreen photoallergy, the condition should be discussed with the patient.

General Principles of Treatment

What treatments are needed depend on the severity of the condition and the patient's wishes. In those who are only affected a few times each year, such as on holidays, first-line photoprotection measures, if necessary supplemented by occasional use of prophylactic topical or systemic corticosteroids, can be enough. For those more severely affected, one of the second-line phototherapy approaches is indicated. Other second-line approaches, such as the fern *Polypodium leuco*tomos extract, which has antioxidant and anti-inflammatory properties, remain experimental (Tanew et al. 2012). For those who remain severely affected, third-line systemic immunosuppression is rarely necessary.

First-Line Sun Avoidance and Protective Measures

- When practicable (and often it is not, as the wishes and needs of the patient's family are important), avoidance of extra environmental sunlight exposure such as vacations in sunnier climes should be avoided. Sometimes advice on the use of UV-absorbing 'museum film' (Dawe et al. 1996) to car and house windows is appropriate.
- Appropriate clothing (tightly woven fabrics).
- Broad-spectrum high-factor sunscreens, applied correctly (thickly, evenly and frequently).
- Avoidance of middle of the day (11 a.m. to 3 p.m.) sunlight.

Second-Line Prophylactic Phototherapy/Photochemotherapy

A randomised controlled study did not detect any difference in efficacy between narrowband ultraviolet B phototherapy and psoralen plus ultraviolet A (PUVA) (Bilsland et al. 1993). PUVA has been shown to be more effective than broadband UVB (Murphy et al. 1987a, b). Because of ease of use and greater safety, narrowband ultraviolet B should generally be the first-line phototherapy for PLE.

Although often termed 'desensitisation', phototherapy for PLE is not considered to work as an immunological desensitisation therapy but rather is thought to work through inducing photoprotection effects and its suppressive effects on the skin immune responses. Factors important in giving it

the best chance of working well include carefully selecting the time of year of administration (too early treatment may lead to loss of effect before it can be 'topped up' by natural UV exposure); treating normally exposed sites only (to avoid limiting treatment through treatment-induced PLE on other sites); methods of preventing, or at least reducing the severity of, PLE provoked during therapy (such as applying a potent topical corticosteroid immediately after treatments); and how many exposures are given (a typical approach is to give a course of 15 treatments, administered three times weekly) (Ferguson 1996; Man et al. 1999).

Prednisolone tablets taken at first onset of the rash of PLE slightly, but significantly, shortened the duration of the eruption (Patel et al. 2000). Use of a potent to very potent topical corticosteroid applied daily from the day before to the third day of a holiday also appears helpful for some with 'holiday only' PLE (Man et al. 2000).

Other Second-Line Treatments for PLE

Various approaches have been tried but overall have failed to enter widespread usage as overall not consistently adequately effective. These include ß-carotene, antimalarial drugs, omega-3 polyunsaturated fatty acids (from fish oil), a non-viable *Escherichia coli* filtrate and a strain of viable *E. coli*. An extract of the tropical fern *Polypodium leucotomos* may according to uncontrolled studies be of value. A recent randomised controlled study suggested that the prophylactic application of a vitamin D analogue can be useful (Gruber-Wackernagel et al. 2011).

For exceptionally severe and refractory cases, systemic immunosuppressive drugs, including azathioprine and cyclosporin, have been used.

The Cutaneous Porphyrias

79

Robert P.E. Sarkany

Key Points

- Porphyrias are caused by defects in the haem biosynthesis pathway.
- Not all porphyrias cause skin disease.
- Porphyrias can only be diagnosed by laboratory porphyrin analyses.
- Porphyrias are generally hereditary diseases, except for porphyria cutanea tarda.
- Porphyria cutanea tarda is often caused by other systemic diseases.
- Photoprotection in the porphyrias must be against visible light.
- Porphyria cutanea tarda and erythropoietic protoporphyria can be associated with liver disease.
- Variegate porphyria can cause dangerous acute porphyric attacks.

Definition and Epidemiology

The porphyrias all result from a partial deficiency of one of the enzymes required for the biosynthesis of haem, thus causing accumulation of the enzyme's substrate. The toxicity profile of the accumulated molecule determines the clinical features of the resulting porphyria.

The Biosynthesis of Haem

Haem is synthesized from simple biochemicals (glycine and succinyl CoA) via an eight-step pathway, each step being catalysed by an enzyme. Synthesis of the pyrrole ring (porphobilinogen (PBG)) is followed by assembly of the tetrapyrrole structure (hydroxymethylbilane). The carboxylic acid side chains of uroporphyrinogen III are progressively decarboxylated via coproporphyrinogen III to protoporphyrinogen, which is then oxidized to protoporphyrin IX. Finally, ferrous iron is chelated into the protoporphyrin's central cavity to form haem. Around 80 % of haem is synthesized in erythroid cell precursors in the bone marrow (for haemoglobin production) (Elder 1999a).

Classification

Porphyrias present with either skin disease or acute attacks or both.

In any porphyria, a partial enzyme deficiency causes the accumulation of porphyrins. The porphyrias may be classified, according to the predominant site of porphyrin accumulation, into erythropoietic (congenital erythropoietic porphyria and erythropoietic protoporphyria) and hepatic (all the others) types (Elder 1999a) (Fig. 79.1). For the clinician, the key division is between porphyrias that cause acute attacks and those that cause skin disease:

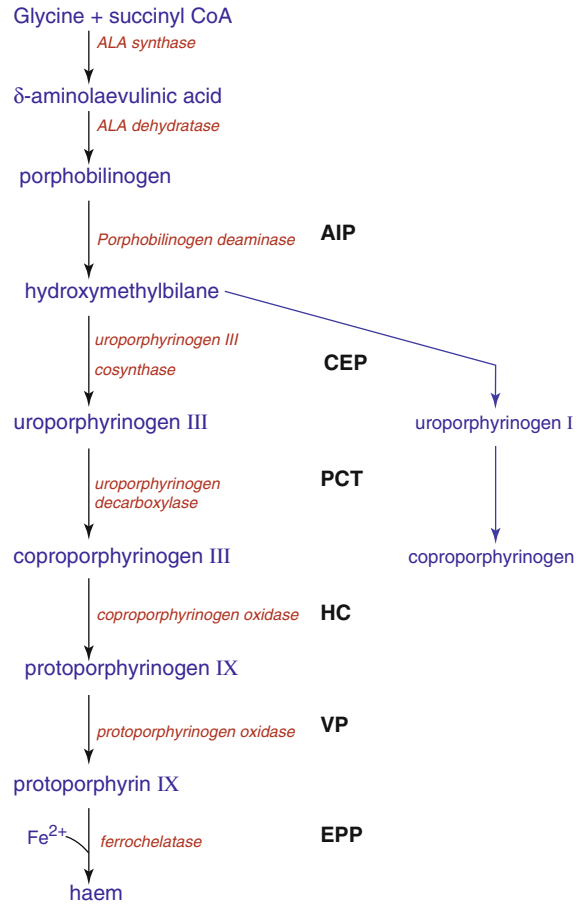

Fig. 79.1 The pathway of haem biosynthesis and the diseases caused by deficiency of each enzyme. *Abbreviations*: *AIP* acute intermittent porphyria, *CEP* congenital erythropoietic porphyria, *PCT* porphyria cutanea tarda, *HC* hereditary coproporphyria, *VP* variegate porphyria, *EPP* erythropoietic protoporphyria

1. Cutaneous disease only:
   - Porphyria cutanea tarda (PCT)
   - Congenital erythropoietic porphyria (CEP)
   - Erythropoietic protoporphyria (EPP)
2. Cutaneous disease and acute attacks:
   - Hereditary coproporphyria (HC)
   - Variegate porphyria (VP)
3. Acute attacks only:
   - Acute intermittent porphyria (AIP)

Basic Concepts of Pathogenesis

Photons of violet light (wavelength peak 408 nm) transform the porphyrin molecule into an excited singlet state. This may revert to the unexcited ground state by emission of characteristic red fluorescence, but intersystem crossing can convert it to an excited triplet state, which interacts with other molecules, particularly molecular oxygen, converting it to excited singlet oxygen in the process. The singlet oxygen stimulates production of hydroxyl radicals which damage tissue directly and indirectly by stimulating complement activation (Lim et al. 1984), mast cell degranulation (Glover et al. 1990) and matrix metalloproteinase activity (Herrmann et al. 1996). The histological site of this phototoxic reaction in the skin determines the clinical characteristics of the porphyria (Brun and Sandberg 1991; Takeshita et al. 2004).

General Principles of Treatment

The management of the skin disease involves preventing violet (Soret wavelength) light penetrating the epidermis. The connection between sun exposure and symptoms is obvious in EPP but is not obvious in the bullous porphyrias where

fragility and blistering are not related to individual episodes of sun exposure. Basic measures include sun avoidance behaviour, sun-protective clothing and hats. Most sunscreens do not protect against violet light. Sunscreens containing reflectant particles, particularly large particle-size titanium dioxide (pigmentary grade), zinc oxide and iron oxide, can effectively protect against violet light (e.g. Dundee sunscreen (Tayside Pharmaceuticals, Dundee, UK)) (Moseley et al. 2001; Kaye et al. 1991). Some window films can absorb violet light, and are useful on car or home windows, particularly in EPP and CEP.

Acute Attacks of Porphyria

AIP, HC and VP can all cause acute attacks, and HC and VP may also cause cutaneous disease. Acute attacks are potentially fatal episodes of an acute systemic neurotoxic reaction, which are frequently triggered by drugs and hormones. This non-dermatological aspect is not covered here. Patients diagnosed by a dermatologist with a porphyria that has the potential to cause acute attacks (e.g. VP) should be referred to a specialist in the management of acute porphyria who will counsel the patient regarding avoidance of acute attack-precipitating factors, treat any acute attacks that occur and genetically test the family for the disease. The diagnosis of an acute porphyria cannot be excluded by porphyrin testing (outside the acute attack situation).

Laboratory Testing in Porphyria

Although clinical features may raise the possibility of a porphyria, the cutaneous presentations of several porphyrias are very similar. Precise diagnosis is essential because of the great differences in clinical management between porphyrias which can be clinically identical. An accurate diagnosis can only be made on the basis of porphyrin analyses carried out in an experienced laboratory. The clinician's role is to suspect the diagnosis of cutaneous porphyria, and to use laboratory testing to confirm whether this is the diagnosis, and if so to precisely identify the porphyria (Table 79.1) (Deacon 1999; Deacon and Elder 2001).

What Samples to Send

In an adult with suspected bullous porphyria, it is generally sufficient to analyse urine and either plasma (where fluorimetry is available) or faeces (where it is not). Urine, plasma and faeces need to be analysed in children, because of the increased complexity of the differential diagnosis. Faecal analysis is necessary when urine and plasma results do not differentiate HC from CEP and, in renal failure, where urine may be unavailable and

Table 79.1 The major biochemical findings in the cutaneous porphyrias

	Urine	Faeces	Red cell	Plasma fluorimetry
Congenital erythropoietic porphyria	Uroporphyrin I; coproporphyrin I	Coproporphyrin I	Zinc- and free protoporphyrin; uroporphyrin I; coproporphyrin I	Peak 615–620 nm
Porphyria cutanea tarda	Uroporphyrin III; heptacarboxyporphyrin	Isocoproporphyrin; heptacarboxyporphyrin (also hex- and pentacarboxy)	Normal	Peak 615–620 nm
Hereditary coproporphyria	Coproporphyrin III	Coproporphyrin III	Normal	Peak 615–620 nm
Variegate porphyria	Coproporphyrin III	Protoporphyrin, coproporphyrin III, X-porphyrin	Normal	Peak 624–627 nm
Erythropoietic protoporphyria	Normal	Protoporphyrin (not diagnostically helpful)	Free protoporphyrin	Peak at 626–634 nm

Adapted from Deacon and Elder (2001)

plasma analysis unhelpful because renal failure increases plasma porphyrins. In suspected EPP, red cells and either plasma or faeces should be analysed.

Handling of Samples

Laboratory testing of body fluids measures porphyrins, since porphyrinogens are spontaneously oxidized to their respective porphyrins outside the body. Porphobilinogen has a tendency to polymerize to other molecules, but porphyrins are reasonably stable when protected from light. All specimens should be kept at room temperature (or 4 °C) in the dark and, ideally, should be analysed within 48 h of collection.

For urine and faecal analysis, fresh random specimens (10–20 mL urine or 5–10 g dry weight faeces) are preferable to 24 h collections. Very dilute urine (creatinine <4 mmol/L) is unsuitable.

Laboratory Analysis of Porphyrins

Old-fashioned qualitative screening methods for detecting porphyrins in specimens (often involving a Wood's light) are insensitive, and negative results are not of value. For all samples, quantitative assessment (spectrophotometric or fluorimetric) is needed and provides results as the total porphyrin concentration. Whole blood or red cell porphyrin testing measures both the total and free protoporphyrin concentrations. Plasma is analysed by fluorimetric scanning, a diagnostically powerful and simple qualitative technique. In urine and faeces, the finding of an increased porphyrin concentration should lead on to high-performance liquid chromatography (HPLC) to rapidly identify the accumulated porphyrins.

Interpretation of Results

In cutaneous porphyrias, the accumulated porphyrin can usually be detected in plasma as an emission peak on spectrofluorimetry. Uro- and coproporphyrin are excreted into the urine and copro- and protoporphyrin into the faeces. Protoporphyrin accumulates in red cells in EPP.

1. *Plasma spectrofluorimetry.* The sample is excited by 410 nm light and fluorescent emissions detected. An emission peak at 615–620 nm indicates the presence of uro- or coproporphyrin and suggests a diagnosis of PCT, HC and CEP, or HEP. A peak at 624–626 nm indicates the presence of a porphyrin–peptide conjugate diagnostic of VP. This 624–626 nm peak is a sensitive indicator of VP. A peak around 633 nm (it can lie between 626 and 634 nm) is caused by protoporphyrin and suggests EPP: EPP is an unlikely diagnosis in the absence of this peak. Plasma porphyrin concentrations, particularly uroporphyrin, increase in renal failure and can be as high as those found in patients with PCT.
2. *Whole blood/red cell.* An increased free protoporphyrin concentration is the diagnostic finding in EPP. The total protoporphyrin concentration includes both free and zinc protoporphyrin. Zinc protoporphyrin is also increased in iron deficiency, lead poisoning and certain anaemias.
3. *Urinary and faecal analysis.* Increased total porphyrin concentration suggests a diagnosis of cutaneous porphyria. The total urine porphyrin concentration is used to monitor disease activity in PCT. HPLC analysis is used to identify the porphyrins once an increased concentration has been found.
   (a) *In urine.* An increase in uroporphyrin (and other highly carboxylated porphyrins especially heptacarboxyporphyrin) is typical of PCT though this does not exclude VP. Coproporphyrinuria, in the presence of normal faecal porphyrin levels, does not indicate porphyria and can be caused by certain drugs, lead toxicity and hepatobiliary disease.
   (b) *In urine and faeces.* Increased coproporphyrin suggests VP but does not exclude HC. Isomer III to isomer I ratios are increased in every porphyria except CEP (where they are decreased). In CEP, excess type I isomers of uro- and coproporphyrin are present in urine and type I coproporphyrin in faeces.
   (c) *In faeces.* In the presence of a plasma spectrofluorimetry peak at 615–620 nm, if urine HPLC does not show the PCT pattern, faecal analysis is required to differentiate HC (increased coproporphyrin

III concentration) from CEP (increased coproporphyrin I concentration). Increased faecal isocoproporphyrin is characteristic of PCT. In renal failure, faecal analysis is vital, since urine may be unavailable and plasma porphyrins are increased in renal failure. Increased faecal protoporphyrin is suggestive but not diagnostic of EPP, since it can also derive from bacterial degradation of haem in the gut.

Porphyrias that Cause Cutaneous Disease But Do Not Cause Acute Attacks

Congenital Erythropoietic Porphyria (Günther's Disease) (ICD-10 E80.0; ICD-9 277.1; OMIM 263700)

CEP is severe and rare and causes lifelong mutilating photosensitivity and haematological disease. It is caused by an autosomal recessive inherited deficiency of the uroporphyrinogen III cosynthase enzyme. This results in massive accumulation of type I isomer porphyrins in erythroid cells which leak into the plasma. It is rare: the incidence in Europe is 0.007/year/10 million population (Elder et al. 2013), and around 200 cases have ever been reported worldwide. Rare adult-onset cases of acquired CEP are reported secondary to myelodysplasia (Sarkany et al. 2011).

Clinical Presentation

CEP has a wide spectrum of presentation, from hydrops fetalis through severe disease starting in infancy and mild forms presenting later in life. The first sign of CEP is often the child's mother noting brown discoloration of amniotic fluid at the onset of labour, or observing pink or brown porphyrin staining of nappies (which fluoresce red under Wood's light).

The Skin in CEP (Katugampola et al. 2012a)

Severe photosensitivity begins in infancy with blisters developing in exposed skin on minimal light exposure. Phototherapy for neonatal jaundice may trigger lesions. Most children are so sensitive to the light that they have problems throughout the year. Exposed (and sometimes non-exposed) skin is fragile. The repeated bouts of inflammation with vesicles and bullae, often complicated by secondary infection, cause mutilating scarring, particularly of the face and hands. This photomutilation may cause erosion of terminal phalanges, onycholysis and destructive changes of the pinnae and nose. Diffuse pseudosclerodermatous thickening may cause microstomia and sclerodactyly-like changes. Hypertrichosis is common, particularly on the upper arms, temples and malar region. Patchy hypo- and hyperpigmentation occur even in minimally exposed areas. A milder late onset form, presenting at any age from the third decade onward, has been described; this presents like PCT and occurs either as a result of mild gene mutations or as an acquired disease secondary to myelodysplasia (Sarkany et al. 2011).

Involvement of eyes and internal organs (Katugampola et al. 2012a):

- Eyes. Keratoconjunctivitis, blepharitis, cataracts, corneal ulcers, scars, cicatricial ectropion and scarring alopecia of eyelashes and eyebrows may all occur. Scleromalacia, pterygium formation, optic atrophy, retinal haemorrhage and scleral necrosis are less common.
- Bones and teeth. Teeth are stained brown and fluoresce under Wood's light. Decreased bone density, osteopenia and osteolytic lesions secondary to erosion by hyperplastic bone marrow can cause pathological fractures. In the hands, there is resorption of terminal phalanges with acroosteolysis and cortical bone rarefaction. Strict avoidance of the sun reduces levels of vitamin D.
- Haematology. Porphyrins in red cells cause haemolytic anaemia. The haemolysis may cause a severe transfusion-dependent anaemia.

Prognosis (Katugampola et al. 2012b)

Most patients used to die by the age of 40, but improvements in supportive care (particularly use of antibiotics) have improved the prognosis. Haematological complications may be fatal. Long-term hypertransfusion may cause iron overload as patients reach adulthood, even when iron chelation

has been used. Bone marrow transplantation now holds out the promise of cure for these patients (see below). The key markers of poor prognosis in CEP are onset of disease in the first year of life and significant haematological involvement.

Diagnosis

- *Biochemical findings*. Massive accumulation in all tissues of type I isomers of porphyrins, mainly uroporphyrin. Red cells and urine contain large amounts of uro- and coproporphyrin (mainly type I) and faeces contain increased concentrations of coproporphyrin (mainly type I). A plasma spectrofluorimetry peak is seen at 615–620 nm. The absence of isocoproporphyrin and the normal level of 5-carboxylic porphyrin excretion in faeces distinguish CEP from hepatoerythropoietic porphyria.

General Principles of Treatment

The photosensitivity is so severe that photoprotection is crucial. Sun avoidance and use of sun protective clothing and hats are essential. Visible light sunscreens (Moseley et al. 2001), and amber window films on windows can reduce exposure to Soret wavelength light, though more opaque films may be necessary (which are obviously not allowed on car windows). Prompt treatment of secondary infection is important. Hypertransfusion with regular blood transfusions to maintain a polycythaemia inhibits endogenous haemoglobin production and decreases porphyrin formation, and may reduce haemolysis and cutaneous symptoms in moderately affected patients. Splenomegaly may increase transfusion requirements and the value of hypertransfusion can decrease at puberty. Hypertransfusion is frequently complicated by iron overload, even when desferrioxamine has been used. Intravenous haematin has been tried in late-onset disease (Rank et al. 1990). Haemolysis worsens the porphyria by causing anaemia. Splenectomy may be necessary where there is hypersplenism. Lights during surgical procedures cause phototoxic reactions, and filters should be used over theatre lights (e.g. Madico TA81XSR). The allogeneic bone marrow transplantation (bone marrow or umbilical cord blood stem cells) is the treatment of choice in severe CEP. It provides long-term cure (Shaw et al. 2001) though the hazards mean that it should be reserved for the worst affected patients and for children with markers of poor prognosis (Katugampola et al. 2012a, b).

Genetic Counselling

Since CEP is autosomal recessive, the chance of each future sibling of an affected child suffering from the disease is 25 %. The diagnosis may be made before birth by measuring the uroporphyrin I concentration in amniotic fluid, which is increased as early as 16 weeks in utero. If the mutations in the index case have been identified, or the foetus is homozygous for the common C73R mutation, prenatal diagnosis from chorionic villous biopsy is possible.

Porphyria Cutanea Tarda (Sarkany 2001) (ICD-10 E80.1 ICD-9 277.1 OMIM 176100)

Porphyria cutanea tarda (PCT) is the commonest porphyria. It is characterized by fragility and blistering of exposed skin. It is usually acquired and is often associated with liver disease. It does not cause acute attacks. In PCT, deficiency of uroporphyrinogen decarboxylase (UROD) causes accumulation of uroporphyrin and other highly carboxylated porphyrins. Seventy-five percent of patients have *type I* (*sporadic*) (enzyme deficiency is acquired and restricted to hepatocytes), due to inhibition of normal UROD enzyme (Elder et al. 1985). Twenty-five percent have *type II* (*familial*) disease where the enzyme deficiency is hereditary, present in all tissues and associated with a UROD gene mutation. The penetrance of the form is lowland; some acquired enzyme inhibition in the liver occurs even in familial PCT. UROD mutation is a risk factor for the development of PCT, rather than representing a separate form of the disease. *Type III* disease is rare and characterized by hereditary enzyme deficiency localized to the liver. *Toxic porphyria*, in which halogenated aromatic hydrocarbons inhibit the enzyme, is rare and mainly affects workers making herbicides. A major epidemic of toxic porphyria in the 1950s in Turkey was caused by hexachlorobenzene added as a fungicide to seed wheat (Dean 1971).

In PCT, UROD enzyme is inactivated by uroporphomethene, a competitive inhibitor (Phillips et al. 2007) generated in the liver by reactive oxygen species in the presence of iron (Elder 1999b). The uroporphyrin diffuses from the plasma into tissues, causing a phototoxic reaction in the upper dermis in exposed skin. This leads to lysis of cells in the superficial dermis with the formation of membrane-limited vacuoles which merge to produce a blister cavity under the basal lamina (Caputo et al. 1983).

The prevalence in most countries is around 1 in 10,000 (Elder 1998).

Clinical Presentation

Sporadic PCT usually presents in middle age although the familial form can occur earlier. Patients describe increased fragility in exposed skin, particularly the backs of the hands, forearms and face, with minor trauma shearing the skin away to cause erosions (Fig. 79.2). Most patients have bullae, which can be over 1 cm in diameter and may be painful. They crust and resolve over a few weeks, leaving atrophic scars, milia and often mottled hyper- or hypopigmentation. Patients rarely associate development of new lesions with sun exposure, but symptoms are generally worse in the summer. Other common features are scarring alopecia following resolution of bullae on the scalp; hypertrichosis, usually on upper face and forehead, sometimes on the ears or arms and occasionally on the whole body; and hyperpigmentation in a melasma-like pattern on the cheeks and around the eyes, or in a diffuse pattern on light-exposed skin, or occasionally in a reticulate distribution (Grossman et al. 1979; Mascaro et al. 1986). Photo-induced onycholysis and accelerated solar elastosis (Mascaro et al. 1986) may occur. Morphoea-like plaques may develop on the head or upper trunk. These plaques may calcify and may require excision and grafting if they ulcerate (Inglese and Bergamo 2005). On the scalp, morphoea-like changes may cause a slowly expanding scarring alopecia (Grossman et al. 1979; Mascaro et al. 1986). Sclerodactyly or facial appearances mimicking systemic sclerosis are reported. Rare presentations of PCT include cicatricial conjunctivitis

Fig. 79.2 Porphyria cutanea tarda: erosions, blisters, pigmentary changes and scarring (Reproduced with permission from: Sarkany (2008)

(Park et al. 2002) and hair darkening (Shaffrali et al. 2002).

Differential Diagnosis

PCT can be clinically indistinguishable from VP, drug-induced pseudoporphyria, renal pseudoporphyria, HC, late-onset Günther's disease or mild hepatoerythropoietic porphyria. Biochemical analysis is necessary to diagnose PCT, and it is particularly important to exclude VP and HC among the differential diagnoses, since they can cause acute attacks.

Diagnosis

- *Biochemical findings* (Elder 1998). In PCT, the urinary porphyrin concentration is increased, consisting mainly of uroporphyrin, some heptacarboxylic acid porphyrin and, sometimes, also hexa- and pentacarboxylic acid porphyrins. A plasma spectrofluorimetry peak is seen at 615–620 nm. Isocoproporphyrin accumulates in faeces. Urine analysis alone is insufficient to diagnose PCT, since a few patients with VP have the PCT urine pattern ('dual porphyria') (Sturrock et al. 1989). In patients with renal failure, faecal analysis is essential, since plasma porphyrins are increased by haemodialysis, and urine collection may not be possible. The biochemical marker of disease activity is quantitative urinary porphyrin excretion measured in a random urine sample.
- *Histopathology* (Wolff et al. 1982). The bullae in PCT are subepidermal with a sparse inflammatory infiltrate and 'festooning' of dermal papillae into the bullae. There is deposition of PAS-positive diastase-resistant fibrillar glycoprotein material in and around upper dermal blood vessel walls and reduplication of the basement membrane. Immunofluorescence reveals IgG, a little IgM, fibrinogen and complement at the epidermal–dermal junction. Morphoea-like lesions in PCT are histologically indistinguishable from other forms of morphoea.
- *The investigation of the patient with PCT.* PCT is a liver disorder with secondary effects in the skin. It is crucial to investigate patients thoroughly both regarding other systemic diseases predisposing to the development of PCT and to assess the severity of any liver disease.

Risk factors for the development of PCT (Bulaj et al. 2000a)

- The major risk factors are genetic haemochromatosis, hepatitis C infection, alcohol and oestrogens. Since some inhibitions of the hepatic enzyme are also required for clinical expression of familial PCT, the same risk factors apply to sporadic and familial PCT. It is essential to investigate for risk factors in all patients diagnosed with PCT.
  - Haemochromatosis. In the USA and Northern Europe, 20 % of PCT patients have hereditary haemochromatosis (Bulaj et al. 2000a; Roberts et al. 1997), usually homozygous for the Cys282Tyr mutation. Homozygosity for this mutation increases the risk of developing PCT 60-fold (Bulaj et al. 2000a). In Southern Europe, haemochromatosis is a less important risk factor.
  - Hepatitis C infection. In Southern Europe, 70–90 % of all PCT patients are infected with the hepatitis C virus (Quecedo et al. 1996; Fargion et al. 1992), compared with around 60 % of patients in the USA (Bulaj et al. 2000a) and 7–36 % in Northern Europe (Linde et al. 2005; Murphy et al. 1993).
  - Alcohol. Between 30 and 90 % of PCT patients consume over 40 g of alcohol daily, and 2 % of all alcoholics with cirrhosis develop PCT (Elder 1999b).
  - Oestrogens. Ingested oestrogens, in the oral contraceptive pill or in hormone replacement therapy, are the sole risk factor in over a quarter of female patients (Bulaj et al. 2000a). Stopping the hormone may be sufficient to induce remission if the duration of therapy has been short (Haberman et al. 1975). If it is not possible to stop the hormone therapy, transdermal drug delivery is a safer alternative than the oral route (Bulaj et al. 2000b).

  Other less common but significant risk factors for developing PCT are haemodialysis and HIV infection (Blauvelt et al. 1992).

Non-insulin-dependent diabetes mellitus, systemic lupus erythematosus, dermatomyositis, hepatitis A and B infection, haematological malignancy, sideroblastic anaemia, thalassaemia and the drug tamoxifen are reported as much rarer associations with PCT.

Most patients possess more than one risk factor for developing PCT, with hepatitis C infection and alcohol being strongly linked in men.

Liver Disease in PCT (Bruguera 1986)

Liver disease is a major concern. In almost all patients, liver biopsy shows increased stainable iron, fatty change and intracellular porphyrin crystals. Fifty percent of patients have more severe changes (lobular necrosis or inflamed fibrotic portal tracts), and cirrhosis occurs in 15 %. As expected, the most severe liver disease is in patients with alcoholism, hepatitis C infection or iron overload (Bulaj et al. 2000a). PCT increases the risk of hepatocellular carcinoma: in Southern Europe, 3 % of PCT patients develop hepatocellular carcinoma during the decade after presentation (Gisbert et al. 2004). Risk factors for developing hepatocellular carcinoma are a symptomatic period longer than 10 years prior to treatment, severe changes on hepatic histology at presentation, hepatitis C infection, male sex and age over 50 years at presentation. Hepatic function must be assessed at presentation in all PCT patients, and patients at high risk of hepatic malignancy require regular ultrasounds and serum α-fetoprotein measurement to detect carcinoma at a treatable stage (Siersema et al. 1992). PCT should be managed as a liver disorder, and the threshold for referral to a hepatologist should be low.

General Principles of Treatment

- *Photoprotection*. Visible light sunscreens (Moseley et al. 2001), filter films for car and home windows, gloves, hats and clothes help control symptoms during the period of several months before specific therapies take effect.
- *Elimination of risk factors.* Stopping oestrogen therapy (Haberman et al. 1975), if it has not been used for more than 2 years, can induce remission. However, elimination of the underlying cause by abstaining from alcohol, or by treating hepatitis C with interferon-α (Sheikh et al. 1998), does not always induce remission. All patients should be advised to abstain from alcohol or oestrogen therapy to prevent exacerbation of the disease.
- *Specific treatments.* Treatment with venesection or low-dose antimalarials is required in most cases. Venesection eliminates hepatic iron overload, thus restoring normal enzyme activity. Around 500 mL of blood is removed every fortnight or so, aiming to induce mild iron deficiency (plasma ferritin below 25 μg/L (Rocchi et al. 1986a; Ratnaike et al. 1988). Blistering usually resolves within 2–3 months, skin fragility within 6–9 months and urine porphyrin concentrations generally normalize within 13 months or so (Mascaro et al. 1986), at which point treatment should be stopped. Hypertrichosis (Mascaro et al. 1986) and sclerodermoid lesions respond more slowly during the years after treatment has stopped. Excision and grafting may be needed for ulcerated sclerodermoid lesions (Mascaro et al. 1986). Desferrioxamine leads to earlier remission than venesection because it rapidly chelates hepatic iron and may be of value in PCT with renal failure but is expensive and inconvenient (Pitche et al. 2003; Rocchi et al. 1986b). Erythropoietin mobilizes hepatic iron into haemoglobin and is the treatment of choice for PCT in renal failure (Sarkell and Patterson 1993). Low-dose antimalarials are very effective. They complex with uroporphyrin and promote its excretion into the bile (Scholnick et al. 1973). Daily doses of chloroquine can cause a dangerous acute hepatitis, but chloroquine at the low dose of 125 mg (Malina and Chlumsky 1981; Ashton et al. 1984) or 250 mg (Valls et al. 1994; Kordac et al. 1989) twice weekly is safe and effective. It leads to clinical remission within 6 months or so and biochemical remission after 6–15 months, at which point treatment is stopped (Malina and Chlumsky 1981; Ashton et al. 1984; Valls et al. 1994; Kordac et al. 1989). Retinopathy does not occur with such low doses of chloroquine (Valls et al. 1994). Low-dose hydroxychloroquine (100 mg twice

weekly) is also effective (Singal et al. 2012). Low-dose chloroquine is the usual treatment of choice. Venesection should be used for patients who do not respond to chloroquine and patients with haemochromatosis. Remission with low-dose chloroquine generally lasts 17–24 months (Malina and Chlumsky 1981; Ashton et al. 1984). With venesection, relapse generally occurs around 2.5 years after the end of treatment (Grossman et al. 1979). Long-term follow-up is necessary for all patients to monitor for relapse (by measuring urinary porphyrin excretion) and for the management of coexisting liver disease.

Genetic Counselling (Elder 1999a)
In view of the identical management of sporadic and familial PCT, the lack of evidence that identifying latent PCT in relatives alters outcomes and the very low penetrance of familial PCT, family screening is not generally done in familial PCT.

Erythropoietic Protoporphyria (ICD-10 E80.0; ICD-9 277.1; OMIM 177000)

EPP is a hereditary porphyria characterized by painful, lifelong photosensitivity and occasionally liver disease. The incidence of EPP in Europe varies between countries (from 0.03 new cases/million/year in Spain to 0.36 in the UK) (Elder et al. 2013). EPP usually results from deficient activity of ferrochelatase, the final enzyme of haem biosynthesis. In a minority of cases, it is caused by gain-of-function mutations in ALAS-2 (the first enzyme in the pathway) (Whatley et al. 2008). The protoporphyrin accumulates in erythroid cells. Photoactivation of protoporphyrin from red cells and plasma causes an acute injury to the endothelium mediated by singlet oxygen and the hydroxyl radical (Brun and Sandberg 1991; Takeshita et al. 2004). Many ferrochelatase gene mutations have been identified in EPP patients, and none are particularly common (Minder et al. 2002). A few adult-onset cases have been reported which are associated with haematological malignancy and may be associated with chromosomal deletions involving the ferrochelatase gene (Sarkany et al. 2006).

Clinical Presentation (Holme et al. 2006; Deleo et al. 1976)
EPP causes immediate pain on exposure to bright sunlight. It presents most commonly in the first year, quite often in babies who may present with crying in their prams in sunny weather. Onset later in childhood does occur, but onset in adulthood is rare. In spring and summer, after anything from a few minutes to an hour or two of sun exposure, patients describe discomfort, tingling or itching in exposed skin, particularly the dorsum of the hands and the face. The severe burning pain can last anything between an hour and several days. Children often find partial relief with cold water and wet cloths, and this feature may be diagnostically useful. Usually, the only physical sign during an attack is oedema, which may be subtle. Many patients experience 'priming' in which sunlight tolerance is reduced on the day after significant sun exposure (Poh-Fitzpatrick 1989). In severe attacks, purpura and crusted erosions or vesicles occasionally occur. Rare cases of EPP with prominent purpura and histological changes resembling a leukocytoclastic vasculitis, acute photo-onycholysis (Marsden and Dawber 1977) or erythematous plaques (Murphy et al. 1985) are described. Physical signs include slight thickening of skin over the metacarpophalangeal and interphalangeal joints; superficial vermicular waxy scarring on the nose; shallow linear, punctate or small circular scars on cheeks and forehead and radial scars around the lips. The skin over the nose, cheeks and forehead can become roughened. Fifteen percent of patients have no physical signs (Holme et al. 2006). Mild variants of EPP may cause diagnostic confusion because of delayed onset of symptoms, shortened duration of attacks and, occasionally, absence of pain. Oedema and predilection of the reaction to the face and dorsal hands and feet are diagnostic clues. There is an occasional association between EPP and a seasonal palmar keratoderma, more commonly seen in autosomal recessive EPP (Holme et al. 2009). Children with

EPP suffer from social isolation due to difficulty joining friends to play outside, and sensitivity to psychosocial issues is important for clinicians. The disease has a profound impact on quality of life (Holme et al. 2006). Symptoms often improve during pregnancy (Holme et al. 2006; Poh-Fitzpatrick 1997). Patients may develop a mild hypochromic microcytic or normocytic anaemia, which can be associated with decreased serum iron levels and increased serum iron-binding capacity (Deleo et al. 1976). With the exception of patients with EPP liver failure, operating theatre lights do not cause any problems during or after surgery in EPP patients (Wahlin et al. 2008). However, operating theatre lights can cause a potentially fatal phototoxic reaction in patients undergoing liver transplantation for protoporphyric liver failure. Vitamin D deficiency associated with osteoporosis is common in EPP, and vitamin D levels need to be monitored and supplemented as required (Holme et al. 2008; Allo et al. 2013).

Diagnosis

Biochemical Investigation (Deacon 1999)

The diagnostic finding is the increased red cell free protoporphyrin concentration. A peak at 633 nm is seen on plasma fluorimetric scanning. Umbilical cord protoporphyrin concentration is not a useful test to identify EPP in newborns (Hanneken et al. 2010).

Histopathology (Ryan and Madill 1968; Epstein et al. 1973)

In the acute phase, there is visible endothelial damage in superficial dermal vessels (Gschnait et al. 1975). In the chronic phase, in exposed areas of skin, PAS-positive diastase-resistant hyaline material is seen in the walls of blood vessels of the upper dermal and papillary vascular plexuses. Immunofluorescence shows immunoglobulins (mainly IgG) in a similar distribution. On electron microscopy, the hyaline material is seen as a greatly replicated, layered and fragmented basement membrane, with fine fibrillar material permeating the capillary connective tissue sheath and extending beyond the vessel walls (Ryan and Madill 1968; Wick et al. 1979).

General Principles of Treatment

(Holme et al. 2006)

No therapy has ever been proven to be effective in EPP mainly because of the lack of an objective test for disease activity in EPP, and high placebo rates make clinical trials difficult. Attention to sunlight protection is the key to management.

- *Photoprotection.* Basic measures include sun avoidance behaviour, sun-protective clothing and hats. It is important to use visible light sunscreens (Moseley et al. 2001). Dihydroxyacetone paint has been used in some patients with EPP (Johnson 1992), and window films, which absorb violet light, can be useful for car or home windows, particularly in severely affected patients.
- *The acute reaction.* For the acute reaction, complete sun avoidance (even through windows) leads to earlier resolution, and fans and cold water provide some pain relief. Antihistamines and most analgesics are of little value. For severe attacks, hospital admission may be necessary for light avoidance and analgesia (usually opiate).
- *Specific therapies.* Oral β-carotene is the most widely used treatment, usually at a dose around 180 mg daily in adults (90 mg daily in children) taken throughout the spring and summer. Proof of efficacy from controlled trials is lacking. Controlled trials of *N*-acetyl cysteine and cholestyramine have shown them not to be of benefit (Norris et al. 1995; Tewari et al. 2012). Short courses of PUVA (Roelandts 1995) and narrow-band UVB (Collins and Ferguson 1995) in the early spring may help, particularly in milder cases. Narrow-band UVB does not overlap with the EPP action spectrum and cannot trigger attacks of pain. Many other systemic treatments with antioxidant or free radical scavenging properties have been used in EPP in an uncontrolled way on small numbers of patients, with conflicting and generally unconvincing results. Afamelanotide, the alpha-MSH analogue, has shown promising results in initial trials (Harms et al. 2009).

Genetic Counselling

Although cases of autosomal recessive inheritance do occur (Sarkany and Cox 1995; Whatley et al. 2004), EPP is generally an autosomal dominant disorder with incomplete penetrance, the disease resulting from co-inheritance of a gene mutation on one ferrochelatase allele with a low expression variant on the other allele. This low expression variant (IVS3-48C) is present in around 10 % of the Caucasian population and is associated with reduced ferrochelatase mRNA levels (Gouya et al. 2002). Overall, the probability of each offspring of an EPP patient suffering from the disease is under 10 %, but testing for the IVS3-48C polymorphism in a patient's partner can indicate more precisely whether there is a significant probability of offspring being affected. The disease is rarely life threatening, so antenatal diagnosis is not required.

Liver Disease in EPP (Sarkany and Cox 1995; Wahlin et al. 2011)

Protoporphyrin is excreted exclusively into the bile. It forms gallstones in around 12 % of patients. It is hepatotoxic, particularly to bile canaliculi, and severe liver damage occurs in 1 % of patients. EPP liver failure requiring transplantation may occur at any age. Patients develop jaundice, worsening photosensitivity and often upper abdominal pain over weeks to months and have severe cholestasis, with a dramatically high red cell protoporphyrin concentration. Liver histology shows deposition of protoporphyrin in vacuoles within bile canaliculi and hepatocytes, which may be accompanied by cirrhosis. Although such acute episodes may resolve spontaneously, the porphyrin-induced cholestasis may become increasingly severe and itself further increase the protoporphyrin concentration in a vicious cycle, in which case the patient will die unless a liver transplant can be performed. Unless filter films are used over operating theatre lights, the very high protoporphyrin concentration may cause a severe phototoxic reaction with postoperative burns. A severe neuropathy may occur after liver transplant (Wahlin et al. 2011). Protoporphyric liver disease recurs in the graft in 69 % of patients over several years, severe enough to require retransplantation in a minority. Patients with severe liver disease have been treated by bone marrow transplantation. Although the marrow transplantation does cure the EPP, the dangers of the procedure mean that it is reserved for these rare, life-threatening situations (Wahlin et al. 2007; Rand et al. 2006). It is vital to recognize impending protoporphyric liver failure early enough that arrangements can be made for a liver transplant if it should become necessary. Thus, all EPP patients should have liver function tests and red cell protoporphyrin concentration checked at least once a year. The appearance of coproporphyrin in the urine has been proposed as an indicator of significant liver disease in EPP (Doss and Frank 1989). Worsening photosensitivity may be the only clinical indication of the development of severe liver disease. Although protoporphyric liver failure is rare, mild abnormalities of liver function tests are common in EPP (Doss and Frank 1989). Since the significance of these abnormalities is unclear, it is advisable to monitor these patients closely and to refer the patient to a hepatologist if the abnormality is persistent or deteriorating. In such patients, an ion exchange resin such as cholestyramine may protect the liver against further porphyrin toxicity. There is no means of identifying those EPP patients at risk of liver failure. Since several cases have been described in siblings, patients with a relative who has suffered protoporphyric liver failure should be treated as being at risk of developing it themselves. Recessive inheritance of EPP may increase the risk of severe hepatic disease (Sarkany and Cox 1995).

Porphyrias That Cause Cutaneous Disease and Acute Attacks

Hereditary Coproporphyria (ICD-10 E80.2; ICD-9 277.1; OMIM 121300)

Like VP, this porphyria presents from puberty onwards. The skin is not affected in most patients suffering from this rare acute porphyria, but around 10–20 % (Kuhnel et al. 2000) of patients have cutaneous involvement with fragility and

blistering in sun-exposed areas, indistinguishable from that seen in PCT or VP. The skin disease may be triggered or exacerbated by intercurrent liver disease (Hawk et al. 1978). Rare variants include a homozygous form characterized by short stature, acute attacks and skin changes with prominent hypertrichosis and pigmentation (Grandchamp et al. 1977) and, harderoporphyria which causes haemolysis in the neonate or bullae. HC is caused by an autosomal dominant inherited deficiency of coproporphyrinogen oxidase. Patients need to be referred to an expert centre for the management of the acute attacks side.

The biochemical findings are of a 615–620 nm peak on plasma spectrofluorimetry, increased uro- and coproporphyrin concentrations in urine and increased coproporphyrin in faeces. Predominance of the type III isomer in faeces is a sensitive indicator of HC (Kuhnel et al. 2000).

Variegate Porphyria (ICD-10 E80.2 ICD-9 277.1 OMIM 176200)

This rare inherited disease causes a bullous porphyria and can cause acute attacks: VP is caused by an autosomal dominant inherited deficiency of protoporphyrinogen oxidase. In addition to causing photosensitization, accumulated coproporphyrinogen and protoporphyrinogen also inhibit PBG deaminase, the probable mechanism for acute attacks in VP. In South Africa, VP is common (due to a founder effect (Van Tuyll van Serooskerken et al. 2012)) with a prevalence in whites and Afrikaner-descended non-whites of 1/200. The incidence of VP in Europe varies between countries in the range 0.01–0.26 new cases/million/year (Elder et al. 2013). At least 80 % of South African carriers of a pathogenic VP mutation are completely asymptomatic (Day 1986).

Clinical Presentation (Day 1986; Mustajoki 1980; Timonen et al. 1990)

- *Skin.* Of those patients with symptomatic VP, around 70 % have cutaneous involvement, and only around 17 % will ever suffer an acute attack (Elder et al. 1997). Usually, the skin disease begins in adolescence or young adulthood. Patients describe skin fragility, usually fairly mild, affecting sun-exposed skin particularly on the backs of the hands. The skin disease is generally indistinguishable from PCT, with painful tense bullae occurring in sun-exposed skin, as well as scarring, pigmentary abnormalities, sometimes pseudosclerodermatous changes of the hands and fingers and occasionally photo-onycholysis. Many patients do not describe worsening in the summer, and the worst problems are often in late summer and autumn. In addition, around half of patients with VP describe mild, transient, light-related eruptions in the early summer. The examination findings of scarring, patches of hypo- and hyperpigmentation at sites of blisters, milia and mild hypertrichosis particularly around the eyes are indistinguishable from PCT. Intercurrent biliary obstruction exacerbates the cutaneous disease since the accumulated porphyrins are excreted into the bile. Acute photosensitivity can occur in patients with disturbed liver function. Hormonally induced hepatic dysfunction may explain the exacerbations of skin disease seen in females taking oral contraceptives and during pregnancy. VP sometimes goes into clinical and biochemical remission in old age. Patients with VP have recently been shown to be at increased lifetime risk of hepatocellular carcinoma (Schneider-Yin et al. 2010).
- *Acute attacks* (Day 1986; Mustajoki 1980; Elder et al. 1997; Von und zu Fraunberg et al. 2002). As in other acute porphyrias, women are three times as frequently affected as men, and 70 % of acute attacks occur between the ages of 20 and 40 years. Around 17 % of patients with cutaneous VP ever suffer an acute attack; the number has declined recently due to improved use of prophylactic measures. The severity of acute attacks varies from mild abdominal pain, sometimes accompanied by vomiting and constipation, through very severe attacks with bulbar palsy and respiratory paralysis. Patients need to be referred to an expert centre for the management of the acute attacks side of the disease.

In *homozygous VP* (Hift et al. 1993), a mutation on both protoporphyrinogen oxidase alleles results in an enzyme activity less than 20 % of normal, compared to the 50 % in other VP patients. In homozygous VP, fragility, bullae and often hypertrichosis develop in exposed (and sometimes nonexposed) skin in neonates or infants, and the skin disease may be severe. Delayed development, epilepsy, sensory neuropathy, nystagmus, various hand deformities and growth retardation also commonly occur. Acute attacks do not occur in these patients. The biochemical findings are the same as in VP, except for the lower enzyme activity.

Differential Diagnosis

VP cutaneous disease is easily distinguished from non-photosensitive blistering disorders. It can be clinically very similar to PCT, late-onset CEP, HC and pseudoporphyria. Biochemical analysis is required to diagnose VP.

Diagnosis

Biochemical Findings

A plasma spectrofluorimetry peak around 626 nm (caused by a porphyrin–protein complex) is diagnostic of VP in the absence of a raised free red cell protoporphyrin level and is present in virtually all symptomatic cases of VP. It may persist during periods of clinical remission when faecal excretion becomes normal and is a more sensitive test than measurement of faecal porphyrins (Hift et al. 2004). A persistently normal faecal protoporphyrin concentration in adulthood in patients with the VP genetic defect has been proposed as a prognostic marker indicating a greater likelihood of the VP never causing any clinical problems and staying clinically latent (Von und zu Fraunberg et al. 2002). The urine contains increased levels of coproporphyrin, and increased concentrations of copro- and protoporphyrin are found in faeces. In a few patients, the urine shows the typical PCT pattern of uroporphyrin accompanied by hepta- and sometimes hexa- and pentacarboxylic acid porphyrins, a situation known as 'dual porphyria' (Sturrock et al. 1989), hence the importance of sending off plasma as well as urine in bullous porphyria, to avoid the misdiagnosis of VP as PCT, with disastrous consequences. During acute attacks, urinary PBG (and ALA) are raised. The urinary PBG usually falls to normal within weeks of the attack resolving but may stay a little increased outside the context of an acute attack (Deacon 1999).

General Principles of Treatment

The key to successful management of the skin disease is photoprotection with sun avoidance using clothes, hats, gloves and visible light sunscreens. The skin disease is rarely severe enough to require filter films for windows. Since the relationship between sun exposure and skin lesions is not obvious, the role of light in producing the skin lesions should be explained to the patient. β-carotene and canthaxanthin have also been claimed to provide limited protection in some patients, and UVB phototherapy may be of value. If liver function tests indicate biliary obstruction, relief of this may reduce cutaneous symptoms. The risk of acute attacks is the key issue for safe management of patients and their families. Patients should be directed to a list of drugs to avoid (The European Porphyria Network), be advised to wear an emergency identification bracelet, to avoid low calorie diets and to become teetotal. The key thing is that expert assistance should be sought to manage the acute porphyria side. Liver transplantation has been used to cure variegate porphyria (and acute intermittent porphyria) in cases where acute attacks are uncontrollable by medical means (Stojeba et al. 2004).

Genetic Counselling

It is important to identify relatives who have latent VP because of the risk of acute attacks. The plasma 624–626 nm peak is found in the majority of cases of latent VP but only from teenage onwards. A positive plasma fluorimetry result is diagnostic of latent VP, but a negative result is uninformative (Long et al. 1993; Da Silva et al. 1995). The only reliable way to identify those carrying the VP gene defect if the plasma scan is

negative is to identify the protoporphyrinogen oxidase gene mutation in the index case and then assess its presence or absence in relatives. This is labour intensive because, outside South Africa, most families have their own private mutation. Relatives found to have the gene defect are at low risk (roughly 5–10 %) of acute attacks and should take all the precautions taken by any patient diagnosed with an acute porphyria. The risk of a patient passing the mutated gene on to each offspring is 50 %, and around 20 % of those carrying the mutation will eventually develop symptoms of some sort.

Pruritus

80

Jacek C. Szepietowski and Adam Reich

Key Points

- Pruritus is defined as an unpleasant sensation which provokes a desire to scratch.
- Itch exerts a negative impact on the patient's well-being, markedly decreasing quality of life and substantially affecting sleep quality.
- Valid assessment of pruritus still remains a challenge and no method of pruritus assessment can be considered as a standard, which would be widely accepted. However, unidimensional scales (e.g., verbal rating scale or visual analogue scale) as well as pruritus questionnaires are the most widely used and valuable methods of pruritus measurement in daily clinical setting to date.
- Successful antipruritic therapy may be introduced, if underlying disease for itch is identified.
- Pruritic patients with normal skin or with secondary scratch lesions require basic sets of laboratory examinations to determine the underlying disease.

Definition and Epidemiology

Pruritus is defined as an unpleasant sensation that produces a desire to scratch. By most researchers and physicians, pruritus and itch are considered as synonymous terms. Itching lasting less than 6 weeks is termed as an acute pruritus, while presenting longer than 6 weeks is defined as a chronic one. Pruritus may be limited to a certain area (localized pruritus) or involve the entire body (generalized pruritus). According to the consensus of the International Forum for the Study of Itch (IFSI), three clinical presentations may be distinguished: (1) pruritus on diseased, inflamed skin; (2) pruritus on normal, non-inflamed skin; and, finally, (3) pruritus with chronic secondary scratch lesions (Ständer et al. 2007).

Pruritus is a very common sensation. It is one of the most frequent and important symptoms in dermatology which may occur with or without visible skin lesions. Based on large epidemiological studies, it is estimated that chronic pruritus may be present even in 8–20 % of the general population. In a self-reported morbidity study, itching was the most frequently mentioned skin symptom. It is a major diagnostic symptom of atopic eczema and urticaria but often may also be observed in patient with psoriasis, eczema, primary cutaneous T-cell lymphomas, dermatitis herpetiformis, and many other skin conditions (Table 80.1). Pruritus may also complicate a number of systemic diseases, like chronic renal disease, cholestatic liver disorders, hematological

malignancies, or endocrinological disturbances (Table 80.2).

Basic Concepts of Pathogenesis

According to the IFSI clinical classification, pruritus, based on pathogenesis, is divided into dermatological (i.e., due to skin diseases), systemic (i.e., due to internal diseases), neurological (i.e., due to neurological diseases), psychogenic/psychosomatic (i.e., due to psychiatric disorders), mixed (i.e., due to overlapping and coexistence of multiple caused), and other category (i.e., with undetermined origin). However, the exact pathomechanism of these subtypes of chronic pruritus has still not been fully elucidated. In the past, pruritus was considered as a variant of subclinical pain, but recent discoveries clearly indicated that it represents a distinct sensation possessing separate neurons dedicated

solely for itch transmission, albeit showing some similarities and cross-linking with feeling of pain. Pruritus may be evoked in the skin by a number of neuromediators, including, but not limited to histamine, proteases, neuropeptides, serotonin, endogenous opioids, prostaglandins, leukotrienes, and some interleukins. Some of them induce itch by direct activation of pruritoceptors on dermal nerve endings, while others act indirectly causing, e.g., mast cell degranulation. However, the exact mechanism, how they induce or modulate itch, frequently remains poorly understood. Pruritus is transmitted to the spinal cord via mechano-insensitive unmyelinated afferent C-fibers that have a particularly low conduction velocity, large innervation territories, and high transcutaneous electrical threshold. To a lesser degree, pruritus may also be transmitted via myelinated delta-A-fibers. At least two different pruritus pathways have been identified, namely, histaminergic (processing histamine-induced itch) and non-histaminergic ones (processing cowhage-induced itch), the latter being mediated via proteinase-activated receptors (PARs). Both pathways overlap, but also show distinct neuronal networks in the central nervous system. In addition, studies on chloroquine-induced itch led to identification of new pruritus receptors on C-fibers, namely, Mrgprs (Mas-related G protein-coupled receptors) belonging to a family of G protein-coupled receptors that are expressed exclusively on peripheral sensory neurons (Wilson et al. 2011). These receptors may be activated by endogenous peptides and by exogenous substances (e.g., chloroquine). Mice lacking a cluster of Mrgpr genes displayed significant deficits in chloroquine-induced itch but not in histamine-evoked itch. It was suggested that Mrgprs may be even more important for non-histaminergic itch transmission, than PARs, which are thought be the most relevant receptors linked with chronic itch sensations (Liu et al. 2011). Another important molecule that has also recently been identified as an important pruritogen, especially in inflamed skin, is interleukin 31 (IL-31). Expression of IL-31 significantly correlated with scratching counts in a mouse model of atopic dermatitis and anti-IL-31 antibodies effectively reduced scratching behavior in these animals (Grimstad et al. 2009). It was also demonstrated that IL-31 is an important cytokine in the pathogenesis of atopic dermatitis in human beings, and its level was related to disease severity, sleeplessness, total serum IgE level, and subjective itch intensity (Raap et al. 2012).

Central transmission of itch may be modulated by endogenous opioid system. Activation of μ-opioid receptors (MOR) in the central nervous system causes pruritus, while activation of κ-opioid receptors (KOR) seems to alleviate itch. Blocking central opioid receptors was supposed to be a potential antipruritic therapeutic modality; however, central-acting drugs may also produce a number of side effects, like nausea and vomiting, sleeping difficulty, fatigue, and reversal of analgesia, which limit their wider use as antipruritic medications. Interestingly, recent data documented that opioid receptors are also present on peripheral sensory neurons and might partake in itch perception, acting on pruritus in a similar way comparing to central nervous system (MOR activation augmenting pruritus, while KOR activation diminishing itch) (Reich et al. 2010; Yamamoto and Sugimoto 2010). Nelson et al. (2006) reported that endogenous opioid-mediated antinociception in cholestatic mice was mediated peripherally supporting the idea of the importance of peripheral opioid system in itch perception. In addition, it was demonstrated that photochemotherapy (PUVA) diminished MOR immunoreactivity in the skin of patients with atopic dermatitis and the decrease of MOR immunoreactivity corresponded with pruritus improvement. It was also suggested that pruritus in psoriasis might be related to the imbalance of peripheral opioid system activation, as subjects with pruritus showed a decreased expression of KOR and dynorphin A (the endogenous KOR agonist) within the epidermis, while the expression of MOR and β-endorphin (the endogenous MOR agonist) was similar in both groups (Tominaga et al. 2007). Based on these observations it could be suggested that lower cutaneous KOR tone might be responsible for chronic pruritus in selected dermatological diseases, like atopic dermatitis and psoriasis. Furthermore,

potentiating peripheral KOR activity via KOR selective ligands or inhibiting peripheral MOR would offer a new possibility of itch controlling (Reich et al. 2012a, 2012b).

Spinal pathway of pruritus has still not been exactly identified. Pruritic stimuli are transmitted in the spinal cord by specific neurons of dorsal horns to the posterior part of the ventromedial thalamic nucleus, which projects to the dorsal insular cortex. Recently identified gastrin-releasing peptide (GRP)-positive dorsal root ganglion neurons seem to be itch-specific. These GRP-positive neurons are located in lamina I of the dorsal spinal cord. A direct injection of a GRP receptor antagonist into spinal cerebrospinal fluid significantly diminished scratching behavior in three independent itch models, while various pain sensations remained unchanged. Similar effect was produced by selective ablation of GRP-positive spinal neurons. It was also shown that these neurons transmit both histamine-dependent and histamine-independent itch sensations, but they seem to mediate more non-histaminergic itch stimuli. Interestingly, transmission of itch stimuli by GRP-positive neurons was modulated by Toll-like receptors 3 (TLR-3). Furthermore, activated by imiquimod TLR-7 were also shown to mediate pruritus transmission in primary sensory neurons (Liu et al. 2012).

Following itch induction multiple sites are co-activated in the brain including anterior cingulate cortex, supplementary motor area, insular cortex, precuneus, cuneus, and inferior parietal lobe predominantly in the left hemisphere. Such multifocal brain activation argues against the existence of a single itch center and reflects the multidimensionality of pruritus. Importantly, it has been demonstrated that the central processing of itch stimuli differs between patients suffering from chronic pruritus and healthy subjects suggesting the existence of central itch sensitization in chronic itch patients.

Assessment of Pruritus

Due to its subjective character, an objective measurement of pruritus remains a challenge. Pruritus can also be assessed according to various dimensions including its intensity, duration, localization or its influence on patient's well-being and quality of life, and thus, different measurement techniques might be best suited for different physician and patient needs. In our opinion, a reliable assessment of pruritus would be of great help in making decisions regarding particular antipruritic therapy and evaluating its efficacy. However, to date, none of available assessment methods have been approved as a gold standard for itch measurements.

Methods of pruritus evaluation can be divided into subjective assessments of itch and measurements of scratching. In addition, brain imaging techniques like positron emission tomography or functional magnetic resonance imaging enable visualization of brain activation during itch episodes and also may help in pruritus characterization, but, for now, in itch studies they are used for scientific purposes only (Table 80.3).

Unidimensional Scales

Among subjective methods of itch assessment, unidimensional intensity scales are most commonly used in daily clinical settings. They include verbal rating scale (VRS: expressions of, e.g., none, mild, moderate, severe, very severe pruritus), visual analogue scale (VAS), or numeric rating scale (NRS). With VRS patients verbally express the degree of pruritus they feel. This is probably the easiest method of pruritus assessment, but to date there is no consensus how many degrees should be included in the scale. In addition, a limited number of possible answers to choose might significantly reduce its power to detect changes of pruritus intensity during antipruritic therapy.

VAS is another method of subjective assessment of itching. It constitutes a 10-cm long line, on which patients mark the severity of itching they feel, knowing that the start point of the line means "no itch" (0 points) and the finish means "worst imaginable itch" (10 points). Based on available data it could be stated that VAS is a valid, reliable, and repetitive method of itch measurement. It shows good correlation with other pruritus assessments like NRS, VRS, or pruritus questionnaires confirming its good convergent

Table 80.3 Methods of pruritus measurements

Type of assessments	Examples of instruments/measurements	Short description
Unidimensional instruments (intensity scale)	Verbal rating scale Visual analogue scale Numeric rating scale	These instruments usually focus on the intensity of pruritus. They are commonly used in daily clinical settings as they constitute an easy and rapid assessment of pruritus. Major limitation is rather simple evaluation of pruritus, which omits many other important aspect of itch beside intensity
Questionnaires	Eppendorf Itch Questionnaire 5D-itch scale Itch Severity Scale 4-item itch questionnaire	Questionnaires enable assessment of different characteristics of pruritus, including, e.g., localization, duration, frequency, intensity, sensory qualities, scratch response, affective dimensions, disability, and many others. Good questionnaire should be balanced in respect of its simplicity, which is important for patients, and complicity to provide as much information as possible for researchers and physicians. They also require some psychometric expertise and time for proper interpretation
Measurement of scratching	Muscle potentials from forearms Motion sensitive limb meters Pressure sensors Infrared video camera taping	These methods were developed to measure pruritus in more objective way, but usually this methodology is expensive and time consuming, and results are difficult for interpretation. Most available devices only enable evaluation of nocturnal scratching
Other methods of pruritus assessment	Quality of life assessment (ItchyQoL) Assessment of psychic status (depression scale, anxiety scales) Assessment of sleeping problems (e.g., Athens Insomnia Scale) Brain imaging (PET, fMRI)	These assessment focus on a very specific aspect of pruritus providing additional valuable information on the comprehensive influence of itch on human beings

validity. VAS changes of 2.3 points seem to be clinically relevant. According to IFSI consensus following grading scoring has been proposed: 0, no pruritus; 0.1–2.9 points, mild pruritus; 3.0–6.9 points, moderate pruritus; 7.0–8.9 severe pruritus; and 9.0–10.0 very severe pruritus (Ständer et al. 2013). The major limitations of VAS include the fact that it does not characterize the clinics of itch (localization, frequency, etc.), does not assess the influence of itch on patient's well-being, relies on patient's memory, and may be inappropriate for patients with motor or cognitive dysfunctions. Furthermore, several problems have to be solved in the future regarding VAS, e.g., how frequent itch should be assessed with VAS and which timespan should the scale refer to. NRS is similar to VAS, as patients indicate a number from 0 to 10 that corresponds to perceived itch intensity. However, results achieved with NRS were revealed to be slightly higher compared to results of VAS. As it is still unclear, whether this difference is of clinical relevance, it is recommended that both scales should not be used interchangeably (Reich et al. 2010, 2012a).

Pruritus Questionnaires

Pruritus questionnaires should be considered as a good alternative or even better as an amendment of unidimensional scales. A number of questionnaires have been developed to date. The major advantage of questionnaires is the fact that they enable assessment of different characteristics of pruritus. Questionnaires may contain questions about localization, duration, frequency, and intensity of itch, sensory qualities, scratch response, opinion of origin, affective dimensions, aggravating or relieving factors, disability, response to current and previous treatments, itch

cognition, coping, and quality of life. According to recent recommendations, the "ideal" questionnaire should consider the patients' perspective, the medical doctors' perspective, as well as needs of various measurements in clinical trials. Regarding patients, it should be easy to understand and to complete, for physicians should provide important information about relevant characteristics of itch and discriminate between different types of pruritus and regarding clinical trials; it must be useful as an outcome measure and should be able to detect changes in itch over time. However, these objectives are frequently conflicting. The more detailed questionnaire is the longer one. However, too lengthy instruments are time consuming and are difficult for repeated assessments, especially in clinical settings. They also require some psychometric expertise and time for proper interpretation, which limit more frequent use of them. Therefore, despite a number of existing itch questionnaires, none has been more widely accepted. Currently, efforts are made to develop a new questionnaire, which will overcome shortcomings of previous questionnaires and will be more frequently used in clinical trials and in daily practice (Weisshaar et al. 2012a).

Measurements of Scratching

Itching provokes a desire to scratch; thus, measurement of scratching might provide valuable data about itch intensity. Measurement of scratching might simply be based on the counting skin lesions induced by scratching, like excoriations or lichenification. However, not all patients scratch their skin with nails; sometimes they only rub itchy skin areas. Therefore, there is not a simple relationship between itch intensity and the type and number of scratch lesions. In some itchy conditions, like in urticaria, excoriations or other scratch marks are observed quite rare, even despite the fact that itching might be very severe.

Several other methods have been developed to assess scratching. They include measurement of hands, feet, or bed motions by scratching (e.g., muscle potentials from forearms, motion sensitive limb meters, electromagnetic movement detector, pressure sensor, fingernail vibration transducer) or images of scratching (e.g., scratch radar or infrared video camera taping). However, this methodology is expensive and time consuming, and results are difficult for interpretation, as many movement episodes do not have to be necessarily connected with itching. In addition, most of available devices only enable evaluation of nocturnal scratching and, thus, are not well suited for the assessment of itch experienced during a day.

Other Methods of Pruritus Assessment

As mentioned above, patients with chronic pruritus seem to demonstrate different processing of itchy stimuli within the brain suggesting an existence of a phenomenon of central sensitization for pruritus in this group of patients. It was also supposed that subjects with chronic pruritus might also be more sensitive to itchy stimuli because of lowering of itch threshold at the periphery. Following this idea, evaluation of tactile thresholds in chronic itch patients might be a valuable adjunct to other pruritus measurements.

Itch also greatly impacts the patient's well-being. Wide range of questionnaires assessing quality of life (QoL) of patients with health problems might also be used in chronic itch subjects. Importantly, a new, itch-specific QoL questionnaire – ItchyQoL – has been developed by Desai et al. (2008). This questionnaire is solely dedicated for the assessment of QoL impairment in itchy patients evaluating three QoL dimensions, namely, symptoms, emotions, and functioning. Pruritus may also cause other psychic problems, including symptoms of depression and anxiety. Again, a number of available questionnaires (e.g., Hospital Anxiety and Depression Scale – HADS, Beck's Depression Inventory – BDI) may help to properly evaluate the impact of pruritus on patient's psyche providing additional valuable information on the comprehensive influence of itch on examined individuals.

Many patients suffering from pruritus also complain of problems with sleeping, which often result in the need to use sleeping medications. Measurement of sleeping problems may provide further data on pruritus severity. The Stanford Sleepiness Scale (http://www.stanford.edu/~dement/sss.html) or the Athens Insomnia Scale may be applied to assess sleep quality and diurnal sleepiness in patients with chronic itch.

Diagnosis

Pruritus is a subjective sensation and its diagnosis is based solely on the patients' complaints. However, in the vast majority of patients, pruritus is a symptom, not a disease, and generally antipruritic therapy may only be successful, if underlying cause is identified. Due to a very complex and heterogeneous pathogenesis, establishing of pruritus origin may be challenging and every patient with itch has to be considered individually. We do believe that the thorough diagnostic procedure enables identification of the underlying cause for itching in most patients.

Every patient with pruritus should undergo careful history and full physical examination. A detailed history of itching episodes should begin with the inquiries onto onset, location, intensity, diurnal rhythm, sleeping problems, and alleviating or aggravating factors surrounding an itching period. In addition, medical history regarding ongoing or past systemic diseases which might evoke itching has to be collected. The physician should also take a thorough medication history to establish the likelihood of drug-induced pruritus as a cause for the itch. Abrupt onset of itch is uncommon for systemic causes of pruritus and is more frequently observed in drug reactions, infestations, and contact dermatitis. Worsening of pruritus after showering is typical for asteatotic eczema, but may also be seen in aquagenic pruritus accompanying polycythemia vera. Increasing of pruritus during night is observed in nearly all types of itch, but is especially characteristic for scabies. The patient history should also include detailed data about symptoms of pruritus in the close relatives, history of travelling, presence of skin lesions, and potential allergens at home or at places where the patient is living.

Physical examination must include a detailed skin assessment. Special attention should be paid to identify any signs of secondary scratch lesions, such as excoriations, erosions, or nodular prurigo-like lesions. Dermatologic pruritus is diagnosed in patients with primary skin lesions that can be linked with itch sensation; however, primary skin eruption must be differentiated from secondary scratch lesions. If primary skin lesions are present, the diagnosis of underlying cause of pruritus is made based on clinical presentation, skin biopsy, and additional examinations, if necessary.

Pruritic patients with normal skin or with secondary scratch lesions require basic sets of laboratory examinations (Table 80.4). If any abnormalities are found, further diagnostic procedures or consultations should be performed to precisely establish the underlying disease (1). In contrast, if all screening laboratory examination are negative, skin biopsy should be considered to exclude subclinical dermatoses or skin conditions camouflaged by secondary scratch lesions. Alternatively, psychogenic/psychosomatic pruritus may be considered as potential explanation for reported itching – psychiatric consultation is then recommended.

Table 80.4 Basic diagnostic procedures recommended in pruritic patients without primary skin lesions

Blood smear with differential blood count
Erythrocyte sedimentation rate
Serum iron level (only in patients with anemia)
Serum urea and creatinine level
Liver function tests including liver enzyme activity and serum bilirubin level
Serum glucose level
Thyroid gland function tests (TSH)
Stool examination for parasite detections
Screening for HBV, HCV, HIV infection (only in at-risk patients)
Neurological consultation
Skin biopsy (only, if all above tests are negative)
Psychiatric consultation (only, if all above tests are negative and psychogenic/psychosomatic pruritus is suspected)

General Principles of Treatment

General Measures

General measures, beside a specific antipruritic treatment, should be used in all patients with itch as a treatment adjunct. This includes wearing of loose, airy clothes made from natural fabrics (e.g., cotton, silk); avoiding contact with wool and animal furs; avoiding hot or frequent baths, spirits, and spicy foods; and keeping proper humidity and tepid temperature of living rooms. In addition, all patients suffering from pruritus should regularly moisturize their skin, as dry skin may exaggerate or in some subjects even cause itching itself. A twice daily application of an emollient is usually sufficient, but in patients with a very dry skin, more frequent skin moisturizing might be recommended (every 2–3 h). A number of emollients are currently available and every patient should try a couple of them to choose the most suitable and convenient formulation. Oil baths with natural or mineral oils may also help to decrease xerosis. Emollients may act as moisturizing agents only or, in addition, may contain some active compounds, like cooling agents (e.g., calamine, menthol) or mild anesthetics (e.g., polidocanol) which further improve their antipruritic activity. In some patients with localized pruritus, itching may be also diminished by using cold wet dressings.

All patients with chronic pruritus must also keep their nails short to decrease the risk of inducing excoriations and other secondary scratch lesions. In those subjects, who severely scratch their skin while sleeping, wearing of cotton gloves should be suggested (Weisshaar et al. 2012b).

Specific Antipruritic Therapy

Topical Treatments

Cooling Agents

It was observed that cooling the skin may decrease itch sensation. As mentioned above, the so-called cooling agents may be added to topical moisturizers. These substances, like menthol, directly activate low temperature receptors in the skin causing the feeling of cold and thus diminishing pruritus. The major limitation of currently available cooling agents is its relatively short-term efficacy, usually lasting not longer than about 30–60 min. Some patients may also develop contact irritant dermatitis upon prolonged use of menthol (Reich et al. 2011).

Local Anesthetics

Localized pruritus, like notalgia paresthetica or postherpetic itch, may be effectively treated with topical anesthetics, e.g., benzocaine or lidocaine. However, their wider and more frequent use is linked with the risk of evoking allergic contact dermatitis. Their clinical efficacy may be also limited by short-term effect and insufficient penetration through the intact, non-diseased skin. They should not also be applied too frequently or on the larger skin areas due to possibility of circulatory system side effects.

If larger areas should be treated, 3 % polidocanol formulations may be used, as this compound possesses weak anesthetic properties. It has been successfully used for itching accompanying psoriasis, for atopic and other forms of dermatitis, and in uremic pruritus (Weisshaar et al. 2012b; Wąsik et al. 1996).

Capsaicin

Capsaicin, an active component of chili pepper, showed antipruritic properties when used regularly on itchy skin areas. Topical capsaicin has been shown effective in the treatment of notalgia paresthetica, brachioradial pruritus, postherpetic itch, or prurigo nodularis. Regular use of capsaicin (at least three to five times a day) causes desensitization and degeneration of sensory nerve fibers that leads to inhibition of transmission of pruritus and/or burning pain stimuli to the central nervous system. However, antipruritic activity of capsaicin is limited by the fact that during the first days of its application, this substance activates sensory C-fibers causing dose-dependent erythema and burning, which sometimes may be very severe. To overcome this shortcoming of capsaicin therapy, formulation containing low concentration of capsaicin might be applied initially, which should be gradually increased to 0.1 % or even greater, as higher concentrations act more rapidly and the treatment effect is more durable.

Alternatively, within the first days, capsaicin treatment may be combined with prior application of local anesthetic, which will decrease the burning sensations.

Recently, a new formulation of capsaicin becomes available, namely, a patch containing 8 % capsaicin. It was shown that single application of this 8 % capsaicin patch for 60 min on itchy area may provide a long-lasting pruritus relief (Ständer et al. 2001; Wallace and Pappagallo 2011).

Antihistamines

Topical antihistamines are rather uncommon antipruritics. Significant risk of allergic contact dermatitis largely limits their suitability for the treatment of chronic pruritus. Topical formulations include 5 % doxepin cream available only in some countries and 0.1 % dimethindene maleate gel. Topical doxepin should be applied to a maximum of 10 % of body surface and the total daily dose must not exceed 3 g, due to potential systemic side effects. It may be tried in atopic and contact dermatitis and in microbic eczema, but usually the treatment should not exceed 1 week. Dimetinden maleate may be used for acute pruritus, e.g., after insect bites (Weisshaar et al. 2012b).

Calcineurin Inhibitors

Calcineurin inhibitors (pimecrolimus, tacrolimus) have been shown to be effective in atopic dermatitis with greater efficacy of tacrolimus compared to pimecrolimus. At the beginning the treatment with both agents may be complicated by burning or itching sensations, which are related to the release of neuropeptides from dermal nerve endings and usually subside within couple of days. Calcineurin inhibitors have been shown to decrease pruritus intensity in a number of other skin conditions, like seborrheic dermatitis, inverse psoriasis, genital lichen sclerosus, or cutaneous lupus erythematosus. They were also suggested to be effective in other pruritus types, but controlled studies did not confirm these observations.

Corticosteroids

Topical corticosteroids should not be considered as antipruritic drugs. However, they can diminish pruritus accompanying cutaneous diseases by decreasing the inflammatory process in the skin. Their longer use is limited by the risk of skin atrophy and related skin problems (e.g., telangiectasis, purpura, impaired wound healing).

Cannabinoid Receptor Agonists

Topical cannabinoid receptor agonists seem to have antipruritic and anti-inflammatory properties, but to date, only uncontrolled studies documented their efficacy in atopic dermatitis, uremic pruritus, prurigo nodularis, and anal pruritus (Szepietowski et al. 2005). Currently they are only available as one of the ingredients of some cosmetics (Table 80.5).

Systemic Treatments

Antihistamines

Antihistamines are the oldest and most widely used antipruritic drugs to date. They are the treatment of choice in the histamine-dependent pruritus, such as urticaria or mastocytosis, and to avoid sedation new, non-lipophilic drugs (e.g., bilastine, levocetirizine, desloratadine) are recommended for these indications. Their efficacy in other pruritus types is a matter of debate. It is suggested that histamine blockade in such situations is usually not sufficient to achieve pruritus improvement and sedative antihistamines are usually prescribed in patients with itching suffering from atopic dermatitis or psoriasis as sedation may result in decreasing of pruritus feeling. However, recent study by our group indicates that even nonsedating antihistamines may be effective in pruritus in psoriasis [unpublished observation]. Importantly, new antihistamines should be usually used in higher doses than approved (up to four times) to achieve significant pruritus decrease.

Opioid Receptor Antagonists and Agonists

As mentioned in the pathogenesis section, current concepts of chronic pruritus consider the imbalance of opioid system as a key player for itch perception. Several studies documented that blockade of μ-receptor with its antagonists (naltrexone, naloxone, nalmefene) significantly

Table 80.5 Overview of topical antipruritic treatment options

Treatment option		Indication	Limitations
Cooling agents (e.g., menthol)		Adjunct therapy for patients with localized or generalized pruritus	Short-term efficacy (usually lasting less than 30–60 min.)
			Some patients may develop contact irritant dermatitis after menthol application
Local anesthetics	Benzocaine, lidocaine	Localized pruritus, like notalgia paresthetica or postherpetic itch	Possible risk of allergic contact dermatitis
			Short-term efficacy
			Not suitable for larger skin areas due to absorption and potential cardiovascular side effects
	Polidocanol	Adjunct therapy for patients with localized or generalized pruritus	Improvement is usually modest
Capsaicin		Treatment of localized itch (notalgia paresthetica, brochioradial pruritus, postherpetic itch, prurigo nodularis)	Feeling of severe burning during first days of use significantly affects the compliance with the treatment recommendations
Antihistamines		Short-term treatment for pruritus in atopic and contact dermatitis, microbic eczema, insect bites	Significant risk of allergic contact dermatitis after prolonged use
Calcineurin inhibitors		Atopic dermatitis, optionally other forms of dermatological pruritus	Licensed only for atopic dermatitis
			Initial therapy may be complicated with transient itching or burning sensations
Corticosteroids		Dermatological pruritus (pruritic dermatoses with inflammation)	Prolonged use connected with the risk of skin atrophy
			Ineffective in other pruritus types
Cannabinoid receptor agonists		Atopic dermatitis, uremic pruritus, prurigo nodularis, anal pruritus	Lack of controlled studies confirming their efficacy
			Only used as compounds in cosmeceuticals (no licensed drugs available)

diminished pruritus severity. These agents were successfully used in uremic pruritus, cholestatic pruritus, prurigo nodularis, and opioid-induced pruritus. The treatment can be started with oral naltrexone monotherapy (25–100 mg/day) or with intravenous naloxone (0.4–2 mg *i.v. or infusion with* 0.2 μg/kg/min) followed by oral naltrexone (50 mg/day). Alternatively, nalmefene in the dose of 20 mg twice daily may be tried (Metze et al. 1999).

Due to potential side effects of μ-receptor antagonists (sleep problems, anxiety, agitation, signs of withdrawal syndrome), recent attempts were directed on the development of κ-receptor agonists that should possibly possess the same antipruritic effect as μ-receptor antagonists, but should be better tolerated by patients. Recently, nalfurafine, a selective κ-opioid receptor agonist, has been approved in Japan for the treatment of uremic pruritus (Kumagai et al. 2010).

Gabapentin and Pregabalin

Gabapentin and pregabalin are antiepileptic drugs that decrease the neuronal transmission acting as GABA (γ-aminobutyric acid) receptor agonists. Both drugs were successfully used in neurological pruritus (e.g., postherpetic itch, brachioradial pruritus) and in severe pruritus of chronic renal failure, cholestasis, and post-burns. Especially patients with uremic pruritus seem to benefit from such treatment most. The initial dose of gabapentin is 300 mg/day and can be gradually (of about 300 mg every third day) increased to the most effective dose (the maximum is 2,400 mg/day, but usually much lower doses are sufficient to control pruritus). Pregabalin is administered in the initial dose of 50–75 mg and can be increased to 300 mg/day. It must be remembered that it may take several weeks to observe the clinical effect of the treatment (Goutos et al. 2010; Solak et al. 2012).

Antidepressants

Many patients with chronic pruritus demonstrate symptoms of depression. On the other hand, depression may also cause pruritus. Consequently, antidepressants, mainly serotonin reuptake inhibitors (e.g., paroxetine or sertraline), were observed to be potent antipruritic compounds. Pruritus relief was noted in polycythemia vera, paraneoplastic pruritus, and prurigo nodularis and, most importantly, in cholestatic pruritus. Mirtazapine is another antidepressant with both noradrenergic activity and serotonergic activity which show some antipruritic efficacy. Because of potential side effects, antidepressants are recommended as a second- or third-line antipruritic therapy (Weisshaar et al. 2012b; Shaw et al. 2007).

Aprepitant

Aprepitant is a new drug that acts via blocking neurokinin 1 receptor, which is activated by a neuropeptide – substance P. Aprepitant is currently used for the treatment of recalcitrant nausea and vomiting during anticancer chemotherapy. However, a number of reports indicated that this compound may also be effective in the treatment of chronic pruritus. The major limitation of such treatment is the very high cost of the drug (Santini et al. 2012).

Cholestyramine

Resins, such as cholestyramine, may be helpful in cholestatic pruritus. The maximal dose is 12–16 g/day. It must be remembered that prolonged use of cholestyramine may cause deficiency of lipid soluble vitamins. Treatment may also be complicated by nausea, flatulence, and constipation, which frequently impair the adherence to therapy.

Cyclosporin A

Cyclosporin A was shown to effectively alleviate pruritus in atopic dermatitis patients. Some authors also suggested its activity in prurigo nodularis. Cyclosporin A is a potent immunosuppressive drug, but improvement of pruritus severity was noted before significant decrease of inflammation was observed, which suggests an additional antipruritic mechanism. The usually applied dose lies in the range of 3–5 mg/kg/day.

Other Treatment Options

Phototherapy

Ultraviolet B phototherapy may be helpful in the treatment of uremic pruritus, cholestatic pruritus, and HIV-associated pruritus. Due to its favorable safety profile, it is worth to try this treatment before other, more toxic therapies are introduced. The exact antipruritic activity of ultraviolet B phototherapy is unknown; it was observed that it decreases the number of mast cells and free nerve endings in the skin (Szepietowski et al. 2002). UVA1 phototherapy showed similar antipruritic efficacy to ultraviolet B treatment in patients with atopic dermatitis. Photochemotherapy (PUVA treatment) may also be of help, mainly in inflammatory skin diseases accompanied by pruritus like psoriasis, atopic dermatitis, lichen planus and in primary cutaneous T-cell lymphomas (mycosis fungoides, Sezary syndrome). In addition, PUVA was observed to be effective in some patients with pruritus accompanying polycythemia vera and in aquagenic itch (Weisshaar et al. 2012b).

Psychotherapy

Some chronic itch patients, especially those suffering from somatoform pruritus, may benefit from psychotherapy. Psychotherapy can also be of great importance in patients with atopic dermatitis to combat stress-related itching episodes. Regarding various psychotherapeutic modalities, habit reversal with awareness training techniques seems to be of greatest relevance in patients with chronic pruritus.

Acupuncture

Both classical acupuncture and electroacupuncture can be considered as an alternative, adjunct therapy for patients with chronic pruritus and may bring them some relief; however, it has not been widely used as antipruritic treatment so far and definitely cannot be considered as first-line therapy.

Key Points

- Psoriasis is a common, chronic, inflammatory, and debilitating skin disease associated with several comorbidities. Histologically, it shows peculiar features resulting from a complex pathogenic mechanism not fully understood.
- Based on the severity of disease, the therapeutic approach is either topical or systemic.
- A wide array of validated treatments, showing antiproliferative and/or anti-inflammatory, are current available.

Definition and Epidemiology

Psoriasis vulgaris is a chronic inflammatory disease characterized by great variation in prevalence within and between countries because of geographical, environmental, and genetic factors. Psoriasis seems to be most prevalent in Caucasian population and less frequent in yellow-brown individuals and in black populations.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_81, © Springer-Verlag Berlin Heidelberg 2015

Prevalence has been shown to vary between 1.5 and 3 % in Europe and the United States. Psoriasis shows a strong genetic susceptibility with non-Mendelian mode of inheritance that plays a key role in its pathogenesis. It has been nearly 30 years since researchers first recognized that certain variations in the HLA system (MHC classes I and II) on chromosome 6p conferred an increased risk of developing psoriasis.

More in detail, people with an allele called HLA-Cw6 are 20 times more likely to have psoriasis than expected by chance. This locus, known as PSORS1, identifies a chromosomal region including a cluster of genes: HCR (alpha-helix coiled-coil rod homolog), CDSN (corneodesmosin), and HLA-C. The PSORS1 locus, although considered the major susceptibility locus for psoriasis, accounts for less than 50 % of familial aggregation in psoriasis.

Based on these findings, multiple susceptibility loci, localized in different chromosomes, have been identified, confirming the genetic heterogeneity of psoriasis.

The analysis by genome-wide association studies linked psoriasis to a larger number of genetic risk factors, identifying more than 30 susceptibility genes.

Together with the genetic predisposition, a wide range of trigger factors have been involved in the pathogenesis psoriasis and include stressful events, depression, anxiety, mechanic damages (Koebner's phenomenon), ultraviolet rays, bacterial and viral infections, alcohol, smoke, and drugs.

Among bacterial infections, it is well documented that the acute onset of guttate psoriasis as well as the exacerbation of the chronic form are induced by streptococcal throat infection in a significant proportion of patients (56–98 %). In these individuals, an acute sore throat precedes by 1–2 weeks the cutaneous sudden eruption and the serological evidence of a recent bacterial infection. Many drugs can precipitate or exacerbate psoriasis and other cutaneous disorders via chemical interaction with genetically susceptible epidermal cells. Beta-blockers; lithium; synthetic antimalarial drugs; nonsteroidal anti-inflammatory drugs; tetracyclines; interferons (IFNs)-α, IFN-β, and IFN-γ; interleukin-2 (IL-2); granulocyte colony-stimulating factor (G-CSF); and angiotensin-converting enzyme (ACE) inhibitors are few examples.

Basic Concepts of Pathogenesis

Psoriasis is characterized by marked epidermal hyperplasia, neo-angiogenesis, and dense dermal and epidermal immune cell infiltrate. Various immune cell types are involved in psoriasis pathogenesis, particularly CD4+ T helper (Th) 17 and Th1 cells that are demonstrated to be central to the pathogenic mechanisms leading to the psoriatic plaque formation. Together with CD4+ T cells, CD8+ T cells infiltrating the epidermis represent the major source of IFN-γ, IL-17, IL-22, and TNF-α, though other T-cell subsets participate to psoriasis pathogenesis such as Th22, Th21, and IL-17-producing γ/δ T cells. Psoriatic lesional skin shows a large amount of these cytokines in addition to increased levels of dendritic cell (DCs)-derived cytokines (IL-23, IL-20, TNF-α) and keratinocyte-derived cytokines and chemokines (i.e. CXCL8, CXCL1, CCL20). Though T cells are the key drivers of most relevant inflammatory circuits, DCs, as well as keratinocytes, offer a relevant contribution to the psoriatic lesional skin formation.

An important role is played by keratinocytes, which amplify skin inflammation and regulate immune cell trafficking through the production of a variety of cytokines, chemokines, and antimicrobial peptides (AMPs). Keratinocytes also synthesize many cytokines that can induce epidermal hyperplasia (autocrine growth factors) or neo-angiogenesis (paracrine growth factors).

Histology

Psoriasis pathognomonic histologic changes are the following: parakeratosis of cornified layer, hypogranulosis, acanthosis with elongation of epidermal crests (papillomatosis), and increased number of mitotic figures in the basal layer and above (Fig. 81.1). In the dermal papillae, typical

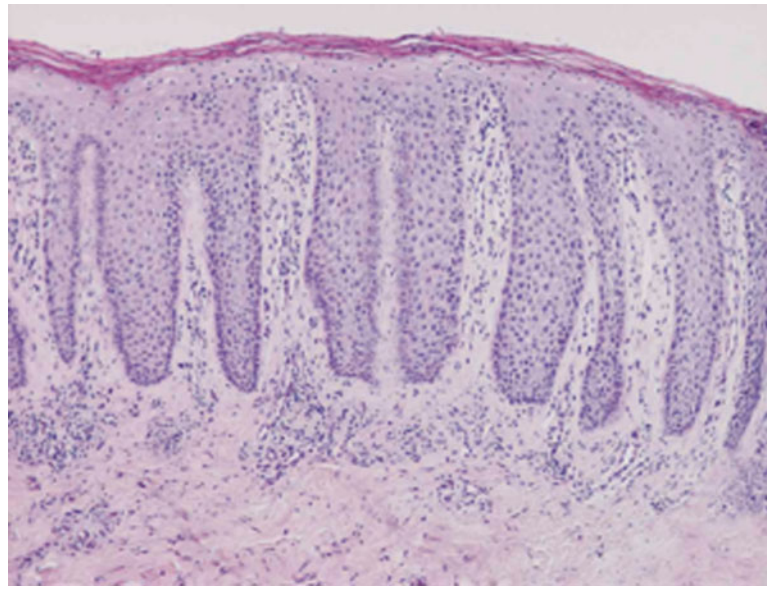

Fig. 81.1 Parakeratosis of cornified layer, hypogranulosis, acanthosis with pale cytoplasm of keratinocytes, and elongation of epidermal crests (papillomatosis) (HE, 10×)

findings are ectatic capillaries perpendicular to the epidermis with stacked erythrocytes (liable of the diagnostic semiologic Auspitz sign) and a lymphocytic infiltrate of variable density. Papillary dermis presents slight oedema, dilated tortuous perpendicularly oriented capillaries of the superficial plexus with extravasated erythrocytes packed within lumina. Within the epidermis of a fully developed lesion (scaly plaque), confluent parakeratosis containing neutrophils, focally compact orthokeratosis, and, sometimes, plasma in parakeratotic areas might be observed. Granular layer is usually reduced, except in those foci beneath areas of compact orthokeratosis, and spongiform pustules can be observed within the spinous, granular, and cornified layers.

Fig. 81.2 Psoriatic lesions on the elbows characterized by prominent hyperkeratosis plaques

Clinical Presentation

Typical psoriatic lesion is characterized by an erythemato-squamous patch or papule usually evolving into a plaque with a sharply demarcated border (Fig. 81.2).

The erythematous patch may vary in colour from light red to "salmon pink" or intense red, typically more evident at the margin, with congested aspect that disappears with vitropression. The squamous component is extremely variable and whitish to silvery colour, and different degrees of coherence to the plaque may be observed. Scales can be small and thin producing a fine pityriasic desquamation or large and thick with an "ostraceous" or "rupioid" appearance. Different combinations of both erythematous and

squamous components determine the various features reflecting the typical polymorphism of psoriatic lesions.

Itching in psoriasis is an important symptom, and it is a common observation that its intensity is dependent on the extent of psoriatic lesions. However, the molecular basis of itching remains largely unexplained.

Morphologic features of psoriasis are extremely proteiform. The most common clinical variant is psoriasis vulgaris (also named plaque-type psoriasis) that occurs in more than 80 % of patients. Erythemato-squamous plaques, round or oval, variable in size, typically affect the elbows and knees, often in a symmetrical pattern, scalp, lower back, intergluteal cleft, and umbilical area.

The number of the lesions can vary from few (minimal psoriasis) to several elements, also confluent that can cover the whole body surface area (generalized and/or universal psoriasis).

Psoriasis can develop at any age and last for just a limited period or for a lifetime, with alternating periods of relapses and remissions. It is difficult to predict the course of the disease, and spontaneous remissions occur with varying frequencies.

The psoriatic lesion may present as punctiform, follicular, guttate, lenticular, nummular, annular, circinate, gyrate, geographic, serpiginous, and linear psoriasis. Moreover, psoriasis can be further classified according to topographic localization in palmo-plantar psoriasis, genital psoriasis, face and ear psoriasis, scalp psoriasis, nail psoriasis, inverse psoriasis, sebopsoriasis, ocular psoriasis, and mucosal psoriasis.

Palmo-plantar psoriasis is characterized mostly by typical scaly patches or less well-defined hyperkeratotic elements often surrounded by an area of erythema.

Guttate psoriasis presents as small (0.5–1 cm in diameter) round or oval lesions scattered more or less evenly over the body, particularly on the upper trunk and proximal extremities, not infrequently on the face and scalp. These drop-like eruptive papules show a salmon-pink hue. A fine scale, which is usually absent in early-stage lesions, may be appreciated on the more established ones.

The onset is often acute, and the eruption is accompanied by slight itching. This form is characteristic of psoriasis in childhood and young adults. Streptococcal throat infection (by group A beta-haemolytic streptococcus) frequently precedes the onset or flare of eruptive guttate psoriasis in children. Guttate psoriasis may be self-resolving, leaving patient free of further relapses, or it may clear temporally to reappear later as patches of plaque psoriasis.

Severe forms of psoriasis include erythrodermic, generalized pustular psoriasis, and psoriatic arthritis. The rate of erythroderma among patients with psoriasis ranges from 3 to 31 %. Erythrodermic psoriasis can evolve from pre-existing chronic plaque psoriasis or rarely can occur de novo as a generalized erythema.

The commonest causes implicated in the development of erythrodermic psoriasis are the following: reaction to some drugs (lithium, beta-blocker, interferon-alpha, antimalarials, anti-inflammatory, tetracyclines, and inhibitors of angiotensin-converting enzyme), withdrawal of systemic and topical corticosteroids, overtreatment with tar or dithranol, PUVA phototoxic reaction, insolation, acute infection, and emotional stress.

Erythrodermic psoriasis is clinically characterized by generalized red-violet erythema and superficial, fine, white scaling. Additional features include oedema, fissures, exudation, and severe nail dystrophy such as subungual hyperkeratosis and onycholysis. The main subjective symptoms associated are varying itching, chills, feeling of cold, movement limitation, fatigue, and malaise. General condition is impaired with fever, lymphadenopathy, weight loss, dehydration, and oliguresis. *Pustular psoriasis* is subdivided in two major clinical variants, localized and generalized, which are characterized by the same elementary lesion, a sterile pustule, and are differentiated by the body surface area involved and, consequently, by the clinical severity. As mentioned above, the elementary lesion is a flat, sterile, non-follicular pustule of variable diameter, ranging from 1 to 5 mm, milk coloured, and generally evolving in yellowish crusts. In some variants, the lesions show the tendency to

confluence with polycyclic margins. Histologically, the pustules are situated in the upper part of spinosus layer and are filled with neutrophils configuring a peculiar aspect named "spongiform pustule of Kogoj". About 2–6 % of patients suffer from inverse form with the involvement of major skin folds (such as groins, axillae, sub-mammary, intergluteal, and periumbilical region).

Erythrodermic generalized pustular psoriasis of *von Zumbusch* is the most severe variant characterized by the following symptoms: acute onset, fever lasting for several days, worsening of general conditions, generalized erythema and oedema, and eruption of sterile pustules of 2–3 mm in diameter. The pustules are disseminated over the trunk and extremities, including the nail beds, palms, and soles. The pustules usually appear as single and then confluent lesions with an exacerbation of the disease. The fingertips may become atrophic in patients with prolonged disease. The oral mucosa is often involved. Characteristically, the disease occurs in waves of fever and pustules. Simultaneously with the pustules, a polyarthritis is likely to occur in many cases. Blood tests show neutrophilic leucocytosis and elevation of ESR.

Psoriatic arthritis (PsA) is an inflammatory arthritis that is commonly associated with cutaneous psoriasis. The percentage of patients with psoriasis which have psoriatic arthritis varies between 5 and 42 %. Many patients are affected by psoriasis several years before developing arthritis. The severity of joint involvement is not related to the pattern of the skin disease. The major extra-articular feature in PsA is psoriasis. In 70 % of the patients, arthritis symptoms develop years after skin changes present, and in 10–15 % arthritis precedes psoriasis, yet a significant family history of psoriasis is useful for the diagnosis. In 15 % of the patients, the initial presentation includes arthritis and psoriasis together. Psoriasis vulgaris is the most frequent form of psoriasis associated with PsA, but pustular and guttate psoriasis have been also reported. Only 35 % of patients with PsA had a relationship between the extent and severity of psoriasis and joint manifestations. Extra-articular manifestations of PsA include conjunctivitis or iritis (in 7–33 % of patients) and aortic incompetence (in less than 4 % of patients) that may occur late during the course of PsA.

Nail psoriasis is reported in 10–55 % of adult psoriatic patients, it is uncommon in children (7–13 %), and it frequently reaches the percentage of 80 % in psoriatic arthritis. Clinical presentation of nail psoriasis is directly related to the specific affected nail apparatus (matrix, nail bed, nail plate, periungual skin) with the following findings: pitting (irregular and not geometrical depressions on the nail plate), oil spots (yellowish or pinkish nail bed discoloration surrounded by an erythematous halo), ridging (Beau's lines, trachonychia), thickening and brittle, onycholysis (detachment of the nail plate from the nail bed), subungual hyperkeratosis (hyperparakeratosis of the nail bed), paronychia, and splinter haemorrhages.

Psoriatic lesions may also involve the oral and genital mucosae. On the tongue, psoriasis shows features of benign migratory tongue or geographic tongue, consisting in one or more erythematous patches with a raised whitish or yellow serpiginous border.

Comorbidities

There is increasing evidence that psoriasis has many immunological and metabolic associations that may play a role in disease in other organ systems. Epidemiological studies have evidenced an association between psoriasis and noncutaneous diseases such as tonsillitis, Crohn's disease, obesity, heart diseases, and chronic alcoholism.

Patients with psoriasis have an increased risk of developing cardiovascular disease and metabolic syndrome compared with controls without psoriasis.

Metabolic and Cardiovascular Diseases

Metabolic syndrome and its components have been largely associated with psoriasis. This syndrome is characterized by several factors including central obesity, atherogenic dyslipidaemia, hypertension, and glucose intolerance. Patients with psoriasis tend to have significantly higher

concentrations of triglycerides and total cholesterol, as well as higher concentrations of low-density lipoprotein and very low-density lipoprotein cholesterol, all of which are established risk factors for cardiovascular disease. An association between psoriasis and type 2 diabetes is supported by several epidemiologic studies. Type 2 diabetes is usually preceded by impaired glucose tolerance, and accordingly psoriatic patients are more likely than healthy individuals to demonstrate insulin resistance when challenged with oral glucose. Obesity is a common comorbidity of psoriasis, and multiple studies have demonstrated that patients with psoriasis are more frequently overweight (BMI $\geq$25 kg/m^2 and <30 kg/m^2) or obese (BMI $\geq$30 kg/m^2) compared with patients without psoriasis.

The cardiovascular system is one of the most commonly affected. This association has been found in several studies: increased rates of concurrent cardiovascular disease including hypertension, diastolic dysfunction, and heart failure have been noted.

Gastrointestinal Diseases

Crohn's disease and ulcerative colitis are chronic inflammatory diseases of the digestive system. The underlying aetiology and exact pathogenesis of the inflammatory bowel diseases are still unknown, but the current hypothesis of their pathogenesis relates to dysregulation of the gastrointestinal immune system in genetically predisposed individuals. Epidemiological, pathologic, and therapeutic connections exist between psoriasis and Crohn's disease. The prevalence of psoriasis in patients with Crohn's disease is 9 %, while in the general population is 2–3 %. Also, a family history of psoriasis has been frequently observed in Crohn's disease patients.

The genetic links between the two diseases were investigated, with findings demonstrating that the susceptibility loci of psoriasis, Crohn's disease, and ulcerative colitis all appear in the *6p21* locus, an area which encompasses the major histocompatibility complex (MHC). This area includes the *IBD3* locus involved in Crohn's disease and ulcerative colitis and the *PSORS1* locus involved in psoriasis. Several non-MHC-related genes, such as the IL-23 receptor (*IL-23R*) and *IL-12B* genes, have been associated with psoriasis, Crohn's disease, and ulcerative colitis. Other genes have been identified that are common to both conditions, residing on chromosomes 16, 4, and 3. NOD2, located on chromosome 16, encodes a cytoplasmic protein that regulates nuclear factor-kappa B (NF-kB) signalling. Polymorphisms of NOD2 associated with Crohn's disease appear to be associated with NF-kB dysregulation.

Liver Disease

Severe abnormalities of liver function may occur in psoriasis and are likely to be related to drugs and alcohol intake. Liver cirrhosis and other associated disorder are much more frequent cause of death and morbidity than in the general population. Non-alcoholic fatty liver disease (NAFLD), comprising a spectrum of conditions ranging from simple steatosis to steatohepatitis (NASH) and cirrhosis, is now regarded as the hepatic manifestation of metabolic syndrome and represents the most common cause of abnormal serum liver enzymes in Western countries, affecting up to one-third of the general population. NASH is characterized by morphological evidence of fatty change with lobular hepatitis, but in the absence of alcoholism. Histological studies of the liver in patients with psoriasis have shown that fatty degeneration within the liver lobules, inflammatory cell infiltration in the portal area, and focal necrosis are more common than in controls. The frequency of NAFLD diagnosed by patient history, blood sampling, and characteristic sonographic features in patients with chronic plaque psoriasis is remarkably greater than that in non-psoriasis control subjects, who were matched for age, gender, and BMI, affecting up to nearly half of these patients and that NAFLD was strongly associated with psoriasis severity independently of potential confounders such as age, gender, BMI, psoriasis duration, and alcohol.

Psychiatric Morbidity and Alcoholism

The most commonly diagnosed conditions are depressive and anxiety disorders. Other less common general psychiatric illnesses encountered included social phobia, alcohol dependence, obsessive–compulsive disorder, post-traumatic stress disorder, and anorexia nervosa. Stress, such as from anxiety, depression, marital problem, or "near-death" experiences, has been identified as a triggering and exacerbating factor in the appearance of psoriasis in most of psoriatic patients. Moreover, depression and suicidal ideation affect many patients with psoriasis.

Alcoholism is a multifactorial disorder and affects virtually every organ system, including the skin. Alcohol may exacerbate pre-existing psoriasis but does not appear to induce it; 13 % of patients with psoriasis are alcoholics, while 18 % of psoriatic patients had a problem with alcohol abuse. Heavy drinking was found significantly more commonly in male patients with severe psoriasis than other group with the disease and could be a symptom of stress caused by severe skin disease.

General Principles of Treatment

Topical Therapies

Corticosteroids

Corticosteroids still represent the milestone in the topical treatment of psoriasis in all age groups. Owing to their anti-inflammatory and antiproliferative properties, they reduce erythema, scaling, and pruritus in psoriasis.

Corticosteroids, ranging from low to high potency, are available in a variety of formulations including creams, emollient cream, ointment, gel, spray, lotion, solution, nail lacquer, tape, and foam.

According to their therapeutic potential, they may be classified into four classes: mild, medium, potent, and very potent. The efficacy rates of ultrapotent corticosteroids range from moderate or better improvement of Physician Global Assessment (PGA) in 58 % of patients to overall improvement of PGA in 92 % of patients, while with mild corticosteroids, PGA improvement has been reported as excellent or good in 41 % of patients and as good or better in 83 % of treated patients.

Usually, lower-potency corticosteroids are used in childhood and on sensitive skin sites including the face, axillae, diaper area, and gluteal cleft, whereas hyperkeratotic areas, such as the palms and soles, or chronic lesions require high-potency corticosteroids.

High-potency agents can be used for a limited period of 2–4 weeks, no more than twice daily and at a dose of no more than 50 g/week. For long-term strategies based on potent corticosteroids, intermittent therapy, weekend therapy, and combined therapeutic schemes with other topical medications could be considered.

Local side effects including skin atrophy, striae, telangiectasia, purpura, rosacea, acneiform dermatoses, and rebound erythema may occur because of long-term therapies at the site of application, particularly at steroid-sensitive areas. Another relevant side effect of chronic application of corticosteroids is tachyphylaxis. Applications should be gradually tapered down in order to avoid rebound effects. To minimize the side effects, it could be useful to consider a switch to lower-potency corticosteroids after successful treatment with potent agents. Moreover, "weekend therapy" or "pulse therapy" should be considered for reducing the amount of corticosteroids, as well as combination therapy or rotation therapy using alternative nonsteroidal drugs such as coal tar, anthralin, calcipotriene, and topical calcineurin inhibitors.

Vitamin D Derivates

Vitamin D3 analogs were introduced in the early 1990s since oral vitamin D was demonstrated to be effective in improving psoriasis. Three vitamin D3 analogs are commonly used for the treatment of psoriasis: calcitriol, calcipotriol, and tacalcitol. They bind to the vitamin D receptor, normalizing keratinocyte proliferation and differentiation and modulating the immune response.

Calcipotriol is available in the form of a cream, solution, or ointment for the treatment of plaque-type psoriasis, scalp psoriasis, and nail

psoriasis, respectively. It has been found to be effective and safe, even when it is associated with sun exposure. Tacalcitol is a synthetic vitamin D3 analog, which is administered once daily. Several studies assessed efficacy and safety of tacalcitol reporting successful clinical outcomes. Treatment with calcitriol shows better tolerability in sensitive and irritated areas of the skin, and thus it may be used in psoriatic children.

Usually local side effects are not severe, and they may include erythema, burning, pruritus, and oedema.

Combined Therapy with Vitamin D3 Derivatives and Corticosteroids

Compound products consisting of calcipotriol and betamethasone dipropionate are currently available. This formulation, combining the action of calcipotriol (regulation of keratinocyte differentiation and antiproliferative effects) with the anti-inflammatory effects of steroids, enhances the effectiveness of this compound, and, presumably, it could offer the possibility of reduction in the dose of either or both single agents, with a potential decrease in the occurrence of their side effects, as assumed by some authors.

Long-term efficacy of this formulation applied once daily resulted in an improvement in PGA ranging from 69 to 74 % of patients continuously treated with the combination compound, achieving "clear" or "almost clear" status with no serious adverse events.

An increasing number of medications, particularly for the scalp, have been developed into innovative, easy-to-use formulations. A lipophilic, non-alcoholic gel containing the same active ingredients (calcipotriol and betamethasone dipropionate) has been developed and used with the same therapeutic scheme (once daily).

Retinoids

Tazarotene represents the only topical retinoid that can be used for plaque psoriasis as gel or cream in 0.05 and 0.1 % formulations. In keratinocytes, tazarotene regulates transcription signalling through the retinoic acid receptors (RAR)-γ, RAR-β, and RAR-α, thus inhibiting proliferation and normalizing differentiation. It also acts as inflammation-suppressing agent.

The use of tazarotene is limited by quite common side effects such as erythema, irritation, and burning that may occur with protracted use, and they might be minimized by using the cream instead of the gel formulation, lowering the concentration, and performing a short-contact therapy or alternate-day applications.

Tars and Anthralin

Coal tar has been used for more than 100 years for the treatment of psoriasis. Coal tar and wood tars (birch, pine, and beech) are available as topical antipsoriatic agents in different formulations, including ointment, cream, gel, lotion, shampoo, and soap.

Tar-based formulations are indicated for the treatment of chronic stable forms of plaque-type psoriasis, scalp psoriasis, and palmo-plantar psoriasis, whereas their use might be limited in sensitive areas, including the genital area and flexural areas, because of their irritant potential.

Coal tar may be used as a monotherapy or in association with UVB (Goëckerman regimen). Its use is limited because of poor patient acceptance due to cosmetic inelegance, including staining of clothes and a potent tar odour that is present in almost all products. Additional potential adverse effects include irritant contact dermatitis, folliculitis, and photosensitivity to UVA light.

Keratolytics

Keratolytics represent a class of therapeutic compounds characterized by the capability of decreasing cell-to-cell cohesion in the stratum corneum and, therefore, promoting the physiologic shedding process. Salicylic acid is a keratolytic agent that is used to reduce hyperkeratosis and increase the absorption of other medications. It is the oldest keratolytic agent used in dermatology at low concentrations, usually ranging from 2 to 6 %. Extensive use may be correlated with important side effects such as salicylate toxicity (salicylism) characterized by dizziness, headache, confusion, and ringing or buzzing in the ears.

Other keratolytic agents include α-hydroxy acids (mainly lactic acid and propylene glycol), urea, and glycerin.

Topical Calcineurin Inhibitors

Topical calcineurin inhibitors could be taken into consideration as a maintenance therapy after a satisfactory steroid therapy, possibly by reducing corticosteroids gradually and introducing calcineurin inhibitors as substitute therapeutic agents. They could constitute a valid alternative to corticosteroids because of their ability to suppress T-cell activation and proliferation. The off-label use of pimecrolimus (1.0 %) and tacrolimus (0.03 and 0.1 %) seems to be effective in treating facial and flexural psoriasis. Their use is limited because of their poor penetration into hyperkeratotic psoriatic plaques, and thus they might be considered as optimal therapeutic option in treating intertriginous areas and more sensitive body sites such as the face where the absorption is naturally increased. However, in order to increase the limited penetration of these agents, they could be applied under occlusion or in combination with keratolytics such as salicylic acid and urea. Regarding the safety profile, only mild side effects including itching, stinging, and the feeling of warmth have been reported.

Phototherapy

It has been well known that natural sunlight improves psoriasis in the majority of patients.

UVB

Mild-to-moderate eruptive plaque-type psoriasis responds rapidly to broadband UVB. Narrowband (311–313 nm) phototherapy is superior to conventional broadband UVB with respect to both clearing and remission times. The initial therapeutic UV dose lies at 75–100 % of the minimal erythema dose (MED). Treatments are given two to four times per week. As peak UVB erythema appears within 24 h of exposure, increments can be performed at each successive treatment. The rate of increase depends on treatment frequency and the effect of the preceding therapeutic exposure. The objective of the dose increments is led to maintain a minimally perceptible erythema as a clinical indicator of optimal dosimetry. Upon clearing, treatment is either discontinued or a maintenance therapy for 1 or 2 months may be prescribed.

Concerning short-term side effects, erythema, dry skin with pruritus, occasional blistering, and all increased recurrence herpes simplex eruptions have been reported. Painful erythema resulting from overexposure is treated with topical corticosteroids. Systemic nonsteroidal anti-inflammatory agents and corticosteroids have also proven useful for severe cases. Excimer laser and monochromatic excimer light utilize specific wavelength (308 nm) belonging to the UVB spectrum, and they appear to offer relapse-free periods and a prolonged stabilization of localized psoriasis comparable or better than that offered by standard topical therapy regimes and by 311 nm UVB treatment.

UVA1

Long-wavelength ultraviolet A light (UVA1, 340–400 nm) has been used to treat skin disease for more than 30 years. UVA1 penetrates deeper than other ultraviolet phototherapies and has different biologic effects than UVB and shorter-wavelength UVA (UVA2, 315–340 nm). UVA1 works via oxygen-dependent mechanisms after photosensitization of endogenous lipids and proteins. UVA1 spectrum has been used in the treatment of psoriasis. The monochromatic coherent and coordinate UVA1 light, based on a 1,064 wavelength neodymium-doped yttrium orthovanadate laser, optically pumped using a 808 nm infrared beam able to achieve a third harmonic 355 nm wave delivery, has shown high success rate in the treatment of mild-to-severe psoriasis reaching both the epidermis and the dermis indicating. From a therapeutic perspective, exposition to the UVA1 radiation therapy can be divided into low (10–30 J/cm^2), medium (40–80 J/cm^2), and high (80–120 J/cm^2) doses. The effects of UVA1 in psoriasis could be associated with the modulation of the local immune response, T-cell depletion, and alterations in apoptosis-related molecules.

Photochemotherapy with Psoralens (PUVA)

Psoralen photochemotherapy (PUVA) is the combined use of psoralens (P) and long-wave UV radiation (UVA). The combination of drug and radiation results in a therapeutic effect, which is not achieved by the single component alone. PUVA is performed by the administration of a fixed dose of a psoralen preparation at a constant interval before UVA exposure. Psoralens are linear furocoumarins, which were originally derived from plants. Currently, 8-MOP (methoxsalen) is most commonly prescribed, but 5-MOP (bergapten) is also used where available. The synthetic furocoumarin 4,5,8-trimethylpsoralen (TMP) is used for bathwater-delivered PUVA. 8-MOP and 5-MOP are available as oral preparations, which either contain crystals, micronized crystals, or solubilized psoralens. Oral psoralens are metabolized in the liver and excreted with the urine within 12–24 h. Topical application of a psoralen molecule *(bath PUVA)* instead of ingestion of the drug has been shown to be very effective, thereby removing the common side effect of nausea occurred after ingestion of the psoralen.

Systemic Treatments

Systemic treatments are generally reserved for moderate-to-severe extensive psoriasis, psoriatic arthritis, erythrodermic psoriasis, pustular psoriasis, moderate psoriasis when topical agents or phototherapy are ineffective or contraindicated, or mild psoriasis in case of severe psychosocial disability (facial/genital psoriasis) or when patients' quality of life is greatly compromised (as in palmo-plantar pustulosis) (Fig. 81.3).

Among those, cyclosporine and methotrexate are considered first-line agents, while acitretin is a second-line therapeutic option, except in the case of pustular erythrodermic psoriasis. Fumaric acid esters are an effective treatment, as demonstrated by several trials performed in Germany, Austria, and the United Kingdom, but they are not available in all European countries (Tables 81.2 and 81.3).

There are several physical measures to define psoriasis severity and the impact of a given therapy: body surface area (BSA), Psoriasis Area and Severity Index (PASI), Psoriasis Global Assessment (PGA), Lattice System Physician's Global Assessment (LS-PGA), Salford Psoriasis Index (SPI), Nail Psoriasis Severity Index (NAPSI), and self-administered PASI (SAPASI). One of the most used psoriasis scoring systems is the PASI that is commonly reported in clinical trials. Fredriksson and Petterson created the PASI in 1978 as a method to evaluate the clinical efficacy of a new treatment for psoriasis. Typically, PASI would be calculated before, during, and after a treatment period in order to determine how well psoriasis responds to the treatment.

Severity is measured by four different parameters: erythema, infiltration and desquamation of the plaques, and the percentage of involved body surface area.

Cyclosporine

Cyclosporine A (CsA) is a decapeptide derived from the fungus *Tolypocladium inflatum* W. Gams. Since the 1970s, its immunosuppressive properties were described, and CsA was introduced in the treatment and prevention of transplant rejection. The beneficial effect of CsA may, at least in part, be attributed to the modulation of T-cell responses: the molecule passively enters into the cell and forms a complex with the cytosolic immunophilin, cyclophilin, causing inactivation of calcineurin-mediated dephosphorylation of the nuclear factor of activated T cells (NFAT). CsA is effective at concentrations ranging from 2.5 to 5 mg\kg\day. The efficacy of intermittent short courses of CsA has generally been expressed as a rapidly produced improvement in all efficacy parameters or as complete clearance of disease and found approximately in 80–90 % of patients. The average duration of treatment has been reported to be between 8 and 16 weeks, and median time to relapse was 72 days. The side effect profile of CsA is well known and predictable. The major safety concerns of CsA therapy are nephrotoxicity, hypertension, and the potential risk of malignancies.

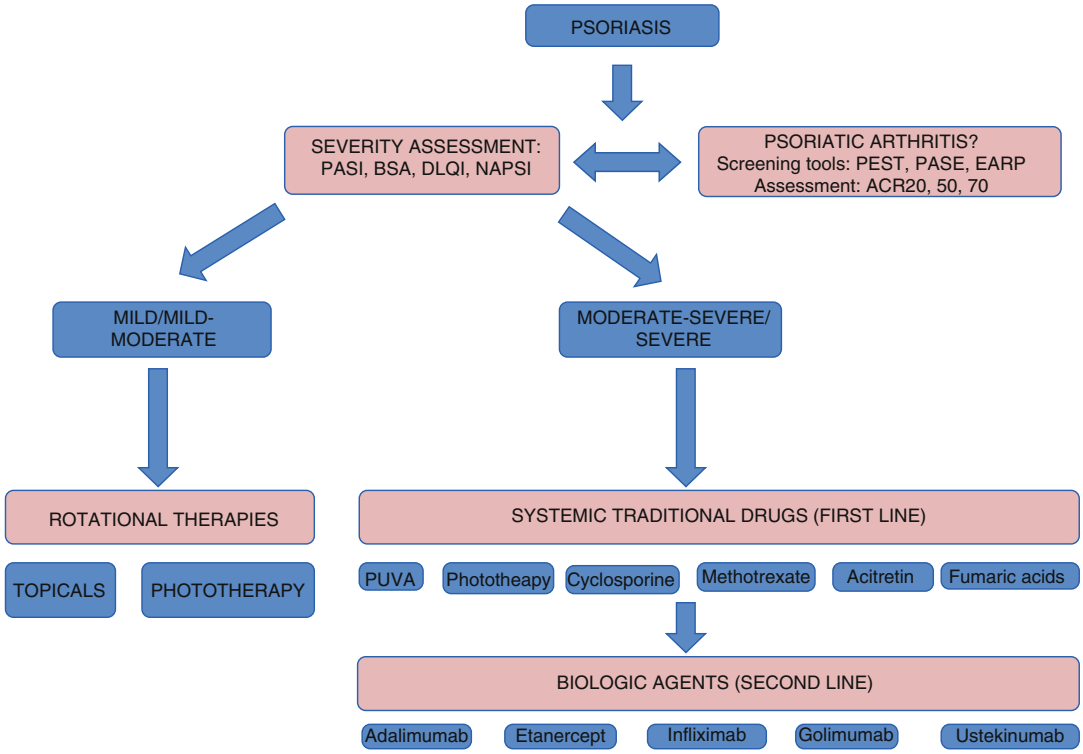

Fig. 81.3 Diagnostic and therapeutic adalimum for plaque-type psoriasis and psoriatic arthritis

Other adverse events observed include gastrointestinal symptoms (diarrhoea, nausea), metabolic abnormalities (hypertriglyceridaemia, hypercholesterolaemia, hyperbilirubinaemia, hypercalcaemia, and hypomagnesaemia), nervous system symptoms (headache, paresthesia), fatigue, gingival hyperplasia, and other general symptoms (influenza-like). Except for some rare cases, these side effects are dose dependent and reversible with treatment interruption or dose adjustments (Tables 81.1, 81.2, and 81.3).

Retinoids

Retinoids are a class of compounds all formally derived from vitamin A (retinol) and successfully used in the treatment of a large spectrum of dermatological and non-dermatological diseases. Acitretin represents the systemic retinoid approved for the treatment of severe psoriasis that, in monotherapy, it is generally more effective for pustular psoriasis than plaque-type, guttate, or erythrodermic psoriasis. When acitretin is used as monotherapy for generalized pustular psoriasis, the initial dose required is 25–50 mg/day. Optimal dosing for individual patients may be achieved through a dose-escalation strategy involving initiation of therapy at low doses (10–25 mg/day) and, if necessary, gradually increasing the dose as tolerated until optimal response is achieved. A rapid resolution of generalized pustular psoriasis is achieved usually within 10 days after initiating acitretin. Mucocutaneous adverse events including cheilitis, skin peeling, alopecia, xerosis, rhinitis, nail dystrophy, epistaxis, sticky skin, retinoid dermatitis, and xerophthalmia may occur (Tables 81.1, 81.2, and 81.3).

Methotrexate

Methotrexate (MTX) is an effective immunosuppressive compound, applied in the prophylaxis and treatment of several diseases. High-dosage MTX is currently used in the treatment of malignancies and in graft-versus-host disease. When used at low or moderate doses, MTX has

Table 81.1 Therapies for psoriasis

	Recommended dose	Remarks
Topical therapies		
Corticosteroids	Once daily	Limited period of 2–4 weeks
	No more than 50 g/week	
Vitamin D3 derivatives	Tacalcitol once daily, calcipotriol twice daily	Their use can be longer than corticosteroids (alone or in combination)
Combined therapy with vitamin D3 derivatives and corticosteroids	Once daily	Limited period of 2–4 weeks
Retinoids	Once daily	Possibility of short-contact therapy
Topical calcineurin inhibitors	Once daily	As maintenance therapy for intertriginous areas
Phototherapy and laser therapy	UVA1: medium (40–80 J/cm^2) and high (80–120 J/cm^2) doses	UVB broad- and narrowband phototherapy
	NB-UVB initial dose (75–100 % minimal erythema dose) to be increased	UVB 308–311 laser therapy
		UVA1 phototherapy
		UVA1 355 nm laser therapy
PUVA	8-methoxypsoralen (8-MOP) 0.3–0.6 mg/kg 1–2 h prior UVA exposure (1 J/cm^2), then increasing UVA doses	
Systemic therapies		
Cyclosporine	2.5–5 mg/kg/die (optimal 4 mg/kg/die)	The average duration of treatment between 8 and 16 weeks and median time to relapse is about 72 days
Methotrexate	5–10 mg weekly as initial dose, escalation dose up to 30 mg weekly	Two dosage schedules (single weekly or intermittent oral schedule (Weinstein regimen))
Acitretin	0.3–0.8 mg/kg/die (optimal 0.5 mg/kg/die)	Useful in pustular and acral psoriasis
Fumaric acid esters	Up to 1.2 g daily	
Adalimumab	80 mg at week 0, 40 mg at week 1, then 40 mg every 2 weeks	
Etanercept	50 mg biweekly for plaque psoriasis for 12 weeks, then 50 mg weekly	
	50 mg weekly for psoriatic arthritis	
Infliximab	5 mg/kg at weeks 0, 2, and 6 and every 8 weeks	
Golimumab	50 mg if body weight <100 kg, 100 mg if body weight >100 kg every 4 weeks	
Ustekinumab	45 mg if body weight <100 kg, 90 mg if body weight >100 kg at week 0, at week 4, and every 12 weeks	

Recommended doses for both topical and systemic therapies

antiproliferative and anti-inflammatory effects and is a useful drug in rheumatoid arthritis, systemic lupus erythematosus, dermatomyositis, sarcoidosis, immunobullous disorders, and psoriasis. MTX has an antiproliferative effect as a folic acid antagonist on the basis of its competitive binding to dihydrofolate reductase. Despite these well-known pharmacological effects, the mechanism of action of MTX at low dose in the treatment of psoriasis remains unclear, having both *immunomodulatory* and profound *anti-inflammatory* properties.

Table 81.2 Common potential adverse events related to the use of systemic conventional therapies and biologics

Agents	Potential occurrence of important side effects				
	Very frequent	Frequent	Occasional	Rare	Very rare
Infliximab	Infusion reactions	Infections, headache, flush, pruritus, urticaria, fever, transaminase elevation	Serum-sickness-like disease, (cutaneous) lupus erythematodes syndrome, severe infections, tuberculosis, anaphylactoid reaction	Opportunistic infections, pancytopenia, vasculitis, demyelinating diseases	
Etanercept	Injection-site reactions, infections (upper respiratory tract, bronchitis, skin infections)	Pruritus	Thrombocytopenia, urticaria, angio-oedema, severe infections (pneumonia, cellulitis, sepsis), weight gain	Anaemia, leucopenia, neutropenia, pancytopenia, vasculitis, subacute and discoid lupus erythematodes, demyelinating disease, tuberculosis	Aplastic anaemia
Adalimumab	Injection-site reaction	Upper respiratory tract infections, sinusitis, injection-site reactions, headache, and rash	Tuberculosis		Drug-induced lupus, lymphoma
Golimumab	Upper respiratory tract infection, viral infections, bronchitis, superficial fungal infections, sinusitis, injection-site reaction	Hypertension, dizziness, paresthesia, constipation, liver enzyme elevations		Vasculitis, other infections and infestations	
Ustekinumab	Upper respiratory infections, headache, tiredness, injection-site reaction, back pain, fatigue	Itching, joint pain, muscle pain or tenderness, injection-site reaction, skin rash or rashes, sore throat, urticaria, depression, diarrhoea, hypersensitivity reaction, dizziness	Other infections	Facial palsy	

(continued)

Table 81.2 (continued)

Agents	Potential occurrence of important side effects				
	Very frequent	Frequent	Occasional	Rare	Very rare
Cyclosporine	None	Renal failure (dose dependent); danger of irreversible renal damage (long-term therapy); hypertension; gingival hyperplasia; reversible hepatogastric complaints (dose dependent); tremor; weariness; headache; burning sensation in hands and feet; reversible elevated blood lipids (especially in combination with corticosteroids); hypertrichosis	Seizures, gastrointestinal ulcerations, weight gain, hyperglycaemia, hyperuricaemia, hyperkalaemia, hypomagnesaemia, acne, anaemia	Ischemic heart disease, pancreatitis, motor polyneuropathy, impaired vision, defective hearing, central ataxia, myopathy, erythema, itching, leucopenia, thrombocytopenia	Microangiopathic haemolytic anaemia, haemolytic uraemic syndrome, colitis (isolated cases), papillary oedema (isolated cases), idiopathic intracranial hypertension (isolated cases)
Methotrexate	Nausea, malaise, hair loss	Elevated transaminases, bone marrow suppression, gastrointestinal ulcers	Fever, chills, depression, infections	Nephrotoxicity, liver fibrosis, and cirrhosis	Interstitial pneumonia, alveolitis
Retinoids	Vitamin A toxicity (xerosis, cheilitis)	Conjunctival inflammation (cave: contact lenses), hair loss, photosensitivity, hyperlipidaemia	Muscle, joint, and bone pain, retinoid dermatitis	Gastrointestinal complaints, hepatitis, jaundice. Bone changes with long-term therapy	Idiopathic intracranial hypertension, decreased colour vision, and impaired night vision
Fumaric acid esters	Diarrhoea, flush	Abdominal cramps, flatulence, lymphocytopenia, eosinophilia	Nausea, dizziness, headache, fatigue, proteinuria, increase in serum creatinine, increase in liver enzymes	Isolated increases in ALT or bilirubin	

Table 81.3 Screening tests required for systemic drug prescription

Agent	Full blood count	Liver enzymes	Serum creatinine	Urine sediment	Pregnancy test (urine)	HBV/ HCV	Serum albumin	PIIINP where available	Electrolytes	Uric acid	Cholesterol, triglycerides	Magnesium	Fasting blood sugar	ESR, CRP	HIV	TB gold quanti-feron
MTX	X	X	X	X	X	X	X	X			X					
Cya	X	X	X	X	X				X	X	X	X				
Retinoids	X	X	X		X						X		X			
FAEs	X	X	X	X	X						X					
Adalimumab	X	X	X	X	X	X					X			X	X	X
Etanercept	x	X	X	X	X	X					X			X	X	X
Infliximab	X	X	X	X	X	X					X			X	X	X
Ustekinumab	X	X	X	X	X	X					X			X	X	X
Golimumab	X	X	X	X	X	X					X			X	X	X

MTX is indicated in moderate-to-severe psoriasis, in symptomatic control of recalcitrant psoriasis not responsive to topical therapy or other systemic therapies such as PUVA or retinoids, in psoriatic erythroderma, in psoriatic arthritis, in acute pustular psoriasis (von Zumbusch type), in localized pustular psoriasis, and in psoriasis that affects certain areas of body so that normal function and employment are prevented. Two dosage schedules for MTX are commonly used: single weekly oral, intravenous, intramuscular, or subcutaneous administration or intermittent oral schedule (Weinstein regimen) of three divided doses over a 24-h period each week (every 12 h three times in 1 week).

An *initial test dose* of 2.5–5.0 mg should be used first to detect any unusual predisposition to toxic effects (Table 81.1).

Several studies have been published concerning the efficacy of MTX in psoriasis. Heydendael et al. (2003) compared MTX to cyclosporine without a placebo arm. At 12 weeks PASI 75 was 60 % for MTX and 71 % for cyclosporine. Similarly, Flytstrom et al. (2008) also compared MTX to cyclosporine without a placebo arm. The mean PASI change from baseline was 72 % in the cyclosporine group and 58 % in the MTX arm.

All forms of therapy (phototherapy, photochemotherapy, MTX, oral retinoids, cyclosporine) for moderate-to-severe psoriasis have varying degrees of long-term toxicity. Although the risk of side effects could increase when MTX is combined with other systemic drugs, in selective cases combination or rotational therapy should be considered in the management of psoriasis. The rotational therapy concept recommends switching from one modality to another before reaching a cumulative toxic range. The first concern on MTX long-term treatment is that hepatotoxicity may occur at approximately 1.0–1.5 g of cumulative dose. Thus, if MTX is discontinued at about 1.0–1.5 g and patients are rotated to another modality, the risk of long-term liver changes can be minimized by providing a "rest period" for several years.

The most commonly reported adverse reactions to the doses of MTX used in the treatment of psoriasis include malaise, bone marrow toxicity, stomatitis, gastrointestinal intolerance, hepatotoxicity, fevers, and alopecia. The severity of side effects is, in general, dose dependent and related to renal and hematologic function. Leucovorin calcium (citrovorum factor or folinic acid) is the only antidote for the hematologic toxic effects of MTX. When an overdose of MTX is suspected for any reason, including minimal renal impairment, the patient should be given leucovorin immediately (Tables 81.2 and 81.3).

Fumaric Acid Esters

Fumaric acid ester (FAE) therapy has proved to be safe and effective in patients with severe psoriasis vulgaris. Fumaric acid and its esters are a group of simple structured compounds. Because fumaric acid itself is poorly absorbed after oral intake, esters are used for treatment. FAEs are almost completely absorbed in the small intestine. Dimethylfumarate is rapidly hydrolyzed by esterases to monomethylfumarate, which is regarded as the active metabolite. The composition of this mixture includes dimethylfumarate, calcium, magnesium, and zinc salts of monoethyl hydrogen fumarate. FAEs, mainly dimethylfumarate, have been successfully utilized with evidence of high clinical efficacy in several double-blind placebo-controlled studies, on patients who had previous failed systemic therapies, such as methotrexate, cyclosporine A, etretinate, and others. Although the mode of action of FAEs in the treatment of psoriasis is not fully understood, recent experimental data reported that FAEs are able to improve psoriasis by modulating leucocyte, keratinocyte, and/or endothelial functions. The first randomized, double-blind trial of FAE therapy for psoriasis was published by Nugteren-Huying et al. in 1990. Three groups consisting of a total of 39 patients with psoriasis were treated for 4 months with FAEs. The first group of patients received a mixture of dimethylfumarate and monoethylfumarate (calcium, magnesium, and zinc salts), while the second group was treated with a mixture of octylhydrogenfumarate and monoethylfumarate as zinc and magnesium salts. Placebo tablets were given to the third group. The results showed a reduction in the lesional skin area of 68 % in the group treated with a combination of dimethylfumarate and monoethylfumarate, while the groups treated

with octylhydrogenfumarate and monoethylfumarate or with placebo showed only a marginal clinical response. There is a characteristic spectrum of adverse events in FAE treatment; therefore, it is important to monitor the patients during the course of therapy. The most frequently noted adverse events associated with FAE treatment are gastrointestinal complaints, which occur in more than two-thirds of patients. The symptoms vary from mild stomach upsets, increased frequency of stools, and tenesmus to stomach cramps, tympanites, and diarrhoea; these become most frequent between weeks 4 and 12. Flushing is seen in about one-third of patients treated with FAE. Symptoms include a sudden redness of the skin and a sensation of heat lasting between a few minutes and a few hours. Headaches may be associated. Frequency of flushing is greatest at the onset of therapy and decreases with prolonged treatment time (Tables 81.1, 81.2, and 81.3).

Biologic Agents

Biologic treatments for psoriasis include anti-TNF-alpha, anti-p40 agents, and anti-IL-17.

Patients suffering from moderate-to-severe psoriasis/PsA that do not tolerate or do not achieve sufficient results with at least two systemic treatments can benefit from a treatment with biological agents (Fig. 81.3). These agents, with their individual clinical profile, demonstrated to be effective in different aspects of the disease, including skin lesions, joint pain and swelling, enthesitis, and dactylitis resulting in a significant improvement either in mobility or in radiographic progression and quality of life parameters. Treatment with biologic agents increases the risk of latent tubercular infection reactivation (Tables 81.2 and 81.3).

Anti-TNF-Alpha

Etanercept

Etanercept is a fully human dimeric fusion protein comprising the extracellular domain of the TNF-α p75 receptor fused to the inert FC portion of IgG1 molecule. Differently from monoclonal antibodies, etanercept is not associated with the development of neutralizing antibodies. This ensures a sustained and prolonged efficacy without loss of response. The FC portion of IgG1 serves to stabilize etanercept and prolongs the median half-life which is 4.8 days. For the treatment of psoriasis, etanercept is prescribed at 50 mg dose twice weekly, for 12 weeks followed by 50 mg weekly, while for psoriatic arthritis is administered at fixed dose of 50 mg weekly (Table 81.1).

Infliximab

This agent is a chimeric anti-tumour necrosis factor-α (TNF-α) monoclonal IgG1 antibody, with high affinity and avidity for soluble and cell surface transmembrane forms of TNF-α. Infliximab is prescribed at the dose of 5 mg/kg of body weight, showing rapid improvement from baseline. The regimen consists of an induction dosing with intravenous drip treatments over 2 h at weeks 0, 2, and 6 and a maintenance dosing with booster infusions at the same dosage every 8 weeks.

Adalimumab

Adalimumab is a fully human monoclonal antibody that binds specifically to TNF-alpha and blocks its interaction with the p55 and p75 cell surface TNF receptors. Adalimumab is prescribed as a subcutaneous injection at the standard dosing regimen: initial dose of 80 mg at week 0 that is followed by 40 mg at week 1, then 40 mg every 2 weeks.

Golimumab

Golimumab (GLB) is the last anti-TNF-α agent approved by the EMA (European Medicines Agency) and FDA (Food and Drug Administration) for the treatment of PsA. GLB is a fully human monoclonal antibody IgG1k neutralizing TNF-α. Randomized clinical trials demonstrated satisfactory efficacy of GLB in comparison to other anti-TNF-α agents in improving signs and symptoms of PsA and also in treating the structural damage caused by the disease. Actually, there are no data showing superiority of TNF-α inhibitors in combination with synthetic DMARDs (disease-modifying

antirheumatic drug) versus TNF-α inhibitor monotherapy, and no comparative studies between anti-TNF-α therapies are available.

Certolizumab

Certolizumab is a polyethylene glycolylated (PEGylated) Fab fragment of a humanized monoclonal antibody that binds and neutralizes human TNF-α. The PEG moiety of the Fab fragment markedly increases the half-life of certolizumab and confers to the drug a unique structure that differs from the other anti-TNF-α agents. Additionally to the PEGylated portion, the smaller molecular weight is responsible of a higher penetration into inflamed tissues. In premarketing studies, certolizumab has been tested at an initial dose of 400 mg followed by 200 or 400 mg every 2 weeks.

Anti-p40 Agents

Briakinumab and Ustekinumab

In the recent years, two antibodies targeting the p40 subunit have been developed: ustekinumab and briakinumab. Briakinumab (abt-874) is a fully humanized antibody that reached a preregistration status, but its development has been discontinued. Conversely, ustekinumab is approved for the treatment of plaque-type psoriasis at the dosage of 45 mg or 90 mg according to patient's weight lower or higher than 100 kg, at week 0, at week 4, and every 12 weeks. Large phase II and phase III trials proved ustekinumab effective and safe in the treatment of psoriasis.

The major phase III trials comparing ustekinumab with either placebo in PHOENIX I/II or etanercept in ACCEPT have confirmed superior safety and efficacy.

PHOENIX I, a 76-week, randomized, double-blind, placebo-controlled, multicenter study enrolling 766 patients, showed 67.1 and 66.4 % of subjects receiving 45 and 90 mg dosages, respectively, who achieved 75 % of improvement by the Psoriasis Area and Severity Index (PASI-75). There results were subsequently confirmed by PHOENIX II study and ACCEPT.

IL-17-Targeting Agents

Three agents targeting the IL-17 signalling have been tested in premarketing phase for the treatment of psoriasis. These biologics, ixekizumab, secukinumab, and brodalumab successfully passed phase II clinical trials and are presently investigated in phase III trials. Ixekizumab and secukinumab are fully humanized antibodies neutralizing IL-17, while brodalumab is a fully humanized antibody binding to IL-17R.

Ixekizumab

Ixekizumab is a humanized IgG4 monoclonal antibody (mAb) neutralizing IL-17A. The safety and efficacy of ixekizumab was evaluated in a phase II, double-blind, placebo-controlled trial with 142 patients affected by moderate-to-severe plaque-type psoriasis. Patients were randomized into five groups receiving 150, 75, 25 mg, 10 mg ixekizumab or placebo, subcutaneously at 0, 2, 4, 8, 12, and 16 weeks. The achievement of 75 % reduction of PASI after 12 weeks of treatment constituted the primary endpoint of the study occurring in 82.1, 82.8, 76.7, 29, and 7.7 % of patients treated with 150, 75, 25, 10 mg ixekizumab or placebo, respectively.

Brodalumab

Brodalumab is a human mAb blocking IL-17RA, the receptor subunit shared by IL-17A, IL-17F, and IL-17A/F heterodimer ligands. The antagonism of IL-17 signalling by brodalumab was initially proven effective in inducing clinical, histologic, and genomic resolution of psoriasis after only 1 week of treatment in a phase I, proof-of-concept study enrolling 10 patients with psoriasis. Further substantiating the efficacy is a more recent phase II, randomized, double-blind, placebo-controlled, dose-ranging study involving 198 patients randomly assigned to receive subcutaneous brodalumab at the dosage of 280 mg monthly or 70, 140, 210 mg brodalumab or placebo at weeks 0, 1, 2, 4, 6, 8, and 10. This 12-week study assessed the efficacy of brodalumab in treating psoriasis with a mean percentage improvement of 45, 85.9, 86.3, 76, and 16 % of PASI score using

280, 210, 140, 70 mg, or placebo, respectively ($p<0.001$ for all comparison versus placebo). Common adverse events occurred with greater frequency in the high-dose brodalumab group; among the serious adverse events, two cases of mild neutropenia (grade III) were reported.

Secukinumab

Secukinumab (AIN 457) is human IgG1κ that neutralizes IL-17A. A phase II, randomized, double-blind, placebo-controlled, parallel-group study evaluated the safety and efficacy of different subcutaneous doses of secukinumab (single dose of 25 mg or monthly administration of 25, 75, or 150 mg) compared to placebo.

Purpuras

82

Torello M. Lotti, Lara Tripo, Alice Garzitto, Aldona Pietrzak, and Ilaria Ghersetich

Key Points

- Purpura is a group of diseases entity characterised by macules and plaques that manifest as skin discoloration caused by extravasation of red blood cells.
- Clinically, purpuras are subdivided into three main types: palpable purpura, non-palpable purpura and capillaritis of unknown cause.
- Different treatments are reserved for palpable purpura, non-palpable purpuras and capillaritis of unknown cause.

Definition and Epidemiology

Purpura is a disease entity characterised by macules. By definition, macules are flat skin lesions not raised above the surrounding skin. Purpura manifests as skin discoloration caused by extravasation of red blood cells.

Pressure by fingers or diascopy fails to blanch the purpuric lesion (Fig. 82.1), thus distinguishing it from erythema and telangiectasia. Purpuric lesions vary in colour from purple to bluish-red or brown with evolution through a greenish-yellow or a brownish-yellow hue due to intradermal chemical degradation of haemoglobin into haemosiderin deposits. Haemosiderin deposits with coexisting chronic inflammation might stimulate melanogenesis. Clinically, purpuras are subdivided into three main types: palpable purpura, non-palpable purpura and capillaritis of unknown cause.

Palpable Purpura: Basic Concepts of Pathogenesis

This clinical condition is mainly related to cutaneous necrotising vasculitis (CNV) characterised by angiocentric segmental inflammation, endothelial cell swelling and fibrinoid necrosis of blood vessel walls. The skin is often the only organ apparently involved; nevertheless, clinically relevant systemic involvement occurs in many cases and skin lesions may just represent the initial signs of a systemic

Fig. 82.1 Purpuric lesions not blanching during diascopy

disease. CNV may also represent the cutaneous manifestation of any systemic vasculitis.

The disorder equally affects patients of both sexes and at all ages; approximately 10 % of cases occur in children. No genetic factors have been recognised.

Many incidental factors, especially drugs (insulin, penicillin, sulphonamides, etc.), chemicals (insecticides, petroleum products), foods (e.g., milk proteins) and infections (viral, bacterial, fungal, protozoan, helminthic), should be considered as the causes of CNV.

CNV has been reported in association with coexisting diseases (e.g., collagen vascular diseases, hyperglobulinaemic purpura, cryoglobulinaemia, inflammatory bowel disease, malignant neoplasm, cystic fibrosis, etc.). In many cases the cause of CNV remains unknown (i.e., in Henoch–Schönlein purpura, urticarial vasculitis, erythema elevatum diutinum, nodular vasculitis, atrophie blanche, cutaneous polyarteritis nodosa).

Although blood vessels of any size may be affected in systemic vasculitis, CNV usually occurs in small venules (post-capillary venules), being characterised by two main histological patterns: a leukocytoclastic form with a presumed pathogenesis mediated by immune complexes and a lymphomonocytic form, in which a cell-mediated pathogenesis is implicated.

More recent data seem also to suggest the participation of a secondary cell-mediated immune response in the late phase of the leukocytoclastic CNV.

In particular, a role of gamma/delta T cells has been suggested in CNV that may indicate multiple potential functions of this subset of T cells in the immune system of the skin. Microscopic examinations of changes show deposition of fibrinogen in the walls of the post-capillary venules in the upper dermis, along with a perivenular and intramural inflammatory infiltrate consisting predominantly of neutrophils. Most T cells infiltrating tissues and organs undergoing fibrosis have the potential to produce high levels of interleukin 4, which is particularly true for the CD8+ or CD4+ CD8+ double-positive T-cell subsets.

As mentioned above, strong experimental and clinical evidence suggests that the leukocytoclastic form of CNV is an immune complex disease. After antigenic exposure, soluble antigen-antibody complexes are formed. In the presence of antigen excess, these complexes can precipitate in the vessel wall. Following the deposition of antigen-antibody complexes, a complex series of events is initiated, ultimately leading to vessel wall damage, fluid and red blood cell *leakage* and ischaemia. In addition to the immunologic events, several non-immunologic factors may play a role in disease expression. Vasoactive amines, especially endogenous histamine, can precipitate the deposition of complexes. Endothelial cells also appear to be primarily involved. These cells may produce and release cytokines that enhance the inflammatory response. Finally, local factors, such as anatomic location and viscosity, may help explain the clinical manifestations of a given vasculitic syndrome.

The fibrinolytic system is responsible for the degradation of fibrin into fibrin degradation products.

Cutaneous fibrinolytic activity is usually increased in the early form of CNV (characterised clinically by urticarial wheals) and reduced or absent in the late phase (clinically manifested by palpable purpura). This may lead to microvascular thrombosis due to excessive intra-/perivascular deposition of fibrin, with consequent tissue hypoxia and necrosis.

Palpable purpura is the major clinical presentation of CNV, whereas erythematous macules, wheals, papules, blisters, large palpable nodules, ecchymoses, pustules, haemorrhagic vesicles, ulcers and a netlike pattern of the skin (livedo reticularis) are less common manifestations (Fig. 82.2).

The eruption most often appears on the legs, persisting for 1–4 weeks, leaving hyperpigmentation and/or atrophic scars, and may be recurrent for years.

Fig. 82.2 Cutaneous necrotising vasculitis. Multiple erythematous macules and necrotic ulcers are present on the shins

Non-palpable Purpura: Basic Concepts of Pathogenesis

Non-palpable purpura is characterised by the distinctive clinical feature of cutaneous non-infiltrated haemorrhagic spots (Fig. 82.3).

Non-palpable purpura is more frequently observed in relation to platelet and vascular tissue alterations (often coexistent), and in such cases, it is frequently characterised by simultaneous gingival bleeding and microhaematuria. Coagulation disturbances, instead, are manifested more frequently in cases with internal haemorrhage (i.e., visceral, intra-articular) that usually lasts for a long time. In dermatological clinical practice, platelet and vascular tissue disorders are often associated, and the patient commonly presents with petechiae, generally without relationship to previous trauma, often accompanied by gingival bleeding and/or micro- or macro-haematuria of recent onset.

One of the most common platelet alterations is an autoimmune disorder called idiopathic thrombocytopenic purpura (ITP). The condition results in immunologic destruction of normal platelets due to the presence of anti-platelet antibodies in the blood. It often occurs in children, being the most common cause of bleeding diathesis in childhood. The onset is associated with a wide range of infections, and recent genetic studies indicate the relationship between disease susceptibility and some genetic polymorphisms. An acute form is likely to resolve spontaneously.

Fig. 82.3 Small (1–2 mm) haemorrhagic macules on the thigh

Coagulation disorders can be inherited (like haemophilias or von Willebrand disease) or acquired and are manifested by deep haematomas and gastrointestinal or intra-articular haemorrhage that generally lasts for several days. In these cases family history and the report of prolonged bleeding after tonsillectomy or dental extraction may be helpful for the diagnosis; however, the family history is usually non-contributory in one-third of haemophiliacs and in all patients with acquired coagulation disorders.

The 'vascular' purpuras, clinically polymorphous, are not usually associated with extracutaneous bleeding, with the exception of the pattern of 'relapsing juvenile epistaxis' (with nasal

bleeding) and the pattern of 'hereditary haemorrhagic telangiectasia' (with possible visceral bleeding).

Careful physical examination may be important for the diagnosis based on the criteria summarised in Table 82.1, together with the information obtained from the diagnostic tests listed in Table 82.2.

Capillaritis of Unknown Cause: Basic Concepts of Pathogenesis

Capillaritis of unknown cause (CUC) is a group of dermatoses whose aetiology is unknown. The fundamental clinical characteristics of CUC consist of red-brownish pigmentation, particularly on the lower extremities. These disorders are much more common in males. Familial incidence has been reported. Histologically CUCs are all similar, the histological examination revealing lymphomonocytic perivascular infiltrate confined to the vessels in the upper dermis with endothelial swelling, extravasation of red blood cells and, in old lesions, haemosiderin deposits in macrophages.

Recent histochemical and ultrastructural studies have suggested that a lymphocyte-mediated immune reaction evoked by unknown circulating antigens might play an important role in the pathogenic mechanism. The group of CUC includes some clinically autonomic varieties, such as Schamberg's disease (Fig. 82.4), eczematide-like purpura of Doucas and Kapetanakis, pigmented

Fig. 82.4 Schamberg purpura. Brownish-red-orange, irregular macules varying in size on the dorsum of the foot and shin. No symptoms of venous insufficiency are present

Table 82.1 Clinical criteria for differential diagnosis among purpuras related to platelet, vascular tissue and coagulative alterations

	Platelet alterations	Vascular tissue alterations	Coagulation disturbances
Sex	Both	Generally women	Generally men
Family history	Generally negative	Often positive	Generally positive
Past history (bleeding)	Generally negative	Often positive	Generally positive
Outbreak	Spontaneous or microtrauma	Spontaneous or microtrauma	Traumatic or spontaneous
Systemic manifestations	Gums, gastrointestinal or genitourinary apparatus	Nasal mucous membrane (males)	Large joints, muscles, visceral organs
Kind of bleeding	Sudden, short duration	Short duration	Long duration (days)

Table 82.2 Principal diagnostic tests in cutaneous and systemic haemorrhagic diseases

Tests	Platelet alterations	Vascular tissue alterations	Coagulation disturbances
Bleeding time	Lengthened	Normal or lengthened	Normal
Platelet count	Sometimes decreased	Normal	Normal
Functional platelet deficiency	Possible	Absent	Absent
Negative pressure test	Positive	Positive	Negative
Hammer test	Positive	Positive	Negative
Hess test	Negative	Often positive	Negative
Partial thromboplastin time	Normal	Normal	Altered
Prothrombin time	Normal	Normal	Altered

purpuric lichenoid dermatosis of Gougerot and Blum, lichen aureus, purpura annularis telangiectodes and purpura telangiectasia arciformis.

Other Purpuras of Dermatological Interest

Senile Purpura

SP is a quite common, benign dermatosis affecting >10 % of individuals over the age of 50. The condition is caused by age-related loss of supportive tissue and damage to the small blood vessels in the skin. It manifests as non-palpable purpura and most complaints are associated with cosmetic issue.

Amyloidosis Purpura

In amyloidosis, purpura may occur because of amyloid deposits within vessel walls, platelet changes or liver disease. The lesions are most commonly located on the eyelids, nose, periorbital region, mouth and neck.

Contact Purpura

A list of substances capable of causing contact purpura includes khaki clothing, azo dyes in clothing, various rubber additives and optical whiteners. In contact purpura, the lesions may involve areas wider than those of actual contact (Fig. 82.5a, b).

Gravitational Purpura

This purpura is often a consequence of chronic venous hypertension of the legs.

It occurs most frequently in adult men. The characteristic clinical feature of the dermatosis is the presence of yellowish-brown, brownish or bluish-violet spots on the lower legs. The lesion may extend to the dorsa of the feet and toes. Oedema, ulceration and sclerosis may be associated.

Fig. 82.5 (**a**) and (**b**) Contact purpura caused by direct contact with hygroscopic granules used for protection of the shoes

Neonatal Purpura

Neonatal purpura may be due to an accentuation of the normal fall of prothrombin within the first week of life. Nowadays the widespread use of vitamin K has reduced its incidence.

Purpura also may be associated with the Wiskott-Aldrich syndrome or with the neonatal rubella syndrome. It may also occur in a child whose mother has systemic lupus erythematosus.

Gardner–Diamond Syndrome

In the Gardner–Diamond syndrome (psychogenic purpura, painful bruising syndrome, autoerythrocyte sensitisation syndrome), the onset of painful ecchymotic lesions usually occurs in middle-aged women with hysterical personality after acute psychoemotional stress, often in areas subjected to microtrauma. The patients may experience concomitant recurrent epistaxis and visceral bleeding.

Initially it was thought that extravasated red blood cells might stimulate the formation of skin-sensitising antibodies, but more recent studies gave negative results. Skin tests with autologous blood cells have been reported to reproduce clinical lesions, but only when the patient had been previously informed about the expected reaction, suggesting a psychogenic origin of this disease. Recent research has shown that this purpuric condition may be caused by systemic or, more often, local (cutaneous) abnormal activation of the fibrinolytic system due to excessive release of tissue-type plasminogen activator from endothelial cells, finally leading to cutaneous haemorrhage.

Main Investigations in Palpable Purpura (CNV)

In patients with CNV, a laboratory screening is always required to confirm the diagnosis and pathogenesis and to determine the extent of involvement of systemic vasculitis and/or the existence of underlying associated diseases.

Laboratory evaluation includes histopathological and immunofluorescence studies, blood tests and urinalysis.

In the leukocytoclastic form, direct immunofluorescence of the lesional skin may show immunoglobulins, complement components and fibrin deposits in the walls of blood vessels and around them; immunoglobulin G (IgG) rather than IgM are more likely to be present when there is an underlying collagen vascular disease, and IgA may be indicative of Henoch-Schönlein purpura.

Decreased levels of complement components are often found in leukocytoclastic CNV associated with rheumatoid arthritis (C1, C4, C2), systemic lupus erythematous (C1q, C4, C2, C3, factor B, C9), cryoglobulinaemia and Sjogren's syndrome. Circulating immune complexes, rheumatoid factor, antinuclear antibodies, antiphospholipid antibodies and cryoglobulins can be detected with antistreptolysin antibodies and hepatitis B (C and A) surface antigens. Moreover, in patients in whom systemic syndromes are being considered, tests such as antineutrophil cytoplasmic antibody (ANCA) for Wegener's granulomatosis may be diagnostically helpful. Urine analysis may reveal proteinuria, haematuria and cylindruria caused by a possible renal involvement. In the lymphocytic form of CNV, these laboratory tests are usually normal or negative.

General Principles of Treatment

Different treatments are reserved for palpable and non-palpable purpuras and capillaritis of unknown cause (Table 82.3).

General Principles of Treatment of Palpable Purpura

In patients with CNV, when possible, identification and removal of causative agents (drugs, chemicals, infections, and foods) represents the best aetiological treatment, followed by rapid clearance of skin lesions, so that no other treatment is necessary. In the remaining cases, local and systemic therapies are recommended.

Local Treatments

Topical therapy (corticosteroid creams) may be helpful in some cases. Gradient support stockings may be useful for lesions on the legs with coexistent chronic venous hypertension.

Systemic Treatment

These treatments include corticosteroids, nonsteroidal anti-inflammatory drugs, colchicine, dapsone, potassium iodide, fibrinolytic agents, aminocaproic acid, immunosuppressive agents, drugs reducing platelet aggregation and antihistamines.

Systemic treatment with oral corticosteroids (prednisone 60–80 mg/day) is advised in the majority of patients for 7–15 days in the acute phase (especially in Henoch-Schönlein purpura, urticarial vasculitis, Behçet's disease).

Table 82.3 Different treatments for palpable and non-palpable purpuras and capillaritis of unknown cause

Palpable purpura	Non-palpable purpura	Capillaritis of unknown cause
In the acute phase (especially in Henoch Schönlein purpura, urticarial vasculitis, Behçet's disease)	In drug-induced purpura	Hydrocortisone creams
Oral prednisone (60–80 mg/day) for 7–15 days	A short treatment (3–7 days) of oral prednisone (0.5–1 mg/kg per day)	PUVA treatment
Vasculitis with more persistent or necrotic lesions	When bleeding is observed in cases with severe thrombocytopenia	Narrow-band ultraviolet B therapy
Acetylsalicylic acid (150–1,000 mg/day) and indomethacin (25–150 mg/day)	Platelet transfusion	In selected cases with reduced cutaneous and plasma fibrinolytic activity
In the chronic forms	Haemophilias	Stanozolol (3–6 mg/day) for 1–3 months or pentoxifylline (300 mg day) for 8 weeks
Oral colchicine (0.6 mg twice daily)	Supplementation of deficient clotting factor	
Erythema elevatum diutinum	Idiopathic thrombocytopenic purpura	
Dapsone (50–200 mg day)	Corticosteroids or immunosuppressants, intravenous immunoglobulins, monoclonal antibodies (e.g., rituximab), splenectomy or new drugs like thrombopoietin receptor agonists (romiplostim, eltrombopag)	
Nodular vasculitis	Disseminated intravascular coagulation	
Potassium iodide (0.3–1.5 g four times daily)	High doses of intravenous heparin (20,000–30,000 U/day) plus antithrombin III (500–1,000 U/day)	
In various types of hypofibrinolytic vasculitis	Hyperfibrinolytic conditions	
Stanozolol (5 mg twice daily) or phenformin hydrochloride (50 mg twice daily) plus ethylestrenol (2 mg four times daily) or heparin (5,000 units twice daily), mesoglycans (50–100 mg/day) or defibrotide (700 mg i.m./day)	Aprotinin (500,000 U) or oral ε-aminocaproic acid preparations (4–6 g/day)	
In the vasculitis associated with livedo reticularis and the livedoid vasculitis	Thrombocytosis-dependent purpuras	
Low molecular weight dextran (500 ml i.v./day)	Anti-aggregating agents [acetylsalicylic acid (100–300 mg/day), ticlopidine hydrochloride (250–500 mg/day), dipyridamole (400–800 mg/day)]	
In the hyperfibrinolytic states of vasculitis	Purpuras due to both microangiopathic and angiophilic microvascular defects	
Aminocaproic acid (8–16 g/day for many months)	Systemic and/or local corticosteroids and administration of vitamin PP (100–500 mg/day) or vitamin C (1–2 g/day), etamsylate (1–1.5 g/day), calcium dobesilate (1–2 g/day)	
In patients with CNV with a rapidly progressive course or with systemic involvement which is not controlled with corticosteroids		

(continued)

Table 82.3 (continued)

Palpable purpura	Non-palpable purpura	Capillaritis of unknown cause
Immunosuppressive agents: cyclophosphamide (2 mg/kg/day), methotrexate (5–25 mg/week), azathioprine (50–200 mg/day) and cyclosporin A (3–5 mg/kg/day)		
In the course of vasculitis induced by immune complexes with concomitant arterial disease		
Drugs reducing platelet aggregation – dipyridamole (400–800 mg/day), acetylsalicylic acid (100–300 mg/day, ticlopidine hydrochloride (250–500 mg/day) – and plasmapheresis		

Nonsteroidal anti-inflammatory drugs, such as acetylsalicylic acid (150–1,000 mg/day) and indomethacin (25–150 mg/day), have been used for vasculitis with more persistent or necrotic lesions.

Some cases of urticarial vasculitis have responded to indomethacin.

Phenylbutazone (400–600 mg/day), oxyphenbutazone (300–400 mg/day) and ibuprofen (600–900 mg/day) are indicated for thrombophlebitis in the course of nodular vasculitis.

Oral colchicine, which inhibits neutrophil chemotaxis, in doses of 0.6 mg twice daily may be helpful in the chronic forms of the disease.

Dapsone (50–200 mg/day) has also been used usually in patients with skin involvement alone (especially in patients with erythema elevatum diutinum).

Potassium iodide (0.3–1.5 g four times daily) is useful for nodular vasculitis.

Fibrinolytic agents can be used in patients with reduction of plasma and/or cutaneous fibrinolytic activity.

Stanozolol (5 mg twice daily) or phenformin hydrochloride (50 mg twice daily) plus ethylestrenol (2 mg four times daily) can be administered for about a year.

Other fibrinolytic agents as heparin (5,000 U twice daily), mesoglycans (50–100 mg/day) and defibrotide (700 mg i.m./day) seem beneficial in various types of hypofibrinolytic vasculitis.

Low molecular weight dextran (500 ml i.v./day) is also indicated in the hypofibrinolytic phase of disease because of its fibrinolytic effect. This seems to produce beneficial effects in the vasculitis associated both with livedo reticularis and with the livedoid vasculitis.

Aminocaproic acid (8–16 g/day for many months) can be used in the hyperfibrinolytic states of CNV. Immunosuppressive agents such as cyclophosphamide (2 mg/kg per day or as a monthly intravenous pulse), methotrexate (5–25 mg/week), azathioprine (50–200 mg/day) and cyclosporin A (3.5 mg/kg per day) are effective, especially in patients with CNV with a rapidly/progressive course or with systemic involvement, which is not controlled with corticosteroids.

In the course of vasculitis induced by immune complexes with concomitant arterial disease, drugs reducing platelet aggregation – dipyridamole (400–800 mg/day), acetylsalicylic acid (100–300 mg/ day) and ticlopidine hydrochloride (250–500 mg/day) – and plasmapheresis can be used.

H1-antihistamines alone or in combination with H2-antihistamines are used to alleviate itch and to block histamine-induced venular endothelial gap formation with resultant trapping of immune complexes. The correction of local factors such as trauma, cold stasis and lymphoedema may also be important.

Experimental Treatments

Recently a patient with intractable systemic vasculitis has been treated with two monoclonal antibodies, Campath-1H and rat CD4.

General Principles of Treatment of Non-palpable Purpura

The treatment of various forms of non-palpable purpura is strictly dependent on their aetiopathogenesis.

Idiopathic thrombocytopenic purpura can be treated with corticosteroids or immunosuppressants, intravenous immunoglobulins, splenectomy or new drugs like thrombopoietin receptor agonists (romiplostim, eltrombopag). In spontaneous bleedings or when platelet counts are less than 10^3 per ml, platelet transfusion is a treatment of choice.

Haemophilias should be treated by regular infusions of deficient clotting factors.

In drug-induced purpura, it is necessary to stop the ingestion of the suspected drug(s). A short treatment (3–7 days) of oral prednisone (0.5–1 mg/kg per day) may be useful, above all in forms with immunological pathogenesis. When bleeding is observed in cases with severe thrombocytopenia, platelet transfusion may be indicated. Disseminated intravascular coagulation may be successfully treated with high doses of intravenous heparin (20,000–30,000 U/day) plus antithrombin III (500–1,000 U/day).

Hyperfibrinolytic conditions can be corrected by administration of aprotinin (500,000 U) or oral ε-aminocaproic acid preparations (4–6 g/day). Thrombocytosis-dependent purpuras may be advantageously treated with anti-aggregating agents – acetylsalicylic acid (100–300 mg/day), ticlopidine hydrochloride (250–500 mg/day) or dipyridamole (400–800 mg/day).

Purpuras due to microvascular defects both of microangiopathic and angiophilic origin require discontinuation of systemic and/or local corticosteroids (or, rarely, other presumably responsible drugs) and administration of vitamin PP (100–500 mg/day) or vitamin C (1–2 g/day) (scurvy), etamsylate (1–1.5 g/day) or calcium dobesilate (1–2 g/day).

General Principles of Treatment of Capillaritis of Unknown Cause

Capillaritis of unknown cause may require hydrocortisone creams, psoralen and ultraviolet A (PUVA) treatment or narrow-band ultraviolet B therapy.

In selected cases with reduced cutaneous and plasma fibrinolytic activity, oral stanozolol for 1–3 months or pentoxifylline (300 mg/day) for 8 weeks may result in complete clearance of purpuric lesions.

Pyoderma Gangrenosum

83

Clio Dessinioti and Andreas D. Katsambas

Key Points

- Pyoderma gangrenosum (PG) is a rare, chronic, neutrophilic skin disease of unknown origin, characterized by painful, sterile, necrotic ulcers with violaceous undermined borders.
- PG is idiopathic in 40–50 % of patients; however, in the remaining cases, it may be associated with underlying diseases including ulcerative colitis, Crohn's disease, leukaemia, monoclonal gammopathy, rheumatoid arthritis and immunodeficiencies.
- PG has been reported as part of PAPA, PASH and PAPASH syndromes.
- Four clinical variants of PG have been described: ulcerative, pustular, bullous and vegetative.
- Extracutaneous pulmonary and splenic neutrophilic infiltrates may rarely occur in patients with PG.
- Despite the paucity of randomized, controlled trials evaluating treatments for PG and the lack of a standardized treatment algorithm, systemic corticosteroids and cyclosporine are often used for severe PG.
- PG may demonstrate a chronic, recalcitrant course posing a therapeutic challenge.

Definition and Epidemiology

Pyoderma gangrenosum (PG) is a rare, chronic, inflammatory dermatosis characterized by painful, sterile, necrotic ulcers with violaceous undermined borders. It was first described by Brocq in 1916 as 'phagédenisme géométrique'.

The incidence of PG is estimated to be 3–10 patients per million per year, affecting mainly patients aged 20–50 years old. It is extremely rare in the paediatric population, with only 4 % of patients being infants and children. Among the childhood cases of PG, 25 % are idiopathic, while familial PG has only rarely been reported.

There is a slight female preponderance. Fifty per cent of cases are associated with an underlying systemic disease, mainly inflammatory bowel disease (IBD), arthritis and lymphoproliferative disorders. PG may cause significant morbidity. Increasing age and male sex are associated with a poorer outcome.

Basic Concepts of Pathogenesis

PG is a neutrophilic dermatosis of unknown aetiology. It belongs to the group of neutrophilic dermatoses including Sweet's syndrome, subcorneal pustular dermatosis, erythema elevatum diutinum and Adamantiades-Behçet's disease. PG has been characterized as a cutaneous autoinflammatory disease. Autoinflammatory diseases are clinically characterized by recurrent sterile inflammation in affected organs, in the absence of high titres of circulating autoantibodies and autoreactive T cells.

Two cases of familial PG were described in two siblings with common variable immunodeficiency (CVID) with unaffected parents, suggesting an autosomal recessive mode of inheritance.

PAPA syndrome includes the clinical triad of PG, acne and pyogenic sterile arthritis. It is a rare autosomal dominant autoinflammatory syndrome, caused by mutations in the proline-serine-threonine-phosphatase protein 1 (*PSTPIP1*) gene (chromosome 15q24–25.1). PSTPIP1 has been shown to bind to pyrin, the protein mutated in familial Mediterranean fever linking both diseases to the same pathway. The mutations lead to a hyperphosphorylation of PSTPIP1, thus increasing its binding affinity to pyrin. As a result, pyrin loses its inhibitory effect on the signalling pathway that cleaves pro-interleukin (IL)-1ß into active IL-1ß. The overproduction of IL-1 beta in turn stimulates the release of proinflammatory cytokines and chemokines, leading to the recruitment and activation of neutrophils.

PASH syndrome (PG, acne, hidradenitis suppurativa) is similar to PAPA but lacks arthritis and does not share the same genetic basis (an increased number of CCTG microsatellite repeats in the *PSTPIP1* promoter region were reported in both patients of Braun-Falco et al). PAPASH syndrome with pyogenic arthritis, PG, acne and hidradenitis suppurativa in a 16-year-old patient was reported by Marzano et al.

Drug-induced PG has been reported with granulocyte colony-stimulating factor, interferon, gefitinib and propylthiouracil.

Clinical Presentation and Variants

The clinical manifestations of PG are outlined in Table 83.1. Four clinical variants of PG have been described: classic (ulcerative), pustular, bullous and vegetative (Fig. 83.1).

Ulcerative PG classically presents as a painful pustule or nodule that becomes a progressively enlarging, painful ulcer with erythematous to violaceous, raised, undermined, irregular borders. Lesions may be single or multiple, coalescing to multicentric, irregular ulcerations. PG most commonly affects the legs, but it may also affect any body area. Ulcers heal with atrophic pigmented scars. PG is accompanied by the phenomenon of pathergy in 20 % of patients, i.e. the development of new lesions or aggravation of existing ones following injury with a sharp object. Associated symptoms include fever, especially during the acute onset of PG, malaise, myalgias and arthralgias.

Table 83.1 Clinical manifestations of pyoderma gangrenosum

Cutaneous	
Ulcerative (classic form)	Very painful ulceration with undermined borders and purulent base
Pustular	Discrete painful pustules surrounded by an erythematous halo
Bullous	Painful bullae surrounded by an erythematous halo
Vegetative	Superficial ulceration without undermined borders or purulent base, slowly progressive
Peristomal	Ulcers in the peristomal area in patients with IBD
Mucosal	Oral, vulvar, penile or scrotal ulcers
Extracutaneous	
Pulmonary system	Pleural effusion, pulmonary cavitation and neutrophilic infiltration
Gastrointestinal	Splenic neutrophilic infiltrates
Cardiovascular	
Skeletal	
Neurological	

IBD inflammatory bowel disease

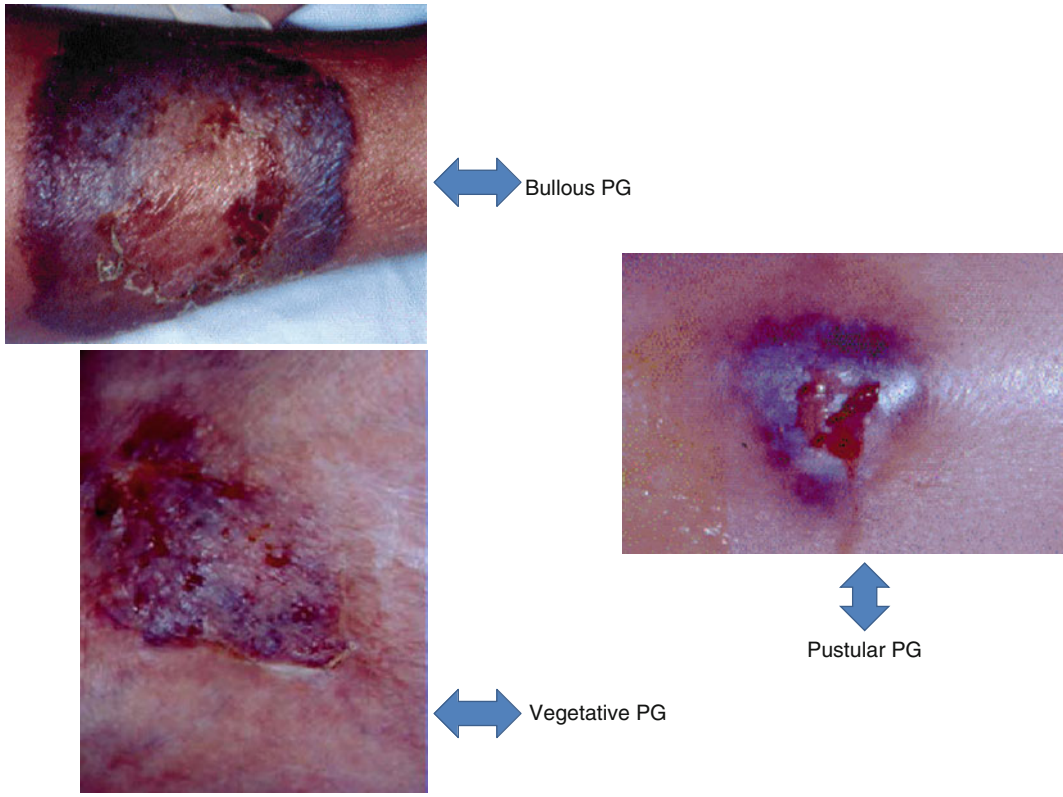

Fig. 83.1 Pustular, bullous and vegetative clinical variants of PG

The pustular variant is characterized by multiple painful pustules with inflammatory halo, fever and arthralgias.

In the bullous form, bullae with perilesional erythema evolve into painful shallow erosions and necrotic ulcers.

Vegetative PG (superficial granulomatous PG) presents with more superficial ulceration, without purulent base, undermined borders or surrounding erythema, which gradually transforms into an exophytic lesion. Unlike classical ulcerative PG, vegetative PG shows an indolent and slowly growing course.

Malignant pyoderma gangrenosum is considered a rare variety of PG with a predilection for the preauricular region, absence of undermined borders, poor responsiveness to treatment and increased risk for relapse.

Mucous membranes are usually spared, but the genital and oral mucosa may rarely be affected. Vulvar, penile or scrotal involvement may occur. Familial PG with oral (pyostomatitis vegetans) and cutaneous body lesions (recurrent, painful ulcers with undermined, violaceous margins and indurated base) has been described by Boussofara et al.

Extracutaneous neutrophilic infiltrates can rarely occur, reported in patients with PG, and any organ system may be affected, including the pulmonary, cardiovascular, skeletal, neurological and gastrointestinal system. The lung is the most frequently involved organ, manifesting by pleural effusion, pulmonary cavitation and infiltration and chronic sterile inflammation on biopsy.

PG is idiopathic in 40–50 % of patients; however, in the remaining cases, PG may be associated with underlying diseases including IBD, rheumatologic and haematological disorders or malignancy (Table 83.2). It represents the second most common cutaneous manifestation of IBD, and it has been reported in 5–20 % of ulcerative colitis (UC) and

Table 83.2 Underlying diseases reported with PG

IBD, gastric and duodenal ulcers
Arthritis: rheumatoid arthritis, osteoarthritis, ankylosing spondylitis
Monoclonal gammopathy, leukaemia, myeloproliferative syndrome
Internal malignancy

1–2 % of Crohn's disease (CD) patients. Marzano et al. report that PG usually appears after the onset of the UC and may correlate with an exacerbation of UC. In only a few cases, PG may appear before the onset of IBD symptoms. Paraneoplastic PG has been reported in association with underlying haematological or solid organ malignancies. In IBD, classic and pustular PGs are most frequently observed, while bullous PG is the most common variant in myeloproliferative diseases.

Diagnosis

The diagnosis of PG is mainly clinical after other conditions have been appropriately ruled out. A detailed medical history for weight loss or altered bowel function may reveal an underlying malignancy or inflammatory bowel disease.

The histopathological features of PG are nonspecific. Histology will rule out other suspected skin diseases. Skin biopsy reveals an ulcerated epidermis with a massive neutrophilic infiltration of the upper and lower dermis.

Laboratory and other investigations should exclude underlying inflammatory bowel disease, haematological malignancy, rheumatological disorder, immunodeficiency or ophthalmological problems (Table 83.3). High C-reactive protein is always present in PG.

Cultures for bacteria and fungi from skin lesions are negative unless there is a superinfection.

Differential Diagnosis

PG should be differentially diagnosed from other diseases presenting with ulcers, including:

- Adamantiades-Behçet's disease: diagnosis based on the new diagnostic International Criteria proposed by Davatchi et al. Apart from genital or oral aphthosis (ulcers), other manifestations should be present.
- Wegener's granulomatosis (WG): c-ANCA positive in 80–90 % of patients with active classic WG.
- Deep fungal infections: special stains for fungi are positive.
- Mycobacterial infections: tissue polymerase chain reaction, tuberculin skin test.
- Protozoal infections (ulcerative amebiasis cutis, acanthamoeba): histology, cultures.
- Syphilis: not painful (usually genital) ulcer, positive serology for syphilis.
- Cutaneous malignancies (squamous cell carcinoma, metastatic skin cancers, lymphomas): usually characterized by slow evolution, not painful, different histology.
- Ulcerative sarcoidosis: histology.
- Self-inflicted lesions (factitia).

Table 83.3 Laboratory investigations for PG

Full blood count, biochemistry
Serum protein electrophoresis
Complement levels
Antinuclear antibody
Antineutrophil cytoplasmic antibodies (ANCA): positive c-ANCA indicate Wegener's granulomatosis
Syphilis serology
HIV serology
Urinalysis
Chest X-ray
Computed tomography: to exclude an underlying malignancy
Bone marrow biopsy: in case of suspicion of a haematologic malignancy (plasma cell dyscrasia, leukaemia)
Colonoscopy: to exclude IBD
Skin biopsy, with Gram and PAS stains
Imaging: for splenic, pulmonary involvement of PG
Cultures from skin ulcers

General Principles of Treatment

As the incidence of PG is low and there are no prospective, randomized, controlled trials evaluating treatments, there are no established guidelines for treatment of PG.

Management of PG should encompass investigations to establish diagnosis, exclusion of an associated underlying disease and appropriate

treatment to reduce pain and promote healing with minimum side effects.

In mild cases and those not associated with systemic disease, topical treatment, prevention of trauma and supportive care may be sufficient for re-epithelialization. In case of a more widespread or rapidly progressive disease, systemic treatment is used. Despite the scarcity of randomized, controlled trials and the lack of a standardized treatment algorithm for PG, systemic corticosteroids and cyclosporine are often used for severe disease. Other treatments may be considered for patients with refractory PG or contraindications to prednisolone or cyclosporine.

When there is an underlying disease, treatment should aim to control this as well. The successful treatment of the associated disease can result in improvement or complete remission of PG.

Relapses are common and may occur in up to 70 % of PG patients.

Topical Therapy: Corticosteroids and Calcineurin Inhibitors

For mild PG, local measures such as dressings, limb elevation, rest, topical corticosteroids or intralesional corticosteroid injections can be sufficient to control the disease process.

An evidence-based review of the literature on treatments for PG in more than 350 patients, by Reichrath et al. in 2005, reported that topical treatment with potent corticosteroids or topical tacrolimus, pimecrolimus or intralesional injections with corticosteroids, as first-line therapy, may be sufficient for selected cases of localized PG, especially for patients with contraindication to oral corticosteroid or cyclosporine therapy, with no underlying systemic disease, or for superficial PG (Fig. 83.2).

General Principles of Treatment

Systemic Therapy

In their evidence-based review, Reichrath et al. suggested that for patients with widespread PG, systemic treatment is in general required. Systemic corticosteroids or cyclosporine, alone or in combination, were recommended as first-line therapy (grade of recommendation B). Response with these agents is usually rapid, while maintenance therapy may be needed. For steroid-refractory PG, immunomodulators and biological response modifiers may be promising. Treatment with mycophenolate mofetil, azathioprine (AZT), methotrexate, infliximab, plasmapheresis, intravenous immunoglobulin therapy, thalidomide, dapsone or interferon alfa received a C grade of recommendation for PG. Systemic antibiotics including tetracyclines (minocycline) have been used in isolated cases (Fig. 83.2).

Glucocorticoids

Corticosteroids, like prednisolone 1–2 mg per kg per day, are widely used for initial therapy, and they are tapered with clinical improvement. However, long-term (more than 4 months) oral glucocorticoid therapy is associated with various side effects, and such patients should be closely monitored and appropriately managed for osteoporosis, arterial hypertension, diabetes, electrolyte imbalance and glaucoma.

Cyclosporine

Cyclosporine A at a daily dose of 2–5 mg/kg may be used for widespread PG after initial steroids or in combination with steroids in resistant cases. Side effects with cyclosporine treatment include arterial hypertension, renal insufficiency, electrolyte imbalance, hirsutism and gingival hyperplasia.

Other Systemic Therapies

Dapsone (1.5–2 mg/kg/day), azathioprine (1.5–2 mg/kg/day), cyclophosphamide (1–1.5 mg/kg/day), methotrexate (15–25 mg/week), intravenous immunoglobulins (400 mg/kg/day for five consecutive days), mycophenolate mofetil and plasmapheresis are considered second-line agents.

Biologic Agents

Biologic agents that have been used off-label for the treatment of PG include anti-tumour necrosis

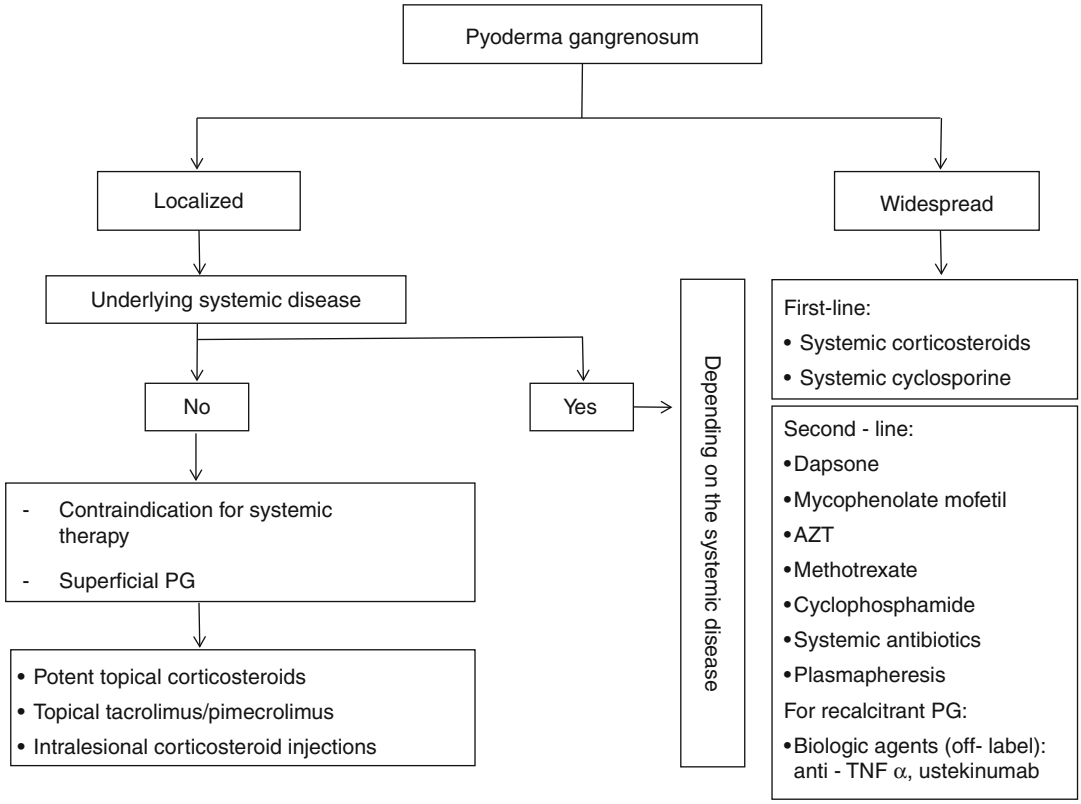

Fig. 83.2 Proposed treatment algorithm for PG (Based on the recommendations by Reichrath et al. 2005)

factor (TNF)-α agents and the interleukin 12/23 inhibitor ustekinumab. Most publications are case reports of anti-TNF therapy of PG in the context of underlying IBD. There is only one randomized, double-blind, placebo-controlled trial investigating the efficacy of anti-TNFα agents in the management of PG. Brooklyn et al. randomized 30 patients with PG (idiopathic or associated with IBD) to receive one infusion of either infliximab 5 mg/kg or placebo at week 0, and nonresponders were offered infliximab at week 2. At week 2, significantly more patients treated with infliximab had improved compared to placebo ($p = 0.025$). Final evaluations at week 6 reported that 29 patients received infliximab with 69 % (20/29) demonstrating a beneficial clinical response.

There have been isolated case reports of the successful use of ustekinumab for severe PG, recalcitrant to previous treatments.

It should be pointed out that, due to the lack of adequate well-designed studies demonstrating their efficacy for PG, biologic agents are not currently approved for the treatment of PG by the FDA or European Medicines Agency (EMA) and thus their high cost is not covered by medical insurances for this condition.

Mycophenolate Mofetil

Li et al. investigated mycophenolate mofetil (MMF) 1–3 g/day as a steroid-sparing agent in a retrospective study in 26 patients with PG. The

average duration of therapy was 12.1 months. All patients received concomitant oral prednisolone (range: 15–80 mg/day), while the majority of patients also received additional immunomodulatory medications. Clinical improvement was reported in 22 patients (84.6 %). Adverse events were reported in 14 patients (53.8 %), including one death after sigmoid colon perforation.

Surgical Intervention

Surgical intervention is not usually carried out in order to avoid pathergy. However, surgical debridement and grafting may be considered in some patients, especially when there is a large amount of necrotic eschar, after the disease is controlled and in conjunction with systemic PG therapy.

Rosacea

84

Síona Ní Raghallaigh and Frank C. Powell

Key Points

- Rosacea is a common inflammatory facial dermatosis, more prevalent in lighter skin phototypes.
- Its pathophysiology remains incompletely understood, but the process involves an abnormal cutaneous innate immunity, neurovascular dysregulation, altered vasculature and epidermal barrier dysfunction.
- The standard classification into four clinical subtypes provides a useful guide to medical treatment.
- While effective medical therapies have been limited in erythematotelangiectatic rosacea (ETTR) to date, newer treatment options such as the α-adrenoreceptor agonist brimonidine tartrate gel help to reduce the transient and persistent erythema experienced by these patients.
- Antibiotics (topical and systemic) are important in the management of papulopustular rosacea (PPR). In recent times, low-dose doxycycline in particular has been shown to be effective in the treatment of this subtype of rosacea.
- Skin care management, patient education and psychological support are important in optimising control of this disease.

Definition and Epidemiology

Rosacea is a chronic inflammatory dermatosis affecting mainly the centrofacial region. Signs and symptoms range from transient and persistent facial erythema, telangiectasia, inflammatory papules and pustules, sebaceous gland hypertrophy and ocular changes, according to the subtype of rosacea involved. Many patients report increased facial skin sensitivity and dryness and can often identify particular exacerbants which may worsen their disease. The progression of rosacea is variable and at times unpredictable, with sporadic periods of exacerbation and remission. For some patients, the psychosocial impact of this disorder can be marked (Figs. 84.1, 84.2 and 84.3).

Fig. 84.1 Erythematotelangiectatic rosacea. Telangiectatic vessels on the nose with surrounding erythema

Fig. 84.2 Papulopustular rosacea. Inflammatory papules and pustules affecting the cheek with surrounding erythema. Note the coexistent rhinophyma as evidenced by tortuous, dilated vessels on the nose as well as large, patulous follicular ostia

Fig. 84.3 Ocular rosacea. Erythema, telangiectasia and oedema of the upper eyelid, with milder features evident on the lower lid. This patient also has features of papulopustular rosacea affecting the cheek

Epidemiology

Rosacea is a common disorder. Exact prevalence rates vary between studies, probably due to discrepancies in disease definition and study populations. Prevalence rates in Caucasian populations range from 0.09 to 22 %. Although ETTR is often clinically indistinguishable from heliodermatitis, general population studies indicate that subtype 1 is more prevalent than subtype 2. A study of 1,000 Irish indoor and outdoor workers reported a prevalence rate of 2.7 % for subtype 2 (McAleer et al. 2008). The fair-skinned are most susceptible, although the disease can occur in darker phototypes. Gender distribution has been shown as equal or with a female preponderance. Men are more likely to develop phymatous changes. Patients usually present between 30 and 50 years of age, and it is estimated that approximately 57 % of cases are diagnosed before 50 years of age.

Classification and Clinical Presentation

Rosacea has been classified into four main subtypes based on predominant lesion morphology (Wilkin et al. 2004) (Table 84.1).

Variants of rosacea include rosacea fulminans (very sudden onset of inflammatory lesions; may have associated fever), rosacea conglobata (inflammatory cysts and scarring) and granulomatous

Table 84.1 Rosacea subtypes – clinical features

Subtype	Clinical features
Erythematotel-angiectatic (ETTR) (Subtype 1)	Flushing
	Persistent erythema
	Telangiectasia
	Skin sensitivity – burning and stinging
Papulopustular (PPR) (Subtype 2)	Persistent erythema
	Papules and papulopustules (unlike acne, heal without scarring)
	Centrofacial distribution but can occur on the scalp, behind the ears, neck and upper chest
	Flushing and skin sensitivity (may be present but tend not to be as severe as in subtype 1)
Phymatous (Subtype 3)	Thickened, nodular skin
	Patulous follicles (early disease)
	Bulbous, distorted features (advanced disease)
	Most commonly affects nose
	Can also affect chin, forehead, ears, eyelids
	May be associated with other features of rosacea or occur in isolation
Ocular (Subtype 4)	Usually bilateral
	Dry, gritty sensation
	Blepharitis
	Meibomian gland dysfunction
	Eyelid telangiectasia and oedema
	Collarettes around eyelashes
	Chalazia and hordeola
	Conjunctivitis
	Keratitis, episcleritis, scleritis, iritis (rare)

rosacea (persistent red-brown to skin-coloured papules; non-caseating granulomatous histology).

Histology

The histopathological findings of rosacea are not diagnostic and biopsy is not usually recommended. Histology may show perifollicular inflammation, perivascular infiltrates, matrix degeneration, actinic elastosis and dilated hyperaemic vessels. The perifollicular infiltrate has been shown to consist mainly of T-lymphocytes and can occasionally assume a granulomatous pattern. Histological features of rhinophyma include sebaceous hyperplasia, dilated infundibula with occasional cysts, suppuration, granulomatous inflammation and focal fibroplasias.

Basic Concepts of Pathogenesis

The pathogenesis of rosacea is complex, multifactorial and likely subtype specific. Numerous pathogenic pathways have been shown to be involved in rosacea, many of which overlap. These include the following.

Dysregulated Innate Immunity

Innate immunity leads to a controlled release of cytokines and antimicrobial molecules such as the peptide cathelicidin (LL-37). In rosacea, there is upregulation of cathelicidin and its processing serine protease (kallikrein 5). Cathelicidin peptides and their enzymes have proinflammatory and angiogenic activity. Toll-like receptors (TLRs) are pathogen-associated molecular pattern sensors that are involved in the innate immunity of the skin. In the lesional skin of patients with rosacea, keratinocytes express elevated levels of TLR2, leading to increased expression and activity of kallikrein proteases. Dysfunction of the innate immune system may be related to other associated features of rosacea such as the skin's response to ultraviolet radiation.

Epidermal Barrier Dysfunction

Dryness, stinging and burning are common features of rosacea. Abnormal skin barrier homeostasis has been demonstrated in rosacea patients, as evidenced by increased transepidermal water loss (TEWL) and increased sensitivity to a skin irritation test. Patients with PPR have a more alkaline centrofacial region and reduced epidermal hydration levels as compared with controls. In addition, these patients have reduced levels of sebaceous long-chain saturated fatty acids, which are known to contribute to the barrier function of the stratum corneum.

Neurogenic Inflammation

Neuromediators, released by sensory nerve endings and other cells such as keratinocytes, activated endothelial cells and fibroblasts, induce neurogenic inflammation, resulting in vasodilatation, oedema and inflammation. Recent research in rosacea has focused on transient receptor potential channels (TRPs) and in particular TRP vanilloid receptor 1 (TRPV1), also known as the capsaicin receptor, and TRP ankyrin receptor 1 (TRPA1). These can be activated by common exacerbants of rosacea such as heat, ethanol or spicy food (TRPV1) or cold, formalin or other chemicals (TRPA1). Activation of TRPV1 and TRPA1 results in the release of substance P and calcitonin gene-related peptide, important mediators of neurogenic inflammation and pain.

Ultraviolet Radiation

While UVR can often trigger rosacea, a definite causal relationship has not been described. An epidemiological study of 1,000 Irish individuals found no association between sun exposure and PPR prevalence but did find an association with ETTR. UVR exposure has been shown to induce angiogenesis, increase the secretion of the angiogenic factors such as VEGF from keratinocytes and produce proinflammatory reactive oxygen species.

Vascular Alterations

Increased blood flow in skin lesions of rosacea has been demonstrated. Rosacea patients flush more readily in response to heat as compared with controls, and their heat pain thresholds have been demonstrated to be lower. In addition, there is elevated expression of vascular endothelial growth factor (VEGF), CD31 and lymphatic endothelium marker D2–40, suggesting the presence of an increased stimulant for vascular and lymphatic cells in rosacea.

Demodex Mites (*D. folliculorum* and *D. brevis*)

Demodex mites are commensals of normal skin but are found in greater numbers in rosacea patients, and infestation has been shown to be associated with an intense perifollicular infiltrate of predominantly CD4 helper T cells. Antigenic proteins related to a bacterium (*Bacillus oleronius*) isolated from a *Demodex* mite have been shown to stimulate an inflammatory response in patients with PPR. *Demodex* mites and their associated bacteria may induce an upregulation in surrounding cutaneous proteases, thereby potentiating the dysregulation of the local innate immune response. It has been proposed that chitin, released from these mites, could serve as the trigger for TLR2 on keratinocytes and link *Demodex* with increased protease activity and cathelicidin-induced inflammation in rosacea.

Differential Diagnosis

The differential diagnosis of the various subtypes is outlined in Table 84.2.

Table 84.2 Rosacea subtypes – differential diagnosis

Rosacea subtype	Differential diagnosis
Erythematotelangiectatic	Heliodermatitis
	Flushing due to systemic causes such as menopause, carcinoid syndrome and phaeochromocytoma
Papulopustular rosacea	Acne
	Perioral dermatitis
	Pityriasis folliculorum
	Rosaceiform dermatitis due to topical calcineurin inhibitors
	Rosaceiform eruption due to EGFR inhibitors
	Steroid-induced rosacea
Phymatous	Morbihan's disease
	Lupus pernio (sarcoid of the nose)
	Lymphoma/angiosarcoma (rare)
Ocular	Chronic blepharitis
	Chronic dry eye syndrome (numerous causes)

General Principles of Treatment

The management of patients with rosacea should involve the following three aspects of care: (a) skin care management, (b) medical therapies and (c) patient education.

Skin Care Management

General principles of skin care useful in the management of rosacea are outlined in Table 84.3.

Medical Treatment

Medical Treatment of ETTR

The treatment of subtype 1 rosacea is often unsatisfactory for both patient and clinician. Of particular importance in these patients is a skin care regime aimed at reducing skin sensitivity and improving epidermal barrier function. In addition, strict photoprotection is advised, as UV exposure may potentiate dermal matrix and vascular damage.

Topical antibiotics such as metronidazole or other agents such as *azelaic acid* may reduce erythema in some patients with ETTR. Azelaic acid is a naturally occurring, straight-chain dicarboxylic acid with anti-inflammatory properties. However, the use of such topical agents in this subtype is often limited by their irritant effects.

Topical *α-adrenoreceptor agonists*, which produce vasoconstriction, have shown early promising results in the treatment of the transient and non-transient erythema of rosacea. Brimonidine tartrate is a highly selective α_2-adrenoreceptor agonist used in ophthalmic solution for the treatment of open-angle glaucoma. Topical brimonidine tartrate gel has been shown in controlled, prospective, randomised clinical trials to reduce the facial erythema of rosacea after single and repeated once-daily applications, with an optimal concentration of 0.5 % gel formulation. No major adverse events were noted in this trial, and tolerability was good. Case reports of other α-adrenoreceptor agonists (oxymetazoline 0.05 % solution and xylometazoline 0.05 % solution; applied to the skin in their nasal decongestant formulations) showed a reduction of facial erythema over several hours in patients with ETTR.

Nonselective *β-blockers* decrease sympathetic activity and have been reported to reduce flushing. By antagonising β-adrenergic receptors on smooth muscles of cutaneous blood vessels, β-blockers produce vasoconstriction. In addition, their anxiolytic effects may reduce the social anxiety that may lead to blushing in some of these patients. There are only a few reports of β-blocker therapy in patients with rosacea, and patient numbers in these reports are small. However, both propranolol (30–120 mg/day) and carvedilol (titrated from 3.25 mg three times a day to 25 mg/day) have been shown to reduce flushing episodes in these patients.

Laser techniques such as pulsed dye laser, intense pulsed light and potassium titanyl phosphate laser may be useful for the treatment of telangiectasia and erythema.

Table 84.3 Skin care management

Use sunscreens with both UVA and UVB protection, and a sun protection factor of 15 or greater. Sun-blocking creams containing the physical barriers titanium dioxide or zinc oxide are usually well tolerated
Use soap-free, pH-balanced synthetic detergents (syndets) and lukewarm water to wash the face
Use cosmetics and sunscreens that contain protective silicones
Water-soluble make-up containing inert green pigment helps neutralise the perception of erythema. Camouflage make-up may also be useful
Moisturisers containing humectants (e.g. glycerin) and occlusives (e.g. petrolatum) may assist in restoring impaired epidermal barrier function
Avoid astringents, toners and abrasive exfoliators and procedures such as dermabrasion
Avoid waterproof cosmetics and heavy foundations that are difficult to remove without irritating solvents or physical scrubbing
Avoid cosmetics that contain alcohol, menthols, camphor, witch hazel, fragrance, peppermint and eucalyptus oil
Avoid environments which may overheat and/or dry the skin such as saunas, heater fans in cars and open fireplaces

Medical Treatment of PPR

Topical and/or systemic antibiotics play an important role in this subtype.

Topical agents can be used as initial therapy in grade 1–2 disease or as maintenance therapy following clearance with systemic antibiotics. A recent Cochrane review confirmed the effectiveness of topical azelaic acid and metronidazole for the treatment of PPR. In comparative studies, azelaic acid 15 % gel was more effective than metronidazole 0.75 % gel in reducing erythema and inflammatory lesions but produced more adverse effects such as stinging and burning. Sodium sulphacetamide 10 % and sulphur 5 % have been shown to be more effective than placebo in reducing erythema and inflammatory lesions. Other topical treatment options for the management of PPR are listed in Table 84.4.

For more severe cases of PPR, *oral antibiotics* should be considered. Specifically, the anti-inflammatory role played by tetracyclines in the management of rosacea is well recognised. Oral tetracyclines have been used in the treatment of rosacea since the 1950s. Data pooled from three studies of oral tetracycline versus placebo involving 152 participants showed that, according to physicians, tetracycline was effective in treating rosacea (OR 6.06, 95 % CI 2.96–12.42). Tetracyclines have many mechanisms of action which may contribute to their effectiveness in their treatment of rosacea. They have been shown to inhibit matrix metalloproteinases (MMPs); downregulate the inflammatory cytokines TNF-α, IL-1β, IL-8 and IL-10; and inhibit cell movement and proliferation, in particular neutrophil migration

Table 84.4 Topical treatments for PPR

FDA approved	Non-FDA-approved topical treatments	Alternatives not commonly used clinically
Metronidazole	Erythromycin b.i.d.	Permethrin
(0.75 % gel or cream; 1 % cream) q.d. or b.i.d.	(2 % solution)	(5 % cream q.d–q.w.)
	May be a useful treatment in pregnant patients where other treatments are contraindicated	Topical antiparasitic agents aimed at reducing the *Demodex* mite population on the skin. Shown to be as effective as metronidazole for the treatment of papules and erythema. May have future role in combination with antibiotics – further studies needed (Kocak et al. 2002)
Azelaic acid	Clindamycin q.d.	Crotamiton 10 % cream/lotion b.i.d.
(15 % gel) b.i.d.	(1 % lotion)	Shown in a retrospective study to be useful in patients with rosacea-like *Demodex* dermatitis. May be irritating (Bikowski and Del Rosso 2009)
Sodium sulphacetamide (10 %) and sulphur (5 %) in cream or lotion q.d. or b.i.d. May include urea	Benzoyl peroxide 5 % and clindamycin 1 % q.d.	Oxymetazoline
		Positive clinical response shown in case reports of ETTR patients using this α-agonist
	Azelaic acid	Pimecrolimus
	(20 % cream b.i.d.)	(1 % cream b.i.d.)
		Although some studies show improvement in erythema with these immunomodulatory agents, there have been case reports of exacerbations, so caution is advised until further studies are performed (Karabulut et al. 2008)
	Tretinoin	
	(0.025 % cream; 0.01 % gel q.d.)	

Table 84.5 Systemic antibiotics for papulopustular rosacea

Doxycycline (only FDA-approved antibiotic treatment for rosacea)	40 mg once daily (30 mg immediate release and 10 mg delayed release)
Doxycycline	50–100 mg once or twice daily
Minocycline	50–100 mg twice daily or sustained action formula once daily
Oxytetracycline	250–500 mg twice daily
Erythromycin	250–500 mg once or twice daily
Metronidazole	200 mg once or twice daily (for 4–6 weeks)

(Golub et al. 1984; Cazalis et al. 2008; Gabler and Creamer 1991). They have also been shown to inhibit granuloma formation, reactive oxygen species and angiogenesis.

In 2006, a once-daily controlled-release formulation of doxycycline monohydrate (40 mg) became the first FDA-approved oral antibiotic treatment for rosacea. Clinical studies have shown this sub-antimicrobial dose of doxycycline to be as effective as the 100 mg dose but with less adverse effects and less bacterial resistance.

Alternative antibiotic treatments include metronidazole or a macrolide (Table 84.5). Antibiotic courses are generally given for 6–12 weeks, and repeated courses may be necessary for future exacerbations.

Isotretinoin has been shown to reduce erythema and papulopustules in treatment-resistant patients, as well as reducing nasal volume and halting the progression of rhinophyma. One study showed that low-dose isotretinoin (10 mg once daily for 4 months) reduced inflammatory lesions, erythema and telangiectasia after 9 weeks. Although further studies are needed, low-dose isotretinoin may be a viable useful alternative, particularly in men and women past child-bearing years.

Medical Treatment of Phymatous Rosacea

Surgical excision, electrosurgery or CO_2 laser can be used to debulk and resculpt the nose. The possibility of recurrence should be explained to the patient. Isotretinoin may help to slow the progression of rhinophyma.

Medical Treatment of Ocular Rosacea

Eyelid hygiene, artificial tears, fusidic acid, metronidazole gel and cyclosporin 0.5 % ophthalmic emulsion are useful treatments for this subtype of rosacea. Systemic antibiotics may be required for the treatment of more severe or persistent disease, and these patients should be referred to an ophthalmologist.

Patient Education

While the chronicity of disease and the likelihood of exacerbations should be explained to the patient, reassurance of the benign nature of rosacea is also important. Advice should be given on the avoidance of triggers as well as the importance of photoprotection. Direct patients to information websites such as those of the National Rosacea Society (www.rosacea.org) or the American Academy of Dermatology (www.aad.org). Finally, acknowledging the psychosocial impact of this disorder may help to guide patients in need of psychological support towards the appropriate services such as counselling or cognitive behavioural therapy.

Sarcoidosis

85

Sven R. Quist

Key Points

- A multisystemic granulomatous disease of unknown cause that most commonly involves the lungs but also the skin (around one-third of cases).
- Cutaneous manifestations could appear as the first sign of sarcoidosis and present as red-brown or violaceous plaques or papules on the head, face, neck, back and extremities.
- Variants include lupus pernio, angiolupoid, ichthyosiform, subcutaneous and ulcerative sarcoidosis, and scars can also be affected.
- Erythema nodosum is a non-specific inflammatory skin finding associated with subacute, transient sarcoidosis.
- Noncaseating epithelioid granulomas without surrounding lymphocytic inflammation characterise histology.
- A complex interaction between genetic factors, antigens and immune response is believed to affect the host susceptibility to sarcoidosis.

Definition and Epidemiology

Sarcoidosis was first described by Sir Jonathan Hutchinson in 1875 and later in the skin as lupus pernio by Besnier in 1889 and as "multiple benign sarkoid of the skin" by Boeck in 1899. Sarcoidosis is a systemic granulomatous disorder of unknown cause. By Even the lung is most commonly affected, lymph nodes, lungs, liver, spleen, bones and eyes and especially the skin can be involved. Skin lesions could frequently appear as the first sign of disease (in up to 35 %) emphasising the important role of the dermatologist for the diagnosis and further investigations. Typically noncaseating epithelioid granulomas without surrounding lymphocytic infiltration can be found within affected organs histologically.

Basic Concepts of Pathogenesis

The current knowledge is that the development of sarcoidosis requires an interplay between infectious and environmental causes and individual genetic factors (HLA phenotype, ACE gene polymorphism) that trigger the disease and affects the cell-mediated immunity. The following events are involved: (a) exposure to an antigen; (b) acquired cellular immunity directed against this antigen and mediated through antigen-presenting dendritic cells or macrophages that recognise, process and present the antigen to a T-lymphocyte receptor via HLA

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_85, © Springer-Verlag Berlin Heidelberg 2015

class II molecules; and (c) antigen-specific T lymphocytes together with immune effector cells finally lead to formation of noncaseating granulomas. Effector cells include $CD4^+$ T-helper 1 cells that promote a non-specific inflammatory response including cytokines interleukin 1, interleukin 2 and interferon gamma. Activated macrophages produce interleukin 10, interleukin 12 and tumour necrosis factor alpha. In this microenvironment various T-cell clones including the gamma-delta subtype are expanded, and monocytes initiate the formation of epithelioid granulomas. Genetic factors are related to the different HLA phenotypes (HLA-1, HLA-B8, HLA-DR3, HLA-DRB1, HLA-DQB1) that determine the severity of sarcoidosis since it has a crucial role in antigen presentation, following cytokine production and granuloma formation. In case the disease is chronic, it progresses to fibrosis in up to 30 % of cases with severe and irreversible tissue damage, whereas granulomas are still reversible.

The potential antigen is still unknown and may also depend on the individual immune constitution, but antibodies to *Mycobacterium tuberculosis* have been detected in serum of affected patients; even cultures are negative in most cases. Other antigens that have been associated with sarcoidosis include *Mycobacterium marinum*, *Propionibacterium* acnes, Epstein Barr, herpes (simplex, zoster or HHV6) and HIV virus infection and non-infectious agents such as mouldy wood or mineral dust from titanium, iron or silica, skin tattoo pigmentation, aluminium and zirconium in cosmetic preparations or dermal fillers for cosmetic use.

Clinical Presentation

In general, this disease has a great variation of manifestations that can involve the skin or other organs that might be affected at different time points during the course of this low predictable disease.

Cutaneous sarcoidosis can be with (specific) or without (non-specific) granulomas. Variants include the following forms:

- Papular or plaque types, often larger lesions, red to brown (some variation in colour exists: diascopy is helpful showing an apple-jelly colour), mostly a sign of a chronic disease (Figs. 85.1a, 85.2a and 85.2e)
- Nodular: annular or angiolupoid (most frequently at the nose), lupus pernio (indurated violaceous mostly on the nose, ears, lips and cheeks), also appearing subcutaneously (Darier-Roussy disease) (Fig. 85.2b–d)
- Erythematous (erythema nodosum), maculopapular
- Scar sarcoidosis (appearing also in tattoos), may indicate systemic involvement
- Miscellaneous: hypopigmented, ulcerative, psoriasiform, ichthyosiform, mucosal, ungual, verrucous, discoid, erythrodermic, necrotising, morphoea-like, with cicatricial alopecia

Non-cutaneous sarcoidosis mostly affects the intrathoracic area but can also affect other different organs:

- Pulmonary involvement: 90 % of cases, bilateral hilar or paratracheal lymphadenopathy without (stage 1 according to X-ray classification) and with infiltration (stage 2), pulmonary infiltration (stage 3) or fibrosis (stage 4), alveolitis and infiltration of bronchioles, blood vessels, pleura and septa leading to air flow dysfunction (FEV, FVC reduction) (Fig. 85.3a, b).
- Ocular involvement: granulomatous uveitis (Heerfordt syndrome: uveoparotid); involvement of iris and lacrimal gland (together with parotid swelling: von Mikulicz syndrome), retina, choroid and sclera; optic nerve neuropathy; danger of vision loss; and development of glaucoma (Fig. 85.3c).
- Liver and spleen involvement: liver involvement mostly silent; cholestasis or portal hypertension can occur; elevation of liver enzymes; very rarely this can lead to liver cirrhosis; fever, night sweat and weight loss are unspecific signs but may indicate liver sarcoidosis.
- Renal involvement can lead to calcium dysregulation of overproduction of vitamin D and hypercalcaemia or hypercalciuria.
- Neurologic involvement: facial nerve or peripheral neuropathy, parenchymal brain

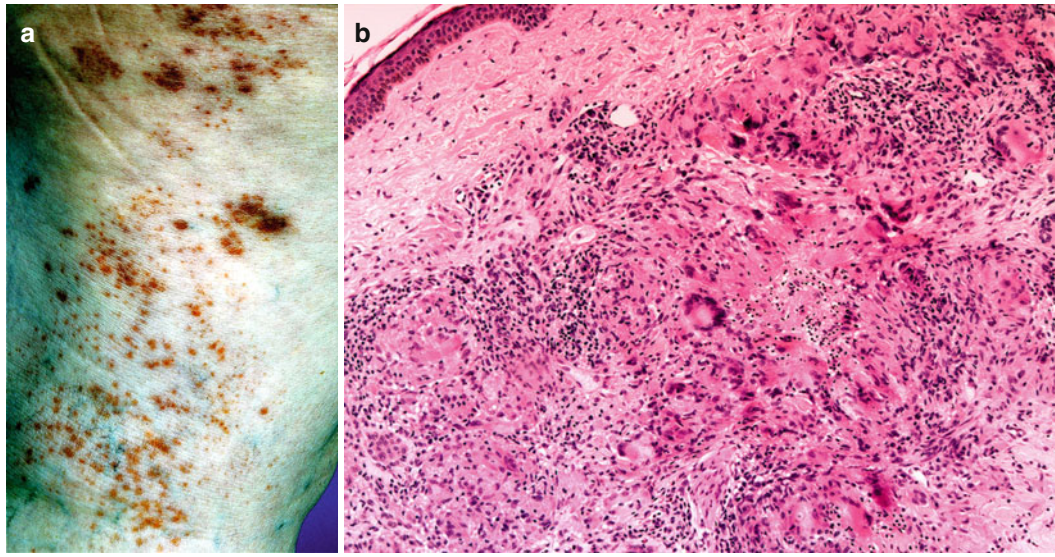

Fig. 85.1 (**a**) Papular cutaneous sarcoidosis after infection with herpes zoster, manifestation in the same dermatome. (**b**) Histopathology of cutaneous sarcoidosis with the presence of noncaseating epithelioid cell granulomas, giant cells and infiltration of lymphocytes

lesions, myopathy, spinal lesions, seizures, stroke, vision loss (Uhthoff phenomenon).

- Cardiac involvement: left ventricular wall or septum frequently affected; often asymptomatic and remains undetected; cardiomyopathy, arrhythmia, palpitations, atrioventricular block, tachycardia, pericardial effusions and heart failure depending on the area involved can occur.
- Bone and joint involvement: chronic mono- or polyarthritis, cystic lesions in bones mostly asymptomatic detectable via MRI or PET (Jüngling ostitis multiplex cystoides).

In general, the occurrence of cutaneous lesions and systemic involvement is considered the most unfavourable condition.

Histopathology

Histology of sarcoidosis is almost identical in affected tissues. This includes the presence of noncaseating epithelioid cell granulomas and infiltration of lymphocytes or plasma cells. Giant cells may be visible, sometimes with inclusions such as asteroid bodies or Schaumann bodies. Granulomas are present in the dermis or subcutis and can occur periadnexal or perineural, and necrosis is detected rarely. More frequently mucin can be found as well as fibrosis in subcutaneous lesions. Whereas CD8+ lymphocytes can be detected in the perigranulomatous area, CD4+ lymphocytes can be detected in the granuloma (Fig. 85.1b).

Systemic Diseases Associated with Sarcoidosis

Several systemic diseases have been reported to be associated with sarcoidosis propagating a common autoimmune pathogenesis which, however, might be to some extent coincidental: dermatomyositis, pyoderma gangrenosum, progressive systemic sclerosis, systemic lupus erythematosus, vitiligo, Wegener's granulomatosis, Sjögren's syndrome, diabetes mellitus, ulcerative colitis, biliary cirrhosis, autoimmune thyroiditis, polycythaemia vera, pernicious anaemia, cutaneous lymphoma and B-cell lymphatic leukaemia.

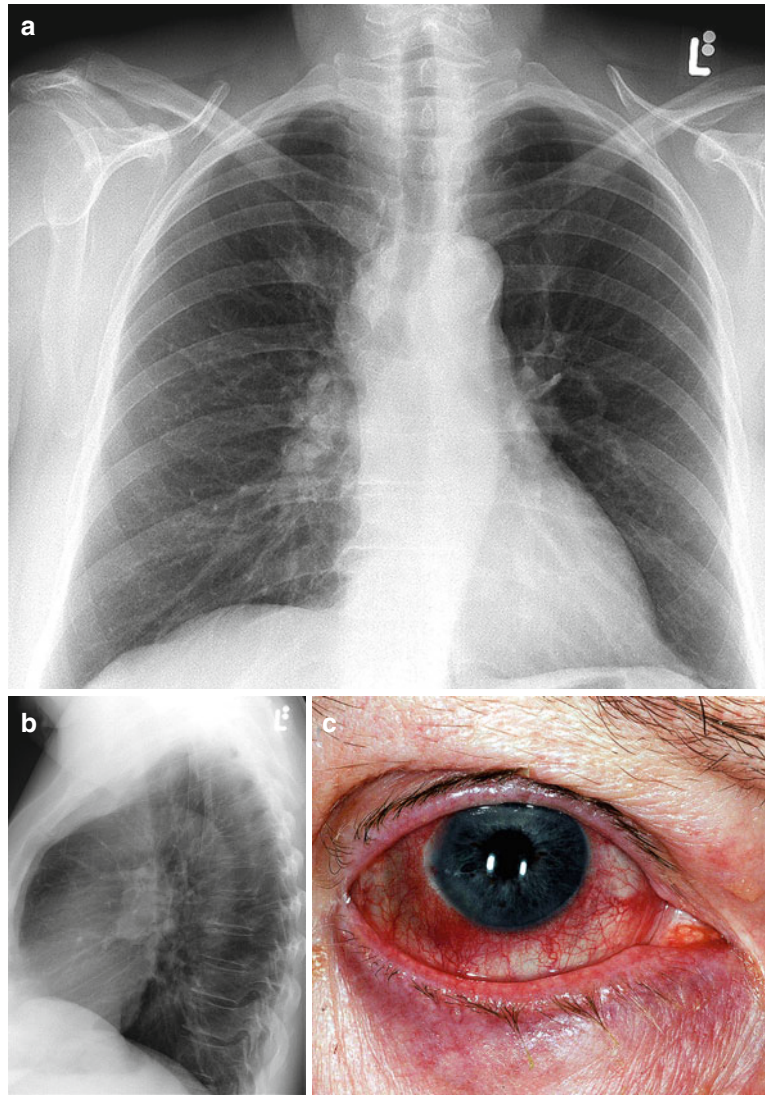

Fig. 85.3 (**a**, **b**) Pulmonary sarcoidosis with bilateral hilar involvement (stage 1). (**c**) Ocular sarcoidosis with Heerfordt syndrome and prominent uveitis

Differential Diagnosis

Similar to syphilis, cutaneous sarcoidosis can mimic other skin diseases stressing the importance of anamnestic, clinical, radiographic, laboratory and histopathological criteria to come to the correct diagnosis:

- Erythema annulare centrifugum, erythema marginatum and urticaria can present annular lesions.
- Tuberculosis, cutaneous lymphomas, histiocytosis, psoriasis vulgaris, discoid lupus erythematosus, prurigo, Sweet syndrome and Well's disease can present papules or plaques.
- Hypertrophic scars or keloids must be differentiated from lupus pernio.
- Onychomycosis, psoriasis vulgaris and lichen planus must be considered for dystrophic nail involvement.
- Vitiligo can present hypopigmented skin lesions.

General Principles of Treatment

Treatment should be cautious since sarcoidosis often spontaneously remits or remains stable, and several treatment options are associated with significant side effects. Furthermore several drugs used are not approved for this disease, so weighing up risks and benefits for each kind of treatment is strongly recommended. Especially cutaneous sarcoidosis is frequently asymptomatic, but in case of organ involvement, especially pulmonary, neural, liver, renal, ocular or cardiac involvement, and when symptoms such as persistent fever, weight loss or hypercalcaemia occur, systemic treatment should be considered.

The main problem is that there are almost no well-controlled and randomised clinical trials that show a clear benefit for a certain treatment in cutaneous sarcoidosis. Most recommendations are generally based on a small number of cases or single case reports which have to be considered. Treatment recommendations will be given based on the best treatment options to cutaneous sarcoidosis.

Topical Treatment

Topical treatment for cutaneous sarcoidosis is recommended if patients have symptoms and feel cosmetically compromised.

Corticosteroids

Treatment with potent topical corticosteroids or repeated (two to three times/week) intralesional injection with triamcinolone acetonide suspension (up to 10 mg/ml, 2) is useful for isolated and thinner cutaneous sarcoidosis lesions. In case lesions do not respond to topical treatment, a switch to oral corticosteroid treatment (prednisolone starting dose 20–40 mg/day) is recommended. Corticosteroids suppress the immune infiltration, the cytokine disbalance and the fibrosis.

Other Options

Cryotherapy, radiotherapy, PUVA treatment, photodynamic therapy and calcineurin inhibitors such as topical tacrolimus have been reported to be beneficial in the treatment of cutaneous sarcoidosis.

Topical Treatments at a Glance

- Topical treatment mainly consists of potent topical corticosteroids.
- Intralesional injection with triamcinolone acetonide suspension can be used for isolated lesions.
- Topical tacrolimus as well as PUVA treatment and cryotherapy might be an additional option for isolated lesions.
- Lesions resistant to topical treatment should be treated systemically starting with corticosteroids.
- Additional cosmetic camouflage might be a helpful advice for patients with cutaneous lesions on the face.

Systemic Treatment

Systemic treatment is recommended when organ involvement and/or symptoms are present. Systemic treatment options range from corticosteroids to several other immunosuppressants that have severe side effects.

Corticosteroids

Systemic corticosteroids should be initiated between 0.5 and 1 mg/kg per day and tapered to 5–10 mg per day when response to treatment is observed. Re-evaluation of treatment should be done after 4–6 weeks and long-term treatment with lower doses for months to years. Short-term treatment is likely to relapse and not recommended. Lack of response within 3 months indicates irreversible changes such as fibrosis or nonresponsiveness to corticosteroids.

Systemic corticosteroids such as prednisone represent the standard treatment in case of rapid progressive skin involvement and/or in case of organ involvement such as the lungs and lymph nodes. They should be initiated between 0.5 and 1 mg/kg per day and tapered to 5–10 mg per day when response to treatment is observed.

A dose of 0.5–1 mg/kg body weight prednisone (or equivalent) for the first month is followed by a slow reduction over the next months, which is recommended. Treatment is likely to continue for years (Baughman et al. 2006a, b), especially in case of lupus pernio. Short-term treatment is likely to relapse and is not recommended. Side effects of corticosteroids include infections, diabetes, hypertension, gastric ulcer and osteoporosis.

Therefore, cortisone-sparing second-line agents such as methotrexate, azathioprine, cyclophosphamide, cyclosporine, chloroquine and TNF-α inhibitors should be initiated to reduce the daily dose of cortisone which will be also the choice in case of steroid-resistant sarcoidosis. Lack of response to corticosteroids within 3 months indicates irreversible changes such as fibrosis or nonresponsiveness.

Chloroquine/Hydroxychloroquine

Antimalarial agents such as chloroquine or hydroxychloroquine have been used successfully in sarcoidosis for decades. Inhibition of antigen presentation and formation of granuloma seems to be their rationale for treatment. Efficacy was tested in small cohorts up to 17 patients. It seems helpful in patients with hypercalcaemia and neurologic and skin involvement. They can be used either as steroid-sparing agent or as monotherapy. Doses used for chloroquine are 50–500 mg and for hydroxychloroquine 200–400 mg/day. Major side effects are nausea and ocular disease resulting in retinopathy or even blindness. Therefore, regular eye evaluation on an at least yearly basis is crucial.

Already in 1961 and 1964, it was shown that chloroquine improved cutaneous and pulmonary sarcoidosis. In a randomised prospective double-blind trial using hydroxychloroquine 2–3 mg/kg/day, a significant improvement after 3–6 months was recognised but not after 12 months, indicating resistance when used long term. Twelve of seventeen patients were able to discontinue all other therapies (Jones and Callen 1990).

Chloroquine has been more tested to be effective than hydroxychloroquine but the latter has a lower incidence of retinopathy.

Methotrexate

Methotrexate is one of the best studied drugs in sarcoidosis. It is given in weekly doses of 10–30 mg, but haematological, gastrointestinal, pulmonary and hepatic side effects are limiting and blood and liver enzymes should be checked regularly. However, it might be tapered to doses as little as 2.5 mg. Response rates can be up to 80 % for cutaneous sarcoidosis when using 10 mg per week orally (Lower and Baughman 1990). In a randomised controlled trial, it has been shown that patients with new onset of disease received prednisone for 4 weeks and were then randomised to receive either methotrexate or placebo the following year. Methotrexate was able to reduce the dose of corticosteroids significantly compared to placebo (Baughman et al. 2000). Symptoms, lung function tests and chest X-ray results did not differ between methotrexate and placebo but in another small case series by 15 % under methotrexate including reduction of skin infiltration. Patients who discontinued methotrexate relapsed, indicating its immune suppressive role.

Thalidomide

Thalidomide has been withdrawn from the market because of its teratogenic effects. However it has been used successfully for a wide range of autoimmune diseases based on small case series. Its main effect is suppression of TNF-α and interleukin 12. In most cases, the starting dose was 200 mg/day in most cases which was either reduced to 100 mg/day after 3–4 weeks, kept at 200 mg/day or had to be increased to 400 mg/day. In a study of 19 patients, feasibility and efficacy of prolonged treatment with thalidomide for cutaneous sarcoidosis associated to pulmonary involvement in patients resistant to corticosteroid treatment has been evaluated. Lower skin scores occurred after 3 and 6 months, serum ACE levels decreased over time at the third month and chest X-ray as well as lung function tests improved during the first 6 months. Minor side effects forcing the suspension of the drug were drowsiness and sedation, constipation, weight gain and axonal sensitive peripheral neuropathy which resulted in discontinuation of the drug in eight

patients (Fazzi et al. 2012). In another case series of 12 patients, complete remission was observed in four patients and partial response in six patients (Nguyen et al. 2004). Due to its safety profile, thalidomide must be regarded as second- or third-line therapy. In another dose-escalation trial where patients received 50 mg initially, doubling the dose each month to a maximum of 200 mg for the treatment of lupus pernio, all 14 patients responded to thalidomide. However, side effects were somnolence, numbness and constipation in lower doses and numbness and rash in higher doses, but only in two patients the maximum dose had to be reduced due to toxicity. Obviously contraception must be strictly performed in women of childbearing potential.

Leflunomide

Leflunomide blocks the synthesis of pyrimidine and the proliferation of T cells. Leflunomide is used orally 10–20 mg/day. It seems to be similarly effective as methotrexate with lower toxicity, but larger clinical trials to test this seem necessary. Leflunomide was tested in a small cohort of 32 patients. Complete or partial response was observed in 12 of 17 patients treated with leflunomide alone and in 13 of 15 patients treated with the combination of leflunomide and methotrexate mostly with chronic ocular and lung involvement (Baughman and Lower 2004).

Fumaric Acid

Even fumaric acids such as a mixture between dimethylfumarate and monoethylfumarate, remains an excellent choice for the treatment of moderate to severe psoriasis, fumaric acids have been used successfully for other autoimmune diseases such as lupus erythematosus, granuloma annulare, lichen planus, necrobiosis lipoidica and cutaneous sarcoidosis. Its effect is to inhibit proliferation of T cells, keratinocytes and fibroblasts and suppress cytokine production. In recalcitrant cutaneous sarcoidosis, it has been used in cases of unsuccessful treatment with corticosteroids and chloroquine. Clinical improvement started only after 2 months and was more evident after 4 months, and complete remission can take as long as 1 year. It can be regarded as a third-line therapy considered for chronic or disseminated skin involvement if other treatments have failed (Klein et al. 2012). Side effects include flush, lymphopenia and minor gastrointestinal complaints.

Tetracyclines and Other Anti-infective Drugs

Since there is evidence that bacteria play an important role in the pathogenesis of sarcoidosis, the use of antibiotics has been suggested in the treatment of cutaneous sarcoidosis. However, modulation of the immune system and anti-inflammatory effects rather than antimicrobial activity may be the main mechanism behind these treatment options. In addition, increasing interleukin-2 production in monocytes and decreasing chemotaxis of neutrophils are observed (Drake et al. 2013). Most experience exists with tetracyclines such as minocycline (Schmitt et al. 2012) which is also effective against propionibacterium acnes, a well-known antigen in sarcoidosis. In a prospective, open-label, non-randomised clinical trial, cutaneous sarcoidosis recalcitrant to corticosteroids and/or quinolones was treated with minocycline 100 mg twice a day for a medium duration of 1 year. Complete response in 8 and partial in 2 (African American with a history of sarcoidosis for several years) of 12 patients was observed, and clinical improvement was observed after 3.2 months. Three patients relapsed after discontinuation of minocycline but responded well to doxycycline (Bachelez et al. 2001). In a retrospective trial, 27 patients with extensive skin lesions (but no lupus pernio) including two ulcers and systemic involvement in 18 patients received minocycline as first-line treatment (18 patients) or second-line treatment (nine patients, most of them had quinolones prior to minocycline). Six patients (22 %) had a complete remission (100 % of the affected body surface), 14 patients (52 %) had a partial remission (50 % of the affected body surface) and seven patients (26 %) did not respond to minocycline (Steen and English 2013). Poor responses to tetracycline have been reported for lupus pernio. The main effects include hyperpigmentation,

dizziness and nausea. However, compared to other treatments for cutaneous sarcoidosis, tetracyclines have a relatively benign safety profile which makes them an attractive choice for a first-line treatment. Treatment could be initiated with minocycline as monotherapy for the first 3 months. In case of an unsatisfactory response, quinolones or low-dose methotrexate might be added as well as additional topical or intralesional corticosteroids for recalcitrant skin lesions.

Since mycobacteria are frequently found in patients with sarcoidosis, antimycobacterial therapy seems another treatment option. Oral treatment with levofloxacin, ethambutol, azithromycin and rifampicin (CLEAR regimen) was tested in a randomised, placebo-controlled, single-masked trial in 30 patients with chronic cutaneous sarcoidosis (Drake et al. 2013). A significant decrease in lesion diameter and reduction in granuloma burden and lesion severity were observed for the CLEAR-treated cohort (14 patients) compared to treatment with placebo (15 patients). Immune transcriptome analysis via gene expression profiles of sorted CD4+ and CD8+ T cells showed activation of interferon signalling pathway, Jak-Stat signalling and mitogen-activated protein kinase.

Anti-TNF-α Agents

Granulomas are composed of macrophages, epithelioid cells, multinucleated giant cells and CD4+ T cells that are surrounded by monocytes, mast cells, CD8+ T cells and B lymphocytes. The finding was that TNF-α plays an important role for the formation and maintenance of granulomas by interfering with the maintenance of these cells at the location of granulomas and microenvironment. This gave the rationale for treatment with drugs that inhibit the production or action of TNF-α, biologic anti-TNF-α inhibitors such as adalimumab, infliximab or etanercept. Treatment with etanercept, even successfully reported in some single cases (Tuchinda and Wong 2006), does not seem very convincing compared to infliximab or adalimumab and is clearly inferior in cutaneous and pulmonary sarcoidosis. Overall, etanercept is not recommended for the treatment as in addition to inferior responsiveness compared to infliximab and adalimumab, it might induce non-infectious sarcoid-like granulomas (Burns et al. 2012).

Overall, there are more reports on the use of infliximab than for adalimumab for treatment of sarcoidosis. Both have achieved favourable results after other treatments were unsuccessful. In a small case series of patients with recalcitrant cutaneous sarcoidosis and multiple organ involvement (lung, lymph nodes, eye) but with multiple unsuccessful systemic pretreatments (corticosteroids, minocycline, thalidomide, methotrexate, quinolones), the patients received infliximab 5 mg/kg at 0, 2, 6 and 8 weeks (three patients) or adalimumab 40 mg every week or every other week (two patients) after a loading dose of 80 mg. All patients improved after three doses over a 2-month period and were still clear after 4 months at least (Wanat and Rosenbach 2012).

It has been demonstrated that infliximab is the most effective drug for treating lupus pernio in recalcitrant cases in one large retrospective series of 54 patients (Stagaki et al. 2009). The objective response rate regarding achieving resolution, near resolution or improvement of lesions was best for infliximab (77 %) and superior to corticosteroids plus noncorticosteroids (29 %), corticosteroids alone (20 %) and noncorticosteroids (11 %). In another case series of ten patients with skin, lung, liver, bone and muscle involvement, all patients responded to infliximab.

In a retrospective clinical trial investigating the efficacy of long-term use of infliximab in 26 patients with proven pulmonary and extrapulmonary sarcoidosis, sustained improvement was observed in 58.5 % of assessed organs whereas in 35.8 % no clinical change, and in 5.7 % a progression was observed. Infliximab has also been used in a large multicentre randomised double-blind, placebo-controlled clinical trial which included 138 patients with pulmonary sarcoidosis. (Patients receive infliximab (3–5 mg/kg) or placebo at weeks 0, 2 and 6 and then all 6 weeks up to 1 year).

Nineteen of these patients had lupus pernio, which generally seems to respond well to infliximab treatment. A significant improvement in the

forced vital capacity was noticed, and even no statistically significant difference in the appearance of facial lesions was evident. Further analysis of the study results suggested that infliximab therapy was most helpful in the severe cases. In a double-blind, randomised, placebo-controlled, open-label clinical trial of adalimumab in the treatment of cutaneous sarcoidosis, adalimumab was administered to ten patients and placebo to six patients. Treatment was given randomly and double-blinded for 12 weeks, followed by an open-label additional 12 weeks and an 8-week no-treatment period. At the end of the 12-week, double-blind phase, there was a significant improvement in the skin lesion in adalimumab-treated patients relative to placebo-treated patients. At the end of the additional 12-week open-label phase, significant improvement relative to placebo was found for target lesion area, target lesion volume and Dermatology Life Quality Index score, whereas no significant changes were seen in pulmonary function tests, radiographic findings or laboratory studies. After the 8-week off-treatment period, there was some loss of this improvement. Overall anti-TNF-α inhibitors might be an interesting option in steroid-resistant sarcoidosis (Denys et al. 2007).

For both anti-TNF-α agents, there is the risk of activation of tuberculosis and the induction of anti-TNF-α antibodies or other autoimmune diseases (systemic lupus erythematosus, vasculitis). Typical side effects include headache, musculoskeletal symptoms, infection, vision problems and dizziness.

Mycophenolate Mofetil

Mycophenolate mofetil was used in doses of 30–45 mg/kg/day to improve skin lesions up to 70–90 % of patients with cutaneous and systemic sarcoidosis that had been refractory to other systemic therapies within 3–6 months. Treatment allowed to taper prednisone. It has been reported also to be effective in neurosarcoidosis, renal sarcoidosis and sarcoidosis uveitis.

Retinoids

Isotretinoin has been used for cutaneous sarcoidosis in same cases in doses of 0.5–2 mg/kg/day. Due to its teratogenic potential, it is problematic since a cohort of patients that develop sarcoidosis include women of childbearing potential.

Azathioprine

There is only little data on the use of azathioprine in sarcoidosis. It is mainly used as a corticosteroid-sparing agent with a dose of 2 mg/kg daily together with prednisolone 0.1 mg/kg. However, experience with azathioprine in sarcoidosis is limited. Side effects include hepatotoxicity, haematotoxicity and gastrointestinal problems.

Cyclophosphamide

Cyclophosphamide is a cytotoxic agent that is used systemically (500–1,500 mg i.v.) every 2–4 weeks. There are no larger case series that have tested the efficacy of cyclophosphamide in cutaneous sarcoidosis. Case reports indicate efficacy in the treatment of neurosarcoidosis or myocardial sarcoidosis (Demeter 1988). Adverse effects include stomatitis, nausea, hepatotoxicity, bone marrow suppression, haemorrhagic cystitis or bladder carcinoma.

Cyclosporin A

Cyclosporin A is attractive regarding its potent inhibition of interleukin2 and suppression of Tlymphocyte proliferation and reduction of monocytes' chemotaxis. However, the clinical benefit is rather low as observed in large patient cohort studies. Patients were randomised in an openlabel study to receive prednisolone alone or in combination with cyclosporin A for 18 months. The use of cyclosporin A did not confer an additional benefit given that the combination group was characterised by an increase in the number of relapse infections and adverse events (Wyser et al. 1997). Pia and colleagues observed a complete and lasting remission in patients treated with the combination of methotrexate, cyclosporin and flucortolone, but the exact role of each agent cannot be determined (Pia et al. 1996).

Allopurinol

Some authors have observed remission of pulmonary and cutaneous sarcoidosis in patients treated with allopurinol that was used originally to treat

hyperuricaemia. Allopurinol is used in doses of 300 mg/day. Its main indication is cutaneous sarcoidosis, and it might be used for recalcitrant cases that are resistant to corticosteroids and quinolones. Side effect profile is low and includes gastrointestinal problems and skin rash. However, larger clinical trials are missing as in a lot of other drugs used for sarcoidosis.

Treatment Algorithm

A potential treatment algorithm of cutaneous sarcoidosis in case of cosmetically significant, symptomatic skin lesions without systemic involvement could start with topical treatment using corticosteroids, either topical potent corticosteroids or in case of recalcitrant single lesions also corticosteroids via intralesional injection.

In case of recalcitrant skin lesions or a rapid advancing disease and/or organ involvement, treatment could start with chloroquine or hydroxychloroquine or systemic corticosteroids and addition of steroid-sparing agents such as chloroquine, hydroxychloroquine or methotrexate. In case there is no improvement after 6–9 months or in case of lupus pernio, the option would be the anti-TNF-α drugs infliximab or adalimumab.

If an antimicrobial trigger is present or assumed, antimicrobial treatment with minocycline or tuberculostatic treatment is an option.

Allopurinol is a third- or fourth-line drug with a low side effect profile.

Systemic Treatments at a Glance

- Glucocorticoids in doses of 0.5–1 mg/kg are recommended in rapid progressive skin and organ involvement.
- Steroid-sparing agents include antimalarial drugs chloroquine and hydroxychloroquine, methotrexate and the less frequently reported drugs azathioprine and mycophenolate mofetil that could be used together with corticoids or alone.
- Chloroquine/hydroxychloroquine and methotrexate are the drugs with the longest experience and have been proven to be successful in treating cutaneous sarcoidosis.
- Anti-TNF-α drugs infliximab and adalimumab are effective in recalcitrant sarcoidosis, and infliximab is a good choice especially for recalcitrant lupus pernio.
- Etanercept was less successful than infliximab and adalimumab and would not be recommended.
- Antimicrobial treatment with minocycline and antimycobacterial treatment regimens are useful when microbial antigens are suspected.
- Thalidomide, fumaric acid, cyclosporine A and allopurinol have shown some efficacy reported in case series and might be used as third- or fourth-line therapy or if the other drugs are less tolerated.

Scabies

86

Anna Górkiewicz-Petkow

Key Points

- Scabies is a contagious skin infestation caused by the human mite *Sarcoptes scabiei*.
- It remains a significant public health problem worldwide. Scabies infestation is independent of socioeconomic situation, age or sex.
- Epidemics of scabies occur in hospitals, nursing homes and schools. Spreading of the disease often depends on late and incorrect diagnosis especially for hyperkeratotic scabies.
- Treatment should be applied preferably after the confirmation of the clinical diagnosis.
- Effectiveness of the medications depends not only on the drugs but also on the proper use according to instructions.

A. Górkiewicz-Petkow
Department of Dermatology, Warsaw Medical University, Warsaw, Poland
e-mail: anna.gorkiewicz@wp.pl

Definition and Epidemiology

Scabies is an ectoparasite skin infestation. The role of mites as a cause of ectoparasite skin infestations in man has often been underestimated. In the presence of a pleomorphic, pruritic and papular eruption, the possibility of mite infestation should be taken into account. Scabies has been recognized for thousands of years. The causative mite was discovered in the seventeenth century.

Basic Concepts of Pathogenesis

The causative mite is *Sarcoptes scabiei* var. hominis. The scabies infestation is independent of socioeconomic situation (although in underdeveloped countries, prevalence is very high). It affects more often younger population. Scabies occurrence rate varies from 2.71 per 1,000 to 46 %. About 300 million people are infected with scabies globally at any given time (accuracy of this estimate is impossible to verify). Epidemics of scabies still occur in schools, hospitals and nursing homes, within families and between immunosuppressed patients. Frequently inadequate epidemiological recognition, and consequent inadequate treatment, is the cause of the spread of disease. Scabies is easily transmitted by skin-to-skin contact or through contaminated environment (dust, chairs, curtains, sheets,

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_86, © Springer-Verlag Berlin Heidelberg 2015

pillows, toys). Adult female mites can survive 24–36 h at room temperature. The incubation period varies from 4 days to 6 weeks. The number of mites living on an infected host varies from 50 mites to several million in crusted (hyperkeratotic) scabies and human immunodeficiency syndromes.

Clinical Presentation

The skin lesions associated with scabies result from a type I and type IV immunological hypersensitivity reaction to the mite or its faecal pellets. Skin lesions are various, depending on local and general immunological response.

The primary complaint of a patient with scabies is itching, particularly at night (it has been suggested that it may be connected with increased activity of the female mite in warmer and darker conditions or to an immune response to the mite and its products). The onset of symptoms is gradual. Pruritus begins slowly (in some varieties of scabies, it is not pronounced); the patient is unable to point the exact date of symptoms or rash. Symptomatic pruritus can persist for 2–4 weeks after treatment, while the dead mites in the outer layers of stratum corneum are sloughed off with normal exfoliation. Conversely in reinfestation, symptoms reappear almost immediately. The most characteristic features of scabies are burrows and vesicles, and the less characteristic are papules, pustules, excoriations, nodules and bullae. Affected areas include the hands (interdigital areas and palms), lateral borders of feet, ankles, elbows, breasts, periumbilical area, genitals (particularly penis and scrotum) and buttocks. In children under 2 years of age, possible involvement of the face and soles is observed. In severe cases or in immunosuppressed patients, scabies can involve the entire skin surface. There have been reports on subungual and nail involvement in persons with crusted scabies or in neonatal scabies. Scabies can coexist as an additional infection with sexually transmitted diseases and different skin diseases like psoriasis, atopic dermatitis and dermatitis herpetiformis, making the diagnosis more difficult.

Complications of Scabies

These include urticarial reactions, persisting dermatitis and pruritus after treatment, nodular lesions and psychological problems (parasitophobia). There are reports on pemphigoid-like eruption and histiocytosis-like lesions in patients treated for scabies. Not recognized scabies infestation is complicated by chronic pyodermas, possibly with MRSA, or streptococcal strain bacterial infection, which can cause renal or heart disease. This problem is emerging in underdeveloped countries.

Clinical Variants of Scabies

Crusted (Hyperkeratotic, Norwegian) Scabies

This is a distinctive form of scabies with a predilection for the physically disabled, mentally ill individuals and immunosuppressed patients, and can, although seldom, also occur in healthy individuals. Keratotic scabies is not very rare and can mimic other skin conditions such as psoriasis, exfoliative dermatitis and T-cell lymphoma, and therefore is often misdiagnosed. The increased use of immunotherapies may also predispose to crusted scabies. The most characteristic lesions are hyperkeratotic plaques (due to excessive keratinocyte proliferation) involving scalp, ears, knees, palms and soles. The lesions are heavily infested with mites, which can be detected also in the patient's environment (bed, linen, floor, carpets). Pruritus is rare but occasionally may be severe. These patients are often a source for scabies epidemics in nursing homes and hospitals.

Neonatal Scabies

Neonatal scabies differs from that seen in older patients by its generalized character involving all body areas. Lesions consist of papules, vesicles and crusts. It often occurs with secondary infection with weeping and desquamation. The itch is not always present.

Diagnosis

There is no standardized method to diagnose scabies. Scabies should be suspected in patients with nocturnal itch, erosions and pleomorphic lesions in typical distribution. A definite diagnosis requires identification of the mite or eggs in the presence of burrows. Burrows may appear as elevated lines or erythematous or oedematous linear lesions, sometimes with vesicle formation at the top. The brownish to black discoloration of the burrows is due to the presence of faeces, eggs or the mite itself. Burrows may be better seen by applying mineral oil on the skin and liquid tetracycline preparations or by burrow ink test. The next possibility to confirm scabies infestation is to demonstrate the scabies mite by extracting the mite by scrapings from the burrows with a sterile needle, by shaving or stripping the lesion with cellophane tape and by examining the obtained material under the microscope (Fig. 86.1).

Other methods include standard dermoscopy of the lesions. Mites appear as small triangular objects within the burrow area. Epiluminescence microscopy requires expensive technically setting. There are reports of using PCR and serological test for scabies-specific IgE and IgG antibodies.

Differential Diagnosis

Skin Eruption Caused by Other Mites

Domestic animals (birds, dogs, cats, and rabbits), dust and grain may be the source of infestation. The main difference in the clinical picture is the lack of burrows. The eruption consists mainly of papules, urticarial lesions and vesicles with no characteristic distribution. The itch persists all day. To confirm the diagnosis, a detailed history about work conditions, hobbies, domestic animals and detection of mites in the environment may be helpful.

Differentiation from Other Skin Diseases

These include allergic dermatitis, pyoderma, ecthymatosis, Darier's disease and dermatitis herpetiformis.

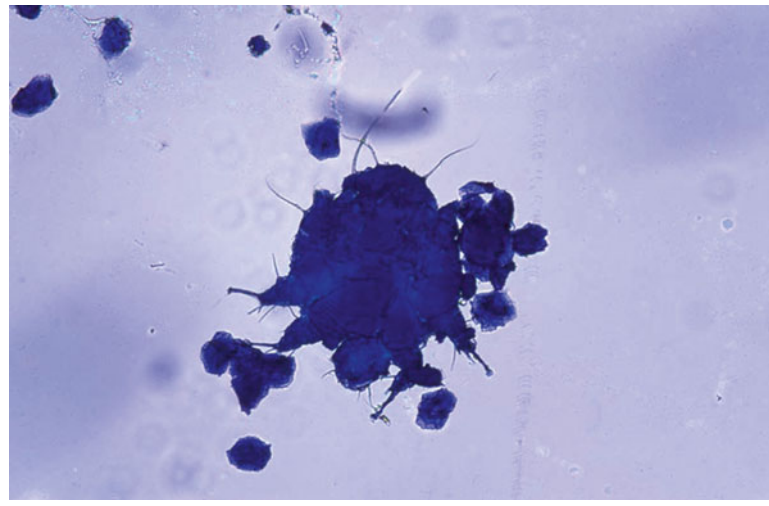

Fig. 86.1 Diagnosis of scabies by scrapings from the burrow

Special Considerations

- Proper diagnosis and choice of adequate treatment of scabies is vital.
- Treatment of endemic disease in nursing homes, schools, large hospitals and communities (ethnic groups, army).
- Diagnosis of crusted scabies.

General Principles of Treatment

General Therapeutic Guidelines

There are a variety of various scabicides so the choice of treatment depends often on the personal preferences of the medical officers, availability of the drug or economic situation of the patient. In each case it is necessary to confirm diagnosis and source of infestation, which relates also to non-human mite infestations. There are several questions to be addressed before starting the treatment. Because the use of scabicides can cause irritation, patients should be warned against overtreatment, and only physicians, in cases of persistent infestation or reinfestation, should decide about repeated applications. If secondary infection is present, antibiotics should be prescribed. Sometimes pruritus persists for several weeks after completion of the treatment. In these patients the antihistamines and emollients may be helpful. Treatment should always be carefully supervised since most failures are due to inadequate application of scabicide. All members of the family and all contacts should be treated, even where there is no evidence of infection. The environment should be decontaminated, especially in cases of crusted scabies. All personal clothing and bed linen should be changed and washed. In large-scale epidemics, it is advisable to establish treatment centres.

Scabicides are also described in the relevant chapter.

Remember:

- To start treatment after confirmation of diagnosis
- To give all instructions and explanations to the patient
- To treat all contacts
- To treat the whole body including intertriginous areas, toenails and subungual areas
- To follow strictly the instructions of the manufacturer
- To choose adequate medication for children, pregnant women or immunocompromised patients
- To be aware of greater permeability of scabicides in patients with impaired skin barrier
- To remove hyperkeratosis before starting topical treatment in crusted scabies

Recommended Therapies (Table 86.1)

Topical Treatments

Pyrethrins

Commercial Preparation: Lyclear Dermal Cream 5 % Permethrin

Permethrin synthetic pyrethroids are well tolerated, adverse reactions are rare, and irritation of the skin is infrequent. For the treatment of scabies in adults, a single application, after a bath, for 8–12 h, repeated in 1 week apart is recommended. Permethrin can be used in neonates and children under 2 years of age in reduced amounts and in pregnant women with caution.

Table 86.1 Recommended topical treatment for scabies

Scabies	
Adults	Permethrin 5 % cream
	Malathion 0.5 % aqueous sol.
	Benzyl benzoate 25 % sol.
	Sulphur 6–15 % ointment
	1 % ivermectin lotion
Pregnant women	Sulphur 6–10 % ointment, crotamitone, (permethrin 5 % cream, benzyl benzoate 10 % – with caution)
Children	Sulphur 6 % ointment, crotamitone
	Permethrin 5 % cream after 2 months of age in reduced amounts
	Benzyl benzoate 10 % (excluding neonates and under 4 months of age)

Treatment schedules in the chapter on scabies and pediculosis

Chlorinated Insecticides

- Gamma-hexachlorocyclohexane – lindane 1 % emulsion
- Commercial preparations – Jacutin, Quellada lotion, Aphtiria

Adverse reactions are possible. Central nervous system (CNS) toxicity occurs only if not properly used or ingested. It is not recommended for neonates, small children under 4 years of age or pregnant women. The following recommendations have been proposed to minimize the potential risk of lindane treatment: it should not be applied after a hot bath which can enhance absorption, in very slim, cachectic patients (atrophy of fat tissue is facilitating absorption) or in patients with massive excoriations or dysfunction of epidermal barrier. Lindane should be washed off the skin after 8–12 h, with only two applications possible in 1 month. Treatment schedule is one or two applications on two consecutive nights. Recently lindane has been withdrawn from the treatment of scabies in many countries due to possible neurotoxicity.

Benzyl Benzoate

- Commercial preparations – Ascabiol 10 % solution for children, 25 % for adults
- Adverse reactions – locally irritant
- Treatment schedules (not unified) – after bath two to three applications with 12-h intervals. May be used in children, excluding neonates, those under 4 months of age and pregnant women in concentration

Anticholinesterase Inhibitors

- Commercial preparation – Derbac-M (malathion 0.5 % aqueous sol.)
- Treatment schedule – single application for 12 h, not preceded by the hot bath. May be used with caution in children and in pregnant women

Sulphur

- 5 %, 10 % in petrolatum base, 25 % in zinc base.
- Adverse reactions – local irritation.
- Treatment schedules – after bath 3 to 4 applications with 12-h intervals. For children lower concentration is indicated. The major disadvantages of sulphur are its unpleasant smell and messy consistency.

Crotamitone

- Commercial preparations – Eurax, Euraxil.
- Crotamitone has lower potential as scabicide but has in addition some antipruritic activities.
- Treatment schedule – after bath on 4–5 consecutive nights. May be used in children and pregnant women. Also used for the treatment of postscabietic pruritus or pruritus of other origin.

Systemic Treatments

Ivermectin

- Commercial preparation – ivermectin (Stromectol).
- Ivermectin is an antiparasitic agent with a structure similar to the macrolide antibiotics, but without antibacterial activity. It is a synthetic derivative of abamectin. The drug has an endectocidal effect causing paralysis by suppressing the conduction of the nervous impulses in the interneuronic synapses of parasites. Ivermectin is widely used for the treatment of onchocerciasis.

Since 1992 there have been reports on systemic administration of this drug for uncomplicated scabies infestations in humans (Polynesia, India, Sierra Leone, Mexico, and the USA) or scabies in HIV-positive patients. A single oral dose of 100 or 200 fg of ivermectin/kg or two repeated doses in weekly interval are given in HIV-positive patients, crusted scabies or epidemics in nursing homes. Sometimes the use of concomitant topical treatment is recommended, e.g. benzyl benzoate. The benefits of oral ivermectin are high therapeutic efficacy (quick relief of pruritus), good tolerance, administration once a weak, lack of local irritation and action on the whole body surface. There are reports on topical use of ivermectin 1 % lotion for

scabies with an effect comparable to 5 % permethrin cream.

Further clinical studies are necessary to evaluate optimal regimen of treatment, to exclude possible interactions with topical treatments (e.g. lindane) and to assess the incidence of serious adverse reactions.

Thiabendazole

Thiabendazole has a broad spectrum of anthelmintic action (strongyloidiasis, cutaneous larva migrans). In South America, there are reports on oral administration of thiabendazole in the treatment of scabies (25 mg/kg for 10 days) and on thiabendazole 5 % cream for topical treatment of scabies applied for 5 consecutive nights.

Seborrheic Dermatitis

87

Andrea Kovacikova Curkova and Maria Simaljakova

Key Points

- Seborrheic dermatitis is a chronic, relapsing, papulosquamous inflammatory skin disorder.
- The etiology is still not completely understood. *Malassezia* yeasts have a major role.
- Satisfactory therapeutic results are achieved with topical antifungal agents of the azole class, which are considered as the first-choice treatment for seborrheic dermatitis offering more sustained relapse-free periods as compared with corticosteroids and without their side effects.
- Topical glucocorticosteroids are also effective, but long-term use should be avoided due to side effects.
- Other topical agents with proven efficacy may be used as complementary therapy.
- Narrowband UVB phototherapy should be considered for severe, widespread, and/or resistant disease.
- Oral antifungals carry the potential risk of serious hepatotoxic side effects from repetitive use.
- Severe and therapy-resistant forms of seborrheic dermatitis can be predictors of some serious conditions such as HIV infection.

Definition and Epidemiology

Seborrheic dermatitis is a chronic recurrent inflammatory skin disorder frequently occurring in infancy and adulthood. It clinically presents with sharply demarcated erythematous papules, patches, and plaques with greasy scales primarily affecting areas of high sebaceous gland activity, namely, the scalp, face, upper chest, upper back, and flexures. Itching can be present. The estimated prevalence of adult seborrheic dermatitis is 3–5 %, with a predilection in men. It has two incidence peaks, the first in the first 3 months of life and the second beginning at puberty and chronically relapsing until the third and fourth decade of life. A higher incidence can be found among patients with HIV infection or neurologic disorders like Parkinson's disease or mood disorders. The etiology and pathogenesis of seborrheic dermatitis remains controversial. However, the focus is put on the involvement of *Malassezia* yeasts or fatty acid metabolites of *Malassezia*, hormones (androgens), sebum levels,

and immune response. Additional factors including drugs, winter temperatures, and stress may exacerbate the disease. The diagnosis is usually clinical, based on history and the appearance and site of skin lesions. A variety of treatment modalities are available, mainly consisting of antifungal agents, topical corticosteroids, keratolytics, and calcineurin inhibitors (immunomodulators). Due to the chronicity of the disease with frequent relapses, a treatment strategy in which effectiveness and potential side effects are weighed should be used.

Basic Concepts of Pathogenesis

Despite a high prevalence of seborrheic dermatitis, the exact cause is not clearly understood. The exact pathogenetic mechanism also remains controversial.

Malassezia Yeasts

Growing evidence indicates that *Malassezia* species (spp.) are a major etiologic factor in the development of seborrheic dermatitis. *Malassezia* yeasts are lipophilic microorganisms that are most often found on skin areas rich in sebaceous glands – the scalp, face, and upper trunk. *Malassezia* spp. yeasts use fats as principal food source and are normal skin commensals of humans of any age. There is an observed variability in the microscopic morphology of *Malassezia* spp. depending on the species. *Malassezia* spp. are dimorphous fungi that are able to exist in both yeast and mycelial forms.

Species distribution of the *Malassezia* yeasts in seborrheic dermatitis shows some geographical characteristics. *Malassezia obtusa* are the most frequent species in patients with seborrheic dermatitis from Eastern Europe. *Malassezia globosa* and *Malassezia restricta* are the predominant species in seborrheic dermatitis in the USA and Japan. In Greece, *Malassezia globosa* and *Malassezia sympodialis* are isolated from patients with seborrheic dermatitis. In Germany and in Bulgaria, *Malassezia furfur* is the most prevalent species. The geographical variations of *Malassezia* spp. are constantly being updated with new data.

The number of *Malassezia* spp. decreases after antifungal therapy with vanishing of skin lesions. The number of the spores is reduced, which in turn increases the relapse-free intervals of the disease. This is probably the strongest evidence for the importance of *Malassezia* yeasts in the development of seborrheic dermatitis.

Malassezia spp. have the ability to produce lipases that can initiate inflammatory response by releasing unsaturated fatty oleic and arachidonic acid from the sebum lipids. Both of these acids have direct irritative and desquamative effects on keratinocytes. Arachidonic acid metabolized by cyclooxygenase produces proinflammatory eicosanoids (specifically prostaglandins), which lead to inflammation and consequent damage of stratum corneum. Keratinocytes in affected areas are stimulated to produce proinflammatory cytokines that further intensify and maintain the inflammatory response. Elevated levels of cytokines were observed from seborrheic dermatitis lesions – IL-1α, IL-1β, IL-2, IL-4, IL-6, IL-10, IL-12, TNF-α, and IFN-γ. These inflammatory mediator molecules were measured from punch biopsy samples using immunohistochemistry. Also nonlesional skin from patients with seborrheic dermatitis showed elevated levels of proinflammatory cytokines compared to normal skin. These data support the inflammatory component of seborrheic dermatitis.

Hormones and Sebum

Despite the fact that seborrheic dermatitis is not always associated with excessive secretion of sebum, 50 % of patients have an oily skin. Sebum lipids are essential for *Malassezia* proliferation and synthesis of initial proinflammatory factors. Therefore, seborrheic dermatitis is most common in puberty and adolescence, during periods of highest sebum production. The occurrence of seborrheic dermatitis in puberty and more commonly among males suggests an influence of androgens on the pilosebaceous unit.

Immune Response

The lipid-rich layer around the yeast seems to play an important role in its transformation from saprophyte to pathogen. The lipids in the cell wall protect *Malassezia* yeast from the host defense mechanisms in the scenario of normal cutaneous commensalism. However, the lipid layer may be altered in seborrheic dermatitis, which leads to a better detection by the immune system of the host followed by an inflammatory reaction. The pathogenesis of the disease is complex. Both nonimmune and immune mechanisms – specific and nonspecific – are involved. Which of the mechanisms will dominate in each individual patient and what will be the degree of severity of the disease with a certain profile of stimulated inflammatory interleukins will depend on the yeast itself (type, amount, pathogenicity) as well as on the individual reactivity of the organism.

There is an increase in the number of natural killer 1+ (NK1+) T cells and CD16 cells associated with complement activation in seborrheic dermatitis lesions, suggesting an intense, irritative, nonallergic immune response. Understanding the ability of *Malassezia* to either upregulate or suppress the individual immune response directed against it may be the key to understanding how *Malassezia* spp. occur both as commensals and as pathogens.

Despite the presence of hypergammaglobulinemia (IgA and IgG antibodies) in patients with seborrheic dermatitis, there are no detected elevated titers of antibodies specific to *Malassezia* antigens. This suggests that the increased immunoglobulin production occurs as a response to yeast toxins and lipase activity.

The strongest evidence for immunodeficiency as an etiologic factor in seborrheic dermatitis is associated with findings that the prevalence of the disease is significantly higher (34–83 %) among HIV-positive and AIDS patients compared to the general population (approximately 3 %). A more severe clinical presentation of seborrheic dermatitis (often affecting extremities) has been observed in HIV-positive patients. Seborrheic dermatitis occurs most often in individuals with a CD4+ T-lymphocyte count of 200–500 and is considered as an early skin manifestation of AIDS. Seborrheic dermatitis in these patients is considered by some authors as a distinctive entity – seborrheic-like dermatitis of acquired immunodeficiency syndrome. Response to antiretroviral therapy is variable with contradictory reports in the literature.

Neurogenic Factors

There have been long clinical observations of the frequent occurrence of seborrheic dermatitis in patients with Parkinson's disease, who may have increased plasma levels of α-melanocyte-stimulating hormone (α-MSH), probably due to the lack of MSH-inhibiting factor as a consequence of insufficient dopaminergic neuronal activity. Treatment with L-dopa restores the synthesis of MSH-inhibiting factor and reduces sebum secretion in patients with Parkinson's disease. The masklike face in Parkinson's disease patients can secondarily lead to the increased accumulation of sebum, thus contributing to the development of seborrheic dermatitis.

Seborrheic dermatitis frequently occurs in patients treated with neuroleptic drugs, as well as in patients with tardive dyskinesia, central nervous system trauma, and facial nerve palsy.

Frequent occurrence of seborrheic dermatitis is also among patients with depressive disorders. This could also be attributed to the altered lifestyle of such patients, to remain indoors, as well as to poor hygiene habits.

Other Factors

Familial predisposition is observed in 28 % of the patients. The only description of HLA typing in non-Caucasian patients with seborrheic dermatitis was published in 1976 by Tsuji et al. The investigators typified an increase in the frequency of HLA-AW30 and/or AW31 and HLA-B12 in seborrheic dermatitis. The oily secretion of the skin and seborrheic status are genetically determined. Stress and urbanization have an unfavorable

effect on the spread of seborrheic dermatitis. Relapses of the disease have a seasonal aspect and are more common in winter. Exposure to sun has a positive effect on the skin lesions. This improvement could be explained with the seasonal changes in the lipid secretion. Changes in pH of the skin may be triggered by hyper- and dysseborrhea. Many shampoos and cosmeceuticals change the pH on the skin surface. In patients with dandruff, neutral to alkaline pH (6.0–7.0) is found in the area of the lesions. The optimal pH for growth of *Malassezia* is between 5.5 and 6.5.

Seborrheic dermatitis can be triggered by emotional stress and sleep deprivation. Diet rich in sugar intake is also blamed for the development of seborrheic dermatitis. A severe seborrheic dermatitis-like rash can be produced by zinc deficiency in patients with acrodermatitis enteropathica and acrodermatitis-like conditions. However, a supplementary zinc therapy usually does not relieve the symptoms of seborrheic dermatitis.

Clinical Presentation

Typical lesions for seborrheic dermatitis are erythematous macules or thin plaques with well-defined borders with fine, dry white or greasy yellowish scales of varying extent and degree of intensity. The predilection areas consist of numerous sebaceous glands, such as the scalp, hairline, eyebrows, glabella, nasolabial folds, external ear, retroauricular region, neck, upper chest, back, axillae, umbilicus, and groins. The disease may either be limited to small areas of the body, or there may be generalized forms and even forms of erythroderma. Patients may often report pruritus of the lesions, predominantly on the scalp and in the ear canal. Complications of the lesions are secondary bacterial infection, which increases the erythema and exudate, local discomfort, and lymphadenopathy close to the affected areas.

Depending on the age group affected, the pediatric form is self-limiting, whereas in adults the disease is chronic. The pediatric form is more prevalent in the first 3 months of life with yellowish adherent scales on the scalp being the most common clinical manifestation. The scales may also develop on the face and in the body folds. If seborrheic dermatitis in an early infancy (first 2 months of life) presents with a generalized form, it is often associated with immunodeficiency. This condition is called erythroderma desquamativa of Leiner. Symptoms include scaling on the trunk and limbs, red patches in the flexural folds, recurrent local and systemic infection, fever, reduced blood protein levels, peeling of the skin, itching, corneal ulcers, wasting of the lymph nodes, anemia, severe diarrhea, wasting, and nervous system deficiency. Greasy scaling is present on the scalp, behind the ears, nose, or eyebrows or around the mouth. If left untreated, the skin infections will cause loss of protein and electrolytes. This disease is caused by a deficit of the complement protein C5. However, case reports have described also deficits in either C3 or C4. Hospitalization is recommended to prevent nutritional deficiencies and infections.

In adults, seborrheic dermatitis is a chronic, relapsing dermatosis that may range from a mild erythema to papular, exudative squamous lesions with periods of exacerbation related to stress, sleep deprivation, and winter months. Scalp lesions extend from a mild desquamation (pityriasis simplex capillitii) to honey-colored crusts firmly affixed to the scalp and hair, which may provoke areas of alopecia (pseudo-tinea amiantacea). Scalp lesions may extend into the forehead skin and form a scaly erythematous border called "corona seborrheica." On the face, involvement of the glabella, the nasolabial folds, and the eyebrows is characteristic (Figs. 87.1 and 87.2). Blepharitis is another symptom of seborrheic dermatitis with honey-colored crusts on the eyelids. In men, the beard area may also be affected with lesions of seborrheic dermatitis. In some individuals, chronic dermatitis of the ear canal may be the only manifestation of seborrheic dermatitis. In the body folds, lesions may acquire a moist, macerated appearance with erythema at the base and around the lesions. They may progress with fissures and secondary infection. On the chest, in the presternal area, lesions of seborrheic

Fig. 87.1 Seborrheic dermatitis in a patient with neurologic disorder

Fig. 87.2 Seborrheic dermatitis on the face and on the chest

dermatitis may occur in two forms: a common petaloid type and a rare pityriasiform type. The petaloid type starts with red to brown follicular and perifollicular papules, which develop to patches that resemble the shape of flower petals, and the scales are over the lesions. The pityriasiform type is probably an acute form of petaloid seborrheic dermatitis, which presents with generalized macules and patches following the skin lines mimicking pityriasis rosea. A generalized exfoliative erythroderma (seborrheic erythroderma) is a serious variant of seborrheic dermatitis.

Differential Diagnosis

The patient's age, gender, affected skin sites, presence of concomitant disorders (especially immunocompromising, neurologic, psychiatric), and family history as well as the patient's daily routine must be taken into consideration when performing differential diagnosis.

The key clinical features to establish diagnosis of seborrheic dermatitis are erythematous and scaling plaques in the scalp, nasolabial folds, eyebrows, and retroauricular regions.

These clinical features may be confused with psoriasis.

Skin biopsy is rarely needed to verify the diagnosis, and associated histologic changes may vary from acanthosis and parakeratosis to spongiosis.

Psoriasis: sharply demarcated erythematosquamous plaques, typical distribution on the scalp, elbows, knees, and lumbosacral area on the back, white-silver color of scales, nail pitting, and distal onycholysis. In the body folds, inverse psoriasis should be differentiated from seborrheic dermatitis. In case of infantile psoriasis, which is very similar to seborrheic dermatitis, it is almost impossible to differentiate between the two conditions. The occurrence of so-called seborrhiasis could be found, indicating a condition with overlapping psoriasis and seborrheic dermatitis on the face.

Atopic dermatitis: history, distribution – extensor surfaces, itch, elevated serum IgE.

Diaper dermatitis: does not affect the body folds, whereas seborrheic dermatitis affects these areas predominantly.

Primary irritant contact dermatitis: history, patch tests.

Dermatophytosis: microscopy with KOH solution, mycology cultivation.

Erythrasma: examination with Wood lamp – coral red fluorescence, bacterial cultivation.

Tinea capitis: microscopy with KOH solution, mycology cultivation.

Pityriasis (tinea) versicolor: on the trunk and upper back. Examination with Wood light – golden yellow fluorescence. Microscopy with KOH solution, mycology cultivation.

Generalized pityriasis rosea: begins with a single "herald patch" lesion most commonly on the abdomen, followed in 1 or 2 weeks by a generalized body rash following the rib line in a characteristic "Christmas-tree" distribution lasting up to 12 weeks. An upper respiratory tract infection may precede all other symptoms.

Acute cutaneous lupus erythematosus: bilateral malar eruption, butterfly erythema; immunologic assessment is required.

Rosacea: chronic erythema on the central face – nose, cheeks, forehead – with telangiectasia, red papules, and pustules. Treatment with topical corticosteroids can aggravate the condition.

Cutaneous lymphoma: skin biopsy (histology), immunohistochemistry, clonal T-cell population, Sezary syndrome (erythroderma), circulating malignant T lymphocytes, and generalized lymphadenopathy.

Cutaneous Langerhans cell histiocytosis: may affect the body folds and the scalp; however, there is a presence of purpuric component in the lesions.

Drug-induced dermatitis similar to seborrheic dermatitis: induced by drugs (gold, buspirone, chlorpromazine, ethionamide, griseofulvin, haloperidol, IL-2, interferon-α, lithium, methoxsalen, methyldopa, phenothiazines, psoralens, and stanozolol, among others).

Nutritional deficiency: riboflavin, pyridoxine, niacin, zinc.

Seborrheic-like dermatitis due to dermatomyositis: severe pruritus of the scalp, Gottron's papules, and a photodistributed poikiloderma.

General Principles of Treatment

Seborrheic dermatitis is a therapeutic problem because of the high incidence of reappearance due to the presence of various predisposing factors. The patient has to be aware of the course of the disease. The objective of treatment consists of controlling the inflammation, the proliferation of the microorganisms, and the oiliness.

Topical treatments are the mainstay of therapy considering the fact that the condition is recurrent, usually mild, and well responding to these agents. The combination of various active ingredients in one single product and the use of rotational therapy are the most effective treatment options.

Recent therapeutic approach is commonly based on topical antifungal, anti-inflammatory, and immunomodulatory agents, thus emphasizing the key underlying pathogenetic mechanisms including excessive proliferation of *Malassezia* spp. with consequent induction of skin inflammatory response. Keratolytics are also highly effective because desquamation is regularly present.

Systemic therapy is required in severe cases with outspread lesions, as well as in cases unresponsive to topical treatments.

Topical Treatments

Antifungal Treatment

Recently, it is generally accepted that initial therapy for seborrheic dermatitis should include topical antimycotics. Topical antifungal agents of the azole class that are usually well tolerated without significant side effects are currently considered as the first-choice treatment. Azole class of antifungal agents (lanosterol 14 alpha-demethylase inhibitors) proved to be most effective in the inhibition of growth of *Malassezia* spp.

Ketoconazole in various vehicles (e.g., cream, foam, gel, and shampoo) showed superior effects

on seborrheic dermatitis among the azole class of antifungals. Ketoconazole shampoo 2 % used twice weekly is effective for scalp seborrheic dermatitis. Intermittent use of ketoconazole 2 % shampoo has been shown to have a significant prophylactic effect. Ketoconazole 2 % cream used twice daily significantly improves lesions of seborrheic dermatitis on the face and chest (similar effect to hydrocortisone 1 % cream). If used intermittently, it is effective in maintaining remission. Ketoconazole also has slight anti-inflammatory properties.

Bifonazole 1 % cream, used once daily, also represents an effective treatment option for seborrheic dermatitis of the scalp and face. A combination ointment containing 1 % bifonazole and 40 % urea reduces seborrheic dermatitis on the scalp.

Miconazole is another effective azole antifungal agent proven to be effective in the treatment of seborrheic dermatitis, either as monotherapy or in combination with hydrocortisone.

Ciclopirox has both antifungal and anti-inflammatory effects. Ciclopirox 1 % cream used twice daily provides a reduction of symptoms of seborrheic dermatitis on the face. Combinations of ciclopirox 1.5 % shampoo with salicylic acid 3 % or zinc pyrithione 1 % are also beneficial. Recent studies report a statistically non-inferior effect of ciclopirox compared to ketoconazole.

Corticosteroids

Corticosteroids (clobetasol propionate) promote anti-inflammatory effect. Long-term use should be avoided because of their well-known side effects. In severe forms of seborrheic dermatitis, low to mild potency topical corticosteroids are effective especially in rapid clearing of visible symptoms, thus limiting inflammation. There is a consensus that topical corticosteroids are useful when applied over a short period, mainly to control erythema and itching. Topical corticosteroids may be used alone or in combination with antifungal agents. Prolonged use is not recommended due to their side effects, such as skin atrophy, telangiectasias, hypertrichosis, and perioral dermatitis. Based on the fact that ketoconazole 2 % foaming gel has been shown to be superior to betamethasone dipropionate 0.05 % lotion in reducing symptoms and lowering the number of *Malassezia* spp., it is still the therapy of first choice.

Calcineurin Inhibitors

Pimecrolimus 1 % cream and tacrolimus 0.03 and 0.1 % ointment decrease cutaneous inflammation by inhibiting the cytokine production driven by T lymphocytes. Calcineurin inhibitors do not have the side effect profile of corticosteroids. In a randomized, double-blind, vehicle-controlled 4-week efficacy clinical trial of twice-daily pimecrolimus 1 % cream in 96 patients, topical calcineurin inhibitor therapy proved to be effective and well tolerated in the treatment of facial seborrheic dermatitis. In another two randomized clinical trials, pimecrolimus 1 % cream proved similar efficacy to topical corticosteroids (hydrocortisone acetate 1 % cream or betamethasone 17-valerate 0.1 % cream). Treatment with topical pimecrolimus also demonstrated longer periods of remission and milder relapses when compared with betamethasone. Pimecrolimus has also been used in comparison to ketoconazole 2 % cream in an open randomized study that showed comparable efficacy. Topical tacrolimus 0.1 % ointment was tried in an open-label 4-week randomized trial against betamethasone 17-valerate lotion and zinc pyrithione 1 % shampoo in 83 patients with scalp seborrheic dermatitis. Tacrolimus ointment showed prolonged efficacy than topical corticosteroids, but the duration of improvement was shorter compared to zinc pyrithione shampoo. Tacrolimus ointment has a highly viscous consistency, which makes it inconvenient to use on the scalp. Application should be limited to lesions of seborrheic dermatitis.

Metronidazole

The effectiveness of 0.75 % topical metronidazole gel is contradictory. In two trials, metronidazole showed greater efficacy than placebo and was equally effective as ketoconazole 2 % cream, while in another study by Koca et al., metronidazole was not found to be superior over placebo in patients with seborrheic dermatitis.

Zinc Pyrithione

Zinc pyrithione has both antifungal and antimicrobial effects. This agent is a common active ingredient in many of the over-the-counter antidandruff shampoos. The available concentration in shampoos is 1 and 2 %, as well as a 1 % cream formulation. In several trials, zinc pyrithione showed lower efficacy compared to ketoconazole. A satisfactory effect was proven when used in combination with ketoconazole.

Lithium Salts

Topical lithium succinate and lithium gluconate may have anti-inflammatory effects. They are effective in treating seborrheic dermatitis in areas other than the scalp. Lithium succinate 8 % ointment showed greater efficacy compared to placebo in the treatment of seborrheic dermatitis in HIV-positive patients. Lithium gluconate 8 % ointment seems to be more effective than ketoconazole 2 %. In an 8-week trial involving 129 patients with facial lesions, lithium gluconate 8 % ointment used twice daily showed better efficacy compared to placebo.

Selenium Sulfide

In a randomized double-blind trial involving 246 patients with moderate to severe dandruff, selenium sulfide 2.5 % shampoo was tested against ketoconazole 2 % shampoo and placebo. Ketoconazole medicated shampoo was better tolerated. Both medicated shampoos showed better efficacy compared to placebo.

Keratolytics

Keratolytics based on salicylic acid (2–6 %) with or without sulfur (2–5 %) help the removal of adherent scales.

Other Topical Treatments

There are few reports of successful treatment of seborrheic dermatitis with benzoyl peroxide, azelaic acid, tacalcitol cream, and MAS064D cream (a nonsteroidal preparation containing multiple active ingredients such as emollients, anti-inflammatory agents, keratolytics, and an antimycotic agent).

Topical Treatments at a Glance

- Topical treatments are the mainstay of therapy.
- The combination of various active ingredients in one single product and the use of rotational therapy are the most effective treatment options.
- The initial and first-choice therapy for seborrheic dermatitis should include topical antimycotics (ketoconazole, bifonazole, miconazole, ciclopirox).
- Topical corticosteroids are useful when applied over a short period, mainly to control erythema and itching.
- Calcineurin inhibitors do not have the side effect profile of corticosteroids. Application should be limited to lesions of seborrheic dermatitis.
- The effectiveness of topical metronidazole gel is contradictory.
- Combination of zinc pyrithione with ketoconazole has proven to be effective.
- Topical lithium salts are effective in treating seborrheic dermatitis in areas other than the scalp.
- Keratolytics are recommended for the removal of adherent scales.

  Selenium and zinc are effective in combination with topical corticosteroids, topical antifungals, or topical immunomodulators.

Systemic Treatments

Orally administered drugs may be used in cases of extensive seborrheic dermatitis and cases resistant to topical treatments.

Oral Antifungal Treatment

Data on the effectiveness of systemic antifungal therapy are limited and not consistent.

The antifungal agents used and their recommended doses are:

- Ketoconazole 200 mg/day for 14–28 days according to the clinical presentation
- Itraconazole 100 mg/day for 21 days
- Terbinafine 250 mg/day for 4 weeks
- Pramiconazole in a single 200 mg dose

Oral ketoconazole 200 mg daily has proven to significantly improve facial seborrheic dermatitis. However, oral fluconazole in a 300 mg single weekly dose has not shown any significantly therapeutic effect.

Itraconazole at an initial dose of 200 mg daily for 1 week, followed by a maintenance single dose of 200 mg every 2 weeks, was useful in patients with moderate to severe seborrheic dermatitis.

Oral terbinafine 250 mg daily has shown greater efficacy on lesions of seborrheic dermatitis in areas other than the face. Due to the possible hepatotoxic effect of systemic antifungals, the benefit of the treatment must be carefully considered.

Pramiconazole is a new triazole agent with potent in vitro antifungal activity against *Malassezia* spp. A single 200 mg dose of pramiconazole shows in vivo efficacy in controlling clinical symptoms of seborrheic dermatitis.

Isotretinoin

Oral isotretinoin as a regulator of seborrhea was suggested for the control of seborrheic dermatitis. Scientific studies on the use of isotretinoin for seborrheic dermatitis have become rare, with the last published in 2003. The doses of the drug used in the study were low (2.5 mg, three times weekly and up to 5 mg/day) with good efficacy. There has been a report on seborrheic dermatitis-like eruption in patients taking isotretinoin for acne.

Systemic Treatments at a Glance

- Oral antifungals are recommended for severe and topical-therapy-resistant seborrheic dermatitis.
- Ketoconazole 200 mg/day for 14–28 days is recommended for seborrheic dermatitis of the face.
- Itraconazole at an initial dose of 200 mg/day for 1 week followed by a maintenance single dose of 200 mg every 2 weeks is recommended for moderate to severe seborrheic dermatitis. An alternative regimen of itraconazole 100 mg/day for 21 days is another option.
- Terbinafine 250 mg/day for 4 weeks is recommended for lesions of seborrheic dermatitis on the trunk.
- Pramiconazole in a single 200 mg dose has shown efficacy in controlling clinical symptoms of seborrheic dermatitis.
- Liver enzymes must be carefully monitored when using systemic treatment with antifungals.
- Isotretinoin in low doses (2.5 mg, three times weekly and up to 5 mg/day) showed good efficacy in seborrheic dermatitis.

Other Treatment Options for Seborrheic Dermatitis

Phototherapy

Ultraviolet B (UVB)

Many patients often notice improvement during the summer months. UVA and UVB light directly inhibit *Malassezia* yeasts cultured from the skin. Narrowband UVB 311 nm is usually used three times per week until clearance or upon completing 2 months of therapy. Patients with widespread seborrheic dermatitis benefit from narrowband UVB phototherapy. The limitations of UVB phototherapy are the frequent visits to a phototherapy unit, a rapid disease relapse appearing usually 2–6 weeks after treatment, burning and itching sensations during phototherapy, and the risks associated with exceeding the maximum lifetime cumulative dose.

Psoralen Plus Ultraviolet A (PUVA)

There have been reports of clearance of seborrheic dermatitis in HIV patients who were administered PUVA treatment (30–262 J/cm^2 every 2–4 weeks). However, there have also been reports of new cases of seborrheic dermatitis appearing during PUVA therapy in patients with psoriasis.

Red and Blue LED Light

Inhibit the growth of *Malassezia* spp. and reduce seborrheic inflammation.

Alternative Therapeutic Approaches

Tea-Tree Oil

Tea-tree (*Melaleuca alternifolia*) oil-based soaps have proven effective in the topical treatment of seborrheic dermatitis due to their potential antifungal effect. They are also available in shampoos for seborrheic dermatitis of the scalp. Rare adverse events have consisted of an occasional irritant dermatitis.

90 % Honey Diluted in Warm Water

Honey is recommended to be gently rubbed in the seborrheic dermatitis lesions for 2–3 min every other day, left on for 3 h before gentle rinsing with warm water.

Fish Oil Supplements

Taking fish oil supplements that contain omega-3 fatty acids may help seborrheic dermatitis. Up to 3 g of fish oil per day is generally considered safe. Fish oil can cause nausea and diarrhea. High doses may increase the risk of internal bleeding.

Patients should be educated to always consult a doctor before adding any alternative treatment of seborrheic dermatitis.

Principles of Treatment at a Glance

- The aim of treatment consists of controlling the inflammation, proliferation of the microorganisms, and the oiliness.
- First-line therapy for seborrheic dermatitis includes local antifungals.
- Topical corticosteroids used for a short course can temporarily relieve itching and erythema.
- Topical calcineurin inhibitors do not have the side effect profile of corticosteroids. Topical application should be restricted to lesions of seborrheic dermatitis.
- Narrowband UVB phototherapy (311 nm) may be efficacious in widespread seborrheic dermatitis.
- Systemic therapy may be used in cases of severe seborrheic dermatitis not responding to topical treatments.
- Wearing smooth-textured cotton clothes helps in avoiding irritation and sweating of seborrheic dermatitis lesions.
- Avoid scratching. Scratching can increase irritation and the risk of infection.
- If one type of medicated anti-dandruff shampoo works for a certain period and then loses its efficacy, try alternating between other types.
- Leave the shampoo on the scalp for the full recommended length of time to allow its ingredients to work.
- Rinse soaps and detergents completely off the body and scalp.
- Use treatments for seborrheic dermatitis exactly as described by the physician.

Seborrhoeic Keratosis

88

António Picoto

Key Points

- Seborrhoeic keratosis, also known as seborrhoeic wart, verruca seborrhoeica senilis or basal cell papilloma, appears as macules and papules, brownish to grey or black, usually symmetrical and predominantly on the face, trunk and extremities.
- It is common in whites and uncommon in black people and Indians.
- The aetiology is unknown.
- Seborrhoeic keratosis is only of cosmetic concern, so treatment should provide a satisfactory cosmetic result. Curettage, cryosurgery, shaving and chemical peeling are among the recommended treatments.

Definition and Epidemiology

Seborrhoeic keratosis, also known as seborrhoeic wart, verruca seborrhoeica senilis or basal cell papilloma, appears as macules and papules, brownish to grey or black.

Sometimes they are polypoid with a "stuck on" appearance and greasy surface with plugged horns, predominantly on the face, chest and back of adult whites.

They are common in whites (third decade onwards) and uncommon in black people and Indians; probably many cases are dominantly inherited. Males and females are equally affected. Black and Asian patients can develop a variant of seborrhoeic keratosis called dermatosis papulosa nigra. This consists of heavily pigmented papules, some pedunculated, on the face, developing as early as adolescence.

While the aetiology is unknown, there are many clinicopathological variants:

- Reticulated seborrhoeic keratosis
- Stucco keratosis
- Clonal seborrhoeic keratosis
- Irritated seborrhoeic keratosis
- Melanoacanthoma
- Dermatosis papulosa nigra

Clinical Presentation

Seborrhoeic keratosis appears exclusively on hair-bearing skin, often in a "Christmas tree" pattern, and mainly on skin rich in sebaceous glands (Fig. 88.1).

It begins as flat brown maculae that slowly transform into greasy papules, with multiple grey or black plugged follicles. The lesions are often located bilaterally and are symmetrical, predominantly on the face, trunk and extremities.

The sudden appearance of a large number of lesions with pruritus may be associated with internal malignancy, and this is the so-called Leser-Trélat sign.

The associated malignancy is typically aggressive and carries a poor prognosis. GI adenocarcinomas are responsible for approximately one-third of the cases and lymph proliferative disorders for about one-fifth of the cases. The entity is controversial because of a simultaneous increased incidence of seborrhoeic keratosis and malignancy in the elderly.

The lesions are benign. There is no evolution towards malignancy, and they become symptomatic when irritated.

They are of cosmetic concern and may cause difficulties when dressing and undressing. There is no spontaneous resolution (Fig. 88.2).

Diagnosis is usually not difficult looking at the characteristics and distribution of the lesions, but on the face early lesions can be difficult to diagnose. One can press the surface of the lesions with the fingernail and confirm their greasy nature.

Dermoscopy is mandatory. We will look for milia-like cysts, pseudofollicular openings and cerebriform structures. There are two different types of milia-like cysts: large ones (cloudy) and smaller ones (starry). Starry milia cysts are prevalent both in seborrhoeic keratosis and melanomas. Cloudy ones are said to have 99.1 % specificity for seborrhoeic keratosis.

Differential Diagnosis

This includes:

- Pigmented nevi
- Actinic keratosis
- Verruca vulgaris
- Pigmented basal cell carcinoma
- Acanthosis nigricans
- Lentigo and lentigo maligna
- Melanoma

Clinical inspection, better done with the help of a dermatoscope, is usually sufficient to establish a firm diagnosis. Reflectance confocal microscopy apparently has a distinct set of criteria for seborrhoeic keratosis.

When doubt persists there should be no hesitation to biopsy for a histological examination.

Fig. 88.1 Seborrhoeic keratoses of the trunk

Fig. 88.2 Seborrhoeic keratosis of the forehead

General Principles of Treatment

It has been mentioned before that seborrhoeic keratosis is only of cosmetic concern, so treatment should provide a satisfactory cosmetic result. The treatment should be explained to the patient and consent obtained. Recommendations for home treatment should be given, preferably in writing.

The aim of the treatment will be to destroy the lesions completely, avoiding recurrence, without much pain and leave a cosmetically acceptable scar.

Recommended Therapies

Curettage

You need a sharp curette and local anaesthesia – lidocaine buffered with potassium bicarbonate. Anaesthetic cream before local injection is also a good option, but you will have to wait 60 min.

If the lesions are multiple and this is generally the case, a plan should be done to act in several sessions.

After curettage there is the problem of stopping the bleeding, and for this pressure with a little peroxide, cautery and CO_2 laser are good options. Observe caution to avoid an ugly scar. Some authors recommend the use of aluminium chloride or Monsel's solution, but there is the risk of staining the skin.

Disposable curettes are best suited for the job, but there is a learning curve with their use.

After the procedure the wound is dressed with an antibiotic or Vaseline.

If the lesion is very thick and papillomatose, then the lesion can be first "cooked" with electrodessication or CO_2 laser followed by curettage.

Cryosurgery

Freezing with liquid nitrogen (about 12 s spray) is also a treatment modality useful for multiple lesions.

Shaving

Shaving excision with scalpel or Gillette blue razor is another possible technique, mainly for thick lesions.

Chemical Peeling

Peeling with TCA from 25 to 35 % can be useful in early thin seborrhoeic keratosis of the face.

In conclusion, there is not a perfect treatment so far for this vexing problem.

Sjögren's Syndrome

89

Athanasios G. Tzioufas
and Haralampos M. Moutsopoulos

Key Points

- Sjögren's syndrome (SS) is a common, chronic autoimmune disorder of unknown origin. The disease affects mainly the exocrine glands, particularly the salivary and lacrimal glands, resulting in dry mouth and eyes.
- In more than a half of patients, it extends beyond the exocrine glands affecting parenchymal organs and small-size arteries producing extraglandular manifestations, including (1) nonspecific, (2) parenchymal organ involvement with periepithelial infiltrates, and (3) vasculitis.
- Skin involvement includes dry skin, flat or palpable purpura, annular erythema, and Raynaud's phenomenon.
- The principal goal in treating the impaired lacrimal and salivary production associated with SS is the successful replacement of glandular secretions.
- Systemic therapy should be considered in patients exhibiting systemic features and tailored to the organ affected and severity including hydroxychloroquine for arthralgias, myalgias, and joint inflammation, methotrexate for florid inflammatory or persistent arthritis, and rituximab. TNFα blockade (infliximab and etanercept) has been proven inefficacious in primary SS in terms of subjective and objective measures of salivary and lacrimal function as well as joint inflammation. Cytotoxic drugs such as cyclophosphamide along with systemic steroid administration (0.5 mg/kg daily) are considered for severe extraglandular manifestations including severe cutaneous vasculitis, glomerulonephritis, and peripheral neuropathy.

Definition and Epidemiology

Sjögren's syndrome (SS) is a chronic autoimmune, systemic disorder. It is characterized by lymphocytic infiltration of the exocrine glands resulting in xerostomia and dry eyes. More than 50 % of patients present with systemic manifestations including arthritis; Raynaud's phenomenon; kidney, liver, and lung involvement; as well as vasculitis. A small (around 5 %) but significant number of patients may develop malignant B-cell lymphoma. The disease presents alone (primary Sjögren's syndrome) or in association

with other autoimmune rheumatic diseases including rheumatoid arthritis and systemic lupus erythematosus.

The two major autoimmune phenomena observed in pSS are (a) lymphocytic infiltration of the affected tissues and (b) B-cell hyperactivity. The latter is manifested by hypergammaglobulinemia and the presence of serum autoantibodies including antinuclear antibodies, rheumatoid factor, cryoprecipitable monoclonal immunoglobulins with rheumatoid factor activity, and antibodies against two ribonucleoproteinic complexes named Ro/SSA and La/SSB, as well as against immunoglobulins (rheumatoid factors).

SS primarily affects women (nine women to every man), mainly in the fourth and fifth decades of life. However, it can occur in people of all ages including children and elderly persons. Epidemiological studies in the general population have shown that SS is a rather common disease since it affects approximately 0.5 % of the total population. Indeed, a thorough review of published epidemiology studies disclosed that the prevalence of the disease ranges from 0.1 % to 4.8 %, with increasing rates in advanced age. Heterogenicity in inclusion criteria, ethnic origin, sample size, and sex distribution between studies contributes to the observed variability.

Basic Concepts of Pathogenesis

As for the vast majority of autoimmune diseases, the leading etiopathogenetic events are yet unknown. It appears that all the interplay between environmental contributors (such as viruses, stress, or hormones) and host's genetic background can lead to inflammatory responses against epithelial tissues. It is highly likely that the disease may develop in three stages: (1) autoimmunity can be triggered by an environmental factor, acting on given genetic background, (2) perpetuation of the autoimmune reactivity becomes chronic through normal immune regulatory mechanisms, and (3) tissue injury occurs as a consequence of the ongoing inflammatory process.

The main body of infiltrating cells in the affected exocrine glands are activated T and B lymphocytes. T cells predominate in mild lesions, and B cells in more severe lesions. Macrophages and dendritic cells also are found. The number of interleukin (IL)-18 positive macrophages is correlated with parotid gland enlargement and low levels of the C4 component of complement, both adverse predictors for lymphoma development. Glandular epithelial cells undergo apoptotic death by signals provided from T cells. Ductal and acinar epithelial cells are activated, playing a significant role in the initiation and perpetuation of the autoimmune injury. In fact, they express class II major histocompatibility complex (MHC) and costimulatory molecules. In addition, the intracellular autoantigens are expressed on cell membranes, thus being able to prime an autoimmune response. Importantly, the epithelial cells produce also inappropriately proinflammatory cytokines and lymphoattractant chemokines necessary for sustaining the autoimmune lesion. In around 20 % of patients, the lesion is organized to ectopic germinal centers containing autoreactive B cells. The epithelial cells express also functional receptors of innate immunity, particularly TLR 3, 7, and 9, that may account for the perpetuation of the autoimmune response. B-cell-activating factor (BAFF) has been found to be elevated in patients with Sjögren's syndrome, especially those with hypergammaglobulinemia. Glandular epithelial cells seem to have an active role in the production of BAFF, since it may be expressed and secreted after stimulation with type I interferon, as well as with viral or synthetic dsRNA. These properties of the epithelial cell introduced the term "autoimmune epithelial," which is the etiologic name of the syndrome.

The triggering factor for epithelial activation appears to be a persistent enteroviral infection (possibly by coxsackievirus strains).

Clinical Presentation

The majority of SS patients display an indolent benign course. The initial manifestations can be nonspecific and usually 6–8 years elapse from the initial symptoms to the full blown development of the disease. The clinical features of SS

can be largely divided into those related to exocrine dysfunction (glandular) and to those affecting other organs beyond the exocrine glands (extraglandular or systemic).

Glandular Manifestations

The principal oral symptom of SS is dryness. Patients describe this as difficulty in swallowing dry food, inability to speak continuously, and a burning sensation. The physical examination shows a dry, erythematous, sticky oral mucosa and atrophy of the filiform papillae. Enlargement of the parotids or other major salivary glands can be seen in 50–60 % of patients.

Ocular involvement is the other major glandular manifestation of SS. Diminished tear secretion leads to the destruction of the corneal and bulbar conjunctival epithelium termed keratoconjunctivitis sicca. The patients describe a burning, foreign-body feeling or a sandy or scratchy sensation under the lids, itchiness, redness, and photosensitivity. Clinical signs include dilatation of the bulbar conjunctival vessels, pericorneal injection, irregularity of the corneal image, and sometimes enlargement of the lacrimal glands.

Involvement of other exocrine glands occurs less frequently and includes a decrease in mucous gland secretions of the upper and lower respiratory tree, resulting in dry nose, throat, and trachea (xerotrachea), and diminished secretion of the exocrine glands of the gastrointestinal tract, leading to esophageal mucosal atrophy, atrophic gastritis, and subclinical pancreatitis. Dyspareunia due to dryness of the external genitalia and dry skin also may occur.

Extraglandular Manifestations

Extraglandular manifestations are seen in many patients with primary SS and divided into (1) nonspecific, (2) parenchymal organ involvement with periepithelial infiltrates, and (3) vasculitis, resulting from the deposition of immune complexes. Nonspecific symptoms include easy fatigue, low-grade fear, myalgias, and arthralgias. Arthritis is seen in 70 % of patients and is nonerosive, leading in some patients to Jaccoud's arthropathy. Raynaud's phenomenon is seen in around 30 % of patients and in some patients may precede sicca manifestations by many years. Pulmonary involvement includes dryness of the tracheobronchial mucosa (xerotrachea) and small airways obstruction. Interstitial disease or pleurisy is uncommon. Acute or chronic pancreatitis is rarely reported. In that case IgG4-related syndrome should be ruled out. Chronic liver disease, resembling stage I of primary biliary cirrhosis, is seen in 2–3 % of patients. Renal involvement includes interstitial renal disease and occasionally glomerulonephritis. Vasculitis is found in approximately 10 % of patients with SS. It affects small, primarily sized vessels. The skin is most commonly affected in the form of palpable purpura, but cases with visceral organ involvement such as the kidney, lungs, and gastrointestinal tract have been described. Neurological manifestations of SS include peripheral sensory or sensorimotor neuropathy as a consequence of vascular involvement. Some cases of myelitis associated with antibody to aquaporin-4 have been described.

Lymphoma is a well-known sequela of Sjögren's syndrome and usually presents later during the course of the illness. Persistent parotid gland enlargement, purpura, leukopenia, cryoglobulinemia, low C4 complement levels, and the presence of IL-18, macrophages, and B cells as well as ectopic germinal centers in minor salivary gland biopsies are predicting factors suggesting the development of lymphoma. Interestingly, the risk factors predicting glomerulonephritis and lymphoma are the same with those that confer increased mortality. Most lymphomas are extranodal, low-grade marginal zone B-cell lymphomas and are usually detected incidentally upon evaluating the labial biopsy. The affected lymph nodes are usually peripheral. Survival before the introduction of B-cell-depleting therapy with chemotherapy is decreased in patients with B symptoms, lymph node mass >7 cm in diameter, and high or intermediate histologic grade.

Skin Involvement

Apart from the eyes and mouth, other mucous membranes as well as the skin may exhibit dryness. Nasal dryness with crusting, vaginal dryness with dyspareunia, cheilitis, and xerosis (dry skin) have been described. Patients with dry skin frequently experience dermal stinging and itching.

Skin biopsy and direct immunofluorescence (DIF) show a pattern consisting of IgG deposits in the basal and suprabasal layers of the epithelium, widespread in the intercellular space and demarcating cell surface membranes.

Purpura is a rather common finding in primary SS patients. Flat purpura is usually seen in hypergammaglobulinemic patients, while palpable purpura is a manifestation of dermal vasculitis. The latter is a predictor factor for lymphoma development in the future.

In recent years, numerous reports from Japan claimed hitherto unreported skin lesions in patients with SS. Annular erythemas consisting of wide elevated erythematosus borders with central pallor are located on the face (especially cheek and periocular skin), upper extremities, and back, occasionally coalescing to form polycyclic patterns. The erythema fades within a few months, leaving no scars or pigmentary changes. There is a striking clinical resemblance to Sweet's syndrome. The most conspicuous histologic finding is the lymphocytic infiltration throughout the dermis around blood vessels and appendices. Annular erythema in primary SS is significantly associated with the presence of serum antibodies against Ro/SSA (100 %) and La/SSB (75 %). The annular erythema in SS differs clinically from the polycyclic annular and papulosquamous erythemas in subacute cutaneous LE (SCLE), especially in its edematous borders without significant scaling.

Raynaud's phenomenon occurs in about 30 % of patients with primary SS and usually precedes the sicca manifestations by many years. SS patients with Raynaud's phenomenon present with swollen hands, but in contrast to scleroderma, they do not experience digital ulcers and telangiectasias.

Pernio-like lesions (chilblain) on the distal extremities were noted in Japanese patients. Reports on other skin disorders are rare: one case in which SS and Sweet's syndrome developed simultaneously and one in which a woman developed poikiloderma atrophicans vasculare after 12 years of SS. Two cases of lipodystrophy have also been reported in patients with SS.

Diagnosis

The diagnosis is made after a careful clinical evaluation in every patient presenting with symptoms of oral and/or ocular dryness. The diagnostic approach consists of a complete systems review, including specific questionnaires to assess oral and ocular dryness, clinical examination, and tests evaluating the degree of exocrine gland dysfunction, the presence of relevant immunological abnormalities, and the extent of organ involvement. Since sicca symptoms can be attributed to several different diseases, the differential diagnosis is rather broad. In clinical practice, investigations that should be offered in patients presenting with sicca symptoms include: (1) assessment of lacrimal gland function by measuring tear production using Schirmer's test (wetting on paper strip of less than 5 mm per 5 min; sensitivity and specificity 76.9 and 72.4 %, respectively) and by staining of the cornea and conjunctiva using rose bengal or the less irritating lissamine green staining, which reveals punctuate or filamentary keratitis lesions, typical of keratoconjunctivitis sicca (KCS) (sensitivity 64.3, specificity 81.7), (2) measurement of unstimulated saliva secretion in a graded tube (less than 1.5 ml/15 min is considered abnormal) (sensitivity 56.1, specificity 80.7), and (3) minor salivary gland biopsy assessing the presence of lymphocytic infiltrates around salivary gland epithelium which is the SS hallmark (sensitivity and specificity 82.4 and 86.2 %, respectively). An average focus score >1 in salivary gland biopsy is considered as a classification criterion for SS. It is calculated as the number of lymphocyte foci per 4 mm^2 surface based on a survey of at least four lobules. A focus is a cluster of at least 50 lymphocytes. Patients should undertake full blood count, serum biochemistry tests, protein electrophoresis, antinuclear antibodies,

antibodies against Ro/SSA and La/SSB autoantigens and rheumatoid factor, as well as viral testing for HCV, HIV, and HTLV-1 virus, infections which can produce a clinical picture resembling SS. Anti-Ro/SSA and anti-La/SSB antibodies can be detected in 70–100 and 35–70 % of patients with SS, with anti-La/SSB being considered a highly specific diagnostic marker for the diagnosis of SS. According to classification criteria for SS, which will be discussed below, the presence of these antibodies along with other features implying the presence of SS is sufficient for establishing SS diagnosis, even in the absence of a positive salivary gland biopsy.

Once SS diagnosis is established, additional investigational tests as cryoglobulins, complement levels, and immunofixation should be also asked, particularly in patients with palpable purpura, peripheral neuropathy, salivary gland enlargement, or in situ demonstration of salivary gland lymphoma. Upper gastrointestinal tract endoscopy; CT scans of the neck, thorax, and abdomen; and bone marrow biopsy should be further offered in order to detect the development and extent of the potentially existing lymphoma.

In order to aid in the classification of the syndrome, the international research community proposed the "European-American consensus group criteria" (EACG), which require the presence of either focal lymphocytic infiltrates in minor salivary glands with a focus score of 1 or more or anti-SSA/SSB autoantibodies in the presence of features suggesting salivary and/or lacrimal gland involvement.

Differential Diagnosis

Differential diagnosis must include other diseases responsible for KCS, xerostomia, and parotid gland enlargement. Sarcoidosis is one of the diseases which can mimic the clinical picture of SS. However, there is a lack of autoantibodies to Ro/SSA or La/SB, and sometimes the minor salivary gland biopsy reveals noncaseating granulomas. Other medical conditions which can mimic SS are lipoproteinemias (types IV and V), chronic graft-versus-host disease, amyloidosis, HIV infection, as well as hepatitis C infection. Major salivary enlargement, particularly in patients without anti-Ro/SSA and anti-La/SSB autoantibodies, should raise the suspicion of IgG4-related syndrome which may present also as chronic pancreatitis, interstitial nephritis, retroperitoneal fibrosis, and aortitis.

General Principles of Treatment

General Therapeutic Guidelines

SS remains an incurable disease, since no therapeutic modality that can alter the course of the disease has been identified. Careful follow-up of patients, including regular outpatient visits; close collaboration with rheumatology, ophthalmology and oral medicine, concentration on simple measures to relieve desiccation, gives the most satisfactory results in the therapy of SS.

Treatment of patients with SS is divided into two parts: (1) treatment of glandular manifestations and their consequences and (2) treatment of the extraglandular manifestations.

Treatment of Glandular Manifestations

The treatment of xerostomia should accomplish the following:

1. Maintain oral hygiene to prevent dental carries
2. Careful examination to diagnose and treat oral candidiasis
3. Systemic therapy to stimulate glandular secretions
4. Use of saliva substitutes

The principal goal in treating the impaired lacrimal and salivary production associated with SS is the successful replacement of glandular secretions. Therapeutic measures for dry eyes include local stimulators of tear secretion, protective bicarbonate-buffered solutions, artificial lubricants, and supportive operative procedures. Cyclosporin A 2 % in olive solution in the form of eye drops has been shown to be relatively effective in placebo-controlled clinical trials. The

choice of therapeutic procedure used depends on the experience the ophthalmologist may have of the disease. Systemic therapy to stimulate glandular secretions includes the use of cholinergic agonist pilocarpine hydrochloride (5 mg four times daily). Contraindications of pilocarpine include pregnancy, history of gastrointestinal ulcer, arrhythmias, and severe, poorly controlled hypertension. Other agonists such as cevimeline "Evoxac" have been shown to improve symptoms of dry mouth. The recommended dose is 30 mg three times a day, and the drug should be used with caution in patients with cardiovascular disease.

Treatment of Extraglandular Manifestations

Systemic therapy should be considered in patients exhibiting systemic features as previously described and tailored to the organ affected and severity. It should be however emphasized that management of extraglandular manifestations is mainly based on case series, open-label studies, and expert opinion based on biological rational and on experience in other autoimmune diseases, given the lack of robust data from controlled studies. Hydroxychloroquine is effective in improving arthralgias, myalgias, and joint inflammation, while methotrexate can be used in cases of florid inflammatory arthritis; for cases of persistent arthritis, rituximab has been shown to significantly improve the tender and swollen joint count. TNFα blockade (infliximab and etanercept) has been proven inefficacious in primary SS in terms of subjective and objective measures of salivary and lacrimal function as well as joint inflammation with augmentation of the already activated type I interferon/B-cell-activating factor axis possibly accounting for this failure. Cytotoxic drugs such as cyclophosphamide along with systemic steroid administration (0.5 mg/kg daily) are considered for severe extraglandular manifestations including severe cutaneous vasculitis, glomerulonephritis, and peripheral neuropathy. Given that B-cell activation is a major finding of the disease, targeted anti-B-cell therapies are a thoughtful approach in patients with vasculitis. Improvement in fatigue scores in a randomized controlled trial and demonstrable efficacy in extraglandular features including cryoglobulinemic vasculitis and peripheral neuropathy with reduction of disease activity indices suggest that B-cell depletion treatment is a promising therapeutic strategy in SS.

Treatment of Skin Manifestations

Patients with dry skin should refrain from daily use of soap, except for skin creases, and from too frequent bathing, especially in hot water. Bath oils and frequent use of emollients (i.e., greases based on lanolin, lanolin/paraffin mixtures, or creams based on emulsifying wax, Macrogol) are beneficial. Increasing the humidity of the environment may also be helpful. Vasculitis limited to the skin (leukocytoclastic vasculitis), which manifests as palpable purpura, does not require specific therapy. Avoidance of cold exposure or emotional stress, together with nifedipine 5–10 mg three times daily, is indicated for decreasing the severity and frequency of Raynaud's phenomenon. Vaginal dryness is a cause of painful intercourse. Vaginal lubricants such as K-Y jelly or the recently available vaginal inserts are helpful. Patients should avoid cortisone creams. In postmenopausal women, estrogen preparations are recommended.

Franco Rongioletti

Abbreviations

ACTH	Adrenocorticotropic hormone
APECED	Autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy
DD	Diabetic dermopathy
FSH	Follicle-stimulating hormone
GA	Granuloma annulare
GH	Growth hormone
HMG-CoA	Hydroxy-methylglutaryl coenzyme A
IGF-1	Insulin-like growth factor 1
LH	Luteinizing hormone
MEN1	Multiple endocrine neoplasia type 1
NL	Necrobiosis lipoidica
PTH	Parathyroid hormone
TSH-(R)	Thyroid-stimulating hormone (receptor)
TSI	Thyroid-stimulating immunoglobulin

Key Points

- As skin manifestations may reflect a life-threatening endocrine or metabolic disease, identifying the underlying disorder is important, so that patients can receive corrective rather than symptomatic treatment.
- Skin signs may be also a marker for the success of therapeutic interventions as it occurs for hyperpigmentation in Addison disease.
- Treatment of skin manifestations in hormone-deficiency conditions relies on the management of endocrine disease that consists of replacing the individual peripheral hormones.
- Treatment of specific conditions such as pretibial myxedema (thyroid dermopathy) or diabetes-associated skin diseases such as necrobiosis lipoidica, granuloma annulare, or perforating dermatosis is difficult, and there is no standard of treatment.
- Controlling hypersecretion of pituitary hormones secondary to adenomas with medical or surgical care improves most cutaneous manifestations of acromegaly, Cushing disease, and hyperprolactinemia.

- Parathyroid surgery should be considered for all patients with symptomatic hyperparathyroidism and associated skin lesions such as calciphylaxis in chronic renal failure.
- Treatment of xanthomas involves normalization of lipid levels but also surgical procedures.
- Encouraging weight loss and treating metabolic syndrome in obese patients improve also associated skin conditions.

Definition and Epidemiology

Endocrine diseases are any diseases caused by the abnormal function of endocrine glands, including the adrenal, pituitary, thyroid, and parathyroid glands. Metabolic disorders involve the disruption of metabolic processes and are caused by genetic errors, hormonal dysfunction, and/or mineral or vitamin deficiency states. Common metabolic disorders include diabetes, hyperlipoproteinemia, and obesity.

Basic Concepts of Pathogenesis of Endocrine/Metabolic Diseases

Adrenal disease includes Cushing syndrome and Addison disease. Cushing syndrome describes the symptoms related to overexposure to glucocorticoids. Currently, the most common cause of Cushing syndrome is due to exogenous or iatrogenic hypercorticism. The term Cushing syndrome also includes cases of hypercortisolism secondary to functional tumors of the adrenal cortex. The designation "Cushing disease" includes cases of hypercortisolism due to overproduction of ACTH as a result of either pituitary overproduction or ectopic ACTH production. Addison disease is defined as primary adrenal gland insufficiency. In Addison disease, usually of autoimmune origin, the ability of the adrenal cortex to produce glucocorticoids (cortisol) and mineralocorticoids (aldosterone) is compromised, resulting in increased levels of pituitary ACTH.

Two main types of thyroid dysfunction can be encountered: hyperthyroidism (sometimes assimilated to thyrotoxicosis, in which the levels of T_4, T_3, or both are elevated) and hypothyroidism caused by a deficiency of them. Almost 60 % of cases of thyrotoxicosis are represented by Graves' disease that is an autoimmune disorder with a variety of circulating antibodies including thyroid-stimulating immunoglobulin (TSI), which binds to TSH-(R) and activates the thyroid hormone synthesis and release and induces the thyroid to grow. Pretibial myxedema and thyroid acropachy are typical manifestations of hyperthyroidism, in particular of Graves' disease. Pathogenesis of pretibial myxedema is unclear, but it appears that pretibial fibroblasts are targets of the autoimmune attack. Trauma on the legs, which result in cytokine release from inflammatory cells, arterial or venous insufficiency, and smoking may be favoring factors.

Hypothyroidism may result from a primary insufficient hormone production by the gland or from a secondary failure of TSH pituitary secretion from the pituitary gland. The most common cause is Hashimoto thyroiditis. Generalized myxedema is the most common skin manifestation of hypothyroidism.

Pituitary gland diseases include an excessive secretion of pituitary hormones as well as hormone deficiency. The main manifestations of pituitary gland diseases are acromegaly, hyperprolactinemia, Cushing disease, and hypopituitarism. Acromegaly is the clinical syndrome that results from excessive secretion of growth hormone. In more than 95 % of cases, the primary cause is a secreting pituitary adenoma. Tissue hyperplasia is the hallmark of the syndrome and is a consequence of the stimulation of growth hormone that promotes sulfation of collagen and synthesis of RNA and DNA. Prolactin is a pituitary hormone that plays a fundamental role in a variety of reproductive functions. It is an essential factor for normal production of breast milk following childbirth. Hyperprolactinemia is a commonly encountered clinical condition due to a prolactin-secreting adenoma (prolactinoma).

Several drugs may result in a significant increase in prolactin serum concentration such as antipsychotic, antidepressant with serotoninergic activity, prokinetics, opiates, estrogens, antiandrogens, antihypertensive drugs, H2-receptor antagonists, anticonvulsants, and cholinomimetics. The term "Cushing disease" is reserved for the pathological condition that is caused by excessive secretion of ACTH by a pituitary adenoma. Roughly, two thirds of the cases of endogenous Cushing syndrome are caused by "Cushing disease." Hypopituitarism is a condition in which there is diminished or absent secretion of one or more pituitary hormones, resulting either from a primary disorder of the secretory cells of the anterior pituitary gland or as a secondary consequence of reduced stimulation by the releasing hormones of the hypothalamus. When the deficiency of anterior pituitary hormones is generalized, the condition is referred to as panhypopituitarism. The most common cause is a pituitary tumor (chromophobe adenoma, craniopharyngioma), but vascular abnormalities (ischemic necrosis), granulomatous inflammation (sarcoidosis), autoimmune disorders (autoimmune hypophysitis), trauma (stalk destruction), infections (syphilis, tuberculosis), Langerhans cell histiocytosis, congenital disorders (Rathke's cleft cyst), and iatrogenic damage (surgery, radiotherapy, ipilimumab) also cause hypopituitarism. A particular well-described cause of acquired hypopituitarism is postpartum pituitary necrosis or Sheehan's syndrome.

Parathyroid hormone (PTH) is secreted by parathyroid glands as a polypeptide which increases calcium levels in the blood through parathyroid receptors in bones, kidneys, and intestines. The condition of elevated blood levels of PTH is known as hyperparathyroidism. If the cause is the parathyroid gland, it is called primary hyperparathyroidism, which may be caused by parathyroid adenomas, parathyroid hyperplasia, and parathyroid cancer. If the elevated levels of PTH do not involve the gland, it is known as secondary hyperparathyroidism. Tertiary hyperparathyroidism results from hyperplasia of the parathyroid glands with subsequent lack of response to serum calcium levels. Both secondary and tertiary hyperparathyroidism are most often seen in patients with chronic renal failure.

Hypoparathyroidism is an endocrine disorder characterized mainly by hypocalcemia due to inadequate parathyroid hormone (PTH) secretion or less often by unresponsiveness to elevated PTH levels (pseudohypoparathyroidism). It may be congenital or acquired. Postsurgical hypoparathyroidism is the most frequent acquired form, but other causes include autoimmunity.

Diabetes is characterized by high serum glucose levels and disturbances of carbohydrate and lipid metabolism that is estimated to affect 151 million people. Clinically, diabetes mellitus can be classified as type 1 and type 2. Type 1 diabetes mellitus, characterized by a specific autoimmune destruction of the insulin-secreting β cells in the pancreatic islets, comprises 5–10 % of all diabetes. Type 2 diabetes mellitus, which accounts for 80–90 % of all cases, affects older and overweight patients and is characterized by a resistance to the action of insulin and inadequate insulin secretion from the pancreas. Cutaneous manifestations are common in diabetes mellitus, with approximately 30 % of patients experiencing some cutaneous involvement during the course of their illness. They can be classified as (I) noninfectious, (II) infectious, (III) related to complications due to vasculopathy and neuropathy, and (IV) related to complications of diabetes treatment. Patients with type 2 diabetes are more prone to develop skin infections, whereas those with type 1 more often have autoimmune-related diseases. The etiopathogenesis of most of noninfectious skin manifestations of diabetes is unknown. Diabetic microangiopathy and neuropathy, immunologic reactions including antibody-mediated vasculitis and Th1 inflammatory-delayed reaction, trauma, genetic component, and irreversible glycosylation of collagen with resistance to degradation by collagenase can play a role.

Skin manifestations can be found in both primary (hereditary) hyperlipidemia and secondary hyperlipidemia (e.g., hyperlipidemia in hypothyroidism or with protease inhibitor administration). Indeed, many drugs can cause hyperlipidemia, including retinoids such as isotretinoin for acne or bexarotene for mycosis

fungoides. The major dermatologic manifestations in hyperlipidemia are xanthomas, tumors comprised, at least in part, of lipid-laden histiocytes.

Obesity has a profound impact on the development of skin manifestations. It causes abnormalities in skin barrier function, sebaceous glands and sebum production, sweat glands, lymphatics, collagen structure and function, wound healing, microcirculation and macrocirculation, and subcutaneous fat and is implicated in a wide spectrum of dermatologic diseases.

Fig. 90.1 Hyperpigmentation of lips and gums in autoimmune Addison disease

Clinical Presentation of Skin Disease in Endocrinological/ Metabolic Diseases

Adrenal Disease

The cutaneous manifestations of hypercortisolism in Cushing syndrome include an accumulation of fat tissues with a characteristic distribution (facial, truncal, and back of the neck) causing the "moon face" with plethora and rubeosis over the cheeks and "buffalo hump." Violaceous striae extending greater than 1 cm in diameter on the abdomen and lower flanks are a pathognomonic sign. The skin eventually becomes atrophic and fragile. Atrophy results in easy bruising manifesting with petechiae and ecchymoses over the extremities. Hyperpigmentation is a feature of adrenocorticotropic hormone (ACTH)-dependent Cushing disease, while it is not a feature of Cushing syndrome due to primary adrenal hypercortisolism. Other skin manifestations include the increased risk for infection and delayed wound healing. The most common skin manifestation of Addison disease is hyperpigmentation, presenting as scattered hyperpigmented macules, diffuse homogenous hyperpigmentation, or hyperpigmentation of the palmar creases and flexural areas. Isolated hyperpigmentation can also involve friction sites, recent scars, genital skin, areolae, and oral mucosa (Fig. 90.1). Darkening of preexisting nevi and longitudinal pigmented bands on the nails has also been reported.

Thyroid Disease

In hyperthyroidism, the skin is smooth, soft, warm, and moist with increased pigmentation, especially on the palms and soles. There is a flushed face, increased sweating, and accelerated nail growth. Skin manifestations are more prominent in Graves' disease and are typically represented by the triad of pretibial myxedema, thyroid acropachy, and exophthalmos in 30 % of patients. Pretibial myxedema occurs up to 14 years after ophthalmopathy, but it has also been reported in patients with hypothyroidism. Its incidence peaks in the fifth to sixth decades of life. Myxedema may also involve other skin areas, such as the arms, the head, the neck, and elsewhere on the legs. There are four main clinical variants of pretibial myxedema: diffuse, nonpitting edema (43 %), plaque-type (27 %), nodular (18 %), and elephantiasis (5 %).

Thyroid acropachy occurs up to 25 years after the onset of thyroid disease and often after hyperthyroidism has been treated. Women are affected four times as often as men. It consists in digital clubbing and diaphyseal proliferation, which on radiograph appears as irregular, lacy, bubbly new bones. Onycholysis, spoon nails, and hippocratic nails may be observed.

Primary generalized myxedema is the most common skin manifestation of hypothyroidism.

In the adult form, fatigue and weight gain, cold intolerance, hoarseness of voice, physical slowness, mental retardation, and constipation are common features. The face is round with periorbital edema, enlarged and protruding lips, macroglossia, and a broad nose. Cold, nonpitting edema involves also the hands and feet. The skin is usually thick, yellowish (due to carotenemia), cold, and dry with livedo on the extremities. Hairs are dry, coarse, and brittle contributing to the diffuse or partial alopecia of the scalp, groin, and even lateral eyebrows. Nails are brittle and thick and grow slowly. Bruising is easy with poor wound healing.

Pituitary Gland Disease

In patients with acromegaly, the skin is thickened and has a doughy feel due to dermal mucin accumulation and edema. The main clinical features are broadened hands and feet with widened, thickened, and stubby fingers. The facial aspect is typical with coarse features including a widened nose, thick lips, frontal bossing, and deep facial lines. Oily skin with widened skin pores and hypertrichosis are also frequent findings, while acne is a less common feature. The skin is also wet with an offensive body odor due to excessive eccrine and apocrine hyperhidrosis leading to a heightened incidence of abscesses in the axillae and intergluteal cleft. Numerous pigmented skin tags are found in up to 45 % of patients. Occasionally, acanthosis nigricans is also a finding. Cutis verticis gyrata, a scalp condition where there are convoluted folds and deep furrows that resemble the surface of the cerebral cortex, can be another sign of acromegaly. The scalp hairs are usually sparse in late stages. A relationship between psoriasis and acromegaly has been reported, based upon an increase of serum GH in some psoriatic patients and an improvement of the dermatitis after surgical pituitary tumor excision or after treatment with somatostatin or dopamine analogues.

The most frequent symptoms of hyperprolactinemia are decreased libido, infertility, oligomenorrhea/amenorrhea, and galactorrhea in women and decreased libido, infertility, gynecomastia, or impotence in men. The skin in hyperprolactinemia becomes thickened, coarse, and greasy, with enlarged pores. Acne vulgaris and seborrhea may develop; androgenetic alopecia may occur also in children and adolescents, where the straight hairline conforms to the adult configuration (calvities frontalis adolescentium). Hyperprolactinemia is one recognized cause of hypertrichosis or hirsutism occurring on the extremities, anterior chest, abdomen, lower back, and beard area.

The cutaneous manifestations of Cushing disease are superposable to those of adrenal Cushing syndrome. Hyperpigmentation is more frequent with Cushing disease and almost absent with adrenal Cushing syndrome. Hypertrichosis is common as well as acne, but, different from acne vulgaris, the lesions are monomorphic, without comedones and cysts. Associated features in women are clitoridomegaly and androgenetic alopecia with male pattern.

Most of the dermatological signs and symptoms of hypopituitarism are similar to those that occur with a primary deficiency of that gland. Thyroid-stimulating hormone (TSH) deficiency results in signs and symptoms of hypothyroidism. In addition to amenorrhea and erectile dysfunction, deficiency of gonadotropins such as luteinizing hormone (LH) and follicle-stimulating hormone (FSH) results in loss of body hair, which is observed in all patients early in the course. Scalp hair tends to be fine and dry, and there may be generalized thinning. Growth hormone (GH) deficiency causes atrophic, dry, and pruritic skin that may be easily traumatized with a delayed time of wound healing. ACTH deficiency gives rise to signs similar to those found in adrenal insufficiency except for the absence of hyperpigmentation.

Cutaneous manifestations in parathyroid-related diseases are rare in sporadic cases but not unusual in familial syndromes. Multiple endocrine neoplasia type 1 (MEN1), also known as Wermer syndrome, is an autosomal dominant entity characterized by the combination of tumors of the anterior pituitary gland, parathyroid glands, and endocrine pancreas. MEN1 is caused by the

loss of function germline mutations in the MEN1 gene mapped to chromosome 11q13, which encodes a protein named menin that acts as a tumor suppressor gene. Cutaneous neoplasms include collagenomas, angiofibromas, melanomas, and lipomas.

In hyperparathyroidism, metastatic calcification occurs as a result of hypercalcemia or hyperphosphatemia. Calcium deposits can be found in the skin, subcutaneous tissues, muscle, tendon, and internal organs. Calciphylaxis is a syndrome usually fatal due to infectious complications and is seen in the setting of end-stage renal disease in patients on dialysis or postrenal transplant. Patients initially develop violaceous, mottled patches and plaques that resemble livedo reticularis on the abdomen, thigh, and hips, which frequently ulcerate. Calciphylaxis can also present with acral ischemia of the fingers, toes, or penis. Proximal location of the necrosis is associated with a mortality rate of 63 %. In calciphylaxis the essential feature is the calcification of dermal and subcutaneous small blood vessels (venules and arterioles).

Signs and symptoms of hypocalcemia are the most prominent features of all forms of hypoparathyroidism; nevertheless, most patients with slowly progressive hypocalcemia remain asymptomatic. Dermatological findings related to hypoparathyroidism are usually mild and nonspecific including xerosis, scaling, edema, rough-fragile hair, alopecia, and mild onychodystrophy. Rarely eczematous dermatitis and hyperkeratotic and maculopapular eruptions have been described. Autoimmune polyendocrine syndrome type has also been described under the names of autoimmune polyendocrinopathy-candidiasis-ectodermal dystrophy (APECED). Its major components are hypoparathyroidism, autoimmune adrenal insufficiency, and chronic mucocutaneous candidiasis.

Diabetes mellitus includes many skin-associated conditions. Necrobiosis lipoidica (NL) is a chronic granulomatous condition that usually appears in the third and fourth decades and is three times more common in women. Although NL occurs in only 0.3–1.6 % of diabetics, it precedes the onset of diabetes mellitus in 15 % of patients, and 75 % of patients with NL have or will develop diabetes mellitus. The lesion is characterized by a non-scaling plaque with a yellow atrophic center, surface telangiectases, and erythematous or violaceous border that may be elevated (Fig. 90.2). In most cases, the lesions are bilateral and confined to the shins. Ulceration occurs in up to 35 % of cases, resulting in pain. Rarely, squamous cell carcinoma has been reported in older, ulcerated lesions.

Diabetic dermopathy (DD) (i.e., shin spots, pigmented pretibial papules) is the most common cutaneous manifestation of diabetes occurring in 7–70 % of all diabetic patients. DD is commonly seen in diabetics with other end-organ damage such as retinopathy, neuropathy, nephropathy, and coronaropathy. Lesions consist of asymptomatic, bilateral, asymmetrical, well-demarcated, annular or irregular atrophic, brownish macules of 4–12 mm in diameter on the shins.

Granuloma annulare (GA) is a benign self-limited, granulomatous inflammatory disease. A weak link with type 1 diabetes has been demonstrated. GA has also been associated with autoimmune diseases, lymphoproliferative conditions, and solid tumors. GA is typically a papular disease which can be divided into a localized, disseminated (more than ten lesions involving

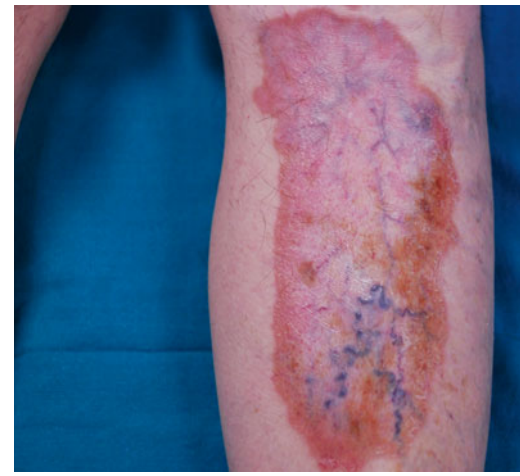

Fig. 90.2 Necrobiosis lipoidica on the shin in a patient with insulin-dependent diabetes

trunk and limbs), or linear type. The most common presentation is the localized, papular form (80 % of cases) that occurs before the age of 30, most commonly in children, and it is twice as often in females. The lesions typically are located on the dorsa of the hands and feet and are characterized by multiple, small, skin-colored or erythematous papules that coalesce into an arcuate or annular pattern. Disseminated, papular GA occurs in 15 % of cases, prevailing in middle-aged and elderly patients. Disseminated GA is the most common clinical pattern in HIV infection. Other main clinical variants include: perforating type with central umbilication or crusts and subcutaneous (deep) type (also known as pseudorheumatoid nodule), most commonly observed in children.

Diabetic thick skin is seen both in type 1 and type 2 diabetic patients. Two forms are described: scleredema and diabetic hand syndrome, which share a common histopathology characterized by thickened dermis and deposition of mucin.

Scleredema diabeticorum occurs in patients with obesity and long-standing, poorly controlled diabetes. The clinical findings are characterized by asymmetric nonpitting induration of the posterolateral aspects of the neck and upper back.

Thickening of the skin on the dorsum of the hands, also known as diabetic hand syndrome or diabetic sclerodactyly, occurs in both diabetic type 1 and diabetic type 2 patients. Clinical presentations start with pebbled knuckles (or Huntley papules) that are multiple minute papules, grouped on the extensor side of the fingers, on the knuckles, or on the periungual surface, and progress to stiffness of the metacarpophalangeal and proximal interphalangeal joints, limiting joint mobility.

Bullosis diabeticorum is a noninflammatory blistering condition occurring in patients with type 2 diabetes. Diabetic bullae most often present as painless, tense, superficial bullae that occur in an acral distribution, mostly on the legs and feet. Direct immunofluorescence studies are negative.

Acquired perforating dermatosis is a rare disorder seen in adult patients, especially those presenting with type 2 and type 1 diabetes mellitus (50 %) and with chronic renal failure (73 %). It is characterized clinically by itching and hyperkeratotic, sometimes umbilicated, or follicular papules and nodules with a central core, situated primarily on the extensor surfaces of the lower and upper extremities, often in a linear fashion. The histological features are not uniform and may resemble any of the four classic perforating disorders: elastosis perforans serpiginosa, reactive perforating collagenosis, perforating folliculitis, or Kyrle disease. This classification is based primarily on the nature of the eliminated material.

Acanthosis nigricans is a cutaneous manifestation of insulin-resistant diabetic patient and may indicate increased risk of type 2 diabetes mellitus. Insulin resistance is the most common association of acanthosis nigricans in the younger age population. Acanthosis nigricans presents as hyperpigmented, velvety plaques involving typical areas such as the posterior neck, axilla, and flexural surfaces.

Hyperlipoproteinemia

The major dermatologic manifestations in hyperlipidemia are xanthomas, tumors comprised, at least in part, of lipid-laden histiocytes including planar xanthomas, tuberous xanthomas, and tendinous xanthomas. Several xanthomas are considered pathognomonic for specific hyperlipidemia disorders, e.g., planar xanthomas in an intertriginous distribution, especially finger web spaces, are pathognomonic for homozygous familial hypercholesterolemia. There are three major subtypes of planar xanthomas: xanthelasmas, intertriginous xanthomas, and palmar crease xanthomas (xanthoma striatum palmare). Eruptive xanthomas are characteristically associated with secondary hyperlipidemia, particularly elevated chylomicrons (of which triglycerides are the principal element) as may be found in poorly controlled diabetes mellitus. Classically they will spontaneously resolve after several weeks. Tuberous xanthomas can involve the elbows, knees, and buttocks. Although familial

dysbetalipoproteinemia (type III hyperlipoproteinemia) is the most common setting, tuberous xanthomas may present in homozygous or heterozygous familial hypercholesterolemia. Tendinous xanthomas present as indurated, flesh-colored nodules that arise slowly over the years and involve the tendons, ligaments, and fascia, in particular the Achilles tendon and extensor tendon of the hands and feet. The most common association is with homozygous familial hypercholesterolemia, for which they are considered a hallmark.

Obesity

Main cutaneous manifestations of obesity include acrochordons, adiposis dolorosa, hidradenitis suppurativa, lymphedema, acanthosis nigricans, striae distensae, and plantar hyperkeratosis. Acrochordons are commonly seen on the neck, axillae, and groin of obese individuals. Adiposis dolorosa, or Dercum's disease, is a rare condition that commonly occurs in obese, middle-aged women. It is characterized by multiple, bilateral, painful lipomas that occur more commonly on the trunk and lower extremities, especially around the knees. Hidradenitis suppurativa is a painful, chronic disease characterized by folliculitis with abscesses, fistulas, and scarring occurring in the apocrine gland-bearing skin of the axillae and groin (Fig. 90.3). Hidradenitis suppurativa affects about 2 % of the population and the majority of patients are obese. Lymphedema can occur secondary to the obesity itself and is seen in the lower extremities and/or large abdominal pannus of extremely obese individuals. Over time, the skin becomes thickened, hyperkeratotic, and fibrotic. Acanthosis nigricans is the most common skin manifestation of obesity, and its incidence and severity tend to increase with the degree of obesity. Plantar hyperkeratosis is a diffuse thickening of the stratum corneum in a horseshoe pattern, affecting the heel, foot arch area, and plantar-medial aspect of the great toe at the level of the interphalangeal joint, and it is considered the most common skin finding in obese patients.

Fig. 90.3 Hidradenitis suppurativa on the groins in an obese patient

General Principles of Treatment

Adrenal Disease

When Cushing syndrome is due to glucocorticoids that are taken for another disease, discontinuing the glucocorticoids will resolve or improve symptoms, with the exception of striae distensae. The hyperpigmentation of Addison disease is very responsive to treatment with physiologic levels of glucocorticosteroids and is one of the more sensitive indices to monitor maintenance therapy doses of replacement glucocorticoids.

Thyroid Disease

Pretibial myxedema may benefit from corticosteroids either in occlusive medication or intralesional injection (10 mg/ml monthly) which are considered the first treatment of choice, especially in early phases. Treatment is less effective as duration and extent of disease is increased. A program of complete decompressive physiotherapy including manual lymphatic drainage, application of multilayered low-stretch bandaging, and intermittent pneumatic compression results in significant benefit. Octreotide, an insulin-like growth factor 1 antagonist, with and without surgical shave removal has been tried, but this is an expensive therapy whose benefit seems questionable. Surgical removal with skin graft can be followed by recurrences. Intravenous

immunoglobulins seem to be a promising therapy especially in the elephantiasic forms. In treatment-resistant elephantiasic thyroid dermopathy, plasmapheresis with and without immunosuppression (e.g., rituximab) has been used in anecdotal cases with variable results. Oral pentoxifylline may be considered only as adjuvant therapy. Treatment for the associated hyperthyroidism does not improve the cutaneous lesions, and, often, localized myxedema develops after treatment. After a follow-up of 25 years, up to 70 % of mild untreated and 58 % of treated severe cases achieved complete or partial remission. Localized myxedema may clear also spontaneously. Tobacco cessation, weight management, and avoidance of skin trauma should always be recommended. Management of thyroid acropachy is similar to dermopathy. Acropachy usually remains stable over the years without complaints in the majority of patients. In 14 % it resolves and in 9 % the condition improves.

In generalized myxedema, symptoms subside with thyroxine administration and recur if it is discontinued. Overall, the most common problem in hypothyroidism is dryness of the skin. It is important to use a gentle cleansing soap with light abrasive properties and to moisturize the skin with petrolatum-based creams, urea (10–20 %), or alpha hydroxy acids.

Hair loss may be a diagnostic problem before becoming a therapeutic challenge. It is essential to distinguish hair problems due to insufficient thyroid hormones (hair dull and brittle) from hair loss as a sign of a paralleling autoimmune attack (telogen effluvium). In the first instance, thyroid hormone administration is mandatory, while in the second a corticosteroid medication, possibly topical, may be beneficial in the long term (at least 4 months).

Pituitary Gland Disease

Controlling GH and insulin-like growth factor 1 (IGF-1) oversecretion improves most cutaneous manifestations of acromegaly, although a full regression is difficult to be attained, especially in patients with long-lasting disease. Facial features improve and puffiness decreases. Ring size decreases along with shoe size, and acanthosis nigricans, cutis verticis gyrata, and psoriasis also improve.

The cutaneous manifestations of hyperprolactinemia improve with systemic therapy. Medical treatment with dopamine agonist drugs (bromocriptine, 10–15 mg daily) is currently the gold standard approach both for microprolactinomas and macroprolactinomas. Bromocriptine as a treatment for prolactinoma has been associated with good therapeutic response of psoriatic lesions on anecdotal basis.

In Cushing disease, the severity of the manifestations does not always correlate with the biochemical indices of the disease. With the exception of striae distensae, cutaneous effects of endogenous hypercortisolism completely heal or improve within the first year after surgical cure of the disease, especially in children.

Concerning hypopituitarism, partial relief from skin dryness can be obtained with emollient creams, but the real treatment is the management of disease that consists of replacing the individual peripheral hormones through oral, transdermal, intramuscular, intranasal, or subcutaneous routes. It is essential that patients are aware about the importance of hormone supplementation and (in the case of cortisol) about the requirement for dosage modifications during acute illness or stress.

Parathyroid Disease

Parathyroid surgery is the standard treatment for all patients with symptomatic hyperparathyroidism in whom there is a reasonable life expectancy. In asymptomatic patients with hyperparathyroidism, surgery is recommended if serum calcium is 1 mg/dL above the upper limit of normal, there is marked hypercalciuria, creatinine clearance is reduced, bone density is reduced, and the patient is younger than 50 years. In sporadic hyperparathyroidism, single-gland parathyroidectomy of the identified adenoma is the recommended approach. For patients with familial hyperparathyroidism, there has to be

balance between the risk of optimal surgical procedures and the morbidity caused by permanent hypoparathyroidism. In the clinical context of renal failure, parathyroidectomy is recommended for symptomatic patients. Recommendations for the treatment of calciphylaxis include the correction of hypercalcemia and hyperphosphatemia, hyperbaric oxygen, appropriate wound care associated with the adequate use of antibiotics, and pain management. Aggressive debridement of cutaneous ulcers improves the outcome of calciphylaxis patients. Recently new medical treatments emerged aiming to reduce the serum concentration of sodium phosphate and to prevent precipitation and calcification. Sodium thiosulfate, a chelating agent with antioxidant efficacy, has been used intravenously in calciphylaxis patients with >90 % of positive result. In hemodialysis patients, improvement in skin ulcers and pain was seen in about 70 %. Nevertheless, sodium thiosulfate was unable to decrease high mortality rate of 71 %. Thrombolytic tissue plasminogen activator has been also tried as a useful adjunctive treatment, and bisphosphonate has also been suggested for mild cases.

Benign cutaneous tumors in the setting of MEN1 including collagenomas, angiofibromas, and lipomas are excised only for cosmetic purposes. Treatment of hypoparathyroidism focuses on correcting the underlying cause, and pharmacologic treatment depends on the nature and severity of the disease. Severe symptoms require intravenous calcium and additional therapy according to each case (oxygen and diuretics for secondary heart failure, etc.). Oral calcium is appropriate for milder cases along with a low-phosphate diet and vitamin D and analogues. Correction of the underlying disease and metabolic imbalances may be a sufficient therapy for skin manifestations, and dermatological basic interventions may be unnecessary other than routine moisturizing for mild cases of xerosis and pruritus. Therapy of chronic candidiasis in autoimmune polyendocrine syndrome involves long-term systemic antifungals (fluconazole, itraconazole) in view of the inadequate response to standard topical medications.

Diabetes Mellitus

NL tends to be chronic. No randomized controlled studies have demonstrated any particularly effective therapy. Topical and intralesional corticosteroids are empirically considered as first-line treatments, lessening the inflammation of early active lesions and the active borders, but worsening the atrophy. Many therapies have been tried with variable success including topical tacrolimus, topically applied bovine collagen, mycophenolate mofetil, cyclosporin A, hydroxychloroquine, UVA1 therapy, photodynamic therapy, and pulsed-dye or fractional CO2 laser. Excision and grafting have been successful, but recurrence may occur. Anti-TNF-α agents such as etanercept and infliximab have been used for refractory, ulcerative NL as well as intravenous immunoglobulin; however, all therapeutical options should be assessed for efficacy and safety by large, randomized, controlled trials. Treatment of the hyperglycemic state does not change the cutaneous lesions, although improvement following pancreas transplantation has been reported. Because localized trauma can cause NL to ulcerate, protection of the legs with elastic support stockings and leg rest is useful.

The evolution of DD is variable and does not appear to be affected by glycemic control. The lesions may persist or resolve spontaneously with scar formation and recur in crops. Treatment is not very effective. Particular attention should be placed on the detection and prevention of diabetic complications such as retinopathy, neuropathy, nephropathy, and coronary heart disease, as patients with DD are more inclined to develop microangiopathies.

No well-designed randomized controlled studies have demonstrated any particularly effective therapy for GA. Localized disease generally is self-limited and resolves within 2 months to 2 years, whereas disseminated disease may last 3–4 years or as long as 10 years. For localized disease, topical or intralesional glucocorticoids, tacrolimus and pimecrolimus, imiquimod, pulsed-dye laser, and cryotherapy have been used with variable success. Because localized GA is self-limited, a “wait and see approach” is also

warranted. For disseminated disease, treatment modalities include retinoids, antibiotics, nicotinamide, dapsone, pentoxifylline, cyclosporine, fumaric acid esters, antimalarials, photodynamic therapy, and ultraviolet therapy including UVA1 phototherapy. Regarding tumor necrosis factor-alpha inhibitors, there are reports reflecting resolution of the disease with this treatment modality, while others show no benefit. Lesions may resolve after biopsy. Recurrences occur in 40 % of cases.

No effective treatment is known for scleredema diabeticorum. Control of the hyperglycemia has little influence on the skin. Many treatments have been tried with variable success. Phototherapy such as UVA1, cyclosporine, low-dose methotrexate, intravenous immunoglobulin therapy, and electron beam therapy have all been reported to be of benefit. Aggressive therapies, however, should be limited to individuals with disabling disease or systemic manifestations.

There is no therapy for diabetic hand syndrome, although strict glycemic control may be helpful. Physical therapy is recommended to prevent limitations in range of motion.

Diabetic bullae heal spontaneously without scarring in 2–6 weeks, but they may be recurrent. Blisters may turn into chronic foot ulcers with complications. Glycemic control does not appear to have a direct correlation with blister formation.

Different treatments have been tried for acquired perforating dermatosis with variable results, such as topical or intralesional steroids, phototherapy including narrowband UVB, topical and systemic retinoids, systemic antihistamines, antibiotics, and allopurinol. Although there have been some reports of the spontaneous disappearance of perforating disorders with the stabilization of diabetes and renal disease, most cases of perforating disease continue for years unless treated.

The most effective treatment for acanthosis nigricans is lifestyle alteration. Weight reduction and exercise can reduce insulin resistance. Keratolytics such as ointments containing salicylic or retinoic acid can be used to reduce thicker lesions in areas of maceration in order to decrease odor. Oral agents that have shown some benefit include etretinate, isotretinoin, metformin, and dietary fish oils. Dermabrasion and laser therapy may also be used to reduce the bulk.

Hyperlipoproteinemia

Many instances of hereditary hyperlipidemia are associated with severe atherosclerotic cardiovascular disease. Secondary hyperlipidemias often abate with correction of the underlying etiology, e.g., cessation of the offending medication, correction of hypothyroidism, etc. Treatment of xanthomas, in particular xanthelasmas, tendinous or tuberous xanthomas, can be surgical, including laser procedures, but additional lesions will likely appear if the underlying hyperlipidemia is not corrected.

Nonsurgical treatment of hyperlipidemia involves pharmacologic agents such as hydroxymethylglutaryl coenzyme A (HMG-CoA) reductase inhibitors (more commonly known as "statins"), fibric acid derivatives, bile acid sequestrates, and nicotinic acid. Statins inhibit the 3-hydroxy-3-methylglutaryl coenzyme A reductase, which is the rate-limiting enzyme for hepatic cholesterol synthesis. This leads to upregulation of LDL receptors and the lowering of plasma LDL cholesterol levels. All statins have this same mechanism of action but vary in their ability to lower LDL. Omega-3 fatty acids are available in a prescription form which has been approved by the United States Food and Drug Administration for use in patients with very high triglyceride levels (greater than 500 mg/dl). The improvement can be greater than with statin monotherapy. Eruptive xanthomas usually resolve spontaneously over the weeks and may result in hyperpigmented scars. Adequate treatment involves controlling the underlying hyperlipidemia with strict dietary therapy. Weight reduction and carbohydrate intake restriction are helpful in cases associated with diabetes. Eruptive xanthomas may herald the risk of atherosclerotic disease and acute pancreatitis. Type III hyperlipoproteinemia (dysbetalipoproteinemia) is typically responsive to pharmacologic therapy, such as fibric acid

agents, nicotinic acid, or statins. Therapy may require a combination of these drugs. It is also important to take note of the genetic counseling ramifications of diagnoses of inherited hyperlipidemia for the individual patient. The potential impact on longevity and family planning can be considerable, and referral to the appropriate genetics specialist, whether a physician geneticist or genetics counselor, should be strongly considered.

Obesity

Acrochordons are benign growths and are removed only for cosmetic reasons. Theoretically, a lower rate of recurrence could be seen in patients who achieve a better control of their diabetes and overweight. However, once an acrochordon is present, it does not seem to regress with weight loss. Treatment is by scissor excision, electrodesiccation, or cryotherapy.

Hidradenitis suppurativa is often a chronic and relapsing condition difficult to treat. The Hurley staging system is often used in clinical practice to document severity and guide treatment. Treatment should include encouraging weight loss and cessation of smoking. Topical steroids and antibiotics such as topical clindamycin 1 %, oral tetracycline (1 g daily), and erythromycin 500 mg twice daily can usually manage mild disease. Retinoids and systemic or intralesional steroids have had variable results. Hormonal contraception of low androgenicity (combined oral contraceptives containing one of the less androgenic progestogens, such as norgestimate, desogestrel, or gestodene) has also been used with better results than antibiotics. Other suggested drugs include oral zinc, metformin for the metabolic syndrome's involvement in the development of hidradenitis, and dapsone that may be an option for maintenance treatment in patients with moderate disease. Anti-TNF-alpha drugs have been shown to be effective, but relapses are common after stopping therapy. However, only surgical excision of all apocrine gland-bearing skin has been shown to effectively treat hidradenitis suppurativa by altering the natural course of the disease.

Lymphedema tends to be a chronic and progressive disease, and patients usually require lifelong treatment. Treatment consists of elevation, elastic stockings, and applying external compression devices. Weight reduction is extremely important in treatment because excess weight decreases the benefit of therapy and worsens the lymphedema. Infection prevention is also important and is accomplished by daily cleansing with mild soap, followed by a moisturizer.

Treatment of striae distensae includes the application of topical tretinoin 0.1 % cream early in the course of the disease. Laser therapy has also shown to be partially effective in the treatment of striae. Early, erythematous lesions respond best to 585-nm pulsed-dye laser, whereas late, hypopigmented scars respond better to the 308-nm excimer laser.

Acanthosis nigricans can be managed by controlling hyperinsulinemia. Weight loss and exercise are thus the best treatment options. Metformin has been shown to be effective. Octreotide, which acts by reducing insulin secretion, has also been shown to be of benefit. Topical antibiotics, retinoids, and keratolytics may also be used for treatment, with variable results.

Skin Disease from Marine Environment

91

Giuseppe Monfrecola and Gabriella Fabbrocini

Key Points

- Many aquatic organisms are able to produce skin eruptions and occasionally systemic reactions.
- These dermopathies are very common among people who sunbathe and work in these conditions.
- Coelenterates are responsible for a wide range of skin reactions due to their poison in the tentacle.
- Injuries from sea urchin spines, which can be broken into the skin, cause local tissue reactions.
- Treatment should be prompt and appropriate and it should be done on the site of contact or sometimes in a systemic way.

Definition and Epidemiology

Many aquatic organisms are able to produce skin eruptions and occasionally systemic reactions. No data are available about the prevalence of marine-related diseases, but it is well known that these dermopathies are very common among people who sunbathe and work in these conditions.

Illnesses and accidents related to the aquatic environment have increased during the last decades, thus leading up to a rapid development of *Aquatic Dermatology*. Oceans, lakes, rivers, ponds, swimming pools, and aquariums contain numerous plants and animals that may be harmful to humans.

Excluding other aquatic dermatological conditions such as infection (i.e., mycobacteriosis), aquagenic urticaria or pruritus, irritant or allergic dermatitis, and barotrauma, cutaneous lesions can be caused by accidental contact with the organisms listed below. During the years, many marine animals have developed some defense towards their natural predators but, on the contrary, they sometimes can use them to attack. These mechanisms are also used against occasional and often unintentional attackers, such as bathers and divers. The venomous bites and stings of various aquatic animals are able to induce not only local skin manifestations, more or less serious, but also systemic reactions with severe shock and possible fatal evolution. Treatment should be prompt and appropriate and

it should be done on the site of contact or sometimes in a systemic way.

Basic Concepts of Pathogenesis

Cnidarians (or Coelenterates)

In recent years, coelenterates are responsible for the most frequent poisoning reactions with respect to other marine species. Among 9,000 species, about 100 are toxic for humans. Jellyfish (Scyphozoa), anemones and coral (Anthozoa), and the Portuguese man-o'-war and fire corals (Hydrozoa) belong to this phylum. Jellyfish, anemones, corals, and hydroids are characterized by the presence on their tentacles of thousands of stinging organelles (nematocysts) containing poison. Nematocysts are sacciform structures containing a spirally coiled thread tube that can be shot quickly with a very high force of ejection. The released thread, like a harpoon, sticks into the enemy tegument and releases its poison. The nematocyst's release can be stimulated by mechanical or chemical stimulus. The cnidarian venoms are mixtures of peptides or proteins (enzymes) with inflammatory, necrotic, hemolytic, and neurological activities. The human skin can be affected by contact with the whole organism or parts of it (disconnected tentacles) and also by contact with other marine species using the cnidarian nematocysts as a weapon (i.e., nudibranchs or the Mediterranean octopus).

The coelenterates, including corals, sea anemones, jellyfish, and hydroids, have tips that can pierce human skin. The nematocysts are particularly abundant on the tentacles of the animal and, after contact, a tentacle can drain thousands of nematocysts in the skin. Typically, the initial lesions appear as small linear papular eruptions that develop rapidly in one or more discontinuous lines, sometimes surrounded by an erythematous area. The pain can be intense and itching is common. The papules may turn into blisters, sometimes evolving into pustules and finally into scab. The systemic manifestations include weakness, nausea, headache, muscle spasms and pain, watery eyes and runny nose, increased sweating, changes in pulse rate, and pleural chest pain.

Regarding the man-o'-war, it looks like a particular jellyfish or a colony of interdependent polyps forming a single body, but it is a siphonophore, whose distinctive appearance is the air pocket which, emerging from the sea, acts as a sail following the wind; hence the name of "caravel." Cubomedusae are the most dangerous among coelenterates, especially the sea wasp (*Chironex fleckeri*) and the square jellyfish (*Chiropsalmus quadrigatus*), and have been responsible for several deaths in the Atlantic, Indian, and Pacific oceans. It is interesting that a specimen of the Portuguese man-o'-war has been found also in Sicily by a surfer. This organism is particularly dangerous for human beings as its tentacles. Reaching 30 m in length, it contains millions of stinging cells with more than 10 different types of poisons. Each poison has its own specific color, and antidotes against the effects of some of them are not well known. The contact with the man-o'-war may cause severe burns, but also just a drop in blood pressure which could provoke collapse and in severe cases anaphylactic shock, cardiac arrest, and death may occur.

Other factors can influence the intensity of human reaction after contact with cnidarians: the patient's sensitivity, the size of the involved body surface, the anatomical site of contact, and the behavior of the patient after the contact. The reaction usually has a toxic nature, but immune-mediated mechanisms have been also described.

Venomous Fish

The poisoning from fish spines are defined as ichthyoacanthotoxicosis. A lot of species of fish, not only in tropical or subtropical areas but also in temperate climates (i.e., the Mediterranean sea), can induce severe injuries after the injection of the poison secreted by their cutaneous glands such as weever fish (*Trachinus* spp.), scorpion fish (*Scorpaena* spp.), zebra fish (*Pterois* spp.), stonefish (*Synanceia* spp.), stargazers (*Uranoscopus scaber*), stingrays, catfish, toadfish (*Thalassophryne* spp.), leatherbacks

(*Scomberoides sanctipetri*), moray (*Murenidi* spp.), and boxfish (*Ostraciontidae* spp.).

Fish reactions were calculated in about 750 bites/year along the US coasts, but the actual incidence is unknown. Poison is contained in one or more pins on the dorsal surface of the animal or in a spine located in the proximal portion of the tail. The lesions usually occur when a diver or a swimming sunbather tread on the dorsal spine (or spines) of the fish, causing the injection of the poison in the foot or leg. Although it is often limited to the affected area, the pain may spread rapidly, reaching its maximum intensity in less than 90 min and gradually decreasing within 6–48 h. Swelling and edema are usually present. Syncope, asthenia, nausea, and anxiety are frequent and may be due, in part, to peripheral vasodilatation. Lymphangitis, vomiting, diarrhea, sweating, generalized cramps, pain, and respiratory difficulty have been described.

Mollusks

The mollusks include conical shells, octopus, and bivalve shells. The *Conus californicus* is the only recognized conical dangerous shell in the waters of North America. Its sting causes localized pain, swelling, redness, and numbness. The bites of American octopus are rarely dangerous. The paralytic shellfish poisoning, caused by the ingestion of some bivalves, "dinoflagellates," is treated with special attention. The treatment is largely empirical.

Echinoderms and Sea Urchins

Echinoderms include several classes of poisonous fish. Some sea urchins have venomous organs (pedicellaria globose) with calcareous jaws with the possibility to pierce human skin, but injuries are rare. Much more common are injuries from sea urchin spines, which can break into the skin and cause local tissue reactions (Fig. 91.1). If not removed, the plugs can migrate into deeper tissues, resulting in a particularly severe granulomatous nodule. Recent cases from the Mediterranean Sea showed the local reaction in the bone and nerve.

Fig. 91.1 Local skin reaction due to injuries from sea urchin spines

General Principles of Treatment (Table 91.1)

Cnidarians (or Coelenterates)

In some parts of the world, it is not recommended any treatment. However, some substances are used, such as vinegar to stop the sting, for the jellyfish square; baking soda in a 50:50 mixture, for the nettles of the sea; and seawater, for the man-o'-war. The tentacles must be removed, preferably with pliers or with gloved hands. The use of aspirin, an NSAID, or other analgesics can be useful. More severe cases may require O_2 or cardiorespiratory assistance. The painful muscle spasms can be mitigated with 10 ml of calcium gluconate 10 % IV. Narcotics are the drugs of choice for intense pain. In the few cases in which

Table 91.1 Etiology, clinical manifestations, and treatment of the most common skin diseases from the marine environment

	Causative agent	Skin reaction	Treatment
Coelenterates	Tentacles, stinging organelles (nematocysts)	Papular eruptions, hemorrhage, scab, weakness, headache, muscle spasms and pain, watery eyes, anaphylactic shock, cardiac arrest	Evaluation of the dermatologist, removed tentacles, seawater, aspirin, analgesic, calcium gluconate and cardiorespiratory assistance, adrenaline
Venomous fish	Pins, plugs	Syncope, asthenia, lymphangitis, vomiting, sweating, and respiratory difficulty	Evaluation of the dermatologist, remove integumentary sheath, antimicrobial and surgical closure of wound, anesthetized with lidocaine
Echinoderms and sea urchins	Plugs, thorns	Granulomatous nodule, tissue reactions	Evaluation of the dermatologist, washing the area and applying a mentholated balm, remove the plugs, vinegar compress

a shock occurs, adrenaline and intravenous fluids can be used. There is an antidote to the bites of some Australian species of coelenterates, but it is useless for the stings of the species in North America.

Venomous Fish

Wounds localized on limbs should be irrigated with salt water if available. It is necessary to remove the integumentary sheath, if it is visible, and the tourniquet could be useful. There are pump-shaped syringes which, causing a depression, are helpful for extracting the most part of the poison. Then the limb should be soaked for 30–90 min in water as hot as the patient can tolerate without receiving damage because it is very sensitive to heat. The wound should be reexamined to check for the presence of residues of the spine. You may need the use of an antimicrobial and surgical closure of wound. The initial measures are taken in case of emergency and, if the pain persists, the wound can be locally anesthetized with lidocaine. Narcotics can be useful too. The primary shock that sometimes immediately follows a sting usually responds to simple measures of support. The bites on the trunk should be evaluated carefully by the dermatologist for the possibility of perforation of internal organs. Strict surveillance of systemic symptoms is necessary. Taking into account that the plugs and stingers remain poisonous for some hours after the death of the fish, it is therefore necessary to avoid taking them full hand when lying on the beach or on the boat. Among fishmongers this risk does not exist because the sellers are obliged to remove thorns and stings before the sale.

Mollusks

Topical measures seem to have low effectiveness. It had been suggested that local injection of adrenaline and the subsequent use of neostigmine could be useful. The serious bites from *Conus* may require mechanical ventilation and measures against shock.

Echinoderms and Sea Urchins

The stings of *G. pedicellariae* are treated by washing the area and applying a mentholated

balm. The spines of the sea urchin must be removed immediately. A bluish discoloration at the site of entry can help to locate the spine, which is sometimes visible on X-ray. Vinegar dissolves most of the spine's surface, but it may be sufficient to wet the wound with vinegar several times a day and apply a vinegar compress. Rarely a small incision to remove the spine can be useful, but as this is very fragile, the operation is not easy. A spine that has migrated into deeper tissues may require surgical removal.

Spitz Nevi

92

Susana Puig, Pedro Zaballos, Cristina Carrera, and Josep Malvehy

Key Points

- A Spitz nevus is a benign melanocytic nevus, with specific clinical and pathological features.
- Spitz nevi pose substantial diagnostic difficulty.
- Dermoscopy increases diagnostic accuracy.
- There are six main dermoscopic patterns associated with these lesions, five ascribed to pigmented Spitz nevi (starburst, globular, reticular, homogeneous, and atypical patterns) and one to the classical variant (vascular pattern).
- Spitz nevus is a benign tumor of spindled and epithelioid melanocytes.
- The main differential diagnosis of atypical Spitz is malignant melanoma.
- No evidence-based treatment recommendations can be made but complete excision is recommended, always in adulthood.

Definition

The pathologist Sophie Spitz described this lesion in 1948 as juvenile melanoma; in her honor, it is named Spitz nevus.

A Spitz nevus (also known as "epithelioid and spindle-cell nevus," "benign juvenile melanoma," and "Spitz's juvenile melanoma") is a benign melanocytic nevus, with specific clinical and pathological treats. The latter terms are generally no longer used as they are misleading: Spitz nevus is a benign lesion and not a melanoma, and it does not only occur in children but also in adults.

In this chapter we will include two close entities, Spitz nevi (including classical and pigmented Spitz nevi) and Reed nevi (pigmented fusocellular nevi).

Epidemiology

Spitz nevi are uncommon. Their annual incidence was estimated in Queensland to be 1.4 cases per 100,000 people (Crotty 1997), where the annual incidence of melanoma in the same population is 25.4 cases per 100,000 people, one of the highest by world standards (Ries et al. 2003).

Although they are most commonly found on people in their first two decades of life, the age range for people with Spitz nevi is from early childhood to elderly, with a mean age of 22 years and a median age of 19 years in one large report.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_92, © Springer-Verlag Berlin Heidelberg 2015

Even though there is an association with sunburn, the cause of Spitz nevi is not yet known.

Clinical Presentation

They are usually small (6 mm or less), raised, pink, red, or light-brown papules that sometimes may resemble hemangioma or pyogenic granuloma (Figs. 92.1, 92.2, and 92.3). Pigmented Spitz nevi have similar characteristics but darker in color (Figs. 92.4, 92.5, 92.6, 92.7, and 92.8). They are usually single but may be multiple and clustered (agminate) or multiple and disseminated (Fig. 92.9). In a recent study performed by Requena and coworkers (2009) including 349 excised Spitz nevi, only 18 % were correctly clinically diagnosed.

Dermoscopy

Dermoscopy is a noninvasive and valuable method for improving the diagnosis of Spitz nevi. An increase in diagnostic accuracy from 56 to 93 % has been reported previously. Spitz nevus can clinically and dermoscopically present either in the classical (reddish pink) variant or the pigmented variant, and dermoscopy has demonstrated that the pigmented variant is much more frequent than the classical one. There are six main dermoscopic patterns associated with these lesions, five ascribed to pigmented Spitz nevi (starburst, globular, reticular, homogeneous, and atypical patterns) and one to the classical variant (vascular pattern) (Figs. 92.1, 92.2, 92.3, 92.4, 92.5, 92.6, 92.7, 92.8, 92.9, and 92.10). Remarkably, the starburst, globular, and atypical patterns accounted for 80 % of cases, representing the major dermoscopic patterns of Spitz nevi.

The starburst pattern is characterized by a prominent black to blue homogeneous pigmentation located in the center of the lesion and pigmented streaks (pseudopods or radial streaming) distributed regularly in a radial arrangement at the edge of the lesion (Fig. 92.4). This pattern is observed in 42–53 % of Spitz nevi (Ferrara et al. 2005).

The globular pattern is characterized by the presence of brown to bluish to black globules distributed throughout the lesion (Fig. 92.10). On occasion, the globules can be arranged in a centrifugal fashion, reminding of an exploding star. These peripheral globules are usually distributed in multiple rows forming the tiered globular pattern which is considered by many authors as a variant of starburst pattern (Ferrara and Argenziano 2012). This pattern is observed in 19–22 % of Spitz nevi.

The reticular pattern is observed in 9–10 % of cases (Fig. 92.5). There is a distinctive type of pigment network associated with pigmented Spitz nevi which is called superficial black network (Fig. 92.6). The black color is due to the presence of excessive amounts of melanin in the stratum corneum which can be removed by tape stripping.

The homogeneous pattern is characterized by a diffuse dark brown to black-bluish color, which lacks evidence of clear-cut streaks at the periphery (Fig. 92.7). This pattern is observed in 6 % of cases.

The atypical (or multicomponent) pattern is observed in 18–25 % of cases and is composed of different colors and structures irregularly distributed, giving a melanoma-like pattern (Fig. 92.8). Because of that, Spitz nevi with this pattern should be excised irrespective of the patient's age.

It is believed that most of these different dermoscopic patterns probably represent different phases in the natural evolution process of Spitz nevi and not distinct clinical and pathological entities. It has been described that pigmented Spitz nevi can evolve from a globular pattern to a starburst pattern and from this starburst pattern to homogeneous pattern (considered a state of senescence). Some authors have observed that the final stage in the natural evolution of Spitz nevi is complete involution of the lesion (Pizzichetta et al. 2002).

The vascular pattern is associated with classical (or hypopigmented) Spitz nevi and is usually composed of dotted vessels, which tend to be monomorphic and regularly distributed throughout the lesion, over a pink background (Figs. 92.1, 92.2, and 92.3). However, it is not uncommon to find vessels with varied morphology

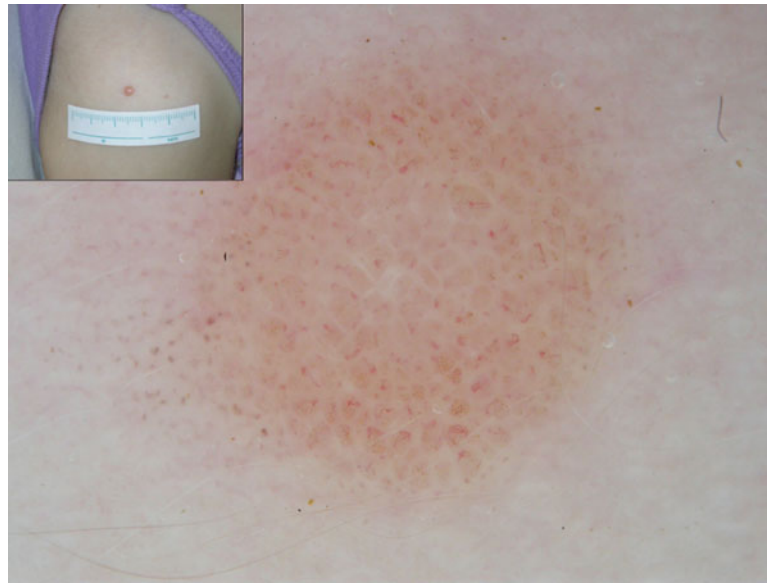

Fig. 92.1 Spitz nevus with a globular pattern located on the arm of an 8-year-old girl

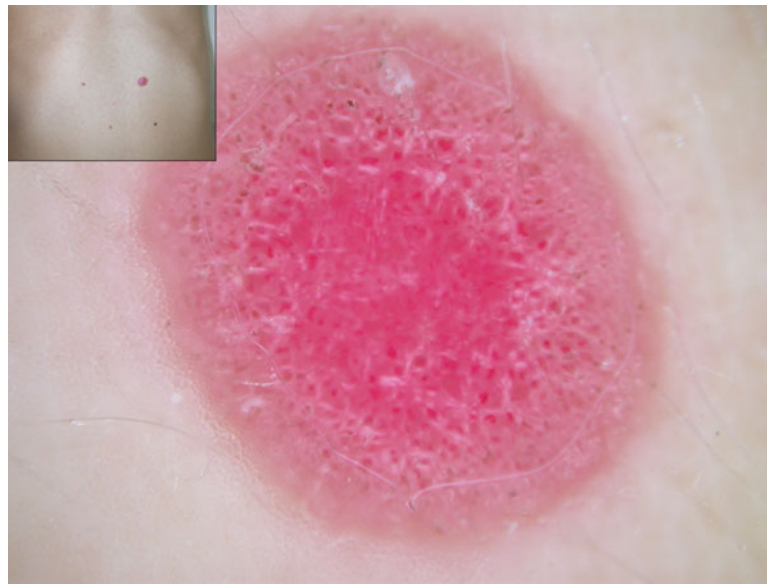

Fig. 92.2 Classical Spitz nevus with a vascular pattern located on the abdomen of a 26-year-old woman

(glomerular, comma, linear, or hairpin vessels), and therefore it is difficult to rule out the diagnosis of melanoma. These "pink" nodular Spitz nevi usually have the highest chances of showing atypical histological features, making it difficult to differentiate them from amelanotic melanomas.

In addition, it is not uncommon for Spitz nevi to show a negative pigment network (also called white network or reverse pigment network) (Figs. 92.1 and 92.3). This reticular structure consists of light areas making up the cords of the network and darker areas filling the holes and was found in 28.8 % of Spitz nevi. Other intersecting

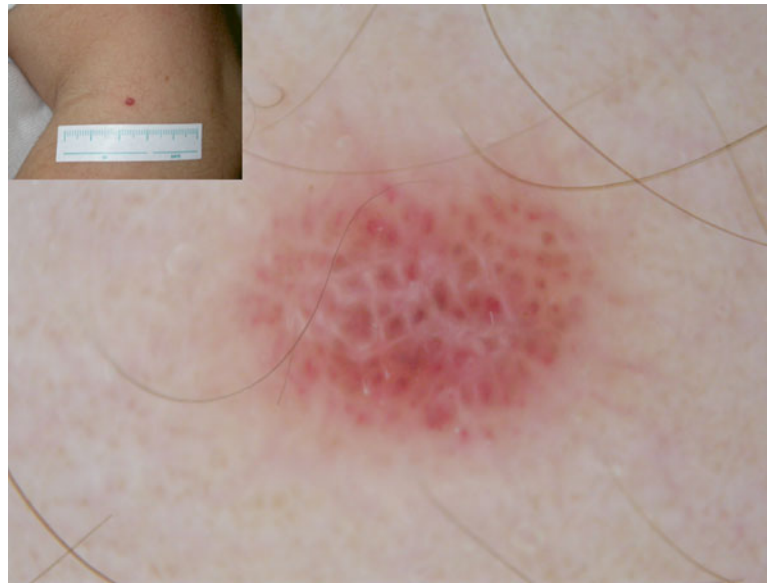

Fig. 92.3 Negative pigment network in a Spitz nevus located on the leg of a 13-year-old girl

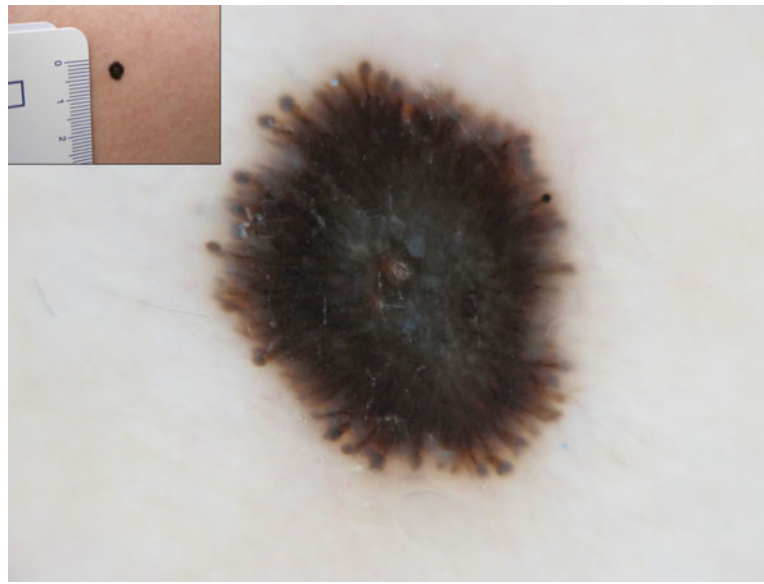

Fig. 92.4 Pigmented Spitz nevus with a starburst pattern located on the buttock of a 15-year-old girl

white lines which can be seen using polarized dermoscopy in some Spitz nevi are chrysalis (also called crystalline or shiny white lines) (Figs. 92.1, 92.2, 92.3, and 92.8). Finally, other dermoscopic structures found in Spitz nevi are regression structures and bluish or reddish halo.

Confocal Microscopy

In vivo reflectance confocal microscopy is a noninvasive imaging technique with cellular resolution that improves the diagnosis of melanocytic and nonmelanocytic tumors.

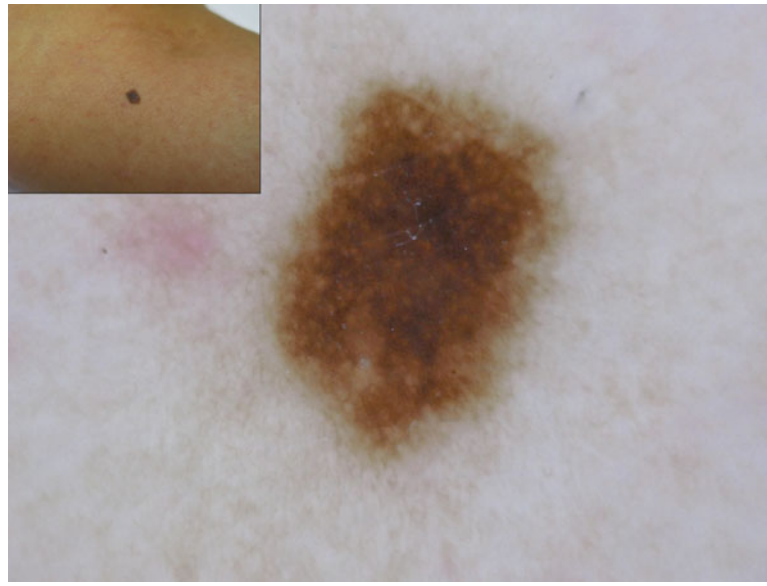

Fig. 92.5 Pigmented Spitz nevus with a reticular pattern located on the leg of a 36-year-old woman

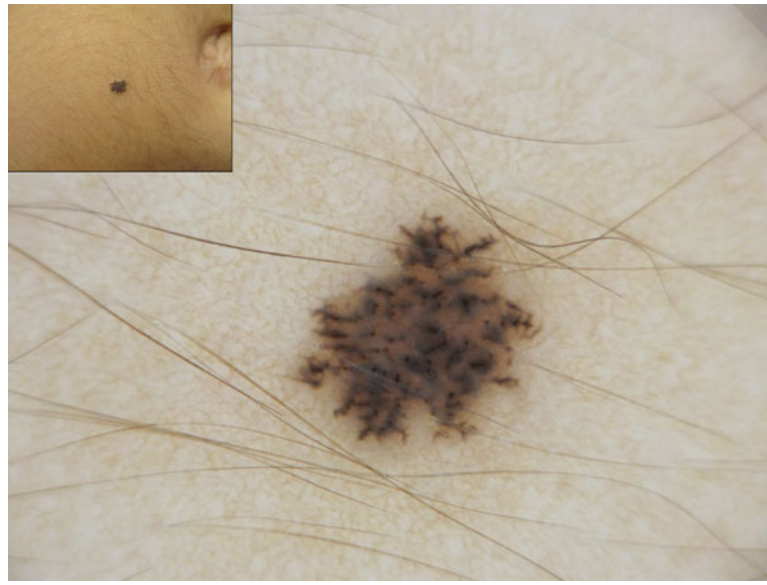

Fig. 92.6 Pigmented Spitz nevus with a reticular pattern (superficial black network) located on the abdomen of a 20-year-old woman

Pellacani and coworkers (2009) studied 40 Spitz nevi by in vivo confocal microscopy compared with 40 MMs and 40 Clark nevi. Some confocal features characteristic for Spitz nevus diagnosis were correlated with histological aspects as the most main features for differentiating Spitz nevi from melanomas: the presence of sharp border cutoff, junctional nests, and melanophages (Fig. 92.10). A limitation of reflectance confocal microscopy was the impossibility to evaluate dermal criteria suggestive of malignancy as lack of maturation or deep mitosis in atypical cells.

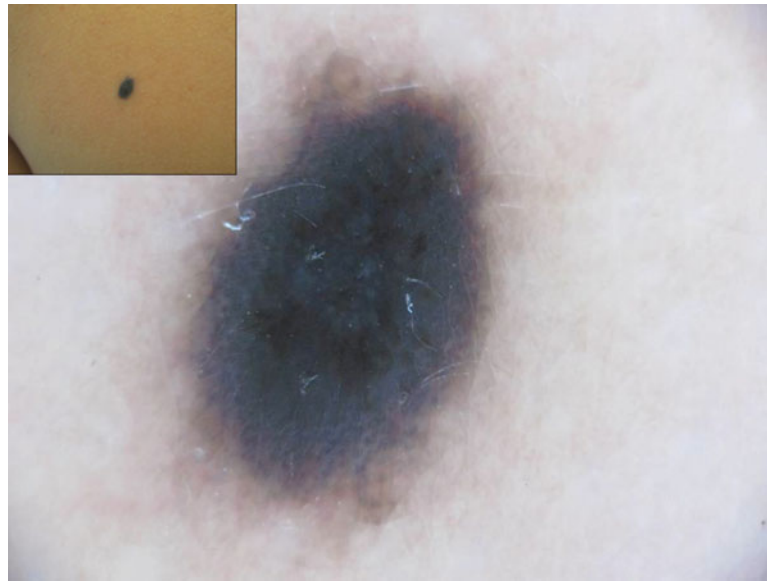

Fig. 92.7 Pigmented Spitz nevus with a homogeneous pattern located on the leg of a 17-year-old man

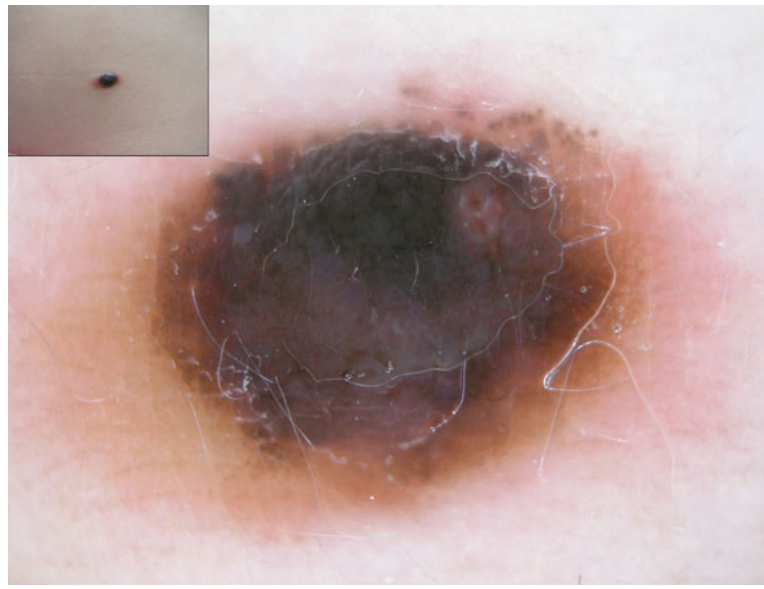

Fig. 92.8 Pigmented Spitz nevus with an atypical pattern located on the abdomen of a 11-year-old boy

Basic Concepts of Pathogenesis

Spitz nevus is a benign tumor of spindled and epithelioid melanocytes. They are symmetric with sharp lateral borders, usually compound nevus with prominent intraepidermal component, but 5 % are junctional and 20 % are dermal.

Spitz nevi characteristically have vertically arranged nests of nevus cells that have both an epithelioid and a spindled morphology (Figs. 92.10 and 92.11). Apoptotic cells may be seen at the dermoepidermal junction, presenting large and well-formed Kamino bodies (eosinophilic hyaline PAS-positive bodies along the

Fig. 92.9 Clinical (*left*) and dermoscopy (*right*) images of a patient with multiples agminated disseminated pigmented Spitz nevi

dermoepidermal junction). Fascicles of spindle cells, perpendicular to epidermis, may be arranged in dermal papillae. These cells have cigar-shaped large nuclei with prominent nucleoli. Epithelioid cells with abundant eosinophilic cytoplasm, distinct cell borders, large nuclei, and prominent nucleoli are dispersed individually. Variable mitotic figures can be seen. Occasional multinucleation and often marked atypia may be present although most cells appear benign and cell maturation occurs in deep portion of tumor.

These lesions may have pagetoid growth, lymphatic invasion, prominent vasculature, and lymphocytic infiltrate. "Consumption of epidermis" (also associated with melanoma) is seen in 10 % of them, defined as thinning of the epidermis with attenuation of basal and suprabasal layers and loss of rete ridges in areas of direct contact with neoplastic melanocytes.

The main histological differential diagnosis is malignant melanoma and common cause of malpractice claims is misdiagnosis as melanoma or melanoma misdiagnosis as Spitz.

Staining may help, being S100, HMB45, and MART1/MelanA positive in Spitz nevi. Spitz nevi also have positive expression of p16 while this could be lost in melanoma. On the contrary, neuropilin-2 (NRP2) is negative in 74 % of Spitz nevi while positive in melanoma. Spitz nevi also show low Ki-67 staining.

Genetic studies of Spitz nevi have shown that most cells have the normal number of chromosomes; however a minority (25 %) of cells have been shown to contain extra copies of parts of some chromosomes, such as the short arm of chromosome 11 (11p).

Occasionally H-RAS mutations were described in Spitz nevi, while usually no N-RAS or B-RAF mutations were identified (van Dijk et al. 2005). Recently B-RAF mutations were found in some classic and atypical Spitz nevi (Fullen et al. 2006).

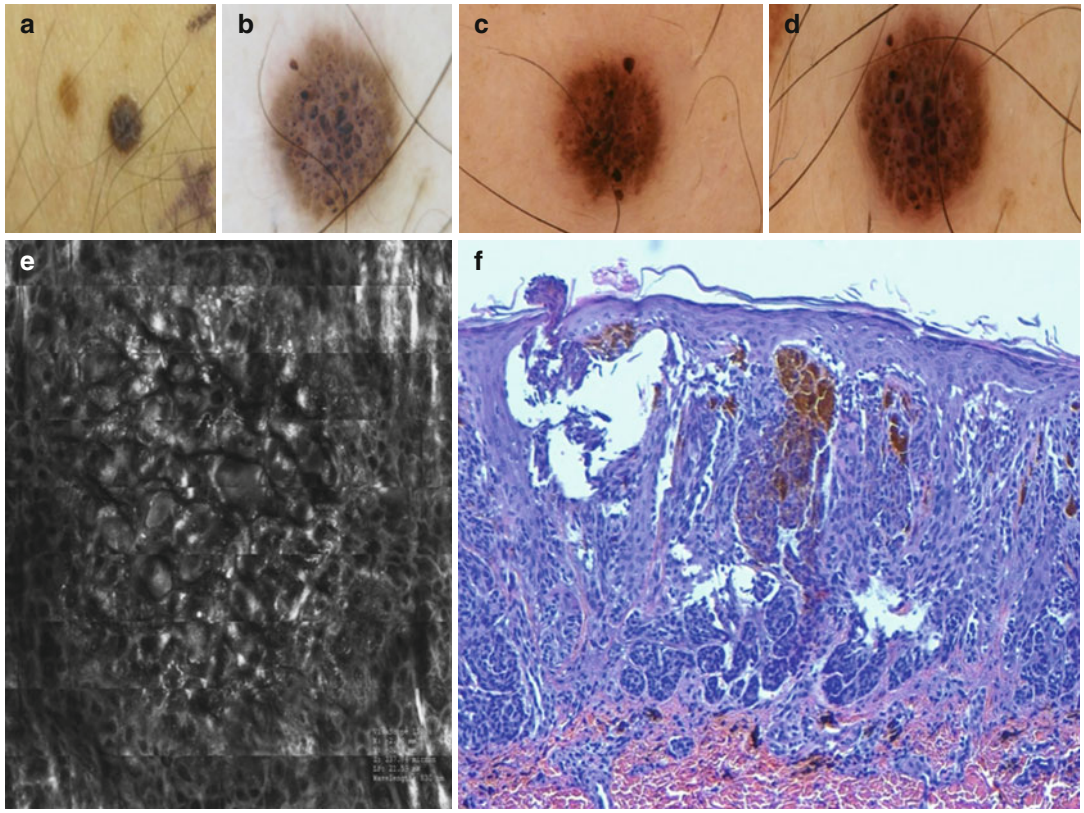

Fig. 92.10 Clinical (**a**) and dermoscopy (**b**) image of an atypical Spitz nevus with globular pattern showing increase in size and change in the distribution of the globules at the periphery between January 2013 (**c**) and January 2014 (**d**). Reflectance confocal microscopy mosaic at dermoepidermal junction (**e**) showing the presence of sharp border cutoff, junctional nests, and melanophages. Hematoxylin and eosin staining ×20 (**f**)

In a study by Díaz and coworkers (2011), fluorescence in situ hybridization (FISH) using probes targeting 6p25 (RREB1), 11q13 (CCND1), 6q23 (MYB), and centromere 6 showed a sensitivity of 73 % and a specificity of 93 % in the diagnosis of spitzoid melanoma in front of pigmented spindle cell nevus because Spitz nevi usually are not showing FISH abnormalities (Horst et al. 2012).

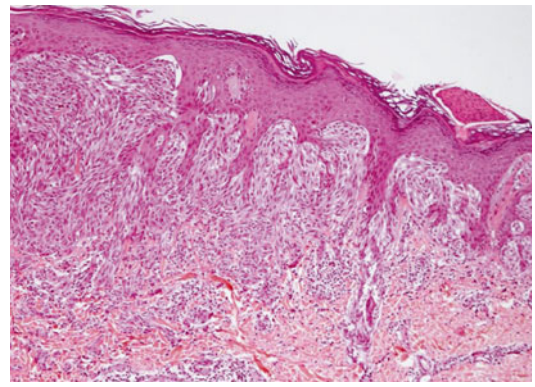

Fig. 92.11 Spitz nevus showing characteristic vertically arranged nests of nevus cells that have both an epithelioid and a spindled morphology. Apoptotic cells may be seen at the dermoepidermal junction, presenting large and well-formed Kamino bodies

Differential Diagnosis

The main differential diagnosis as previously discussed is spitzoid melanoma. Inside spitzoid lesions, there is a spectrum of tumors of difficult

diagnosis. In this setting, even expert pathologists have difficulties to classify such a lesion as benign or malignant. These lesions are classified as atypical Spitz tumors (ASTs) and show some worrisome treats and uncertain biological behavior.

Spitzoid melanoma is exhibiting under histopathology asymmetry, irregular lateral borders, uneven base, pagetoid scatter of melanocytes, uneven nests of melanocytes, lack of maturation, spindle cells not perpendicular to surface, epidermal spread, and ulcerated surface, and most cells show malignant characteristics.

General Principles of Treatment

No clear consensus exists for the management of Spitz nevi (SN) or atypical Spitz tumors (ASTs), particularly in the pediatric population. In adults all lesions with "spitzoid" features should be completely removed with limited margins for a correct pathological evaluation. Even in the case of symmetrical lesions, spitzoid melanomas cannot be ruled out based on clinical examination in adults. In young children (less than 7 years), most dermatologists consider that Spitz nevus can be monitored based in clinical and dermoscopical recognition of the characteristic patterns. However some dermatologists recommend the removal of all suspected Spitz tumors independently of the age of the patient, whereas others perform partial biopsy (Metzger et al. 2013). In the case of excision due to equivocal diagnostic features, a partial excision is not recommended due to the risk of insufficient sample for diagnostic assessment and recurrence. Shaving biopsies should be avoided in raised lesions where the pathologist may have difficulties for the final diagnosis of benignity, and the most important criteria are based in the examination of the deep part of the tumor that can be missed in a superficial biopsy.

ASTs may involve regional lymph nodes but distant metastases are rare. In AST there is controversy on the benefit of performing sentinel lymph node biopsy especially in young patients. In addition the significance of the presence of spitzoid cells in the sentinel node is not equivalent to malignant metastasis. The indication of the surgical and staging of these difficult lesions should be accomplished in experienced multidisciplinary centers and discussed with the patient. In the absence of any demonstrated benefit in overall survival with sentinel node biopsy, most authors consider that overtreatment should be avoided, especially in children. Complete excision and monitoring of regional lymph nodes with sonography in ASTs is considered a good option in these atypical tumors. In the case of regional subclinical or clinical metastasis in lymph nodes detected by sonography, the treatment should follow the melanoma guidelines and complete lymphadenectomy has to be considered.

Squamous Cell Carcinoma

93

Marta Grazzini and Vincenzo De Giorgi

Abbreviations

5-FU	5-Fluorouracil
AK	Actinic keratosis
5-ALA	5-Aminolevulinic acid
AMM	Amelanotic malignant melanoma
BCC	Basal cell carcinoma
COX	Cyclooxygenase
EGFR	Epidermal growth factor receptor
NMSC	Nonmelanoma skin cancer
PDT	Photodynamic therapy
PpIX	Protoporphyrin IX
PUVA	Photochemotherapy
SCC	Squamous cell carcinoma
SK	Seborrheic keratosis

Key Points

- Malignant tumors of the epidermis are referred to as nonmelanoma skin cancer (NMSC). NMSC is the most frequent type of malignancy in humans and comprehends two major entities: squamous cell carcinoma (SCC) and basal cell carcinoma (BCC).
- SCC is more common in older men, but besides older age and male sex, major risk factors are light skin, family history, residence at latitudes near the equator, and exposure to ultraviolet radiation.
- The initial manifestation of SCC is known as actinic keratosis.
- Invasive SCCs are generally larger, more advanced plaques or nodes, often covered with a thick, irregular, horny material, and sometimes with ulceration.
- The dermatoscopic features of SCC are a nonspecific pattern with scales and grouped glomerular blood vessels surrounded by a whitish halo.
- The usual therapies for individual SCC and actinic keratosis (AK) work destructively by surgically removing the lesion.

Definition

Malignant tumors of the epidermis are referred to as nonmelanoma skin cancer (NMSC). NMSC is the most frequent type of malignancy in humans and comprehends two major entities: squamous cell carcinoma (SCC) and basal cell carcinoma (BCC). SCC arises on sun-exposed areas of the skin and mucosa but they can also occur in covered parts of the body, particularly in patients that have other predisposing factors.

SCC arises from epidermal keratinocytes that grows in a destructive way and typically manifests as a spectrum of progressively advanced malignancies, ranging from a precursor actinic keratosis (AK) to invasive SCC and finally to metastatic SCC. SCC may spread to regional lymph nodes and in late stages cause death.

Epidemiology

Although NMSCs are the most common cancers, they are regularly excluded from national cancer registries and cancer databases because they usually do not affect survival; therefore, the exact incidence and the associated mortality rate cannot be determined precisely.

However, the incidence of SCC has increased noticeably over previous decades. NMSC is considered the most common human malignancy, and nearly 30 % of white people living in areas of exposure to high ultraviolet radiation will acquire an NMSC in their lifetime. The age-adjusted incidence of this cancer among whites is 100–150 per 100,000 persons per year, and the age-specific incidence among persons over the age of 75 years is approximately 10 times that rate.

SCC is more common in older men, but besides older age and male sex, major risk factors for development of NMSC include light skin, family history, residence at latitudes near the equator, and exposure to ultraviolet radiation. Indoor tanning, which is already an established risk factor for malignant melanoma, is recently added in the list of SCC risk factor for both squamous cell carcinoma and basal cell carcinoma.

Basic Concepts of Pathogenesis

There are a number of factors (acquired and genetics) that can play a key role in predisposition to SCC (Table 93.1). Patients often have multiplicity of factors that are sufficient to induce SCC development.

Sun exposure is considered the principal cause for NMSC. In particular a history of exposure to sunlight during childhood, or history of sunburns, may be the most important behavioral risk factor. Occupational exposure to ultraviolet radiation can also be implicated. The relative risk of SCC is three times as high among people born in areas that receive high amounts of ultraviolet radiation from the sun as among people who move to those areas in adulthood.

Table 93.1 Risk factors for the development of cutaneous squamous cell carcinoma

Exposure to ultraviolet radiation
Exposure to ionizing radiation
Infection with human papillomavirus, especially types 6, 11, 16, and 18
Exposure to chemical carcinogens
Immunosuppression
Genodermatosis
Presence of precursor lesions

Although the relation is not understood, human papillomavirus infection has been associated with SCC. Human papillomavirus types 6 and 11 are frequently found in patients with tumors of the genitalia and type 16 in those with periungual tumors. A link between human papillomavirus and SCC related to epidermodysplasia verruciformis has also been reported.

Chemical agents have historically been a major cause of SCC. Arsenic, used in various medications in the past, can also stimulate carcinogenesis. Arsenic exposure produces invasive tumors and carcinoma in situ on the skin, whether or not the skin is exposed to the sun, as well as arsenical keratoses on the palms and sole. Treatments with radiation therapy such as photochemotherapy (PUVA) can act as an independent carcinogen factor. In addition, patients treated with immunosuppressive drugs resulted to have an increased risk of developing SCC, as compared with the general population, suggesting the hypothesis that also the immune system can play a key role in the development of NMSC (Hoogendijk-van den Akker et al. 2013).

Clinical Presentation

The initial manifestation of SCC is known as actinic keratosis (actinic = sun, keratosis = scaly

spot) (AK). These scaly erythematous spots could be around 5–6 mm in diameter and usually rough with colors ranging from red to brown. AK and SCC occur predominantly in sites with chronic exposure to sunlight such as the face, scalp, neck, and dorsal hand.

Between 1 and 10 % of AK progress into invasive squamous cell carcinoma. Other precancerous conditions that may evolve into SCC include bowenoid papulosis and epidermodysplasia verruciformis. Patients with bowenoid papulosis, which is often associated with human papillomavirus types 16 and 18, present with hyperpigmented papules that have histological features identical to those of Bowen's disease, a type of squamous-cell carcinoma in situ. Epidermodysplasia verruciformis consists of widespread, flat warts that may degenerate into carcinoma in situ or invasive squamous cell carcinoma. The most common forms of SCC in situ are Bowen's disease and erythroplasia of Queyrat. Patients with Bowen's disease present with sharply demarcated, erythematous, velvety, or scaly plaques on sun-exposed areas. Erythroplasia of Queyrat is less common and occurs on the glans penis of uncircumcised men as red, smooth plaques. Invasive SCCs are generally larger, more advanced plaques or nodes, often covered with a thick, irregular horny material, and sometimes with ulceration (Fig. 93.1). Lesions were in general not painful or with no discomfort with the exception of the bleeding

Fig. 93.1 An SCC of the left arm of a patient. The lesion appeared as red node, with irregular horny material and with ulceration

Fig. 93.2 An SCC of labial mucosa that appeared as node and grows fast and soon becomes locally aggressive and disruptive

that can occur in ulcerated lesions. SCC may be locally aggressive (Fig. 93.2), and in rare instances, cutaneous SCC may metastasize to regional lymph nodes or distant sites. The 5-year rate of recurrence of primary cutaneous lesions is 8 %, and the 5-year rate of metastasis is 5 %. Verrucous carcinoma is a less common variant of invasive squamous-cell carcinoma. The indolent, cauliflower-shaped tumors resemble large warts and are locally aggressive but are less likely to metastasize.

Diagnosis

The diagnosis of SCC, although easily made in typical cases, may sometimes be difficult. On this regard, dermatoscopic examination can play a central role to increase the specificity of the diagnosis of such lesions. In fact, the superiority of dermatoscopy over clinical examination has encouraged dermatologists to adopt this device for routine clinical practice, with a progressive spread of dermatoscopy use and to nonpigmented skin tumor and many other kinds of nonpigmented skin lesions including vascular lesions. Zalaudek et al. (2006) defined a specific pattern for the diagnosis of AK called "strawberry" pattern. The strawberry appearance is typified by a reddish pseudonetwork intermingled with hair follicle openings, which are surrounded by whitish halos.

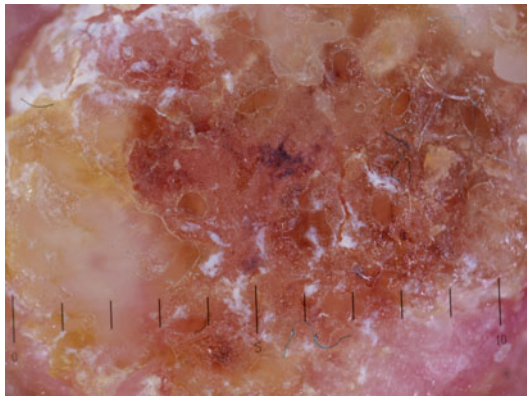

Fig. 93.3 A dermatoscopic image of SCC with a nonspecific pattern, scales, and grouped glomerular blood vessels surrounded by a whitish halo

The dermatoscopic features of SCC are a nonspecific pattern with scales and grouped glomerular blood vessels surrounded by a whitish halo (Fig. 93.3). A scaly surface, brown globules, and glomerular vessels can be seen in the dermatoscopic examination of pigmented Bowen's disease. Pigmented SCC can present a dermatoscopic pattern resembling melanocytic lesions with globules, radial streaks, and homogeneous blue pigmentation and can lead a physician to a wrong diagnosis.

Histological examination is mandatory to confirm the clinical diagnosis.

Histologically SCC consists of irregular masses of epidermal cells that proliferate downward into the dermis.

In well-differentiated carcinomas, tumor cells are pleomorphic/atypical but resembling normal keratinocytes from prickle layer (large, polygonal, with abundant eosinophilic (pink) cytoplasm and central nucleus). Their disposal tends to be similar to that of normal epidermis: immature/basal cells at the periphery, becoming more mature to the center of the tumor masses. Tumor cells transform into keratinized squames and form round nodules with concentric, laminated layers, called "cell nests" or "epithelial/keratinous pearls." The surrounding stroma is reduced and contains inflammatory infiltrate (lymphocytes). Poorly differentiated squamous carcinomas contain more pleomorphic cells and no keratinization. Histological grading of SCC is based on the degree of cellular differentiation. Low-grade tumors are comprised of uniform cells, resembling mature keratinocytes, with intracellular bridge and keratin production. High-grade SCCs are instead characterized by atypical cells, loss of intracellular bridges, and minimal or absent keratin production. Tumors are graded on a scale of 1–4 based on increasing percentage of undifferentiated cells, so-called Broders' Grading System (Table 93.2).

Table 93.2 Broders' grading system for squamous cell carcinoma

Grade	% Undifferentiated cells	Other features
1	<25	Keratinization
2	<50	
3	<75	
4	>75	Atypia, loss of intracellular bridges

Differential Diagnosis

Facial AK is a differential diagnosis of cutaneous melanoma (lentigo maligna) since pigmented facial AK may have a broken-up pseudonetwork. Pseudonetwork can be observed in dermatoscopic examination of certain benign pigmented facial lesions such as AK, ephelide, and junctional nevus.

The SCC must be differentiated from BCC, keratoacanthoma, hypertrophic AK, irritated seborrheic keratosis (SK), and amelanotic malignant melanoma (AMM).

Nonpigmented BCCs are much more common than pigmented BCC. In the dermatoscopic examination, nonpigmented BCCs can be often easily distinguished from any other skin lesion by their asymmetrical arborizing vessels, pink color, and focal ulceration. White regression areas may be seen.

Keratoacanthoma can resemble SCC but it tends to grow more quickly to form an SCC and frequently has a central ulcerated crater (Fig. 93.4). Dermatoscopically white circles, keratin, and blood spots are useful clues to differentiate SCC and keratoacanthoma from other raised nonpigmented skin lesions. The diagnosis of SK is generally clinical; sometimes the differentiation

Fig. 93.4 A keratoacanthoma of the lip that can resemble an SCC but tends to grow more quickly to form an SCC and has a central ulcerated crater

between irritated SK and SCC may be difficult in the clinical aspect. Although the classical dermatoscopic criteria of SK that include multiple milia-like cysts and comedo-like openings and additional structures such as hairpin blood vessels can help the diagnostic accuracy.

AMM lesions represent approximately 2–8 % of all melanomas, presenting without or with little pigmentation, respectively. The paucity of pigmentation makes this type of tumor hard to identify, making clinical differential diagnosis difficult. The dermatoscope is a major instrument allowing the evaluation of pigment and above all determining characteristic vascular structures unseen by the naked eye. Such vascular patterns have an important role on the suspicion of melanoma in doubtful nonpigmented lesions. Dermatoscopically AMM can initially show dotted vessels and, as the thickness increases, the vascular polymorphism increases with hairpin and linear-irregular vessels associated with milky-red areas, reticular depigmentation, and chrysalis. Differential diagnosis between pigmented SCC and melanocytic lesions is difficult in some cases.

General Principles of Treatment

The aim of the treatment of SCC can be stated simply as follows: to eliminate the disease, to secure the best functional and cosmetic results, and to avoid relapse. The treatment should take into consideration not only the SCC but also actinic keratosis from whom the SCC has originated. The usual therapies for individual AK/SCC work destructively by surgically removing the lesion. These should always be considered for isolated lesions or early presentations of AKs.

The standard treatment of AK/SCC is excision, followed by histological examination to confirm the diagnosis and to insure that the entire tumor has been removed (Table 93.3, Fig. 93.5).

Brief Overview on the Treatment of Actinic Keratosis

Destructive therapies include liquid nitrogen cryotherapy, curettage with or without electrodessication, and shave excision. The benefits of these techniques are that they are quick, procedurally simple, and easy.

Cryotherapy

Cryotherapy is one of the most commonly utilized techniques, with liquid nitrogen being the most frequently selected cryogen. Applying cryotherapy to the affected area lowers the skin to temperatures that destroy atypical AK cells. This technique is ideal if lesions are scattered or limited in number or for patients who are noncompliant with topical regimes. Cryotherapy is advantageous in that it is generally well tolerated and does not require local anesthetic, but downsides include pain during the procedure and frequent permanent hypopigmentation.

Curettage

Curettage consists of using a curette to mechanically remove atypical cells. A shave excision using a surgical blade is another technique. These may be followed by electrocautery, which will destroy additional atypical cell layers as well as provide hemostasis. These techniques are most appropriate for treating individual AKs, cases where a biopsy is required to rule out SCC, or for hypertrophic AKs that are refractory to other treatments.

Table 93.3 Therapeutic options for actinic keratosis and squamous cell carcinoma

Treatment	Dosage	Advantage	Disadvantage
Therapeutic option for actinic keratosis			
Surgery		Gold standard	You can treat single or a few lesions
		Histological examination is permitted	
Liquid nitrogen cryotherapy, curettage, CO_2 laser treatment		Quick procedure	Multiple lesions can be treated
		Well tolerated	
Diclofenac	Twice daily for 60–90 day	Well tolerated	Less effective treatment
		Can be used in an area up to 25 cm^2	
Imiquimod 5 %	3 times per week for 4 weeks	Good clearance	Marked inflammation and erythema with crusting of the skin
		Good cosmetic appearance after inflammation	May need mild topical steroid to reduce inflammation
PDT		Good cosmetic results	Discomfort treatment for the patients
		Can treat the entire cancer field	Not effective in thick AK
Therapeutic options for SCC			
Surgery		Gold standard	You can treat single or a few lesions
		Histological examination is permitted	
PDT		Good cosmetic results	Discomfort treatment for the patients
		Can treat the entire cancer field	The efficacy is lower in comparison to other diseases
Radiotherapy		Useful in selected cases (elderly patients, head and neck)	
Cryotherapy		Quick procedure	The efficacy is lower in comparison to surgery
		In small SCC or when the surgical treatments are refused/contraindicated	

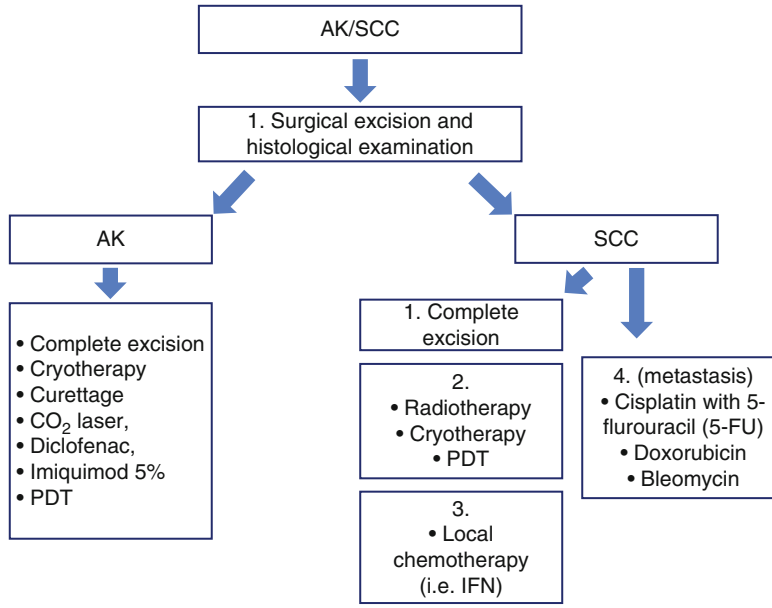

Fig. 93.5 Therapeutic algorithm in AK and SCC

Diclofenac and Imiquimod

For patients with multiple AKs, a different therapeutic approach, known as field therapy, is needed with the goal of "field therapy" for the eradication of both the clinically visible and subclinical AKs within the treatment area. As regards to chemical treatments, diclofenac and imiquimod are the most frequently used in Europe. Diclofenac 3 % gel is a nonsteroidal anti-inflammatory drug that is believed to exert its effects through the inhibition of cyclooxygenase (COX), especially COX-2. Topical 5 % imiquimod cream (Aldara®) is indicated as a treatment for AKs and superficial basal cell carcinomas. It is also used off label for treating Bowen's disease, invasive SCC, lentigo maligna, molluscum contagiosum, keloid scars, and others. Imiquimod acts as a toll-like receptor-7 agonist, which results in modification of the immune response and stimulation of apoptosis, thereby disrupting tumor proliferation.

5-Fluorouracil

The antimetabolite 5-fluorouracil (5-FU) was the first approved topical field therapy. Discovered serendipitously when AKs were noted to become inflamed and subsequently resolved in patients receiving systemic 5-FU as a chemotherapeutic agent, it was eventually designed into an effective topical formulation.

Photodynamic Therapy (PDT) and Other Treatments

Procedural field therapies may be an appropriate option for patients who require minimal downtime, are unlikely to adhere to a topical approach, have AKs resistant to topical therapy, or favor an optimal cosmetic result. Treatment options for procedural field therapy include also photodynamic therapy, manual dermabrasion, laser resurfacing, cryopeeling, and chemical peels. Each of these techniques treats AKs by destroying the superficial layers of the skin through physical or chemical means. Photodynamic therapy (PDT) is a procedural field therapy that utilizes topical 5-aminolevulinic acid (ALA) or methyl aminolevulinate (Metvix®/Metvixia®) to target AKs. These molecules preferentially find their way into the hyperproliferating cells, which lack normal cell to cell adhesion junctions, and are converted intracellularly to protoporphyrin IX (PpIX). This photosensitizer is then exposed to blue or red light, which corresponds to the peaks in the absorption spectrum of PpIX, resulting in a phototoxic reaction that destroys the abnormal cell. PDT is not ideal for treating thicker or deeper AKs and is generally reserved for patients who exhibit an inadequate response to topical field therapy or cryosurgery.

SCC: First Line of Treatment Is Surgical Excision, Followed by Histological Examination

The standard treatment of SCC is excision, followed by histological examination to insure that the entire tumor has been removed. In NMSC with features that predict a high risk of recurrence, such as ulceration, large size, special location, or aggressive histological subtype, special measures may be necessary. Surgery may be conventional or microscopically controlled, the latter procedure referred to as "Mohs' surgery," after its originator. In this procedure, the targeted lesion is excised and the circumferential margins are assessed microscopically for residual tumor. Margins remaining involved undergo repeated excisions, followed by histological assessment, until negative margins are obtained.

Other Treatments Available

When surgical removal is not feasible, alternative treatment options include ionizing radiation, cryotherapy, and photodynamic therapy.

Even if SCC is a radiosensitive tumor, radiotherapy is usually preferred when other techniques cannot be performed for definitive treatment of selected cases (elderly patients, location on head and neck, poorly differentiated histological pattern) and for palliation of inoperable tumors. Cryotherapy may be used in small SCC when other surgical treatments are refused by the patients or contraindicated, particularly in patients with bleedings disorders.

Cutaneous SCC is not as sensitive as basal cell carcinoma to photodynamic therapy with 5-aminolevulinic acid (ALA). The average rate of complete response is around 70 %.

Intratumoral injection of biological control agents (usually interferons) or cytostatic agents, as well as systemic chemotherapy, may be needed in special cases. Chemotherapy and biological therapy with interferon-α (IFN-α) and cis-retinoic acid are active but give limited results (Cranmer et al. 2010).

Metastatic SCC

No standard treatment of metastatic disease has been formulated, although combinations of cisplatin with 5-fluorouracil (5-FU), doxorubicin, or bleomycin have demonstrated some degree of efficacy, achieving complete responses in some cases (Sadek et al. 1990). Clearly, the relative rarity of patients with high-risk, potentially fatal, squamous cell carcinoma of the skin has limited prospective efforts to define ideal management.

Future Treatments

Drugs targeting the epidermal growth factor receptor (EGFR) are currently a significant nonsurgical option for advanced SCC beyond radiotherapy and conventional chemotherapy. The future of anti-EGFR-targeted therapies in the treatment of skin cancer is discussed. Other strategies to potentiate the antitumor activity of cytotoxic agents such as docetaxel or cisplatin are also discussed (Gaffney et al. 2013). Targeted molecular therapies are becoming increasingly widespread and an understanding of the evidence for their use as well as their side effect profile is important in order to offer patients informed and current advice.

Syphilis

94

Michael A. Waugh

Key Points

- Syphilis is still a frequent sexually transmitted infection (STI), caused by *Treponema pallidum*, with very serious consequences not only for the index patient but sexual partners if the diagnosis is missed.
- There are authoritative guidelines for its treatment.
- The therapeutic guidelines by Centers for Disease Control (CDC) and Prevention for syphilis in adults in the different stages of the infection are followed in this chapter.

Syphilis is still a frequent sexually transmitted infection (STI) with very serious consequences not only for the index patient but sexual partners if the diagnosis is missed.

In Europe the incidence has increased in recent years. It has been realized over the last 50 years that it is common in men who have sex with men (MSM). In the last 30 years in MSM, its coexistence with HIV has been frequently found. When syphilis is diagnosed, HIV and hepatitis B and C should be screened for at the same time in all adults as well as other sexually transmitted infections. In heterosexuals it has become more frequent though unfortunately again often misdiagnosed. It has always been recognized in sex workers and their clients, but it is not infrequently found in "swinger" groups with multiple sexual partners and intravenous drug users.

There are authoritative guidelines for its treatment. Those of Centers for Disease Control (CDC) and Prevention, Atlanta, USA, are followed in this chapter.

Only syphilis in adults will be considered here.

Definition

Syphilis is a systemic disease caused by *Treponema pallidum*. On the basis of clinical findings, the disease has been divided into a series of overlapping stages, which are used to help guide treatment and follow-up. Persons who have syphilis might seek treatment for signs or symptoms of primary infection (i.e., ulcer or chancre at the infection site), secondary infection (i.e., manifestations that include, but are not limited to, skin rash, mucocutaneous lesions, and

This chapter is the copy of CDC guidelines. The copied part has been reported between brackets (all the chapter)

lymphadenopathy), neurologic infection (i.e., cranial nerve dysfunction, meningitis, stroke, acute or chronic altered mental status, loss of vibration sense, and auditory or ophthalmic abnormalities, which might occur through the natural history of untreated infection), or tertiary infection (i.e., cardiac or gummatous lesions). Latent infections (i.e., those lacking clinical manifestations) are detected by serologic testing. Latent syphilis acquired within the preceding year is referred to as early latent syphilis; all other cases of latent syphilis are either late latent syphilis or latent syphilis of unknown duration. Treatment for both late latent syphilis and tertiary syphilis might require a longer duration of therapy because organisms might be dividing more slowly; however, the validity of this concept has not been assessed.

Diagnosis

Dark-field examinations and tests to detect *T. pallidum* in lesion exudate or tissue are the definitive methods for diagnosing early syphilis (CDC). Although no *T. pallidum* detection tests are commercially available, some laboratories provide locally developed PCR tests for the detection of *T. pallidum*. A presumptive diagnosis of syphilis is possible with the use of two types of serologic tests: (1) nontreponemal tests (e.g., Venereal Disease Research Laboratory [VDRL] and RPR) and (2) treponemal tests (e.g., fluorescent treponemal antibody absorbed [FTA-ABS] tests, the *T. pallidum* passive particle agglutination [TP-PA] assay, various EIAs, and chemiluminescence immunoassays). The use of only one type of serologic test is insufficient for diagnosis, because each type of test has limitations, including the possibility of false-positive test results in persons without syphilis. False-positive nontreponemal test results can be associated with various medical conditions unrelated to syphilis, including autoimmune conditions, older age, and injection-drug use (Nandwani and Evans 1995; Association of Public Health Laboratories (APHL) 2009); therefore, persons with a reactive nontreponemal test should receive a treponemal test to confirm the diagnosis of syphilis.

Nontreponemal test antibody titers may correlate with disease activity, and results should be reported quantitatively. A fourfold change in titer, equivalent to a change of two dilutions (e.g., from 1:16 to 1:4 or from 1:8 to 1:32), is considered necessary to demonstrate a clinically significant difference between two nontreponemal test results that were obtained using the same serologic test. Sequential serologic tests in individual patients should be performed using the same testing method (e.g., VDRL or RPR), preferably by the same laboratory. The VDRL and RPR are equally valid assays, but quantitative results from the two tests cannot be compared directly because RPR titers frequently are slightly higher than VDRL titers. Nontreponemal test titers usually decline after treatment and might become nonreactive with time; however, in some persons, nontreponemal antibodies can persist for a long period of time – a response referred to as the "serofast reaction." Most patients who have reactive treponemal tests will have reactive tests for the remainder of their lives, regardless of treatment or disease activity. However, 15–25 % of patients treated during the primary stage revert to being serologically nonreactive after 2–3 years (Romanowski et al. 1991). Treponemal test antibody titers should not be used to assess treatment response.

Some clinical laboratories and blood banks have begun to screen samples using treponemal tests, typically by EIA or chemiluminescence immunoassays (CDC 2008; Pope 2004). This strategy will identify both persons with previous treatment for syphilis and persons with untreated or incompletely treated syphilis. The positive predictive value for syphilis associated with a treponemal screening test result might be lower among populations with a low prevalence of syphilis.

Persons with a positive treponemal screening test should have a standard nontreponemal test with titer performed reflexively by the laboratory to guide patient management decisions. If the nontreponemal test is negative, then the laboratory should perform a different treponemal test (preferably one based on different antigens than the original test) to confirm the results of the initial test. If a second treponemal test is positive, persons with a history of previous treatment will require

no further management unless sexual history suggests likelihood of re-exposure. Those without a history of treatment for syphilis should be offered treatment. Unless history or results of a physical examination suggest a recent infection, previously untreated persons should be treated for late latent syphilis. If the second treponemal test is negative, further evaluation or treatment is not indicated.

For most HIV-infected persons, serologic tests are accurate and reliable for the diagnosis of syphilis and for following a patient's response to treatment. However, atypical syphilis serologic test results (i.e., unusually high, unusually low, or fluctuating titers) can occur in HIV-infected persons. When serologic tests do not correspond with clinical findings suggestive of early syphilis, use of other tests (e.g., biopsy and dark-field microscopy) should be considered.

Clinical signs of neurosyphilis (i.e., cranial nerve dysfunction, meningitis, stroke, acute or chronic altered mental status, loss of vibration sense, and auditory or ophthalmic abnormalities) warrant further investigation and treatment for neurosyphilis. Laboratory testing is helpful in supporting the diagnosis of neurosyphilis; however, no single test can be used to diagnose neurosyphilis in all instances. Cerebrospinal fluid (CSF) laboratory abnormalities are common in persons with early syphilis. The VDRL in cerebrospinal fluid (CSF-VDRL), which is highly specific but insensitive, is the standard serologic test for CSF. When reactive in the absence of substantial contamination of CSF with blood, it is considered diagnostic of neurosyphilis; however in early syphilis, it can be of unknown prognostic significance (Lukehart et al. 1988). Most other tests are both insensitive and nonspecific and must be interpreted in relation to other test results and the clinical assessment. Therefore, the laboratory diagnosis of neurosyphilis usually depends on various combinations of reactive serologic test results, CSF cell count or protein, and a reactive CSF-VDRL with or without clinical manifestations. Among persons with HIV infection, the CSF leukocyte count usually is elevated (>5 white blood cell count [WBC]/mm^3); using a higher cutoff (>20 WBC/mm^3) might improve the specificity of neurosyphilis diagnosis (Marra et al. 2004a). The CSF-VDRL might be nonreactive even when neurosyphilis is present; therefore, additional evaluation using FTA-ABS testing on CSF can be considered. The CSF FTA-ABS test is less specific for neurosyphilis than the CSF-VDRL but is highly sensitive; neurosyphilis is highly unlikely with a negative CSF FTA-ABS test (Jaffe et al. 1978).

General Principles of Treatment

Penicillin G, administered parenterally, is the preferred drug for treating all stages of syphilis. The preparation used (i.e., benzathine, aqueous procaine, or aqueous crystalline), the dosage, and the length of treatment depend on the stage and clinical manifestations of the disease. Selection of the appropriate penicillin preparation is important, because *T. pallidum* can reside in sequestered sites (e.g., the CNS and aqueous humor) that are poorly accessed by some forms of penicillin. Combinations of benzathine penicillin, procaine penicillin, and oral penicillin preparations are not considered appropriate for the treatment of syphilis. Reports have indicated that practitioners have inadvertently prescribed combination benzathine-procaine penicillin (Bicillin C-R) instead of the standard benzathine penicillin product (Bicillin L-A) widely used in the United States. Practitioners, pharmacists, and purchasing agents should be aware of the similar names of these two products to avoid using the inappropriate combination therapy agent for treating syphilis (CDC 2005).

The effectiveness of penicillin for the treatment of syphilis was well established through clinical experience even before the value of randomized controlled clinical trials was recognized. Therefore, nearly all the recommendations for the treatment of syphilis are based not only on clinical trials and observational studies, but approximately 50 years of clinical experience.

Parenteral penicillin G is the only therapy with documented efficacy for syphilis during pregnancy. Pregnant women with syphilis in any stage who report penicillin allergy should be desensitized and treated with penicillin (see section "Management of patients who have a history of penicillin allergy").

Jarisch-Herxheimer Reaction

The Jarisch-Herxheimer reaction is an acute febrile reaction frequently accompanied by headache, myalgia, fever, and other symptoms that usually occur within the first 24 h after the initiation of any therapy for syphilis. Patients should be informed about this possible adverse reaction. The Jarisch-Herxheimer reaction occurs most frequently among patients who have early syphilis, presumably because bacterial burdens are higher during these stages. Antipyretics can be used to manage symptoms, but they have not been proven to prevent this reaction. The Jarisch-Herxheimer reaction might induce early labor or cause fetal distress in pregnant women, but this should not prevent or delay therapy (see section "Syphilis during pregnancy").

Management of Sex Partners

Sexual transmission of *T. pallidum* is thought to occur only when mucocutaneous syphilitic lesions are present. Although such manifestations are uncommon after the first year of infection, persons exposed sexually to a patient who has syphilis in any stage should be evaluated clinically and serologically and treated with a recommended regimen, according to the following recommendations:

- Persons who were exposed within the 90 days preceding the diagnosis of primary, secondary, or early latent syphilis in a sex partner might be infected even if seronegative; therefore, such persons should be treated presumptively.
- Persons who were exposed >90 days before the diagnosis of primary, secondary, or early latent syphilis in a sex partner should be treated presumptively if serologic test results are not available immediately and the opportunity for follow-up is uncertain.
- For purposes of partner notification and presumptive treatment of exposed sex partners, patients with syphilis of unknown duration who have high nontreponemal serologic test titers (i.e., >1:32) can be assumed to have early syphilis. For the purpose of determining a treatment regimen, however, serologic titers should not be used to differentiate early from late latent syphilis (see section "Latent syphilis," Treatment).
- Long-term sex partners of patients who have latent syphilis should be evaluated clinically and serologically for syphilis and treated on the basis of the evaluation findings.

Sexual partners of infected patients should be considered at risk and provided treatment if they have had sexual contact with the patient within 3 months plus the duration of symptoms for patients diagnosed with primary syphilis, 6 months plus duration of symptoms for those with secondary syphilis, and 1 year for patients with early latent syphilis.

Primary and Secondary Syphilis

Treatment

Parenteral penicillin G has been used effectively for more than 50 years to achieve clinical resolution (i.e., the healing of lesions and prevention of sexual transmission) and to prevent late sequelae. However, no comparative trials have been adequately conducted to guide the selection of an optimal penicillin regimen (i.e., the dose, duration, and preparation). Substantially fewer data are available for non-penicillin regimens.

Recommended Regimen for Adults[a]

Benzathine penicillin G 2.4 million units IM in a single dose

[a]Recommendations for treating syphilis in HIV-infected persons and pregnant women are discussed later in this report (see sections "Syphilis among HIV-infected persons" and "Syphilis in pregnancy")

Available data demonstrate that additional doses of benzathine penicillin G, amoxicillin, or other antibiotics in early syphilis (primary, secondary, and early latent) do not enhance efficacy, regardless of HIV status (Figs. 94.1, 94.2, 94.3, 94.4, 94.5, 94.6, 94.7, 94.8, and 94.9).

Fig. 94.1 Primary syphilis – chancre male

Fig. 94.3 Primary syphilis – chancre anus

Fig. 94.2 Primary syphilis – chancre female

Fig. 94.4 Primary syphilis – chancre tongue

Other Management Considerations

All persons who have syphilis should be tested for HIV infection. In geographic areas in which the prevalence of HIV is high, persons who have primary syphilis should be retested for HIV after 3 months if the first HIV test result was negative.

Patients who have syphilis and symptoms or signs suggesting neurologic disease (e.g., meningitis and hearing loss) or ophthalmic disease

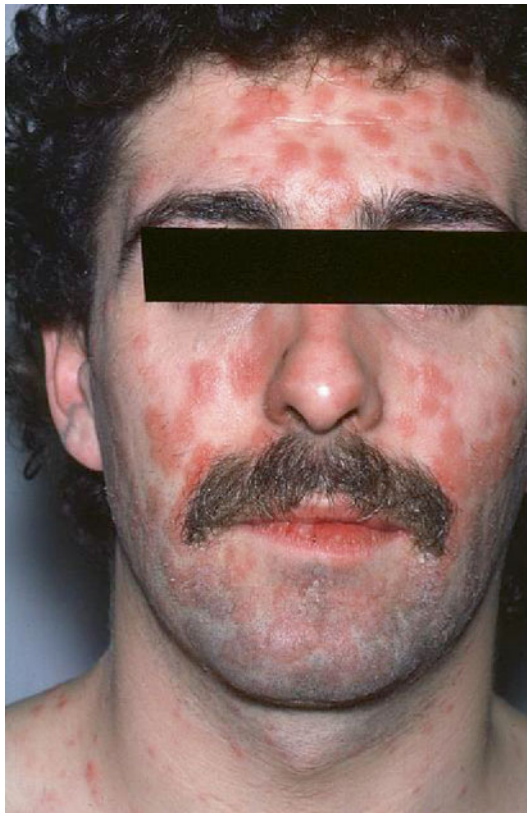

Fig. 94.5 Secondary syphilis – man's face

Fig. 94.6 Secondary syphilis – female trunk

Fig. 94.7 Secondary syphilis – hands

Fig. 94.8 Secondary syphilis – feet

Fig. 94.9 Secondary syphilis – condylomata lata

(e.g., uveitis, iritis, neuroretinitis, and optic neuritis) should have an evaluation that includes CSF analysis, ocular slit-lamp ophthalmologic examination, and otologic examination. Treatment should be guided by the results of this evaluation.

Invasion of CSF by *T. pallidum* accompanied by CSF laboratory abnormalities is common among adults who have primary or secondary syphilis (Lukehart et al. 1988). Therefore, in the absence of clinical neurologic findings, no evidence exists to support variation from the recommended treatment regimen for early syphilis. Symptomatic neurosyphilis develops in only a limited number of persons after treatment with the penicillin regimens recommended for primary and secondary syphilis. Therefore, unless clinical signs or symptoms of neurologic or ophthalmic involvement are present or treatment failure is documented, routine CSF analysis is not recommended for persons who have primary or secondary syphilis.

Follow-Up

Treatment failure can occur with any regimen. However, assessing response to treatment frequently is difficult, and definitive criteria for cure or failure have not been established. In addition, nontreponemal test titers might decline more slowly for persons who previously have had syphilis (Ghanem et al. 2007). Clinical and serologic evaluation should be performed 6 and 12 months after treatment; more frequent evaluation might be prudent if follow-up is uncertain.

Patients who have signs or symptoms that persist or recur or who have a sustained fourfold increase in nontreponemal test titer (i.e.,

compared with the maximum or baseline titer at the time of treatment) probably failed treatment or were reinfected. These patients should be retreated and reevaluated for HIV infection. Because treatment failure usually cannot be reliably distinguished from reinfection with *T. pallidum*, a CSF analysis also should be performed.

Although failure of nontreponemal test titers to decline fourfold within 6–12 months after therapy for primary or secondary syphilis might be indicative of treatment failure, clinical trial data have demonstrated that >15 % of patients with early syphilis treated with the recommended therapy will not achieve the two-dilution decline in nontreponemal titer used to define response at 1 year after treatment (Rolfs et al. 1997). Persons whose titers do not decline should be reevaluated for HIV infection. Optimal management of such patients is unclear. At a minimum, these patients should receive additional clinical and serologic follow-up. If additional follow-up cannot be ensured, re-treatment is recommended. Because treatment failure might be the result of unrecognized CNS infection, CSF examination can be considered in such situations.

For re-treatment, weekly injections of benzathine penicillin G 2.4 million units IM for 3 weeks are recommended, unless CSF examination indicates that neurosyphilis is present (see section "Neurosyphilis"). In rare instances, serologic titers do not decline despite a negative CSF examination and a repeated course of therapy. In these circumstances, the need for additional therapy or repeated CSF examinations is unclear, but is not generally recommended.

Management of Sex Partners

See section General principles, "Management of sex partners."

Special Considerations

Penicillin Allergy

Data to support the use of alternatives to penicillin in the treatment of early syphilis are limited. However, several therapies might be effective in nonpregnant, penicillin-allergic patients who have primary or secondary syphilis. Doxycycline 100 mg orally twice daily for 14 days (Ghanem et al. 2006; Wong et al. 2008) and tetracycline (500 mg four times daily for 14 days) are regimens that have been used for many years. Compliance is likely to be better with doxycycline than tetracycline, because tetracycline can cause gastrointestinal side effects. Although limited clinical studies, along with biologic and pharmacologic evidence, suggest that ceftriaxone (1 g daily either IM or IV for 10–14 days) is effective for treating early syphilis, the optimal dose and duration of ceftriaxone therapy have not been defined (Hook et al. 1988). Azithromycin as a single 2 g oral dose is effective for treating early syphilis (Riedner et al. 2005; Hook et al. 2002, 2010). However, *T. pallidum* chromosomal mutations associated with azithromycin resistance and treatment failures have been documented in several geographical areas in the United States (Lukehart et al. 2004; Mitchell et al. 2006; Su et al. 2006) as well as some other countries. As such, the use of azithromycin should be used with caution only when treatment with penicillin or doxycycline is not feasible. Azithromycin should not be used in MSM or pregnant women. Close follow-up of persons receiving any alternative therapies is essential.

Persons with a penicillin allergy whose compliance with therapy or follow-up cannot be ensured should be desensitized and treated with benzathine penicillin. Skin testing for penicillin allergy might be useful in some circumstances in which the reagents and expertise are available to perform the test adequately (see section "Management of patients who have a history of penicillin allergy").

Pregnancy

Pregnant patients who are allergic to penicillin should be desensitized and treated with penicillin (see sections "Management of patients who have a history of penicillin allergy" and "Syphilis during pregnancy").

HIV Infection

See section "Syphilis among HIV-infected persons."

Latent Syphilis

Latent syphilis is defined as syphilis characterized by seroreactivity without other evidence of disease. Patients who have latent syphilis and who acquired syphilis during the preceding year are classified as having early latent syphilis. Patients' conditions can be diagnosed as early latent syphilis if, during the year preceding the evaluation, they had (1) a documented seroconversion or fourfold or greater increase in titer of a nontreponemal test, (2) unequivocal symptoms of primary or secondary syphilis, or (3) a sex partner documented to have primary, secondary, or early latent syphilis. In addition, for persons whose only possible exposure occurred during the previous 12 months, reactive nontreponemal and treponemal tests are indicative of early latent syphilis. In the absence of these conditions, an asymptomatic person should be considered to have late latent syphilis or syphilis of unknown duration. Nontreponemal serologic titers usually are higher during early latent syphilis than late latent syphilis. However, early latent syphilis cannot be reliably distinguished from late latent syphilis solely on the basis of nontreponemal titers. All patients with latent syphilis should have careful examination of all accessible mucosal surfaces (i.e., the oral cavity, perianal area, perineum and vagina in women, and underneath the foreskin in uncircumcised men) to evaluate for internal mucosal lesions. All patients who have syphilis should be tested for HIV infection.

Treatment

Because latent syphilis is not transmitted sexually, the objective of treating patients with this stage of disease is to prevent complications. Although clinical experience supports the effectiveness of penicillin in achieving this goal, limited evidence is available to guide choice of specific regimens.

The following regimens are recommended for penicillin nonallergic patients who have normal CSF examinations (if performed):

Recommended Regimens for Adults[a]

Early latent syphilis

Benzathine penicillin G 2.4 million units IM in a single dose

Late latent syphilis or latent syphilis of unknown duration

Benzathine penicillin G 7.2 million units total, administered as 3 doses of 2.4 million units IM each at 1-week intervals

[a]Recommendations for treating syphilis in HIV-infected persons and pregnant women are discussed later in this report (see sections "Syphilis among HIV-infected persons" and "Syphilis in pregnancy")

Available data demonstrate no enhanced efficacy of additional doses of penicillin G, amoxicillin, or other antibiotics in early syphilis, regardless of HIV status.

Other Management Considerations

Patients diagnosed with latent syphilis who demonstrate any of the following criteria should have a prompt CSF examination:

- Neurologic (e.g., auditory disease, cranial nerve dysfunction, acute or chronic meningitis, stroke, acute or chronic altered mental status, and loss of vibration sense) or ophthalmic signs or symptoms (e.g., iritis and uveitis)
- Evidence of active tertiary syphilis (e.g., aortitis and gumma)
- Serologic treatment failure

If a patient misses a dose of penicillin in a course of weekly therapy for late syphilis, the appropriate course of action is unclear. Pharmacologic considerations suggest that an interval of 10–14 days between doses of benzathine penicillin for late syphilis or latent syphilis of unknown duration might be acceptable before restarting the sequence of injections. Missed doses are not acceptable for pregnant patients receiving therapy for late latent syphilis. Pregnant women who miss any dose of therapy must repeat the full course of therapy.

Follow-Up

Quantitative nontreponemal serologic tests should be repeated at 6, 12, and 24 months. A CSF examination should be performed if (1) titers increase fourfold, (2) an initially high titer (≥1:32) fails to decline at least fourfold (i.e., two dilutions) within 12–24 months of therapy, or (3) signs or symptoms attributable to syphilis develop. In such circumstances, even if the CSF examination is negative, re-treatment for latent syphilis should be initiated. In rare instances, despite a negative CSF examination and a repeated course of therapy, serologic titers might fail to decline. In these circumstances, the need for additional therapy or repeated CSF examinations is unclear.

Management of Sex Partners

See section General principles, "Management of sex partners."

Special Considerations

Penicillin Allergy

The effectiveness of alternatives to penicillin in the treatment of latent syphilis has not been well documented. Nonpregnant patients allergic to penicillin who have clearly defined early latent syphilis should respond to therapies recommended as alternatives to penicillin for the treatment of primary and secondary syphilis (see section "Primary and secondary syphilis," Treatment). The only acceptable alternatives for the treatment of late latent syphilis or latent syphilis of unknown duration are doxycycline (100 mg orally twice daily) or tetracycline (500 mg orally four times daily), both for 28 days. These therapies should be used only in conjunction with close serologic and clinical follow-up. Based on biologic plausibility and pharmacologic properties, ceftriaxone might be effective for treating late latent syphilis or syphilis of unknown duration. However, the optimal dose and duration of ceftriaxone therapy have not been defined, and treatment decisions should be discussed in consultation with a specialist. Some patients who are allergic to penicillin also might be allergic to ceftriaxone; in these circumstances, use of an alternative agent might be required. The efficacy of these alternative regimens in HIV-infected persons has not been well studied.

Pregnancy

Pregnant patients who are allergic to penicillin should be desensitized and treated with penicillin (see sections "Management of patients who have a history of penicillin allergy" and "Syphilis during pregnancy").

HIV Infection

See section "Syphilis among HIV-infected persons."

Tertiary Syphilis

Tertiary syphilis refers to gumma and cardiovascular syphilis but not to all neurosyphilis. Patients who are not allergic to penicillin and have no evidence of neurosyphilis should be treated with the following regimen:

Recommended Regimen

Benzathine penicillin G 7.2 million units total, administered as 3 doses of 2.4 million units IM each at 1-week intervals

Other Management Considerations

Patients who have symptomatic late syphilis should be given a CSF examination before therapy is initiated. Some providers treat all patients who have cardiovascular syphilis with a neurosyphilis regimen. These patients should be managed in consultation with an infectious disease specialist.

Follow-Up

Limited information is available concerning clinical response and follow-up of patients who have tertiary syphilis.

Management of Sex Partners

See section General principles, "Management of sex partners."

Special Considerations

Penicillin Allergy

Patients allergic to penicillin should be treated in consultation with an infectious disease specialist.

Pregnancy

Pregnant patients who are allergic to penicillin should be desensitized and treated with penicillin (see sections "Management of patients who have a history of penicillin allergy" and "Syphilis during pregnancy").

HIV Infection

See section "Syphilis among HIV-infected persons."

Neurosyphilis

Treatment

CNS involvement can occur during any stage of syphilis. However, CSF laboratory abnormalities are common in persons with early syphilis, even in the absence of clinical neurological findings. No evidence exists to support variation from recommended treatment for early syphilis for patients found to have such abnormalities. If clinical evidence of neurologic involvement is observed (e.g., cognitive dysfunction, motor or sensory deficits, ophthalmic or auditory symptoms, cranial nerve palsies, and symptoms or signs of meningitis), a CSF examination should be performed.

Syphilitic uveitis or other ocular manifestations frequently are associated with neurosyphilis and should be managed according to the treatment recommendations for neurosyphilis. Patients who have neurosyphilis or syphilitic eye disease (e.g., uveitis, neuroretinitis, and optic neuritis) should be treated with the recommended regimen for neurosyphilis; those with eye disease should be managed in collaboration with an ophthalmologist. A CSF examination should be performed for all patients with syphilitic eye disease to identify those with abnormalities; patients found to have abnormal CSF test results should be provided follow-up CSF examinations to assess treatment response:

Recommended Regimen

Aqueous crystalline penicillin G 18–24 million units per day, administered as 3–4 million units IV every 4 h or continuous infusion for 10–14 days

If compliance with therapy can be ensured, the following alternative regimen might be considered:

Alternative Regimen

Procaine penicillin 2.4 million units IM once daily

PLUS

Probenecid 500 mg orally four times a day, both for 10–14 days

The durations of the recommended and alternative regimens for neurosyphilis are shorter than the duration of the regimen used for late syphilis in the absence of neurosyphilis. Therefore, benzathine penicillin, 2.4 million units IM once per week for up to 3 weeks, can be considered after completion of these neurosyphilis treatment regimens to provide a comparable total duration of therapy.

Other Management Considerations

Other considerations in the management of patients who have neurosyphilis are as follows:

- All persons who have syphilis should be tested for HIV.
- Although systemic steroids are used frequently as adjunctive therapy for otologic syphilis, such drugs have not been proven to be beneficial.

Follow-Up

If CSF pleocytosis was present initially, a CSF examination should be repeated every 6 months

until the cell count is normal. Follow-up CSF examinations also can be used to evaluate changes in the CSF-VDRL or CSF protein after therapy; however, changes in these two parameters occur more slowly than cell counts, and persistent abnormalities might be less important (Marra et al. 2004b, 2008). The leukocyte count is a sensitive measure of the effectiveness of therapy. If the cell count has not decreased after 6 months or if the CSF cell count or protein is not normal after 2 years, re-treatment should be considered.

Limited data suggest that in immunocompetent persons and HIV-infected persons on highly active antiretroviral therapy, normalization of the serum RPR titer predicts normalization of CSF parameters (Marra et al. 2008).

Management of Sex Partners

See section General principles, "Management of sex partners."

Special Considerations

Penicillin Allergy

Limited data suggest that ceftriaxone 2 g daily either IM or IV for 10–14 days can be used as an alternative treatment for patients with neurosyphilis (Hook et al. 1986; Shann and Wilson 2003). However, the possibility of cross-reactivity between ceftriaxone and penicillin exists. Other regimens have not been adequately evaluated for treatment of neurosyphilis. Therefore, if concern exists regarding the safety of ceftriaxone for a patient with neurosyphilis, skin testing should be performed (if available) to confirm penicillin allergy and, if necessary, desensitization in consultation with a specialist.

Pregnancy

Pregnant patients who are allergic to penicillin should be desensitized and treated with penicillin (see section "Syphilis during pregnancy").

HIV Infection

See section "Syphilis among HIV-infected persons."

Syphilis Among HIV-Infected Persons

Diagnostic Considerations

Although they are uncommon, unusual serologic responses have been observed among HIV-infected persons who have syphilis. Most reports have involved serologic titers that were higher than expected, but false-negative serologic test results and delayed appearance of seroreactivity also have been reported (Kingston et al. 2005). Regardless, both treponemal and nontreponemal serologic tests for syphilis can be interpreted in the usual manner for most patients who are coinfected with *T. pallidum* and HIV.

When clinical findings are suggestive of syphilis but serologic tests are nonreactive or their interpretation is unclear, alternative tests (e.g., biopsy of a lesion, dark-field examination, and PCR of lesion material) might be useful for diagnosis. Neurosyphilis should be considered in the differential diagnosis of neurologic disease in HIV-infected persons.

Treatment

Compared with HIV-negative patients, HIV-positive patients who have early syphilis might be at increased risk for neurologic complications (CDC 2007) and might have higher rates of serologic treatment failure with currently recommended regimens. The magnitude of these risks is not defined precisely, but is likely small. No treatment regimens for syphilis have been demonstrated to be more effective in preventing neurosyphilis in HIV-infected patients than the syphilis regimens recommended for HIV-negative patients (Rolfs et al. 1997). Careful follow-up after therapy is essential.

Primary and Secondary Syphilis Among HIV-Infected Persons

Treatment

Treatment of primary and secondary syphilis among HIV-infected persons is benzathine

penicillin G, 2.4 million units IM in a single dose.

Available data demonstrate that additional doses of benzathine penicillin G, amoxicillin, or other antibiotics in early syphilis do not result in enhanced efficacy, regardless of HIV status (Rolfs et al. 1997).

Other Management Considerations

Most HIV-infected persons respond appropriately to standard benzathine penicillin for primary and secondary syphilis. CSF abnormalities (e.g., mononuclear pleocytosis and elevated protein levels) are common in HIV-infected persons, even in those without neurologic symptoms, although the clinical and prognostic significance of such CSF abnormalities with primary and secondary syphilis is unknown. Several studies have demonstrated that among persons infected with both HIV and syphilis, clinical and CSF abnormalities consistent with neurosyphilis are associated with a CD4 count of ≤350 cells/mL and/or an RPR titer of ≥1:32 (Marra et al. 2004a; Libois et al. 2007; Ghanem 2009); however, unless neurologic symptoms are present, CSF examination in this setting has not been associated with improved clinical outcomes.

The use of antiretroviral therapy as per current guidelines might improve clinical outcomes in HIV-infected persons with syphilis (Marra et al. 2008; Ghanem et al. 2008a, b).

Follow-Up

HIV-infected persons should be evaluated clinically and serologically for treatment failure at 3, 6, 9, 12, and 24 months after therapy.

HIV-infected persons who meet the criteria for treatment failure (i.e., signs or symptoms that persist or recur or persons who have a sustained fourfold increase in nontreponemal test titer) should be managed in the same manner as HIV-negative patients (i.e., a CSF examination and re-treatment). CSF examination and re-treatment also should be strongly considered for persons whose nontreponemal test titers do not decrease fourfold within 6–12 months of therapy. If CSF examination is normal, treatment with benzathine penicillin G administered as 2.4 million units IM each at weekly intervals for 3 weeks is recommended.

Management of Sex Partners

See section General principles, "Management of sex partners."

Special Considerations

Penicillin Allergy

HIV-infected, penicillin-allergic patients who have primary or secondary syphilis should be managed according to the recommendations for penicillin-allergic, HIV-negative patients. Patients with penicillin allergy whose compliance with therapy or follow-up cannot be ensured should be desensitized and treated with penicillin (see section "Management of patients who have a history of penicillin allergy"). The use of alternatives to penicillin has not been well studied in HIV-infected patients. These therapies should be used only in conjunction with close serologic and clinical follow-up.

Latent Syphilis Among HIV-Infected Persons

Treatment

HIV-infected persons with latent syphilis should be treated according to the stage-specific recommendations for HIV-negative persons:

- Treatment of early latent syphilis among HIV-infected persons is benzathine penicillin G, 2.4 million units IM in a single dose.
- Treatment of late latent syphilis or syphilis of unknown duration among HIV-infected persons is benzathine penicillin G, at weekly doses of 2.4 million units for 3 weeks.

Other Management Considerations

All HIV-infected persons with syphilis and neurologic symptoms should undergo immediate CSF examination. Some studies have demonstrated that clinical and CSF abnormalities

consistent with neurosyphilis are most likely in HIV-infected persons who have been diagnosed with syphilis and have a CD4 count of ≤350 cells/ml and/or an RPR titer of ≥1:32 (Marra et al. 2004a; Libois et al. 2007; Ghanem 2009); however, unless neurologic symptoms are present, CSF examination in this setting has not been associated with improved clinical outcomes.

Follow-Up

Patients should be evaluated clinically and serologically at 6, 12, 18, and 24 months after therapy. If, at any time, clinical symptoms develop or nontreponemal titers rise fourfold, a repeat CSF examination should be performed and treatment administered accordingly. If during 12–24 months the nontreponemal titer does not decline fourfold, CSF examination should be strongly considered and treatment administered accordingly.

Management of Sex Partners

See section General principles, "Management of sex partners."

Special Considerations

Penicillin Allergy

The efficacy of alternative nonpenicillin regimens in HIV-infected persons has not been well studied. Patients with penicillin allergy whose compliance with therapy or follow-up cannot be ensured should be desensitized and treated with penicillin (see section "Management of patients who have a history of penicillin allergy"). These therapies should be used only in conjunction with close serologic and clinical follow-up. Limited clinical studies, along with biologic and pharmacologic evidence, suggest that ceftriaxone might be effective (Dowell et al. 1992; Smith et al. 2004). However, the optimal dose and duration of ceftriaxone therapy have not been defined.

Neurosyphilis Among HIV-Infected Persons

Treatment

HIV-infected patients with neurosyphilis should be treated according to the recommendations for HIV-negative patients with neurosyphilis (see section "Neurosyphilis").

Follow-Up

If CSF pleocytosis was present initially, a CSF examination should be repeated every 6 months until the cell count is normal. Follow-up CSF examinations also can be used to gauge response after therapy. Limited data suggest that changes in CSF parameters might occur more slowly in HIV-infected patients, especially those with more advanced immunosuppression (Marra et al. 2004b; Ghanem et al. 2008a). If the cell count has not decreased after 6 months or if the CSF is not normal after 2 years, re-treatment should be considered.

Management of Sex Partners

See section General principles, "Management of sex partners."

Special Considerations

Penicillin Allergy

HIV-infected, penicillin-allergic patients who have neurosyphilis should be managed according to the recommendations for penicillin-allergic, HIV-negative patients with neurosyphilis. Several small observational studies conducted in HIV-infected patients with neurosyphilis suggest that ceftriaxone 1–2 g IV daily for 10–14 days might be effective as an alternate agent (Marra et al. 2000; Dowell et al. 1992; Smith et al. 2004).

Syphilis During Pregnancy

All women should be screened serologically for syphilis early in pregnancy. Most states mandate screening at the first prenatal visit for all women (Hollier et al. 2001); antepartum screening by nontreponemal antibody testing is typical, but in some settings, treponemal antibody testing is being used. Pregnant women with reactive treponemal screening tests should have confirmatory testing with nontreponemal tests with titers. In populations in which use of prenatal care is not optimal, RPR test screening and treatment (if the RPR test is reactive) should be performed at the time that pregnancy is confirmed (World Health Organization 2005). For communities and populations in which the prevalence of syphilis is high and for patients at high risk, serologic testing should be performed twice during the third trimester (ideally at 28–32 weeks' gestation) and at delivery. Any woman who delivers a stillborn infant after 20 weeks' gestation should be tested for syphilis. No infant should leave the hospital without the maternal serologic status having been determined at least once during pregnancy.

Diagnostic Considerations

Seropositive pregnant women should be considered infected unless an adequate treatment history is documented clearly in the medical records and sequential serologic antibody titers have declined. Serofast low antibody titers might not require treatment; however, persistent higher titer antibody tests might indicate reinfection, and treatment might be required.

Treatment

Penicillin is effective for preventing maternal transmission to the fetus and for treating fetal infection (Alexander et al. 1999). Evidence is insufficient to determine optimal, recommended penicillin regimens (Walker 2001):

Recommended Regimen

Pregnant women should be treated with the penicillin regimen appropriate for their stage of infection.

Other Management Considerations

Some evidence suggests that additional therapy can be beneficial for pregnant women in some settings (e.g., a second dose of benzathine penicillin G 2.4 million units IM administered 1 week after the initial dose for women who have primary, secondary, or early latent syphilis) (Wendel et al. 2002). When syphilis is diagnosed during the second half of pregnancy, management should include a sonographic fetal evaluation for congenital syphilis, but this evaluation should not delay therapy. Sonographic signs of fetal or placental syphilis (i.e., hepatomegaly, ascites, hydrops, fetal anemia, or a thickened placenta) indicate a greater risk for fetal treatment failure (Hollier et al. 2001); such cases should be managed in consultation with obstetric specialists. Evidence is insufficient to recommend specific regimens for these situations.

Women treated for syphilis during the second half of pregnancy are at risk for premature labor and/or fetal distress if the treatment precipitates the Jarisch-Herxheimer reaction (Klein et al. 1990). These women should be advised to seek obstetric attention after treatment if they notice any fever, contractions, or decrease in fetal movements. Stillbirth is a rare complication of treatment, but concern for this complication should not delay necessary treatment. All patients who have syphilis should be offered testing for HIV infection.

Follow-Up

Coordinated prenatal care and treatment are vital. Serologic titers should be repeated at 28–32 weeks' gestation and at delivery as recommended for the disease stage. Providers should ensure that the clinical and antibody responses

are appropriate for the patient's stage of disease, although most women will deliver before their serologic response to treatment can be assessed definitively. Inadequate maternal treatment is likely if delivery occurs within 30 days of therapy, if clinical signs of infection are present at delivery, or if the maternal antibody titer at delivery is fourfold higher than the pretreatment titer. Serologic titers can be checked monthly in women at high risk for reinfection or in geographic areas in which the prevalence of syphilis is high.

Management of Sex Partners

See section General principles, "Management of sex partners."

Special Considerations

Penicillin Allergy

For treatment of syphilis during pregnancy, no proven alternatives to penicillin exist. Pregnant women who have a history of penicillin allergy should be desensitized and treated with penicillin. Oral stepwise penicillin dose challenge or skin testing might be helpful in identifying women at risk for acute allergic reactions (see section "Management of patients who have a history of penicillin allergy").

Tetracycline and doxycycline usually are not used during pregnancy. Erythromycin and azithromycin should not be used, because neither reliably cures maternal infection nor treats an infected fetus (Walker 2001). Data are insufficient to recommend ceftriaxone for treatment of maternal infection and prevention of congenital syphilis.

HIV Infection

Placental inflammation from congenital infection might increase the risk for perinatal transmission of HIV. All HIV-infected women should be evaluated for syphilis and receive treatment as recommended. Data are insufficient to recommend a specific regimen for HIV-infected pregnant women (see section "Syphilis among HIV-infected patients").

Syphilis in Pregnancy

Pregnant women should be treated with the first line therapy option appropriate for the stage of syphilis and if allergic to penicillin should be desensitized (Janier et al. 2014).

General Principles Management of Sexual Partners

The Guidelines for contact tracing, management of sexual partners and notification of syphilis cases are detailed in 2014 European guideline on the management of syphilis (Janier et al. 2014).

Systemic Sclerosis

95

Matteo Zanardelli, Zoulikha Zarrab,
and Aldona Pietrzak

Key Points

- Systemic sclerosis is a chronic multisystemic progressive disease that affects the skin and internal organs.
- Raynaud's phenomenon and skin sclerosis are the first signs of the disease.
- Based on the clinical features, the course of the disease and its prognosis can be distinguished in limited, diffuse and overlap systemic sclerosis.
- The therapy should be adjusted according to the severity and progression of the disease.
- Therapy should limit primary vascular damage and subsequently regulate the immune response and the fibrosis. Symptomatic treatments, vasoactive, antifibrotic and immunosuppressive agents, can be taken into consideration in the treatment of the disease.

Definition and Epidemiology

Systemic sclerosis is a chronic multisystemic progressive disease that affects the skin and internal organs. Generally, Raynaud's phenomenon and vascular changes are the first clinical manifestations followed by sclerotic and fibrotic changes. It is a rare disease: the incidence is 8–12 patients per million population and about 75 % of patients are woman. It has the highest case-specific mortality of any of the autoimmune rheumatic diseases: the 5-year survival is about 50–70 % when pulmonary hypertension is present. It is determined by the involvement of the heart and lung (pulmonary fibrosis, pneumonia) and in some populations of higher frequency of the kidney (uraemia, malignant hypertension).

Basic Concepts of Pathogenesis

Systemic scleroderma is a complex disease, since three systems seem to be involved: the blood vessels, the immune system and the fibroblast. The microvasculature compartment seems to be affected earlier as a first involvement of the diseases. As in other various autoimmune diseases, the pathogenesis can be related to a genetic predisposition and modulated by environmental factors. The disease may be immunologically triggered and is (auto)immune mediated. The altered immune response at skin level is highlighted by the activation of T lymphocytes,

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_95, © Springer-Verlag Berlin Heidelberg 2015

abnormal cytokine production and polyclonal B-cell reactivity. The alteration of the microvasculature environment may dysregulate the release of fibroblast mediators (cytokines and growth factors) leading to progressive fibrosis of skin and internal organs. A significant deposition of collagen type I is released by fibroblasts. Skin changes are caused by abundant accumulation of homogeneous, densely packed collagen fibres, septa penetrating into the subcutaneous tissue, loss of appendages, perivascular lymphocytic infiltrates and thickening of the vessel wall with subsequent devascularisation.

Clinical Presentation

The heterogeneity of systemic sclerosis arises from the range of disease manifestations that vary between patients. Generally, the first symptoms of the disease are Raynaud's phenomenon, skin sclerosis and arthralgias (Figs. 95.1, 95.2, 95.3a, b). Cutaneous sclerosis and the involvement of various internal organs such as gastrointestinal tract, lung, heart, kidney and musculature appear later. Systemic sclerosis is defined by one major criterion (proximal scleroderma) and three minor criteria (among sclerodactyly, digital pitting scars or loss of substance on the distal finger pad and bibasilar pulmonary fibrosis). Based on the clinical features, the course of the disease and its prognosis can be distinguished in:

Fig. 95.1 Sclerodactyly and digital pitting scars (With permission of Prof. Grażyna Chodorowska and Prof Dorota Krasowska) (Photo by dr B. Wawrzycki)

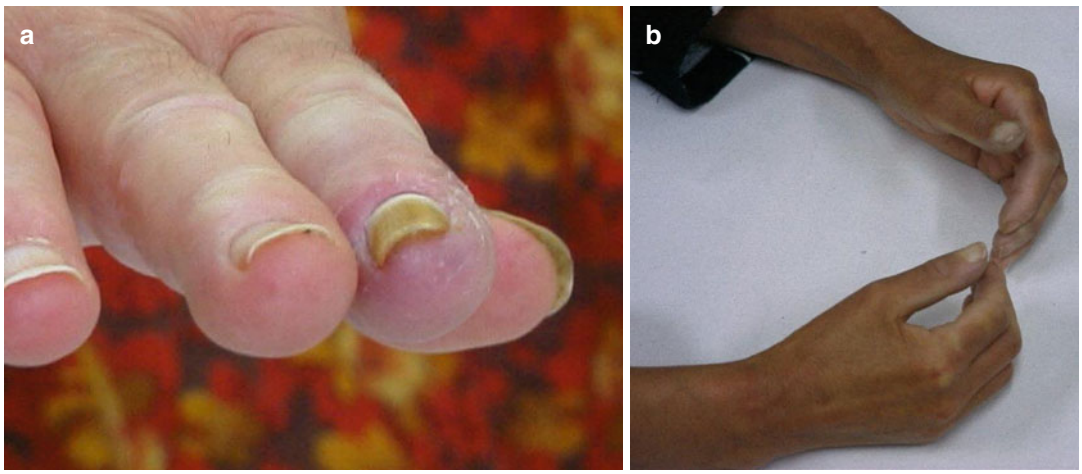

Fig. 95.2 (**a**, **b**) Sclerodactyly (With permission of Prof. Grażyna Chodorowska and Prof Dorota Krasowska)

Fig. 95.3 Raynaud's phenomenon

- *Limited scleroderma*: Raynaud's phenomenon for years at presentation. The sclerosis is limited to the hands, feet, face and forearms or absent. It includes the classic CREST (calcinosis cutis, Raynaud's phenomenon, oesophageal dysfunction, sclerodactyly and telangiectasia) syndrome. The incidence of pulmonary hypertension, trigeminal neuralgia, calcinosis and telangiectasia is late. The dilated nail fold capillary loops are dilated.
- *Diffuse scleroderma*: Raynaud's symptoms are visible within 1 year of the onset of skin alterations. The truncal and acral skin are significantly involved. Myocardial dysfunction, diffuse gastrointestinal disease, interstitial lung disease and oliguric renal failure appear earlier and are clearly visible. Systemic lupus erythematosus Sjögren's syndrome and dermatomyositis can be confused with the disease. They are characterized by U1RNP, La, Ro and Pm-Scl antibodies, respectively.
- *Overlap systemic sclerosis*: The features of scleroderma are present together with those of another autoimmune rheumatic disease, as systemic lupus erythematosus, Sjögren's syndrome and dermatomyositis can be confused with the disease. They are characterised by fibrillarin or PM-Scl antibodies. Serologic features of systemic lupus erythematosus, rheumatoid arthritis or Sjögren's disease can be noted.
- Early diagnosis is not always simple. Skin thickening of the fingers extending proximal to the metacarpophalangeal joints is sufficient for the diagnosis. If that is not present, seven additive items apply, with varying weights for each: skin thickening of the fingers, fingertip lesions, telangiectasia, abnormal nail fold capillaries, interstitial lung disease or pulmonary arterial hypertension, Raynaud's phenomenon and disease-related autoantibodies. Antinuclear antibodies are found in 97 % of cases, using HEp-2 cells as substrate.

Centromere antibodies are detectable in 50–70 % of limited variants of the disease as CREST syndrome and antitopoisomerase antibodies (anti-Scl-70) in about 36 % of cases of systemic diffuse scleroderma. The increase of collagen metabolism, due to the activation of fibroblasts, is revealed with high level of β-galactosidase and N-terminal procollagen III propeptide. Early identification of the disease is of great importance from both scientific and clinical points of view. Studies performed in patients at the early stage of the disease might foster research on the processes that play a crucial role in the pathogenesis.

Differential Diagnosis

- Raynaud's phenomenon. Generalised morphea and multiple plaque morphea
- Overlap with systemic lupus erythematosus and dermatomyositis
- Sclerodermiform porphyria cutanea tarda
- Scleromyxoedema: paraproteins, light chains
- Genetic acrogeria
- Haematologic disease as cryoglobulinemia, cold agglutinin disease and hyperviscosity syndrome
- Scleroderma-like lesions, as amyloidosis, scleromyxoedema, mucinosis and lichen sclerosus et atrophicus
- Scleroedema adultorum (Buschke's disease) with acute onset and visible after an infection
- Graft-versus-host disease after transplantation
- Eosinophilic fasciitis
- Chronic graft-versus-host disease

General Principles of Treatment

The therapy should be adjusted according to the severity and progression of the disease. The quantitative measurement of skin score and severity of skin involvement is desirable for follow-up studies. Therapy should limit primary vascular damage and subsequently regulate the immune response and the fibrosis. However, at present, there is no proven antifibrotic agent.

General Recommendations

General recommendations include: avoiding of the changes of temperature, protection from cold, regular physical activity using small balls to avoid contractures of the hands, regular dentistry controls and homeostasis of the oral cavity as long as possible and high diet content of proteins and vitamins. The skin should be protected with clothes and lubrificated with emollients. Nicotine should be avoided. Moreover, psychological guidance, based on interview counselling and autogenous training, is helpful.

Recommended Therapies

Symptomatic Treatment

The cyclooxygenase (COX)-II inhibitors Celebrex), small doses of glucocorticosteroids or nonsteroidal antiphlogistics are used for arthralgia, arthritis and tendon pain.

The reflux oesophagitis can be successfully treated with the proton pump inhibitor omeprazole (20–40 mg/day per os), antacids and H_2 antagonists (cimetidine, ranitidine). Metoclopramide (Paspertin), 3×10 mg/day per os, acts as gastroprokinetic. Small bowel bacterial overgrowth (diarrhoea) can be inhibited by tetracycline, ampicillin and metronidazole using also probiotics. Some sources recommend use of piascledine.

Vasoactive Substances

Vasculopathy is an important feature of systemic sclerosis and involves both the peripheral and visceral vessels. Approximately 50 % of patients with systemic sclerosis suffer from digital ulceration associated with vasculopathy at some point in their disease history. Other complications include critical digital ischaemia, paronychia and finger pulp loss.

Pulmonary arterial hypertension (PAH), developing due to obliterative angiopathy of the pulmonary arteries, is currently the leading cause of scleroderma-related deaths.

- *Calcium channel blockers* are the therapy of choice in Raynaud's phenomenon. Nifedipine 510 mg, three tablets/day, is suggested. Alternatives are nitrendipine, verapamil and nicardipine.
- *Pentoxyphylline*, 0.4–0.8 g/day, acts as a vasodilator and exerts, in addition, immunomodulatory and antifibrotic effects.
- *Prostacyclins* inhibit platelet aggregation and mediate vasodilatation. Intravenous infusions of prostaglandin E_1, e.g. 0.5–2.0 ng/kg per min, are more effective and better tolerated than oral doses of the prostacyclin analogue iloprost (100–300 μg/day). Side effects can be headache, flush and hypotension.
- *Angiotensin-converting enzyme inhibitors*, e.g. captopril (4×12.5 mg/ day) or enalapril (10 mg/day), are useful in patients suffering from hypertension. They represent a considerable advance in preventing or treating acute renal crisis.
- Patients with digital ulcers may benefit from the use of flexible *hydroactive dressings* such as DuoDERM, Sorbsan and antimicrobial creams or hydrogen peroxide solution (1.5–3 %) or silver sulfadiazine cream.
- *Digital sympathectomy and radial microarteriolysis* for a critically ischaemic digit are the last resort for treatment of ischaemic digit.
- *Antagonist of angiotensin II receptor type I* (losartan) exerts clinical benefit in Raynaud's phenomenon after 12 weeks.
- *Clonidine* as an antihypertensive agent (3×0.15–0.3 mg/day p.o.) may be considered.

- *Prazosin* as a receptor blocker (1–4 mg/day p.o.) can be used.
- *Ketanserin* (60–120 mg/day p.o.) as a serotonin antagonist can be considered, but it seems to have low relevance.
- *Fibrinolysis-enhancing* drugs, as dextran, tissue plasminogen activator, urokinase and stanozolol, can be tried.
- *New proposed substances* are endothelin receptor antagonists and phosphodiesterase-5 (PDI-5) inhibitors used for the treatment of PAH and for combination therapy in patients who do not respond to therapy with single agents.
  - Attempts of Viagra

Immunosuppressive Agents

Immunosuppression is considered a cornerstone of therapy of diffuse progressive disease and systemic sclerosis-related interstitial lung disease (SLD). However, the evidence for efficacy of immunosuppressive drugs in treating the disease-related organ involvement is limited.

- *Methotrexate* (MTX) inhibits the intracellular purine and pyrimidine metabolism, amino acid synthesis and polyamine synthesis. Additionally, MTX increases extracellular adenosine concentrations. In vivo MTX shows numerous immunomodulatory effects. It is able to limit the cellular adhesion, the clonal proliferation of T and B cells, the IL-1β production by mononuclear cells and the production of proinflammatory cytokines by activated T cells. If used for skin thickening treatment in the absence of lung disease, MTX with a dose of 15–25 mg once weekly can be exploited for treatment. The use of oral or subcutaneous dosing will be determined based on gastrointestinal tolerance and skin involvement.
- *Ciclosporin A* (1.5–5 mg/kg of body weight per day) is more selectively directed against T cells, IL-2 release and other cytokines. Side effects, as nephrotoxicity, limit its use.
- *Photopheresis* (extracorporeal photochemotherapy) inhibits activated T cells. Long-term treatment, more than 18–36 months, in cycles every 4 weeks, has shown a beneficial effect on disabling symptoms such as fingertip ulcer, hand motility, Raynaud's phenomenon and skin stiffness.
- *Mycophenolate* is available commercially as mycophenolate mofetil (MMF, CellCept) and mycophenolate sodium (MS, Myfortic). After absorption, it is hydrolysed and transformed to the active drug mycophenolic acid. Its use is aimed at the treatment of systemic lupus erythematosus and other autoimmune diseases. Mycophenolic acid reversibly inhibits lymphocyte proliferation, through the block of guanosine monophosphate production, a purine essential for lymphocyte amplification. Mycophenolate can be considered a second-line therapy for treatment of skin thickening in the disease. The maximum dose is 3 g per day in divided doses.
- *Cyclophosphamide* is an alkylating agent used in the treatment of malignancy, vasculitis and lupus nephritis. Its immunomodulatory properties derive from the reduction of B- and T-cell proliferation, through the disruption of DNA integrity. Cyclophosphamide is an important agent to consider for diffuse skin disease if there is concurrent lung disease. If administered intravenously, it should be used at 500 mg/m^2 on the first infusion and then increased to 750 mg/m^2 or higher for subsequent infusions if patient laboratory parameters and side effect profile will allow for it. Oral cyclophosphamide should be administered at a dose of 2 mg/kg/day as tolerated.
- *Azathioprine* is a prodrug and the active form is 6-mercaptopurine (6-MP). 6-MP is a purine structural analogue that reduces de novo synthesis of purines, decreasing cellular proliferation. Azathioprine should be considered as an alternative agent for skin involvement when there is intolerance or unresponsiveness for other agents. The proposed oral doses range from 2 to 3 mg/kg/day.
- *Prednisolone* is considered *by some of the authors* the most effective drug in the early inflammatory stages or episodes of the disease

(with significant immunological activity). At the onset, 40–80 mg/day is tapered off to a maintenance dose (about 10 mg/day). Prednisolone can be combined with other immunosuppressants, in particular with cyclophosphamide (2 mg/kg body weight per day per os).

- *Intravenous immunoglobulin* (IVIG) contains polyclonal IgG antibodies harvested from pooled human plasma. It is proposed for the treatment of a variety of immune diseases. Its mechanism of action is based on the autoantibodies neutralisation, the blocking of the Fc receptors on the surface of B cells and macrophages and the inhibition of inflammatory mediators. Its use lacks robust evidence at this time. If used, it should be administered in a liquid pasteurised form. Five percent concentrated preparation of IVIG should be dosed at 2 g/kg over 2–5 days and administered monthly for up to 6 months.
- *Autologous hematopoietic stem cell transplantation*. Although the results of this study indicate that severe immunosuppression followed by stem cell transplantation is beneficial compared with traditional immunosuppression, further studies involving the greater numbers of patients are needed to establish the role of this treatment strategy
- *Biological therapies*. Several biological therapies have been approved for treating patients with connective tissue diseases such as rheumatoid arthritis or lupus erythematosus disseminates. So far, only few open-label studies have investigated the safety and efficacy of biological therapies in patients with systemic sclerosis. Although it is not a clear demonstration of their efficacy and the studies are limited, the most accredited biological drugs block TGF-β_1, TNF-α and CD-20 pathways.
- *Kinase receptor inhibitors.* Based on experimental and clinical evidence, kinase receptor inhibitors have been proposed as a treatment option in patients with severe SSc. Further studies are needed to clarify the role of imatinib mesylate and other kinase receptor inhibitors, such as dasatinib or nilotinib.
- *Oral administration of bovine type I collagen* (0.1 = −0.5 mg daily) for 12 months reduces the T-cell reactivity to human collagen I, appears to be well tolerated and improves the skin score.

Antifibrotic Substances

- *Penicillin G* (10 million IU/day intravenously within 30 mm for 14 days) acts as prolyl hydroxylase inhibitor with beneficial effects.
- *D-penicillamine* inhibits the cross-link formation of collagen fibrils. In higher doses, side effects such as bone marrow depression, proteinuria, gastrointestinal ulcer, *dysgeusia*, pemphigus, myositis and rash are significant. Recently, it has been shown that high-dose therapy (750–1,000 mg/day) is not superior to low-dose therapy (125 mg every other day) and similar to placebo. Therefore, it can no longer be recommended, the more so as 80 % of the adverse event-related withdrawals occurred in the high-dose patients.
- *Psoralen and ultraviolet A* (PUVA) bath photochemotherapy enhances collagenase activity of fibroblasts and improves skin sclerosis, in particular in generalised morphoea.
- *UVA1* high-dose therapy reduces skin-infiltrating T cells, and it upregulates the expression of matrix metalloproteinase-1 (collage-nase-1). UVA1 phototherapy-treated skin lesions were markedly softened after 9–29 exposures.
- *Minocycline* (50–100 mg/twice daily) is worth trying in early diffuse systemic sclerosis.

Alternatives and Experimental Treatment

- Treatment with *interferon-γ* (3 × 50 μg/week s.c.) is associated with the skin score normalisation and lack of worsening of internal organs. Improvement could not be observed.
- Planned studies with *recombinant human relaxin* were cancelled due to ineffectivity, although in a previous study, 25 mg/kg per day was associated with reduced skin thickening, improved mobility and improved function after 24 weeks.

- *Retinoids*, vitamin D analogue, colchicine, griseofulvin, potassium para-aminobenzoate (Potaba) and cyclophenyl cannot definitely be recommended.

Acute and Chronic Telogen Effluvium

96

David Hugh Rushton

Key Points

- Hair loss is distressing to many patients.
- In telogen effluvium (TE), once the initiating factor is identified, reassurance is often all that is required. However, the physician should be aware of a possible underlying issue if the increased hair shedding does not resolve.
- At the initial consultation, time must be given to evaluate all possible factors that might have affected the individual up to 4 months prior to the patient becoming aware of an increase in hair shedding.
- Frequently hair loss induces changes in the patient's hair care and grooming routines, which can result in an artificial increase in the observed shedding. Patients should be advised to maintain their normal hair care routine.
- If nutritionally induced hair loss has been identified, either a change in dietary habits or taking the appropriate or stopping the inappropriate supplement should address this problem. The physician also needs to explain the time lag between correcting the imbalance and the patient seeing a reduction in hair loss. In long-standing chronic TE (CTE), many months are required to return the long hair volume to its former status.
- In conditions that result in hair density changes, increased hair shedding is often the first indication of an impending problem and a modified unit area trichogram will aid diagnosis.

Definition and Epidemiology

Hair is considered to be a major component of an individual's general appearance. Throughout history, and in most (although not all) civilisations, scalp hair has been associated with positive signals such as beauty and power. Baldness or hair loss on the other hand has a negative attribute.

The psychological impact of hair loss results in a measurably detrimental change in self-esteem and is associated with images of reduced worth. It is not surprising that both men and women find hair loss a stressful experience even in conditions where a complete recovery can be expected. Yet the distress, even by a temporary loss of hair, profoundly affects an individual's self-confidence and quality of life. This can result in the sufferer seeking help from unscrupulous organisations selling useless, ineffective lotions and potions for large sums of money. Compounding matters, many sufferers will, upon

seeing an increase in hair shedding, change their hair care and grooming habits, thus adversely affecting the aesthetic appearance and inducing an apparent increase in the perceived hair loss. In addition, there may also be a relative increase in sebaceous matter and scaling due to ineffective and inefficient shampooing, which can also exacerbate the loss of hair.

In this chapter we focus on commonly presenting causes leading to acute and chronic telogen effluvium without any change in hair density (parting width unchanged). However, in severe acute or persistent chronic conditions where increased hair shedding is occurring, the possibility of a lag phase issue should be considered. Although increased hair shedding may be present in conditions where there is reduced hair density (Rushton 1993), these will only be briefly discussed. Conditions that involve a delay in the initiation of the new anagen cycle (a lag phase issue) that results in a reduction in the relative number of visible hairs, i.e. reduced hair per cm^2, will not be fully covered. The reader should consult the endocrine literature in such cases for an in-depth guide to the appropriate investigations and treatment options.

Basic Concepts of Pathogenesis

Three hair variables define the aesthetic profile of an individual, (a) the number of hairs per cm^2, (b) hair diameter, and (c) the length of the anagen growth phase and related subsequent release of the telogen hair. In a normal healthy individual in whom there is no underlying scalp scaling malady, these variables exist in a steady state. Only when there is an alteration to one or a combination of these variables is the aesthetic hair prolife changed and hair loss observed.

In telogen effluvium (TE), there is generally no change in the number of hairs per cm^2 nor is there a change in hair diameter; however, an increase in the number of telogen hairs, with a corresponding relative decrease in the number of growing hairs, affects the observed hair when combing and shampooing. Many physicians like to undertake a 'pull test' to confirm hair loss is occurring. This is unnecessary in TE since the patient already knows more hair than normal is falling out. Not only is extracting a large amount of hair from the scalp in a single 'pull' painful, it can cause further distress to an individual already anxious about losing hair. Furthermore, the 'pull test' provides no objective data or useful information about the cause of the hair loss.

If the effluvium is severe or there is a delay in the initiation of the new anagen cycle, there can be a temporary reduction in hair density. In the majority of telogen effluvium cases, no change in hair density occurs. Figure 96.1 illustrates the impact of a decrease in the anagen phase and the resulting relative increase in daily hair shedding for a given total scalp hair density. For example, with a total hair density of 150,000 hairs and an anagen duration of 7 years, the individual would lose 59 hairs per day; however, if the anagen duration was to reduce to 5 years, then the daily hair loss would rise to 82, an increase of 39 %. If the TE lasts only for a few weeks, most individuals would be unaware of any increase in hair shedding, but when shedding is observed, it can set off an adverse sequence of events.

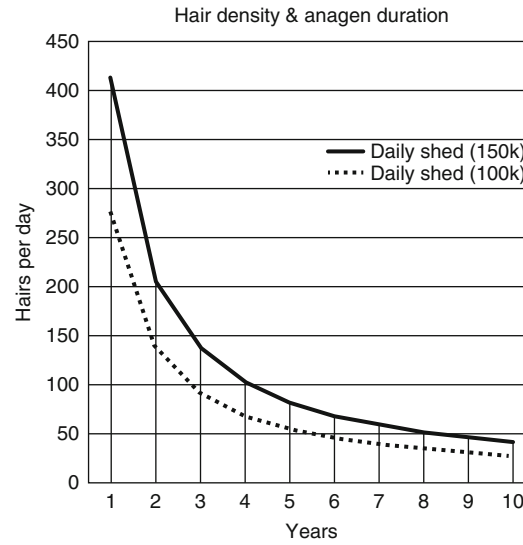

Fig. 96.1 Projected daily hair shedding for an individual with a total hair density of 150,000 or 100,000 hairs with anagen durations from 1 to 10 years

For example, if an individual shampooed every 2 days but as a consequence of seeing an increase in hair shedding they then reduce their shampooing frequency, this would result in an apparent increase in hair lost on subsequent shampoos. This induced change is of course not a true increase but an observed difference in their hair shedding due to the relative change of their hair care routine.

It is frequently quoted that 100 hairs are lost each day; from Fig. 96.1, this corresponds to 4-year anagen duration for a total hair density of 150,000 and approximately 3 years for a total hair density of 100,000. Assuming an average monthly growth rate of 1.2 cm, such individuals would respectively be able to grow their hair to 58 cm or 43 cm in length. Obviously not all of the hair would have grown to these lengths because for 3 months, 9,000 hairs are in telogen, representing respective telogen values of 6 and 9 %. Quoting a general daily hair shedding amount or giving specific percentages for anagen or telogen hair is meaningless. Individuals have their own parameters for these variables and it is the relative change for them, which is the critical factor.

A change in the anagen/telogen (A/T) equilibrium can occur from many events, and it is important to try to identify any alteration to the patient's medical history, hair care routine, scaling maladies, and lifestyle changes. Common events include changes in medication dosages, starting or stopping a medication (oral contraceptive), childbirth (postnatal), fever, illness, miscarriage, menstrual dysfunction, excessive vitamin A intake, weight loss (crash dieting), and surgery involving a general anaesthetic.

Diagnosis

The Initial Consultation

It is of paramount importance to spend time taking a full and complete history of the events that occurred 4 months before the patient became aware of increased hair shedding. Often the cause can be identified and the appropriate reassurance and guidance given. In many cases no further action is required and reassurance alone is sufficient to ease the patient's fear that they will not become bald. It is also important to explain the time delay involved before they will see a reduction in the amount of hair being shed. When TE is linked to a prescription medication, whether an alternative preparation could be prescribed requires careful consideration. A sympathetic understanding is often needed, as many patients are more worried about their hair loss than the underlying medical issue. Simply dismissing the patient's hair loss concerns as unimportant can cause unnecessary distress.

Drug and patient information leaflets frequently list alopecia as a reported side effect but the association is often tenuous; where proven the frequency is relatively rare. However, there are groups of drugs which in all family members cause hair loss (a relative alteration to the anagen/telogen ratio); for example, anticoagulants (heparin, heparinoids, and coumarins) and many cytostatic agents induce an anagen effluvium. Dawber and Van Neste and Van Neste and Rushton publications give a comprehensive list of drugs that can cause hair loss.

When hair loss is a reported side effect, this is often stated as alopecia. However, the very word alopecia to the layperson is often taken to mean they will go bald. Explaining the various types of alopecia requires skill to allay any unfounded fears of the patient becoming bald. It should also be remembered that the published data proving drug-induced hair loss is somewhat limited. Demonstrating cause and effect is particularly difficult in medication-induced TE. Establishing a positive causative link usually requires rechallenging the patient with the drug once the hair loss has abated, but patients are often unwilling to restart a medication they believe caused their hair loss.

The recently identified role of the exogen phase in hair shedding could explain synchronised hair moults in animals and the non-synchronised hair shedding in humans. How the hair is released in exogen is still unknown but

some medications appear to induce a premature telogen effluvium by activating the exogen pathways. It is not unusual to discover a patient observing increased hair shedding within 4 weeks of starting a prescribed medication. The hair morphology of the shed hair is that of a telogen bulb indicating the premature release of the telogen hair. Examination of the shed hairs distinguishes the hair from an anagen effluvium, as would occur with chemotherapy, from a true telogen effluvium. Whether an altered exogen phase continues to operate during drug therapy is the subject of ongoing research.

Since TE only becomes evident if the disturbance to the anagen/telogen balance lasts long enough to induce an observed increase in hair shedding, it is important to recognise that the underlying cause may not be immediately obvious and should alert the physician to consider undertaking some biochemical investigations. This situation is usually encountered if the cause(s) does not self-correct and the hair shedding has been present for 6 months or more; in this situation chronic telogen effluvium is the diagnosis.

Fig. 96.2 Hair samples presented at consultation by a patient complaining of unexplained chronic telogen effluvium over a 7-year period. Her mother obtained the sample on the right at the age of 18 years, a family tradition in her culture (the hair in females is traditionally left uncut from birth until their 18th birthday). The *left* sample was cut when aged 27 due to the distress of persistent unexplained increased hair shedding for the previous 5 years; the hair had not been cut since her 18th birthday and weighs 30 % less than the *right* sample

Chronic Telogen Effluvium

Chronic telogen effluvium (CTE) occurs where there is a relative decrease in the proportion of growing hair (anagen) and an increase in telogen hair, which has persisted for at least 6 months. This results in a reduction in the long hair volume (less hair to clip up or tie back in the ponytail; Fig. 96.2) and a frequent complaint seen in dermatological clinics. In addition, compared with the normal hair growth situation (Fig. *96.3*), there is a relative increase in the incoming new hair (Fig. *96.4*).

In the absence of an obvious cause for persistent increased hair shedding, biochemical investigations frequently reveal no apparent problem. This situation is compounded by current laboratory practice where the lower female reference ranges for some haematological variables (haemoglobin [Hb], red blood cell count [RBC], and serum ferritin) were derived from arbitrarily assigned parameters. Unfortunately these studies contained a significant number of iron-deficient females. The significance of this can be seen when a male presenting with a Hb of 125 g/L (12.5 g/dL) would be considered anaemic and investigated, yet such a value in the female is deemed normal with no further action considered; this situation also applies for RBC and serum ferritin. Given that in non-human mammals there is no sex difference for Hb or RBC concentrations (veterinarians do not evaluate ferritin), I would recommend employing the lower male reference ranges for Hb, RBC, and serum ferritin until the appropriate studies in proven iron-replete women

Fig. 96.3 The normal presentation of scalp hair from an individual being studied during the establishment of normal parameters for hair variables in females (Rushton D.H. Chemical and morphological properties of scalp hair in normal and abnormal states.1988, PhD Thesis; Welsh School of Pharmacy, University of Wales)

Fig. 96.4 Typical presentation of chronic telogen effluvium (CTE) in a 28-year-old female patient complaining of unexplained increased hair shedding for over 2 years. Note the abnormal number of short hair compared with the presentation found in a normal 28-year-old female (Fig. 96.3)

have been undertaken. With regard to the currently cited parameters for other micronutrients and various vitamins, conflicting reference range values are widespread and objective evidence supporting specific parameters is lacking.

The role of nutrition in hair growth is well established in severe malnutrition, anaemia, and anorexia nervosa. However in the absence of an underlying pathology, nutritional effects are poorly understood. Investigating chronic telogen effluvium in apparently healthy individuals and, in particular women, requires a different approach. Employing reference ranges constructed to define the limits of illness must be interrupted in relation to the fact that most individuals complaining of CTE are apparently healthy. Consequently, optimising blood variables for the non-essential tissues often requires higher concentrations than those used to define illness.

Studies have shown that CTE arises from a nutritional imbalance and iron deficiency appears to be the most frequent cause. While 34 % of premenopausal females have CTE, it is well recognised that while there is widespread iron deficiency in menstruating females, many do not experience increased hair loss. The recently identified iron-regulating hormone hepcidin is involved in hair follicle iron metabolism and haemochromatosis where there is variable penetrance; a similar situation might operate in CTE.

Data from 200 apparently healthy women complaining of CTE showed depleted iron stores (as assessed by serum ferritin) as the main finding. Sixty-five per cent failed to achieve the lower reference level for males (40 ng/ml), while 95 % had a serum ferritin level below (70 ng/ml), the 99 % confidence limit for iron staining in the bone marrow; the accepted 'gold standard' for being iron replete. Total iron binding capacity (TIBC) values not only reflect the iron transport status; they also indicate protein insufficiency. TIBC levels in the lower half of the reference range, indicating an adequate iron status, were found in women with low serum ferritins. These findings suggest that a large number of women with CTE might also have a suboptimal intake of first-class proteins. Normally, TIBC increases in response to iron deficiency with concentrations above or in the upper half of the reference range. Furthermore, 28.5 % of this group had a raised serum folic acid level suggesting excessive vitamin supplementation, which was probably taken to treat their excessive hair shedding.

Despite the accumulating publications linking unexplained chronic telogen effluvium and low serum ferritin concentrations in women, some dermatologists still believe there is no association at all or that the link is tenuous. These views, based on five subjects with no objective follow-up hair data or serum ferritin values or with

confounding and contradicting issues, were subsequently criticised. Despite these shortcomings, both are still widely cited. It is noteworthy that the homozygous 'Mask' mouse (a hepcidin knockout mutant that inhibits iron absorption) fed on a normal mouse diet develops a gradual loss of body but not facial hair leading to almost complete trunk nudity within 4 weeks. In addition, they become iron deficient and anaemic and the females are infertile. However following iron supplementation to their normal diet, all symptoms completely resolve.

Excessive intake of vitamin A causes hair loss, as can vitamin A deficiency. Low serum zinc (Zn) is frequently cited to cause hair loss, but with the exception of acrodermatitis enteropathica, there is little evidence to support this widespread belief. However both low vitamin A and Zn have been linked to increased skin exfoliation and scaling, which if present on the scalp can induce hair loss. Recently low vitamin D concentrations <20 nmol/L (8 ng/ml; 2.5 nmol/L, equals 1 ng/ml) have been associated with increased hair shedding, but further work is needed to confirm the role of low vitamin D concentrations and hair loss.

Acute and Chronic Telogen Effluvium in Patients with Impending or Exhibiting Reduced Hair Density

The possibility of increased hair shedding in patients with reduced hair density, particularly in women, needs to be considered. While the previous sections detailed how to investigate acute and chronic telogen effluvium without a change in hair density, sometimes telogen effluvium occurs initially in patients in whom reduced hair density will become a future problem; in these cases a hormonal imbalance should be considered. In those presenting with reduced hair density, the possibility of coexisting factors, as described above, should be considered.

When the clinical history is unhelpful in identifying a possible cause for reduced hair density, how do you proceed? Understanding tissue sensitivity is an important concept in the absence of any gross pathology (hyperandrogenism; acne and/or hirsutism); you have to consider tissue sensitivity in a patient with a normal androgen status. This situation is challenging in a busy clinical environment since such patients require additional time to identify a potential problem. In these cases such patients would benefit from undergoing a hair analysis. The ideal test is the modified unit area trichogram, which evaluates two variables that are diagnostic for male and female pattern hair loss that is actively progressing and is much more sensitive than a 'pull test' or a scalp biopsy. In the modified unit area trichogram, a sample of at least 50 hairs is required. The individual hairs are epilated in the direction of hair growth from the area under investigation and then placed onto a microscope slide with double-sided tape. The percentages of telogen ≤30 mm in length and vellus hair (hair ≤40 μm in diameter ≤30 mm in length) are determined. If the per cent of telogen hair ≤30 mm is above 6.1 % in males or 7.2 % in females (Rushton et al. 1990) or the per cent of vellus hair is >10.2 in males or >13.0 in females, then an active androgenic drive must be considered. When both variables are elevated, treatment should not be delayed.

In males, finasteride 1 mg (Propecia) a 5α-reductase inhibitor has proven effective in around 40 % of men by preventing the conversion of testosterone to dihydrotestosterone (DHT) via the 5α-reductase pathway. Dutasteride, a type I and type II 5α-reductase inhibitor, has yet to undergo formal evaluation for use in male pattern hair loss. While minoxidil does not appear to affect the 5α-reductase pathway, it can prolong the anagen phase, thereby limiting the number of transitions into telogen and delaying the progression of male pattern hair loss.

Figure 96.5 lists the treatment options for hair loss in women with respect to likely outcomes, but help in enabling the patient to achieve an acceptable aesthetic appearance often requires addressing the hair care as well as the medical needs.

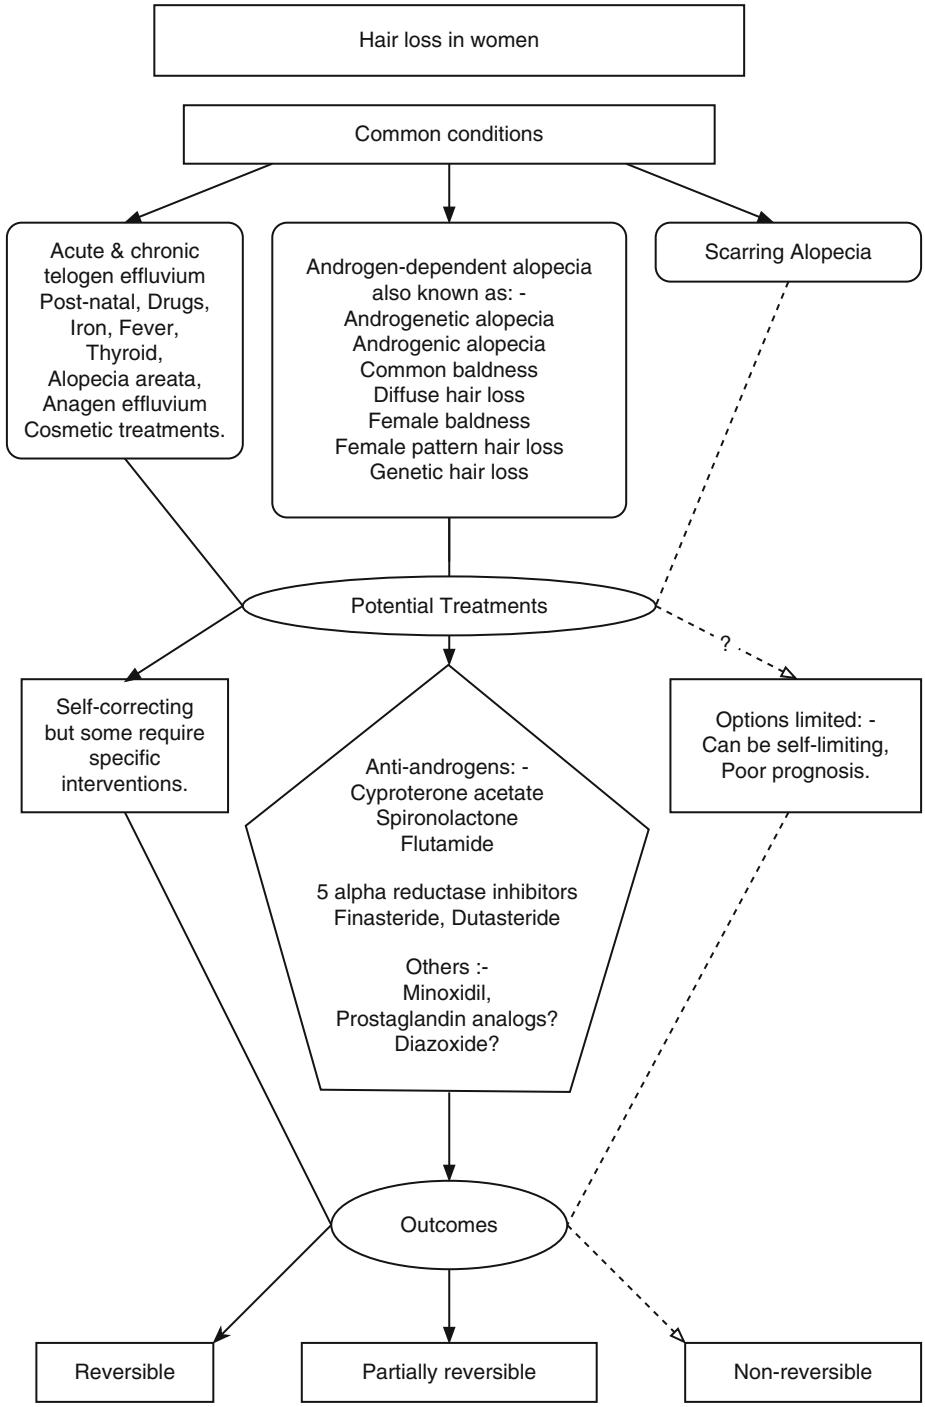

Fig. 96.5 Flow chart for common hair loss conditions in women

Telogen effluvium, at a glance

Hair loss is distressing to many patients and simply dismissing their concerns is both irresponsible and unethical. Too often the patient is dismissed because hair loss is non-life threatening.

In TE once the initiating factor is identified, reassurance is often all that is required. However, the physician should be aware of a possible underlying issue if the increased hair shedding does not abate.

At the initial consultation, time must be given to evaluate all possible factors that might have affected the individual up to 4 months prior to the patient becoming aware of an increase in hair shedding.

Frequently hair loss induces changes in the patient's hair care and grooming routines, which can result in an artificial increase in the observed shedding. Patients should be advised to maintain their normal hair care routine.

If nutritionally induced hair loss has been identified, either a change in dietary habits or taking the appropriate or stopping the inappropriate supplement should address this problem. The physician also needs to explain the time lag between correcting the imbalance and the patient seeing a reduction in hair loss. In long-standing CTE, many months are required to return the long hair volume to its former status.

In conditions that result in hair density changes, increased hair shedding is often the first indication of an impending problem. Undertaking a modified unit area trichogram will identify an active androgen-mediated condition.

Tinea Versicolor (Pityriasis Versicolor)

97

Zoulikha Zarrab, Matteo Zanardelli, and Aldona Pietrzak

Key Points

- Tinea versicolor (TV), also known as pityriasis versicolor, is a superficial fungal infection of the skin, caused by lipophilic fungi of the genus *Malassezia*, and it is characterized by fine scaly patches and macules.
- Clinical varieties: hypochromic and hyperchromic. The course for both the varieties is chronic.
- The treatment of TV is based on antifungal therapy. Topical therapy is recommended for limited cases. In case of extensive or recurrent cases, systemic treatments can be considered. Long-term management has to be performed to avoid relapses.

Definition and Epidemiology

Tinea versicolor (TV), also known as pityriasis versicolor, is a superficial fungal infection of the skin. Normally it is caused by lipophilic fungi of the genus *Malassezia*. The fungal species inducing TV are *M. globosa*, *M. sympodialis*, and *M. furfur*. Clinical signs are very clear since different fungi species develop filaments and induce the peculiar stratum corneum damage, characterized by depigmentation and inflammation. TV is one of the commonest skin diseases with a wide geographical range. This infection may occur in healthy individuals and in immunocompromised patients, although it is not a marker of human immunodeficiency virus (HIV) infection.

Basic Concepts of Pathogenesis

Malassezia yeast belongs to a group of fungi that are normally commensals on human and animal skin. They metabolized fatty compounds in sebum and most of the species are lipophilic. The presence of yeast and hyphae in the skin of patients with TV was first described by Eichested in 1864. In 1873, Rivolta suggested that yeast was also present in dandruff. The genus *Malassezia* was described in 1889 and *Malassezia furfur* was the name given to the organism seen in pityriasis versicolor (PV). Sabouraud considered that there was a distinct difference between the yeast that caused pityriasis versicolor and those on scaly

scalps, named *Pityrosporum or Malassezia*. In 1961 first, and other studies later, demonstrated the connection between *M. furfur* in scales of TV and the yeast, *P. orbiculare*, grown in laboratory culture. The apparent conflict between the two different names of the genera, *Malassezia* and *Pityrosporum*, has been resolved with the molecular genetic techniques applied to taxonomy. The genetic markers of the yeast, seen in scalp scales, were shown to be identical to the organisms seen in the pityriasis versicolor on the skin. The molecular genetic techniques highlighted more species than originally suspected. Today we recognize seven main species – *M. furfur*, *M. sympoidalis*, *M. pachydermatis*, *M. globosa*, *M. obtusa*, *M. sloffiae*, and *M. restricta* – and less common species as *M. dermatitis*, *M. nana*, and *M. yamatoensis. M. furfur* and *M. globosa* are involved in TV, where there is a transformation of the yeast phase into the mycelial phase. Mycelium invades the keratinocytes of the stratum corneum and induces skin depigmentation by tyrosinase activity inhibition.

Some circumstances favor TV development:

- High sebum production.
- Humidity: this explains the prevalence in warm climates and the increase in situation of hyperhidrosis and occlusive clothes.
- Familial/individual factors have also been reported.
- Immunological factors may be involved in the pathogenesis, but these are almost unknown. Investigations show that the host does not show a cell-mediated immune deficiency to *Malassezia* mycelial antigens. Patients are instead often sensitized by *Malassezia* (IgG response).

Clinical Presentation

Two clinical varieties are reported: hypochromic and hyperchromic variants.

Hypochromic or hypopigmented TV is characterized by hypochromic patches or macules covered with fine scales, initially with irregular borders that progressively converge to form large patches. Their size varies from a few millimeters to several centimeters. This form usually occurs in dark-skinned individuals.

The hyperchromic or hyperpigmented variety consists of light brown patches with scales on the surface. Especially in the axillary region, the groin, and the submammary folds, mixed clinical presentations may be found. In fact the name "versicolor" is due to the numerous variations in the color of the macules, from brown to pink or to white.

TV does not affect the palms, soles, and mucosae. The legs and foot are usually not affected. Lesions involving the face can be present in adults and in children. Scales can be removed easily with the fingernail.

Both clinical varieties are often asymptomatic. Sometimes pruritus may be present but rarely disturbs the patient. The visible nonaesthetic lesions are instead more disturbing for patients. Without treatment, TV usually has a chronic evolution. The lesions grow in number. Sun exposure deepens the color of the lesions. After treatment, recurrences are very frequent, and consecutive treatments are often necessary.

Diagnosis

The diagnosis is usually made clinically. It is often easy because of the characteristic macules and the distribution of lesions. The variable clinical features of TV and the existence of other skin disorders with similar findings make it preferable to be confirmed with mycological direct microscopic examination (potassium hydroxide preparation; KOH). Both hyphae and yeast cells are evident in a pattern that is often described as "spaghetti and meatballs." Moreover, in a third of cases, examination with Wood's lamp reveals yellow to yellow-green fluorescence. Direct microscopy may be easy by the use of scotch tape. The adhesive rubber is pressed against the skin and mounted on a slide. It is a reliable and easy method to assess the value of treatment. Culture or pathological examinations are usually not necessary for the diagnosis. With the periodic acid-Schiff (PAS) staining, fungal elements are detected in the stratum corneum.

Differential Diagnosis

The differential diagnosis of TV includes several common and uncommon skin disorders. The KOH preparation is a simple and well-established method to confirm the diagnosis. The skin diseases that have to be differentially diagnosed from PV are the following:

- Pityriasis alba: it presents with hypopigmented macules and small patches on the face and rarely on the upper extremities. Fine scales may be visible. The disorder is common in children with an atopic history.
- Pityriasis rosea: it consists of erythematous macules and small patches in a "Christmas tree-like" distribution on the trunk. They exhibit a collaret of scales. A large patch usually precedes the widespread eruption. In dark-skinned individuals, hyperpigmentation can be clearly visible.
- Confluent and reticulated papillomatosis of Gougerot and Carteaud: this uncommon cutaneous disorder usually appears in young adults. It is characterized by hyperpigmented, scaly patches with a reticulated appearance involving the neck, the chest, and the upper back.
- Vitiligo: it is a common disease characterized by totally "ab initio" depigmented macules and patches. In contrast, TV exhibits hypopigmented skin lesions.
- Erythrasma: it can present erythematous or hyperpigmented patches in the axillae or groin. It is included in the differential diagnosis with TV involving the intertrigo. Lesions of erythrasma exhibit coral red fluorescence upon illumination with Wood's lamp.
- Secondary syphilis: patients may present with erythematous to brown macules, papules, or small plaques in a generalized distribution. Lesions are also often present on the palms and soles.
- Mycosis fungoides: it is characterized by hypo- or hyperpigmented erythematous patches on the skin, with a predilection for the trunk and extremities. The hypopigmented variant of the disorder occurs most commonly in individuals with dark skin.
- Seborrheic dermatitis: it is usually more erythematous than pityriasis versicolor and typically has thicker scales. The involvement of seborrheic areas, as the scalps, eyebrows, and nasolabial folds, allows us to identify the correct diagnosis.

General Principles of Treatment

The general therapeutic guideline for TV consists of topical and oral treatment. For children only topical treatments are recommended. After the treatment, depigmentation usually persists for several months: sun exposure is necessary for repigmentation. Recurrent episodes are common because is a commensal of skin flora. Especially if the patient lives in a warm and humid area, medical cleaners one or two times a week to avoid relapse should be prescribed.

Topical Treatment

Several topical treatments are available for the treatment of TV as:

- Propylene glycol, 50 % in water twice daily for 2–4 weeks.
- Zinc pyrithione shampoo, once a day for 2–4 weeks.
- Selenium sulfide, 2.5 % suspension, three times a week. It must be applied for 15 min on the skin before being washed off.
- Cyclopiroxilamine, once–twice a day for 2 weeks.
- Terbinafine, cream of solution 1 %, once a day for 2–4 weeks. Terbinafine can be combined with propylene glycol in topical products, as spray. The spray remains active for several hours after application (highly lipophilic and keratophilic).
- Imidazole derivatives, as miconazole, isoconazole, tioconazole, voriconazole, ketoconazole, bifonazole, sulconazole, clotrimazole, and econazole. One application per day for weeks is usually sufficient.

These antifungal drugs may be preferred by the patient in non-cream forms, such as a gel and a spray, when available.

Some therapeutic strategies involve the use of topical treatments for a short period or for a

short contact. For example, a short treatment of 3 consecutive days with 1 % bifonazole cream seems to be efficient. Moreover with the application of ketoconazole (emulsion 2 %) on the skin surface (including hair and face) for 5 min, after 1 month, 84 % of the patients have a negative scotch test, and after 1 year, 80 % have no recurrence.

Prophylactic Treatment

Relapses in TV are very common. Thus it is important that the time of the therapeutic management should be considered carefully. First it is necessary to suppress predisposing factors, especially excessive sun exposure, use of oily tanning lotions, and excessive sweating.

Prophylactic pyrithione zinc-based soap or selenium sulfate-based soap can be useful in the long-term management. They can be used once–twice a week for many months. Some patients have recurrences in summer, when the climate is warm and the perspiration is favored. We suggest the use of these soaps as an adjuvant therapy also during the pharmacological treatment, as well as after treatment or in the period of the year critical for the relapse.

Application of ketoconazole emulsion before summer can be useful for asymptomatic patients with previous relapses.

Systemic Treatments

When topical treatments fail, oral treatment may be considered and exploited. When patients have frequent relapses, the therapeutic response and the compliance may be better with the oral medications.

The therapeutic regimens of the different treatments are the following:

- Itraconazole: tablets (pills) 200 mg/day for 5–10 days.
- Fluconazole: pills 300 mg (one single dose). The penetration and absorption after ingestion of fluconazole in the skin is rapid.
- Ketoconazole: pills 200 mg/day for 7–15 days. Liver function tests may be necessary.

The newer azoles (itraconazole and fluconazole) show a safe profile. There are no published pediatric studies comparing the efficacy of itraconazole versus fluconazole for the treatment of TV. Studies in adults suggest that the initial cure rates with both drugs are comparable. There is some evidence from adult studies that relapses are less frequent with fluconazole treatment.

Toxic Epidermal Necrolysis (TEN) and Stevens-Johnson Syndrome (SJS)

98

Grace Obeid, Laurence Valeyrie-Allanore, and Pierre Wolkenstein

Abbreviations

BSA	Body surface area
EMM	Erythema multiforme major
GVHD	Graft-versus-host disease
IVIg	Intravenous immunoglobulin
SJS	Stevens-Johnson syndrome
SSSS	Staphylococcal scalded skin syndrome
TEN	Toxic epidermal necrolysis
VAS	Visual analog scale

Key Points

- Stevens-Johnsons syndrome (SJS) and toxic epidermal necrolysis (TEN) are two variants of the same acute, rare, life-threatening, severe drug reaction characterized by extensive necrosis and sloughing of the epidermis, erosions of the mucous membranes, and severe constitutional symptoms.
- SJS and TEN are usually drug induced with antibacterial sulfonamides, anticonvulsant agents, oxicam NSAIDs, and allopurinol being the most frequently causative agents.
- Pathogenesis is complicated but implicates the activation of CD_8^+ cells and liberation of granulysin along with other toxins.
- Early withdrawal of the culprit drug(s) and supportive therapy remain the cornerstone of SJS/TEN treatment and aim to prevent irreversible sequelae.
- Specific treatments have been investigated, and some of them, mainly cyclosporine, seem to be promising for SJS/TEN patients.

Definition and Epidemiology

Toxic epidermal necrolysis (TEN) is a rare, life-threatening, usually drug-induced, mucocutaneous disease characterized by extensive necrosis of the epidermis and widespread sloughing of the skin and mucosal surfaces. TEN and Stevens-Johnson syndrome (SJS) are considered to be two variants of the same pathological process differing only by the degree of skin involvement with an involved body surface area (BSA) of <10 % in SJS and >30 % in TEN. The incidence of TEN is evaluated to 0.4–1.2 cases per million person-years. TEN occurs in all age groups but is more frequent in women, the elderly, and HIV-infected patients. According to the published data, the mortality rate in TEN varies from 25 to

Aminopenicillins
Cephalosporins
Quinolones

30 % (Harr and French 2010; Mockenhaupt et al. 2008). A prognosis score entitled SCORTEN (see Table 98.1) was proposed in 2000 for SJS/TEN (Bastuji-Garin et al. 2000) and was found to be an efficient tool to predict mortality rate in this group of patients. SCORTEN is a 7-point score with each point corresponding to a variable and a mortality rate varying from 3.2 % for a score of 0–1 point to 90 % for a score ≥5 points. SCORTEN should be performed on day 1 and repeated on day 3 post-admission (Chang et al. 2011). Surviving patients maintain an increased risk of morbidity with a 5-year survival rate of 65 %.

Basic Concepts of Pathogenesis

TEN is considered to be a hypersensitivity reaction to a drug in at least 70 % of cases (Sassolas et al. 2010). It typically occurs between day 7 and day 21 after exposure to the culprit drug but can be delayed (until 8 weeks after the exposure) in some cases or precipitated in case of repeated exposure. In 1995, Roujeau et al. described an increased risk of TEN with a number of drugs including sulfonamides, aromatic anticonvulsants, allopurinol, oxicam NSAIDs, aminopenicillins, cephalosporins, and quinolones. More recently, the European Severe Cutaneous Adverse Reaction (EuroSCAR) study identified mainly the same drugs and added marketed drugs to finally list nevirapine, lamotrigine, carbamazepine, phenytoin, phenobarbital, co-trimoxazole and other antiinfective sulfonamides, sulfasalazine, allopurinol, and oxicam nonsteroidal anti-inflammatory agents as being high-risk medications (Mockenhaupt et al. 2008) (see Table 98.2).

Sassolas et al. (2010) developed an algorithm for assessment of drug causality in Stevens-Johnson syndrome and toxic epidermal necrolysis (ALDEN). This tool takes into consideration six parameters with a score of −1 to 10 for each. In a particular TEN case, a given drug is considered as very probably the causative agent if the score is [≥6], probably the causative agent if the score is [4–5], possibly the causative agent if the score is [2–3], unlikely the causative agent if the score is [0–1], and very unlikely the causative agent if the score is [<0] (see Table 98.3).

Even though drug hypersensitivity is, by far, the most frequent etiology, not all TEN cases are drug induced. Other causative factors have been identified such as *Mycoplasma pneumoniae* infection, contrast agents, vaccination, cytomegalovirus reactivation, and other viral diseases including Coxsackie virus.

Physical factors including ultraviolet light and x-rays may trigger drug-induced SJS/TEN, and the sites of exposure are typically the most affected by the disease.

Idiopathic SJS/TEN is defined by cases where no causative factor can be identified.

Table 98.3 ALDEN score

Description of the parameter	Score
Period between the drug intake and onset of reaction (index day)	
5–28 days	3
29–56 days	2
1–4 days	1
>56 days	−1
Drug started on index day	−3
With previous history of adverse reaction, 1–4 days	3
With previous history of adverse reaction, 5–56 days	1
Presence of drug in the body on index day	
Stopped on the index day or within 5 times the elimination half-life before the index day	0
Stopped at a time point before the index day by <5 times the elimination half-life	−1
Stopped at a time point before the index day by >5 times the elimination half-life	−3
Previous history of adverse reaction	
SJS/TEN from same drug	4
SJS/TEN from similar drug	2
Other reactions from similar drug	1
No history of exposure to the drug	0
Previous use without any reaction	−2
Continued drug use beyond index day	
Stopped or unknown	0
Continued	−2
Drug notoriety from previous results of the SCAR study	
High risk	3
Lower risk	2
Under surveillance	1
All other drugs, including newly released drugs	0
No evidence of association	−1
Other possible etiologic alternatives	
Infectious agents	−1
If the patient is taking multiple drugs and at least has a score >3, subtract 1 point from each of the other drugs	−1

The pathological mechanism underlying SJS/TEN is only partially elucidated despite many advances that have been made during the past years in this field.

Among the demonstrated facts regarding the SJS/TEN pathogenesis, it has been shown that this hypersensitivity reaction is mainly a T-cell-mediated disease with predominating $CD8^+$ lymphocytes in blister fluid and in perivascular superficial dermis with an evidence of epidermal exocytosis. $CD8^+$ cells play a major role in keratinocyte apoptosis induction but are also assisted by $CD4^+$ cells (are mainly represented $CD4^+$ cells with strong expression of CD40 ligand) and various cells of the innate immune system including $CD3^-CD56^+$ NK cells, dendritic cells, mast cells, $CD14^+CD16^+$ monocytes, granulocytes, and NK/T cells. $CD8^+$ cells are considered to be the major inducers of apoptosis along with natural killer (NK) cells. The complex interaction between all of the above-listed cell types leads ultimately to the release of tumor necrosis factor-alpha (TNF-α), nitric oxide (NO), interleukin 8 (IL-8), and cell adhesion molecules causing the massive epidermal damage despite the relatively limited number of immunological cells in TEN lesions.

The remaining still unresolved question is the exact mechanism leading to T-cell stimulation by a particular drug in TEN. Two major theories are being discussed and studied recently: The first suggests that the drug directly binds to specific major histocompatibility complex (MHC) I allotype and T-cell receptor (TCR) leading to a T-cell response (Pichler et al. 2011). This concept has been demonstrated in patients with known hypersensitivity reactions to sulfamethoxazole (SMX) (Castrejon et al. 2010). The second theory claims that the drug or its metabolites act as haptens and render keratinocytes antigenic, therefore stimulating T cells via antigen presenting cells (APCs). This second concept was demonstrated in both abacavir- and SMX-induced TEN (Chessman et al. 2008; Castrejon et al. 2010).

Regardless of the initial mechanism, $CD8^+$ cell (among others) activation results in apoptosis of the keratinocytes via the exocytosis of mainly granzyme B/perforin and granulysin. This latter was shown to be the major cytotoxic agent, increasing early during the course of the disease and exhibiting its cytotoxicity in a dose-dependent fashion, with significantly higher levels of granulysin in blister fluid and in blood when compared to co-secreted substances including granzyme B, perforin, and soluble Fas ligand (FasL). Furthermore, a positive correlation was detected between granulysin levels and the body

surface area involved (Chung et al. 2008). However, this molecule does not seem to be specific to SJS/TEN and may be observed in other bullous diseases such as generalized fixed drug eruption (Schlapbach et al. 2011).

Soluble Fas ligand (FasL), nitric oxide (NO), and tumor necrosis factor-α (TNF-α) also contribute to keratinocyte apoptosis. Important to note is that, despite its cytotoxic potential, TNF-α activates on the other hand the antiapoptotic nuclear factor-kappaB (NF-κB) pathway allowing a protective role in TEN and making its inhibition inefficient and even dangerous.

Finally, we should emphasize on the demonstrated genetic predisposition of certain populations and ethnic groups to drug hypersensitivity reactions (manifesting as SJS/TEN) with the use of specific drugs. In fact, a strong association was found between patients with SJS/TEN induced by aromatic antiepileptic agents, including carbamazepine, phenytoin, oxcarbazepine, and lamotrigine and human leukocyte antigen (HLA)-B*1502 in Han Chinese, Thai, Malaysian, and South Indian populations (Man et al. 2007; Locharernkul et al. 2008), but not in Japanese, Korean, or European populations (Lonjou et al. 2006). Similarly, a strong association was reported between HLA-B*5801 and allopurinol-induced SJS/Lyell patients in Han Chinese and in the European descent (Lonjou et al. 2008). In Europeans, abacavir-induced SJS/Lyell is associated with HLA-B*5701 (Mallal et al. 2002) and carbamazepine-induced SJS/Lyell with A*3101 (McCormack et al. 2011). This genetic predisposition seems to be specific to both the ethnicity and the drug but is still unable to explain the onset of the disease.

Clinical Presentation

TEN begins most frequently with a prodromal phase of nonspecific signs and symptoms including fever, malaise, headache, rhinitis, cough, anorexia, pharyngitis, chest pain, vomiting, diarrhea, myalgias, and arthralgias lasting for several days. Often, antibiotics and anti-inflammatory treatments are given during this phase of the disease and may create a confusing factor while searching for the culprit drug.

Painful inflammation and ulceration of the mucosal surfaces (involving at least two mucosal sites) occur in 90 % of cases and may precede cutaneous manifestations. By the end of the prodromal phase, it starts and manifests as pain upon swallowing, photophobia, burning eyes, and painful micturition. Oral mucosae are involved in 71–100 % of cases, ocular mucosae in 50–78 %, anogenital mucosae in 40–63 %, and the three mucosal sites in 34–50 % of patients.

Skin eruption appears as a morbilliform rash with symmetrical lesions distributed initially over the face, neck, chin, proximal extremities, and upper trunk. The rash then extends to the rest of the body. Individual lesions are typically irregularly shaped, erythematous, dusky-red, purpuric macules that coalesce progressively (Fig. 98.1). Otherwise, they may consist of atypical targetoid macules, and the coalescence of necrotic lesions leads to diffuse erythema with a skin that becomes tender to touch and lateral pressure producing detachment of the epidermis from the dermis, known as the Nikolsky sign. Skin lesions then evolve to flaccid blisters that break easily leading ultimately to denudation of the epidermis in sheets resembling wet cigar paper revealing large areas of exposed dermis (Fig. 98.2).

The percentage of skin detachment determines a classification into three categories: SJS <10 %

Fig. 98.1 Skin eruption with extensive blisters and erosions

Fig. 98.2 Toxic epidermal necrosis. Denudation of the epidermis in sheets involving mainly the trunk

of body surface area (BSA), SJS/TEN overlap between 10 and 30 %, and TEN >30 % of BSA.

In severe cases of TEN, internal organs may be affected by the disease, most frequently the respiratory tract with sloughing of the respiratory tract mucosa in some cases and the gastrointestinal tract with symptoms including diarrhea, abdominal pain, esophageal and gastrointestinal bleeding, excretion of necrotic intestinal epithelium, etc.

Diagnosis

A case of TEN is diagnosed based on clinical and histologic features.

Following a prodromal phase that lasts for up to 2 weeks, clinical manifestations (described above) of TEN begin. A "progression phase" characterized by erythema and sloughing of the epidermis extending to a certain level of body surface area (BSA) along with mucous involvement is followed by a "plateau phase" where systemic complications are the most likely to occur. A progressive clinical improvement signals the "regression phase" with lightening of the erythema and drying of the removed epidermis. Reepidermization then takes place at a variable rate.

Histologic features include full-thickness epidermal necrosis, subepidermal split, and a scant lymphocytic infiltrate at the dermoepidermal junction. Recently, a retrospective review of clinical records and biopsy specimens showed that full-thickness epidermal necrosis is associated with mortality but is not an independent predictive factor for hospital death (Valeyrie-Allanore et al. 2013).

Recently, certain serum markers for the early detection of TEN have been studied but remain controversial. They include granulysin levels and serum high-mobility group protein B1 (HMGB1) levels. The latter seems however to increase in other bullous diseases and therefore is not specific to SJS/TEN cases (Pichler et al. 2011).

Differential Diagnosis

Many dermatological diseases may mimic TEN especially during the early stages and before the establishment of the full clinical picture. The differential diagnosis of TEN includes, among many others:

- *Generalized bullous fixed drug eruption*: Even though constitutional symptoms are seldom present and mucous membranes are less frequently involved in generalized bullous fixed drug eruption compared to TEN, distinction may be difficult between the two conditions especially that histological findings are comparable. The milder course of the disease, the absence of sequelae, and the rapid recovery of patients affected by generalized bullous fixed drug eruption are important distinguishing features.
- *Staphylococcal scalded skin syndrome* (SSSS): In SSSS, epidermolysis at the subcorneal level is caused by exotoxins released by *Staphylococcus aureus* and may be clinically mistaken with TEN. However, SSSS spares the mucous membranes and affects more

frequently the pediatric population. In doubtful cases, a skin biopsy revealing the superficial blistering level confirms the diagnosis.

- *Erythema multiforme major* (EMM): Distinction between EMM with mucous membrane involvement has been differentiated from SJS/TEN based on clinical presentation and etiological factors (infectious agents rather than medications).
- *Drug-induced linear IgA dermatosis*: This disease presents as annularly disposed bullous lesions with or without mucous involvement. Direct immunofluorescence studies reveal linear deposits of IgA at the basement membrane and help therefore to rectify the diagnosis.
- Severe acute *graft*-versus-*host disease* (GVHD): Acute GVHD that occurs in the bone marrow and in allogenic hematopoietic stem cell transplant patients may be a bullous disease affecting both the skin and the mucous membranes. Stage IV GVHD with histological full-thickness epidermal necrosis may be difficult to differentiate from TEN. Diarrhea and alterations in liver function tests are other features of GVHD.

General Principles of Treatment

As soon as a case of TEN is suspected, management of the disease should respect the following steps:

(a) Confirmation of the diagnosis (see above)
(b) Evaluation of the severity and the prognosis of the disease (see above)
(c) Identification and early withdrawal of the culprit drug(s)
(d) Early initiation of the supportive therapy in a specialized unit and discussion of a systemic treatment

Identification and Early Withdrawal of the Culprit Drug

A thorough medication history is mandatory in order to determine the drug that is the most likely responsible for the severe drug eruption. All the medications or applied substances used for the last 2 months should be listed with the date of introduction and, if applicable, the date of withdrawal for each of them, along with the date of onset of both the mucocutaneous and prodromal symptoms. Typically, the aforementioned algorithm "ALDEN" is used to identify the causative drug in daily practice. Once the potential offending drugs are identified, they should be withdrawn as soon as possible for it was shown that the early withdrawal of the culprit drugs is associated with an increased survival rate.

Supportive Treatment

TEN patients should be transferred into a dermatological intensive care unit or a burn center when the SCORTEN (which should be evaluated accurately on admission) exceeds 1 and to a medical intensive care unit when the pathological process extends to the pulmonary mucosae with PO_2 level <80 mmHg, mainly for a symptomatic treatment associated or not to a specific treatment, depending on each case.

Supportive care includes:

- Evaluation of the patient's general condition (vital signs, state of consciousness, SaO_2, PO_2, etc.).
- Evaluation of the extent of necrolysis using the rule of nines.
- Urgent fluid and electrolyte replacement in order to compensate electrolyte imbalance and fluid loss throughout the skin due to edema and cutaneous sloughing. Peripheral venous access must preferably be outside the affected skin area.

The amount of required fluids depends on the sloughing skin surface and equals two-thirds to three-fourths the amount that would be necessary in a burn case affecting the same skin surface. A formula that could be helpful during the acute phase is the following:

"1.5 ml × % of peeling or potentially peeling skin × kg/day"

A diuresis of 50–80 ml/h should be targeted during this phase using a normal saline solution and adjusted depending on the daily blood tests:

- Regulation of glucose blood levels.
- Hypercaloric and hyperprotidic enteral nutrition through a nasogastric tube, starting at 1,500 ml/day with gradual increase in daily nutrient intake.
- Prophylactic anticoagulation therapy in order to prevent deep venous thrombosis.
- Pain management with initiation of morphine therapy when pain exceeds a score of 4 on a 10-point visual analog scale (VAS).
- Maintaining an environmental temperature of approximately 28 °C.
- Bacterial and fungal cultures of the skin, blood, and urine at least twice weekly. Antibiotics should not be initiated unless an infection is documented.

Wound Care

Cutaneous Care

Wound care should be performed many times daily using petroleum jelly ointment, and the skin should be manipulated carefully. Nonadhesive dressings are the most adequate for TEN cases, and hydrocellular dressings such as "Coloplast" are classically used. More recently, "Biobrane" which is a temporary biosynthetic skin dressing and umbilical cord mesenchymal stem cell transplantation have been shown to improve clinical outcome (Boorboor et al. 2008). A daily bath using diluted chlorhexidine (1/5,000e–1/10,000e) should be done, if tolerated by the patient.

Mucous Membrane Care

Oral mucosae are subject to adhesion formation and should consequently be taken care of on a daily basis using gargles such as bicarbonate and chlorhexidine mouthwash.

Emollients such as petroleum jelly should be applied extensively on external genital organs. Ophthalmological exam and care are mandatory in all TEN patients. The use of antibiotic eyedrops, vitamin A, and antiseptic agents every 2 h during the acute phase, along with adhesions lysis, helps in preventing irreversible sequelae. When the corneal damage is more pronounced, amniotic membrane transplantation and scleral contact lens may be used to optimize visual acuity and minimize corneal damage.

Systemic Treatment

To date, symptomatic support and nursing care measures remain the cornerstone in the treatment of SJS/TEN in the absence of a consensual gold-standard treatment that would shorten the natural course of the disease or halts its progression. A number of immunomodulating molecules have, however, been tested on small series of patients suffering from SJS/TEN with variable, mostly unsatisfactory, outcomes. They include:

Systemic Corticosteroids

Systemic corticosteroids have been used for a long time in the treatment of SJS/TEN, but this approach is still subject to debate because of contradictory outcomes in terms of reduction in mortality rate in this group of patients. Furthermore, a higher risk of infectious complications and a longer hospital stay have been described in corticosteroid-treated patients (Kardaun and Jonkman 2007). Systemic corticosteroids seem to be beneficial in TEN German patients but not in TEN French patients. Other persisting domains of uncertainty are the modality of treatment delivery (pulse therapy or nonpulsed therapy), the most convenient time to introduce the treatment in the course of the disease, the right posology to use, and the dosage-tempering scheme to adopt before completely discontinuing the treatment.

Systemic corticosteroids have also been used in combination with other treatments (such as IVIg and anti-TNF-α) for TEN patients and with encouraging results, but there is still no established consensus clearly indicating their introduction in patients suffering from TEN.

Thalidomide

Even though thalidomide exhibits an anti-TNF-α activity and should theoretically improve TEN, a prospective trial of thalidomide in TEN was interrupted before its end because of increased

mortality in the treated group. This is explained by the fact that TNF-α, besides its role in the disease induction, also activates the antiapoptotic nuclear factor-kappaB (NF-κB) pathway allowing a protective role in TEN. Surprisingly, a few case reports of TEN successfully treated with anti-TNF-α have been published afterward in the literature (Kreft et al. 2010).

Intravenous Immunoglobulin (IVIg)

Through binding Fas ligand, IVIg are able to inhibit Fas-mediated cell death and have therefore been used in the treatment of TEN. A decrease in disease progression rate was noted in the original study for doses ranging from 0.2 to 0.75 g/kg body weight per day for four consecutive days (Morici et al. 2000). In spite of the initial encouraging results, no mortality benefit was found in more recent studies (Bachot et al. 2003). Lately, a meta-analysis showed that although high-dose IVIg improved mortality and that treated children had a good prognosis, the evidence still does not support a clinical benefit of IVIg (Huang et al. 2012).

Furthermore, IVIg treatment may result in nephrotoxicity leading to renal failure and must therefore be manipulated with caution in patients with impaired kidney function.

This therapeutic strategy is no longer used in the daily practice in our severe cutaneous reaction center.

Plasmapheresis or Hemodialysis

Both techniques aim to remove the causative agent, its metabolites, or proinflammatory cytokines from the circulation in an attempt to discontinue the evolution of the disease. This therapeutic means has been classically proposed in cases that were refractory to supportive therapy and other systemic treatments, with dramatic improvement in most of the patients. More studies need to be done so as to bring enough proof to the use of plasmapheresis and hemodialysis in TEN cases.

Cyclosporine

Cyclosporine is a calcineurin inhibitor that blocks the function of T cells. Cyclosporine has recently been used with success in the treatment of SJS/TEN in a phase II open trial done on 29 patients using 3 mg/kg/day for 10 days, tapered over a month (Valeyrie-Allanore et al. 2010). Cyclosporine could be efficient in blocking the disease progression. Further studies are required, however, to validate the efficacy of cyclosporine in TEN patients.

A number of other treatment options have been attempted in a small number of SJS/TEN patients with encouraging outcomes. They include granulocyte colony-stimulating factor (GCSF) and N-acetylcysteine (NAC).

Complications and Sequelae

Beyond the early acute phase of the disease, late complications and sequelae may occur and involve both the skin and the mucous membranes. On the cutaneous level, dyspigmentation is one of the most frequently encountered sequelae manifesting either as hypo- or hyperpigmentation persisting for months or years. Eruptive melanocytic nevi, along with pruritus, have also been described following TEN cases. Skin appendages' damage can eventually result in onycholysis, onychodystrophy, loss of fingernails, and hair thinning. Ocular sequelae remain the most common complication of TEN and occur in up to 75 % of cases. Early ophthalmologic care aims to reduce the incidence of ocular sequelae ranging from eye dryness and sandy sensation to corneal scarring and blindness. Other ocular complications include symblepharon, trichiasis, photophobia, subconjunctival fibrosis, entropion, ectropion, and sicca syndrome. The lips and oral cavity should be taken into consideration when treating a patient with TEN in order to avoid many of the complications occurring at this level such as xerostomia, reduced salivary flow and pH, periodontal disease, gingival inflammation, and oral discomfort. The abovementioned complications are usually reversible but can lead to synechiae formation. On the other hand, pulmonary, gastrointestinal, and genitourinary tract involvement may result in permanent esophageal, bronchial, vaginal, urethral, and anal strictures

requiring surgical correction. Dyspareunia has been reported as another complication in female patients and erosive balanitis, urethral erosions, and phimosis in male affected individuals. A multidisciplinary team including a dermatologist, an ophthalmologist, a psychiatrist, a gynecologist, and an odontologist must follow up the patient for at least 1 year following the severe drug reaction.

Gonococcal Urethritis

99

Christina Stefanaki

Key Points

- Gonococcal urethritis is caused by *Neisseria gonorrhoeae*.
- *N. gonorrhoeae* is transmitted through sexual contact and vertically.
- Gonorrhea remains a major public health problem.
- Gonorrhea manifests in men as acute anterior urethritis with dysuria and profuse and purulent discharge.
- Diagnosis of gonococcal infection is based on the identification of the microorganism in secretions from infected sites using Gram stain, culture, and/or molecular biology techniques. No test offers 100 % sensitivity and specificity.
- *Neisseria gonorrhoeae* has developed resistance to multiple classes of antibiotics, and recently, resistance and even clinical failures to ceftriaxone and cefixime have been confirmed.
- According to the European guidelines for the diagnosis and treatment of gonorrhea in adults, uncomplicated gonococcal urethritis should be treated with ceftriaxone 500 mg intramuscularly (IM) as a single dose together with azithromycin 2 g as a single oral dose.
- Sexual partners in the preceding 60 days should be treated as well.
- A test of cure is recommended in all cases.
- Treatment failures and resistant strains should be reported to health authorities.

Definition and Epidemiology

By definition, urethritis is characterized by urethral inflammation that can result from infectious and noninfectious conditions and symptoms and, if present, include discharge of mucopurulent or purulent material, dysuria, or urethral pruritus. Gonococcal urethritis is caused by *Neisseria gonorrhoeae*.

Basic Concepts of Pathogenesis

Neisseria gonorrhoeae is a Gram-negative aerobic coccus-shaped bacterium typically found in pairs, usually visualized intracellularly in polymorphonuclear leukocytes. The bacterium is capable of attaching to columnar epithelial cells via pili or fimbrae, and the most common sites of attachment are the mucosal cells of male and

female urogenital tracts. PilC and Opa are outer membrane proteins that aid the attachment of the microorganism, and then intracellular invasion is mediated by adhesins and sphingomyelinase. After endocytosis, the bacterium replicates and proliferates locally, producing inflammation. Gonococcus, by producing a variety of peptides and lipids, is capable of causing tissue destruction. The bacterium escapes the host defense mechanisms by intracellular replication and by the production, by certain strains, of immunoglobulin A proteases that cleave the heavy chain of the immunoglobulin. Gonococcus is very susceptible to environmental shifts outside the cells, such as temperature changes, ultraviolet light, and drying, and is easily killed under those conditions.

Neisseria gonorrhoeae is restricted only to humans and is transmitted through sexual contact (vaginal, anal/or oral) and vertically from mother to child at parturition.

The incubation period ranges from 2 to 8 days, with most infections being symptomatic within 15 days.

Epidemiology

Gonorrhea remains a major public health problem. In 2008, the World Health Organization (WHO) estimated 106 million cases among adults worldwide (3.4 million in the WHO European region). In the European Union (EU), gonorrhea was the second most commonly reported bacterial sexually transmitted infection (STI) after chlamydia in 2010. However, the incidence is underestimated because of suboptimal diagnostics, case reporting, and surveillance. In the United States, gonorrhea is the second most commonly reported notifiable infection, with >300,000 cases reported during 2011. As men are becoming symptomatic, the infection is reported three times more frequently in men than women. Young age (15–29 years), sexual orientation (men having sex with men are considered more vulnerable), and ethnic minority are considered risk factors for gonorrhea.

Clinical Presentation

Gonorrhea has a broad spectrum of clinical manifestations in both men and women ranging from asymptomatic and symptomatic localized infections to disseminated infections. Generally the primary infection tends to involve mucous membranes consisting of columnar epithelium, and the sites more commonly involved are the urethra, cervix, rectum, pharynx, and conjunctiva.

Typically gonorrhea manifests in men as acute anterior urethritis with dysuria and profuse and purulent discharge. About one quarter of infected men present with less pronounced symptoms, with a mucopurulent discharge similar to non-gonococcal etiologies evident only after urethral manipulation. Even without treatment, symptoms subside after a period of 6 months. Only about 10 % of the infected men remain asymptomatic.

Complications include inflammation of Cowper and Tyson glands, epididymitis, prostatitis, and orchitis. Unilateral testicular pain and swelling indicates epididymitis or orchitis.

Clinical manifestations of gonorrhea and complications are summarized in Table 99.1.

Diagnosis

Diagnosis of gonococcal infection is based on the identification of the microorganism in secretions from infected sites (urethra, endocervix, posterior pharynx, anus) using Gram stain, culture, and/or molecular biology techniques. No test offers 100 % sensitivity and specificity (Table 99.2).

For gonococcal urethritis Gram stain is positive in more than 95 % of symptomatic men. However, it can give false-negative results in asymptomatic infection. In Gram-stained smears, gonococci are visualized as Gram-negative diplococci within neutrophils.

The gold standard for the diagnosis of gonococcal urethritis is culture and should be performed in all cases. Thayer-Martin (antibiotic containing selective media) or selective New York media are used for culture. Culture, accompanied

Table 99.1 Clinical manifestations of gonorrhea and complications

Gonococcal infection		
Men	Women	Children
Asymptomatic (10 %)	Asymptomatic (50 %)	Ophthalmia neonatorum
Urethritis	Cervicitis	Vulvovaginitis
Proctitis	Proctitis	*Complications* Blindness Disseminated infection
Pharyngitis	Pharyngitis	
Gonococcal ophthalmia	Gonococcal ophthalmia	
Complications Prostatitis Epididymitis Orchitis Disseminated infection	*Complications* Bartholinitis Salpingitis PID Perihepatitis (Fitz-Hugh-Curtis syndrome) Ectopic pregnancy Infertility Disseminated infection	

Proctitis: asymptomatic in 50 %, common in those who practice anal intercourse or by autoinoculation in women, manifests with rectal mucopurulent discharge, pain at defecation, constipation, and tenesmus
Pharyngitis: usually asymptomatic, symptoms range from pharyngeal erythema and cervical lymphadenopathy to ulceration with pseudomembrane formation
Cervicitis: vaginal discharge, dysuria, intermenstrual bleeding, menorrhagia
Bartholinitis: acute swelling of the Bartholin's gland with swelling of the labial fold and purulent discharge upon pressure
PID (*pelvic inflammatory disease*): lower abdominal pain, vaginal bleeding, dyspareunia, adnexal or cervical motion tenderness, fever
Gonococcal ophthalmia and ophthalmia neonatorum: due to self inoculation or unusual sexual practices, purulent conjunctivitis, can rapidly progress to keratitis and corneal opacities and blindness
Perihepatitis (*Fitz-Hugh-Curtis syndrome*): rare, PID is accompanied by right upper quadrant pain due to inflammation of the adjacent peritoneum
Disseminated infection: rare, usually in women during menstruation and neonates (0.5–1 % of patients). Classic triad of migratory polyarthritis, tenosynovitis, and skin rash consisting of hemorrhagic pustules. May result in endocarditis and meningitis

Table 99.2 Diagnosis of gonococcal infections

Anus[a]	+	+	+++
Urine[a]	–	–	++

Indications of different methods according to the site of infection
[a]Confirmation of positive culture for *N. gonorrhoeae* by a molecular method is mandatory in extragenital sites

by the antimicrobial susceptibility tests, allows the identification of resistant gonococci to common antibiotics and the better surveillance of the infection. The sensitivity of culture is high for genital samples providing that specimen collection, transport, storage, and isolation procedures are optimized.

Molecular techniques such as nucleic acid hybridization tests and nucleic acid amplification tests (NAATS) are widely used for the diagnosis of gonococcus. NAATS, particularly PCR, are highly sensitive and specific and superior to culture for diagnosis of gonococcal urethritis. If non-culture techniques are used for diagnosis, regional monitoring of gonococcal antimicrobial susceptibility is needed.

All persons found to have gonorrhea also should be tested for other STDs, including chlamydia, syphilis and HIV.

Differential Diagnosis

Gonococcal urethritis should be differentiated from other causes of urethral discharge like *Chlamydia trachomatis* and *Trichomonas vaginalis*.

General Principles of Treatment

Effective treatment is a cornerstone of gonorrhea control efforts, but treatment is complicated by the ability of *N. gonorrhoeae* to develop resistance to antimicrobial therapies. *Neisseria gonorrhoeae* has developed resistance to multiple classes of antibiotics including penicillins, tetracyclines, macrolides, and fluoroquinolones. During the 1990s and 2000s, fluoroquinolone resistance in *N. gonorrhoeae* emerged in the United States, becoming prevalent in Hawaii and California and among men who have sex with men (MSM) before spreading throughout the United States. In 2007, because of emergence of fluoroquinolone-resistant *N. gonorrhoeae* in the United States, CDC no longer recommended fluoroquinolones for treatment of gonorrhea, leaving cephalosporins as the only remaining recommended antimicrobial class. Previous data indicated that ceftriaxone as a single intramuscular injection of 250 mg provided high and sustained bactericidal levels in the blood and was highly efficacious at all anatomic sites of infection. On the other hand, a single oral dose of cefixime 400 mg did not provide bactericidal levels as high nor as sustained as an intramuscular 250 mg dose of ceftriaxone and demonstrated limited efficacy for treatment of pharyngeal gonorrhea (Tables 99.3, 99.4, 99.5 and 99.6).

The minimum inhibitory concentration (MIC), the lowest antimicrobial concentration that inhibits visible bacterial growth in the laboratory, is used to assess antimicrobial susceptibility. Increasing MICs can predict the emergence of resistance. During recent years a steady rise in minimum inhibitory concentrations (MICs), resistance, and even clinical failures to ceftriaxone and cefixime have now been confirmed. Since 2000, treatment failures with the use of third-generation cephalosporins have been reported in Japan. In Europe there were reports of treatment failures with cefixime standard treatment in England and Norway in 2010. In 2011, the first *N. gonorrhoeae* strain with decreased susceptibility to cefixime and subsequent treatment failure was reported in Austria. The first case of genital infection of highly cefixime- and ceftriaxone-resistant *N. gonorrhoeae* in Europe was reported in France, and a suspected ceftriaxone-resistant strain was reported in Spain, and subsequently ceftriaxone treatment failure of pharyngeal gonorrhea was reported in Sweden. The results from the European Gonococcal Antimicrobial Surveillance Programme (Euro-GASP) have shown that susceptibility to cefixime and ceftriaxone is decreasing in Europe. In this emergent situation of gonorrhea becoming untreatable, WHO has published the global action plan to control the spread and impact of antimicrobial resistance in *Neisseria gonorrhoeae*, the European Centre for Disease Prevention and Control (ECDC) has published the response plan to control and manage the threat of multidrug-resistant gonorrhea in Europe, and the Centers for Disease Control and Prevention (CDC) have also taken action for the United States.

Already in 2010 CDC's sexually transmitted diseases (STDs) treatment guideline combination therapy was recommended for gonorrhea with a cephalosporin (ceftriaxone 250 mg intramuscularly or cefixime 400 mg orally) plus either azithromycin orally or doxycycline orally, even if nucleic acid amplification testing (NAAT) for *C. trachomatis* was negative at the time of treatment. Those guidelines recommended combination antimicrobial therapy to combat the infection and to avoid the development of multidrug resistance, rather than adopting the administration of an increased dose of cephalosporins. According to limited data, combination antimicrobial therapy with extended-spectrum cephalosporins and azithromycin seems to show synergy in vitro and in vivo. Unfortunately, published data are very limited on the treatment of multidrug-resistant gonorrhea, and treatment recommendations are based on early clinical efficacy trials, pharmacokinetic/pharmacodynamic considerations, in vitro antimicrobial susceptibility surveillance data, case reports of antimicrobial resistance, and anticipated trends in antimicrobial resistance.

According to the European guidelines for the diagnosis and treatment of gonorrhea in adults,

Table 99.3 First-line treatments for different manifestations of gonorrhea according to the European guidelines

First-line treatment for gonorrhea					
Urethritis, proctitis, cervicitis	Pharyngeal infection	Conjunctivitis (adults)	Disseminated infection	PID	Epididymitis, orchitis
Ceftriaxone 500 mg IM single dose + Azithromycin 2 g single oral dose	Ceftriaxone 500 mg IM single dose + Azithromycin 2 g single oral dose	The eye should be irrigated with sterile saline solution once. Ceftriaxone 500 mg IM as a single dose for 3 days	Ceftriaxone 1 g IM or IV every 24 h for 7 days	Ceftriaxone 500 mg IM as a single dose + Doxycycline 100 mg oral dose twice daily + Metronidazole 400 mg oral dose twice daily for 14 days	Ceftriaxone 500 mg IM single dose + Doxycycline 100 mg oral dose twice daily for 10–14 days

Table 99.4 Second-line treatments for different manifestations of gonorrhea according to the European guidelines (see text)

Urethritis, proctitis, cervicitis	Pharyngeal infection	Conjunctivitis (adults)	Disseminated infection	Epididymitis, orchitis
1. Cefixime 400 mg oral single dose + azithromycin 2 g single oral dose	1. Ceftriaxone 500 mg IM single dose	1. Spectinomycin 2 g IM single dose daily for 3 days	Spectinomycin 2 g IM every 12 h	Ciprofloxacin 500 mg single oral dose[a] + Doxycycline 100 mg oral dose twice daily for 10–14 days
2. Ceftriaxone 500 mg IM single dose	2. Ciprofloxacin 500 mg single oral dose[a]	2. Azithromycin 2 g oral single dose + doxycycline 100 mg oral dose twice daily 1 week + Ciprofloxacin 250 mg oral dose daily for 3 days[a]		
3. Spectinomycin 2 g IM single dose + azithromycin 2 g single oral dose	3. Ofloxacin 400 mg single oral dose[a]			
	4. Azithromycin 2 g single oral dose[a]			

[a]Fluoroquinolone or azithromycin resistance are excluded by appropriate laboratory susceptibility testing

uncomplicated gonococcal urethritis should be treated with ceftriaxone 500 mg intramuscularly (IM) as a single dose together with azithromycin 2 g as a single oral dose. Azithromycin tablets may be taken with or without food, but gastrointestinal side effects can be less if taken after food. If ceftriaxone 500 mg for IM injection is not available, the IM suspension can be mixed as follows: 3.5 ml of 10 mg/ml lidocaine without adrenalin is suspended into a 1 g vial of ceftriaxone and mixed; 2 ml of the mixture is drawn and injected IM. On the other hand for the treatment of uncomplicated urogenital gonorrhea, CDC recommends combination therapy with a single intramuscular dose of ceftriaxone 250 mg plus either a single dose of azithromycin 1 g orally or doxycycline 100 mg orally twice daily for 7 days. The use of azithromycin as the second antimicrobial is preferred to doxycycline because of the convenience and compliance advantages of single-dose therapy and the substantially higher prevalence of gonococcal resistance to tetracycline than to azithromycin, particularly in

Table 99.5 Penicillin allergy

Spectinomycin 2 g IM as a single dose + Azithromycin 2 g oral single dose
Alternative regimen
Ciprofloxacin 500 mg oral as a single dose or ofloxacin 400 mg oral as a single dose or azithromycin 2 g as a single oral dose[a]

[a]Only if fluoroquinolone or azithromycin resistance are excluded by appropriate laboratory susceptibility testing

Table 99.6 Pregnancy and breastfeeding[a,b]

Recommended treatment
Ceftriaxone 500 mg IM single dose
Alternative regimen
Spectinomycin 2 g IM single dose

[a]The safety of azithromycin in pregnancy has not been confirmed, but clinical experience indicates that it may be safely used. It should only be used under medical supervision if the expected benefit to the mother is thought to be greater than the possible risk to the fetus. Azithromycin passes into breast milk and is not recommended whilst breastfeeding

[b]Pregnant and breastfeeding women should not be treated with fluoroquinolone or tetracycline antimicrobials

strains with elevated cefixime MICs. Moreover, ceftriaxone and azithromycin seem to show synergy both in vitro and in vivo.

When ceftriaxone cannot be used for treatment of urogenital or rectal gonorrhea, two alternative options are available: cefixime 400 mg orally plus azithromycin 2 g orally, if ceftriaxone is not available or administration of injectable antimicrobials is not possible or refused by the patient, or spectinomycin 2 g IM as a single dose together with azithromycin 2 g orally in a single dose, if ceftriaxone cannot be given because of severe allergy or in case of resistance to extended-spectrum cephalosporins. CDC gives also the option of azithromycin 2 g orally in a single dose.

Cefixime 400 mg p.o. is no longer recommended as a first-line treatment of gonorrhea, and it is only an alternative option in cases when ceftriaxone cannot be administered. It should never be given without azithromycin 2 g p.o., because continued resistance to cefixime might hasten the development of resistance to ceftriaxone, the last antimicrobial that is known to be highly effective in a single dose for treatment of gonorrhea. Maintaining effectiveness of ceftriaxone for as long as possible is critical.

Several other injectable cephalosporins like ceftizoxime 500 mg IM, cefoxitin 2 g IM with probenecid 1 g p.o. and cefotaxime 500 mg IM have shown effectiveness against gonorrhea except pharyngeal infection; however, they offer no advantage over ceftriaxone, and they are not recommended. Other cephalosporins given orally, like cefpodoxime 400 mg or cefuroxime axetil 1 g, are not effective for pharyngeal infection, raise the same concerns for resistance as cefixime and should not be used.

Spectinomycin an effective alternative option for treatment of gonorrhea unfortunately is not available in many countries. It has poor efficacy against pharyngeal infection.

Azithromycin 1 g is not recommended as treatment failures have been documented, and there are concerns about possible rapid emergence of antimicrobial resistance. Those concerns are not that great with the 2 g dose which is preferred. However, treatment with azithromycin 2 g should be limited only in cases when antimicrobial susceptibility is already known or when there is known allergy to cephalosporins. Already high level azithromycin resistance and treatment failures have been observed in Europe.

Fluoroquinolones once a first-line treatment for gonorrhea are no longer recommended because of widespread worldwide resistance. Only when ceftriaxone cannot be administered and the antimicrobial sensitivity is already known, ciprofloxacin 500 mg p.o. or ofloxacin 400 mg p.o. as a single dose may be given.

Azithromycin 2 g which is included in standard treatment for gonorrhea is the preferred treatment for *C. trachomatis*, and it is well known that coinfection with *C. trachomatis* is common. If treatment for gonorrhea does not include azithromycin, doxycycline 100 mg oral dose twice daily for 7 days should be given unless coinfection has been excluded with NAAT testing.

Treatment of Sexual Partners and Follow-Up

For all patients with gonorrhea, every effort should be made to ensure that the patients' sex partners from the preceding 60 days are evaluated and treated for *N. gonorrhoeae* with a recommended regimen. Patients should abstain from sexual contact for 7 days after the recommended regimen until they and their partners are completely cured.

Patients should be assessed after treatment to ensure resolution of symptoms, compliance with therapy, and partner's notification and treatment. It is important to exclude reinfection, particularly in cases of treatment failure, as the alternative could be resistance to standard treatment.

A test of cure is recommended in all cases to identify persisting infection and emerging resistance, particularly in cases of pharyngeal infection, which is substantially harder to treat than genital and anorectal infections. In symptomatic patients, test of cure is performed with culture 3–7 days after completion of therapy, which permits antimicrobial sensitivity testing, and can be supplemented a week later with a NAAT for increased sensitivity if culture is negative. In asymptomatic patients, test of cure can be performed with a NAAT 2 weeks after completion of treatment. If the NAAT is positive, every effort should be made to perform a confirmatory culture and antibiotic susceptibility testing before further treatment is given.

Treatment Failure

If infection persists after the follow-up test of cure, reinfection by an untreated partner should be excluded first. If reinfection is unlikely, treatment should be guided by antimicrobial susceptibility tests. Ideally, as much clinical and laboratory data as possible should be collected and reported on treatment failures. If antimicrobial susceptibility testing is impossible to obtain or if *extended-spectrum cephalosporin resistance identified* according to European guidelines for treatment of gonorrhea, the following combination therapy could be tried:

- Ceftriaxone 1 g IM as a single dose *together with* azithromycin 2 g oral single dose
- 2 g azithromycin single oral dose + gentamicin 240 mg single IM dose

According to WHO two other regimens could be tried: 2 g azithromycin single oral dose + spectinomycin 2 g single IM dose OR either gentamicin 240 mg IM or spectinomycin 2 g IM.

The combination of azithromycin and gentamicin is currently under clinical study and may be valuable if infection persists after treatment with ceftriaxone. For many years gentamicin (together with doxycycline) has been successfully used in Malawi, Africa, and high in vitro susceptibility in Europe has been proven. However, a recent meta-analysis found that single-dose gentamicin 240 mg IM treatment resulted in a pooled cure rate of 91.5 %, failing to meet the current criteria of ≥95 % effectiveness for recommended treatment for gonorrhea. Further trials are needed to confirm the efficacy of this treatment regimen.

Decreased susceptibility of *N. gonorrhoeae* to cephalosporins and other antimicrobials is expected to continue to spread; therefore, state and local surveillance for antimicrobial resistance is crucial for guiding local therapy recommendations.

Urethritis: Nongonococcal

100

Irene Stefanaki

Key Points

- Nongonococcal urethritis (NGU) represents the commonest form of urethritis in developed countries.
- There is a wide range of responsible microorganisms, with *Chlamydia trachomatis* identified more frequently. However, in almost half of cases, no specific pathogen is detected.
- Patients with symptoms or objective signs should undergo testing with a Gram-stained urethral swab or first-pass urine specimen.
- Males with confirmed or suspected urethritis should be tested for *N. gonorrhoeae* and *C. trachomatis*.
- Patients with NGU should be offered a therapeutic regimen effective against *C. trachomatis*.
- Patient follow-up and proper management of sexual contacts are essential to ensure therapeutic success.

Definition and Epidemiology

It is a urethral inflammation not caused by *Neisseria gonorrhoeae*.

It is the commonest form of urethritis in Europe, the USA, Canada, and Australia. Although the related symptoms and signs are usually mild or absent and therapeutic regimens easy to follow, it has the potential of serious sequelae on the reproductive system of males and their female partners if the condition remains undiagnosed and untreated.

Basic Concepts of Pathogenesis

Urethritis may be due to infectious agents (bacterial, viral, fungal), noninfectious conditions (e.g., mechanical or chemical trauma, urethral strictures, and foreign bodies), or both. In infectious nongonococcal urethritis (NGU), the commonest pathogen is *Chlamydia trachomatis* accounting for 15–40 % of cases with a predilection for younger ages, followed by *Mycoplasma genitalium* (see Table 100.1). Other microorganisms including *Trichomonas vaginalis* (rates depending on its prevalence in the community, uncommon in men who have sex with men (MSM)), HSV, HPV, adenovirus, *Candida* sp., *N. meningitidis*, *Haemophilus* sp., *Moraxella catarrhalis*, *Streptococcus* sp., urinary tract infections, and enteric bacteria (in cases of insertive anal intercourse) are more uncommon, whereas in approximately 50 % of cases, no pathogen can be

Table 100.1 Infectious agents in NGU

Pathogen	Detection rates (%)
Chlamydia trachomatis	15–40
Mycoplasma genitalium	10–25
Trichomonas vaginalis	1–20
HPV, *Candida* sp., *N. meningitidis*, *Haemophilus* sp., *Moraxella catarrhalis*, *Streptococcus* sp.	<10 %
Urinary tract infections	<10 %
HSV	<5 %
Adenovirus	<5 %
Enteric flora	<5 %
Ureaplasma urealyticum	Controversial

detected. *Ureaplasma urealyticum* colonizes the urethra in 30–40 % of healthy sexually active young males, but it has also been implicated in the pathogenesis of NGU.

It is speculated that the etiology of asymptomatic NGU may differ from symptomatic NGU, because detection rates of *C. trachomatis* and *M. genitalium* are lower in asymptomatic patients.

Clinical Presentation

NGU may be asymptomatic or cause mild to moderate urethral irritation, pruritus, dysuria, and minimal urethral discharge which is often noticed in the morning or after urethral massage.

Complications of NGU include epididymitis/orchitis which, if left untreated, can eventually lead to male infertility and Reiter's syndrome. In the case of chlamydial and probably *M. genitalium* NGU, female partners who are not referred for screening and therapy could potentially develop pelvic inflammatory disease (PID) with subsequent possible infertility or extrauterine pregnancy.

Physical Examination

The aim of physical examination is to check for the presence of urethral discharge, detect any observable concomitant sexually transmitted diseases (STDs), diagnose other conditions that could imitate NGU, and search for possible complications. Therefore, it should include:

- Inspection of the urethra for obvious discharge
- Inspection of the genitalia (including the perianal area) for any signs of other STDs (e.g., syphilis, condylomata acuminata, herpes simplex)
- Palpation of the urethra for possible strictures, abscesses, or foreign bodies
- Palpation of the testes and spermatic cord for signs suggestive of orchitis/epididymitis

Diagnosis

1. *Confirmation of urethritis*. Urethritis can be confirmed either with the sign of urethral discharge on physical examination or with the following laboratory tests revealing WBCs in the anterior urethra:
   (i) A Gram-stained urethral smear containing ≥5 WBCs per high-power microscopic field.
   (ii) A centrifuged and Gram-stained first-pass urine (FPU) specimen demonstrating ≥10 WBCs per high-power microscopic field.

   In the case of observable urethral discharge, urethral smear is preferable to FPU since it will assist to exclude gonococcal urethritis and probably demonstrate other pathogens (*T. vaginalis*, *Candida* sp.). Leukocyte esterase test on FPU and methylene blue-stained urethral smear have also been used but have lower sensitivity.

   All patients with confirmed or suspected urethritis should be tested for *N. gonorrhoeae* and *C. trachomatis*.
2. *Exclusion of gonococcal urethritis. N. gonorrhoeae* can be ruled out by the absence of polymorphonuclear leukocytes with intracellular Gram-negative diplococci in a Gram-stained urethral specimen and by diagnostic tests specific for gonococcal infection (culture of urethral smear, nucleic acid hybridization tests, or single nucleic acid amplification tests (NAATs)).

3. *Detection of causative microorganism*. Patients with NGU should be tested for *C. trachomatis*, since it is an STD reportable to health authorities; furthermore, its diagnosis could enforce compliance to treatment, partner notification, and proper management, as well as provide an opportunity for health education. Available tests for *C. trachomatis* in urethral swab specimens include NAATs, nucleic acid hybridization tests, enzyme-linked immunosorbent assay tests (ELISA), direct immunofluorescence, and cell culture, with NAATs having the higher sensitivity (90–95 %). In the case of overt urethral discharge, microscopic examination of a urethral specimen could detect *Candida* sp. (KOH preparation) and *T. vaginalis* (wet preparation). *M. genitalium* can be detected by NAAT, although in clinical practice this is not performed routinely.

Differential Diagnosis

NGU should be differentiated from the following conditions:

- By definition NGU has to be distinguished from gonococcal urethritis. Clinically, gonococcal urethritis is characterized by a more abrupt initiation of abundant purulent urethral discharge that causes considerable discomfort; diagnosis of *N. gonorrhoeae* is confirmed by Gram stain microscopy of urethral smear and specific testing as previously described.
- Chronic or acute prostatitis can manifest as pelvic pain, urethral discomfort, and premature ejaculation.
- Upper urinary tract infection is sometimes accompanied by minimal urethral discharge.
- Noninfectious causes of urethritis include mechanical or chemical trauma corresponding to individual sexual practices, urethral strictures and fissures, abscesses, or foreign bodies. Males with venereophobia often manipulate their penis to check for signs of disease, resulting in self-induced urethral irritation.

General Principles of Treatment

If laboratory-based diagnosis is not available, symptomatic patients should be treated for both gonorrhea and chlamydia. If NGU has been confirmed by Gram-stain microscopy, therapy should be initiated as soon as possible, even before the results of specific tests for *N. gonorrhoeae* and *C. trachomatis* are available.

According to 2009 European guideline on the management of male NGU and 2010 CDC STD treatment guidelines, recommended regimens include either azithromycin at a single dose of 1 g or doxycycline 100 mg orally twice a day for 7 days. Both drugs are highly effective against *C. trachomatis*. Azithromycin has the additional advantage of a single dose, with subsequent better compliance. In the case of urethritis caused by *M. genitalium*, azithromycin seems to be more beneficial compared to doxycycline, although treatment failures can be observed with both drugs. Azithromycin and doxycycline are generally effective against other NGU pathogens, with the exception of *T. vaginalis* that responds to metronidazole or tinidazole. Alternatively, patients can receive erythromycin, ofloxacin, or levofloxacin. Recommended and alternative therapeutic schemes are reviewed in Table 100.2.

All of the above therapeutic schemes appear to be efficacious. Randomized clinical studies comparing the cure rates of each regimen are difficult to perform, since the causal microorganism is often not identified.

Patients should refrain from sexual contacts for 1 week (7 days after treatment with azithromycin or during the 7 days of therapy with doxycycline), provided that by that time they are asymptomatic and their partners have also been treated.

Patients with NGU should be monitored for other STDs (including syphilis and HIV). As in all cases of STD counseling, patients should be informed about the 3 month "window" period that precedes serologic detection of these diseases in order to have a repeat test 3 months after the first screening.

Patients with concomitant HIV infection should be managed in the same way as HIV-negative patients. Pathogens causing urethritis facilitate the transmission of HIV.

Follow-Up

An initial follow-up contact with the patient to ensure that symptoms have subsided, and that the patient and his partners have completed therapy without having unprotected intercourse during the period defined by the provider, is advised 3 weeks after completing therapy. If all of the above conditions are fulfilled, a test of cure is not necessary; otherwise, the patient should be reassessed and re-treated. This follow-up visit is also useful in reviewing the results of the screening test and dealing with other STDs that may have been diagnosed. Earlier assessment is not suggested, because urethral discharge and associated symptoms can persist for sometime after NGU therapy, although the infectious cause has been eradicated.

For patients with documented chlamydial urethritis, a further follow-up visit after 3–6 months is advisable in order to repeat testing for *C. trachomatis*, since reinfection during the first 6 months following treatment is not unusual in this group.

Partner Referral

All sexual partners of males with NGU should be assessed and treated, even in the absence of specific diagnosis of a pathogen. The exact preceding period for defining partners at risk is not established, but it should involve at least 2 months prior to diagnosis, or even longer according to the individual history of sexual contacts. Patients and their partners should be informed that symptoms and signs may be absent or mild –especially in the cases of cervical, anal, or pharyngeal infection – and that failure to treat partners could result in reinfection of the person initially treated, as well as in possible complications for all involved sexual contacts. Management of partners should follow the same guidelines previously mentioned.

Pregnant partners of males with NGU cannot receive doxycycline, ofloxacin, or levofloxacin. However, azithromycin is considered safe and effective and can be administered at the standard single dose of 1 g orally. Alternatively, pregnant women can receive amoxicillin 500 mg orally three times a day for 7 days or erythromycin as described in Table 100.2, although gastrointestinal side effects related to erythromycin could result in noncompliance with the latter. A test of cure 3 weeks after completion of therapy is recommended for all pregnant women with documented chlamydial infection to ensure cure.

Persistent and Recurrent NGU

Approximately 10–20 % of patients continue to have symptoms or physical signs 1–3 months after completion of therapy for NGU. If compliance to initial therapy and proper partner management are ensured, these patients are considered to have persistent/recurrent NGU.

Etiology of persistent NGU is not clear but could be attributed to:

- Failure of the recommended schemes (especially doxycycline) to eradicate *M. genitalium*. Therapy with moxifloxacin 400 mg daily for 7 days has proved effective, but there have been reports of severe hepatotoxicity and Stevens–Johnson syndrome. Some authors propose more extended regimens with azithromycin to avoid resistance of *M. genitalium*.
- Resistance of *U. urealyticum* to doxycycline.
- Cases of NGU caused by *T. vaginalis* require therapy with metronidazole or tinidazole.

First- and second-line treatments for persistent/recurrent NGU are summarized in Table 100.3.

Treatment with metronidazole or tinidazole is only advised when *T. vaginalis* is suspected as the responsible organism (e.g., in areas with high prevalence of *T. vaginalis* or when detected by

Frances Lawlor and Anne Kobza Black

Key Points

- The hallmark lesion in urticaria is the weal.
- Urticaria can be acute (<6 weeks) or chronic. Chronic urticaria may be spontaneous or inducible (physical) and may last years.
- Taking a history and examining the patient are extremely important as is an explanation about the condition and its treatment.
- Treatment is given to suppress symptoms if possible.
- Treatment is with minimally sedating antihistamines in an "updosing" regimen. Antihistamines are taken regularly as "prophylaxis" to keep the disease controlled. Systemic steroids are not recommended.
- Second- and third-line drugs may be prescribed, being added to the existing regimen.

Definition and Epidemiology

Urticaria appears on the skin as multiple short-lived erythematous, macular, annular and wealing lesions which usually itch. Each lesion lasts less than 24 h. The lesions change continually, and weals vary in size from tiny (1–2 mm) to very large (several centimetres). Angioedema, a deeper form of urticaria, presents as swellings of the eyes, lips, ears and other areas. It involves subcutaneous or submucosal tissues. These swellings may last between 24 and 72 h, are often not itchy and also leave normal skin. Angioedema may occur alone (pure angioedema) or concurrently with the urticaria.

A physical urticaria is one which occurs in response to a specific physical stimulus. The physical stimuli which produce lesions are divided into mechanical trauma (friction and pressure), change in temperature (cold and heat), light and water. Physical urticarias often occur in association with spontaneous urticaria and with each other. Recently it has been proposed that urticarias provoked by exercise, heat and emotion (cholinergic urticaria), by water (aquagenic urticaria) and contact urticaria are reclassified as urticaria cause unknown.

Any urticaria which remits in up to 6 weeks after onset is acute urticaria. Urticaria lasting longer than 6 weeks is defined chronic urticaria.

There are no data relating specifically to the incidence of acute urticaria in the population. Chronic urticaria comprises 70 % of all urticaria patients seen

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_101, © Springer-Verlag Berlin Heidelberg 2015

at dermatology clinics. Women are affected twice as frequently as men. Twenty percent of patients seen in urticaria clinics have physical urticarias.

Basic Concepts of Pathogenesis

Acute Urticaria

The most dramatic urticaria, acute allergic urticaria is an IgE-mediated allergic reaction which may be associated with systemic anaphylaxis. Many of these patients are atopic subjects. Systemic anaphylaxis is a rare but serious manifestation. A minor IgE-mediated reaction may present solely as urticaria without systemic symptoms. This response may be provoked by insect stings, drugs, blood products, latex and by various foods, for example, fish, milk, nuts, beans, shellfish, eggs, potatoes, celery, parsley or spices. Acute urticaria may also be associated with viral or bacterial infections, ingestion of medication such as antibiotics or non-steroidal anti-inflammatory drugs or with the onset of thyroid disease, but frequently no cause or association is found. Aspirin is the sole cause of urticaria in some people and worsens the disease in 50 % of patients. The mechanism is non-immunological, but the precise mechanism has not been defined. Other non-steroidal anti-inflammatory medication may behave in the same way. Codeine and morphine release histamine from mast cells.

Angiotensin converting enzyme inhibitors may cause severe angioedema and should be stopped if possible in patients with urticaria and angioedema. In occasional cases pseudoallergens including dyes (e.g. tartrazine, sunset yellow and red and blue dyes) and preservatives (e.g. benzoic acid, salicylates and ascorbic acid) have been reported to cause acute urticaria.

Chronic Urticaria

In the absence of a physical provoking factor, *no underlying allergic or medical cause is found in most cases*. In patients presenting with pure angioedema, it is necessary to consider hereditary angioedema (HAE). Type 1 HAE affects 85 % of sufferers. There is a quantitative deficiency of C1 esterase inhibitor (C1INH). This deficiency is autosomal dominantly inherited due to a mutation on the C1INH inhibitor gene on chromosome 11. Type 2 HAE affecting 15 % of the sufferers shows a functional defect of C1INH. Type 3 HAE has been recognised recently. This is less clearly categorised and very rare. It is familial, occurs in women, is considered oestrogen dependent, and some families show a mutation in the gene encoding for factor 12. An acquired form of HAE has occurred in lymphoproliferative disease, for example, B-cell lymphoma as well as systemic lupus erythematosus and both rectal adenocarcinoma and thyroid carcinoma.

It is suggested that the term *chronic spontaneous urticaria* be used instead of chronic idiopathic urticaria because some subtypes of chronic urticaria have been delineated.

Pathogenesis

Up to 40 % of CU patients express mast cell-activating factors which appear to be directed against the high-affinity IgE receptor (FcεRI) and against IgE. The subclasses are usually IgG1 and IgG3, which bind complement, and participation of complement in enhancing histamine release is probable in some patients. This points to an *autoreactive* (autoimmune) aetiology. The suggestion of an autoimmune aetiology of the disease in these patients is supported by association with thyroid autoimmunity, another autoimmune disease, a strong association with HLA-DRB1 (DR4) and by the response to treatments designed to remove, reduce or neutralise autoantibodies.

There is no easy or commercially available test to detect the autoantibodies directed against high-affinity IgE receptor (FcεRI) and IgE. A screening test is the use of the autologous serum skin test, to detect a weal-inducing factor in the serum of patients with active chronic urticaria, and further identification is the measurement of differential histamine release from normal basophils of low and high IgE occupancy. Some units use a blood test, the basophil histamine release

assay as the measure of autoimmune aetiology. It is now commercially available at RefLabs ApS, Copenhagen, Denmark.

A further subgroup may be associated with infection either viral or bacterial.

In Europe, *Helicobacter pylori*, hepatitis B and C and possibly Streptococcus A and dental infections can occasionally cause chronic urticaria. Parasite infections may cause urticaria outside Europe.

Another subgroup contains those patients who suffer pseudoallergic reactions to dyes and preservatives in foods. These reactions are non-allergic, dose dependent and usually delayed.

Clinical Presentation

The clinical characteristics of the lesions have been described above. It is generally not appreciated how severely the condition affects the quality of life because of the itching, occasional pain and the disfigurement and unpredictability of the lesions. Patients who attended a hospital urticaria clinic had a similar quality of life in many aspects as those waiting for a triple coronary bypass.

Although 50 % of patients with urticaria had been cleared in 6 months to a year, up to 25 % of those with urticaria with or without angioedema still had lesions 20 years later. The clinical course in any patient is impossible to predict, although there is often a gradual tendency towards improvement. Some patients have intermittent episodes, and most develop exacerbations during infections.

Diagnosis

The diagnosis is clinical as patients may not have visible lesion when assessed:

- The *initial interview* with the patient will give nearly all available useful information.
- If there are no specific indicators in the history, *the only routine investigation* suggested is a full blood count, erythrocyte sedimentation rate and urine analysis.
- If the history is suggestive of *physical urticaria*, challenge tests should be performed if possible to confirm the diagnosis. Clinical examination should include testing for symptomatic dermographism. Routine tests for immediate food *allergy* (e.g. *prick* tests) *are not indicated*, but may be performed to investigate a suspected food allergen in the history. If patients strongly suspect a *dietary factor*, *a p*lacebo-co*ntrolled challenge testing* to food additives may be carried out, and a positive result confirmed by re-challenge, or a low pseudoallergen diet can be tried for 4–6 weeks to access response. If *C1INH inhibitor deficiency* is suspected, *the plasma level of C4* is the screening test for hereditary angioedema. Treatment of HAE is not covered.
- A *skin biopsy* is necessary to demonstrate a suspected *urticarial vasculitis* or may be helpful to confirm delayed pressure urticaria.

Differential Diagnosis

The main differential diagnosis of urticaria is *urticarial vasculitis*. Here weals last 3–7 days and are burning, painful or itchy, purpuric, urticarial and very occasionally bullous. Bruised-looking angioedema is suggestive of urticarial vasculitis which is often poorly responsive to antihistamines. An autoimmune disorder such as lupus erythematosus should be considered in patients with confirmed urticarial vasculitis.

Other *differential diagnoses* include acute inflammatory skin conditions in the early phase, such as acute contact dermatitis, erythema multiforme and prebullous eruptions. In the early stages of inflammatory diseases when the swellings may fluctuate, conditions such as acute contact dermatitis and collagen vascular diseases including lupus erythematosus and dermatomyositis and granulomatous cheilitis may be confused with angioedema.

General Principles of Treatment

Patient Education

1. *Where this is no obvious cause of urticaria from the history and clinical examination, it is important for the patient to understand that the condition is not allergic in origin*, except in certain acute cases. "Ordinary" (spontaneous) urticaria is not associated with any underlying diseases, not fatal, not malignant, not contagious and not curable. However, there is usually a tendency to improvement, it can be emphasised at the onset of urticaria, and most will remit spontaneously within weeks. Once chronic, having lasted for more than 6 weeks, in 50 % of patients the disease will remit within 1 year. However, no promises can be made as in some it will last years.
2. *Patients should understand that an exhaustive series of tests will not be helpful*.
3. *Patients should be requested to avoid the drugs which exacerbate urticaria* including ACE inhibitors and non-steroidal anti-inflammatory drugs especially aspirin and histamine liberators such as codeine, but paracetamol is usually tolerated.
4. *Low pseudoallergen diets can be tried for a defined period in those patients who suggest a pseudoallergen-related problem and who wish to adhere to them*. Otherwise diets should only exclude substances proven to be a problem.
5. *Keeping* cool, cool baths and soothing topical applications, e.g. Calamine cream or 1 % menthol in a moisturising base, and minimising alcohol are helpful in some people.

Overview of Drug Treatment

1. *The treatment of urticaria is with minimally sedating H1 antihistamines. The condition can usually be controlled with H_1 antihistamines taken in adequate dosage*.

   The aim of drug treatment for urticaria with antihistamines is to decrease the itch and the number and size of duration of the weals. It may not be possible to completely control the condition without an unacceptable level of side effects.
2. *Since each individual patient responds uniquely, it may be necessary to change antihistamines and use doses higher than those recommended by the manufacturers, "off label" prescribing*.

   Current advice is to use one minimally sedating antihistamine in upto fourfold dosage, i.e. four tablets/day. The increased dose may be more potent due to an anti-inflammatory effect. This is described as "updosing". Dosage can be increased at approximately 2 week intervals. A combination of antihistamines of a different chemical group such as loratadine 10 mg in the morning and cetirizine 10 mg in the evening is not recommended but appears to be useful in practice. If the patient does not respond to updosing, it is suggested that a second-line treatment is added.

   Antihistamines are well absorbed when taken orally, and absorption is not related to the ingestion of food (except for fexofenadine where grapefruit juice reduces serum levels). The timing of tablet taking is important and should be related both to the time of day when the urticaria is at its worst and to the half-life of the drug or its active metabolite. The half-life is longer in the elderly, so the drug may accumulate, and the half-life is shorter in children who tolerate higher doses. It is necessary to be aware of renal impairment and liver impairment as different antihistamines are metabolised in different ways. Tablets should be taken regularly, and patients should understand that it can take time to reach steady blood levels after every dose increase.

   The currently available minimally sedating antihistamines are safe from the cardiac point of view, although in those with heart disease, bilastine, mizolastine and rupatadine can affect the ECG. One should also be aware generally of congenital QT prolongation and concomitant use of tricyclic antidepressants, some antipsychotics, antiarrhythmic drugs and electrolyte imbalance especially with the above three listed antihistamines. One must

be aware, when using certain antihistamines, the accumulation of the drugs by inhibition of degradation by cytochrome P450 by drugs metabolised by the same pathway. Loratadine, desloratadine and rupatadine and mizolastine are metabolised in this way. So one must be aware of possible interactions with azoles and macrolide antibiotics and careful in liver disease when using these drugs.

3. *There has been a change in recommendations with regard to prescribing in pregnancy*. Although most women try to avoid taking drugs in the first 3 months of pregnancy, H1 antihistamines are not teratogenic in humans and have not caused any problems in practice to date, and it is now suggested that taking minimally sedating antihistamines cetirizine and loratadine in pregnancy is safe, as is chlorpheniramine. However, if possible they should be stopped about 1 week before delivery to avoid any effects on the neonate. Antihistamines are excreted in small amounts in breast milk, and so breastfeeding may be a problem. Any antihistamine has the potential to worsen urticaria. The mechanism is not known, but it is suggested that this may be due to a direct toxic effect on the mast cell membrane.

   Only if the above first-line treatment fails should one consider second-line and then third-line treatment.

   Minimally sedating antihistamines are therefore first-line drug treatment for urticaria. This group of drugs includes cetirizine, levocetirizine, fexofenadine hydrochloride, loratadine, desloratadine, acrivastine (very short-acting), mizolastine, bilastine, ebastine and rupatadine. These drugs are H1 receptor inverse agonists shifting the H1 receptor into an inactive state. Generally they do not cause significant drowsiness, psychomotor impairment or anticholinergic side effects, although updosing with cetirizine is capable of inducing drowsiness. However, there is individual variation, and patients should be warned of these rare possibilities, and also excess alcohol should be avoided. Generally all these antihistamines are as effective as each other in clinical trials.

   It should be emphasised to the patient that the antihistamine is not a cure but is best taken regularly as a prophylactic until the urticaria resolves.

4. Antihistamines available (see also antihistamines chapter):
   (a) *Cetirizine* is derived from hydroxyzine. The manufacturers' recommended dose is 10 mg over 24 h. It is excreted by the kidneys and may cause problems in the elderly where lower doses should be given. The drug rarely causes drowsiness but does more frequently if the dosage prescribed is from 20 to 40 mg/day.
   (b) *Levocetirizine* is a metabolite of cetirizine.
   (c) *Loratadine* is an effective antihistamine with no significant sedation.
   (d) *Desloratadine* is a metabolite of loratadine.
   (e) *Mizolastine* is also an effective antihistamine; manufacturers recommend a dose of 10 mg per day. Prolongation of the QT interval has occurred in occasional patients, so the dose should not be increased.
   (f) *Acrivastine* is not usually potent enough alone to control urticaria. The manufacturers' recommended dose is 8 mg three times a day. It is helpful if a rapid response to treatment is sought and as an adjunct to treatment with other antihistamines as it has a fast onset and a short duration of action.
   (g) *Ebastine* at a dose of 10 mg daily is an effective antihistamine with no significant sedation or side effects or interactions with other medications.
   (h) *Rupatadine* is effective and interacts as described previously (see Chaps. 1 and 2).
   (i) *Fexofenadine hydrochloride* is an active metabolite of terfenadine without cardiotoxic effects. To date, few adverse effects and no drowsiness have been reported.
5. *Classical antihistamines*:

   If necessary and if sedation might be helpful, a sedating antihistamine could be

used especially for nighttime sedation. The group includes *chlorpheniramine maleate*, *hydroxyzine hydrochloride and diphenhydramine hydrochloride*. *Doxepin*, a tricyclic antidepressant with a powerful antihistaminic activity, can control urticaria when used on its own but may be better for night sedation of the anxious patient. With the exception of hydroxyzine, these drugs tend to be less effective than the second-generation antihistamines.

6. *Second-line treatment*: *If the patient is symptomatic after 4 weeks*, *it is suggested that the antihistamine be changed and/or a trial of a leukotriene antagonist* (*e.g. montelukast 10 mg*) *instituted for a month to see if there is a response*.
7. *Third-line treatment*: *Drugs added to the existing antihistamine regimen* include H2 antihistamine, cyclosporin, dapsone, methotrexate, mycophenolate mofetil and omalizumab.
   (a) *H2 Receptor Antagonists*
   The results of trials combining H_1 and H_2 receptor antagonists are conflicting, but though some show a significant improvement compared to either medication alone, in practice the combination is disappointing and does not usually produce a clinically significant improvement. The most recent European Guidelines suggest them as third-line treatment.
   (b) Cyclosporin
   Cyclosporin is effective in many patients. A response may be noticed after 2 weeks. The dosage is between 3 and 5 mg/kg/day.
   Baseline antihistamines must be continued and the usual blood tests and blood pressure estimations performed.
   (c) *Dapsone*
   Dapsone may be helpful when control is not achieved with full dosage of antihistamine. After an FBC and a G6PD level estimation, it seems wise to start with a low dose and increase until control is achieved, as tolerated.
   (d) *Omalizumab*
   Omalizumab is an effective treatment in many patients. It is expensive and regimens continue to evolve. The drug is injected monthly usually in a dose of 150 mg or 300 mg. It seems that some patients go into remission after one to three treatments, but most who improve relapse at this stage if the drug is stopped. It should be reserved for those with a severe limitation in both quality of life and whose urticarial activity score is high and who have not responded or are not suitable for other third-line therapies.
   (e) *Methotrexate*
   Methotrexate, used in the same way and with the same checks as psoriasis, is an effective treatment.
   Onset of action is slow, but good control can be achieved.
   (f) *Mycophenolate Mofetil*
   Mycophenolate mofetil can be effective, used in the same dosage and with the same checks as in Bullous pemphigoid. It has a slow onset of action.
8. *Other Treatments Used*
   (a) *Ultraviolet B and PUVA* have been effective in some patients.
   (b) *Intravenous immunoglobulin and plasmapheresis* have been used in those severely affected. Although there are some controlled studies which demonstrate that the addition of medication with in vitro mast cell-stabilising properties, such as ketotifen, nifedipine and theophylline, to antihistamines leads to improved control of urticaria, these are not mainstream treatments.
   (c) *Systemic steroids should not be used* for the treatment of urticaria except in exacerbations and for 3–7 days, in a dose of up to 30 mg /day. They are not always effective, and the side effects are unacceptable in the long term.
   Longer-term therapy may be occasionally necessary for severe urticarial vasculitis and delayed pressure urticaria not

responding to other therapy but should only be used at lower dosage in the long term.

Treatment of Angioedema

Acquired ordinary angioedema should be treated in the *same way as urticaria* with a dosage of H_1 antihistamine which suppresses the disease. If angioedema occurs in the mouth and causes systemic problems, e.g. dyspnoea, dysphagia, wheezing or syncope, *epinephrine* (*adrenaline*) (0.5 mg–1.0 ml of 1:1,000 mg/ml solution intramuscular or subcutaneous injection) should be used. Adrenaline is available for self-administration by patients as a mini-jet (0.5 ml) or as an adrenaline EpiPen (0.3 ml for an adult or 0.15 ml for paediatric use). Patients should be taught how to self-administer and when to administer. Patients with a history of severe oropharyngeal and laryngeal angioedema or anaphylaxis should have two in-date ones available for emergency use, as a repeat dose should be administered after 10 min if the initial response is not satisfactory.

Treatments for the Physical Urticarias

Symptomatic Dermographism

This usually responds well to treatment with H_1 antihistamines; ultraviolet B therapy at suberythrogenic doses two to three times/week for 8 weeks minimum may provide additional improvement.

Delayed Pressure Urticaria

This nearly always occurs in conjunction with chronic urticaria, but the pressure urticaria may be the major problem. Baseline treatment is with H_1 antihistamines and pressure on the skin minimised as far as possible. Large doses of antihistamine may have an effect on pressure-induced weals. In very severe disease, a short course of prednisolone (30 mg daily) can be given, but side effects are unacceptable if long-term use is contemplated. Many drugs have been used in this disabling disease including *intravenous immunoglobulin, montelukast*, *cyclosporin*, *dapsone*, *mycophenolate mofetil*, *etanercept*, *chloroquine and omalizumab*, but response to therapy continues to be uncertain.

Cholinergic Urticaria

Cholinergic urticaria responds partially to antihistamines.

Danazol (200–800 mg) or *stanozolol* (2.5–10 mg daily) may be used in resistant disease, with occasional effect. Drugs which have been used include beta blockers and omalizumab. A small group improved when desensitised to their own sweat. Some patients can control their problem by inducing tolerance.

Cold Urticaria, Localised Heat Urticaria, and Vibratory Angioedema

In these conditions *H_1 antagonists* are usually effective. Induction of tolerance by repeated graduated exposure to the physical precipitant may be helpful but is cumbersome to perform and needs to be maintained.

It is important to warn patients with cold urticaria against cold water bathing due to the risks associated with systemic histamine release and potential drowning. Etanercept given for other medical reasons has been a successful treatment, as have omalizumab and anakinra.

Severe localised heat urticaria has responded to omalizumab.

Solar Urticaria

This condition is difficult to treat. Staying inside during the bright part of the day and UV film on the windows help. Regular application of a *high-factor sunblock* active against UVB and UVA may help. *Antihistamines* should be used as first-line drug treatment. *Ultraviolet light* in small increments has produced tolerance.

If the above measures are not helping, intravenous immunoglobulin and cyclosporin have been used.

Aquagenic Urticaria

This rare physical urticaria usually responds to conventional *H_1 antihistamines*.

Proposed Treatment Algorithm in Urticaria

- *Take a full clinical history*:
  - Remove any identifiable cause, e.g. foods in IgE-mediated reactions and physical factors.
- *Discuss the diagnosis with the patients*:
  - General advice – explanation and information
  - Advise avoidance of aggravating factors:
    - NSAIDS, ACE inhibitors, codeine and morphine.
    - Minimise heat, stress and alcohol.
    - Avoid pseudoallergens in diet if proven to be a problem.
- *Treatment of urticaria*:
  - Emphasise that treatment must be taken regularly.
    - Second-generation, nonsedating antihistamines are the first-line treatment (normal dose).
  - Updose ×2, every 2 weeks if the symptoms persist.
    - Updose (×4) second-generation antihistamines or change antihistamine/add leukotriene antagonist (if the symptoms persist).
    - Add second- and/or third-line treatment as necessary.
  - Cyclosporin/methotrexate/mycophenolate mofetil/omalizumab.
  - All drugs are added to the updosed antihistamine regimen.
  - IVIG, plasmapheresis, danazol (Dapsone), UVB and PUVA have also been used.

Varicella

102

Theognosia Vergou

Key Points

- Varicella is transmitted mainly by airborne droplets or less commonly by direct contact with the vesicular fluid from skin lesions. Varicella is highly contagious (80–90 % transmissibility rates between family members).
- After the prodromal symptoms, the skin eruption appears, with the hallmark pathognomonic sign of varicella being the clinical presentation of lesions at different stages of development at the same time, in any part of the body.
- Varicella in pregnant women needs attention. The highest risk for the embryo is between the 7th and the 20th week of pregnancy.
- In adults and immunocompromised patients, primary varicella pneumonia is a very important complication, with mortality rates 10–30 %.

Definition and Epidemiology

Varicella, commonly referred to as chickenpox, is a highly transmissible infection caused by varicella-zoster virus (VZV), a DNA virus of the herpes group, transmitted by direct contact with infective individuals. Varicella is the primary infection of this highly contagious virus, while herpes zoster is the result of viral reactivation. Although varicella commonly occurs as a benign disease of childhood, it may be associated with life-threatening complications when it affects adults, pregnant women, newborns or immunocompromised patients. It mainly affects children below the age of 10 years old and shows peaks in winter and spring.

Basic Concepts of Pathogenesis

Varicella-zoster virus (VZV) is the causative agent of two diseases, varicella (chickenpox) and zoster (shingles). After an acute varicella infection is cleared, VZV establishes latency in the ganglia from which it can emerge later in life to give rise to a secondary infection, zoster. In contrast to varicella, which is disseminated, zoster, occurring in partially immune hosts, is usually limited to the dermatomes innervated by the ganglia in which reactivation occurs.

In Europe, 90 % of children get infected with VZV before 12 years of age, and around 95 % of adults are immune to VZV.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_102, © Springer-Verlag Berlin Heidelberg 2015

Varicella is transmitted mainly by airborne droplets or less commonly by direct contact with the vesicular fluid from skin lesions. Varicella is highly contagious (80–90 % transmissibility rates between family members). Primary viraemia results after viral replication to the regional lymph nodes (2–4 days). The virus is removed by cells of the reticuloendothelial system, which represent the major site of viral replication. Fourteen to sixteen days after the exposure to the virus, skin lesions are present. Secondary viraemia follows, with replication of the virus to the liver, the spleen and other organs. After temporary immunity following varicella infection, VZV reactivation (with the clinical form of herpes zoster) may occur, due to the decline of cell-mediated immunity (CMI), as a consequence of ageing or other immune-suppressing processes.

Clinical Presentation

The incubation period ranges from 11 to 20 days. After this period, the prodromal symptoms include fever, malaise, headache and myalgia. The skin eruption usually starts from the scalp and the face with later centripetal distribution to the trunk. The eruption may extend to the proximal part of upper extremities and thighs. The initial skin lesions are erythematous macules that very rapidly evolve to papules and then to vesicles surrounded by an erythematous halo ("dewdrops on a rose petal"). Vesicles evolve later to pustules and finally to crusts that disappear in 7–10 days without residual scarring. The hallmark pathognomonic sign of varicella is the clinical presentation of lesions at different stages of development at the same time, in any part of the body (Figs. 102.1 and 102.2). The lesions may be very pruritic. Secondary bacterial infections are one of the most common complications and may result to characteristic scars due to scratching.

In most cases, severe complications are described in adults, pregnant women, newborns and immunosuppressed patients. In adults and immunocompromised patients, primary varicella pneumonia is a very important complication, with mortality rates 10–30 %. Neurological complications include encephalitis, acute cerebellar ataxia, Reye syndrome, etc., are rare and are usually seen in immunocompromised patients. Haemorrhagic type of varicella is rare, with skin lesions filled with haemorrhagic content. The patient suffers from high fever and severe malaise. Other rare complications are optic neuritis or keratitis, myocarditis, arthritis, pancreatitis, hepatitis, vasculitis and orchitis.

Varicella in pregnancy is a situation in which the physician needs to be vigilant. It carries a 2 % risk of embryopathy. The reported incidence of gestational varicella is 1–7 per 10,000 pregnancies. Regarding the mother, an increased risk for disseminated varicella or primary varicella pneumonia exists. Intrauterine infection may take place, due to the viraemia of the mother. The highest risk for the embryo is between the 7th and the 20th week of pregnancy. If maternal varicella happens in the first two trimesters of pregnancy, this may cause congenital varicella syndrome, which is characterised by skeletal hypoplasia and abnormalities, neurological and ocular defects, low birth weight and skin scars. If the mother is infected in late pregnancy, this may result to premature delivery or stillbirth. In the case of maternal infection 5 days before or 2 days after the delivery, then the newborn will have varicella between the fifth and the tenth day of birth, due to the fact that there was no time for the embryo to get sufficient maternal antibodies. Perinatal varicella is associated with 20 % mortality rates.

Differential Diagnosis

Differential diagnosis has to be done between other generalised vesicular eruptions, such as:

- Dermatitis herpetiformis
- Disseminated herpes simplex (HSV typically has more localised lesions at the site of primary infection)
- Eczema herpeticum
- Vesicular viral exanthems (Coxsackie, ECHO)
- Pityriasis lichenoides et varioliformis acuta (PLEVA is a chronic inflammatory disorder)
- Rickettsialpox (the initial lesion is the site of the mite bite)
- Drug eruptions

Figs. 102.1 and 102.2 The characteristic pathognomonic sign of varicella is the presentation of lesions at different stages of development at the same time (papules, vesicles, pustules)

- Contact dermatitis
- Insect bites or scabies
- Bullous impetigo

Diagnosis

In most cases varicella diagnosis is made mainly by clinical examination and history. A Tzanck smear will show characteristic multinucleated epithelial giant cells, but it cannot rule out an HSV infection. The same also applies for skin biopsy. Viral culture is the most specific test, but not the most sensitive. Serology shows retrospective diagnosis of varicella, with the presence of IgM antibodies and a fourfold increase in the IgG antibodies. During the second to third week of infection, both antibodies reach their peak, with IgM declining quickly and IgG staying at low levels for life. Other diagnostic tools are immunofluorescence and PCR.

General Principles of Treatment

Symptomatic therapy for varicella includes antihistamines and emollients for pruritus and antipyretics for fever. It is sufficient for children with a normal immune system. Topical antibiotics may be needed for secondary bacterial infections, or even systemic antibiotics, if there is a widespread bacterial infection. Compresses or rinses with saline for skin, perineal and mouth lesions are helpful.

Acyclovir is indicated in immunocompromised adults and children. It is not recommended routinely for the treatment of uncomplicated varicella in otherwise healthy children. It is generally indicated for the treatment of otherwise healthy adults, due to the very increased risk of varicella complications and disseminated disease. The initiation of treatment has to take place within 24–72 h after the onset of cutaneous eruption. The oral dose for adults is 800 mg, five times daily for 7 days, and the dose for children is 20 mg/kg (higher dose is 800 mg), four times daily for 5 days. Another approved therapeutic form for children is as follows: in children <2 years old, 200 mg, four times daily; 2–5 years old, 400 mg, four times daily; and >6 years old, 800 mg, four times daily for 5 days. In immunocompromised adults or in adults with severe complications, acyclovir is administered intravenously, 10 mg/kg (500 mg/m^2), every 8 h for 7–10 days, and the same dose also applies for children. The oral dose for adults for valaciclovir is 1 g, three times daily, for 7 days, and the dose for famciclovir is 500 mg, three times daily, for 7 days. Both drugs have an indication only for the treatment of herpes zoster and have also been used for varicella in adults.

Passive immunisation is achieved with varicella-zoster immunoglobulin (VZIG). It is important for the administration to take place within 3 days of exposure, and the protective effect lasts for 3 weeks. It is indicated, at a dose of 125 U/kg, in immunocompromised patients that did not have varicella in

the past and that are exposed in an environment with varicella. It can also be administered in pregnant women with serious exposure to varicella, and there are reports in the literature that it could lower the risk for congenital varicella syndrome. Neonates of pregnant women that had clinical symptoms of varicella 5 days before or 2 days after delivery have to be protected with VZIG as soon as possible. Even though there are no controlled clinical trials for intravenous acyclovir in this case, experts recommend it, at a dose of 15–30 mg/kg/day. VZIG is also indicated for the passive immunisation of immunocompromised children after an important exposure to varicella or herpes zoster.

In the case of a possible exposure to varicella in a pregnant woman with unknown immune status, serum testing should be performed. If the serum results are negative or unavailable within 96 h from exposure, VZIG should be administered. Women with significant varicella infection in pregnancy should be treated with oral antiviral agents (e.g. acyclovir 800 mg, five times daily). In cases of progression to varicella pneumonitis, maternal admission to hospital should be seriously considered. Intravenous acyclovir can be considered for severe complications in pregnancy (oral forms have poor bioavailability). The dose is usually 10–15 mg/kg or 500 mg/m^2 IV, every 8 h, for 5–10 days, for varicella pneumonitis, and it should be started within 24–72 h of the onset of rash.

Active immunisation with live attenuated VZV vaccine is available in several countries outside Europe (Australia, Canada, Costa Rica, Ecuador, Israel, New Zealand, Oman, Panama, Qatar, Saudi Arabia, South Korea, Taiwan, the United Arab Emirates, Uruguay and the USA), as well as some European countries (Germany, Greece, Latvia, Luxembourg) and regions (7 out of 21 in Italy, 2 out of 17 in Spain) have introduced routine varicella vaccination after 1995.

Initially a single-dose vaccine was performed in children aged 11–14 months. Additionally, catch-up vaccinations for all susceptible children and adolescents were recommended, with two doses in children over 13 years of age. In many countries, after 2006, a combined measles-mumps-rubella-varicella (MMR-V) vaccine is available, licensed with a two-dose schedule (the second dose at the age of 4–6 years old).

Epidemiologic data have shown that paediatric varicella cases decreased by 67 % and paediatric hospitalisations by 43 % after the implementation of the vaccine. There are also reports from studies showing that due to the vaccination programmes against varicella, there is an important decrease in the incidence of herpes zoster. This has been explained based on the fact that the acquired active immunisation with the vaccine protects ten times more than the natural immunisation after a varicella infection during the childhood. Some single-country modelling studies have shown the opposite results, thus an increase in herpes zoster incidence. The most recent data from a model-based evaluation from three European countries supports the idea that, after varicella immunisation, an increase of herpes zoster incidence is not a certain fact and it rather depends on the presence or absence of factors promoting a strong boosting intensity and which might or might not be heavily affected by changes in varicella circulation due to mass immunisation. These findings might explain the opposed empirical evidences observed about the increases of herpes zoster in sites where mass varicella vaccination is ongoing.

Vascular Birthmarks: Vascular Malformations and Haemangiomas

103

Fabio Arcangeli and Davide Brunelli

Key Points

- Vascular malformations and haemangiomas are among the most common dermatological conditions that can be observed in infancy, and the dermatologist is often involved in the first diagnosis or acts as an important consultant when planning therapeutic and follow-up strategies. Precise knowledge of the natural history of these pathologies and the general implications arising from them is essential to be able to direct parents toward making an informed therapeutic choice.
- Today vascular anomalies are described according to the ISSVA (International Society for the Study of Vascular Anomalies) classification drawn up at the 1996 workshop in Rome. Haemangiomas can be considered benign tumours characterised by an abnormal proliferation of capillary vessels. Their history shows rapid growth in the first months of life, followed by a slow involution in subsequent years. Capillary malformations, in contrast, are characterised by the presence of permanently abnormally dilated capillaries. These do not regress spontaneously but grow in proportion to the somatic development of the individual. Both conditions can have different degrees of severity, and they also involve the visceral organs in the context of complex syndromal patterns.

Vascular Malformations

Definition

Within the group of vascular malformations (Table 103.1), the capillary malformations (CM), more commonly known as port wine stains, are the most frequently occurring and have the highest epidemiological profile. They are characterised by the presence of capillary anomalies at the level of the papillary and reticular regions of the dermis: the vessels are permanently dilated, giving rise to the typical skin colouration that can vary from pale red to deep purple. They are present at birth in 0.3 % of newborns with an equal distribution between the two sexes.

Table 103.1 Updated ISSVA classification of vascular anomalies

Vascular tumours	Vascular malformations
Infantile haemangiomas	*Slow-flow vascular malformations*
Congenital haemangiomas: rapidly involuting congenital	Capillary malformation (CM)
Haemangioma (RICH); noninvoluting congenital haemangioma (NICH)	Port wine stain Telangiectasia
Tufted angioma (with or without Kasabach-Merritt syndrome)	Angiokeratoma
Kaposiform haemangioendothelioma (with or without Kasabach-Merritt syndrome)	Venous malformation (VM)
	Common sporadic VM
Spindle cell haemangioendothelioma	Bean syndrome
Other, rare haemangioendotheliomas	Familial cutaneous and mucosal venous
Epithelioid	Malformation (VMCM)
Composite	Glomuvenous malformation (GVM)
Retiform	(Glomangioma)
Polymorphous	Maffucci syndrome
Dabska tumour	Lymphatic malformation (LM)
Lymphangioendotheliomatosis	*Fast-flow vascular malformations*
etc.	Arterial malformation (AM)
Dermatologic-acquired vascular tumours	Arteriovenous fistula (AVF)
Pyogenic granuloma	Arteriovenous malformation (AVM)
Targetoid haemangioma	*Complex combined vascular malformations*
Glomeruloid haemangioma	CVM, CLM, LVM, CLVM, AVM-LM, CM-AVM
Microvenular haemangioma	
etc.	

C capillary, *V* venous, *AV* arteriovenous, *M* malformations

Basic Concepts of Pathogenesis

There is not yet a generally accepted explanation for this phenomenon. Among the most accredited theories is the one put forward by Waner and Suen in 1999, who postulated that the existence of a relative or absolute lack of autonomic and sensory innervation was the basis for this pathology. The lack of adequate innervation would cause alteration in the vasoregulatory mechanisms resulting in permanent vessel dilation and increased blood flow in the affected areas. A recent discovery of undoubted interest is that of a somatic mutation of the GNAQ gene on the 9q21 chromosome that would seem to confirm the universally accepted but never proven hypothesis of the presence of a somatic mutation being the basis of both capillary malformation and its associated syndromes.

Clinical Presentation

The extent of the CM can vary from a few millimetres to over 50 % of the body surface, affecting almost any somatic region, although port wine stains occur most frequently on the head and neck (Fig. 103.1). When they occur on the face, over 50 % of the CMs affect only one of the three cutaneous areas corresponding to the sensory branches of the trigeminal nerve. Clinical diagnosis is normally straightforward with a skin biopsy only rarely necessary for confirmation. CMs do not regress but grow according to the somatic development of the individual, and over the years, the surface becomes darker and subject to such phenomena as thickening and nodular hypertrophy (cobbling). In adulthood these phenomena may cause significant clinical conditions, with the increased disfigurement leading to

Table 103.2 Principal syndromes associated with the presence of capillary malformations

Name	Clinical features		
Sturge-Weber	Craniofacial CM (periorbital and temporal area)	Ophthalmic lesions (choroid haemangiomas) and homolateral leptomeninges (vascular anomalies, calcification)	Neurological (epilepsy, sometimes mental retardation) and ocular (glaucoma) symptoms
Parkes Weber	CM involving a lower limb	Arteriovenous microfistulas	Hypertrophy of the skeleton and soft tissues
Klippel-Trenaunay	CM involving a lower limb	Complex venous malformation	Gigantism of the limb

Fig. 103.1 Capillary malformation of the face before and after three treatments with 595 nm FPDL

psychological damage and sometimes very marked functional disorder. Even less clinically significant cases are capable, from early infancy, of producing negative effects on a child's cognitive, social and psychological development with inevitable repercussions in adult life. To this can be added the anxiety and sense of guilt that normally afflict the parents, emotional factors that can complicate problems of family equilibrium to the extent that this pathology can be considered a condition that is not limited to a merely aesthetic issue. For these reasons, requests for treatment are becoming ever more numerous, particularly now that the proliferation of new communications media makes it easier to access detailed information about the technological solutions available and the clinical issues that accompany them. It is known that this condition is associated with some syndromes (see Table 103.2), the most well known and frequently occurring is Sturge-Weber syndrome, which can be observed in particular in patients with a port wine stain affecting the part of the skin corresponding to the first branch (V_1) of the trigeminal nerve.

General Principles of Treatment

Traditional attempts at therapy (surgery, radiation therapy, cryotherapy, diathermic coagulation, dermabrasion or simple cosmetic camouflage) have always left both patients and therapists dissatisfied, and these have often caused blemishes that are even more unsightly than at the start. The first attempts at treating CMs with laser equipment (CO_2, Argon and Nd:YAG) were equally disappointing both because of their lack of effectiveness

and because of the resultant scarring, sometimes very serious, resulting from the application of the flash lamp. It was only in the 1980s and 1990s that greater knowledge of selective photothermolysis led to the development of an apparatus specifically designed for CM treatment, the dye laser, which very soon became the therapeutic gold standard for the treatment of this pathology.

The Dye Laser

Dye lasers belong to a class of equipment whose active medium is an organic dye in a liquid state, normally in an alcohol solvent. The dye is made to circulate rapidly in a cylindrical cell excited by a flash lamp as is the case for solid-state lasers or Argon or Nd:YAG lasers. The apparatus used in dermatology uses mainly *rhodamine 6G*: the dye is excited by a high-intensity flash lamp from which the laser takes its international name *flash lamp-pumped dye laser* (FLPD), and the result is the emission of light at a wavelength of 595 nm, the ideal compromise between selectivity and depth of penetration within the skin. The target for CM treatment is the oxyhaemoglobin contained in the malformed capillary bed. According to the studies by Greenwald and Tan, the first appreciable results after exposure to laser light were confined to the superficial plexus (0.5 mm) and were characterised by an aggregation of erythrocytes, breakage of the vessels and haemorrhaging. Deeper down (0.5–1.1 mm) a disseminated infiltration of polymorphonucleates was observed, mainly perivascular and alternating with areas of lymphocyte infiltration. One week after the treatment, the vessels had been replaced by a fine granular tissue, and at the level of the papillary dermis, they presented a lumen of a smaller diameter. One month later, no abnormally dilated capillaries were observed: the treated areas presented a lumen of a small diameter, thin walls and a notably greater quantity of endothelial cells and pericytes. The epidermis showed no alterations after 30 days from treatment. In this study, using a 577 nm apparatus, the minimum flux needed to produce tangible alterations was estimated as 3 j/cm^2, while the more considerable alterations were found starting from 5 j/cm^2. Today the most commonly used starting flux, which varies according to the specifications of the equipment used, is between 5.6 and 10.12 j/cm^2. The ideal diameter of the spot is considered to be between 7 and 10 mm. The universally adopted exposure time, from the first experiences of CM treatment, is 450 μs, the lowest thermal release time (TRT) threshold for the cutaneous capillary plexus. Using a wavelength of 595 nm, this can be increased to 3.0 ms, making it possible to act on vessels of a larger size. These exposure times result in the immediate appearance of the characteristic purple colouration that represents an important end point for the treatment. Checking the tonality of the purpura offers the therapist the opportunity to make an indirect assessment of its efficacy. Any evidence of greyish areas within the typical purple colouration most probably represents an area of hyperexposure to the laser light, while reduced colouration probably suggests too low a flux or an inadequate target. The purpura regresses in 10–14 days, but this can be followed, some days after treatment, by the appearance of small water blisters which then give way to crusty surface scabs. Although these phenomena disappear rapidly, they appear quite dramatic when they first appear, and therefore it is advisable to show patients or their family some photographs illustrating the different stages in the evolution of these phenomena.

When to Begin Treatment, Success Rate and Adverse Side-Effects

Personal experience and numerous publications on this subject confirm that treatment should be undertaken as early as possible. Early treatment is more successful because the capillary bed is more superficial, the diameter of the vessels smaller and the epidermis is thinner, thus enabling greater light penetration and last but not least, the more limited extent of the lesions, making it possible to cover a greater area in the same session. Not only is the therapeutic success more obvious, but fewer treatments are required than in adult-

hood. The location of some CMs, such as on the lower limbs, can be completely untreatable in an adult, but there may be some hope of improvement if treated at an early age. For these reasons, the first intervention should be planned to start from the first months of life with the prospect of significant clearing in a few sessions spaced 4–5 months apart. Depending on the response, it may then be necessary to schedule some "maintenance" treatment sessions at a frequency to be determined according to the clinical development of the condition. Regardless of the amount of clearing obtained, periodic laser treatment is capable of arresting or reducing such involution phenomena as thickening and cobbling that can be observed in the most deep-seated conditions. The treatments are given under a general anaesthetic to the youngest children and those with lesions on the face. In these cases the eyes must be protected with a metal screen, particularly if the area to be treated is the eyelids or the area around the eyelids. Adults are quite able to withstand treatment in outpatients without the need for a local anaesthetic or sedation.

The success rate reported in the numerous published works on this topic can vary quite dramatically, this being largely influenced by the age of the patient and the size and location of the lesions. A positive judgement of the treatment expressed by patients or their families can exceed 80 % for facial lesions in paediatric patients, but this decreases notably for adults and for lesions on the extremities. The size of the lesions, particularly in adult patients, seems to affect the response to the treatment in a linear way, in particular for affected areas over 100 cm^2. Adults too can respond very well to treatment, particularly in cases with limited lesions, while there is a very low response for more extensive lesions, particularly when these affect the extremities. Despite the considerable aesthetic improvement, complete clearing of CMs has only been observed in about 10 % of cases.

Adverse side effects are very rare, under 1 % of cases, but they are possible, and therefore this must be clearly explained before undertaking treatment. Most unwelcome are those represented by hypertrophic and keloid scarring that is later particularly observable in treatments to the neck. Atrophic scarring has also been reported, generally reversible over a period of 12–18 months. Moreover post-inflammatory hyperpigmentation and hypopigmentation can be observed, usually transitory and largely influenced by the skin phototype. Indeed, melanin can compete with haemoglobin in the wavelengths between 585 and 590 nm and partially absorb the laser energy. Pigmentation disorders after treatment are therefore more common in darker phototypes and are also influenced by the degree of tanning present when the therapy is applied.

Recurrence of Vascular Manifestations

Although this methodology today represents the benchmark treatment for CM conditions, two main problems still exist: the recurrence of the vascular manifestations and the cases that fail to respond to treatment.

In the years following treatment, the vascular condition gradually reverts in a large number of the cases treated, something that has been noted and confirmed by studies that use objective assessment methods. This fact must therefore be clearly explained before undertaking treatment, since it is likely that further "maintenance" sessions will be needed over the years. Despite this evidence, the majority of patients state that they are satisfied with the treatment, apart from the partial revascularisation. The result is most probably due to the gradual onset of the return of colouration and thus to the changes in perception associated with this.

Alternative Treatments

Some cases, between 20 and 30 %, according to the literature, show little or no response to FPDL treatment, and to date, it is virtually impossible to predict, prior to treatment, which lesions will show the best response, despite the various instrumental approaches suggested to remedy

this problem, principally Doppler sonography and videodermatoscopy. When there is a poor response, substantial benefits cannot be obtained by changing the parameters of the apparatus, such as exposure time or flux, although the double-pass technique, at 595 and 585 nm, does seem more promising.

Other lasers have been proposed as complementary or as alternatives to the dye laser when there is no response, among them the alexandrite 755 nm and the Nd:YAG 1,064 long pulse lasers. Even though the results are still limited and contradictory, they appear to provide useful support in the treatment of CM conditions. Consideration is also being given to the use of IPL (intense pulsed light) equipment, supported by some interesting work and, more recently, the use of photodynamic therapy. In addition to the use of complementary or alternative apparatus to the dye laser, further research is being done on some drugs such as angiogenesis inhibitors, rapamycin and imiquimod.

Haemangiomas

Definition

Infantile haemangiomas (IHs) are very common benign vascular lesions composed of endothelial cells. They are found in approximately 10 % of all newborns and infants up to the age of 12 months (20 % in premature infants). They are three to four times more common in females.

Basic Concepts of Pathogenesis

The pathogenesis of infantile haemangioma, in spite of having been recently reviewed, is still not completely understood, although it has been postulated that growth factors and hormonal and mechanical influences affect the abnormal proliferation of endothelial cells.

Numerous studies support the hypothesis that the primary defect is intrinsic to endothelial cells in that the underlying factor in the development of the tumour is a mutation in a critical gene in a precursor stem cell, and the clonal expansion of this single cell carrying a somatic mutation leads to haemangiogenesis. In the proliferation stage of a haemangioma, there is rapid proliferation of new blood vessels that arise as clonal primitive stem cells differentiating into endothelial cells and pericytes, and there is an increase in the expression of proangiogenic factors, such as VEGF, bFGF, PDGF, IGF-2, HIF-1alpha, MMP-2 and MMP-9. In particular, VEGF (vascular endothelial growth factor) seems to play a key role in the pathogenesis of haemangiomas in that it stimulates both proliferation and migration, increases vascular permeability, stimulates angiogenesis and inhibits apoptosis.

In contrast, the regression phase is characterised by a reduced expression of these factors and the endothelial cells, followed by lobular deposition of fibrofatty tissue.

VEGF expression is also increased by hypoxia: tissue hypoxia seems to be the most powerful inducer of vasculogenesis and angiogenesis involved in the pathogenetic mechanism. Recent studies have shown an association between placental hypoxia and haemangioma.

An alternative theory implicates the expression of placental vascular epitopes in haemangioma in which high levels of immunostaining are displayed for the GLUT1 glucose transporter, a surface protein that is highly expressed in most embryonic and foetal endothelial cells but lost in most tissue, except at blood-tissue barriers, including microvessels in the central nervous system and the placenta. It has been hypothesised that embolisation of placental endothelial cells to the foetus plays a role in the pathogenesis of haemangiomas, because this would explain the exclusively perinatal or congenital presentation of this pathology.

The role of the renin-angiotensin system has recently been explored with beta-blockers causing a reduction in renin activity. The effect of propranolol on haemangioma is not currently completely understood, but with improving knowledge of the pathogenesis of infantile haemangioma, several possible mechanisms for the action of the beta-blocker have been found. It is believed that propranolol leads to suppression of angiogenesis, through a reduction in the expres-

sion of such proangiogenic factors as VEGF, vasoconstriction of the capillaries and the induction of apoptosis.

Clinical Presentation

IHs generally appear in the first 2 weeks of life, and they typically evolve with a phase of rapid proliferative growth up to the fourth to sixth months of life, followed by a slow spontaneous involution phase that is complete by the fifth year in 50 % and the seventh year in 70 % of cases, but in 30 % of cases, the regression phase can be prolonged up to the ninth to tenth year of life.

RICH (rapid involuting congenital haemangiomas), whose proliferation stage occurs during endouterine life and that have reached their maximum size at birth, subsequently regressing over the first 2 years of life, are a separate type of haemangioma and are not considered a variant of IH.

While IHs can be located on any area of the skin, the majority appears on the head and neck (60 %), followed by the trunk (25 %) and limbs (15 %).

Clinically superficial IHs present as macules or papules that are pink or red in colour, at times preceded by blanching of the involuted skin followed by fine telangiectasias. During the proliferative growth phase, IHs tend to become raised, well demarcated, a bright red in colour, plaque or tumour-like, with a smooth lobulate surface.

In addition to superficial IHs located on the dermis, there are deep IHs located subcutaneously that present as masses covered by normal skin, sometimes of a bluish colour that can be compressed by pressure. Mixed IHs also exist that are superficial and deep and that have the clinical characteristics associated with both types.

Regression is expressed clinically, with a lessening of the depth in colour of the superficial component until greyish areas appear, especially at the centre, tending to become more extensive with the gradual reduction of the subcutaneous mass that becomes less consistent, more flaccid and exhibits less expansion during increased intravascular pressure (e.g. crying).

At the end of the regression phase, the majority of cases exhibit permanent results such as telangiectasias, dilated superficial veins, epidermal atrophy and excess skin.

Complications

Ulceration and Bleeding

Ulceration and bleeding are the most common complications.

Ulceration occurs in 10–25 % of cases and is most frequent for IHs located in folds, the anogenital area and on the lips, especially the lower lip. In these areas an increase in local moisture and rubbing can favour the erosion of IHs, particularly mixed IHs – combined superficial and deep IHs. Moreover, ulceration occurs most frequently in IHs in the rapid proliferation stage with taut surfaces.

It may take months to heal these with constant intervention and scarring as the outcome.

While bleeding is frequent, in some 40 % of cases, this is usually mild and transitory, and it can be easily arrested simply by continuous compression for 3–4 min. Serious haemorrhage is very rare.

Secondary infection can occur and this is the main cause of painful conditions.

An ulcerated lip IH can hinder feeding and lead to poor oral intake.

Treatment includes local medication, oral antibiotics, pulsed dye laser treatment and, in some cases, also surgical excision. The best treatment is currently considered to be oral propranolol which has proven efficient at controlling the associated pain and promoting tissue repair in 2–6 weeks.

Functional Impairment

Visual obstruction must always be considered when an IH affects the eyelids, particularly the upper lid, or the periorbital area in general.

Periorbital haemangiomas are often the cause of secondary astigmatism due to alterations of

the corneal curvature. Less frequent are strabismus and visual axis obstruction which can result in amblyopia and permanent vision loss.

In all cases in which the periorbital area is affected, it is necessary to arrange an early visit to an oculist.

Therapy is indicated not only in cases of detected or suspected visual impairment but also in all situations considered at risk, and propranolol administered orally is currently considered the first-line treatment in such situations.

IH of the upper lip or intranasal area can hinder nasal breathing.

Even when IHs are only superficial, located on the lower third of the face and in the cervical and chin area, particularly if these are bilateral, they can be associated with IHs of the upper airway and may be suspected in cases of sleep apnoea, stridor or a hoarse cry.

The diagnosis can be confirmed by laryngoscopy or by MRI. However, even when there are no symptoms, all newborns with IHs located on the lower third of the face should be referred for an ENT consultation in order to make an accurate assessment of the airways.

In these cases, oral propranolol is also the first choice of treatment.

Multiple Cutaneous Haemangioma

In cases of multiple cutaneous haemangioma, with the presence of more than five, there is a risk of hepatic haemangioma, which must be assessed by way of abdominal ultrasonography. Hepatic haemangioma is usually asymptomatic and does not require therapy. However, if present, careful follow-up is recommended with serial ultrasounds to monitor its size.

In cases of ten or more haemangiomas (diffuse neonatal haemangiomatosis), not just the liver but all the visceral organs may be affected with life-threatening potential. The main cause of early mortality is congestive heart failure because of the reduction in the circulating haematic mass. In these cases a complete imaging study (MRI, ultrasonography) must be performed. Treatment involves the use of steroids in general, interferon alpha and, above all, propranolol.

Associated Malformations

Large segmental haemangioma of the face (>5 cm in diameter), mainly if this involves the frontal-temporal or mandibular areas, in approximately 30 % of cases, is associated with PHACE syndrome, an acronym denoting posterior fossa malformations, haemangiomas, arterial anomalies, cardiac anomalies, eye abnormalities and, rarely, sternal clefting or supraumbilical raphe. One or more of these extracutaneous congenital anomalies may be present. All patients with a large facial segmental haemangioma should be investigated with MRI and MRA of the head and neck, echocardiogram and ophthalmologic evaluation. Treatment with propranolol may be started but with extreme caution because of the documented risk of stroke and ischaemia in cases characterised by reduced arterial pressure. The recommended regimen is three daily doses, starting with the minimum then gradually increasing.

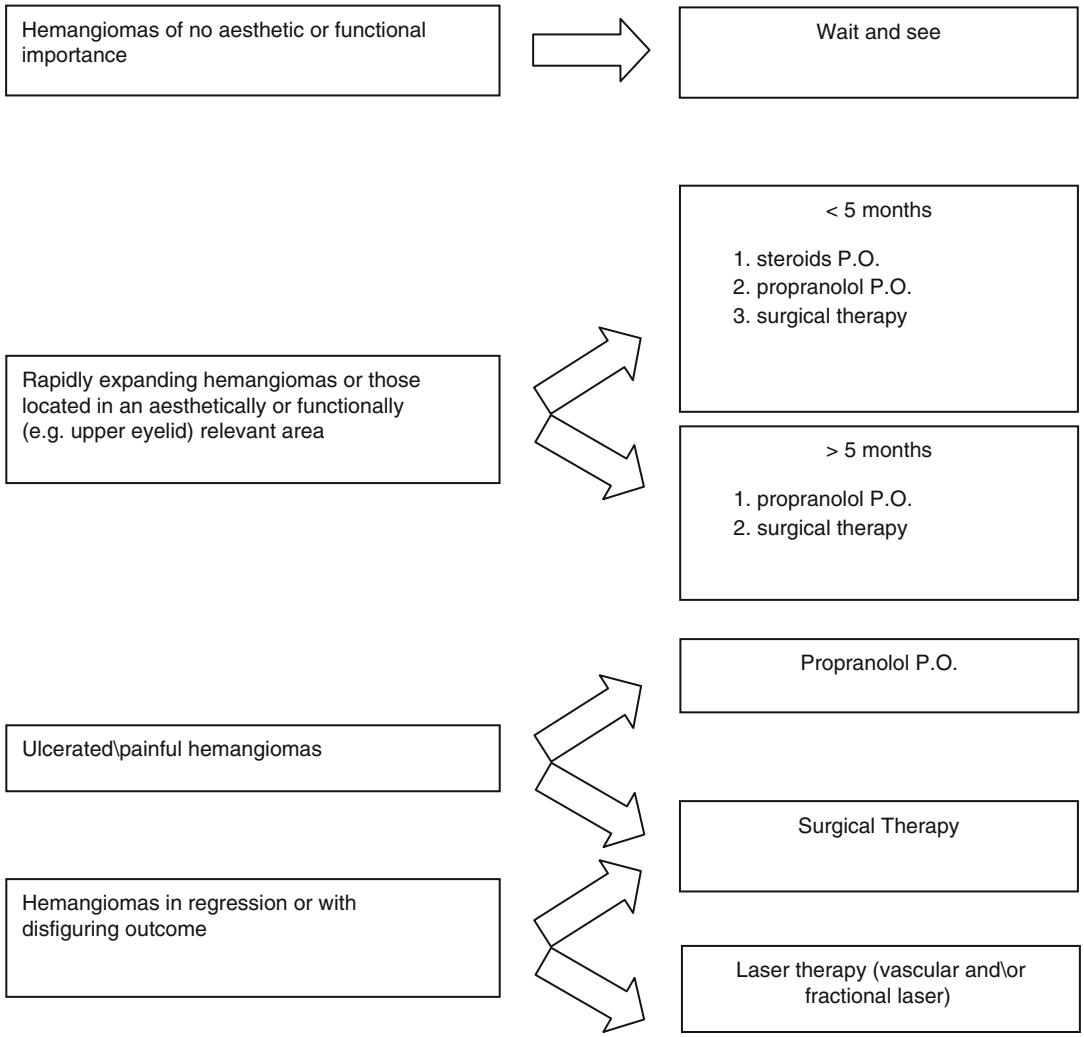
Large segmental IH involving lumbosacral or perineal regions may be associated with other underlying congenital anomalies as described in LUMBAR syndrome (lower body haemangioma, urogenital anomalies, ulceration, myelopathy, bony deformities, anorectal malformations, arterial anomalies, renal anomalies), PELVIS syndrome (perineal haemangioma, external genitalia malformations, lipomyelomeningocele, vesicorenal abnormalities, imperforate anus, skin tag) and SACRAL syndrome (spinal dysraphism, anogenital, cutaneous, renal and urological anomalies, angioma of lumbosacral localisation). All these acronyms refer to the same group of malformations that can be associated in extremely variable ways.

In all cases without neurological symptoms, without clinical evidence of sinus or ulceration before the first 3 months of life, intervention may be limited to an ultrasound examination, delaying a spinal MRI with contrast.

General Principles of Treatment

Currently all authors are in agreement, maintaining that, in the majority of cases of haemangioma in which, depending on its location, size and

Table 103.3 Management of haemangioma: current treatment options in M. Bufalini Hospital, Cesena, Italy



stage of evolution, a good aesthetic outcome can be predicted at the end of the spontaneous involution stage, there are no indications for medical or surgical treatment. No treatment should be given, adopting a "wait and see" approach in all cases in which no functional impairments or disfigurements are present or predicted.

The major goals for IH management have recently been identified as minimising physiological and psychological distress, prevention of life-threatening complications or any complications that obstruct vital structures, such as the airway or visual pathway and treatment of such complications if they arise, in addition to prevention of disfigurement due to residual skin changes after the involution phase.

The initial decision is whether to treat with local or systemic therapy and the identification of patients who require surgical therapy. In general, local agents are best employed for small, superficial and localised haemangiomas, while systemic therapy is reserved for larger haemangiomas, those showing more aggressive growth and those carrying a high risk of functional impairment. Surgery is indicated for cases in which medical treatment has proven insufficient to produce the expected improvement in a short time, for example, painful ulcerated haemangioma, or haemangioma causing closed palpebral ptosis, and to correct unwanted results, generally at the end of the involution stage but sometimes before that if there is major psychological distress. See Table 103.3.

Topical Treatments

Several topical agents have been proposed for IH. Recent studies have supported the efficacy of timolol maleate 0.5 % gel-forming solution for treating small and superficial haemangiomas, demonstrating a reduction in redness and thickness within the first 2 weeks. Topical imiquimod cream may also be considered in early IH of the head and neck; possible complications to be considered include irritation, crusting and ulceration. Intralesional steroids maintain a useful role as a local treatment for select cases, particularly for early localised haemangiomas of the lip or nasal tip: triamcinolone is usually employed, and the doses should not exceed 1–2 mg/kg per injection.

Systemic Treatments

None of the pharmacological treatments in current use to combat the growth of haemangiomas or to encourage their regression have obtained official recognition and are therefore to be considered off-label.

Until recently oral corticosteroids were the mainstay of treatment for IH, but in the last few years, propranolol has dramatically changed the management of this pathology. It is now considered by most experts to be first-line therapy when systemic treatment is indicated.

Corticosteroids

The efficacy of steroids in the treatment of IH is extensively documented. Prednisone or prednisolone is usually administered at doses of 2–5 mg/kg/day as a single daily dose. Betamethasone can also be used at a dose of 0.10–0.30 mg/kg/day. They are effective in halting haemangioma growth during the proliferation phase. This therapy should be given either continuously or in cycles of 15–20 days alternating with a 7-day break until the end of the proliferation stage and then gradually decreasing. The possible side effects depend largely on the daily dose and duration of the treatment. These can include gastrointestinal upset and irritability, weight gain, a cushingoid appearance, hypertension, growth delay, adrenal suppression and immunosuppression by height. In doses of 2–3 mg/kg/day in a 15-day cycle, the side effects are generally reduced to easy irritability and insomnia. Moreover, it must not be forgotten that the normal vaccination programme should be changed, arranging for the vaccine to be administered no less than 15 days after the last cortisone treatment.

Propranolol

Propranolol is a non-cardioselective beta-blocker without any intrinsic sympathomimetic action. The efficacy of the treatment is almost constant and rapid, particularly in the proliferation stage, showing improvements within 2 months of the start of therapy. Because it is easy to witness renewed three-dimensional growth of the haemangioma when the therapy is suspended before the end of the proliferation stage, the current recommendation is to proceed with therapy until at least the end of the first year of life.

The action mechanism is not fully understood. However, the drug produces effects of vasoconstriction, inhibition of the renin-angiotensin system with consequent inhibition of the proliferation of immature endothelial cells, modulation of VEGF secretion with consequent blocking of endothelial proliferation and the induction of apoptosis.

Despite there not being a unanimously shared protocol, consensus guidelines from a multidisciplinary expert panel have recently proposed brief inpatient hospitalisation for monitoring during induction of the treatment, with initial dosing starting at 0.5 mg/kg/day divided into three daily doses, increasing slowly to the desired dose. The goal for oral propranolol dosing is 2–3 mg/kg/day divided into three doses. Side effects included sleep disturbance, cold hands and feet, hypotension, bradycardia and symptomatic hypoglycaemia. The medication should be administered after feeding to prevent hypoglycaemic episodes.

Other centres recommend a preliminary echocardiogram and an electrocardiogram, together with monitoring of cardiac frequency, arterial

pressure, respiratory frequency and glycaemia. Some experts recommend an initial dose of 1 mg/kg/day in two daily doses.

The contraindications are those already known for propranolol: asthma, bradycardia (<45 beats a minute), arterial hypotension, Raynaud phenomenon and a predisposition for hypoglycaemia.

Other therapies in sporadic cases are represented by interferon alpha and vincristine. These are medications that act very slowly and are haemotoxic and neurotoxic.

Laser Treatment

Laser treatment, mainly delivered by a flash lamp-pumped pulsed dye laser (PDL) 595 nm, is generally useful for haemangioma in the flat macular stage and for correcting telangiectatic effects at the end of the involution stage. It has also been proposed as a treatment for ulcerated haemangiomas, although orally administered propranolol is currently considered the most advantageous treatment.

An ablative fractional carbon dioxide laser has recently been used to improve anetodermal effects and scarring at the end of the involution stage (Fig. 103.2).

Surgical Excision

Surgical treatment of involuted haemangiomas is quite common because the natural evolution of the condition does not always produce satisfactory results. Indeed, cutaneous defects, such as

Fig. 103.2 Involuted haemangioma with atrophic skin and telangiectasias. Before treatment (*1*) after three sessions with 595 nm FPDL (*2*). Additional fractional CO2 laser treatment (*3*) with satisfactory final result (*4*)

Fig. 103.3 Surgical treatment of disfiguring regressed haemangioma of the cheek

atrophic scarring, anetodermic and tumoral fibrofatty skin, often result at the end of the involution stage with significant cosmetic or functional impairment.

Surgical treatment is also suggested for ulcerated and painful haemangiomas, if medical treatment proves ineffective, for haemangiomas causing functional alterations, such as haemangiomas that cause palpebral ptosis with obstruction of the visual field and that have not responded to medical treatment.

In more general terms, surgical treatment should be considered, even before the end of the involution stage, in all cases in which it could bring improvements or prevent permanent effects with a major aesthetic impact. Because the presence of cosmetically disfiguring lesions in early childhood can have serious psychosocial repercussions, the state of the haemangioma should be assessed at the age of 3–4 for relevant permanent after-effects. In all cases in which it is reasonable to predict an unfavourable outcome, as, for example, large haemangiomas or those which have shown notable three-dimensional growth with stretching of the associated skin, the possibility of producing a better outcome with surgical treatment should be considered (Fig. 103.3).

Vitiligo

104

Electra Nicolaidou, Andreas D. Katsambas, and Torello M. Lotti

Key Points

- Vitiligo is an acquired chronic disease characterized by circumscribed depigmented macules and patches that result from a progressive loss of functional melanocytes.
- Autoimmune processes, deficiency of melanocyte growth factor, enzymatic self-destruct mechanism and abnormal neurogenic stimulus leading to dermatomal melanocyte destruction have been postulated as possible pathogenetic factors.
- The course of vitiligo is unpredictable.
- At present, no entirely effective treatment is available.
- Cosmetic cover-up alone is quite acceptable to some patients with vitiligo.
- Topical corticosteroids and topical calcineurin inhibitors can be used alone or in combination in localized disease.
- Phototherapy is the treatment of choice in generalized disease.
- Narrowband UVB phototherapy has superseded psoralen plus UVA (PUVA) photochemotherapy in the treatment of vitiligo because it has been shown to be clinically more effective and it is characterized by a better side effect profile.
- Surgical treatment with autologous transplantation techniques may be an option for patients with limited and stable disease.
- Depigmentation should be considered when vitiligo patients have >80 % cutaneous involvement and are recalcitrant to repigmentation.

Definition and Epidemiology

Vitiligo is an acquired chronic disease characterized by circumscribed depigmented macules and patches that result from a progressive loss of functional melanocytes.

It affects approximately 0.5–2 % of the general population and it occurs in all races and both sexes. Vitiligo onset during childhood (<12 years old) is common. Most studies report

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_104, © Springer-Verlag Berlin Heidelberg 2015

a disease onset before the age of 12 in about 25–30 % of patients.

In 20 % of vitiligo cases, a family history can be detected. Several studies indicate the importance of genetic factors in the development of vitiligo, which represents a heterogeneous genetic disease with environmental influences.

Basic Concepts of Pathogenesis

Vitiligo is a multifactorial disorder, characterized by selective destruction of the melanocytes in the depigmented patches.

Autoimmune processes (i.e. presence of circulating organ-specific autoantibodies, evidence of autoantibodies to normal human melanocytes, decrease of T-helper cells), deficiency of melanocyte growth factor, enzymatic self-destruct mechanism and abnormal neurogenic stimulus leading to dermatomal melanocyte destruction have been postulated as possible pathogenetic factors. It is likely that vitiligo vulgaris in humans represents a multitude of pathophysiological mechanisms, i.e. a variety of different diseases. A "convergence theory" in which different causal factors may act independently or synergistically to induce disappearance of melanocytes is a reasonable possibility. In some patients, vitiligo is associated with other diseases, mainly of autoimmune nature, like alopecia areata, thyroiditis, pernicious anaemia, diabetes and Addison's disease. Appropriate studies for these conditions are recommended when there is clinical suspicion.

Clinical Presentation

Lesions are round or oval macules, sharply demarcated and pure white. They are distributed, usually symmetrically, around orifices (lips, eyes, anogenital areas), over bony prominences such as the wrists, elbows and knees and in intertriginous areas. In affected areas, the hair usually is also white. Margins of the lesions may become hyperpigmented. At times, the pure white patches are surrounded by an area of the skin that is intermediate in colour before merging in the normal-coloured skin. This is known as trichome vitiligo and is mostly seen in black people. Vitiligo can be classified into two major clinical types, segmental and nonsegmental, according to the distribution of lesions.

The course of vitiligo is unpredictable. In some cases, the lesions remain stable over many years (mostly segmental vitiligo), but in others, they can enlarge in size while new patches appear to involve large portions of the skin surface (mostly nonsegmental type). However, spontaneous repigmentation may occur in 10–20 % of patients, mainly in sun-exposed areas. Repigmentation usually begins perifollicularly creating pigmented spots that gradually may enlarge and coalesce.

Diagnosis

Skin biopsy with special staining for melanocytes is the only significant examination but usually is not necessary. Histology reveals the absence of melanocytes which appear to be replaced by Langerhans cells in the lesions. A lymphomonocytic infiltrate is sometimes present in the marginal areas.

Differential Diagnosis

Wood's light examination should be part of the evaluation of every patient with vitiligo. It is most useful to differentiate the pure white appearance of the amelanotic vitiligo macules from the tan-white or grey-white colour of the relatively hypomelanotic disorders, presented in the table below:

Pityriasis alba	Fine scales on the lesions
Postinflammatory leucoderma	Irregular mottling of hyperpigmented and hypopigmented blotches
Tinea versicolor	Microbiology, Wood's lamp
Piebaldism	Hyperpigmented macules within the depigmented areas
Naevus depigmentosus	Present at birth, unilateral, stable

(continued)

Morphea	Speckled appearance, palpable induration, scleroatrophy
Hypomelanocytic leprosy	Anaesthetic macules
Chemical leucoderma	History of repeated exposure to phenols and sulphhydryls
Idiopathic guttate hypomelanosis	Numerous, small, white macules mainly distributed on the legs of dark-skinned individuals
Tuberous sclerosis	Congenital, dull to off-white confetti macules, seizures and mental retardation

General Principles of Treatment

- At present, no entirely effective treatment is available. Regardless of the treatment used, repigmentation may be slow and never be complete.
- Many patients will require only reassurance and advice on the use of the sunscreens and cosmetic camouflage. Active treatment is indicated in patients who have a marked cosmetic disability, particularly those whose lifestyle, self-esteem and productivity have been affected by the disease.
- New patches are possibly triggered by physical trauma (Koebner phenomenon), especially during spreading phases. It is recommended to avoid medical or surgical cosmetic procedures which can traumatize skin like deep peeling, lifting, etc.
- With the existing treatment methods, different results are obtained at different sites of involvement, i.e. vitiliginous patches over bony prominences respond poorly, while lesions on the face and body respond much better.
- If the involved site has no hair follicles, therapy usually fails because hair follicles seem to be necessary to supply new melanocytes.
- Treatment method should be chosen after consideration of the age of the patient, the areas involved and the extent of the disease.
- Spontaneous repigmentation occurs in about 10–20 % of patients and usually is only partial.
- Avoidance of the sun is highly recommended, especially in patients with widespread disease. Broad-spectrum sunscreens (SPF30 or greater) should be applied to all exposed skin, 30–60 min prior to sun exposure to decrease the short- and long-term effects of UV radiation and to reduce the contrast between the normal skin and the vitiliginous areas.

Recommended Therapies

(a) Cosmetic camouflage
(b) Repigmentation
(c) Depigmentation (extremely widespread disease – greater than 50 % of the body surface area)

Cosmetic Camouflage

Cosmetic cover-up is quite acceptable to some patients with vitiligo. Camouflage may be achieved with various cosmetics and stains containing mainly aniline dyes and dihydroxyacetone (DHA). "Quick Tan" preparations containing dihydroxyacetone (3–5 %) are produced by many cosmetic firms. DHA is a sugar that binds with the amino acids of the corneum layer inducing the production of coloured components that change from yellow to brown giving the skin a tanned effect. DHA dyes are easy to apply; they are neither dirty nor greasy. The pigmentation appears a few hours later and the application has to be repeated until the desired result is obtained. These dyes do not provide protection against UV radiation and phototherapy can be used. When cosmetics and make-up are used, the contribution of a professional cosmetician is of great help in demonstrating how to choose and apply the appropriate product.

Topical Treatments

Topical Corticosteroids

Topical corticosteroids (TC) are a first-line treatment for localized areas of vitiligo for both children and adults. A meta-analysis showed that half of patients with vitiligo affecting less than 20 % of body surface area achieved >75 % repigmentation with either super-potent or potent TC. Cutaneous atrophy was observed in 14 % and 2 % of patients, respectively. Other local side effects of TC include telangiectasia, hypertrichosis, acneiform eruptions and striae.

Newer potent TC such as mometasone furoate and methylprednisolone aceponate are largely devoid of these side effects and they also present negligible systemic side effects, so they should be preferred.

Currently, there are no studies available on the optimal schemes of TC treatment in vitiligo patients. Continuous treatment schemes can be used for up to 3 months, while discontinuous ones (15 days per month) may be used for up to 6 months. Facial lesions can be treated as effectively and with fewer side effects with calcineurin inhibitors. The latter can also be used in conjunction with TC for both facial and body lesions.

Topical Calcineurin Inhibitors

Tacrolimus and pimecrolimus are topical calcineurin inhibitors (TCI) that are useful in treating vitiligo patients because they have immunomodulatory effects without the side effects of TC.

Calcineurin is an intracellular protein which acts as a transcription factor for cytokines such as interleukin-2 and tumour necrosis factor-alpha (TNF-α). Tacrolimus and pimecrolimus, through inhibition of calcineurin, affect the activation/maturation of T cells and inhibit the production of cytokines, such as TNF-α. Patients with vitiligo have elevated TNF-α and tacrolimus treatment decreases tissue counts of TNF-α. Moreover, TCI enhance melanocyte migration and differentiation.

Tacrolimus and pimecrolimus are approved for patients with atopic dermatitis older than 2 years of age. Tacrolimus 0.03 % is approved for children 2–15 years of age. However, the off-label use of TCI has been shown to be safe and effective in the treatment of vitiligo, in both adults and children. Compared to TC, TCI provide similar to slightly inferior results. Tacrolimus provides similar to slightly higher response rates, compared to pimecrolimus. Face and neck lesions respond best. Twice-daily applications are recommended and occlusion may help with recalcitrant lesions on the extremities. If effective, prolonged treatment (e.g. longer than 12 months) may be proposed.

The combination of TCI and phototherapy or sun exposure is currently not recommended by the US Food and Drug Administration, to avoid a synergistic immunosuppressive effect. However, several studies have shown a synergistic effect between narrowband UVB phototherapy or 308-nm excimer laser and tacrolimus.

The most common side effects of TCI are local reactions, such as burning sensation, pruritus and erythema. Today, there is no evidence to suggest that there is an elevated risk of nonmelanoma skin cancer or lymphoma in adults or children under tacrolimus treatment.

Phototherapy

Ultraviolet (UV) radiation has been used extensively to treat patients with vitiligo. It is believed that UV has both immunosuppressive and melanocyte stimulatory effects.

UVB Phototherapy

1. Narrowband UVB Phototherapy

   Narrowband UVB (NB-UVB) radiation was used initially for the treatment of psoriasis, after the observation that wavelengths around 311 nm provoked less erythema and, at the same time, were most effective for complete clearance of psoriasis lesions. NB-UVB light sources emit polychromatic light, but the 311–313-nm wavelength range predominates in the emission spectrum.

   During the past decade, NB-UVB phototherapy has superseded psoralen plus UVA (PUVA) photochemotherapy in the treatment of vitiligo because it has been shown to be clinically more effective and it is characterized by a better side effect profile.

There is no universally accepted protocol for NB-UVB, so treatment protocols differ from study to study. Sessions are performed twice or thrice weekly, on nonconsecutive days. The initial dose ranges from 100 to 280 mJ/cm^2. The dose is subsequently increased in most studies by 10–20 % per session. In many studies, the dose is held constant when mild erythema develops. Generally, after the first few sessions, the rate of increase is individualized for each patient.

Overall response of vitiligo to NB-UVB has been variable. More than 75 % repigmentation (which is considered cosmetically acceptable repigmentation) has been achieved by 12.5–75 % of treated patients in different studies, after approximately 1 year of treatment (Fig. 104.1). Facial lesions and patients with skin phototype III–V respond better to treatment. Treatment is usually continued as long as there is ongoing repigmentation or over a maximum period of 1–2 years.

Combination of NB-UVB with topical corticosteroids may provide better results. Potent topical steroids could be applied once daily for 3 weeks per month for the first 3 months of treatment.

Acute adverse effects during NB-UVB are not frequent, include only erythema, pruritus and xerosis and usually resolve after topical applications of emollients. Chronic adverse effects of NB-UVB include photo-ageing and photocarcinogenesis. NB-UVB has been shown to induce DNA damage in cell cultures, as well as in human skin and animal models, a mechanism that leads to carcinogenesis. However, a recent study did not provide evidence for an increased skin cancer risk in psoriasis patients treated with either broad-band or NB-UVB. In another study, no increased risk for melanomas or squamous cell carcinomas was detected in patients receiving NB-UVB for diseases other than vitiligo, but an increased risk was evident for basal cell carcinomas. No data are available so far regarding carcinogenesis in vitiligo patients treated with NB-UVB, but since the development of skin cancer in vitiligo patients seems to be rare, it is rational to expect that vitiligo patients will not have an increased risk compared to other patients receiving NB-UVB. Until more data are available, NB-UVB is considered less carcinogenic than PUVA, but still it should be used cautiously and patients receiving long-term therapy should be followed up regularly.

2. Narrowband UVB Focused Microphototherapy
It is possible to treat exclusively vitiligo patches avoiding normally tanned skin especially in children and if the surface affected does not exceed 20 % of the total body surface. A phototherapy device (BIOSKIN®) allows selective narrowband UVB (311-nm) treatment limited to the white patches. The main characteristics of the BIOSKIN® generator are that it produces UVB rays, in a spectrum of 300–320 nm, with maximum emission at 311 nm; the energy displayed by the UVB generator is 10–100 mJ/

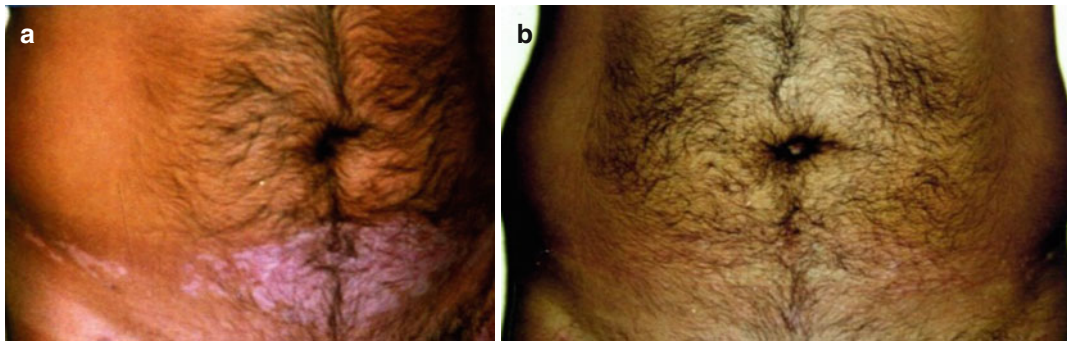

Fig. 104.1 Vitiligo lesions on the abdomen before (**a**) and after 8 months treatment with narrowband UVB phototherapy (**b**)

cm²/s and the diameter of the light spot is 1 cm. This device has been particularly efficient in the treatment of limited affected areas and segmental vitiligo. This technique has several advantages: it does not increase the colour contrast between normally pigmented skin and affected skin, and the total irradiation dose is minimal depending on the percentage of body surface affected. The method consists of weekly sessions of irradiation of all vitiligo patches. The dose is 20 % lower than MED, which is measured before the beginning of the treatment. This phototherapy treatment permits a differentiated irradiation. Thus, it is possible to irradiate the hands and feet with a dose five or six times higher than the dose used for eyelids.

UVA Photochemotherapy

1. Topical UVA Photochemotherapy
   Topical psoralen photochemotherapy may be considered for patients with limited involvement (less than 20 % of the body surface) or localized disease. It can be used to treat both children over 2 years old and adults. Dilutions of 1 % 8-methoxypsoralen are made with alcohol or lotions for final concentrations of 0.01–0.1 % in order to minimize adverse phototoxic reactions. The preparation is applied to the vitiliginous areas 30 min prior to exposure to UVA. The initial UVA dose is 0.12 or 0.25 J/cm² and is increased by increments of 0.12 or 0.25 J/cm² weekly according to the patient's skin type. After a moderate asymptomatic erythema is achieved, the UVA and psoralen dosage should be maintained at a constant level to retain the minimal degree of erythema. Treated areas should be washed with soap and covered with broad-spectrum sunscreen before the patient leaves the physician's office. Treatments are given once or twice per week. The psoralen should be applied by hospital or medical personnel and not by the patient. For 6–8 h after the treatment, unnecessary exposure to sunlight must be avoided because of the high potential of developing severe phototoxic reactions. Hyperpigmentation may develop in perilesional normal skin during treatment; this is a temporary phenomenon that resolves after the treatment stops.

   The major side effects of topical photochemotherapy are a severe phototoxic reaction and blistering, and patients should be warned of this before the treatment begins. If erythema and blistering develop, treatments are stopped until the reaction subsides. Upon reinstitution of therapy, the UVA exposure is usually decreased to half the previous dosage.

   Topical PUVA cannot be considered a first choice treatment for any type of vitiligo. However, topical PUVA is preferable to oral PUVA in patients with hepatic and gastrointestinal (uncertain absorption) disorders, cataract, poor eye protection and poor compliance and when shorter irradiation times are necessary (children and claustrophobic individuals).
2. Oral UVA Photochemotherapy
   Oral photochemotherapy is currently used in adult patients with generalized vitiligo as a second-line therapy, after NB-UVB.

   Contraindications for oral photochemotherapy include abnormal liver function, ocular defects including cataracts and pregnancy. In addition, the presence of photosensitivity disorders contraindicates the use of both oral and topical PUVA. Oral psoralens are not usually recommended for children under 12 years of age. Before therapy is begun, the following tests are required:

   Blood count
   Erythrocyte sedimentation rate
   Antinuclear antibodies
   Liver function tests
   A baseline ophthalmologic examination

   All these examinations should be repeated yearly. The maximum recommended 8-methoxysporalen dose is 0.6 mg/kg. It should be taken orally 2 h before UVA exposure. Patients may occasionally experience some gastrointestinal irritation (nausea, vomiting, abdominal pain) with psoralen, which becomes less frequent when the drug is taken after food. An initial dose of 1–2 J/cm² is generally given, with subsequent increments of 1 J/cm² at every other visit until moderate asymptomatic erythema is observed. The dose of UVA must be adjusted, depending on the sensitivity of the individual patient. Treatments

are given twice weekly but never on 2 consecutive days.

Protective UVA glasses should be worn for 24 h after oral psoralen intake. As a UVA source, PUVA cabinets are usually used (320–400-nm-emitting fluorescent tubes).

If the patient is unable to come to the physician's office for treatment, trioxysalen (4,5,8-trimethylpsoralen), in a dose of 0.6 mg/kg, and sunlight are suggested. An initial sun exposure of 5 min is recommended. The best time for sun exposure is from 10 a.m. to 2 p.m. Subsequent exposures are increased in increments of 5 min with each treatment until a mild erythema is attained, after which the exposure times are held constant until an increase is necessary to maintain the erythema. Treatments are given three times weekly but not on 2 consecutive days.

Trioxysalen is less phototoxic than 8-methoxypsoralen and less effective as a repigmenting agent. Patients should apply broad-spectrum sunscreens to the treated areas immediately after the treatment and limit further sun and UVA exposure.

PUVA-induced repigmentation is permanent in the majority of patients, but some may require maintenance treatment. Psoralen photochemotherapy induces maximal repigmentation of the face and neck; intermediate responses on the trunk, arms and legs; and minimal responses on the hands and feet. Treatment should be continued for at least 6 months to a year before the patient is classified as recalcitrant. Often as many as 200–300 treatments are required to produce a uniform repigmentation of the vitiliginous areas.

PUVA photochemotherapy carries a slightly elevated risk for both nonmelanoma skin cancer and melanoma. Long-term treatment may induce xerosis, "PUVA lentigines" and premature photo-ageing. The maximum recommended lifetime exposure to PUVA should be limited to 1,000 J/cm^2.

Laser Therapy

The best studied and most used laser therapy for vitiligo is the xenon chloride monochromatic excimer laser, which emits a monochromatic light of 308 nm and induces photobiological effects similar to NB-UVB. Several studies have shown response of vitiligo patches to excimer laser and it has been approved by the US Food and Drug Administration for the treatment of both vitiligo and psoriasis. Sessions are performed 2–3 times a week for a period of 4–36 weeks.

Compared to NB-UVB phototherapy, excimer laser has been reported to have better clinical outcomes. Repigmentation greater than 75 % is usually reported for 15–50 % of treated lesions. Location of lesions seems to be the best predictor of response: lesions on the face, neck and trunk respond in a better way than lesions on extremities. Lesions on the hands and feet tend to have the least favourable prognosis. Combination of laser treatment with either topical hydrocortisone or topical tacrolimus provides better results than laser treatment alone.

The sessions are generally well tolerated and side effects are minimal. Mild to severe erythema is usually reported, while blisters and pruritus are observed occasionally. Excimer laser permits the selective treatment of only lesional skin and ensures no unnecessary treatment of healthy skin. Thus, the patient receives less radiation. Furthermore, the unsightly tanning of all perilesional skin is avoided and perilesional tanning is usually limited to small areas around the lesion that have received the laser pulse during treatment. On the other hand, this selectivity makes the treatment of extensive vitiligo very time consuming and may not prevent the occurrence of new lesions at untreated body sites. Finally, another drawback of laser treatment, compared to NB-UVB, is its high cost.

Systemic Treatments

Systemic Corticosteroids

The use of systemic corticosteroids for therapy of vitiligo is useful, considering the relationship between benefits and side effects, mainly for the treatment of active, rapidly progressive generalized disease. In these patients, oral mini-pulse therapy with betamethasone or dexamethasone in a dose of 2.5–7.5 mg for 2 consecutive days per week for up to 6 months has shown the ability to

arrest the progression of the disease and to induce repigmentation. Oral mini-pulse steroid therapy can also be used as an adjunct to phototherapy in the first months of treatment.

Surgery

Surgical treatment with autologous transplantation techniques may be an option for patients that fulfil the following criteria:

(a) Stable disease for at least 6 months
(b) Unsatisfactory response to medical treatment
(c) Absence of Koebner phenomenon
(d) No tendency for scar formation
(e) Age above 12 years

Melanocyte transplantation techniques include punch grafts, split-thickness skin grafts, suction blister grafts and autologous melanocyte suspension transplants. Surgical techniques can be combined with phototherapy for best results.

Adverse outcomes include scarring, graft failure, infection, cobblestone texture and variegated pigmentation.

Depigmentation

Depigmentation should be considered when vitiligo patients have >80 % cutaneous involvement and are recalcitrant to repigmentation. The process is permanent and irreversible, and the patient will be permanently photosensitive. For these reasons this form of therapy should be considered for patients over 40 years old who have had an adequate trial of phototherapy and have failed or are unwilling to undergo repigmentation therapy. The dermatologist must feel confident that complete depigmentation will be not only cosmetically satisfactory but also psychologically acceptable, especially in black patients:

- *Monobenzyl ether of hydroquinone* (MBEHQ) is used as a depigmenting agent (Fig. 104.2). It destroys melanocytes. The treatment starts with 10 % concentration of MBEHQ by diluting the full-strength preparation with any water-soluble vehicle. The preparation is then applied to the pigmented areas twice daily. The concentration is increased by 5 % every 1 or 2 months until the patient is using 20 % MBEHQ.

  Patients should be advised that effective treatment may require several months to 1–2 years of therapy. The major side effect of MBEHQ therapy is dermatitis, which usually responds rapidly to topical applications of steroids. Other common side effects include contact dermatitis, pruritus, xerosis, greying of the hair and, following application to periocular skin, conjunctival melanosis and corneal pigment deposition.
- *Laser depigmentation.* The Q-switched ruby laser (694 nm) is capable of destroying selectively melanin and melanocytes. The

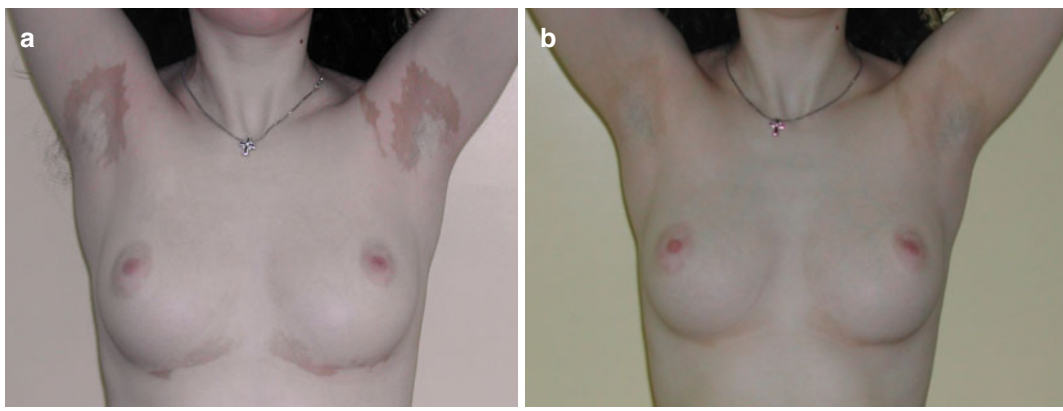

Fig. 104.2 Generalized vitiligo with a few islands of normally pigmented skin before (**a**) and after 6 months depigmentation treatment with 20 % monobenzyl ether of hydroquinone (**b**)

established method consists of a previous test session to evaluate the safety and efficacy of this technique on the patient. The response to this test is evaluated 2 months after the test, and if there is no response, laser depigmentation should be discouraged.

If the depigmentation test has caused significant depigmentation, the treatment can be continued until the desired bleaching effect has been achieved. This technique is safe (no drug is required). The contraindications are the same as those for depigmentation with bleaching agents.

Alternative and Experimental Treatments

L-Phenylalanine

When taken orally (1–3 g/day for 12–36 weeks) and followed by UVA irradiation, it is a promising agent for the treatment of childhood vitiligo.

Topical Khellin

Khellin is a furanochromone chemically related to psoralens. Khellin has been used in combination with sunlight or in combination with UVA (KUVA). Khellin can be administered either topically (2 % solution in 90 % acetone and 10 % propylene glycol) or systematically (100 mg) followed by UVA irradiation 1–2 h later, three times a week. The results are variable. Regular monitoring of liver enzymes should be performed and the treatment should be stopped if liver enzyme levels increase.

Pseudocatalase

Due to the report that patients with vitiligo have very low catalase activity, a group of investigators applied a vehicle with pseudocatalase twice daily, followed by a twice-weekly total body suberythema UVB irradiation. Excellent repigmentation was noted in 90 % of patients after almost 15 months. However, subsequent studies and especially a randomized, double-blind, placebo controlled clinical trial failed to show any benefit in adding pseudocatalase to NB-UVB treatment.

Melagenina

Melagenina is an alcoholic extract of human placenta. The active ingredient is an α-lipoprotein of low molecular weight. Melagenina is applied topically three times a day. One of the daily applications is followed by a 15-min solar or infrared exposure. The results are rather conflicting and the use of melagenina still remains experimental until random double-blind studies are done for both efficacy and safety.

Traditional Chinese Medication

Although some Chinese physicians believe that the administration of some Chinese medicinal herbs may be beneficial for vitiligo, lack of scientific data renders these treatments experimental.

Permanent Tattooing

Permanent dermal micropigmentation using a nonallergic iron oxide pigment can permanently tattoo recalcitrant areas of vitiligo (i.e. the hands, perioral region and hairline).

Vulvar Diseases

105

Silvestrs Rubins, Ilze Viberga, and Andris Rubins

Key Points

- The vulva is a gynecologic organ with dermatologic anatomy. The spectrum of potential vulvar diseases is large, although only few of them are uniquely vulvar.
- Vulvar infections are the most common, while vulvar cancer is very rare.
- There is no uniform classification of vulvar disease. Vulvar dermatoses are grouped according to the principles of willanism. The vulva is also an important signaling organ of endocrine and genetic pathology.
- Diagnostic and therapeutic arsenal is large. Nevertheless only few drugs are marketed as vulvar or for vulvar conditions.
- New achievements in microbiology, pharmacology, molecular biology, and oncology can improve the prognosis and quality of life in many vulvar diseases substantially.

VLP Vulvar lichen planus
VVS Vulvo-vestibulitis syndrome
WLE Wide local excision

Definition

The vulva is the female external genitalia and includes the mons pubis, labia majora, labia minora, clitoris, vestibulum, and vestibular glands. Arterial blood to the vulva is provided by the internal pudendal artery and venous return by pudendal veins. Vulvar lymphatics drain to inguinal and femoral nodes. Lymph from the midline vulva drains bilaterally. Innervation of vulva are performed by three nerves: ilioinguinal, posterior femoral cutaneous, and pudendal. The vulva lies in close proximity to the lower abdomen, inguinal and perianal regions, vagina, urethra, and anus. The microbial diversity and load of the vulvar area are much higher than in other parts of the skin. A papillary dermis is absent in the clitoris and labia minora.

Clinical Presentation

Vulvar Ulcers

Genital ulcer disease (GUD) is a general term used to describe genital ulcers in both sexes. Vulvar ulcers may have multiple causes (Table 105.1). Syphilis ulcer is typically a single, not painful, infiltrated lesion accompanied by unilateral inguinal lymphadenopathy. Herpetic ulcers are numerous, painful erosions or ulcers covered with whitish film accompanied with inguinal lymphadenopathy. Vulvar involvement can occur also in herpes zoster and varicella. Ulcus molle has a painful, purulent ulcer and purulent inguinal lymphadenopathy. In donovanosis or granuloma inguinale, multiple granulomatous ulcers and inguinal mass or pseudobubo are observed. Lymphogranuloma venereum (LGV) develops in three phases: from papule to ulcer, then to red and swollen inguinal lymph nodes, and finally to genital elephantiasis. Tuberculosis can also present itself with vulvar ulcers and mimic sexually transmitted infection (STI). In vulvar diphtheria, ulcers are covered with a pseudomembrane and there are additional nasopharyngeal and systemic signs. Primary cytomegalovirus (CMV) infection can cause acute, painful vulvar ulcers.

In Behçet's disease, painful genital ulcers can be one of the diagnostic symptoms in addition to other extragenital signs, e.g., oral ulcers, uveitis, positive pathergy test, and skin lesions. Ulcus vulvae acutum or Lipschütz ulcer is a rare, purulent, necrotic vulvar ulcer which most often develops together with flu-like illness in prepubertal girls. The etiology of Lipschütz ulcer is not known but possibly involves Epstein-Barr virus (EBV), CMV, mumps virus, and influenza A infection. Mycoplasma pneumonia can be associated with acute, extensive, painful, destructive vulvar ulcers in adult women. Ulcerative vulvitis in Reiter's syndrome is another rare form of vulvar ulcers with additional signs of conjunctivitis, arthritis, and psoriasiform skin lesions. Crohn's disease can involve the vulva and cause deep ulcers and formation of fistulas. Pyoderma gangrenosum very rarely involves the vulva and typically has painful, necrotic ulcers. Invasive vulvar cancer and other vulvar neoplasias can cause ulcers. Idiopathic vulvar ulcers can be HIV/AIDS associated. Other miscellaneous causes of vulvar ulcers include opportunistic infections, radiation, drugs, postsurgical wounds, chemicals, biologic substances, and mixed infections.

Diagnosis of vulvar ulcers is based on clinical appearance, symptoms, and laboratory methods such as microscopy, culture, polymerase chain reaction (PCR), and biopsy. Treatment follows established guidelines in known cases. Ulcers of unknown etiology are managed by local corticosteroids, peroral antibiotics, and immunosuppressive drugs.

Vulvitis and Vestibulitis

Vulvitis, vestibulitis, or vulvo-vestibulitis is an inflammation of the outer female genitals, presenting as redness, itching, burning, pain, and dyspareunia. Vulvitis is rarely isolated but

Table 105.1 Diagnosis and management of infectious vulvar ulcers and vulvitides

Pathology	Etiology	Diagnostic tests	Treatment
Syphilis ulcer	*Treponema pallidum pallidum*	Dark-field microscopy	Benzathine penicillin G 2.4 MU IM single injection (for primary syphilis)
		PCR	Alternatives: tetracycline, doxycycline, erythromycin (all PO)
Herpes ulcer	*Herpes simplex virus 1, 2*	Serology – HSV 1 and HSV 2 IgM Immunofluorescence PCR	Famciclovir – 125–1,000 mg PO 2–3× daily, 1–7 days Valaciclovir – 500–1,000 mg PO 2–3× daily, 3–7 days

Streptococcal ulcer/ vulvitis	Group A beta-hemolytic streptococcus Group B streptococcus	Microscopy, culture	Penicillin V 500 mg PO 3× daily, 14 days Erythromycin 500 mg PO 3× daily, 14 days (For local treatment, please see Table 105.6)
Donovanosis	*Klebsiella granulomatis*	Microscopy, Giemsa stain, Donovan bodies Culture PCR	Azithromycin 1 g PO 1× weekly, 3–4 weeks Erythromycin 500 mg PO 4× daily, 21 days Ofloxacin 200 mg 2× a day PO for 21 days Ciprofloxacin 500 mg PO 2× daily, 21 days
Lymphogranuloma venereum	*Chlamydia trachomatis*, serovars L1, L2, L2a, L3	PCR, culture	Doxycycline 100 mg 2× day PO for 21 days Erythromycin 500 mg 4× a day PO for 21 days Azithromycin 1 g 1× a week PO for 3 weeks
Ulcus molle	*Haemophilus ducreyi*	Gram-stain microscopy, culture, PCR	First choice: Azithromycin 1 g PO single dose Ceftriaxone 250 mg i.m. single injection Alternative: Ciprofloxacin 500 mg 2× day PO for 3 days Erythromycin 2 g per day PO for 7 days

Fig. 105.1 (**a**) Erosive papules and condylomata lata on labia majora and edema indurativum and erosions of labia minora; secondary syphilis. (**b**) Condylomata lata on labia majora and minora; secondary syphilis. (**c**) Condylomata lata on labia majora and perineum; secondary syphilis

Fig. 105.2 (**a**) Erosive papules on labia majora and minora; secondary syphilis. (**b**) Condylomata lata, secondary syphilis. (**c**) Condylomata acuminata, HPV infection

usually develops secondary to a vaginal process (vulvovaginitis) inguinal or perianal pathology. Candida vulvitis or vulvovaginitis is the most common type of infectious vulvitis. Predisposing factors are numerous: asymptomatic carriage, peroral antibiotic use, contraceptives, diabetes, and HIV/AIDS. Treatment is with either local or systemic antifungals; both of them are equally effective. Streptococcal vulvitis or vulvovaginitis due to group A β-hemolytic streptococcus is more often seen in prepubertal girls than adult women, often recurrent, and usually associated with nasopharyngeal or gastrointestinal carriage of bacteria. The treatment is antibacterial. Vulvitis circumscripta plasmacellularis or Zoon's vulvitis is a disease of unknown etiology characterized by shiny, red-brown macules on the labia. Treatment options include high-potency topical corticosteroids, topical calcineurin inhibitors, 5 % imiquimod cream, cryotherapy, intralesional injections of triamcinolone, or interferon alpha. Postcoital or seminal vulvitis occurs after unprotected intercourse as either localized vulvar urticaria, vulvar angioedema or generalized urticaria, or facial angioedema. A pathogenic mechanism is type I hypersensitivity reaction possibly caused by prostate-specific antigen (PSA). Acute and subacute vulvar eczema (allergic or irritant), manifests itself clinically as vulvitis. Inguinal erythrasma, intertrigo, and tinea inguinalis can spread from the inguinal region to the labia majora to cause vulvitis. Vulvar psoriasis can have a chronic, symmetrical vulvitis without vaginitis. Diagnosis and treatment of primary cause improves or cures vulvitis. For idiopathic cases topical corticosteroids or calcineurin inhibitors are commonly used.

Vulvar Dermatoses

According to the ISSVD (International Society for the Study of Vulvovaginal Disease) 2011 classification, all vulvar dermatoses are divided into eight main groups (with further subdivision) (Table 105.2): (1) skin-colored lesions; (2) red lesions, patches and plaques; (3) red lesions, papules and nodules; (4) white lesions; (5) dark-colored lesions; (6) blisters; (7) erosions and ulcers; and (8) edema. Histologically the ISSVD recognizes eight patterns of pathological reactions in the vulva: spongiotic, acanthotic, lichenoid, sclerotic, vesiculobullous, acantholytic, granulomatous, and vasculopathic.

Dermatoses which can be seen in the vulva (besides the already mentioned ulcers and vulvites) are numerous: different erythemas, intertrigo, erysipelas, vitiligo, pityriasis versicolor, lichen planus, lichen simplex chronicus, vulvar lentigo, melanoma, psoriasis inversa, condylomata acuminata, Bowenoid papulosis, squamous cell carcinoma, basal cell carcinoma, condylomata lata, molluscum contagiosum, Fox-Fordyce diseases, seborrheic dermatitis, scabies, pubic lice, seborrheic keratosis, furuncle, acne inversa, epidermoid cyst, vulvar polyp, herpes simplex, herpes zoster, varicella, lupus erythematosus, pemphigus vulgaris, bullous pemphigoid, Hailey-Hailey disease, Darier's disease, and Stevens-Johnson's syndrome (SJS). Vulvar involvement can occur in pathologies of other organs and systems, e.g., diabetes (candida vulvitis), Crohn's diseases (ulcers, vulvitis, edema), and HIV/AIDS (secondary ulcers, vulvitis, tumors). Drug eruptions in the vulva most commonly present as fixed drug eruption (erythema fixatum), erythema multiforme, and SJS. Bullous and acantholytic diseases such as pemphigus vulgaris vegetans, Hailey-Hailey disease, and Darier's disease can also involve vulva. Diagnostic principles and treatments used in vulvar dermatoses are similar to other parts of the body.

Pathologies of Vulvar Glands

Bartholin's gland is located in the lower third of the vulva. Its main purpose is to lubricate the labial opening of the vagina. Bartholin's gland pathologies are obstruction of the duct, inflammation, cyst, abscess, benign tumors (nodular hyperplasia, adenoma, adenomyoma), and adenocarcinoma.

Bartholin's gland cyst and abscess is an interlabial mass or two bilateral lesions. Bartholin's gland abscess is typically caused by *E. coli*, *Bacteroides*, and *Prevotella* species, as well as

Table 105.2 ISSVD 2011 classification of vulvar dermatological disorders

1. Skin-colored lesions	(a) *Skin-colored papules and nodules* – papillomatosis of the vestibule and medial labia minora (a normal finding; not a disease), molluscum contagiosum, warts (HPV infection), scar, vulvar intraepithelial neoplasia (VIN), skin tag (acrochordon, fibroepithelial polyp), nevus (intradermal type), mucinous cysts of the vestibule and medial labia minora, epidermal cysts, mammary-like gland tumor (hidradenoma papilliferum), Bartholin's gland cyst and tumor, syringoma, basal cell carcinoma
	(b) *Skin-colored plaques* – lichen simplex chronicus and other lichenified diseases, vulvar intraepithelial neoplasia
2. Red lesions: patches and plaques	(a) *Eczematous and lichenified diseases* – allergic contact dermatitis, irritant contact dermatitis, atopic dermatitis (Fig. 105.3b), eczematous changes superimposed on other vulvar disorders, diseases clinically mimicking eczematous disease, lichen simplex chronicus, lichenification superimposed on an underlying preceding pruritic disease
	(b) *Red patches and plaques* (no epithelial disruption) – candidiasis, psoriasis, vulvar intraepithelial neoplasia, lichen planus, plasma cell (Zoon's) vulvitis, bacterial soft tissue infection (cellulitis and early necrotizing fasciitis), extramammary Paget's disease
3. Red lesions: papules and nodules	(a) *Red papules* – folliculitis, wart (HPV infection), angiokeratoma, molluscum contagiosum (inflamed), hidradenitis suppurativa (early lesions), Hailey-Hailey disease
	(b) *Red nodules* – furuncles, wart (HPV infection), prurigo nodularis, vulvar intraepithelial neoplasia, molluscum contagiosa (inflamed), urethral carbuncle and prolapse, hidradenitis suppurativa, mammary-like gland adenoma (hidradenoma papilliferum), inflamed epidermal cyst, Bartholin's duct abscess, squamous cell carcinoma, melanoma (amelanotic type)
4. White lesions	(a) *White papules and nodules* – Fordyce spots, molluscum contagiosum, wart, scar, vulvar intraepithelial neoplasia (VIN), squamous cell carcinoma, milium, epidermal cyst, Hailey-Hailey disease
	(b) *White patches and plaques* – vitiligo, lichen sclerosus, postinflammatory hypopigmentation, lichenified disease, lichen planus, vulvar intraepithelial neoplasia (VIN), squamous cell carcinoma (SCC)
5. Dark-colored lesions	(a) *Dark-colored patches* – melanocytic nevus, vulvar melanosis, postinflammatory hyperpigmentation, lichen planus, acanthosis nigricans, melanoma in situ
	(b) *Dark-colored papules and nodules* – melanocytic nevus, warts (HPV infection), vulvar intraepithelial neoplasia (VIN), angiokeratoma, hidradenoma papilliferum, melanoma
6. Blisters	(a) *Vesicles and bullae* – herpesvirus infections (herpes simplex, herpes zoster), acute eczema, bullous lichen sclerosus, lymphangioma circumscriptum, immune blistering disorders
	(b) *Pustules* – candidiasis, folliculitis
7. Erosions and ulcers	(a) *Erosions* – excoriations, erosive lichen planus, fissures arising on normal tissue (idiopathic, intercourse related), fissures arising on abnormal tissue (candidiasis, lichen simplex chronicus, psoriasis, Crohn's disease, etc.), vulvar intraepithelial neoplasia (eroded variant), ruptured vesicles, bullae and pustules, extramammary Paget's disease
	(b) *Ulcers* – excoriations (related to eczema, lichen simplex chronicus), aphthous ulcers (Lipschütz ulcer, secondary to other diseases – Crohn's, Behçet's), Crohn's disease, herpesvirus infection, ulcerated squamous cell carcinoma, primary syphilis (chancre)
8. Edema	(a) *Skin-colored edema* – Crohn's disease, idiopathic lymphatic abnormality (congenital Milroy's disease), postradiation and postsurgical lymphatic obstruction, postinfectious edema (esp. staphylococcal and streptococcal cellulitis), postinflammatory edema (esp. hidradenitis suppurativa)
	(b) *Pink or red edema* – venous obstruction (e.g., pregnancy, parturition), cellulitis (primary or superimposed on already existing edema), inflamed Bartholin's duct cyst/abscess, Crohn's disease, mild vulvar edema (may occur with any inflammatory vulvar disease)

Neisseria gonorrhoeae, *Chlamydia trachomatis*, and *Pseudomonas aeruginosa*. Treatment modalities for Bartholin's duct cyst and abscess include gland incision and drainage, catheterization (fistulization), marsupialization, and excision. Catheterization and marsupialization are the most effective methods, while aspiration alone is the least effective with the highest recurrence rate. CO_2 laser vaporization can achieve a cure rate of above 95 % in a single session. Rectovaginal fistula can occur after surgical removal of Bartholin's gland.

Skene's gland and duct are periurethral structures histologically and functionally resembling the male prostate and are called female prostate. Skene's gland is also the principal source of prostate-specific antigen (PSA) in female. Main pathologies are Skene's cyst, pseudocyst, abscess, calculi, and carcinoma. Skene's duct cyst can have symptoms of superficial, external dyspareunia and voiding difficulties. Skene's abscess presents as vulvar pain, enlarged labium majus, and erythema around the urethra. Diagnosis is clinical and done with ultrasound and MRI. Treatment is incision and drainage or excision. Paraurethral cyst arising from Skene's glands can also be seen in female newborns. Clinically it usually looks as a round, yellowish interlabial nodule. Diagnosis can be made in prenatal ultrasound. Invasive treatment is similar to adults, although a nonsurgical approach is more relevant, because paraurethral cysts often disappear spontaneously in the first year of life.

Fox-Fordyce is a disease of apocrine glands with folliculocentric papules and pruritus. Physical trauma can contribute to its development including laser hair removal. Treatment is with different topical agents (retinoids, clindamycin, corticosteroids) and oral retinoids or contraceptives. In resistant cases, mechanical destruction or surgical removal of apocrine glands can be done.

Acne inversa or hidradenitis suppurativa can affect the vulva in females and is characterized by recurrent, painful, deep-seated nodules and abscesses of apocrine gland-bearing skin. Diagnosis and staging is aided by ultrasound. Treatment includes systemic antibiotics, retinoids, and biologics. In advanced cases only radical surgery and grafting are curative.

Vulvar Edema and Vascular Pathology

Vulvar edema can be caused by infections, neoplasia, pregnancy, systemic diseases, drugs, allergies, medical and surgical procedures, and many other acquired or congenital factors. It can be mild, massive, unilateral, or bilateral with or without vulvar redness, ulcers, erosions, lymphadenopathy, and systemic signs. Common causes of vulvar edema are genital herpes, syphilis (*edema indurativum*), donovanosis, and postsurgical or postradiation lymphedema; less often causes are tuberculosis, Crohn's disease, acquired lymphangioma circumscriptum, and congenital vulvar lymphedema. Massive vulvar edema with ascites can precede preeclampsia and eclampsia in pregnancy. Vulvar elephantiasis can be seen in filariasis, LGV, tuberculosis, donovanosis (pseudo-elephatiasis), localized lympedema, malignancy, obesity, and trauma. Diagnosis of vulvar edema is usually clinical and anamnestical. Treatment can range from ice packs, wet dressings, and hydrotherapy to systemic drugs, hospitalization, intensive care, and surgery.

Arteriovenous malformation of the vulva is a pedunculated soft tissue mass most commonly located on the labia majus. Treatment is by simple excision. Vulvar varicosities can be one sided or bilateral. Pregnancy is the most common cause. Rare causes include pelvic congestion syndrome and Klippel-Trenaunay-Weber syndrome. Treatment is surgical removal and sclerotherapy.

The Clitoris, Mons Pubis, and Hair

The normal size of the clitoris is about 16 mm in adult females and 6 mm in full-term newborns. Acquired clitoral hypertrophy is most often caused by virilism and hyperandrogenemia; other causes include neurofibromatosis, pseudohypertrophy, hemangioma, angiokeratoma, and amebiasis.

Congenital clitoromegaly can be due to congenital adrenal hyperplasia (CAH), true hermaphroditism, female pseudohermaphroditism, 46,XY gonadal dysgenesis, and androgen exposure in utero.

The mons pubis is a place typical of some vulvar diseases. Pediculosis pubis is rather rarely seen in the industrialized world. Vulvar folliculitis – just the opposite – is very common. Vulvar furuncle and even carbuncle can also develop in the vulvar area. Other diseases typical in the mons pubis are molluscum contagiosum, scabies, melanocytic nevi, seborrheic keratoses, Bowenoid papulosis, seborrheic dermatitis, and trichomycosis. Hirsutism or male pattern pubic hair growth toward the umbilicus occurs in females in hyperandrogenic states of different causes.

Melano-Pigmentary Disturbances

It is estimated that one in every ten women has a pigmented vulvar lesion. Common benign pigmented vulvar lesions include vulvar melanosis, vulvar lentigo, postinflammatory pigmentation, nevi, pigmented seborrheic keratosis, pigmented follicular cysts, and vulvar tattoo. Dysplastic nevi or atypical melanocytic nevi of the genital type and cellular blue nevus can also be observed in the vulva. Pigmented vulvar intraepithelial neoplasia, malignant melanoma, and pigmented basal cell carcinoma are examples of malignant tumors. Dermoscopy is useful as a noninvasive tool to diagnose vulvar pigmentations. Histopathology offers additional diagnostic accuracy, especially for lesions that look similar in dermoscopy. Atypical, suspicious pigment lesions are usually excised.

Vitiligo in the vulvar area is rather common. Differential diagnosis is usually with vulvar pityriasis versicolor, lichen sclerosus, lichen simplex chronicus, amelanotic melanoma, and vitiligo-like depigmentations. Treatment of vulvar vitiligo includes calcineurin inhibitors and corticosteroids. Changes in genital pigmentation can be observed also in CAH, Addison's disease, neurofibromatosis, Dowling-Degos disease, and laser-assisted hair removal. Racial differences in vulvar pigmentation are also important.

Vulvar Lichens

The three most common forms are lichen simplex chronicus, lichen planus, and lichen sclerosus (Table 105.3).

Lichen simplex chronicus (LSC) clinically appears as lichenification of labial surfaces with fissures and slight scaling. Intense, sometimes unbearable itch is a chief complaint. The itch-scratch cycle maintains the pathological process. Etiologic factors can be numerous including atopic eczema, contact dermatitis (Fig. 105.3b), and other pruritic anogenital diseases. Many cases are idiopathic. Diagnosis is based on the clinical picture and skin biopsy. Established treatment is with ultrapotent corticosteroid ointments for 4–12 weeks. Second-line treatment is with topical calcineurin inhibitors. Other alternatives are peroral prednisolone and intramuscular triamcinolone.

Vulvar lichen planus (VLP) has three clinical forms in the vulva: classic or papulosquamous, erosive, and hypertrophic. Erosive lichen planus of the vulva (ELPV) is the most common type. Typical symptoms include burning, itch, and dyspareunia. Vaginal scarring and stenosis may occur in long-standing disease. Vulvovaginal-gingival syndrome is a subtype of ELPV, where erosive, desquamative lesions are seen on the vagina or gingiva, usually not simultaneously. First-line treatment for VLP is very potent topical corticosteroids, while alternative treatments are topical calcineurin inhibitors (pimecrolimus 1 % and tacrolimus 0.1 %). Very potent corticosteroids can achieve symptomatic relief in more than 70 %, but complete resolution in not more than 30 %. From all ELPV patients, about 5 % progress to VIN and 5 % to squamous cell carcinoma.

Lichen sclerosus (LS) (Fig. 105.3a) is a chronic disease of the anogenital region. Autoimmune factors such as autoantibodies to extracellular matrix or basement membrane zone, *Borrelia burgdorferi* infection, and hormonal and genetic factors can have a role in pathogenesis. Clinically LS often starts as sharp-demarcated erythema on the clitoris and upper part of the labia minora, then gradually

Table 105.3 Management of vulvar lichens

Pathology	First-line treatment	Second-line treatment	Third-line treatment/other recommendations
Lichen simplex chronicus	Clobetasol propionate 0.05 % ointment 1–2× daily to 2× weekly for 4–12 weeks or	Tacrolimus 0.1 % ointment/ cream 1–2× day; up to 2 years	Prednisolone 20–40 mg PO 1× daily AM for 7–14 days Triamcinolone acetonide 40–80 mg IM 1× daily to 1× monthly
	Clobetasol butyrate 0.05 % ointment 1× daily to 2× weekly for 4–12 weeks or Betamethasone valerate 0.1 % ointment 1× daily to 2× weekly for 4–12 weeks	Pimecrolimus 1 % cream 2× daily; up to 2 years	Avoidance of irritants and contact allergens Breakup of itch-scratch cycle: sedating antihistamines, sedating tricyclics, selective serotonin reuptake inhibitors Repair of epidermal barrier
Lichen planus	Clobetasol propionate 0.05 % ointment 1–2× daily to 2× weekly for 4–12 weeks or	Tacrolimus 0.1 % ointment/ cream 1–2× day; up to 2 years	Triamcinolone acetonide 10 mg/ml – 0.5–1 ml intralesionally Triamcinolone acetonide – 40–80 mg IM 1× daily to 1× monthly
	Clobetasol butyrate 0.05 % ointment 1× daily to 2× weekly for 4–12 weeks or Betamethasone valerate 0.1 % ointment 1× daily to 2× weekly for 4–12 weeks	Pimecrolimus 1 % cream 2× daily; up to 2 years	Prednisolone 20–40 mg PO 1× daily AM for 7–14 days Vaseline – to protect erosive surfaces against urine
Lichen sclerosus	Clobetasol propionate 0.05 % ointment 1–2× daily to 2× weekly for 4–12 weeks or	Tacrolimus 0.1 % ointment/ cream 1–2× day for up to 2 years	Topical estrogens Topical testosterone (rarely used due to virilization)
	Clobetasol butyrate 0.05 % ointment 1× daily to 2× weekly for 4–12 weeks or Betamethasone valerate 0.1 % ointment 1× daily to 2× weekly for 4–12 weeks	Pimecrolimus 1 % cream 2× daily; up to 2 years	Retinoids – local or systemic Phototherapy – UVA1, UVB, PDT Surgery for scarring and stenosis

involves all of the labia minora, and spreads to the labia majora and perineum, developing the classic LS picture, single or multiple porcelain-white plaques. Vaginal scarring and narrowing are typical complications of LS. First- and second-line treatment options are similar to other vulvar lichens – potent and very potent corticosteroids and topical calcineurin inhibitors, local or systemic retinoids, PDT, phototherapy, and surgery.

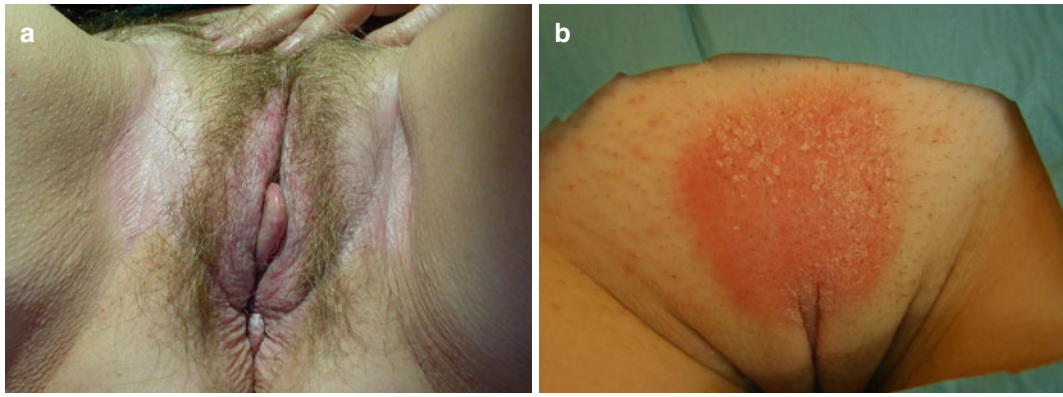

Fig. 105.3 (**a**) Lichen sclerosus. (**b**) Contact dermatitis

Benign Tumors of the Vulva

Due to different histological structures, the number of benign vulvar tumors is large. Some examples of benign vulvar tumors include epidermal cysts, hidradenoma papilliferum, syringoma, hemangioma, angiokeratoma, nevi, lipoma, vulvar polyp, angiomyofibroblastoma, vulvar endometriosis, primary Langerhans cell histiocytosis of the vulva, and many others. Their diagnosis and management is similar to other parts of the body.

Syringoma is a benign tumor from the intraepidermal portion of eccrine sweat ducts. A vulvar location is rare. Clinically, it appears as tiny, skin-colored papules, mainly on the labia majora. Diagnosis is verified histologically. Treatment includes CO_2 laser and radiofrequency. Angiomyofibroblastoma is another rare, benign, well-circumscribed mesenchymal tumor presenting as a nodule or mass on the labia majora. Differential diagnosis is with Bartholin's cyst, lipoma, and aggressive angiomyxoma. Diagnosis is by histology. Treatment is simple excision.

Vulvar Intraepithelial Neoplasia

Vulvar intraepithelial neoplasia (VIN) is a carcinoma in situ. According to the 2004 ISSVD classification, VIN is divided into three types: usual, differentiated, and unclassified. Usual-type VIN is further subdivided into warty, basaloid, and mixed (warty/basaloid) types. All VINs which neither belong to usual nor differentiated type are unclassified. VIN is replacing also terms such as Bowen's disease, erythroplasia of Queyrat, and Bowenoid papulosis. Usual-type VIN can be regarded as HPV-associated or HPV-caused diseases. Although the HPV positivity is not as high as in cervical cancer, more than 50 % of basaloid- and warty-type VINs are positive for HPV 16 and HPV 18 DNA. Differentiated-type VINs in 30–50 % of cases show association or develop in lichen sclerosus. The clinical picture of VIN is variable and unspecific – elevated, flat, warty, white, red, and brown lesions. The diagnosis of VIN is visual and by colposcopy, biopsy, and histology. Cytology is not reliable. HPV-DNA testing and presence of phosphorylated ribosomal S6 in biopsy can be of additional value to separate usual- and differentiated-type VIN. Treatment options for VIN include laser ablation or excision, skinning vulvectomy, wide local excision, and 5 % imiquimod cream topically. Wide local excision of VIN is regarded as the most effective method.

Cancers of the Vulva

Primary cancers of the vulva are rare and account for approximately 5 % of all gynecological malignancies and less than 1 % of all malignancies in women. Squamous cell carcinoma is the most common type of vulvar cancer at 90–95 %, followed by melanoma at 5 %, and adenocarcinomas and other cancers at 5 %.

Squamous Cell Carcinoma

Two different pathways are proposed for SCC development – HPV dependent and lichen sclerosus. In the first, high-risk types of HPV, e.g., HPV16, trigger usual-type VIN development and later warty/basaloid-type SCC. In the second, keratinizing SCC develops from differentiated VIN within a background of lichen sclerosus. Diagnosis and treatment of vulvar SCC is according to FIGO staging and treatment recommendation: early-stage vulvar cancer (FIGO I–II), intermediate-stage vulvar cancer (FIGO III), and locally advanced or metastatic (FIGO IV). A microinvasive carcinoma with less than 1 mm stromal invasion and less than 2 cm in size (FIGO stage IA) is surgically excised with a 1 cm resection margin without lymphadenectomy. For SCC invasion deeper than 1 mm, lymph node staging is done, and if sentinel lymph node is positive for metastasis, either unilateral or bilateral lymphadenectomy is performed. In intermediate or locally advanced tumor, treatment depends on tumor location, size, and invasion and lymph node status; main types of operations are wide excision and ipsilateral superficial lymphadenectomy, wide excision and bilateral inguinofemoral lymphadenectomy, and radical vulvectomy with bilateral inguinofemoral lymphadenectomy. Metastatic vulvar SCC is treated with radiotherapy, chemoradiotherapy, and polychemotherapy. Erlotinib, an anti-EGFR tyrosine kinase inhibitor, has been used in clinical trials. Recurrence rate in SCC is high, especially with a tumor size of more than 35 mm, tumor-free surgical margin of less than 8 mm, and depth of stromal invasion of more than 4 mm. Chronic lymphedema and vulvar and groin wounds are typical posttreatment side effects.

Vulvar Adenocarcinomas

Primary vulvar adenocarcinomas are rare tumors classified into vulvar Paget's disease, sweat gland carcinomas, "breast-like"carcinomas, and vulvar apocrine adenocarcinoma. Vulvar Paget's disease or extramammary Paget's disease is the most common type of primary vulvar adenocarcinomas. Females 65–75 years of age are typically affected. Itching, eczema-like lesions on the labia, and enlarged inguinal lymph nodes are typical clinical presentations. Pruritus can be long-standing, with several years before diagnosis. Treatment is surgical excision, CO_2 laser, imiquimod and PDT, cryosurgery and PDT.

Skene's gland adenocarcinoma is a rare neoplasm of the female periurethral glands histologically resembling prostate adenocarcinoma. Diagnosis is made histologically. Immunohistochemical staining with PSA and preoperative and postoperative measurements of PSA are of diagnostic value. Treatment is by excision.

Bartholin's gland carcinoma is another rare neoplasm of the vulva. Histologically squamous, adenoid cystic, transitional, and combined types are recognized. Treatment is by hemivulvectomy with or without lymph node dissection, total vulvectomy and bilateral inguinofemoral lymph node dissection with or without radiotherapy and chemotherapy. Local recurrence and distant metastases are seen in one-third of patients.

Vulvar Melanoma

The vulva is the most common site of mucosal melanomas. Vulvar melanoma is the second most common vulvar malignancy after SCC. Postmenopausal women are typically affected. Vulvar melanomas differ from cutaneous and vaginal melanomas having a high percentage of c-KIT mutations.

Pigmented lesion or vulvar mass, pain, itching, and bleeding are characteristic symptoms of vulvar melanoma. Anatomical distribution favors the clitoris and labia minora in 60–70 %. Mucosal lentiginous melanoma, nodular melanoma, and superficial spreading melanoma are the three most common types in the vulva. About 10 % of vulvar melanomas are amelanotic or desmoplastic. Amelanotic melanomas can simulate lichen sclerosus or be associated with it. Differential diagnosis for amelanotic melanoma includes also VIN and SCC. Diagnosis of vulvar melanoma is established histologically with the help of immunohistochemistry. Clark, Breslow, or Chung system is used for microstaging. Correct and precise mapping of sentinel lymph nodes (SLN) in the inguinal and femoral area can be substantially improved with 3D fusion images of SPECT and CT scans. Positive SLN are found in 20–30 % of cases of vulvar melanoma. Molecular screening for activated c-KIT mutations shall be done.

Treatment depends on anatomical location, size of tumor, depth of invasion, and stage of disease (Table 105.4). Wide local excision is

Table 105.4 Treatment of vulvar premalignancies and cancer

VIN	Usual-type VIN	*First choice* WLE with 0.5 cm PM *Second choice* CO_2 laser excision or vaporization Simple vulvectomy Skinning vulvectomy *Others* Imiquimod 5 % cream 3× a week
	Differentiated-type VIN	*First choice* WLE with 0.5 cm PM *Second choice* CO_2 laser excision or vaporization Simple vulvectomy Skinning vulvectomy

AJCC American Joint Committee on Cancer (2009 Melanoma Staging and Classification), *FIGO* Fédération Internationale de Gynécologie et d'Obstétrique, *HVLNE* hemivulvectomy with superficial inguinal lymphadenectomy, *PM* peripheral margin, *PO* peroral, *RVLNE* radical vulvectomy with inguinofemoral lymphadenectomy, *SCC* squamous cell carcinoma, *VIN* vulvar intraepithelial neoplasia, *WLE* wide local excision

preferred for thin lesions (<1 mm) and hemivulvectomy or radical vulvectomy with bilateral inguinofemoral lymphadenectomy for deeper lesions with nodal involvement. Local imiquimod therapy has been tried with partial success in vulvar melanoma.

For metastatic melanomas, dacarbazine monochemotherapy or polychemotherapy and adjuvant interferon alpha radiotherapy are used. Unfortunately, vulvar as well as mucosal melanomas have low response rate to chemotherapy. Radiotherapy may reduce the local recurrence but not the overall survival. In recent years several new therapeutic agents, classes of drugs, and treatments have been registered or are in clinical trials for metastatic melanoma, among them are CTLA-4 antibodies (ipilimumab, tremelimumab), interleukin-2 (vemurafenib, dabrafenib), anti-PD-1 (nivolumab, lambrolizumab), MEK inhibitors (trametinib), c-KIT inhibitors (imatinib, sorafenib), adoptive cell transfer, and combined therapies. Ipilimumab at 3 mg/kg alone or in combination with interleukin-2 or gp-100 has shown complete response in 6–17 % of patients, 2-year survival rate in 24 %, and 5-year survival rate from 13 to 23 %. Vemurafenib and other BRAF inhibitors are not really useful in vulvar melanomas, because they lack BRAF V600E mutations. For patients with metastatic vulvar melanoma, the highest hopes and expectations can be attributed to c-KIT inhibitors. In clinical trials imatinib 400–800 mg/day has shown complete response in 6 %, partial response in 23 %, and total disease control in 53 %; 1-year survival rate was achieved in 40–51 % and 2-year survival rate in 16–20 %. Similar results are obtained or will be expected with nilotinib. Adoptive cell transfer (ACT) is a new individualized method with high and durable response comparable to vemurafenib and ipilimumab. In ACT, tumor-infiltrating lymphocytes (TIL) are taken from the melanoma of the patient, cultured, and reinfused back. Response rate ranges from 20 to 70 % depending on the method. Prognosis in metastatic vulvar melanoma is generally worse than in cutaneous. Recurrence rate is 30–50 %. The average 5-year survival rate is 36 %.

Vulvar Itch and Vulvodynia

Vulvar itch or pruritus vulvae is a very common and important symptom. Besides anamnesis and clinical aspects, age of the patient is important. In young women vulvar pruritus is most often caused by infections and allergies – vulvovaginal candidiasis, enterobiasis, diabetes, scabies, pediculosis pubis, and vulvar eczema; in postmenopausal women it is more often caused by lichen sclerosus, VIN, and other benign and malignant tumors. Treatment is with local or systemic anti-infectives, corticosteroids, calcineurin inhibitors, surgery, and oncologic drugs.

Vulvodynia presents with vulvar pain, burning sensation, and dyspareunia without obvious physical cause. Formerly it was known as "burning vulva syndrome" and more correctly can be called "aidoiodynia." Some 10–20 % of females are estimated to be affected worldwide. Vulvodynia can be generalized involving all vulvar structures or localized to some parts, e.g., clitorodynia and hemivulvodynia. Vulvo-vestibulitis syndrome (VVS) is a type of focal vulvodynia. Disturbed pain perception, vulvar hypersensitivity, psychosexual problems, and vaginal infections are proposed pathogenic factors of vulvodynia. Diagnosis is based on anamnesis, clinical examination, pain assessment via Q-tip test, and tampon test. Treatment is done with amitriptyline cream, vaginal cream with conjugated estrogens, pelvic floor physiotherapy, biofeedback, cognitive-behavioral therapy, systemic amitriptyline, gabapentin, botulinum toxin A, posterior vestibulectomy, and simple vulvectomy.

Vulvar Injury, Mutilation, and Structural Pathologies

The vulva can be traumatized or deformed by sharp or blunt trauma, rape, sexual abuse, mutilation, diseases, chemicals, and other agents.

Female circumcision or female genital mutilation (FGM) is a ritual religious practice of some communities mainly in Africa and the Middle East. The top three countries practicing FGM are Egypt, Sudan, and Mali. The average age when

girls are circumcised is 10 years. Depending on the extent, FGM is graded into four types. The most common is FGM type II, when the clitoris and labia minora are removed. FGM is bound with many complications: psychosocial trauma, acute and chronic pain, bleeding, infections, cysts, narrowing of the vaginal opening, and partum and postpartum risks. Treatment is mostly symptomatic using analgesics, anti-infectives, neuroleptics, and lubricants. Surgical correction or reconstruction can be tried in some cases.

Structural pathologies of the vulva can include acquired defects (synechia, fusion of labia, stenosis) or congenital anomalies such as agenesis of labia, imperforate hymen, malformations of clitoris, hypospadia of female urethra, hermaphroditism, and female pseudohermaphroditism. Treatment is mostly surgical.

Diagnosis

Correct diagnosis of vulvar diseases involves experience both in gynecology and dermatology (Table 105.5). Anamnesis of the disease, age, social and ethnic background, sexual habits, and medication use is important as well as history of gynecologic and dermatologic pathologies. Vulvovaginal inspection shall be followed by full-body examination, paying special attention to the perineum, lower abdomen, axilla, oral mucosae, scalp, and lymph nodes. Sexual partners or legal representatives of children or teenagers must be consulted or examined. All pruritic lesions of the vulva deserve a very careful examination, because they can be an early sign of malignancy. Different methods of microscopy, culture, PCR, serology, and blood analysis can diagnose most of the causes of vulvar ulcers, erosions, and vulvites. Biopsy and histopathology remain a golden standard in most dermatological diagnosis. Vulvar pigment lesions can be examined with dermatoscopy and laser confocal microscopy. Hormonal and genetic investigations are necessary in endocrine and structural pathologies. Women with hirsutism shall be tested for polycystic ovary syndrome, androgen-secreting tumors, adrenal hyperplasia, Cushing syndrome, and thyroid function. Ultrasonography, MRI, 3D fusion images of SPECT, and CT scans have become popular, noninvasive methods to diagnose cysts, urethral and periurethral pathologies in females, and sentinel lymph nodes.

Table 105.5 Diagnostic methods in vulvar diseases

Method	Indication
Microscopy	Herpes, syphilis, donovanosis, ulcus molle
Culture	Bacterial, fungal, viral infections
Patch test, prick	Allergic vulvitis, vulvar edema
Dermatoscopy	Pigmented vulvar lesions, scabies, pediculosis
Colposcopy	VIN, squamous cell carcinoma
Confocal microscopy	Similar to dermoscopy
Histology and immunohistochemistry	Vulvar melanoma, VIN, SCC, any other unknown clinical condition
Pain assessment tests	Vulvodynia
Blood and hormonal analysis	Autoimmunity, infections, hirsutism
Ultrasound, MRI, CT scan	Cysts, abscesses
PCR	Bacterial, fungal, viral infections
Acetic acid	VIN, SCC

General Principles of Treatment

Local treatment options include antibacterial solutions, creams and ointments, hydrotherapy, corticosteroids, estrogens, and testosterone-containing creams (Table 105.6). Antimicrobial treatment for infectious vulvar ulcers or vulvovaginitis is well established internationally in many guidelines. Noninfectious and non-oncologic ulcers or vulvar inflammations are treated with corticosteroids and other immunosuppressives. Although ultrapotent and potent topical corticosteroids remain standard treatment options for vulvar lichens, calcineurin inhibitors are as effective but with better safety profile. Topical calcineurin inhibitors can also be used for psoriasis inversa, contact dermatitis, seborrheic dermatitis, and vitiligo. Amitriptyline vaginal cream is another advancement in vulvo-

Table 105.6 Local treatments in vulvar diseases

Drug/formulation/dosage	Indication
1. *Antifungals*	
1.1. Nystatin, 100,000 U vaginal tablet, 2–6× a day or in severe cases every 1–2 h till complete healing and then additional 8–10 days	Candida vulvitis, intertrigo
1.2. Ketoconazole, 2 % cream, 2× daily for 2–4 weeks	Candida, dermatophytes, seborrheic dermatitis
1.3. Econazole nitrate, 1 % cream, 1–2× a day for 2–4 weeks	
1.4. Miconazole nitrate, 2 % cream, 7 days; vaginal applicator, 1× daily at night: 100 mg for 7 days, 200 mg for 3 days, 1,200 mg single dose	
1.5. Butoconazole, 2 % cream, 7 days; 2 % sustained release cream 5 g, 1 day	
1.6. Terconazole, 0.4 % cream, intravaginally 1× daily for 7 days; 0.8 % cream or 80 mg vaginal suppositories, intravaginally 1× daily for 3 days	
1.7. Tioconazole, 6.5 % ointment, intravaginally at night, single dose	
1.8. Ciclopirox olamine, 0.77 % cream, 2× daily for 4 weeks	
2. *Antibacterials*	
2.1. Tetracycline, 3 % ointment, 1–3 daily, 5–10 days	Bacterial vulvar infections, ulcers
2.2. Meclocycline, 1 % cream, 1–2× daily, 5–10 days	
2.3. Fusidic acid, 2 % cream/ointment, 1–3× daily, 5–10 days	
2.4. Metronidazole, 5 % vaginal cream, 1× daily intravaginally for 6 days	
2.5. Clindamycin, 2 % vaginal cream, 1× daily intravaginally for 3 days	
2.6. Mupirocin, 2 % ointment, 1–3× daily, 5–10 days	
2.7. Silver sulfadiazine, 1 % cream, 1–2× daily till healing	Wounds, burns
3. *Hormones*	
3.1. Estriol, 0.05 % vaginal cream, intravaginally 1× daily 1 week, then 2× weekly	Atrophy, dry vagina, pruritus vulvae, dyspareunia, vaginal stenosis, lichen sclerosus
3.2. Estradiol, 0.01 % vaginal cream, 2–3× daily on vulvae	
3.3. Conjugated estrogens, vaginal cream, intravaginally continuously (21 days on, then 7 days off) or cyclically (2× weekly)	
3.4. Testosterone propionate, 2 % cream/ointment/gel, 2× daily for 3–4 months; not more than 50 g in the first 2 months and not more than 10–25 g in the next 2 months	
4. *Antiseptics/astringents*	
4.1. Aluminum acetate, 5 % solution	Microbial vulvitis
4.2. Burow's solution, 5 % aluminum acetate diluted in water (1:20–1:40)	
4.3. Tannic acid, 2 % solution	
4.4. Boric acid, 1 % solution	
4.5. Ichthammol, 2 % solution	
4.6. Potassium permanganate, 1: 10,000 solution	
4.7. Hydrogen peroxide, 1–3 % solution	
4.8. Povidone-iodine, 4 %, 5 %, 10 % solutions;10 % ointment; 2.5 % dry powder spray	
4.9. Silver nitrate, 0.5 %, 1 %, 10 % solutions	
5. *Anti-parasite*	
5.1. Permethrin, 5 % cream, over whole body (except head) for 12 h	Scabies
5.2. Benzyl benzoate, 10 %/25 % emulsion, 1–3 applications over whole body for 72 h	
5.3. Lindane, 1 % lotion, whole body application (except head); wash off after 8–12 h	
5.4. Permethrin, 1 % cream rinse, apply for 10 min to dry hair, then wash off	Pubic lice
5.5. Lindane, 1 % shampoo, apply for 4 min to dry hair, then wash off	
5.6. Ivermectin, 0.5 % lotion, apply for 10 min to dry hair, then wash off	

Table 105.6 continued

Drug/formulation/dosage	Indication
6. *Antiviral*	
6.1. Aciclovir, 5 % cream, 5× daily for 5–10 days	Genital herpes
6.2. Penciclovir, cream, every 2 h, 4–5 days	
6.3. Podophyllotoxin, 5 mg/1 ml solution, 2× a day for 3 consecutive days; maximum – 4 weeks	Genital HPV infection
6.4. Imiquimod, 5 % cream, 3× a week; maximum – 16 weeks	
7. *Antineoplastic*	
7.1. Imiquimod, 5 % cream, 3× a week; maximum – 16 weeks	Basal cell carcinoma, usual-type VIN
7.2. Fluorouracil, 5 % cream, 1–2× daily; maximum – 12 weeks	
8. *Esthetic*	
8.1. Botulinum toxin type A, solution of 50/100/200/500 U in vials, 25–200 U per treatment or individually matched doses	Vulvodynia
8.2. Fillers – Hyaluronic acid, solution 20 mg/ml in vials, 0.5–6 ml per treatment	
9. *Anesthetic*	
9.1. Lidocaine, 2 % gel, 1 fingertip unit (0.5 g) 1× daily	Pruritus vulvae, vulvodynia
9.2. Lidocaine (25 mg)/prilocaine (25 mg), 5 % cream, 1 fingertip unit (0.5 g) 1× daily	

dynia treatment to decrease systemic drug use (Table 105.6 and 105.7).

Vulvar surgery helps to solve not just purely surgical or oncological problems but is used in chronic inflammatory diseases, vulvar lichens, and vulvodynia as well. Benign lesions are usually treated with simple incision, drainage, marsupialization, ablative and vascular laser, radiofrequency, cryosurgery, esthetic labial surgery and reconstructive vulvar surgery, PDT, and phototherapy. In neoplasia, either wide local excision, hemivulvectomy, or radical vulvectomy with bilateral lymphadenectomy is used. New drugs and treatment against metastatic melanoma and squamous cell carcinoma give hope to the patients and physicians that a 5- to 10-year survival can be achieved in the nearest future. Besides drugs and surgical treatments, psychological support and rehabilitation is important, especially in vulvar cancer, after vulvar injury, mutilation, or radical surgery.

Finally, prevention shall not be forgotten in vulvar diseases. This applies to STI and safe sex behavior, hypoallergenic intimate hygiene and clothing, vaccination against HPV infections, and early recognition of malignancy.

Table 105.7 Systemic and surgical treatments in vulvar diseases

Medication/device	Specification	Indication
Antibiotics	Azithromycin Erythromycin Clindamycin Penicillins Cephalosporins	Bacterial ulcers and vulvitides, vulvar furuncle, abscess, secondary infected wounds
Antifungals	Fluconazole, itraconazole, ketoconazole	Vulvovaginal candidiasis
Antivirals	Acyclovir, famciclovir, valacyclovir	Genital herpes, vulvar herpes zoster
Retinoids		
Immunosuppresives	Corticosteroids, azathioprine, methotrexate, thalidomide	Autoimmune bullous diseases, atopic dermatitis, psoriasis, vulvar lichens
Biologics	1. Anti-TNF, anti-IL-12/ anti-IL-23p40 2. c-KIT inhibitors 3. EGFR tyrosine kinase inhibitors	1. Psoriasis, autoimmune bullous diseases 2. Metastatic vulvar melanoma 3. Metastatic squamous cell carcinoma
Cryotherapy	Cryogun, cryoprobe, cryo-application	HPV infection, seborrheic keratosis, VIN
PDT		
Phototherapy	UVB, UVA, PUVA, Re-PUVA	Psoriasis, lichen sclerosus
Ablative laser surgery	CO_2, erbium:YAG	VIN, Bartholin's/Skene's abscess
Vascular lasers	Nd-YAG, KTP, PDL	Hemangioma, venous lake
Pigment lasers	Q-switched Nd-YAG, alexandrite	
Radiofrequency	Surgical	Similar to ablative lasers
Surgery	1. Incisional/excisional surgery 2. Skinning vulvectomy 3. Wide local excision 4. Hemivulvectomy 5. Radical "en bloc" vulvectomy 6. Lymphadenectomy – superficial inguinal or inguinofemoral 7. Esthetic vulvar surgery	1. Bartholin's/Skene's abscess 2. Vulvar intraepithelial neoplasia 3. Vulvar intraepithelial neoplasia 4. Vulvar cancer 5. Advanced vulvar cancer 6. Vulvar cancer 7. Vulvar mutilations, scarring, stenosis

Warts: Cutaneous and Anogenital

106

Antonios Kanelleas and Electra Nicolaidou

Key Points

- Cutaneous and anogenital warts are caused by human papillomaviruses (HPVs), a large group of more than 120 genotypes that infect the epithelia of the skin and/or mucosa.
- Cutaneous warts are very common especially in young children. They can resolve spontaneously.
- Anogenital warts are listed among the sexually transmitted infections. They are highly prevalent in both sexes and are typically caused by HPV 6 and 11.
- Persistence of cervical infection with a high-risk HPV type represents the single most important factor for the development of cervical pathology, including cervical carcinoma.
- Immunosuppressed patients are at a higher risk of developing persistent HPV infection.
- No definitive, etiological treatment for HPV infection exists. Available treatments locally destroy infected tissue. Eradication of virus is not possible up to now.
- Highly effective prophylactic vaccines are licensed for the prevention of type-specific HPV infection.

Definition and Epidemiology

Cutaneous and anogenital warts are the clinical manifestations of an infection with human papillomaviruses (HPVs). Up to date there are more than 120 different HPV types that have been fully characterized. Both conditions are very common and can affect all age groups. A subset of HPV (most often types 16, 18, 26, 31, 33, 35, 39, 39, 45, 51–53, 56, 58, 59, 62, 66, 68, 73, 82) has been designated as high-risk types. They have been implicated in the pathogenesis of cervical cancer and its precursor lesions, of malignancies at the anogenital area and the upper aerodigestive tract, and, rarely, of squamous cell carcinoma of the digit. In the case of immunosuppression, HPV infection can persist, increasing the risk of developing anogenital malignancies.

Cutaneous warts can affect any part of the skin but mainly the fingers, the soles, and the face. They are more prevalent in childhood, ranking as one of the three most common dermatoses in children, with an overall prevalence of 20 % in schoolchildren. The majority will regress spontaneously within a year or 2 from the initial infection. Reinfection with the same type of HPV virus is uncommon after complete clearance.

Transmission occurs via direct skin-to-skin contact or indirectly through contaminated surfaces and objects (e.g., swimming pools, towels, etc.). Minor abrasions and breaks of skin's integrity are usually needed to expose basal keratinocytes to HPV. Autoinoculation of the virus is also a major factor of viral spreading.

Anogenital warts are one of the most common sexually transmitted infections (STIs) in the adolescent and adult population. They are uncommon in prepubertal children, and although vertical transmission has been described, the possibility of sexual abuse needs to be excluded when they are diagnosed in that age group. The prevalence of cervical HPV infection varies greatly between different countries and age groups and ranges from 20 to 45 %. Similar rates are described in men. The impact of genital HPV infection to public health is alarmingly high, both in terms of number of visits to doctors and fiscally. It is estimated that the annual cost in the USA is over $6 billion, making it the second most costly STI after HIV.

Transmission occurs mainly by intimate contact (skin to skin or mucosa to mucosa) with individuals who manifest clinical or subclinical lesions. Circumcision seems to be protective in carrying and transmitting HPV infections. Risk factors include first sexual intercourse at an early age, frequency of intercourse and multiplicity of sex partners, partner's number of sexual partners, and concomitant sexually transmitted diseases.

Most anogenital HPV infections will eventually resolve by themselves in a period that may extend from months to years. Recurrences are common, either with or without treatment, especially within the first year. The median duration of high-risk type infection in women is reported to be around 8 months. Persistent cervical infection is observed in 30 % after the first year and in 9 % after the second year. Persistence of cervical infection with a high-risk HPV type represents the single most important factor for the development of cervical pathology, including cervical carcinoma. Altogether, HPV types 16, 18, 31, and 45 constitute for more than 80 % of the cervical cancers worldwide. Routine cytology screening tests with the Pap smear are suggested by international authorities as a major preventive measure of cervical carcinoma.

Immunosuppression, e.g., due to HIV or in organ transplant patients, appears to change the natural course of HPV-related oncogenesis. HPV infections are more frequent, persistent, and more likely to progress to intraepithelial neoplasias in immunosuppressed patients.

Basic Concepts of Pathogenesis

Cutaneous and anogenital warts represent hyperproliferative growths of terminally differentiated keratinocytes of the skin and mucous membranes infected by HPV. Papillomaviruses are nonenveloped, double-stranded DNA viruses, approximately 55 nm in diameter. The capsid is a spherical, icosahedral coat composed of two virally encoded proteins: L1 and L2. It surrounds the viral DNA, thus protecting it from degradation and also enabling adhesion to target cells. It is not surrounded by any lipoprotein envelope, being stable and resistant to environmental stress such as heat, detergents, and desiccation. HPV DNA does not encode any of the known polymerases, kinases, or proteases that are currently used as targets of anti-herpes and anti-HIV drugs.

HPV is highly host specific and no cross infection with other animal papillomaviruses has been reported. The HPV proliferative cycle is completed only in fully differentiated squamous epithelia. The infection starts when the virus finds a way to enter the active, proliferating basal epithelial cells, usually through an abrasion or trauma. As the infected basal cells divide, some of them migrate away from the basal layer toward the surface and others remain on site, acting as a long-standing reservoir of viral DNA. Viral shedding acts as immediate way of viral transmission. Depending on the capacity and activity of basal cells infected, the infection will prove itself to be either transient or persistent. An immune response by the host is mounted, mainly a cell-mediated one. Langerhans cells and infiltrating lymphocytes target and recognize even low levels of viral proteins expressed in the basal and Malpighian layers. There is no viremic phase;

therefore a systemic immune response is avoided. However, approximately 60 % of patients with anogenital lesions develop low titer-specific antibodies, which tend to last even after clearance.

The natural history of HPV infection is either spontaneous regression or in some cases progression to premalignant and malignant lesions. As mentioned before, different types have different oncogenic potential. HPV types 16 and 18 are linked to cervical carcinoma via increased expression of E6 and E7 genes. The current model of multistage carcinogenesis requires a time lag of several decades after initial infection combined with an accumulation of genetic mutations due to environmental or other factors. HPV types 5 and 8 are frequently detected in squamous cell carcinomas in patients with epidermodysplasia verruciformis (EV). Most cases of EV are sporadic but about 25 % of cases have been reported to display autosomal or X-linked recessive inheritance. Two types of lesions are observed, one resembling plane warts and another similar to pityriasis versicolor. Malignant transformation of at least one lesion occurs in more than 50 % of patients.

Clinical Presentation

Clinical features present in various forms depending on the type of HPV, the affected site, and the immune status of the host. We distinguish between cutaneous and mucosal types of HPV; however there are exceptions to this virus tropism.

Common warts (verruca vulgaris) appear in various sizes as firm, hyperkeratotic, rough papules that can form large masses by confluence. They are due mainly to HPV 2. They may occur anywhere on the skin but preferably on dorsum of hands and fingers and around or beneath the nails *(periungual warts)*. Children under 12 years of age are frequently affected. Common warts are usually asymptomatic but may be tender. About 95 % will clear spontaneously within 4 years. It seems that clearance is slower in adults. Malignant transformation is extremely rare but has been reported in immunosuppressed hosts.

Plantar warts (verruca plana) are caused by HPV 1, 2, 4, 27, and 57. They first appear as small, grainy papules and soon evolve into a well-defined, rounded lesion with keratotic surface. Most of the plantar warts develop under pressure points such as the heel or the heads of the metatarsal bones. Mosaic warts are formed by the confluence of closely grouped small-size warts. The epithelial ridges of the plantar skin are not continued over the wart surface. After paring down the surface, small black dots are revealed, which represent the thrombosed capillaries. Pain during walking is common but varies in intensity. Pressure over plantar warts produces pain. Duration of lesions is very variable. Children have a better prognosis compared to adults. Mosaic warts, however, can be extremely difficult to treat. Distinction from corns, calluses, and punctate keratoderma needs to be made.

Plane warts (flat warts) are due mainly to HPV 3 and 10. They are small, 1–5 mm in diameter, round or polygonal, smooth, and flat papules. They can be skin colored or pigmented. The face, dorsum of hands, and shins are sites of predilection. Linear arrangement of contiguous warts is a characteristic sign. Regression is possible and usually associated with inflammation (pruritus, erythema, edema, depigmented halo around the wart). Resolution is completed within a month.

Filiform and digitate warts occur mainly in males. They appear on the face, nostrils, and neck. They can be clustered or irregularly distributed.

Anogenital warts are common in both sexes and are caused mainly by HPV 6 and 11. They are often asymptomatic but may cause discomfort. The typical lesion is soft, pink, elongated, and sometimes filiform, pedunculated, or cauliflower-like (condyloma). Flat papular lesions can also be observed. Lesions can be solitary or multiple and vary in size from 1 to 2 mm up to several cm. They affect mucosal surfaces and keratinized skin. Typical sites of predilection are the glans penis (Fig. 106.1), the corona, and frenulum in men and labia minora (Fig. 106.2) and anus in women. These sites represent areas of greater coital friction. Other areas include the

Fig. 106.1 Genital wart on penis (urethra)

Fig. 106.2 Multiple anogenital warts on vulva, perineum

perineum, the penis shaft, the pubic area, labia majora, inguinal folds, and scrotum. Duration of lesions varies from a few weeks to many years. Recurrences are expected in about 25 % of cases, with an interim period ranging from 2 months to more than 20 years. Viral DNA can be found in clinically and histologically healthy skin adjacent to lesions. This finding probably correlates with recurrences after clinical cure. The development of large masses, induration, pain, and discharge raises the suspicion of malignant change (including Buschke-Löwenstein tumor) and warrants immediate biopsy.

Diagnosis

Diagnosis is usually made on clinical terms. The acetic acid test can be a useful tool, but it is not widely used because of its low sensitivity and specificity. Application of 5 % acetic acid results in characteristic whitening of the suspected lesion within 5–10 min of the application. Atypical lesions may need to be biopsied to histologically confirm the diagnosis. Histological findings are variable, reflecting the great number of clinical presentations of HPV-related lesions. A common pattern in epithelial cells is the presence of cytoplasmic vacuoles isolating the pyknotic nucleus from the cytoplasmic membrane. These cells with this characteristic vacuolization as termed as koilocytes (hollow cells). The presence of koilocytosis is a useful feature which distinguishes verrucae from other types of papillomas. Other methods available for the laboratory diagnosis of HPV infection include: detection of virus particles by electron microscope, immunohistochemistry or immunocytochemistry using type-common or type-specific antibodies, DNA hybridization on tissue extracts or in situ, and PCR for HPV DNA. The last two assays allow HPV typing and are useful in identifying oncogenic types. Serological assays are not used because of low antibody titers and variable intervals between infection and seroconversion.

Anogenital warts warrant further investigation such as colposcopy and Pap smear; orthosigmoidoscopy, if found perianally; and screening for other common sexually transmitted diseases (STDs).

Differential Diagnosis

Common warts may resemble seborrheic keratoses, actinic keratoses, acrokeratosis verruciformis, acrochordons, and keratoacanthoma. Even amelanotic melanoma can imitate a long-standing, resistant to treatment periungual wart. Suspicion should rise if erosions and pigmentation are present. Lichen planus may resemble flat warts. Both can present themselves in a linear way. However, lichen planus is distinguished by the whitish net-like pattern (Wickham's striae).

Plantar warts must be differentiated from clavi (corns). The misdiagnosis is usual. A verruca typically presents black dots and punctate hemorrhage after paring it down. In clavus, pain can be induced if pressure is applied vertically on the center of the lesion, while in verrucae pain also appears when pressure is applied sideways at the borders of the lesion. Punctate porokeratosis, poroma, and hyperhidrotic pitting can also mimic plantar warts. In immunosuppressed patients, warts can appear in large number and in unusual sites and can resemble molluscum contagiosum lesions. The latter are dome shaped with a characteristic central umbilication.

Differential diagnoses for anogenital warts include seborrheic keratoses, lichen planus, melanocytic nevus, syphilitic condylomata lata, pearly penile papules, and vestibular papillomatosis. The latter two entities represent normal anatomic variants in men and women, respectively. Pearly penile papules consist of several rows of miniature papules, 1–2 mm, along the coronal sulcus. Vestibular papillomas are tiny projections of regular shape at the introitus vulvae and the labia minora. Syphilis serology obviously is needed to exclude *T. pallidum* infection. Sebaceous glands of the prepuce and labia majora can appear as white-gray to yellow small papules and sometimes are misdiagnosed as genital warts. Bowenoid papulosis consists of red-brown papules or confluent whitish plaques that may be difficult to differentiate from benign condylomas. It usually affects male patients and most of the time a biopsy is needed to establish a diagnosis. Finally, one should always have in mind the possibility that a recalcitrant to treatment, long-standing lesion may be a premalignant or malignant lesion. Vulvar, penile, and anal intraepithelial neoplasias and squamous cell carcinoma are entities that are included in this category. HPV 16, 18, 31, and 33 are the types frequently implicated in their pathogenesis.

General Principles of Treatment

Up to date no definitive and etiological treatment has been found for cutaneous and genital warts. Our approach is limited to tissue destructive therapies in order to stop viral shedding from the infected sites. None of these methods eradicate HPV. Let it be noted that where treatment trials have been placebo controlled, a 30 % response rate has been observed in the placebo group. Depending on the site and the extent of the lesions, we choose from a wide array of available options. First-line treatments are usually the topical ones, moving then to more aggressive treatments. For anogenital warts in particular, first-episode patients should be offered screening for other STDs. Also, they should be encouraged to notify their partner(s).

Cutaneous Warts

Several combinations of keratolytic and caustic agents are commercially available. Salicylic acid 12–26 % either alone or in combination with lactic acid has been used successfully over the last years. Mono- and trichloroacetic acid, silver nitrate 10 % solution, cantharidin, phenol, formic acid, pyruvic acid, 5 % glycolic acid, formaldehyde soaks, and glutaraldehyde solution are other options. All these agents need to be carefully administered with clear instructions by the physician. Possible side effects include irritation of the surrounding skin. Less common topical treatments have been tried with varied results such as sensitization with diphencyprone, intralesional

therapy with DNA inhibitors such as bleomycin and 5-fluorouracil, immunomodulatory therapy with imiquimod, photodynamic therapy with topical 5-aminolevulinic acid and white light irradiation, and sodium salicylate 2 % iontophoresis. All common and less common topical treatments are listed in Table 106.1.

More aggressive techniques that are doctor administered and result in topical tissue destruction include: cryotherapy (with liquid nitrogen), curettage and cautery, surgical excision, laser, and intense pulsed light.

Cryotherapy with the use of liquid nitrogen is one of the most widely used treatments for cutaneous warts. It is easy, quick, and effective. The wart is frozen with a 2 mm surrounding halo for approximately 5–10 s. Hyperkeratotic warts need to be pared down before cryotherapy. Sometimes, two freeze-thaw cycles per session are administered. The treatments are repeated every 2–3 weeks. Common side effects include blister formation and transient hypopigmentation. Curettage and cautery is another way of removing the lesion along with electrosurgery to cauterize its base. Scarring is the most significant side effect. Surgical excision is used for removing recalcitrant to treatment warts or when there is diagnostic doubt. Histological confirmation is the most important advantage of this method. When other destructive methods have failed, lasers can be used. Pulsed-dye 585 nm laser, Er:Yag, Q-switched Nd:Yag 532 nm, CO_2, and intense pulsed light are among the ones that have been used. Besides the high treatment cost, they can be painful and may induce disfiguring scarring.

As far as systemic treatments are concerned, oral cimetidine, oral levamisole (anthelmintic drug), oral zinc sulfate, and oral retinoids have been used with moderate results. There are also some anecdotal reports regarding the use of topical cidofovir 1–3 %, vitamin D3 derivatives, hypnotherapy, and a combination of salicylic acid and imiquimod.

Table 106.1 Topical treatment for cutaneous warts at a glance

Common topical treatments	Less common topical treatments
Salicylic acid 12–26 % with or without lactic acid	Formaldehyde soaks
Mono- and trichloroacetic acid	Glutaraldehyde solution
Silver nitrate 10 % solution	Immunotherapy with diphencyprone or with squaric acid dibutylester
	Intralesional bleomycin, zinc sulfate, interferon, or formic acid
	Imiquimod
	5-Fluouracil
	Photodynamic therapy
	Tretinoin
	α-Lactalbumin-oleic acid
	Zinc oxide 20 % ointment
	Duct tape application
	Localized heat therapy

Anogenital Warts

Currently available treatments for anogenital warts are classified into patient-applied and doctor-applied modalities (Table 106.2). Data collected and analyzed confirm that only surgical therapies have a primary clearance rate approaching 100 % and that recurrences can occur after all therapies. The recurrence rate, including new lesions at previously treated or other sites, could reach 30 % or even more. All therapies are associated with local irritation reactions, such as burning, erythema, erosions, and pain.

Table 106.2 Treatments for anogenital warts at a glance

Patient-applied treatments	Doctor-applied treatments
Podophyllotoxin (0.15 % cream or 0.5 % solution)	Cryotherapy
Imiquimod 5 % cream	Trichloroacetic acid (TCA) 80–90 %
Sinecatechin 15 % ointment (in the USA, not in Europe)	Surgery: electrosurgery, curettage and cautery, scissors excision, laser, excision under general anesthesia
	Podophyllin 20–25 % resin (in the USA, not in Europe)

Patient-applied modalities include podophyllotoxin, imiquimod, and sinecatechin. *Podophyllotoxin* (0.15 % cream or 0.5 % solution) is an antimitotic drug that is inexpensive, easy to use by the patient, and safe. Each treatment cycle consists of twice daily application for 3 days, followed by 4 days of rest. This cycle can be repeated if necessary for up to 4 weeks. Use of solution is more convenient for penile warts; the cream can be used for vulvar and anal warts. Clearance rates of 36–83 % have been reported. Meatal warts and warts on keratinized skin can often prove refractory. Recurrence rates of 6–100 % have been reported. It is contraindicated during pregnancy. Podophyllin resin 20–25 %, although available in the USA as doctor-applied treatment, is not generally recommended in Europe due to its mutagenic potential, severe systemic toxicity, and moderate efficacy.

Imiquimod is a topically active immunomodulator that stimulates production of interferon alpha and similar cytokines, necessary to mount an immune response to the warts. Its effects are mediated through agonistic activity toward toll-like receptors (TLR) 7 and 8. Consecutively, nuclear factor-kappa B (NF-κB) is activated which leads to the induction of pro-inflammatory cytokines, chemokines, and other mediators. Antigen-presenting cells and other components of innate immunity are activated, and eventually, a profound T-helper (Th1)-weighted antitumor cellular immune response is mounted. Moreover, independent of TLR-7 and TLR-8, imiquimod causes receptor-independent reduction of adenylyl cyclase activity. Finally, imiquimod induces apoptosis of tumor cells at higher concentrations. It is supplied as a package of 12 individual sachets containing 5 % cream. It is applied three times weekly at bedtime and it is washed off the following morning. Treatment continues until clearance or for a maximum up to 16 weeks. Our impression is, based on clinical experience, that it is more effective on mucosal surfaces and perianally. Any local reactions can be managed by a temporary cessation of treatment for a few days or by reducing the frequency of application. Rare systemic reactions (fever, lymphadenopathy, flu-like syndrome) have also been reported. Clearance rates have been reported between 35 % and 75 %, being higher in women and in the perianal area. Relatively low recurrence rates (6–26 %), comparing to other treatments, have been reported. Animal studies have not revealed any teratogenicity; however its safety during pregnancy has not been established.

Sinecatechin 15 % ointment is a green tea extract with an active product of catechins. It is available in the USA but not in Europe; it should be applied three times daily for no longer than 16 weeks. It should not be washed off after use. No data are available regarding its safety and efficacy compared to other treatments. It should not be used during pregnancy.

Doctor-administered therapies include cryotherapy, trichloroacetic acid (TCA), and surgery.

Cryotherapy is a widely used modality which destroys warts by ice-induced cytolysis. It can be delivered either by "open" or "closed" systems, i.e., with a spray gun device (liquid nitrogen) or a cryoprobe (nitrous oxide or carbon dioxide). The lesion and a surrounding halo of healthy skin are frozen for up to 15 s. One or two freeze-thaw cycles can be administered per session. Cryotherapy is performed at 1–2 weekly intervals. Local reactions include blistering, pain, and transient hypopigmentation. It is a simple, inexpensive technique, safe during pregnancy. Its clearance rates depend on compliance to the administration protocol and can vary between 44 % and 75 %. Recurrence rates are 21–42 % 1–3 months after clearance.

Trichloroacetic acid (TCA) 80–90 % solution is a caustic agent that destroys warts by chemical coagulation of proteins. Although widely used, it has not been investigated properly. It is applied sparingly on the wart either by a cotton tip or an applicator, on a weekly basis. It is most suitable for small, keratinized anogenital warts. It is corrosive and may cause scarring. Resolution rates of 56–81 % with recurrence rates of 36 % have been reported. It is safe during pregnancy.

A variety of *surgical treatments* is available including electrosurgery, curettage and cautery, shave excision, scissor excision, and laser therapy. Their main advantage is the elimination of the warts at a single visit. Routine use of local

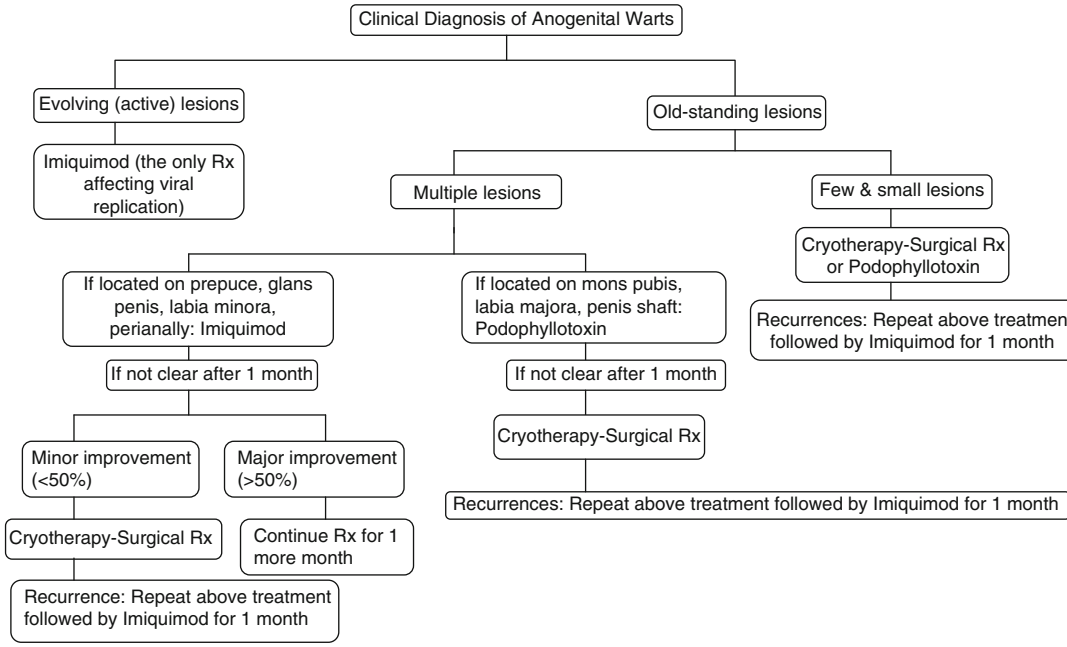

Fig. 106.3 Treatment algorithm for anogenital warts

anesthetic is recommended. Lidocaine 2 % either with or without adrenaline is the most commonly used one. Because most of the warts are exophytic, the resulting wound extends into the upper dermis. If performed carefully and care is taken to control the depth, surgical treatments leave satisfactory cosmetic results. Hemostasis can be achieved by electrocautery or chemical styptics (silver nitrate). Suturing is usually not necessary. Carbon dioxide and YAG lasers destroy warts by emitting very high power densities delivered to small tissue volumes. Fumes from laser treatment and electrocautery contain contagious particles and adequate measures to prevent virus spreading should be used (masks, smoke evacuator). For bulky and extensive warts, anal and intra-anal warts, and significant lesions in children, surgical removal under general anesthesia is indicated.

All treatments have shortcomings; therefore several combination protocols have been used by clinicians. Data evaluating these combinations are limited and further investigation is needed. The same applies for treatments that are generally not recommended due to lack of sufficient data, such as topical or intralesional interferon.

It is obvious that treatment decisions are made based on site, number and extent of lesions, and patients' preferences and needs. A suggested treatment algorithm that is followed by the authors is illustrated in Fig. 106.3.

Prevention

Anogenital warts' spreading is associated with sexual behavior, increased number of partners, and lack of condom use. It is believed that anogenital warts are more common in smokers. Although there is no robust evidence that smoking cessation improves the outcome of treatment or affects recurrence rates, there is a strong rationale from both an individual and a public health promotion point of view for advising smoking cessation. Regular use of condoms reduces but does not eliminate the possibility of viral infection. Nowadays, two HPV vaccines based on virus-like particles are commercially available: a

quadrivalent vaccine against HPV 6, 11, 16, and 18 (Gardasil; Merck) and a bivalent against HPV 16 and 18 (Cervarix; GlaxoSmithKline). There are studies showing near-complete protection (over 90 %) against vaccine-type HPV-associated anogenital warts, low-grade and high-grade intraepithelial dysplasias, and cervical cancer for at least 5 years. Vaccination consists of three intramuscular injections preferably within a period of 6 months according to the following schedule: 0, 2, and 6 months for Gardasil and 0, 1, and 6 months for Cervarix. If flexibility in the vaccination schedule is necessary, it must be noted that the minimum interval period for both vaccines between first and second dose should be no less than 1 month. Also, the third dose should be between 5 and 12 months after the first dose for Cervarix and at least 3 months after the second dose for Gardasil. The need for a booster dose has not been established. Both vaccines are indicated for young girls above 9 years old and for females up to 26 years of age, who did not receive or complete the vaccine series when they were younger. The quadrivalent vaccine can also be used in males 9–26 years old. National vaccination programs vary worldwide. Obviously, these vaccines are most effective when all doses are administered before onset of sexual contacts. The goal is a global vaccination scheme for children and adolescents, so as to establish herd immunity and finally virus elimination.

Xanthomas

107

Dimitrios Sotiriadis and Aikaterini Patsatsi

Key Points

- In all cases of xanthomas, a thorough detection of a lipid disorder is of great significance.
- Among the different clinical types of xanthomas, eruptive xanthomas, as well as tuberous and tendinous xanthomas, are associated with an underlying hyperlipidemia, which must be detected.
- When the type of an underlying lipid disorder is identified, proper treatment serves in the clinical remission and the prevention of atherosclerosis and pancreatitis.
- Xanthelasmas are mostly found in normolipemic patients and their treatment is based on surgical procedures or destructive modalities.

Definition

Xanthomas are lesions characterized by the accumulation of lipid-rich macrophages, the foam cells. They may develop in the setting of an altered systemic lipid metabolism.

Basic Concepts of Pathogenesis

Xanthomas have been associated with disorders of lipoprotein metabolism, despite the fact that only a minority of individuals with such disorders develop xanthomas.

A high plasma concentration of lipids leads to the permeation of lipoproteins through the walls of dermal capillaries. The lipid is then taken up by dermal macrophages, which evolve into foam cells.

More than one clinical type of xanthomas may be present in a particular lipoprotein disorder (Table 107.1).

Clinical Presentation

Xanthomas present clinically as yellow or yellow-brown papules, nodules, or plaques.

The amount of lipid present and the depth of accumulated foam cells define the color of lesions. There are distinct clinical forms of

Other primary dyslipidemias	
Cerebrotendinous xanthomatosis	
Sitosterolemia	
Secondary hyperlipidemia	

xanthomas, with different clinical morphology, sites of predilection, and mode of development:

- Eruptive xanthomas
- Tuberous xanthomas
- Tendinous xanthomas
- Plane xanthomas

Eruptive Xanthomas

Eruptive xanthomas are small, yellow papules, 1–4 mm of size, with a peripheral erythematous halo. They erupt in crops over pressure points and over the extensor surfaces of the arms, legs, and buttocks (Fig. 107.1).

Fig. 107.1 Eruptive Xanthomas

Eruptive xanthomas are a characteristic skin manifestation in patients with familial lipoprotein lipase deficiency which leads to a massive accumulation of chylomicrons in the plasma and

a severe elevation of plasma triglyceride levels (type I pattern, according to Frederickson's classification of familial hyperlipidemia). This hyperlipidemia is extremely rare and may present in early childhood with acute pancreatitis. Apolipoprotein C-II deficiency is another form of type I hyperlipidemia, in patients with genetic defects of the apolipoprotein C-II gene, associated with the eruptive presentation of xanthomas.

This type of xanthomas rarely presents in patients with familial hypertriglyceridemia, leading to the accumulation of VLDL and to severe elevations of plasma triglyceride levels (type IV) or in patients with the combined form of hypertriglyceridemia (type V).

Tuberous and Tendinous Xanthomas

Tuberous xanthomas present as yellow or red nodules located on the extensor surfaces of the extremities, palms, and buttocks. Their initial presentation is that of soft, small, papules, resembling eruptive xanthomas. In the course of time, they enlarge and become firm but they do not attach to underlying structures like tendinous xanthomas.

Tendinous Xanthomas

Arise in tendons, ligaments, and fascia as deep, nontender, firm nodules of various sizes that move with the affected tendon. They are usually 1 cm or larger in size and are most frequently located on the Achilles tendons and the extensor tendons of the hands, elbows, and knees.

Tuberous or tendinous xanthomas may present in patients with familial LDL receptor deficiency and familial defective apoprotein B-100 defects, leading to the accumulation of LDL and elevation of plasma cholesterol levels (type II pattern of hyperlipidemia). These patients have severe atherosclerosis. They may also present in patients with familial dysbetalipoproteinemia (type III) or with sitosterolemia.

Tuberous xanthomas may develop in patients with familial combined hyperlipoproteinemia, leading to the accumulation of both LDL and VLDL, with variable elevations of both triglyceride levels and cholesterol levels in the plasma (type IIb pattern of hyperlipidemia).

Tendinous xanthomas may be found in patients with cerebrotendinous xanthomatosis.

Plane Xanthomas

Plane xanthomas present as soft yellow macules and slightly elevated papules and plaques located anywhere on the body, with a predilection for surgical or acne scars.

This clinical type may present in patients with familial hypercholesterolemia (type II), with familial dysbetalipoproteinemia, leading to the accumulation of LDL (beta-VLDL) and an increase in both triglyceride levels and cholesterol levels in the plasma (type III), with apolipoprotein A-1 deficiency, with dysproteinemias or with biliary obstruction.

Depending on their location, plane xanthomas are further subdivided into xanthelasmas, intertriginous xanthomas, palmar xanthomas, and diffuse (generalized) plane xanthomas.

The most common type, *xanthelasma palpebrarum (XP)*, occurs on the eyelids (Fig. 107.2). Patients with this type of xanthomas are mostly normolipemic. Xanthelasmas may present in patients with type II or type III pattern of hyperlipidemia, as well as in patients with apolipoprotein A-1 deficiency, with dysproteinemias, with biliary obstruction, or with secondary hyperlipidemias.

Fig. 107.2 Xanthelasma Palpebrarum

Intertriginous xanthomas present at the intertriginous areas and are pathognomonic of homozygous (type II) familial hypercholesterolemia.

Palmar xanthomas are yellow to orange, flat, linear lesions in the creases of the palms and fingers. They are sometimes subtle, requiring proper lighting in order to be recognized. They are most commonly seen with type III hyperlipidemia.

Diffuse (generalized) plane xanthomas present as macular, yellowish discoloration or plaques, involving particularly the trunk and neck. There is a significant association with lymphoreticular neoplasms and not with lipemic disorders.

Differential Diagnosis

- Lichen amyloidosis
- Disseminated granuloma annulare
- Necrobiotic xanthogranuloma
- Erythema elevatum diutinum
- Necrobiosis lipoidica
- Sarcoidosis

General Principles of Treatment

The most important principle in the treatment of xanthomas is to first detect the presence or not of an underlying hyperlipidemia. Treatment of the underlying disease aims not to improve the aesthetic outcome but to reduce the risk of atherosclerosis associated with lipoprotein disorders.

Eruptive xanthomas usually respond within weeks after initiation of systemic treatment, tuberous xanthomas resolve after months, while tendinous xanthomas take years to resolve or may persist indefinitely.

Xanthomas are very often, but not always, associated with underlying hyperlipidemia.

Treatment of hyperlipidemia consists of diet and lipid-lowering drugs, e.g., statins, bile acid-binding resins, fibrates, and nicotinic acid. Although there are only few well-documented studies to establish the therapeutic efficacy of these agents, eruptive and tuberous xanthomas usually resolve within weeks or months after treatment initiation (Table 107.2). Local surgical or destructive approaches are used mainly for xanthelasmas (Table 107.3).

Diet Therapy

Although diet remains the first step to reduce hyperlipidemia, several studies have reported only modest cholesterol-lowering benefits, generally in the range of a 5–10 % decrease in LDL cholesterol levels. Some patients, however, will have remarkable reduction, up to 25 %, in LDL cholesterol, on diet therapy. In any case, the results of diet should be assessed at least after 4 weeks.

Decreasing total caloric intake and body weight are very important and make a significant impact on lipid levels.

Diet should be very low in total fat or in saturated fats and high in poly- and nonsaturated fats.

There are several nutritional processes to diet therapy. "Mediterranean diet" is a very famous strategy, which maintains total fat at approximately 35–40 % of total calories but replaces saturated fat with nonsaturated ones, such as that found in olive oils. Unfortunately this diet is less likely to reduce HDL cholesterol and to lead to weight loss.

Low-fat, high-carbohydrate diet may result in reduction in HDL cholesterol and dietary changes may also decrease lipid levels in blood. Soluble fiber, garlic, vitamin C, soy protein, and plant sterols may result in reduction of LDL cholesterol. In addition, diet rich in antioxidant vitamins, such as found in fruits and vegetables may also be helpful.

Finally, diet therapy is the most effective management for all types of chylomicronemia.

Systemic Treatments

Several lipid-lowering agents have been proposed for primary hypercholesterolemia treatment, including niacin (nicotinic acid), bile acid-binding resins, HMG-CoA reductase inhibitors, and fibric acid derivatives. In general, the therapeutic goal is approached slowly, following up for side effects and being supportive to diet or other, non-drug therapies.

Nicotinic Acid (Niacin)

Nicotinic acid acts probably through decrease of the hepatic synthesis of VLDL with secondary reduction in LDL and increase in HDL cholesterol levels. This agent will also reduce triglycerides by half, will significantly lower lipoprotein-a levels, and will also increase plasma homocysteine levels. However, because of the need of high doses of nicotinic acid (~3–4.5 g/day) for its hypolipidemic effects, only 50–60 % of patients are able to take full doses due to the increased incidence of side effects.

Flushing, nausea, skin dryness, acanthosis nigricans-like eruption, urticaria, and hyperpigmentation are common side effects. Exacerbation of gout or peptic ulcers may occur. Although nicotinic acid may increase blood sugar in some patients, recent data have shown that it may be administered to diabetics.

Bile Acid: Binding Resins (Cholestyramine, Colestipol)

The resins cholestyramine and colestipol have the advantage of being not absorbed and they work by binding bile acids in the intestinal tube, causing reduction of their enterohepatic circulation. The result of this action is the increase of liver bile acids production, using hepatic cholesterol to do so. Thus, hepatic LDL receptor activity increases with decrease in plasma LDL levels. It has been observed that in some patients, treated with these agents, triglyceride level tends to increase slightly. Therefore, bile acid-binding resins should be used with caution in those with high levels of triglycerides.

Cholestyramine may be most effective in children with inherited hyperlipidemia, in young women of childbearing age, and during pregnancy – but it is contraindicated in type I hyperlipoproteinemia. However, patients – especially children – do not comply, due to the side effects of these drugs, including gastrointestinal symptoms, nausea, gas, and taste disturbance. The dose of cholestyramine is 12–36 g/day (in divided doses) and of colestipol is 20 % higher.

HMG-CoA Reductase Inhibitors (Statins)

These drugs act by inhibiting 3-hydroxy-3-methylglutaryl CoA reductase, the enzyme that facilitates the intracellular cholesterol biosynthesis, with a consequent upregulation of hepatic LDL receptor expression and increased clearance of the LDL from the circulation. Statins are the most effective drugs that reduce cholesterol levels. They have also a moderate action to increase LDL and a slight action to decrease triglyceride levels. Statins have proven to be effective in patients with heterozygous FH and familial defective apolipoprotein B-100 and in patients with secondary dyslipidemias. Atorvastatin (10–80 mg/day), lovastatin, pravastatin (10–40 mg/day), simvastatin (5–40 mg/day), rosuvastatin, and fluvastatin, usually given once a day in the evening, may be used alone or in combination

with other agents such as cholestyramine. In severe cases the combination therapy with statins and LDL apheresis has been particularly effective.

The major side effects of statins are myopathy and hepatotoxicity but they are rare; higher doses cause more side effects. Coadministration of drugs such as fibric acids, erythromycin, or cyclosporine increases the risk of myopathy. Females of childbearing age should be informed about the teratogenicity of statins.

Fibric Acid Derivatives (Gemfibrozil, Fenofibrate, Clofibrate)

Fibrates' main effect is to reduce the synthesis and increase the breakdown of VLDL particles, with secondary effects on LDL (reduce about 10–15 %), triglyceride (reduce about 40 %), and HDL (raise about 15–20 %) levels. These agents are the treatment of choice of severe hypertriglyceridemia and of type III hyperlipoproteinemia. The usual doses, given in the morning, are gemfibrozil (600–1,200 mg/day), fenofibrate (150 mg/day), and bezafibrate (400 mg/day).

Side effects include hepatitis, chololithiasis, myopathy, and increase serum levels of creatinine. The incidence of hepatitis and myopathy may be higher among patients who are also taking other lipid-lowering agents (e.g., the combination of gemfibrozil and statins increases the risk of myopathy).

Ezetimibe

It is the newer lipid-lowering drug that reduces total and LDL cholesterol levels.

It works by inhibition of the intestinal lipid transporter Niemann-Pick C1-like protein. Ezetimibe reduces LDL cholesterol about 15–20 % when used as monotherapy and can further reduce LDL levels in combination with statins. It is generally well tolerated and is the drug of choice in sitosterolemia treatment.

LDL Apheresis

This treatment has been indicated for the most severe cases of hypercholesterolemia. Immunoabsorption, dextran sulfate absorption (DSAL), and heparin-induced extracorporeal LDL precipitate are the most common methods of LDL apheresis.

This therapeutic approach may be applied every 1–2 weeks and can be combined with statins or with other hypolipidemic drugs and suitable diet.

Topical Treatment Approaches

Surgical procedures or destructive modalities are mainly used for xanthelasma palpebrarum treatment. Although XPs are not strictly considered to be treated, patients very often seek removal for aesthetic reasons.

There are many methods available, e.g., microsurgical techniques, blepharoplasty, electrodesiccation, cryosurgery, chemical cauterization (TCA, BCA), and lasers, each with its advantages and disadvantages.

Electrodesiccation and cryosurgery were used mainly in the past for small, stable, and isolated XP, but the cosmetic results of those modalities are generally not acceptable enough.

Surgery is the classical method of treatment for xanthelasma removal. Microsurgical techniques provide excellent results, especially for small XPs. Unfortunately there is a high risk rate (30–40 %) of recurrences, and therefore, patients do not opt gladly this method.

Surgical excision is also indicated for a few cases of tuberous xanthomas.

Trichloroacetic acid (TCA) in different concentrations has been used as tissue cauterant since 1926.

In a recent, well-documented paper, Haque and Ramesh evaluated various strengths of TCA (50, 70, 100 %) in XP lesions. The lesions were categorized according to size and clinical form (flat, papular, or papulonodular). The authors conclude that the selected concentration of TCA for short use is proportional to the clinical severity. Each lesion should be treated for about 1–2 min until the development of frosting. TCA 100 % is recommended for papulonodular XP, TCA 70 % for flat plaques, and TCA 50 % for macular XP.

In any case, according to the current available literature, TCA 70 % seems to be a simple and effective method which achieves a higher rate of patients' satisfaction, despite the fact that TCA 95 % has an overall higher clearance rate.

Main problems of TCA application are determination of the sufficient quantity of the solution that should be applied, the potential need of reapplication and the appropriate time for this action, and, of course, the possibility of side effects.

Most common side effects associated with TCA application include hypo- and hyperpigmentation, while atrophy, scarring, and ectropion are rare and occur usually with higher concentrations (95–100 %).

Use of bichloroacetic acid (BCA) is relatively restricted and seems to be less effective, compared to TCA.

Ablative laser surgery for treating XPs was introduced more than 30 years ago.

Carbon dioxide (CO2) laser, Erbium:ND-YAG laser, Argon laser, and KTP laser are popular options and the results seem satisfactory. Main disadvantage of this option is the induction of pain, and thus, some form of anesthesia is required. Moreover, patients are unable to work for several days.

Nonablative laser (pulsed dye laser) therapy promises good clearance rates in approximately two thirds of the lesions, usually without local anesthesia or major side effects.

Hypo- and hyperpigmentation in about 5–15 % of patients are the most common complications of laser therapy, while persistent erythema, scars, or ectropion rarely occurs. Care must be taken always to protect the eyes.

Combined ablative and nonablative laser surgery may be recommended for the treatment of tuberous lesions. It is very important to emphasize that the risk of recurrence is estimated to be about 40 % and remains almost the same in comparison with the surgical removal. In addition, the wavelength, pulse duration, number of passes, and number of sessions may vary.

In conclusion, management of XPs is difficult, mainly because of the strong possibility of recurrences, regardless of the mode of selected modality.

Methods

Acne Scar Treatment

108

Antonio Rusciani, Francesco Ricci, and Giuseppe Curinga

Key Points

- Acne is a chronic inflammatory disease of the pilosebaceous follicles that can leave temporary or permanent scars in a high percentage of patients.
- Techniques at the physician's disposal for the treatment of acne scars are continually increasing.
- Several treatments are now available: from peeling to cryotherapy, fillers, autologous fat implants, lasers, dermabrasion, microdermabrasion, microsurgery, compressive medication, and steroid infiltration.
- The choice of the treatment depends on the type of the scar; their shape, depth, and dimension; the presence of acne active lesions; and personal choices.

G. Curinga
Plastic Surgeon, Palermo, Italy

Definition and Epidemiology

Acne is a chronic inflammatory disease of the pilosebaceous follicles characteristically but not exclusively affecting adolescents, having a 35–90 % prevalence in young people between the ages of 14 and 19, generally resolving spontaneously after age 20 in men and age 25 in women. However, in some cases, usually in women, acne can persist through adulthood. The occurrence of scars, more or less pronounced, in patients with previous acne is >80 % of patients. About 5 % of patients present with a severe form of acne, and especially in these cases, acne can result in permanent scars that can be highly disfiguring and conditioning for the patient, causing serious social discomfort and decreased self-esteem.

Typology of Scars

Acne scars can be atrophic, hypertrophic, or keloid. They can vary in shape, depth, and dimension and often coexist in the same patient. The scars also can be associated with skin discoloration (hypo- or hyperpigmentation).

Atrophic Scars

These scars are typically depressed, differing in form and dimension; they can be wide and

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_108, © Springer-Verlag Berlin Heidelberg 2015

shallow (boxcar scars) or narrow and deep (ice-pick scars). When the subcutaneous tissue is severely damaged, they can form tunnels or wide retractions that significantly alter the contours of the face.

- Boxcar scars: these usually are large and superficial. The best treatments in these cases are fillers, peeling, and fractionated CO_2 laser.
- Ice-pick scars: these have a pointed aspect, half walls, extending vertically and deeply (>2 mm). The upper or superior opening is usually wider than the infundibulum. This type of scarring can be treated with punch surgery, ablative fractionated CO_2 laser, and autologous fat grafts.
- Subcutaneous tunnel and scar contractures: these strongly alter the contours of the face. In these cases, surgical excision and aesthetic reparation give more satisfactory solutions.

Elevated Scars

- Hypertrophic scars: these are nodular, with an irregular surface; they can be treated with steroid injections.
- Keloid scars: fortunately, these are quite rare because they are extremely difficult to treat. The rate of unsuccessful treatment is high because often the treated lesions recur or worsen. The best treatments in these cases are steroid injections, compressive medication, or cryotherapy.

General Principles of Treatment

Techniques at the physician's disposal for the treatment of acne scars are continually increasing. All scars can be treated successfully if one is familiar with the various techniques available, the limits, and the indications for each of them. Often the same patient has diverse types of acne scars; therefore, it is fundamental for the physician to know the different therapeutic possibilities and to integrate the various techniques.

Selection of Patients

First and foremost, it is necessary to distinguish the patients with active acne lesions from the patients with scars from preexisting acne. The patients with acne in the active phase may present comedones, papules, pustules, and scarred lesions. In this phase, surgical correction is not particularly indicated; it is instead advisable to treat the acne lesions in the active phase in order to prevent or at least minimize future scarring. Instead, it is possible to surgically treat patients with scars from previous acne.

Treatment of Acne Scars

Minor Surgical Treatment

Peeling

The purpose of peeling is to encourage epidermic exfoliation through the use of chemical agents; these are preferably indicated in the treatment of superficial atrophic scars (boxcar scars). One may employ various types of acids separately or in combination; however, for severe scarring, deep peeling is necessary, as with phenol or trichloroacetic acid (TCA). The skin is cleaned with alcohol after which the acid is applied with a swab. To alleviate post-peeling burning and pain, one may apply ice packs or cold water. Phenol, generally used at 50 % according to the formula backer, can cause liver, kidney, or cardiac damage if absorbed in excessive quantities; further, it can cause postinflammatory hyperpigmentation, especially in subjects with dark skin. TCA peels are safer since they are free of systemic side effects; they can be used at various concentrations according to the desired results to be obtained.

- TCA 20 %: it causes a very superficial exfoliation; thus, it is not very effective for deep scars.
- TCA 35 %: it is used for small and superficial scars as it is a medium-depth peel. After the treatment, the patient is not bandaged but must avoid sun exposure for 3 months using the

highest level sunscreen to reduce the risk of postinflammatory hyperpigmentation.

- TCA 50 %: it is indicated for large and superficial scars. During the first week post-treatment, the patients must be bandaged so the use of TCA has been progressively replaced by equally effective and less disabling techniques (i.e., CO_2 fractionated laser). This peeling causes deep exfoliation with the formation of scabs that detach and expose the epidermis rosea below.
- 50 % is the maximum concentration used; at higher concentration levels, there is a risk of causing atrophic scars and postinflammatory hypo-/hyperpigmentation. However, a new variant of peeling with TCA is the CROSS (chemical reconstruction of skin scars) technique that uses focal applications of TCA at elevated levels of concentration (65–100 %) on the small ice-pick scars; if not done with caution, the risk of creating discoloration or atrophy remains high.

Compressive Medication

External compression using silicone sheets or occlusive dressings can be used to treat recent keloid scars (<6 months). This consists in the application of these dressings to the scars without excessive pressure for 12–20 h, then removed, washed with soap, and reapplied. This type of treatment is also useful for surgically corrected keloid scars to prevent recurrence. The occlusive dressing is not recommended on areas with hair because it can cause folliculitis. The silicone sheets should be replaced every 1–2 weeks, the occlusive bandages every 1–2 months.

Steroidal Infiltration

Localized infiltration of steroids (usually triamcinolone acetonide) is a valid therapeutic alternative for the treatment of hypertrophic or keloid scars, especially when the scars are recent. The steroid works by interfering with the mechanism of scar formation, making it regress. Generally, triamcinolone acetonide 40 mg comes diluted in 3–4 ml of saline solution. Even with this technique, it is preferable to proceed gradually to reduce the risk of inducing cutaneous atrophy. Systemic absorption of the steroid is minimal; therefore, it is extremely rare to observe systemic side effects such as hirsutism, striae distensae, or Cushing's syndrome.

Cryotherapy

This is quite an obsolete technique once used to treat keloid scars. Following infiltrative anesthesia with lidocaine 1–2 %, the freezing of the keloid is carried out with liquid nitrogen. Often more than one session is necessary, 4–6 weeks apart; however, it is preferable to proceed gradually because, especially in patients with a dark complexion, overly aggressive cryotherapy may destroy the melanocytes, leaving behind marked hypopigmentation. Generally, after the treatment, a necrotic crust will form that heals within 2–3 weeks.

Fillers

These are natural or synthetic substances that are injected into depressed scars to fill them from the bottom upward (Fig. 108.1). Fillers are particularly indicated for shallow atrophic scars, although not particularly indicated for ice-pick scars. These fillers may consist of:

- Calcium hydroxyapatite is an optimal polymer for this type of defect as it acts as a support and stimulus for collagen growth, thus having a deep and long-term filling effect (up to 2 years).
- Polylactic acid is a very good filler for correcting acne scars as it not only fills but also stimulates dermal fibroblasts, obtaining a long-lasting effect (up to 2 years).
- Autologous fat (see the following caption).
- Hyaluronic acid is rapidly reabsorbed into the body; therefore, it is not the most recommended product to correct this type of defect.
- Collagen, a material biocompatible with cutaneous tissue, can be used with moderate

Fig. 108.1 A common filler, new microneedles, and cannulae

success and also has been progressively replaced by products with reduced allergenic potential.

All the materials listed above can be considered safe enough, although transient side effects such as lividity, erythema, or formulation of nodules/granulomas cannot be excluded. Fillers with silicone are now banned in most countries because this synthetic material has generated many cases of granulomatous reactions and improper migration from the point of infiltration.

Autologous Fat Implants

This is used to correct large scars; it is economic and completely biocompatible, does not provoke allergic reactions, and lasts from several months to several years, although the actual duration can be unpredictable. Several factors are indicated in the survival of long-term fat: the patient's age, the site from which the fat is taken, and the technique of processing and implanting. The technique involves the removal of fat from a donor site, preferably under tumescent anesthesia, and subsequent purification by washing, to preserve the vitality of the adipocytes, finally placing the implant immediately, under local anesthesia. All steps involving manipulation of adipocytes are conducted via Luer-Lok syringes to prevent exposure to air and the risk of oxidation. In unfavorable conditions, the graft can be lost after 4 weeks, while in other cases the correction lasts for years.

We can summarize three surgical steps:

Harvesting: the selected anatomical donor region is anesthetized with Klein solution; the necessary amount of adipose tissue is removed by means of invasive microcannulae with a maximum diameter of 1.5 mm connected to 10 cc Luer-Lok syringes (Fig. 108.2).

Purification: multiple methods are used. We prefer washing with saline solution in LL syringe in order to reduce contact with oxygen and related oxidation of adipocytes, for a total of about ten washes (Fig. 108.3).

Implant: adipose tissue presents as bright yellow, using 1.5 mm diameter cannulae for the implantation, and is implanted in the hypodermis at the base of the scars (Fig. 108.4).

The technique is effective, reproducible, minimally invasive, and free of significant complications as it does not require general anesthesia or sedation, and the improvements in the cutaneous quality are always guaranteed (even in the absence of lasting and satisfactory volumetric changes) thanks to the "staminalization" of the fibrous subcutis typical of acne.

CO_2 Laser-Erbium

The advent of laser surgery has created a true revolution in the treatment and resurfacing of acne scars. The two lasers most used are the

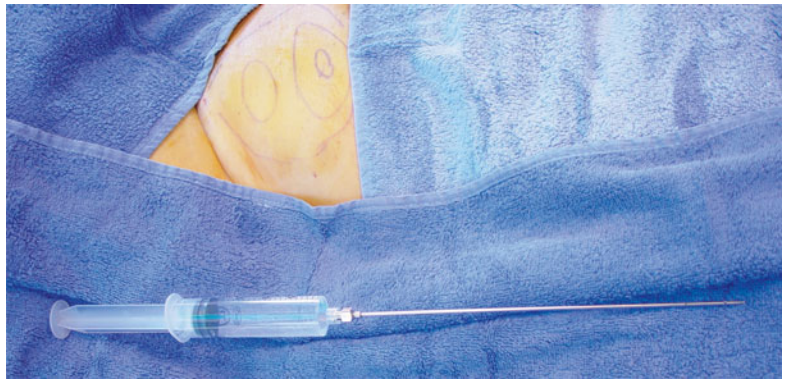

Fig. 108.2 Tumescent anesthesia with syringe and multihole cannula for infiltration

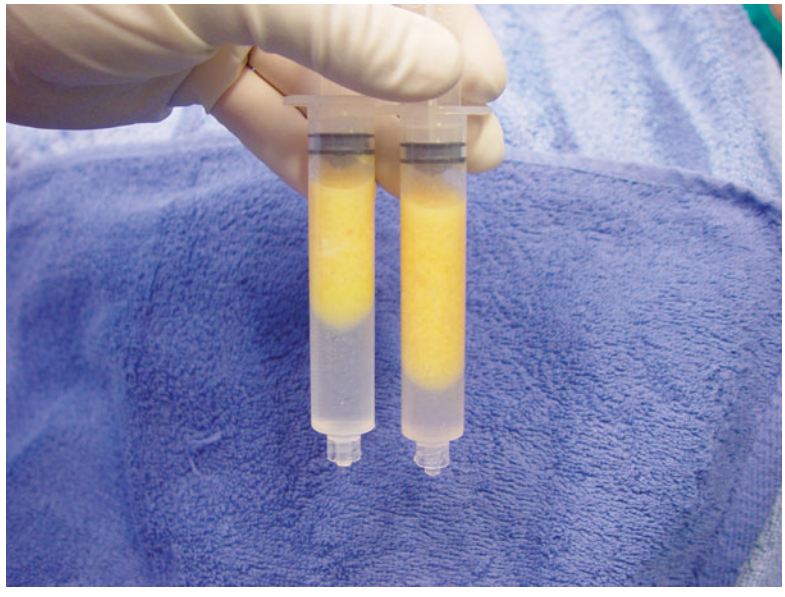

Fig. 108.3 Fat's decanting in FS

Fig. 108.4 Cannula for implant

CO_2 and the Er:YAG. With these lasers, it is possible to evaporate with precision small areas of cutaneous tissue removing only the most superficial layers. The non-fractionated ablative technique was gradually replaced by the fractional modality that exploits the principle of fractional photothermolysis producing microscopic vertical columns of thermal damage separated between them by healthy tissue. Fractionation has notably reduced post-treatment irritation (erythema, swelling) and the risk of side effects such as hyperpigmentation. Fractionation, in turn, can be utilized in the ablative modality that determines various degrees of cutaneous vaporization stimulating healing with the formation of new collagen and elastin or in the non-ablative modality that does not vaporize but heats the skin and thus is better tolerated by the patient. Generally, the ablative technique causes an erythema of variable duration that lasts between 3 and 14 days (1–3 days for non-ablative), and the risk of postinflammatory hyperpigmentation lasts about a month (15 days with non-ablative). The major indications for using the fractionated technique are atrophic scars, while for ice-pick scars surgical excision is preferred, a few weeks following resurfacing. This technique has also proved moderately useful for hypertrophic scars and hyperpigmentation. The laser setting depends on the depth of the scars, generally using only the erbium laser for the more superficial scars, and using the CO_2 alone or in combination with the erbium for medium to deep scarring. The technique, non-fractionated and non-ablative, is decidedly less effective, and its use is limited to very mild acne scars.

Dermabrasion-Microdermabrasion

Dermabrasion is a technique, now obsolete, known since the First World War, that consists of removing with wire brushes or abrasive diamonds the epidermis and the superficial dermis, leaving behind noticeable scars. Furthermore, this technique is contraindicated in subjects with dark skin, black skin, and olive skin which raise the risk of hyperpigmentation. Microdermabrasion is a variant of its predecessor that uses less traumatic instruments; however, it is an extremely operator-dependent procedure, and other techniques have shown greater efficacy and safety.

Treatment of Discoloration

Postinflammatory hyperpigmentation of scars can be treated with bleaching preparations (e.g., undecylenoyl phenylalanine or diacetyl boldine), light skin peeling, or pigmentary laser. Scars with persistent erythema can be treated with a vascular laser (e.g., dye laser) or pulse light. Hypopigmented scars are more difficult to treat although non-ablative fractionated laser has proved quite useful in these situations.

Microsurgery

When performed by experienced personnel, this remains one of the best treatments, using two techniques:

- Punch microsurgery: punches from 0.5 to 2 mm are used, depending on the size of the scars. After local anesthesia, the scars are carried away, and the full-thickness tissue loss is repaired with absorbable 5-0, 6-0 sutures, intradermal nonabsorbable nylon 6-0 sutures, or external 7-0 sutures with nylon. Ideal for treating small ice-pick scars.
- Cold blade microsurgery: classic surgery with local anesthesia and a No. 15 blade. Usually used for extensive scarring and elongated scars for which it is not possible to use punch surgery. Suturing is the same as aforementioned.

Cases

Patient 1: box scars of the face treated with microsurgery and lipofilling, followed by CO_2 laser treatment

Patient 2: acne scars treated with microsurgery (plus nevus) and lipofilling, followed by erbium lasers treatment

Biopsy

109

Eckart Haneke

Key Points

- Histopathology is the most important method in dermatology and requires good biopsy specimens for diagnosis.
- In most European countries, biopsies are daily routine procedures for virtually all dermatologists.
- Poor biopsy specimens hinder the diagnostic process and there are many pitfalls in performing biopsies.

Indications for Biopsy

Each piece of tissue that is removed should be examined histopathologically. However, multiple benign lesions such as acrochordons, seborrhoeic keratoses or mollusca contagiosa may not require histopathology though one representative lesion should be sent for histopathologic examination. The extent of a biopsy is governed by the suspected clinical diagnosis: whereas benign lesions may be partially or sequentially removed, a diagnostic therapeutic excisional biopsy is indicated for malignant lesions such as melanoma.

The most important reasons for biopsy are:

- To make or confirm the diagnosis
- Tumour grading and staging
- Follow-up
- Scientific documentation

Biopsies can be divided according to the

- Instrument used for biopsy
- Depth of biopsy
- Tissue biopsied

Biopsy Techniques

Punch Biopsy

The punch is a cylindrical knife that cuts into the tissue while rotating it on its longitudinal axis with some downward pressure. Disposable punches are commonly used because they are usually sharper and less traumatizing. Punch diameters range from 1 to 8 mm with those of 4 and 6 mm being most often used for diagnostic purposes. They are held vertically on the skin surface and the tissue cylinder is cut out with turning motions under slight pressure. The tissue is then gently lifted, either with a forceps or the tip of an injection needle that has been bent to

90°, and it is cut at the level of the subcutaneous fat. Extreme caution is necessary not to squeeze the tissue specimen as this will give rise to hourglass deformation of the tissue cylinder with crush artefacts of inflammatory and often also neoplastic cells rendering the biopsy more or less useless.

Punch biopsies are not adequate for lesion of or extending into the fat tissue or for bullous lesions as the blister roof will inevitably be sheared off. They are also not indicated when architectural features are necessary components of the lesion. Small punch biopsies may be left for second-intention healing whereas those of 4 mm and more are usually sutured. Monofil suture material, 5-0 or 6-0, gives good cosmetic results. A modified cross-stitch technique with the stitches over the skin running parallel ensures excellent defect closure.

Scalpel Biopsy

The scalpel is the universal instrument for any type of biopsy and virtually all tissues. Most diagnostic biopsies are performed as fusiform or elliptical excisions of tissue. Although many different types of scalpel blades are available, the pointed #11 blade usually gives the best results, especially for smaller biopsies. Its sharp tip is vertically stabbed into the skin and the desired biopsy is sectioned with either a straight cut through the entire skin down to the subcutaneous fat or with gently stabbing motions, carefully avoiding 'carving' motions. Depending on the type of lesion, the biopsy should either include the entire lesion, a representative portion of it from one end to the other, or the margin with both the centre of the lesion and normal surrounding skin. A small drawing showing the lesion, the biopsy and how it is supposed to be cut in the laboratory should accompany the biopsy so that the histopathology lab can see how the biopsy was performed and how it has to be sectioned in order to yield adequate sections for histological diagnosis.

The biopsy defect is usually closed with simple interrupted stitches, 5-0 for most localizations, 6-0 for the face, 7-0 for the eyelids and 4-0 for the scalp, trunk and extremities. Buried sutures using monofil absorbable material give the best cosmetic result. For particularly delicate locations, the suture should be secured with suture strips. Tissue glue is adequate for narrow defects that can be closed without tension. However, scar dehiscence remains a common problem, particularly on the back. Tiny dog-ears may develop when the length-to-width ratio was too small; they are particularly disturbing on convex surfaces in the face.

Electrical Scalpel and Laser Biopsies

Classical electrosurgery with kHz alternating current gives huge margins of heat destruction that are not suitable for histological examination. However, both radiofrequency at around 3.8 MHz and CO_2 laser are much less tissue damaging and may be used in highly vascularized areas. They have the advantage of leaving an almost bloodless field due to the heat generated by these devices. The disadvantages are heat artefacts of the margins of the biopsy specimens and prolonged healing with inferior cosmesis of the biopsy scar.

The suture technique depends on the site, size and depth of the wound, but in many cases, small wounds are left for second-intention healing.

Curette Biopsy

Even though the curette is useful to remove superficial lesions, it is too coarse an instrument for almost all diagnostic biopsies. It yields tissue debris that no longer allows the architecture of the lesion to be evaluated. However, an alternative is the sharp ring scalpel, which allows strips of tissue to be cut superficially from the skin without severe tissue damage.

The resulting defect is left for second-intention healing. Use of a hemostyptic solution or electrocautery to stop the bleeding etches or burns the wound base and excessively prolongs the healing time; often a whitish scar is the result. Application of a thick padded dressing with plenty of ointment to adsorb the blood and avoid sticking to

the wound is therefore recommended. This can be removed after 24 h and only an antibiotic ointment is applied several times a day. It should be continued for several days in order to avoid drying out of the wound. Healing is twice to three times faster with moist wound healing.

Depth of Biopsy

Tangential (Shave) Biopsy

This very superficial biopsy is a simple, inexpensive and time-honouring procedure. It should only be used for very superficial lesions involving the epidermis and papillary dermis. The lesion is slightly raised, either by gently pinching the skin around it or by injecting a sufficient volume of local anaesthetic under it. A #23 scalpel, or for very small lesion #15, is pressed flat on the neighbouring skin and the lesion superficially biopsied or excised with back-and-forth sawing movements parallel to the skin surface. Depending on the size of the scalpel blade, relatively large superficial biopsies can be taken resembling split-thickness skin grafts. The thin specimen is transferred with the scalpel blade upside down onto wet gauze and gently spread. A small piece of filter paper is then pressed on it where it sticks. The perfectly spread specimen is immersed into 4 % formalin solution for fixation. For embedding and sectioning, the specimen is laid between two foam sheets and brought into the cassette.

The wound is left for second-intention healing. We do not favour haemostasis as this delays wound healing.

Tangential biopsies are ideal for seborrhoeic keratoses, actinic keratoses and other lesions sitting on the skin or only affecting the epidermis and papillary dermis. They are not adequate for most inflammatory lesions or those extending into the hair follicles and for most tumours.

Full-Thickness Skin Biopsy

In most instances, a full-thickness skin biopsy including the epidermis, papillary and reticular dermis and superficial subcutaneous fat is the best option. It is indicated for virtually all dermatoses including inflammatory, autoimmune bullous disorders and most skin tumours. The universally useful instrument for these biopsies is the scalpel. Biopsies can be taken from everywhere and in all depth levels needed, including fat, fascia, muscle and other structures. A scalpel biopsy is usually fusiform and does not have to have a wide transverse diameter; rather, when indicating on the report sheet that the biopsy specimen has to be cut lengthwise, a narrow but longer biopsy gives even more information. Marking the specimen can help the laboratory in the orientation of the specimen.

Biopsies of subcutaneous tissue may be taken for the diagnosis of lesions in the hypodermis; whether or not overlying dermis and epidermis are included depends on the specific problem. However, inflammatory diagnoses always require the overlying skin.

Tissue for Biopsy

Scalp

Scalp biopsies are frequently taken for diagnostic purposes. For the diagnosis of alopecias, two punches may be taken resulting in a figure-of-eight defect: One of the punch specimens is cut horizontally at different levels, the other one vertically. Care has to be taken to orient the punch along the axis of the hair follicle. The margins of the figure-of-eight-shaped defect are moved parallel to each other so that a tongue-in-groove picture results. Two stitches keep the wound together yielding a lazy S scar line.

Ear

A biopsy including the cartilage is indicated for the diagnosis of relapsing polychondritis and pseudocysts of the helix. Local anaesthesia is performed in the retroauricular fold and a narrow spindle with underlying cartilage is taken from the back of the pinna. The skin is closed with a running suture without touching the cartilage.

Cartilage only is taken for the treatment of chondrodermatitis nodularis helicis as a subcutaneous chondrectomy via a short incision of the helix margin along its posterior aspect.

Vermilion of the Lip

Vermilion biopsies are indicated for precancers and carcinomas as well as for rare isolated labial involvement of psoriasis and other dermatoses. An incisional biopsy should always be a narrow spindle oriented perpendicular to the mouth opening. Benign and precancerous lesions do not require inclusion of the orbicularis oris muscle, which is, however, necessary for suspected labial carcinoma.

Oral Mucosa

Biopsies of the labial and buccal mucosa are as easy to perform as skin biopsies. However, the common infiltration local anaesthesia causes an instream of plasma into the epithelium with vacuolization of keratinocytes, crescentic deformation of their nuclei as well as intra- and intercellular deposition of immunoglobulins and other proteins. For suspected immunodermatoses, a regional block of the mental or infraorbital nerve should be used if possible. Suture is performed either intramucosally or with soft threads.

Both the hard palate and the attached gingiva are rarely biopsied. The biopsy should be small as suture is usually not possible; the wound may be sealed with dental silicone paste.

Biopsies of the dorsum of the tongue involve both the epithelium and the lingual musculature. A narrow spindle of tissue is excised and the wound sutured without tying the knot too tight.

Minor salivary gland biopsy is a valuable adjunct for the diagnosis of Sjögren's syndrome. After mental block anaesthesia, a 2 cm incision is made between the vermilion and the fornix inferior opposite the second incisor. The wound is gently spread exposing the peppercorn-sized greyish-glossy labial glands. These are separated from the underlying submucosa using blunt-tipped curved scissors. Six to eight glands should be collected. Infiltrates of more than 50 lymphocytes are typical, but epithelial islands are rare in minor salivary glands.

Axilla and Other Apocrine Regions

Inflammatory and tumourous lesions may occur. Biopsy site and size are chosen according to the suspected lesion. Since these are intertriginous regions with maceration due to eccrine sweat and often heavy bacterial and fungal colonization, airtight dressing must be avoided and dry sterile ones reapplied every 24–48 h.

Breast and Nipple

Punch and scalpel biopsies are commonly oriented along the relaxed skin tension lines, but those of the nipple always in radial manner. A vasoconstrictor added to the local anaesthetic agent causes the nipple to contract and is therefore not recommended. A layered suture with fine material is used to prevent scar dehiscence and the patient is asked to wear a tight-fitting sports bra for the next days.

Penis and Scrotum

The glans penis often presents plaque-like red lesions; the differential diagnosis of which can be difficult. Superficial infiltration anaesthesia elevates the lesion and allows for easier separation of the superficial glans skin from the subepithelial connective tissue. The defect is sutured with fine simple stitches.

Prepuce and penile shaft are biopsied like any other skin region.

Biopsies of scrotal lesion should include the epidermis, dermis and tunica dartos. This is a layer very rich in smooth muscle bundles extremely sensitive to pressure from tying a knot tightly.

Vulva

The labia minora are similar to scrotal skin. However, biopsies for suspected malignancies must reach into deeper tissue. A superficial biopsy is not sufficient for the exact diagnosis of Paget's disease.

Lesions of the labia minora are biopsied by removing a full-thickness wedge of tissue and a two-layered suture is used for repair.

Palms and Soles

Both inflammatory and neoplastic lesions occur. For small lesions, a 3–4 mm punch is ideal. If possible the handedness of the patient is respected: e.g. the left palm is chosen for right-handers.

Biopsies for the sole of the foot have to be kept as small as possible. A punch is ideal. Local anaesthesia is commonly very painful and infiltration may have to be started from the side of the foot. The subcutaneous tissue with its elastic cushion function is unique in the human body. Even though the skin appears to be resilient, sutures tend to cut through due to the stress and strain from walking and running.

Nails

Histopathology is the gold standard for the diagnosis of nail diseases. This requires, however, an optimal biopsy. The nail forms a functional unit with the tip of the digit and the distal interphalangeal joint and is made up of four different components: matrix and nail bed, the proximal and two lateral nail folds, the hyponychium and the cuticle, and the nail plate. Understanding the physiology and biology of nail growth is essential for a good nail biopsy.

Lesions of the nail folds are biopsied according to their size and orientation; if Bowen's disease is suspected, a very superficial biopsy is adequate to make the diagnosis. Digital recurrent herpes simplex can be diagnosed from a Tzanck smear or a blister roof biopsy. Pemphigus of the nail usually hides as suppurative chronic paronychia and may be diagnosed by a Tzanck test. For the diagnosis of autoimmune collagen diseases, a crescentic biopsy of the free margin of the proximal nail fold was recommended. For more tissue, a wedge of the proximal nail fold with its base at the free margin may be performed. Nail bed lesions can be biopsied with a 3 or 4 mm punch; whether or not the overlying nail plate is removed prior to biopsy depends on the condition. Usually the nail plate will shear off anyhow so it can be removed facilitating the biopsy procedure. If a scalpel biopsy is taken from the nail bed, the long axis of the spindle must be oriented longitudinally along the direction of the unique nail bed rete ridges. In contrast, a deep matrix biopsy must be oriented in transverse direction in order to prevent longitudinal post-biopsy scar, which would result in a split nail. A matrix punch biopsy must not be wider than 3 mm at maximum.

For the diagnosis of longitudinal melanonychia, a tangential biopsy technique was developed that avoids the risk of post-biopsy nail dystrophy. The proximal nail fold is cut at its both sides, separated from the underlying nail plate and reflected. The nail plate is then gently separated from the matrix at one side, cut transversely between the proximal and middle third just 3 mm beyond the pigmented streak and opened in a trap-door manner exposing the origin of the longitudinal melanonychia. A very shallow incision is carried out around the lesion with an adequate safety margin, usually 3 mm, sometimes more, and the scalpel blade is pressed on the matrix parallel to cut the lesion out tangentially by sawing back-and-forth motions. The thin slice of matrix is laid on wet gauze, transferred to filter paper and immersed into formalin. The nail plate is laid back and fixed with a stitch, and the proximal nail fold is laid back and also fixed with stitches or suture strips. Healing is without nail dystrophy as the biopsy leaves the morphogenetic onychodermis behind allowing for complete restitution of the matrix.

Muscle

Muscle biopsies are performed in dermatology for the diagnosis of dermatomyositis. The most

commonly affected muscle is the triceps. Local anaesthesia is performed for the skin by infiltration of the subcutaneous tissue. The muscle is not directly injected. An incision is made through skin, fat and fascia. Two bites of a suture are made with a sufficiently big needle in a distance of 1.5–2 cm and gently tied. The muscle is carefully isolated between the sutures using blunt-tipped scissors and cut beyond the sutures so that the muscle tissue can be lifted out without touching it with a forceps. It is of utmost importance not to squeeze or otherwise traumatize the tissue as skeletal muscle cells are extremely sensitive. Depending on the preferences of the laboratory, the fixative is chosen; some authors stretch the specimen out by pinning the sutures on a small plate of cork or cardboard.

Artery

Arteritis temporalis is the classical indication for an arterial biopsy in dermatology; it may even be curative in the sense that it prevents extension of the disease. The artery is usually palpable as a hard string. The skin is incised over it; the artery dissected with enough periarterial tissue around it, ligated on both sides of the artery biopsy; and the interior part is taken for histopathology. Sometimes there is a diffuse erythematous swelling not permitting the artery to be palpated. Then a deep biopsy is taken at its supposed localization; as the artery is occluded, there is no risk of excessive bleeding.

Occasionally, a venous biopsy is taken. Again, the vein is ligated proximally and distally and then a 1 cm long piece is biopsied.

Nerve

The classical nerve biopsy site is the sural nerve. This is infrequently done in dermatology as many skin biopsies contain enough nerves to make the diagnosis of some disorders. Sural nerve biopsy is an invasive procedure performed in the operating room, and it carries potential risks such as pain and permanent sensory loss distal to the biopsy site. In fact, punch biopsies of the skin are recommended for the diagnosis of neuropathies by neuropathologists. The density of small fibres can be measured easily in skin sections immunostained with antibodies against markers expressed by peripheral nerve fibres, such as protein gene product 9.5, microtubules and neuropeptides.

Testicle

In some countries, andrology and male fertility diagnostics are part of dermatology. Although spermiogrammes give a lot of information, azoospermia, such as in the Sertoli cell-only syndrome, requires confirmation by a testicular biopsy. The scrotum is anaesthetized next to the raphe scroti and an incision is made through the scrotal skin, then the other deeper layers which are individualized and clamped as they will have to be sutured individually. The testicle is identified by its smooth and shining surface. A small spindle is taken, about 10–15 mm long, 5 mm wide and 10 mm deep. The tissue is very fragile and has to be handled with utmost care. Fixation is with Carnoy's or other solutions allowing better tissue conservation and details than formalin. The testicle is sutured with catgut as the other deeper layers, and a skin sutured completes the procedure. The patient gets a light dressing and a suspensory; the testicles are laid on a small cushion for about 24 h.

Conclusion

Biopsies are indispensable procedures in dermatology. Most techniques are easy to perform and yield a wealth of information not matched with any other technique. Histopathology, immunofluorescence, immunohistochemistry, cultures and polymerase chain reaction from biopsy material as well as many other sophisticated techniques allow most diagnoses to be made with certainty.

Botulinum Toxin in Aesthetic Medicine

110

Barbara Boone and Koen De Boulle

Key Points

- Thanks to its proven efficacy and favourable safety profile, the injection of botulinum toxin (BT) is rapidly gaining popularity in the field of aesthetic medicine.
- Although BT is FDA approved only for the treatment of vertical glabellar lines, hyperkinetic facial lines and primary axillary hyperhidrosis, off-label use in the approach of dynamic wrinkling and sculpting of the face is widespread.
- There are different BT products on the market each with their specific characteristics.
- A thorough history and clinical examination should be performed before treatment in order to identify contraindications and to adjust the patient's expectations which are sometimes too high.
- The patient should be well informed about possible risks and side effects.
- A correct treatment procedure demands a thorough knowledge of the product used, human anatomy and the injection technique. Despite this knowledge one should always be aware of possible complications and have the know-how to handle them.
- This review aims at giving a better insight in the responsible use of BT as a minimal invasive technique in aesthetic medicine.

General Principles

During the eighteenth century, consumption of improperly preserved or stored meat and blood sausages gave rise to botulism with general muscle paralysis and many deaths in Germany. Justinus Kerner was the first to link these cases to the presence of a toxin or poison in the sausages in anaerobic conditions. He concluded that the toxin acts on the motor nerves and the autonomic nervous system and that it is strong and lethal even in small doses.

On December 14, 1885, a large outbreak of botulism occurred in Ellezelles (Belgium) after the meal of pickled and smoked ham during a funeral ceremony. Different guests noticed symptoms as mydriasis, diplopia, dysphagia and dysarthria followed by increased muscle paralysis. Three persons died. Emile Pierre Marie Van

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_110, © Springer-Verlag Berlin Heidelberg 2015

Ermengem, Professor of Microbiology at the Ghent University, isolated an unknown bacterium in the ham and the corpses of the victims and called it *Bacillus botulinus* (botulinus = intestine, sausage).

During the first decades of the 1900s, it was discovered that seven different strains of *Bacillus botulinus* exist. They each produce their specific neurotoxin serotype (A, B, C1, D, E, F, and G). In 1949 Burgen discovered that BT blocked the release of acetylcholine at neuromuscular junctions.

During World Wars I and II, BT was known as a potential lethal biological weapon.

In 1946 Schantz produced the first batch of toxin which was the basis for the later clinical production. During the 1970s, Alan Scott, an ophthalmologist from San Francisco, used BT serotype A in the treatment of strabismus and blepharospasm. In 1989 BT, as manufactured by Schantz, was approved by the FDA in the use of strabismus, hemifacial spasm and blepharospasm. Later, the FDA has approved other BT drugs and of a broader range of BT treatment indications.

In 1992 Carruthers JD and Carruthers JA published the first reports regarding improvement of glabellar frown lines in patients treated with BT because of blepharospasm. Since 2002 BT is FDA approved for the treatment of these glabellar frown lines.

In 1994 Khalaf Bushara showed BT to inhibit sweat production. In 2004 the FDA approved BT in the treatment of idiopathic axillary hyperhidrosis.

Currently clinical indications for BT are still expanding and the off-label use of the drug is widespread.

Mechanisms of Action: Pathophysiology and Pharmacokinetics

BT is synthesised by the bacterium *Clostridium botulinum*. There are seven different serotypes (A, B, C1, D, E, F, and G). Only serotype A and B are used for clinical implications because their effect lasts longer in comparison to the other serotypes. BT is a very lethal substance with an LD_{50} (= lethal dose, dose causing death in 50 % of a mouse population after intraperitoneal injection) ranging between 0.1 and 1 ng/kg body weight.

The neurotoxin is initially synthesised as a precursor protein and consists of one chain with a molecular weight of 150 kDa. Then the protein undergoes post-translational, activating changes. Specific proteolytic activity, also called 'nicking', causes the formation of a light (50 kDa) and a heavy (100 kDa) chain which are interconnected by a strongly conserved disulphide bridge. This neurotoxin is non-covalently bound to non-toxic haemagglutinins, which impart stability and thereby prevent degradation. Also these non-toxic proteins would potentiate the biological activity of the neurotoxin.

BT exerts its effect via inhibition of exocytosis of the neurotransmitter acetylcholine at the cholinergic nerve ends. Under normal circumstances, release of acetylcholine in the synaptic cleft causes activation of the target cells amongst which the striated and smooth muscle cells as the eccrine sweat glands. Striated muscles are innervated by cholinergic neuromotoric nerves, whereas eccrine sweat glands (involved in the process of hyperhidrosis) are innervated by post-ganglionic cholinergic sympathetic nerves.

Acetylcholine is present in vesicles at the cholinergic nerve terminals. Fusion of the vesicles with the cellular membrane of the nerve terminal is achieved via three different SNARE (soluble N-ethylmaleimide-sensitivity factor attachment receptor) proteins and causes the release of acetylcholine.

BT diffuses through systemic circulation towards the presynaptic membrane. There the heavy chain portion of the molecule binds to the cell membrane of the motor nerve via an unidentified high-affinity acceptor molecule. Internalisation of the toxin occurs as the protein passes through the cell membrane of the motor nerve and into its cytoplasm through endocytosis. By high acidity in the endosome, the toxin undergoes conformational changes causing translocation of the light chain towards the cytosol. The light chain with its very strong zinc-dependent

endopeptidase activity then binds with high specificity to three different SNARE protein complexes. BT serotype A and E cleave the synaptic vesicle protein SV2 of SNAP-25 (synaptosomal-associated protein of 25 kDa); BT serotype B, D, F and G cleave synaptotagmin I and II of VAMP (vesicle-associated membrane protein); and BT serotype C cleaves both syntaxins as SNAP-25. This cleavage procedure enables vesicles containing acetylcholine to attach to the cell membrane.

Recently it has been observed that BT not only inhibits the release of acetylcholine but also influences the release of other neurotransmitters as noradrenaline, dopamine, serotonin, ATP and glutamate.

The clinical effect of BT starts 2–3 days after injection and reaches its maximal point at 5–6 weeks. This effect is only temporary. Previous nerve-impulse activity is restored over the course of several months. This phase consists of nerve sprouting and reestablishment of the original nerve connection. The duration of the effect of BT is not determined by its molecular target (cleaved SNARE proteins are degraded with a half-life of 1–2 days) but by its intrinsic proteolytic activity. This activity differs between the different BT serotypes. Serotype A has the longest duration of action. During nerve sprouting, new nerve endings emerge and connect to the neuromuscular junction after the original nerve ending is blocked. Eventually the new nerve sprouts retract and the original nerve ending regains its function. Clinical findings suggest the process of nerve sprouting would not take place at the level of the eccrine sweat glands, since the effect goes up to 6–12 months. An additional difference between both target organs is the fact that BT causes muscles to atrophy, whereas eccrine sweat glands do not undergo structural changes. This observation explains why the interval of administration can be extended when treating muscles but not when treating eccrine sweat glands.

Classical kinetic and distribution studies cannot be performed with BT since the applied dosages are extremely low and the molecule is quickly and irreversibly bound to the cholinergic nerve endings. Allergan has performed distribution studies in animals with Botox® and Vistabel®. They show a slow muscular diffusion of ^{125}I- BT serotype A, followed by a rapid systemic metabolisation and urinary excretion. Radioactivity is bound to large protein molecules at the injection site, whereas it is bound to small protein molecules in the plasma. Sixty percent of the radioactivity is excreted within 24 h. The toxin is probably metabolised by proteases and the molecular components are recycled by the classical metabolic pathways.

In conclusion BT is not expected to be present in the peripheral blood at measurable levels following intramuscular or intradermal injection at the recommended doses. The recommended quantities of neurotoxin administered at each treatment session are not expected to result in systemic, overt distant clinical effects as muscle weakness in patients without other neuromuscular dysfunction. However, subclinical systemic effects have been shown by single-fibre electromyography after intramuscular doses of BT appropriate to produce clinically observable local muscle weakness.

Pharmacology of BT

Several BT products are widely available. They differ in composition, serotype, concentration, toxin complex size, molecular weight, target protein, biological activity, risk of antigenicity, pH, storage, indication of use and geographic distribution. The most commonly used BT products for facial aesthetics are Botox®, Dysport® (Azzalure®) and Xeomin® (Bocouture®). Other BT products are available in select geographic regions: Korean Neuronox® is approved for cosmetic indications in different countries, as is the Chinese Lanzhou BT, in South America and some other countries under the name Prosigne®. New BT drugs are under development at Tokushima University (Japan) (PureTox®) and at the Mentor Corporation (USA) (see Table 110.1).

Some of the clinically relevant properties of the different commercially available BT products are commented below.

Molecular Composition

BT drugs consist of the BT component and excipients. Excipients include lactose, sucrose, gelatine, dextran or serum albumin for stabilisation purposes and buffer systems for pH calibration.

The BT component is formed by botulinum neurotoxin (BNT) and by non-toxic proteins also known as complexing proteins. BNT consists of a heavy amino acid chain with a molecular weight of 100 kDa and a light amino acid chain with a molecular weight of 50 kDa. Both chains are interconnected by a single disulphide bridge. The non-toxic proteins are divided according to the presence or absence of haemagglutinating properties.

BNT and complexing proteins form BT with a molecular weight of 450 kDa. Two BT molecules associate to a dimer with a molecular weight of 900 kDa. In incobotulinum (Xeomin®/ Bocouture®) and PureTox®, the complexing proteins could be removed during the manufacturing process so that the products contain isolated monomeric BNT only. These differences in molecular weight lead towards a different range of spread of the toxin in the tissue after injection. Botox® is the largest BT molecule with a low risk of migration beyond the target tissue and a highly predictable result as a consequence. On the other hand, 'pure' neurotoxin would have a lower risk of immunogenicity (see below).

The use of different excipients in different BT products also has clinical implications. Due to a low pH, injection with rimabotulinum is painful. The Chinese Hengli® BT contains bovine gelatine, leading to a higher risk of the development of allergic reactions and spongiform encephalopathy.

Serotype

Only BT serotype A and B are used for therapeutic purposes. As for the cosmetic indications, BT serotype B is not approved and thus used to a much lesser degree than serotype A. There are some major differences between both serotypes. The target molecules of serotype A and B are SNAP-25 and VAMP respectively. Serotype A has a longer duration of action than serotype B. Serotype A exerts a stronger effect on the skeletal muscles than serotype B. The risk of systemic spread with autonomic side effects is much larger with serotype B compared to serotype A.

Biological Activity, Antigenicity and Immunological Quality

The biological activity of BT is given in mouse units (MU). One mouse unit describes the amount of BT which would kill 50 % of a BT-intoxicated mouse population (= lethal dose 50 or LD_{50}). Although mouse units are defined by international convention, the activity assays used by the manufacturers are performed differently so that the activity labelling of the different BT drugs cannot be compared directly. One mouse unit of onabotulinum is equivalent to approximately 3 MU of abobotulinum. The activity of onabotulinum and incobotulinum would be identical; however recent research suggests the activity of onabotulinum to be higher. The potency labelling of different BT serotypes can also not be compared directly. The motor effect of onabotulinum and rimabotulinum seem to be comparable on a 1:40 ratio. For treatment of autonomic disorders, this conversion ratio is different since BT serotype B has relatively stronger autonomic and relatively weaker motor effect as compared to BT serotype A. A new assessment modality for onabotulinum toxin, the cell-based potency assay (CBPA), reduces the need for animal testing substantially (by 95 % over next 3 years) and has been applauded by animal rights advocacy groups. CBPA for onabotulinum toxin uses a specific cell line that can evaluate all four phases of botulinum toxin action: binding, internalisation, translocation and SNAP-25 cleavage. This method is sensitive to measure the complex mechanism of action in very small quantities of neurotoxin and has been successfully cross-validated with the LD50 assay. Also this is suitable for use in a high-capacity and in a highly quality-controlled environment. In 2011 this assessment method has been approved by the FDA for the USA, Canada and Switzerland and

has at the same moment been filed with the relevant health authorities in the European Union.

Since BT drugs are foreign proteins, the human immune system may respond to them with the formation of antibodies. These antibodies can be directed against the 150 kDa neurotoxin, the non-toxic complexing proteins or both. Antibodies against the non-toxic proteins are described in 40–60 % of treated patients. They do not influence the neurotoxin activity and are referred to as non-neutralising antibodies. However, when antibodies are formed against the neurotoxin itself, they block its pharmacological effect, and they are termed neutralising or blocking antibodies.

The risk of antibody formation is proportional to the amount of antigen presented to the immune system. The total amount of bacterial protein and neurotoxin content in 100 MU onabotulinum, abobotulinum and incobotulinum is 5 ng, 0.87 ng and 0.44 ng respectively. By means of sensitive ELISA technique, it was found that 100 MU of onabotulinum, abobotulinum and incobotulinum contain 0.73 ng (15 % of total protein content), 0.65 ng (75 % of total protein content) and 0.44 ng (100 % of total protein content) of neurotoxin, respectively. Although the formation of non-neutralising antibodies would not lead to therapeutic failure, the presence of complexing proteins potentially increases the immunogenic risk of neutralising antibody formation. Therefore, it has been proposed that reducing the foreign protein load of BT by removal of the complexing proteins would help to reduce the formation of neutralising antibodies, without affecting therapeutic efficacy. The use of purified neurotoxin preparations (e.g. incobotulinum) could potentially reduce the rate of secondary treatment failure.

Based on the data mentioned above, calculations show the highest specific neurotoxin activity in incobotulinum (227 MU/ng) followed by abobotulinum (154 MU/ng) and onabotulinum (137 MU/ng). As incobotulinum and onabotulinum would have the same biological activity, these findings suggest that some of the 150 kDa neurotoxin is likely to be inactive. When BT is manufactured and stored, conformational changes can inactivate it. This additional amount of inactivated neurotoxin or 'toxoid' may increase the production of neutralising antibodies and the risk of therapeutic failure. Besides the process of inactivation, also the presence of non-activated or 'unnicked' neurotoxin influences antibody formation. Before BT exerts its function, it must be activated or 'nicked' to form the dichain moiety (light chain linked to a heavy chain by a disulphide bond). Some of the serotypes (e.g. A and F) are inherently activated and nicked by proteases endogenous to the bacterial strain by which they are produced, whereas others (e.g. B and E) are activated by exogenous proteases like trypsin after secretion by *Clostridium botulinum*. BT serotype A is recovered from cultures more than 95 % nicked. Therapeutic BT preparations are often subjected to a step designed to increase the percentage of nicked neurotoxin during the production process, since unnicked neurotoxin increases the risk of formation of neutralising antibodies. Moreover unnicked neurotoxin may also compete with nicked neurotoxin for binding sites, resulting in a reduced clinical effect.

The amount of inactive BNT determines the immunological quality of a BT drug. When the immunological quality is high, the amount of inactive BNT is low, the biological activity is high and the antigenicity is low. When the immunological quality is low, the drug has low biological activity, resulting in high antigenicity. The relationship between biological activity (MU) and the amount of BNT (ng) is called the specific biological activity which serves as a parameter for the immunological quality of BT drugs. As shown in Table 110.1, the specific biological activity varies substantially between different therapeutic preparations.

Indications and Other Uses

BT is a strong therapeutic agent with various indications. In 1989 Botox® was FDA approved for the treatment of strabismus, blepharospasm and hemifacial spasm. Afterwards FDA approval was obtained for different BT drugs and the following indications: treatment of

persistent muscle spasms in neck and shoulders, persistent muscle spasms in the wrist and hand of patients who have suffered a stroke, foot deformity in children of 2 years or older caused by persistent muscle spasms in the legs due to cerebral palsy, leakage of urine due to bladder problems associated with spinal cord injury or multiple sclerosis, chronic migraine, glabellar frown lines and hyperkinetic facial lines and excessive sweating of the armpits. Moreover, its off-label use in the treatment of hyperfunctional larynx, temporomandibular disorders (bruxism), gastrointestinal disorders (chronic anal fissure, achalasia), tremors and tics, sialorrhoea and benign prostate hypertrophy is widespread (see Table 110.1).

Today Botox®/Vistabel® is approved for the treatment of glabellar frown lines and hyperkinetic facial or upper facial lines in 76 and 19 countries respectively. Dysport®/Azzalure®/Reloxin® and Xeomin®/Bocouture® are approved for glabellar frown lines in 42 and 14 countries respectively. As for cosmetic indications, BT is also used for brow lifting, treatment of brow ptosis, bunny lines, perioral wrinkling, marionette lines, gingival smile, mental crease, dimpled chin, platysmal bands, reducing columellar show, reducing lateral oblique forehead lines (formerly called sleeping lines) and mandibular contouring.

Contraindications

Patients treated with BT should be selected carefully. During the intake consultation, the following issues should be addressed.

Allergies

Patients with a known hypersensitivity to BT or any of the other ingredients of BT drug (e.g. albumin) should not be treated. Patients with a known bee and wasp venom allergy have a higher risk of the development of neutralising antibodies against BT with a therapeutic failure as a consequence.

Neuromuscular Disorders

Caution is required when using BT in patients with pre-existing pareses as in amyotrophic lateral sclerosis, myopathies and motor polyneuropathies or in patients with impaired neuromuscular transmission, such as myasthenia gravis and Lambert–Eaton syndrome, since this can potentiate muscle weakness. Moreover the risk of developing clinically significant systemic side effect as dysphagia and breathing problems is higher in this patient population.

Medication

Medicines influencing the cholinergic signalling process can alter the effect of BT. Different antibiotics (aminoglycoside, spectinomycin, lincosamide, polymyxin), anticholinesterases, neuromuscular inhibitors (succinylcholine, tubocurarine derivates, muscle relaxants), kinin and magnesium sulphate potentiate the effect of BT with a theoretically increased risk of pareses as a consequence. Whether these interactions are relevant in a therapeutic situation remains open.

4-Aminoquinolines (chloroquine) diminish the effect of BT.

Pregnancy and Breastfeeding

No data are available concerning the effects of the use of BT in humans on fertility or foetal development. Animal studies suggest reproductive toxicity. The use of BT during pregnancy is contraindicated as a precautionary measure until further experience is gained. It is not known whether BT is excreted in human milk or whether it has any effect on the infant's nervous system. Therefore it is advised not to treat during lactation.

Infection and Inflammation

Infectious (e.g. herpes, impetigo, tinea) or inflammatory (e.g. eczema, psoriasis, acne) diseases at the injection site should be adequately treated before injecting BT.

Bleeding Diathesis

The risk of ecchymoses, haematomas and bleeding is higher in patients with an elevated bleeding tendency due to illness (e.g. thrombocytopenia, haemophilia) or medication (anticoagulants and antiaggregants).

Breathing and Swallowing Problems

High-dose BT can induce diffuse muscle weakness with breathing and swallowing problems as a consequence. Therefore, one should be careful when treating patients with known breathing (e.g. asthma, COPD) or swallowing difficulties.

Side Effects

The occurrence of side effects of BT is dependent on the dose administered, the treatment location and the product that has been used. An abundance of evidence has found the approved formulations of BT medicines to be exceedingly safe, particularly at the very low doses used for facial aesthetics. Most importantly, when used for aesthetic indications, all adverse events that do occur are reversible, with no long-term sequelae. *Reactions at the injection site* (pain, erythematous papule, haematoma, crust) and *headache* can occur during the first hours after injection and are considered to be caused by the injection technique rather than by the toxin. Limited *muscle weakness and ptosis* can be observed 1 week after treatment with a spontaneous recovery after 2–4 weeks. This side effect is caused by diffusion of the product to the adjacent muscles. Since onabotulinum has a larger molecular structure than abobotulinum and incobotulinum, the risk on diffusion is lower. Ptosis of the upper eyelid is a known side effect after treatment of dynamic forehead wrinkles with BT and results from migration of the toxin to the levator palpebrae superioris muscle. A therapy recommended to treat ptosis from administration of BT is the use of apraclonidine 0.5 %, which is an alpha2-adrenergic agonist causing Müller muscles to contract, quickly elevating the upper eyelid 1–3 mm. Analogously, muscle weakness in the upper arm can occur after injection of BT because of axillary hyperhidrosis. Another similar phenomenon is the development of dysphagia following BT injections in the sternocleidomastoid muscle in the treatment of cervical dystonia, causing diffusion of the toxin to the oesophagus muscles with swallowing problems as a consequence.

When treating primary axillary hyperhidrosis, *compensatory sweating* beyond the axillary region is reported in 4.5 % of patients within 1 month after treatment. No anatomical distribution pattern can be observed. In 30 % of affected patients, the problem spontaneously disappears within 4 months.

Allergic reactions as urticaria, serum sickness or anaphylaxis after treatment with BT are extremely rare.

Systemic adverse effects are adverse effects in tissues distant from the injection site and based upon BT transport within the blood circulation. These effects only occur when very high doses of BT are administered.

Systemic side effects can be motoric and/or autonomic. High doses of BT serotype A mainly cause motor adverse effects (dysphonia, dysarthria, breathing difficulties, dysphagia), whereas high doses (4,000 MU) of BT serotype B in addition can give rise to autonomic adverse effects (xerostomia, xerophthalmia, accommodation difficulties, irritation of nasal or genital mucosae, urinary incontinence, constipation).

Once systemic symptoms are observed, hospitalisation of the patient is required. Indeed systemic affection can be slowly progressive and very persistent. Meticulous supportive care is necessary. A rising pCO_2 signals alveolar hypoventilation and requires endotracheal intubation to maintain airway patency. Administration of antitoxin is advised; however this antitoxin cannot affect BT polypeptides that have already entered cells. Functional recovery may take several weeks to months and occurs once the neurotoxin is excreted or metabolised.

Although BT can produce indirect *central nerve system* effects, direct ones beyond the alpha

motorneuron have not been described after intramuscular injection. BT remains predominantly concentrated at the presynaptic nerve ending of the neuromuscular junction. Only a small portion is transported centripetally by retrograde axonal transport. This transport is so slow that BT is inactivated by the time it reaches the central nervous system. Retrograde transsynaptic passage of active BT in the central nervous system has not been described. Affection of the central nerve system via transport through the blood–brain barrier is excluded due to BT's molecular size.

However, BT can exert an indirect effect on the central nervous system by modulating the sensory input with secondary reorganisation of the intracortical exciting and inhibiting motor neurons. This effect can explain the effectiveness of BT in the treatment of chronic pain syndromes as migraine.

As mentioned above, the development of *neutralising antibodies* against BNT can lead towards *therapeutic failure*. This risk is facilitated by administration of high doses of BT per treatment session and the presence of non-toxic complexing proteins and non-active neurotoxin. Also exogenous factors as lectins (agglutinin, phytohaemagglutinin, concanavalin, cholera toxin, wasp venom) can stimulate the immune response against BNT.

Studies show the antigenic epitopes of BNT to be localised at the H_c fragment of the heavy chain of the molecule. The antigenic epitopes are analogous in the different BNT serotypes. If neutralising antibody production is suspected because the clinical effects of botulinum toxin decline, biochemical and/or functional tests can be employed to detect antibodies against BNT.

Attempts to overcome the effects of antibody-induced treatment failure have limited success. Once neutralising antibodies are present one BNT serotype, switching to another is unlikely to produce a clinical response because immunoresistance to the second serotype will develop swiftly. The antigenic epitopes of BNT are highly conserved with cross reactivity as a consequence. Also administration of massive doses of BT cannot overcome antibody-induced treatment failure as it exacerbates the problem because the antibody response will increase when the antigen dose is increased. Several studies show anti-BNT antibody titres to decline during time. However, with reintroduction of the toxin, the immune system is activated again, leading to the formation of new antibodies. Thus a temporary pause in the administration of BT injections to overcome the problem of antibody formation is not useful. Depletion of anti-neurotoxin antibodies by means of plasmapheresis and administration of intravenous immunoglobulins or immunosuppressant drugs is mentioned sporadically with variable results.

Since the approach of the presence of neutralising antibodies is difficult, prevention of the formation of these antibodies should be emphasised. It is important to keep the BT dose per treatment as low as possible and to make the interval between different treatment sessions as long as possible. Treatment with BT serotype B more often leads to the formation of neutralising antibodies than treatment with BT serotype A. This could be explained by the large administration doses of BT serotype B and by the fact that BT serotype B preparations contain up to 25 % non-activated BNT with a lower immunological quality and a higher immunogenic capacity as a consequence.

Fortunately the problem of therapeutic failure due to the presence of neutralising antibodies rarely occurs in the treatment with BT for aesthetic indications, since the doses and administration frequency are low. In addition it has been shown that the presence of neutralising antibodies not always leads to a diminishing clinical effect.

Most BT preparations contain human serum albumin. This is a derivate of human blood. Theoretically *transmission of known and unknown pathogens* cannot be excluded. In order to prevent infections, donors are carefully selected and screened for infectious markers. In addition BT preparations undergo several production steps in order to inactivate and eliminate viruses. Until now no reports on viral transmission after treatment with albumin-containing medications produced following the specifications of the European Pharmacopoeia have been reported.

Clinical Practice

Aesthetic Counselling and Considerations

A thorough anamnesis and clinical investigation should be performed before treatment with BT.

An accurate medical history can uncover potential contraindications for treatment. Prior to treatment, the procedure, its potential complications and the large variability of effects among patients must be explained to the patient. In-depth questioning of the patients must be conducted to clarify patient's treatment goals. The patient should be well informed about the temporary effect of the treatment. Also it should be explained that wrinkling is due not only to muscle activity but also to a loss of elasticity and volume and to the influence of gravity. Since BT only causes relaxation of the muscles, sometimes it is not sufficient in the treatment of wrinkling and should be combined with other anti-ageing techniques such as fillers and peels. Patients who present with severe, deep wrinkles may have unrealistic expectations as to the outcome of BT treatment. Clinicians can help avert dissatisfaction by setting overall aesthetic goals with patients, developing an overall treatment plan and establishing realistic expectations for the outcome.

It is mandatory to take photographs of the face at rest and in contraction prior to the first injection and preferably at each injection session. It is advisable to schedule a 2-week follow-up appointment especially for first-time patients who need to be photographed and evaluated.

In many countries it is mandatory to obtain a written informed consent from the patient and to clearly mention all the given clinical and product information in the patient's medical file.

Aesthetic planning involves understanding and assessing the patient's desires and preferences in the context of an overall treatment plan. The evolving emphasis on facial shaping and enhancement argues against treating any one area in isolation, without regard to its effect on other areas.

Prior to BT treatment of axillary primary hyperhidrosis, a Minor starch-iodine sweat test should be performed. An iodine solution is applied to the skin and allowed to air-dry. Once dry, the area is dusted with potato flour. Then sweating is encouraged. When sweat reaches the surface of the skin, the starch and iodine combine, causing a colour change from yellow to dark blue, allowing sweat production to be actively visualised. Although the treatment area usually locates at the hairy zone of the axilla, a sweat test should be performed to discover ectopic areas of sweat glands and also to trace differences in sweating intensity so that the distribution of BT injection volumes can be adapted to the intensity of sweating.

Pre- and Post-procedural Considerations

All available BT serotype A drugs are supplied in a vial containing powder. Different available BT drugs have different storage conditions. Ona- and abobotulinum should be stored at low temperature, whereas incobotulinum can be stored at room temperature, which might be an advantage (see Table 110.1). Reconstitution of the drug should be performed with 0.9 % non-preserved saline. The dilution differs according to the BT drugs used and the number of units to be injected. Preserved saline can also be used to reconstitute the vial. The presence of benzyl alcohol renders the injections almost pain free due to its anaesthetic properties known since 1946. Benzyl alcohol works through an increase in cell membrane lipid fluidity. One should only be aware in fragrance-sensitive patients for potential cross-allergic reactions, with flares of contact dermatitis.

It is recommended to avoid agitation and foam during reconstitution since there would be a risk of loss of BT biological activity. When reconstituting incobotulinum, the vial should softly be turned around to avoid the toxin to adhere to the glass wall due to the absence of complexing proteins.

Before injection the solution should be carefully inspected: only a clear, colourless solution without floating particles can be injected.

Reconstituted vials should be used within 4 h after reconstitution. Clinical experience and published data suggest that potency can be maintained for up to 6 weeks with proper storage at 2–8°.

The number of units to be injected depends on the specific region of treatment but also on muscle mass, skin thickness and texture. Muscle mass is influenced by gender and individual variation. Generally the muscles of men are greater in mass and require higher doses of BT. Skin thickness may influence the injection technique and the required doses. In general thicker skin requires higher doses of BT.

Before injection with BT, the treatment area should be thoroughly disinfected with non-alcoholic disinfectants since alcohol inactivates BNT. For the injection, plastic single-use syringes are recommended. A 30-gauge needle is standard, but several practitioners report reduction of pain with the use of a 32-gauge needle. Also the use of ice packs or topical anaesthetic cream can reduce the discomfort associated with the injections.

Patients should be advised to avoid the intake of medications that inhibit clotting such as vitamin E, aspirin and nonsteroidal anti-inflammatory drugs for a period of 10–14 days before treatment.

During BT treatment, patients should be placed in a comfortable position, ideally with their head supported. An upright or slightly reclined position is ideal for cosmetic injections. For the treatment of axillary sweating, patients should lie down with both their arms crossed behind the head.

After BT injections patients should not massage or rub the treatment area and should avoid pressure on the injected zone. Patients should be advised to contract the injected area for approximately 2 h in order to expedite uptake of the toxin. Limiting activity and heat exposure may reduce unwanted diffusion of the toxin; however these recommendations are not based on documented physiological observations or data.

In assessing response to a starting treatment, it is recommended seeing patients at 14 days after treatment. At that time adjustments of dosing or touch-ups can be made. When this assessment is not necessary, the typical interval for retreatment of wrinkles or axillary hyperhidrosis is 3–4 months or 6–12 months respectively.

Specific Treatment Areas, Treatment Regime and Dosage

Different panels of experts have already developed consensual guidelines for treating the ageing face with BT. Here you find a compact overview of the most frequently treated zones and applied techniques. Doses given are for ona- and incobotulinum; approximate dosages for abobotulinum can be determined using a 2.5:1 to 3.0:1 conversion ratio. For more detailed information, we refer to the written consensus recommendations (Carruthers et al. 2004, Raspaldo et al. 2011a, b, Lorenc et al. 2013).

Vertical Glabellar Frown Lines

The musculature of the glabellar complex, responsible for the vertical frown lines, is the most common site for BT injections. Target muscles for treatment are the corrugator supercilii, the procerus and the depressor supercilii which all have the function of brow depression. In order to study the musculature and identify the injection sites, the patient should frown. Usually five to seven injection points are used: one to two points in the centre of the glabella and two points bilaterally at the medial portion of the corrugator supercilii muscle. In order to avoid eyelid and/or brow ptosis, BT should be injected 5–10 mm above the orbital rim and medial of the mid-pupillary line. Injections are given more superficially at the tail of the corrugator or at the subdermal insertion points and somewhat deeper (intramuscularly) at the more medial body of the corrugator muscles based on frown pattern. The recommended total treatment dose of onabotulinum for the glabellar region is 20 MU. However, total doses up to 80 MU have been described, depending of muscular mass (see Fig. 110.1).

Fig. 110.1 BT treatment of glabellar frown lines

Fig. 110.2 BT in crow's feet: evolution after single treatment over time

Horizontal Forehead Lines

Horizontal forehead lines are caused by the activity of the frontalis muscle, which is the only levator muscle of the upper face elevating the eyebrows and the skin of the forehead. There is a considerable interindividual variation in structural features of the frontalis. This variation plays an important role in the treatment plan. To avoid lowering of the (eye)brows, injections should start 1–2 cm above the orbital rim and inside the segment delimited by the mid-pupillary vertical lines and doses should be low. Usually 1–2 MU onabotulinum per injection point and 8–12 injections sites are advised. The pattern of injection and doses needed will vary depending on the height of the forehead, the volume of the muscle and the placement of the eyebrows at rest. The injections should be given in the hypodermis, avoiding bone contact. It is strongly recommended to associate treatment of the horizontal forehead lines with treatment of the glabellar region in order to obtain a harmonious balance between elevator and depressor muscles. Frontalis muscles can extend laterally and if not treated this can induce a 'Mephisto look'. This peaked brow can be brought down by the injection of 1–2 MU onabotulinum in the lateral temporal part of the frontalis muscle.

Crow's Feet Lines

The wrinkles at the lateral canthus are caused by contraction of the lateral portion of the orbicularis oculi muscle and to a lesser degree the zygomaticus muscles. As with horizontal forehead lines, lower doses are preferable. Typically two to four injection points are required with a starting dose of 6–12 MU onabotulinum per canthus. The injections should be given very superficial with avoidance of hitting one of the many small superficial vessels in the area. They should be kept well laterally, approximately 1–1.5 cm from the orbital rim, and the needle should be oriented away from the orbit. Also injections should stay above the zygomatic arch to avoid lip and cheek ptosis (see Fig. 110.2).

Lower Eyelid

A prominent bulge and wrinkling of the lower eyelid is partially caused by the pretarsal portion of the orbicularis oculi muscle. One intradermal injection at the mid-pupillary line approximately 2 mm inferior to the lid margin with 1–2 units onabotulinum is usually sufficient to reduce the bulge and to widen the palpebral aperture size. Bruising is common in the area and lid ectropion can occur. Injections medial to the mid-pupillary line can weaken the blink reflex and result in dry eyes. Injections lateral to the mid-pupillary line increase the risk for lower lid ectropion. Dry eyes, scleral show and loose lower eyelids should alert the injector the possibility of problems with the treatment of this zone with BT.

Lateral Oblique Forehead Lines

Lateral oblique forehead lines had previously been defined as 'sleeping lines'. There are arguments to support the premise that these lines are not caused by sleeping position but arise instead from the repeated contraction of powerful frontalis and orbicularis oculi muscles and can therefore be successfully treated with onabotulinum toxin A. Each lateral oblique forehead line can be treated by injections medially to this line, in two sites, 2 cm apart, using two units at each site (the lowest point situated 1.5 cm above the orbital bony rim). Two more units need to be injected at a third site, 1 cm lateral to the oblique forehead lines, midway between the hairline and the eyebrow.

Brow Lift

Brow ptosis is common and gives the patient a tired appearance. Most patients desire to have eyebrows that are positioned slightly higher, more arched and more symmetrical.

The position of the eyebrow is affected by a continuous interaction between elevator (frontalis muscle) and depressor (procerus, corrugator, depressor supercilii, internal part of orbicularis) muscles. The depressor muscles should be treated while maintaining the elevator muscle function. Treatment of the glabellar complex as described above can help in raising the medial portion of the eyebrow. In order to raise the external eyebrow, an injection should be given subcutaneously at 4–5 mm of the orbital ridge under the brow tail, directed away from the eyelid. Doses of 2–4 MU onabotulinum per side can be administered. Also the treatment of the crow's feet lines can be helpful.

When treating eyebrow position, appropriate dose adjustments are very important in order to obtain a symmetrical result.

Bunny Lines

Bunny lines are horizontal wrinkles that form across the bridge of the nose and are accentuated with speech, smiling and frowning. They are produced by the transverse portion of the paramedian nasalis muscle and occasionally the levator labii superioris alaeque nasi muscle. Very small doses of onabotulinum are needed, typically 2–5 MU onabotulinum per side. A midline procerus injection of 1–2 MU onabotulinum will address the transversal nasal lines. Injections should be given in the hypodermis and at an oblique angle perpendicular to the nasal vault. Placement is particularly important on the nose as the levator labii superioris alaeque nasi and the levator labii superioris both originate along the medial aspect of the malar prominence. Diffusion of BT towards these muscles can cause drooping of the upper lip.

Reducing Excessive Columellar Show

One can speak of excessive columellar show when exposure of the inner lining of the nostrils is visible for 4 mm or more when looking to the nose laterally in active condition. It is mainly due to the over contraction of one and/or two muscles (levator labii superioris ala nasi and depressor septi nasi). Depending on the relationship of the alar rim and the columella, three forms of the columellar show can be seen: upper, lower and combined.

The medial alar portion of the levator labii superioris ala nasi, also called the levator ala nasi, elevates the wing of the nose and dilates the nostrils which results to retracted alar rim and making it more arched (upper show). The depressor septi nasi primarily pulls the nasal septum downwards and makes it more pronounced (lower

show). The combined show is the combination of both the upper and lower show which is due to the hyperfunction of the two muscles. Excessive use of the muscles mentioned above under physical, emotional stress or unconsciously and repeatedly contracting these muscles lead to a more pronounced upper, lower or combined show. The most common among the three is the upper show.

Excessive columellar show can be corrected by injecting botulinum toxin midway along the levator alae nasi. A dose of 4 U onabotulinum toxin could reduce this unwanted condition for up to 12 weeks.

Perioral Region

Rejuvenation of the mouth can be achieved using small doses of BT. Outcomes are usually maximised when combined with other techniques such as fillers of resurfacing.

Vertical perioral rhytids are caused by the orbicularis oris muscle which is the sphincter muscle of the mouth. Fibres derive partially from other muscles inserted into the lips and from muscles associated with the lips. Because of the complex functions of this region and the interplay of muscles, treatment of the perioral region deserves careful attention. Two to four injections sites should be symmetrically distributed per lip quadrant. Injections can be given just above or slightly away from the vermillion border directly in the folds. Avoid treating the corners of the lip and the midline of the upper lip as this can result in drooling and flattening of the lip respectively. A maximum dose of 1 MU onabotulinum per injection site with a total of 4 MU onabotulinum per lip is advised. Overtreatment should be avoided since this can result in significant dysfunction including difficulty in pursing the lips.

Marionette Lines and Depressor Anguli Oris

Oblique lines radiating downward from the oral commissures, called marionette lines or melomental lines, are partially formed by the hyperactivity of the depressor anguli oris (DAO) at its medial insertion. As corners of the mouth turn downwards with age, it portrays sadness or anger. Weakening the DAO with BT minimises downward pull on the dermal insertions of the muscle and can raise the oral commissures due to the activity of the opposing zygomatic muscles. Injections in the DAO should be given superficially 1 cm above the mandibular border at the intersection of the line passing through the nasalis ala and the corner of the mouth. Higher injections in the DAO at its upper third part are more efficacious but have a high risk of paralysing the depressor labii inferioris. Also treatment of the depressor anguli oris that is too close to the mouth can result in unwanted injection of other muscles and produce oral incompetence, drooling and asymmetrical smile. An average dose of 2 MU onabotulinum per injection point is advised.

Gingival Smile

Excessive display of gingival tissue during smile is an aesthetically unpleasant condition known as ‘gummy’ smile. This is partially related to hyperactivity of the upper lip elevator muscles (levator labii superioris and levator labii superioris alaeque nasi). Different injection techniques with BT have been described. Injections should be given deep and 1 cm above the lower insertion of the nostril. Doses should be low (2 MU onabotulinum per injection site) in order to prevent drooping of the upper lip (see Fig. 110.3).

Chin

A deep mental crease or chin dimpling can be improved by paralysing the mentalis muscle. Only one injection with BT is generally necessary to weaken the muscle, although some experts inject two sites. A total of 5–10 MU onabotulinum can be injected ideally at the inferior and near midline part of the muscle to avoid diffusion to the depressor labii inferioris muscle, causing lower lip incompetence and drooling. Injections should be given deeply and perpendicular to the skin surface. Combined treatment with fillers can improve the aesthetic outcome.

Neck

Vertical neck bands and cords may become very prominent in some individuals. These bands are caused by the platysma, a broad and thin sheet of

Fig. 110.3 Gummy smile: injection in M. levator labii superioris alaeque nasi

Fig. 110.4 Platysmal bands treated with BT

muscle, originating in the pectoral and deltoid muscles and extending upward, covering the neck's anterolateral aspect. Treatment with BT can only be performed in a strictly selected patient population: patients must have retained a satisfactory skin elasticity in the neck and have only minimal descent of submental fat. It is suggested to inject 2–4 MU onabotulinum every 1–2 cm per band which results in 2–4 injection sites per band (see Fig. 110.4). A maximal dose of 50 MU onabotulinum for the global neck treatment is accepted. It is recommended to grasp the band with the nondominant hand and inject intramuscularly. High doses and deep injections should be avoided since they increase the risk of general neck weakness, dysphagia and dysphonia.

Horizontal neck lines can be treated but are much less responsive than the vertical neck bands.

Mandibular Contouring

A hypertrophic masseter muscle, which is involved in mastication, may lead to a square jaw contour. Injection with BT can reduce muscle hypertrophy leading to a slimmer, oval-shaped lower face. In order to define the injection sites, the borders of the masseter muscle must be determined while the patient is clenching teeth. Two to six injections should be given at 1 cm away from the borders and in the muscle lower half. Also they should be given intramuscular up to bone contact and perpendicular to the skin surface. An average dose of 25–30 MU onabotulinum per masseter muscle should be administered.

Primary Axillary Hyperhidrosis

Primary axillary hyperhidrosis is a common disorder for which treatment is often a therapeutic challenge. When topical treatment with

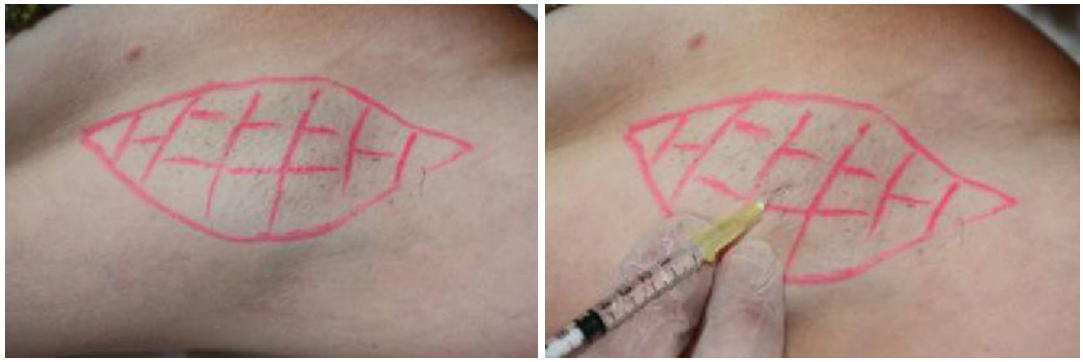

Fig. 110.5 BT treatment of primary axillary hyperhidrosis

aluminium salts does not reduce the sweat secretion, the next step is treatment with BT. After disinfection the sweating area should be demarcated and subdivided in squares of 1–2 cm^2. A vial of 100 MU onabotulinum should be diluted with 4–5 mL 0.9 % non-preserved or preserved saline. Afterwards 3–5 MU onabotulinum is injected intradermally into each square, totalling 50 MU per axilla (see Fig. 110.5). Higher dosing, up to 150 U of onabotulinum toxin, divided over both axillae, might be associated with more intense reduction in hyperhidrosis or longer duration of the hypo- or anhidrotic result.

Recent Development

A major disadvantage of the treatment with botulinum toxin is the administration route. Since many consumers are needle adverse and would prefer a more noninvasive alternative, a targeted alternative may be found in topical BT.

Nanotechnology allows the potential to deliver molecules into the skin which normally do not penetrate the corneal layer. Recently two companies developed topical BT gels. By using nanospheres and absorption enhancers, the toxin is delivered into the skin and can exert its function of inhibiting the release of acetylcholine and thereby blocking the neuromuscular transmission. Studies so far have mainly focussed on treating axillary hyperhidrosis and lateral canthal lines.

Transdermal Corp. (Birmingham, Michigan) has developed CosmeTox®, a topical BT cream based on commercially viable ionic nanoparticle technology. Different studies revealed efficacy, stability and safety of the product. The product is FDA approved in the treatment of facial rhytids and (axillary and palmoplantar) hyperhidrotic conditions.

RT001 (Revance Therapeutics, Newark, California) is another topical BT cream consisting of the combination of 150 kDa BT coupled with a peptidyl macromolecule transport system. Analogously to CosmeTox®, different clinical studies showed the product to be safe and efficacious in the treatment of facial wrinkles and hyperhidrosis.

Possible side effects of topical BT treatment are temporary, involuntary muscle contractions and transient local reactions as tenderness, erythema, eczema and folliculitis. A potential risk of topical BT is misuse. Misapplication could lead to ptosis or facial asymmetry. These limitations will be a source of debate as to under which conditions the topical product can be used and prescribed.

Capillaroscopy

111

Giorgio Filosa and Rossella De Angelis

Abbreviations

aCL	Anticardiolipin antibodies
DM	Dermatomyositis
NC	Nailfold capillaroscopy
RP	Raynaud's phenomenon
SLE	Systemic lupus erythematosus
SP	Scleroderma pattern
SSc	Systemic sclerosis
UCTD	Undifferentiated connective tissue disease

Key Points

- Capillaroscopy is a 'non-invasive' method of undoubted value in the recognition of morphological and functional abnormalities of the microcirculation at the nailfold skin.
- Nailfold capillaroscopy (NC) should be performed in all fingers.

- In healthy individuals the capillaroscopic pattern is generally characterised by an homogeneity in morphology, diameter, orientation and distribution of the capillaries, which appear as 'inverted U' or 'hairpin', and arranged as a 'comb', with the major axis parallel to the skin surface.
- NC is useful in the study of scleroderma pattern (SP) of the connective tissue diseases. The SP can be observed in more than 90 % of patients with systemic sclerosis (SSc), in about 75 % of patients with dermatomyositis and in over 50 % of patients with mixed connective tissue. Morphological aspects and characteristics of the scleroderma, a microangiopathy, may vary in relation to its evolutionary stage. In the early phases it is mainly characterised by the alteration of normal capillaries with unevenly distributed dilated loops. In the most aggressive forms, the avascular areas and the anarchic newborn capillaries emphasise the architectural disorder that can be considered hallmark of SSc.
- NC measures also variations of capillary dimensions and density ('microvascular remodelling') under treatment, and this could be the potential major clinical application of this technique, for monitoring the response to drug treatment.

General Principles

Capillaroscopy is a 'non-invasive' method of undoubted value in the recognition of morphological and functional abnormalities of the microcirculation. Its use dates back to the early twentieth century but remained mostly confined to the experimental until the 1980s. Since then, the clinical applications of capillaroscopy have progressively developed, especially in the field of rheumatology, to become an essential top-level examination in patients with Raynaud's phenomenon and play a key role in the diagnosis and prognosis of systemic sclerosis (SSc).

The 'in vivo' study of the microcirculation is mostly carried out at the nailfold skin, due to the fact that in this district, the major axis of the capillaries runs parallel to the skin surface, while in other areas the capillaries have a perpendicular course to the skin.

Nailfold capillaroscopy can be realised with various optical devices, which may vary from a simple magnifying glass up to a video capillaroscope with optical contact probes. The use of an ophthalmoscope or a dermatoscope is the easiest method for a wide-ranging and direct assessment of the nailfold microcirculation, albeit with low sensitivity to the limited level of magnification (20×). A reflex camera equipped with a good optical kit allows an adequate overview, while a stereomicroscope and a transmitted light microscope (magnifications ranging from 10× to 100×) provide a general observation and a simultaneous analysis of details of the single loops. In recent years, the videocapillaroscopy with optical probes has opened new and original perspectives in the study of microcirculation, for the chance to explore both the nailfold and the entire skin microcirculation. The images of capillaries captured through the probe are shown on a monitor, where the examination is particularly easy for the sharpness and the amplitude of the field of observation. The instrument can be equipped with software that uses algorithms for image storage and allows immediate printing.

Nailfold capillaroscopy should be performed in all fingers, with the lens correctly positioned perpendicularly to the examining surface. The application of a cedar oil drop on the skin allows to get the best conditions of visibility. The survey should be carried out after a period of 'acclimatisation', lasting from few minutes to half an hour, with regard to the difference between outdoor and room temperature.

The main parameters to be analysed in the course of the examination are the skin transparency, the visibility of the subpapillary venous plexus, density and spatial distribution of the loops, the length and diameter of the capillaries and the flow characteristics (Table 111.1).

In healthy individuals the capillaroscopic pattern is generally characterised by a homogeneity

Table 111.1 Capillarosopic nailfold patterns

Primary Raynaud's phenomenon	Normal pattern
Systemic sclerosis	'*Early*' pattern (few enlarged/giant capillaries, few haemorrhages, no evident loss of capillaries), '*active*' (giant capillaries, capillary haemorrhages, mild disorganisation of the capillary network) and '*late*' pattern (enlargement of the capillaries, few or absent giant capillaries and haemorrhages, avascular areas) (Figs. 111.2, 111.3 and 111.4)
Dermatomyositis	Similar to those in patients with SSc and with features of angiogenesis that can represent the dominant characteristic
Mixed connective tissue disease	Wide variability scleroderma pattern predictive of the development of pulmonary hypertension
Undifferentiated connective tissue disease	Most normal
Systemic lupus erythematosus	Tortuosity, loop elongation, enlarged and/or branching loop scleroderma pattern in 5 % of cases
Sjögren's syndrome	Non-specific
Psoriatic arthritis and psoriasis	Non-specific microhaemorrhages and reduction in length ('dwarf loops')

in morphology, diameter, orientation and distribution of the capillaries, which appear as 'inverted U' or 'hairpin', and arranged as a 'comb', with the major axis parallel to the skin surface (Fig. 111.1).

The number of capillaries varies from 9 to 13 per mm, and the morphological and structural features of the nailfold microcirculation tend to remain constant over time. The capillary characteristics and the microvascular network can have a wide interindividual variability, due to many factors such as age, sex, race and occupation. Isolated abnormalities in distribution, morphology and orientation are not uncommon in the healthy subject, and their presence can be related with a wide range of conditions such as manicure, nail biting, microtraumas and manual activities.

Nailfold capillaroscopy is indicated in all those conditions in which it is presumed or there is already existing microangiopathy; furthermore, capillaroscopy may allow a better understanding of the pathophysiological aspects regarding the microvascular involvement in systemic diseases.

Several marked alterations of the main capillaroscopic parameters can be observed in the presence of a microangiopathy, with significant changes in the course, morphology and spatial distribution of the capillary loops, contributing to the disruption of the normal microvessel network.

The 'Scleroderma Pattern'

The wide variety of the changes observed in SSc and in the so-called scleroderma spectrum disorders is well known as the 'scleroderma pattern'. The expressions of the scleroderma microangiopathy are various and mainly characterised by architectural disorder, homogeneous and inhomogeneous ectasia, microhaemorrhages, marked capillary neoformation and reduction in the number of capillaries until the appearance of avascular areas (Fig. 111.2).

The scleroderma pattern can be observed in more than 90 % of patients with SSc, in about 75 % of patients with dermatomyositis, in over 50 % of patients with mixed connective tissue disease and, to a lesser extent, in patients with undifferentiated connective tissue disease (UCTD) and with Sjögren's syndrome.

Morphological aspects and characteristics of the scleroderma microangiopathy may vary in relation to its evolutionary stage. In the early phases it is mainly characterised by the alteration of normal capillaries with unevenly distributed dilated loops. In the most aggressive forms, the avascular areas and the anarchic newborn capillaries emphasise the architectural disorder that can be considered hallmark of SSc.

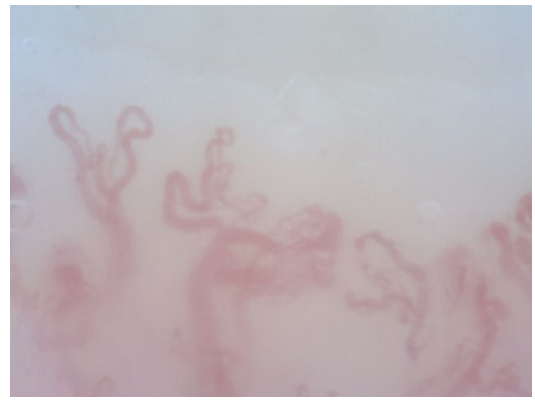

Fig. 111.2 Nailfold capillaroscopy ×200. Systemic sclerosis: architectural derangement with newly formed capillaries

Capillaroscopy in Autoimmune Diseases

Raynaud's Phenomenon

The nailfold capillaroscopy can be considered the method of first use to make a clear distinction between 'primary' and 'secondary' Raynaud's phenomenon (RP).

In a patient with clinically isolated RP, the presence of one or more of the typical abnormalities of the scleroderma microangiopathy (even if limited to a single finger) should be regarded as evidence of a significant secondary nature and justifies the execution of further investigation, such as the research of anti-nuclear antibodies. Moreover, the capillaroscopic findings allow to stratify the risk of a significant evolution towards a 'scleroderma spectrum disorder' over 5 years in patients with isolated RP, using a composite algorithm based on the presence of dilated capillaries, microhaemorrhages and density of capillaries. The association of this type of capillaroscopic abnormalities with a positive 'specific' antinuclear antibody (anti-centromere or anti-topoisomerase I) makes it possible to develop a predictive model able to assess the evolution of RP towards a true SSc.

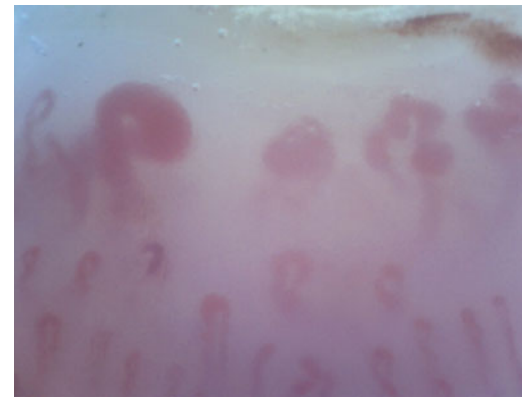

Fig. 111.3 Nailfold capillaroscopy ×200. Systemic sclerosis: extremely dilated loops ('giant capillaries')

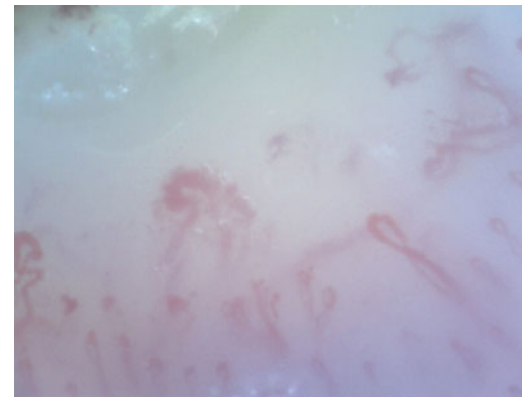

Fig. 111.4 Nailfold capillaroscopy ×200. Systemic sclerosis: loss of capillaries with a marked disorganisation of the capillary bed

Systemic Sclerosis

Capillaroscopy can be regarded as the most valuable technique for detecting the early features of microangiopathy in SSc, with the morphologic changes of the nailfold that have been extensively studied. They include architectural derangement of the nailfold microvascular network, enlarged loops, neovascularisation, loss of capillaries and avascular areas. Such capillary abnormalities can be recognised, even in the early stages of SSc, when clinical features of the disease are limited to RP. A marked increase in capillary size is the most characteristic feature of the nailfold capillary bed in SSc, the shape being largely heterogeneous.

Previous studies on nailfold capillaroscopy had partially graded the vascular damage in SSc, distinguishing two main groups of capillary abnormalities for prognostic purpose, the first characterised by extremely dilated nailfold capillaries with no clear avascular areas ('slow pattern') (Fig. 111.2) and the latter by extensive loss of capillaries with a general disorganisation of the capillary bed ('active pattern') (Figs. 111.3 and 111.4). About 10 years ago, microvascular alterations have been reclassified into three different patterns, including 'early' pattern (few enlarged/giant capillaries, few capillary haemorrhages, no evident loss of capillaries), 'active' pattern (frequent giant capillaries, frequent capillary haemorrhages, mild disorganisation of the capillary network) and 'late' pattern (irregular

enlargement of the capillaries, few or absent giant capillaries and haemorrhages, extensive avascular areas).

In SSc patients a significant association between the severity of the involvement of the skin and internal organs and the capillaroscopic patterns has been found. Patients with extensive avascular areas have an increased risk to develop digital ulcers and to present a more significant skin, pulmonary and cardiac involvement.

Capillaroscopy is also used for prognostic purposes to identify patients with high risk of developing digital ulcers and pulmonary arterial hypertension. In particular, the 'quantitative' analysis of some abnormalities (number of megacapillaries, maximum capillary diameter, total number of capillaries) allows to build a prognostic index with high specificity and sensitivity, able to predict the appearance of digital ulcers.

Dermatomyositis

Dermatomyositis (DM) is distinguished from polymyositis for the substantial involvement of the microcirculation in the skin and muscle and for the relief of capillaroscopy alterations in about two-thirds of the subjects.

In patients with DM capillaroscopic abnormalities may be similar to those that can be found in patients with SSc, with architectural derangement of the nailfold capillary network and features of angiogenesis that, in some cases, can represent the dominant characteristic. In patients with polymyositis without cutaneous involvement, the capillaroscopic pattern usually shows aspects that fall in the normal range.

Patterns characterised by a rapid change of the capillaries' morphology occurring even in a few days were also described.

Mixed Connective Tissue Disease

The nailfold microvascular pattern of mixed connective tissue disease may present a wide variability, ranging from a normal pattern to frankly pathological features. Capillaroscopic alterations typical of the scleroderma pattern are detectable in more than half of patients. The presence of avascular areas is associated with interstitial lung disease, and the finding of a scleroderma pattern seems to be predictive of the development of pulmonary arterial hypertension.

Undifferentiated Connective Tissue Disease

The undifferentiated connective tissue disease (UCTD) is a condition in which there are signs and/or symptoms of a systemic autoimmune disease that do not meet the classification and/or diagnostic criteria of a 'major' connective tissue disease. In most subjects the nailfold capillaroscopic arrangement is normal. In some patients, especially those with RP, it is possible to observe non-specific expressions of microangiopathy, with predominance of tortuous capillaries and homogeneous and inhomogeneous ectasia. In this case, a follow-up seems appropriate in order to identify a possible evolution towards an SSc. Abnormalities of the scleroderma pattern can be observed in association with the simultaneous presence of anti-RNP antibodies and RP.

Systemic Lupus Erythematosus

The main capillaroscopic abnormalities described in systemic lupus erythematosus (SLE) patients include increased tortuosity, loop elongation, enlarged and/or branching loops and increased visibility of the subpapillary venous plexus, although in about 50 % of patients, the capillaroscopic pattern is similar to that of healthy subject. In some cases loops take on a convoluted course, named 'meandering capillaries'. A true scleroderma pattern is observed as significant in a minimum proportion of patients (5 %), when associated with RP and anti-RNP antibodies.

Antiphospholipid syndrome (APS) patients and SLE patients with anticardiolipin antibody (aCL)-positive titres show microvascular alterations, suggesting a direct damage of the vascular endothelium triggered by aCL. Symmetrical

microhaemorrhages at the nailfold were found particularly in patients showing both serum IgG and IgM aCL with marked microvascular damage related to the occurrence of thrombotic manifestation.

Sjögren's Syndrome

In patients with Sjögren's syndrome, capillaroscopic alterations are unusual and, when present, are considered as non-specific. Some authors have observed a reduction in capillary density in the presence of RP or systemic manifestations of the disease. The relief of a scleroderma pattern holds predictive value with respect to a possible evolution towards an 'overlap' with SSc.

Rheumatoid Arthritis

The capillaroscopic framework in patients with rheumatoid arthritis does not show changes characteristic or representative of a microvascular damage. In most cases the capillaroscopic pattern is similar to those of the healthy subject. In some patients it is possible to observe thin and elongated loops together with a strong visibility of the subpapillary venous plexus, valued in the past as a distinctive element of a 'rheumatoid arthritis pattern'. These anomalies are considered non-specific and by some probable expression of a concomitant steroid therapy.

Psoriatic Arthritis and Psoriasis

Capillaroscopy in patients with psoriatic arthritis may reveal a series of abnormalities such as non-specific microhaemorrhages and reduction in length ('dwarf loops'), the latter probably related to a reduction of visibility secondary to hyperkeratosis. Examination of the untreated psoriatic skin shows many uniformly arranged tortuous and dilated capillaries, appearing as bushy, with a highly distinctive pattern. In the perilesional skin, capillary loops show a parallel course with respect to the skin surface and with a lengthened apex directed towards the marginal zone of the lesion. The number of capillary loops per area unit seems to increase in perilesional skin compared to lesional skin. In the normal-appearing skin, the capillary loops become perpendicular to the surface of the skin.

These changes are reversible and may regress with the disappearance of the psoriatic lesions.

Capillaroscopy in Therapy Monitoring

The role of capillaroscopy in therapy monitoring awaits further improvement. Changes described after therapy mainly refer to dynamic studies in which the parameters used were the variations of blood flow and capillary permeability. A single oral administration of 10 mg of nifedipine has demonstrated a prompt antagonist effect on the cold-induced reduction of capillary permeability in patients with SSc (Grassi et al. 1994). Very few studies reported morphological modifications and numerical loop change at nailfold later than vasoactive therapy. A decreased capillary loss was observed after cyclosporine (2.5 mg/kg/day) and intravenous iloprost, during an open, double-arm trial in which 20 SSc patients were randomised to receive treatment with either iloprost alone or in association with low-dose long-term CyA (Filaci et al. 1999). A development of nailfold microvascularisation, characterised by an increase of the loop number and a reduction of avascular areas, was described in four patients with SSc, after a 3-year treatment sequence with iloprost (Faggioli et al. 2006). A significant decrease in avascular areas was observed in 16 % of patients with mixed connective tissue disease after iloprost, throughout a sequential evaluation of 3 years (de Holanda Mafaldo Diógenes et al. 2007). Measure variations of capillary dimensions and density ('microvascular remodelling') could be the potential major clinical application of this technique, for monitoring the response to drug treatment. The development of new computer-based systems, with the visualisation of single loops' picture, may improve the reproducibility,

especially the ability to guarantee examination of the same capillaries at different time points, thus applying this technique to longitudinal studies and clinical trials.

Conclusions

Capillaroscopy is a well-recognised method for the early detection of SSc and related conditions. The diagnosis of SSc should be considered in any patient with RP indicating the typical nailfold capillaroscopic changes included in the 'scleroderma pattern'. Moreover, capillaroscopy shows a predictive value with regard to the more aggressive variants of SSc and is helpful to assess the microvascular involvement in other autoimmune disorder, such as SLE. The 'classic' approach to capillaroscopy is based on the use of optical instruments (macrophotography, stereomicroscopy, dermatoscopy) that guarantees a global evaluation of the entire nailfold area ('widefield capillaroscopy'). Apart from being time-consuming, this procedure limits the realisation of high-quality documentation. The availability of new computer-driven videomicroscopy systems has greatly simplified the acquisition and recording of images of excellent quality, with a computer-based system for image acquisition and measurement. Digital storing of the images, with the consequent option of printing immediately for reports, and/or saving on support may give the possibility to send the images via the Internet for 'telediagnosis' and 'teleconsultation', thus contributing to the spreading of the technique.

Chemical Peelings

112

Ilaria Ghersetich, Lara Tripo, Alice Garzitto, and Torello M. Lotti

Key Points

- A chemical peeling involves the application of an exfoliating chemical agent on the skin to produce a controlled injury with subsequent removal of superficial lesions within the skin layers.
- Many peelings are available today and produce therapeutic and cosmetic benefits.
- Chemical peelings are commonly used in dermatological practice to treat sun-damaged and sun-related pigmentary dyschromias, postinflammatory hyperpigmentation, melasma, acne, and acne scars.

General Principles

A chemical peeling involves the application of an exfoliating chemical agent on the skin to produce a controlled, partial-thickness injury with subsequent removal of superficial lesions within the skin layers, regeneration of new tissue with improvement of skin texture, and long-lasting therapeutic and cosmetic benefits.

Chemical peelings are commonly used in dermatological practice for the treatment of sun-damaged skin with actinic elastosis, facial wrinkles and actinic keratoses, sun-related pigmentary dyschromias (especially lentigo simplex), postinflammatory hyperpigmentation and melasma, acne and acne scars, warts, and rough oily skin with enlarged pores.

Classification of Chemical Peeling

On the basis of wound depth, chemical peelings are classified as follows.

Superficial Chemical Peels

They penetrate the epidermis down to the dermal-epidermal interface. Examples of superficial peeling agents are listed in Table 112.1. The peeling agent used is one of the most important determining factors for peeling depth, but many other factors should be considered including length of application, Fitzpatrick skin type, prepeeling treatments, and repeeling. Although the procedure is standardized as much as possible, a "light" peeling agent can sometimes result in a deeper peel.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,

Pyruvic acid 40–50 %

Table 112.2 Medium-depth chemical peeling agents

Trichloroacetic acid, 35–50 %
Jessner's solution + TCA 35 %
Glycolic acid 25–70 % + TCA 35 %
Salicylic acid + TCA 35 %
Pyruvic acid 70 %

Medium-Depth Peels

They can be obtained with agents or a combination of agents (Table 112.2) that produce an injury deep down into the upper reticular dermis.

The application of medium-depth peeling agents induces both full-thickness dermal necrosis and partial-thickness dermal necrosis.

Trichloroacetic acid (TCA) alone or in combination with other agents is the mainstay of medium-depth chemical peels.

Combination chemical peels attempt to maximize the therapeutic effects of different agents while minimizing adverse reactions and side effects through decreased concentrations of caustic agents.

In general, a combination chemical peel consists of two wounding agents: the first causes epidermal thinning or necrosis (Jessner's solution (JS) (Table 112.3), glycolic acid (GA), salicylic acid (SA)), while the second (TCA 35 %), which penetrates easily and deeper, accomplishes dermal necrosis.

These peelings are relatively simple and associated with a favorable risk/benefit ratio. However, proper patient selection, with attention to both medical and psychological factors, requires sound experience. The indications for these peelings are both medical and cosmetic conditions. Primary medical conditions include diffuse actinic keratosis, and cosmetic conditions include mild to moderate wrinkles, dyschromias, solar elastosis, solar lentigines, melasma, and postinflammatory hyperpigmentation.

Table 112.3 Jessner's solution

Ethanol (95 %)	100 cm^2

Table 112.4 Baker-Gordon's phenol formula

Phenol USP 88 %	3 mL
Distilled water	2 mL
Septisol soap	8 drops
Croton oil	3 drops

Deep Chemical Peels

These involve the use of chemoexfoliants that penetrate to the mid-reticular dermis. Deep chemical peels entail longer healing times and increase the potential for complications. Baker-Gordon's formula (Table 112.4) is the most commonly used deep chemical peeling agent. Deep phenol peeling can lead to irreversible hypopigmentation because of the melanotoxicity of phenol and, thus, is not advised for dark skin types. Cardiac arrhythmia and hepatorenal toxicity may occur with systemic absorption; therefore this peel must be performed with very slow application in pigmentations and melasma.

Salicylic Acid

SA is an organic aromatic carboxylic acid with a hydroxyl group in position beta. It is a hydrophobic lipophilic phenolic compound. The application of SA 30 % in ethanol can produce detachment of corneal cells, basal cell proliferation, and activation of fibroblasts in the skin. An important advantage of SA over other superficial peeling agents is that it is a safe and efficacious treatment for acne and dyschromias in subjects with skin types V and VI (Fitzpatrick's

Fig. 112.1 Before and after SA in acne

Table 112.5 Modified Unna's paste

Resorcinol	40 g
Zinc oxide	10 g
Benzoinated axungia	28 g
Ceyssatite	20 g

classification). SA can also be used in combined peelings to achieve thinning of the epidermis that permits better penetration of other caustic agents, such as TCA or pyruvic acid (PA) (Fig. 112.1).

Resorcinol Peeling

Currently the resorcinol formula most often used is modified Unna's paste (Table 112.5). Resorcinol (*m*-dihydroxybenzene) is structurally and chemically related to phenol. It is soluble in water, alcohol, and ether and acts as a potent reducing agent. Application of resorcinol induces a split at the granular cell layer, vasodilatation, increased mitosis of the basal cell layers, fibroblast proliferation, and formation of a thickened dermal band. It also has bactericidal and keratolytic properties.

This type of peeling is quite easy to handle and has a low risk of side effects (temporary hyperpigmentation and occasional contact allergy). It is recommended especially for subjects with acne, including comedogenic acne, and is successful in clearing pigmentary acneic outcomes and very superficial scars. Melasma usually responds favorably too.

Pyruvic Acid

This is an α-keto acid that converts physiologically to lactic acid, and its additional properties make it a particularly effective topical peeling agent.

This very potent acid can be used as a peeling agent, without risks of scarring, in concentration between 40 and 70 % in a well-balanced proportion between water and ethanol.

The application of PA in the abovementioned concentration induced keratinocyte detachment with thinning of the upper layers of the epidermis.

PA penetrates down to the upper papillary dermis and causes dermal–epidermal separation and increased production of collagen, elastic fibers, and glycoproteins.

In addition to its keratolytic and desmoplastic properties, PA has also demonstrated antimicrobial activity.

Thus, PA can be employed as a superficial-medium peeling agent in subjects with inflammatory acne, moderate acne scars, greasy skin, actinic keratosis, and warts.

Fig. 112.2 Before and after PA in acne

We have also achieved good results in the treatment of photodamaged skin (fine wrinkles and localized superficial hyperpigmentations – color mismatch) (Fig. 112.2).

Glycolic Acid

GA, an α-hydroxy acid (AHA), has been the most popular peeling agent over the past 10–15 years.

We use solutions of 50–70 % GA made with water or combination of water, alcohol, and propylene glycol.

These solutions are clear, are not sensitive to light, and are highly stable (more than 2 years) but evaporate easily (the bottle must be kept tightly closed).

The application of high concentrations of GA reduces corneocyte cohesion (interacting with ionic bonds on the cellular surface) immediately above the granular layer and induces complete epidermolysis, epidermal and dermal thickening, reversal of basal cell atypia, dispersal of melanin, and increased synthesis of glycosaminoglycans and collagen; it may also improve the quantity and quality of elastic fibers.

Clinically these effects on the epidermis and dermis result in an improvement of skin surface irregularities, dyschromias, minor wrinkles, and moderate acne (Fig. 112.3).

An in vivo preliminary study by our group showed an increase of epidermal Langerhans cells in three subjects treated for 1 month with GA (70 % peeling once a week and daily home therapy with a 10 % lotion). In the same subjects, we also demonstrated an increase in the mRNA of transforming growth factor-β (TGF-β), a cytokine that is critically involved in dermal matrix remodeling.

Interestingly, all these effects occurred without any evident inflammatory outcome. GA also has anti-inflammatory activity combined with antioxidant properties. This strengthens the hypothesis that the mechanism of action of the AHAs and related substances is a specific direct effect on the skin, one that goes beyond the irritating effect.

It is very important to note that the effect of a GA peel depends on the length of time it is left on the skin, and thus, the peel needs to be neutralized with water or sodium bicarbonate with

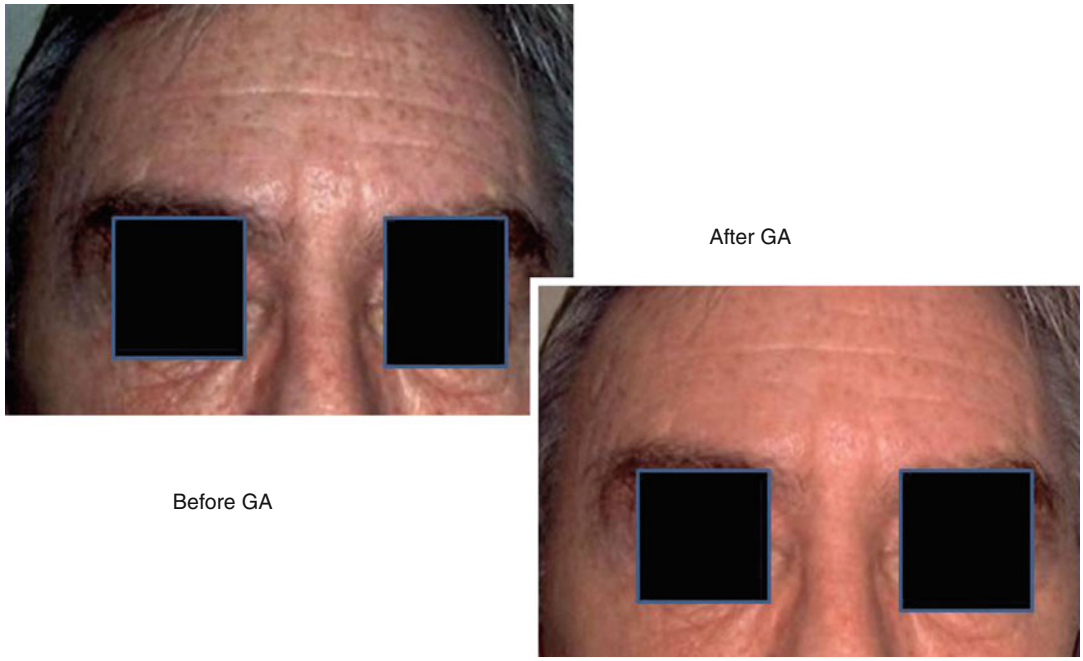

Fig. 112.3 Before and after GA in photoaging

perfect timing to prevent deeper dermal penetration that would lead to variable healing, crusting, and even scarring.

Tretinoin 10 % Mask

This peeling involves the application of a face mask with a high concentration of tretinoin (10 %). After 1 h the cream is removed. The skin becomes reddish on the first to second day, and superficial exfoliation starts on the third to fourth day and lasts approximately 1 week. Only one application per week for four to five sessions is needed, and it is possible to obtain clinical results that are similar to those that could be achieved with a common tretinoin cream used for 5–6 months, without the occurrence of the typical side effects. This mask can be effective in preventing and treating skin aging (whether spontaneous or photoinduced) and hypermelanosis (especially melasma, where it can be used to safely treat also phototype V–VI patients) (Fig. 112.4).

Trichloroacetic Acid

TCA can be used at different concentrations (10–20 % for superficial peels, 30–50 % for medium-depth peels) that lead to different peeling depths. In all cases the peeling is easy to control and predictable because it is neutralized by serum in superficial dermal blood vessels.

This acid is nontoxic systemically. The solution is clear and transparent with no precipitates and is not sensitive to light, and no refrigeration is necessary; it is stable for at least 2–3 weeks.

TCA causes necrosis and exfoliation of normal and actinically damaged cells and also precipitates epidermal proteins. Histological and ultrastructural studies have demonstrated that TCA peeling can renovate epidermal polarity, reducing epidermal intracytoplasmic bodies, increasing the number of fibroblasts, and increasing the deposition of collagen type I. Generally these effects become visible after 1 month of treatment. The main indications for TCA peeling are moderate photoaging with sun elastosis, slight wrinkles, superficial localized hyperpigmentations, and actinic keratoses (Fig. 112.5).

Fig. 112.4 Before and after tretinoin mask in melasma

Fig. 112.5 TCA

Clinical Uses of Chemical Peels

The first step in treating a subject with a chemical peel is to determine any possible contraindications for peeling. For instance, a patient with recurrent herpetic lesions on the face may need to either avoid medium and deep chemical peels or require pre-procedural oral antiviral therapy (acyclovir). Before a superficial peel, we do not administer prophylaxis for herpes simplex unless the patient has had herpetic lesions within 2 weeks prior to the chemical peel procedure. Other contraindications (Table 112.6) include oral therapy with retinoids that may alter postpeel healing (it is

Table 112.6 Relative contraindications for chemical peels

Fitzpatrick skin type IV–VI
High degree of photoaging
Daily sun exposure
Past history of superficial X-ray treatment
Present or recent use of oral retinoids
Recent cosmetic surgery
Big smokers
Use of anticoagulants (warfarin)
Chemotherapy
HIV infection
History of recurrent herpes simplex
Hypertrophic scar or keloid formers
Unrealistic expectations

Table 112.7 Major indications for chemical peels

Facial skin rejuvenation
Dyschromias: melasma, postinflammatory hyperpigmentations, lentigo
Acne and acne scars
Greasy skin

best, in our experience, to wait at least 6 months after cessation of the oral retinoid before medium and deep peelings are performed).

As stated above, there are many indications for chemical peels (Table 112.7). Each case requires a specific treatment depending on the severity of the disorder and the characteristics of the patient. Thus, each treatment must be personalized. However, we can propose general guidelines for the major disorders that can be treated with chemical peels.

Postpeel care is similar for all types of chemical peels; in particular all subjects must avoid sun exposure for at least 1 month after superficial peels and 6 months after medium-depth peels, use sunscreens, and apply facial moisturizers daily. After superficial peels subjects can return to social life immediately, using cosmetic camouflage if necessary. For medium and deep peels, a 7–10-day stay at home period is necessary, and the subject must follow a very careful postpeel care procedure (described below).

Facial Rejuvenation

The wrinkles, textural alterations, diffuse dyschromias, yellowing, and mottling characteristics of photodamaged skin can be significantly improved with chemical peels.

Superficial peels are recommended for subjects with early photoaging or those who do not want to experience the temporary discomfort following medium and deep peel treatments.

Before performing any kind of chemical facial peel, it is advisable to treat the subjects for at least 2 weeks with topical applications of tretinoin (0.025 %), bleaching agents (4 % hydroquinone, azelaic acid), and 1 % hydrocortisone to decrease the risk of postinflammatory hyperpigmentation and promote wound healing. Subjects could also apply AHA creams (8–15 % GA) or PA creams for long periods (remembering to interrupt the application for at least 1 week after each chemical peeling); this reduces the thickness of the stratum corneum and helps to maintain the effect of the peeling.

Peeling with 70 % GA is recommended for only mildly photodamaged skin with fine wrinkles. To improve fine wrinkles effectively, the peeling is done in a series of four to six repeated treatments, once every 3–4 weeks. Before each peeling, the skin must be degreased with alcohol or acetone in order to remove surface debris, oils, and portions of the stratum corneum to allow uniform penetration of the peeling agent.

The acid can be applied with a special brush, cotton bud, or gauze. Once the acid has been applied to the whole face (starting from the forehead and then spreading to the cheeks, chin, upper lip, and nose), it is necessary to wait to see if erythema or "frosting" occurs.

Frosting may occur with GA peeling as a spotted pattern indicating epidermolysis, consisting in detachment of the epidermis from the papillary dermis. Generally, the aim of GA peeling is a slight exfoliation (without side effects) to make the skin smoother. The occurrence of "frosting" presents no additional benefit, but rather discomfort for the individual with increased risk of postinflammatory hyperpigmentation and scarring. Therefore, the acid must be neutralized immediately if frosting appears. The length of time of the application varies extremely from one subject to another in an unpredictable manner. It is advisable to observe subjects carefully during applications to build expertise based on personal experience. There is a great difference in manufacturing methods for products from different companies, and it is not advisable to use products you have not tested personally before performing a peeling. The acid must be neutralized with water or sodium bicarbonate to prevent deep dermal penetration, "overpeel." Following the peeling, no cream containing AHA should be applied for 1 week; if the patient does not show signs of irritation, erythema, or abrasion, no specific postpeel care is necessary.

In cases of significant erythema, topical non-halogenated steroids should be prescribed. If overpeel with abrasions occurs, application of an antibiotic ointment is recommended for at least 1 week.

Peeling with PA is suggested for subjects with mild to moderate photoaging with numerous dyschromias and rough skin with dilated pores. If the skin appears particularly thickened, a peeling with SA should be performed 1 week before beginning the series of PA peels in order to induce thinning of the epidermis that permits deeper, more uniform penetration of PA.

Before the application of SA, the skin is degreased with alcohol or acetone. The peel solution is applied with a brush or a cotton-tipped applicator starting from the forehead and progressing down to the cheeks, chin, upper lip, nose, and eyelids.

Subjects experience a stinging and burning sensation that increases progressively and then decreases rapidly when the peeling agent is neutralized with water. A small fan will help the subjects tolerate this discomfort better. The hydroethanolic vehicle volatilizes, leaving a white precipitate of SA on the skin surface.

SA does not need to be neutralized, but a splash of water on the skin stops the burning sensation and the SA precipitate is removed very easily. If the SA is applied in multiple layers and left on the skin for a longer time (>3 min), the skin turns grayish, meaning that frosting has occurred. Frosting is not required in this type of peel.

PA is applied after degreasing the skin with alcohol. Since PA causes very intense burning, we suggest applying it to small areas (forehead, one cheek at a time, chin, nose, and upper lip) and neutralizing each area with sodium bicarbonate before progressing to the next one. It is best to apply PA with a gauze and scrub gently and continuously for about 1 min. When PA vapors are inhaled, they are pungent and irritating to the upper respiratory mucosa so a small fan should be used during the procedure.

To achieve a satisfactory result, four to six peelings are required, to be done once every 3–4 weeks.

Subjects will experience tightening of the skin and desquamation, and only rarely abrasion for a few days immediately after the peeling. Therefore, it is necessary to prescribe a moisturizing cream that should be applied daily.

Some authors also suggest the use of multiple SA peels, at 4-week intervals, for the treatment of moderate photoaging.

This procedure presents several advantages over the other superficial chemical peels. First, the main benefit of SA compared to GA is its predictability.

It is easy to achieve uniform application and there is no worry about timing or overpeeling: also, the peel causes superficial anesthesia (burning ceases rapidly).

This type of peeling causes significantly more desquamation than GA.

In cases of more advanced photoaging, with skin laxity and diffuse dyschromias, peelings with 35 % TCA alone or preceded by the application of JS or 70 % GA are recommended.

The face is cleaned with a gauze pad soaked with acetone, alcohol, or chlorhexidine gluconate until the sebaceous oils have been thoroughly removed. The eyes are protected with sterile ophthalmic ointment, gauze pads, and hypoallergenic tape or goggles.

Oral or intramuscular anxiolytics may be used. Local anesthesia is not required.

A cotton-tipped applicator is moistened with TCA and rolled against the wall of the glass cup to remove excess fluid.

The TCA is applied to the skin area to be treated by firmly rubbing the moistened applicator in a circular or linear fashion, and the substance is allowed to penetrate for a few seconds, after which a further application is made, sometimes followed by a third application. Usually application is started from the forehead and progresses to the cheeks, chin, upper lip, and nose. Once the skin has been treated, it slowly changes color, becoming whitish gray as a result of chemical coagulation of the epidermis (frosting).

The frost appears more rapidly with high concentrations of TCA and may not appear with low concentrations, especially if the skin has not been adequately degreased.

After the acid is applied, a dry gauze pad is used to blot (not wipe) excess TCA.

Neutralization, as used for GA, is not necessary.

TCA stings when it is applied, and the severity depends on the concentration. The pain increases, normally peaking approximately halfway through the procedure.

A handheld fan may be helpful to soothe discomfort.

Often, anatomical facial subunits require different concentrations of TCA, i.e., for the forehead, cheeks, and chin 40 % and for the periorbital regions 18 %.

TCA should not be passed directly over the eyes. When eyelids are treated, particular care must be used to avoid seepage of TCA onto the sclera.

Immediate postoperative care consists of application of an antibiotic ointment, sometimes followed by a hydrogel dressing.

Subjects must be warned to expect various skin changes such as: (a) itching; (b) transitory marked hyperpigmentation, possibly associated with edema; and (c) exfoliation, which is never regularly distributed all over the treated areas but generally starts at the periorbital and perioral areas and ends at the forehead.

It is very important not to remove the skin in this phase to avoid postinflammatory hyperpigmentation. Generally, during the days that follow, the peeling subjects must avoid use of soaps and detergents, apply antibiotic creams or ointments twice a day, and use total sunblock screens; direct sun exposure must be avoided for at least 4–5 months.

In some cases the skin maintains a pinkish color for 2–3 weeks following exfoliation.

A nonhalogenated corticosteroid cream or zinc oxide paste may accelerate return to normal skin color.

The final result of TCA peels can be appreciated 3–4 weeks after the treatment.

The skin will appear tightened, with a general improvement in skin texture, rhytides will be much less evident, and the skin color will be more homogeneous.

For skin rejuvenation it is also possible to use two caustic agents to increase the depth of the peeling while reducing side effects. 70 % GA and 35 % TCA and JS and 35 % TCA are the combined peelings most often performed.

Seventy percent GA is uniformly applied to the cutaneous surface (as formerly described) and then neutralized. Then, 35 % TCA is applied on the same areas.

JS is applied evenly to the skin, after appropriate degreasing with either cotton-tipped applicators or a 2×2 cm gauze, to achieve a light but even frosting.

The frosting achieved with JS is much lighter than that with TCA and produces less discomfort to the patient.

A mild erythema appears with a faint tinge of frost evenly all over the face. JS does not need to be neutralized. At this point the 35 % TCA is applied evenly with a cotton-tipped applicator, and the acid is left on the skin for a few moments until a white frost appears. The peel is then neutralized with water.

Combined peels usually require a longer time for the procedure, approximately 20 min, and this is sometimes unpleasant for the treated patient.

The effects of these combined peels are comparable to that of 50 % TCA, but with lower risk of complications, especially scarring.

Dyschromias

Melasma, postinflammatory hyperpigmentations, and photoinduced dyschromias can be improved with PA, modified Unna's paste, tretinoin 10 % mask, or 35 % TCA peels. We believe that 35 % TCA gives the best results in dyschromias due to photoaging, while PA, tretinoin 10 %, and resorcinol peels are more effective in cases of melasma and postinflammatory hyperpigmentation. However, chemical peels alone are not adequate in such cases. Simultaneous treatment with bleaching agents (4 % hydroquinone, azelaic acid, kojic acid) and lifelong use of sunblock screens is a must for these individuals.

Acne and Acne Scars

There are various peeling options for the treatment of greasy skin and acne.

Greasy skin is characterized by skin thickening and increased sebaceous secretion, giving the face a shiny appearance, especially on the nose and forehead. Superficial chemical peels with SA or PA can significantly improve this unpleasant situation. The same results are obtained with these two kinds of peelings, although SA peels require fewer applications. In particular, two peeling sessions with a 3-week interval are adequate with SA, while at least three sessions are necessary with PA.

The peeling procedures and postpeel care are the same as for facial rejuvenation.

Very satisfying results are obtained using SA and PA in acne patients. These two peeling agents can be used in comedogenic, inflammatory, and nodular acne and papular and pustular rosacea because of their keratolytic and bactericidal properties. Repeated treatments, one peeling every 2–3 weeks for a total of six to eight treatments, are necessary to achieve clinically significant benefits. Also 70 % GA and JS have been reported to be effective for the treatment of facial acne, but in our experience the best results, with minimal discomfort for the subjects and lower risk of complications, are achieved with SA and PA peels. GA and JS should not be used in cases of inflammatory acne.

Moreover, modified Unna's paste is recommended in cases of comedogenic acne and in clearing pigmentary acneic outcomes and very superficial acne scars.

This paste is applied with a spatula to the area to be treated and left on for 1–2 h.

The post-application reaction resembles that of a first-degree burn with further exfoliation of dark brown skin that generally lasts for 7–10 days. Postpeel care includes a 1-week home stay period for cosmetic reasons and the use of antibiotic and moisturizing creams for 10 days and total sunblock screens for at least 2 months. It is advisable to pretreat the patients (as for skin rejuvenation) with topical 0.025 % tretinoin, topical bleaching agents (4 % hydroquinone, azelaic acid), and 1 % hydrocortisone.

In cases of acne scars, only moderate (partial) results are obtained with chemical peels; laser resurfacing is usually recommended. However, some good results can be obtained with 35–50 % TCA peels or combined peels (GA-TCA or JS-TCA).

Complications

Obviously, the deeper the peeling goes, the higher the risk of complications will be. The most frequent complications are listed in Table 112.8. Most of the complications listed occur after phenol peeling; hyperpigmentation is the only true complication that occurs after superficial or medium-depth peel.

Table 112.8 Complications of chemical peels

Pigmentary changes	Hyperpigmentation Hypopigmentation Depigmentation (porcelain) Mixed combination pigmentation Lines of demarcation Nevus accentuation
Scarring	Atrophic Hypertrophic Keloidal
Infections	Streptococcal or staphylococcal folliculitis (acne-like eruptions) *Pseudomonas* infections Toxic shock syndrome Herpes simplex Epstein-Barr virus keratitis
Prolonged erythema or pruritus	
Textural changes	Uneven texture Enlarged pores
Atrophy	
Milia	
Cold sensitivity or cold urticaria	
Cardiac arrhythmias	
Laryngeal edema	
Poor physician/patient relationship	
Allergic reactions	

There is an evident difference in color with clear boundary lines between the exfoliated and the non-treated areas. Generally this is temporary, and uniform skin color will be observed within 1–2 months.

The most feared complication following chemical peels is hyperpigmentation.

This is often due to even minimal sun exposure but may occur without such exposure, especially in dark-skinned subjects (Fitzpatrick IV–V). Hyperpigmentation can be treated with bleaching agents, generally with good results. It sometimes disappears spontaneously after some months. It is more difficult to treat a hypopigmentary outcome caused by destruction of melanocytes. This may be a permanent side effect, and it usually occurs with deep peelings (50 % TCA or phenol).

Infections associated with peelings are very rare, but the frequency of this complication increases with the depth of the peeling and is more pronounced in the case of crusts formation allowing bacterial colonization. The most common pathogens are *Streptococcus* and *Staphylococcus* species. A small percentage of patients manifest *Streptococcus* and *Staphylococcus* infection as folliculitis or acne-like eruptions.

Infections due to *Pseudomonas* are very rare.

A herpes simplex infection may be reactivated by any peeling agent (superficial, medium, or deep).

Suitable local and/or systemic therapy with antibiotics or antiviral drugs provides quick relief and if well timed can prevent scar formation.

Allergic reactions are generally very rare, and most occur after resorcinol peels.

An allergic reaction is often difficult to diagnose since the symptoms may be similar to alteration induced by the peeling itself (erythema and edema).

Identification and therapy of this complication is mandatory, since it drastically increases the likelihood of side effects such as hyperpigmentation and scarring.

Persisting erythema lasting for 2–3 weeks is considered a normal event, especially after medium and deep peels.

Erythema persisting more than 3 weeks may indicate hypertrophic scar formation.

Overpeel after 25% TCA

Fig. 112.6 Overpeel after TCA

Scarring is certainly the most dreadful complication.

The risk of scars is greater in subjects who undergo deep peelings or overpeel (Fig. 112.6) with superficial and medium peels, those with a past history of hypertrophic scarring or keloid formation, and those who have recently undergone systemic treatment with isotretinoin or in cases of postpeel infection or allergic reaction.

Different scarring reactions are possible, including flat, hypopigmented, depressed atrophic areas; thickened, elevated areas; and keloid.

The treatment differs according to the type of scar and involves the use of intralesional steroids, Silastic plasters, laser therapy, cryotherapy, and even excision and surgical revision of the scar in the most extreme cases.

Written Informed Consent to Chemical Peeling

Each individual that is going to be treated with a cosmetic procedure that involves a risk of complications should provide signed written, informed consent.

It is appropriate to give the patient a form with written information on side effects and complications, discomfort, and temporary skin changes that may or may not occur.

Figure 112.7 shows a draft form of written informed consent.

The undersigned _____ herewith gives formal consent to the chemical peeling treatment at _____.
The treatment has been explained to me and I have had the opportunity to ask questions.
This procedure will cause a modification in treated area of my face / body which may be unpleasant.
My face will become red and successively pigmented as if sunburnt.
Exfoliation will then start and last about 10 days.
An erythema may persist for 15-20 days. Have been informed that there is a minimum risk of side-effects, such as hyperpigmentation and scarring (very rare).
I agree that photographs of me trated may be taken.
Date_____--
Patient's signature (or patient's parents if < 18 years old)

Fig. 112.7 Informed consent form

Conclusions

Chemical peelings are an efficacious and safe approach to the treatment of some cutaneous problems of aesthetic natures. To avoid any undesired side effects, they should be performed by a specialist and according to a standardized procedure, when possible. Apart from the well-known chemical exfoliating effect, the stimulatory activity of some of the chemical peeling agents (GA and TCA) on fibroblasts has been described in numerous studies. For this reason, the use of these substances in photoaging can be recommended, and there is also a possibility that they can be used in other skin lesions. Further investigation of the exact molecular mechanism inducing fibroblast activation and subsequent collagen synthesis is definitely needed. Several studies document the benefit of combining chemical peeling with topical tretinoin, but comparative studies on the use of topical tretinoin and chemical peeling, mostly with GA, have not yielded fully satisfactory results to date. In any case the most successful chemical peeling agent seems to be TCA that can be used for superficial, medium, and deep peelings. Depth of penetration is easily noted when frosting occurs; neutralization is not needed; and there is no systemic toxicity. The combined use of two substances to peel the skin has proved to be successful. Proper degreasing, use of GA or JS, and 35 % TCA are steps that usually make peelings very effective. The amount of each agent applied governs the intensity and thus the efficacy of the peel. The variables should be adjusted according to the individual skin type and the area of the body being treated. Familiarity with the technique of single or, better, combination peeling, especially in subjects with moderate/severe signs of photodamage, is a prerequisite for expert use of this safe and inexpensive tool for effective chemical resurfacing of the skin.

Reflectance Confocal Microscopy 113

Caterina Longo and Giovanni Pellacani

Key Points

- Reflectance confocal microscopy (RCM) is a new noninvasive technique that allows to rapidly explore the skin at nearly histologic resolution.
- Since its inception, RCM was applied mainly in the field of melanocytic lesions because melanin is the strongest source of contrast for this method.
- In skin oncology, RCM stands up as an add-on test for the diagnosis of melanoma being capable of improving the specificity of a narrow selected population of dermoscopically equivocal lesions. Despite melanoma diagnosis, it has been applied for the diagnosis of basal cell carcinoma for which this technique reached a very high diagnostic accuracy and for the diagnosis of other nonmelanoma skin cancer. Other fields of application include inflammatory and infectious skin diseases although few studies on large scale are still needed.

General Principles

The ultimate goal of early melanoma diagnosis is the detection of all melanomas, while minimizing the number of excisions of nevi. To achieve this goal requires the clinician to not only be able to identify specific melanoma features but to also recognize the distinct aspects of nevi. To complicate the matter, several pigmented and nonpigmented lesions are in differential diagnosis with melanoma. Besides melanoma diagnosis, clinicians deal with the overwhelming number of nonmelanoma skin cancer (i.e., basal cell carcinoma) for which a clear-cut diagnosis is warranted as well as a good subtype differentiation to choose the most appropriate treatment.

Dermoscopy is regarded as first-line diagnostic technique, and in 2008 the evidence-based Clinical Practice Guidelines for the Management of Melanoma in Australia and New Zealand gave the recommendation that training and utilization of dermoscopy are recommended with the highest grade (grade A: body of evidence can be trusted to guide practice) for clinicians routinely examining pigmented skin lesions. However, a small quote of melanoma may turn as featureless on dermoscopy, while some nevi may be regarded as melanomas.

Reflectance confocal microscopy (RCM) is a novel imaging technique that has been proved to improve the specificity for melanoma diagnosis when used as a second-level examination for dermoscopically difficult-to-diagnose lesions.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_113, © Springer-Verlag Berlin Heidelberg 2015

Following its application on skin oncology, RCM has been used in several clinical situations including inflammatory skin diseases, treatment monitoring, and infectious diseases, just to name a few.

In this chapter we provide a summary of the main application of confocal microscopy in clinical practice.

Basic Principles and Instruments

Two confocal microscopes are commercially available. Although the laser light used and the basic principle are the same in both types, they are fundamentally distinct in their approach: one is a full-scale microscope constituted by a large scanning head and the other is a handheld device. The former confocal microscope (VivaScope® 1500, Lucid Inc., Rochester, NY, USA) contains a probe (the head of the microscope) that is attached to the skin by using a disposable plastic window that is in turn taped to a metal ring. A confocal microscope consists of a point source of light, condenser, objective lenses, and a point detector (Australian Cancer Network Melanoma Guidelines, 2008; Skvara et al. 2005). The pinhole collects light emanating only from the in-focus plane. The mechanism of bright contrast in reflectance confocal microscopy is backscattering. In grayscale confocal images, structures that appear bright (white) have components with high refractive index compared with their surroundings and are similar in size to the wavelength of light. Backscattering is primarily governed by the structures' refractive index compared to the surrounding medium. Highly reflective skin components include melanin, collagen, and keratin. The confocal scanning produces high-resolution black and white horizontal images (0.5×0.5 mm) with a lateral resolution of 1.0 μm and axial resolution of 3–5 μm. A sequence of full-resolution individual images at a given depth is acquired and "stitched" together to create a mosaic ranging in size from 2×2 to 8×8 mm. A vertical VivaStack® can be imaged. It consists of single high-resolution images acquired from the top skin surface up to 200 μm, corresponding to the papillary dermis, to obtain a sort of "optic biopsy."

The handheld RCM has been recently introduced on the market (VivaScope® 3000). This version is a smaller, flexible device that is quite useful in difficult-to-access areas. Unlike the 1500 version, it has a manual control for laser power on the probe, imaging depth, and capture, but it does not allow scanning of a large field of view, needed, for example, to analyze the architecture of tumors. The application of handheld device is for surgical pre-mapping or when multiple site imaging is requested.

Melanocytic Tumors

Nevi

The realm of common acquired nevi includes a variety of clinically different nevi. Traditionally, they are classified based on histopathologic criteria in junctional, compound, and intradermal nevi. Although this classification does not encompass the clinical variability of these lesions, it offers a good understanding of the confocal findings according to different skin depths. Moreover, a perfect correlation between dermoscopy and confocal substrates is helpful to interpret the histopathologic substrate.

Junctional nevi usually do not represent a clinical challenge since dermoscopy shows a regular pigmented network ranging in color from light brown to dark brown or orange hue. Confocal microscopy shows the presence of a regular honeycomb pattern and ringed junctional architecture due to the alternation of hyporeflective dermal papillae surrounded by bright polygonal cells. Few junctional nests can be present at time and they enlarge the interpapillary space. In compound nevi presenting a mixed dermoscopic pattern, it is frequent to observe the presence of several junctional nests that generate a "meshwork pattern." When a blue color is present upon dermoscopy, RCM images highlight the presence of plump bright cells corresponding to melanophages, usually seen into the dermal papilla close to a tiny canalicular vessel. The intradermal nevi with a predominant dermal component usually show a regular epidermis and the presence of

large aggregates of roundish monomorphous cells ("clod" pattern) when the nested population is superficially located. In case of a deep dermal component, the limited laser depth penetration hampers the visualization of the melanocytic proliferation.

Besides the stereotypical dermoscopic and confocal aspects of these lesions, some nevi can be challenging either from a clinical point of view or histopathologic ones. Several terms have been coined to refer to these lesions such as "dysplastic" or "atypical" nevi although a precise correlation between the clinical "atypical" aspects and the "atypical" histologic appearance has not found yet. Recently, the exact correlations between the histopathologic findings in the so-called dysplastic nevi and the confocal findings such as the bridging of the nests and the inflammatory infiltrate have been defined. However, a clear-cut distinction from severe atypical nevi and incipient melanoma is not always feasible, and it is strongly operator dependent either for pathologist or clinicians. In the presence of flat, reticular lesions, digital monitoring with short- and long-term follow-up represents the best strategy to avoid the excision of benign nevi and to not miss melanoma that do not fulfill all dermoscopic and confocal criteria to be classified as such at baseline.

Another difficult scenario is represented by the morphologic universe of Spitz tumors. Spitz/Reed nevi represent a family of lesions that show a variety of clinical and dermoscopic aspect, histologic features, and biologic attitudes.

A good correlation between histopathology and confocal microscopy is reached for the pagetoid spread that can be readily detected by the RCM as well as for the presence of a sharp lateral demarcation and spindled cells. Other parameters include the presence of junctional and dermal nests, parakeratosis, transepidermal melanin elimination, and inflammatory infiltrate rich in melanophages. No structures referable to Kamino bodies were observed on RCM. However, a deep assessment of cytologic and architectural changes is not possible by means of RCM, and thus, the management of Spitz tumors relies on the integration of clinical information and dermoscopic aspects.

Besides common nevi, Spitz nevi, and atypical nevi, another category consists of the so-called special nevi. They include a variety of different nevi such as recurrent nevi, Meyerson's nevi, and uncommon histopathological variants such as balloon cell nevus, just to name a few. Recurrent nevi are benign lesions that may regrow after partial excision (shaving) or trauma, but they can be challenging in case of unknown histological diagnosis of the primary tumor. Recurrent nevi do not exhibit prominent pagetoid or lateral spread of melanocytes and atypical nests at the junction, whereas recurrent melanomas were typified by the presence of classical RCM diagnostic criteria.

Although the diagnosis of Meyerson's nevus is usually rendered on a clinical ground, RCM can be used for cases with subclinical and not clear-cut dermoscopic criteria. In these cases, RCM allows the visualization of spongiotic vesicles in vivo, as round to ovoidal dark spaces, visible in the superficial layers of the epidermis around a typical melanocytic nevus.

Balloon cell nevus is a rare variant of nevus that is characterized by the presence of multiple aggregated white to yellow globular structures on dermoscopy. RCM reveals the presence of melanocytes within the nests with a vacuolized cytoplasm, visible as shiny grayish areas surrounding a dark nucleus.

Melanoma

The role of RCM for the diagnosis of melanoma and its characterization in different subtype has been demonstrated over the past decades.

Distinctive RCM criteria for melanoma diagnosis have been identified and validated.

The most relevant criteria include the presence of pagetoid spread, cytologic atypia at the DEJ, nonspecific architecture (nonedged papillae), melanocytes infiltrating dermal papillae, and atypical nesting including several nest types in particular sheetlike structures and cerebriform nests (Fig. 113.1). Pagetoid spread, also named

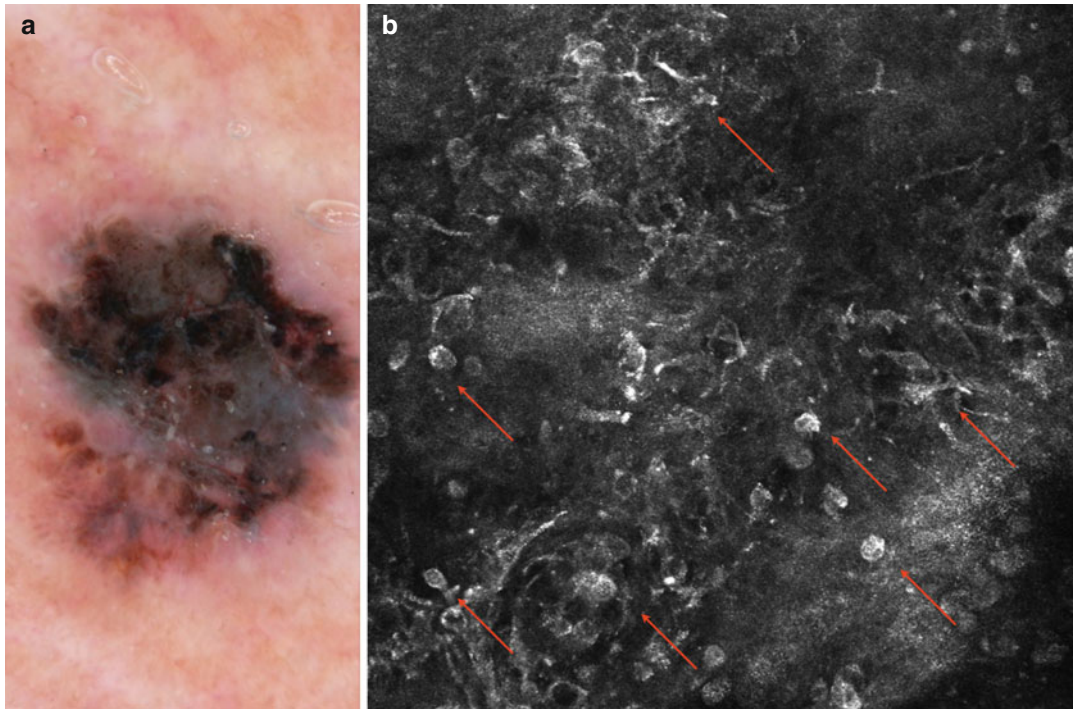

Fig. 113.1 (**a**) Dermoscopy of a melanoma showing a multicomponent pattern. (**b**) RCM reveals the presence of several pagetoid cells with bright cytoplasm and dark nucleus (*arrows*)

as epidermotropism or pagetoid melanocytosis, is one of the most striking and reproducible criteria, and it refers to the presence of atypical melanocytes, round or dendritic shaped, arranged as single cells or small nests, scattered within the epidermis. Localization of these cells, at the periphery of the lesion, in the center, or widespread, is crucial for identifying early melanomas displaying few confocal clues.

The presence of cytologic atypia is defined by the occurrence of atypical melanocytes at the dermoepidermal junction. When evaluating the architecture, melanomas typically show the absence of either a "regular" ringed, clod, or meshwork pattern as usually seen in common nevi. Instead, they are typified by an obvious interruption of the architecture with the onset of the so-called nonedged papillae associated with the presence of atypical melanocytes. Dermal nesting encompasses a wide range of confocal presentations according to distinct melanoma subtype and level of invasion (i.e., Breslow thickness). Nests can show up as dense and sparse nests, as sheetlike structures, and, rarely, as cerebriform nests. A newly defined entity named "nested" melanoma of the elderly is typified by the presence of compact nests with atypical melanocytes upon RCM.

An RCM score (based on six distinct morphologic features) was described and appeared to be the best method to differentiate melanoma from nevi. Another study (Guitera et al. 2010) established the additive value of this method when used with dermoscopy: in 326 cases, the specificity for the diagnosis of melanoma was doubled, with comparable sensitivity. RCM and dermoscopy together resulted in a false-negative rate of only 2.4 %. RCM was particularly efficient for amelanotic lesions. RCM features of difficult diagnosis were also published like nodular melanoma and small melanomas. In the largest RCM study to date, which included over 700 lesions suspicious for malignancy, a two-step method for the diagnosis of melanoma and basal cell carcinoma was reported. The diagnostic accuracy of the BCC algorithm was 100 % sensitivity and

88.5 % specificity (Guitera et al. 2010). The diagnostic accuracy of the melanoma algorithm was 87.6 % sensitivity and 70.8 % specificity.

Another field of application of RCM is represented by facial lesions for which a biopsy is not always accepted by the patients, and furthermore, a punch biopsy is not always enough material for the pathologist to make a conclusive diagnosis. RCM provides a fast diagnosis for pigmented and nonpigmented lesions on the face. The RCM diagnostic criteria of 284 difficult macules of the face were described in 2010 by Guitera et al. with a method (LM score composed of eight criteria) resulting in 93 % sensitivity and 82 % specificity for the diagnosis of lentigo maligna. The handheld RCM can be used to identify quickly and efficiently the microscopic features of malignancy, and a recent case series shows its interest in small amelanotic papules of the face.

Despite its application for the diagnosis, RCM can be used for a presurgical mapping of the tumor which often may present indistinct clinical borders. In a study analyzing 37 lentigo maligna, RCM produced "major" changes to the management in 73 % of the patients (Guitera et al. 2013).

Malignant Nonmelanoma Skin Tumors

RCM was extensively applied for the diagnosis of basal cell carcinoma (BCC) and for the characterization of actinic keratosis (AK) and, in few reports, for squamous cell carcinoma diagnosis.

Basal Cell Carcinoma

The hallmark for BCC diagnosis is the presence of basaloid islands that can show up as tightly packed aggregates with peripheral palisading and lobulated shape (Fig. 113.2). They could be more

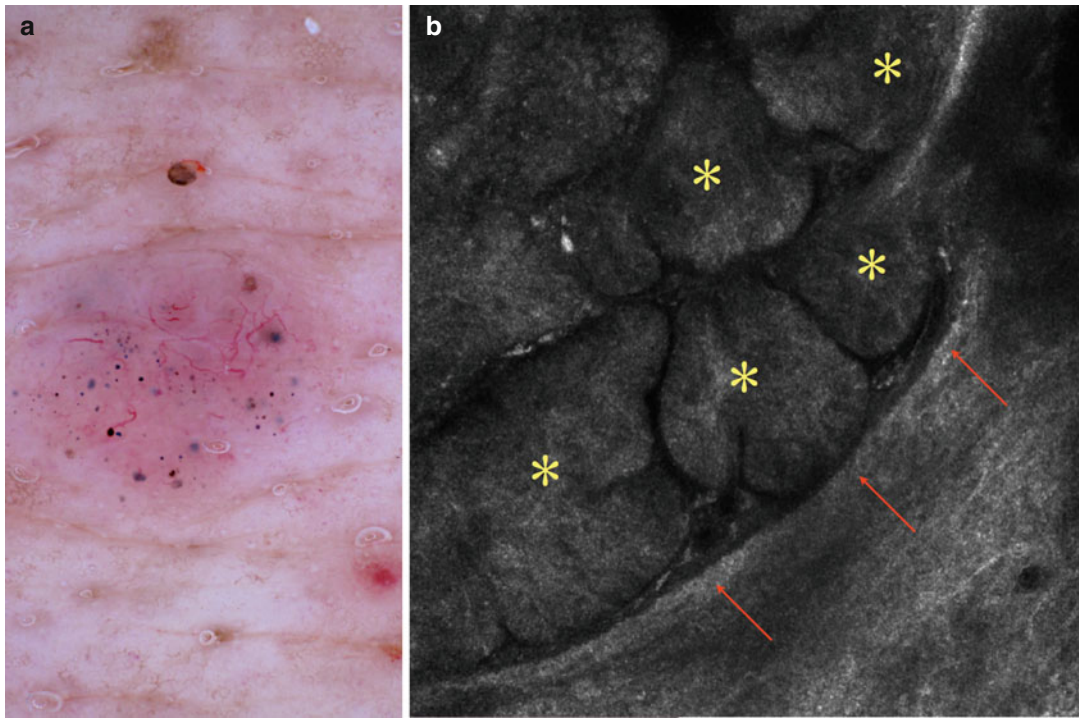

Fig. 113.2 (**a**) Dermoscopy of a nodular basal cell carcinoma typified by the presence of arborizing vessels and multiple *blue-gray dots*. (**b**) RCM shows the presence of tightly packed basaloid islands (*asterisks*) with peripheral palisading and outlined by a dark clefting (*arrows*)

or less refractive according to the presence of pigmentation within the tumor islands and in the surrounding (melanophages or free melanin). Additional features include the presence of the streaming of the epidermis and presence of blood vessels. Basaloid aggregates are outlined by dark spaces that correspond to mucin and often are surrounded by a prominent vascularity. Histopathologically, the aggregates correspond to the basaloid islands. Interestingly, RCM highlights very well the presence of dendritic melanocytes entrapped within the basaloid islands observable in heavily pigmented BCC.

Recently, the value of RCM in subtyping different BCC has been provided. The possibility to have a preoperative characterization of BCC is essential to choose the most appropriate treatment without performing a biopsy. Moreover, RCM for the diagnosis of nodular BCC showed 100 % sensitivity and 99.1 % specificity.

RCM was also used to define the specific features of fibroepithelioma of Pinkus (Longo et al. 2012) that show a typical "fenestrated pattern" that facilitate the recognition of this tumor.

Actinic Keratosis and Squamous Cell Carcinoma

Actinic keratosis and squamous cell carcinoma display the presence of variable keratinocytic atypia. At the stratum corneum, superficial disruption with single detached keratinocytes seen as bright, polygonal cells of high reflectance can be observed. Furthermore, nucleated, highly reflective cells with dark center and sharp demarcation appear within the stratum corneum corresponding to parakeratosis. Atypical honeycomb pattern and architectural disarray of variable degree are seen at the level of the stratum granulosum and stratum spinosum corresponding to different degrees of keratinocyte dysplasia on histopathological exam. In squamous cell carcinoma an atypical honeycomb or disarranged pattern of the spinous–granular layer is found along with round nucleated cells corresponding to pleomorphic keratinocytes (Fig. 113.3). Round blood vessels traversing through the dermal papillae perpendicular to the skin surface and scale crust appearing as brightly reflective amorphous

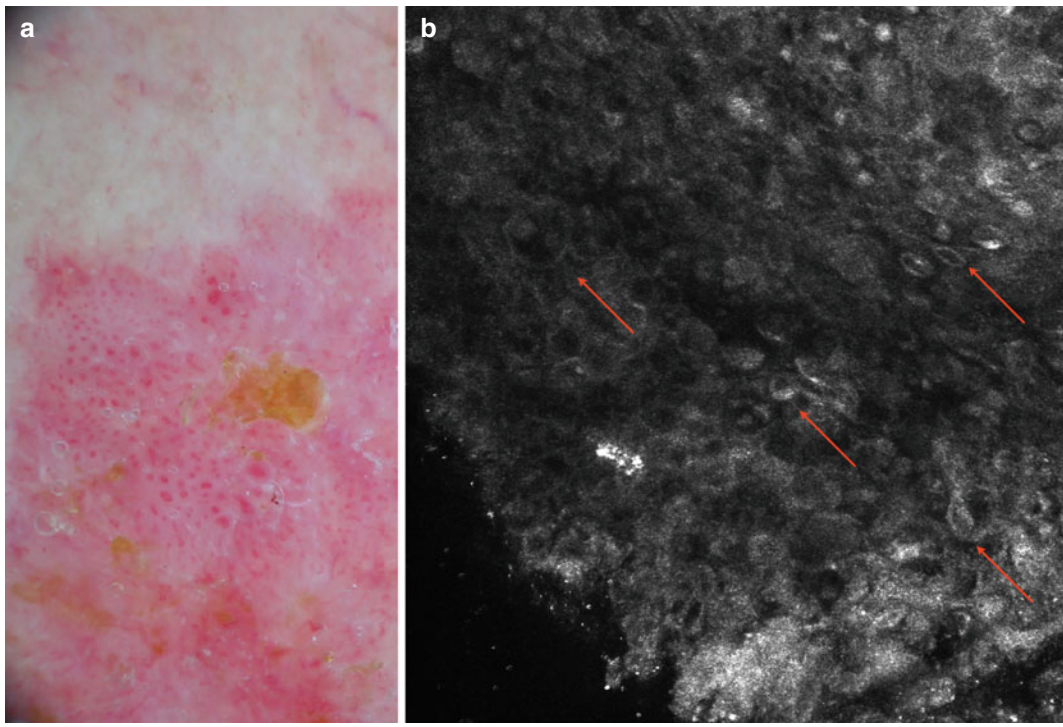

Fig. 113.3 (**a**) In situ squamous cell carcinoma that shows multiple glomerular vessels on dermoscopy. (**b**) RCM reveals the presence of marked dyskeratosis with atypical keratinocytes (*arrows*)

islands on the surface of the skin are common findings in SCC. In cases with marked hyperkeratosis or abundant scale covering the entire lesion, in-depth imaging is limited by the keratin scattering, limiting exploration of the DEJ, which is fundamental for complete diagnosis.

Other Tumors

Paget's disease is an uncommon type of intraepidermal adenocarcinoma. The first description of Paget's disease by means of RCM regarded a pigmented variant (Longo et al. 2007). Later, a case series on more cases of nonpigmented tumors was performed. As a clue, RCM shows the presence of large atypical pagetoid cells that can be present singly and in clusters. The presence of pagetoid spread and other confocal features, in the appropriate clinical context, may allow distinction from other inflammatory diseases that may appear similar clinically.

Inflammatory Skin Diseases

Inflammatory skin diseases include spongiotic dermatitis, psoriasiform diseases, diseases with interface involvement, and pigmentary nontumoral skin disorders (i.e., vitiligo, melasma).

The main feature of spongiotic dermatitis on RCM is the presence of inter- or intracellular spongiosis. This corresponds to an increased intercellular brightness due to inter- or intracellular fluid accumulation that leads to the appearance of a regular honeycomb morphology. When spongiosis is more pronounced, it is possible to detect vesicle formation that appears as well-demarcated, dark, hollow spaces between granular and spinous layer keratinocytes. Commonly, exocytosis is associated with spongiosis, whereby the inflammatory cells are seen on RCM as bright, round, highly refractive structures of about 8–10 μm, interspersed between keratinocytes. Inflammatory cells may also be observed to various extents in a perifollicular, perivascular, or interstitial dermal distribution.

Psoriasiform disease is distinguished by the presence of an increased number of nonrimmed papillae at the dermoepidermal junction, resulting in a junctional profile similar to that of normal skin but with papillae surrounded by faint rings of basal keratinocytes, instead of the typical bright rings.

The hallmark in interface dermatitis is the inflammatory involvement of the dermoepidermal junction. The inflammatory cells tend to obscure the junction profile and the dermal papillae with a more diffuse involvement in lichen planus and a focal distribution in lupus erythematosus. In the latter, the presence of inflammatory infiltrate can be seen in proximity of the adnexa that usually appear dilated (larger than 80–100 μm) and filled by highly refractive material in the lumen (hyperkeratotic infundibula).

Among the acquired pigmented disorders, RCM has been used to study vitiligo. Vitiligo lesional skin shows disappearance of the normal brightness at the dermoepidermal junction where the edged papillae appear as a remnant of the preexisting papillary ring.

Infectious Diseases

RCM has been applied in some infectious diseases although studies based on large cases are not available. Superficial mycosis can be easily detected by RCM since it has a high-level resolution for the upper epidermis. *Dermatophyte hyphae* appear as bright linear branching structures within the epidermis with an excellent correlation with the ones seen upon light microscopy. With the same high resolution, it is possible to detect the presence of *Demodex folliculorum* within the hair follicles that show up as multiple roundish well-outlined structures corresponding to the head-down mites. *Sarcoptes scabiei* is readily observed using within the burrow.

Conclusions

RCM discloses a new morphologic universe that is close to histopathology with the added value of being performed in vivo and over time.

As for any new technique, a dedicated training is needed to learn the basic notions and how to interpret them in the appropriate clinical context.

Since its first application, RCM emerged as a unique technique that may radically change the way to look at a given skin lesion and may offer not only an additional diagnostic help but also new insight into biologic phenomenon that cannot be merely explored with other devices. In the future, new studies will be performed to validate the current findings and to open new field of applications.

Cryosurgery

114

Aleksandar L. Krunic and Leonardo G. Marini

Key Points

Cryodestruction by liquid nitrogen is a very efficient method of treatment for various benign and malignant skin conditions. Proper planning of freezing and assessment of depth by monitoring the halo around the spray freeze or cryoprobes technique can successfully ablate many suitable lesions. Complications are minimal, no anesthesia is necessary, and the cost is low.

Table 114.1 Terminology of using subzero temperatures in biology and medicine

Cryobiology	Effects of subzero temperatures on a living system
Cryogenics	Development of freezing temperatures within a living tissue or cell
Cryotherapy	Therapeutic use of cold in a wide sense
Cryosurgery	Well-aimed and controlled destruction of disease tissue by application of cold

Modified from Zouboulis (1999)

General Principles

Cryosurgery refers to well-aimed and controlled application of freezing temperatures for the destruction of diseased tissue (Table 114.1) (Zouboulis 1999). Although primarily used for cutaneous lesions, cryosurgery is now getting wider applications in gynecology, urology, ophthalmology, neurosurgery, cardiology, and oncology. Since the discovery of liquid nitrogen in the 1940s, the modern era of cryosurgery has begun with myriad of procedures being performed in the outpatient settings with high safety and effectiveness, low cost, ease of application, good cosmetic results, and no need for local anesthesia.

History

Cryosurgery has been used in dermatology for the last 150 years. The first attempts were to treat lesions of lupus vulgaris (skin tuberculosis) with cold ice. Later on liquid helium, liquid air, and liquid oxygen were used, especially upon discovery of the vacuum flasks to store cryogens by James Dewar at the end of the nineteenth century. The ideal cryogen, liquid nitrogen, once discovered in the 1940s, quickly gained popularity by having the lowest boiling temperature of

−196 °C and being noncombustible. The initial application with cotton-ball method, preferable in the early 1950s, soon revealed inefficient due to the inability to achieve complete and optimal freezing of below −20 ° C at the treatment site. In the early 1960s, numerous sophisticated devices have been developed not just to preserve and deliver cryogen in the spray or contact technique, but also to monitor the temperature inside and below the treated lesions provided controlled and reliable cryodestruction of the targeted lesion. The works of dermatologist Setrag Zacarian and engineer Michael Bryne from Connecticut pioneered the use of cryogen spray units, now widely used for the application of cryosurgery worldwide.

Mechanism of Action

The biological changes that occur during the freezing process are divided to three phases, (a) direct tissue (cell injury), (b) vascular phase (vessel injury), and (c) inflammatory (immunological) phase, which is recently getting more and more attention due to the effects of improving antigen presentation in the frozen tissue and stimulation of the protective immune response.

(a) *Direct Cell Injury* – The initial drop of the temperature by rapid freezing speed of 100 °C/min first produces extracellular ice and cell dehydration (which is potentially reversible) also known as *heterogeneous nucleation*. Further freezing results in the formation of intracellular ice, since dehydrated cells open aquaporins, special channels in the cell membrane to fight the dehydration and improve water balance. The size of the ice crystals is very important, since larger crystals formed by rapid temperature decrease have more damaging effect. Intracellular ice crystals damage the mitochondria, endoplasmic reticulum, and other cell organelles inducing irreversible cell destruction also known as *homogenous nucleation*. This phase occurs when temperature drops below −20 to −25 °C, for keratinocytes, but much sooner for melanocytes (−4 to −7 °C) and sebocytes and hair follicles (−15 °C). Hence, the cryosurgery on hairy areas or pigmented skin can result in permanent alopecia or hypopigmentation, respectively. *Tissue thawing* at slow speed (spontaneously or up to 10 °C/min) contributes to more volume changes and intracellular edema due to the reversal of the osmotic gradient as well as intracellular water recrystallization. Thawing time should be at least 1.5 times longer than the freezing time for adequate cryosurgery. Fibroblasts die at −30 to −35 °C and are more resistant to freezing. That is why cryodestruction of malignant tumors requires −50 °C of freezing temperatures for the complete damage of tumor cells and its stroma, while benign lesions for optimal treatment need much lower freezing for −20 to −25 °C where just destruction of keratinocytes is sufficient without the destruction of the collagen supporting network. Furthermore, the preservation of stroma in cryodestruction of benign lesions is responsible for the lowest incidence of keloids in cryosurgery in comparison to any other surgical modality. The effect on cell viability reaches maximum at approximately 100 s of freezing, so the *optimal duration of freezing* is up to 30 s for benign lesions and 60 s for malignant tumors. A *second freeze-thaw cycle* causes more cell death and is required when malignant tumors are treated; for benign lesions, on the contrary, it is not essential. The treatment time of 30 s usually forms epidermo-dermal separation and hemorrhagic blister but never produces scarring or keloids. On the contrary, 60 s freezing (desirable for malignancies) results in cryonecrosis and formation of a scar.

(b) *Vascular Phase* – Cryogenic injury produces significant vascular changes including stasis, tissue anoxia, edema, focal capillary damage, hemorrhage, and microthrombosis. Thrombosis of all vessels is seen when temperature drops to −15 to −20 °C.

(c) *Immunological* (*Inflammatory*) *Phase* – An immunological response to cryosurgery was suggested in the late 1960s. This area is now

experiencing a great deal of research. The fact that the frozen tumor remains "in situ" after cryoablation enables macrophages, neutrophils, and dendritic cells to infiltrate in the first 48–72 h attracted by the cytokine milieu produced by cryodestructed cells. Later, lymphocytes migrate into the area contributing to augmentation of the immune response. Recent papers have suggested the stimulation of "protective response" after cryodestruction with suppression of T-reg lymphocytes, which are crucial for tumor survival and its escape from the host immune system. The evaluation of methods of augmenting the protective immune response after cryoablation with the use of adjuvants like imiquimod or cytotoxic compounds like podophyllin is currently also undergoing intensive investigation.

Equipment

Cryosurgery equipment (Fig. 114.1a–d) consists of cryogen liquid and its container, cryogun with different cryoprobes, spray tips, and attachments for intralesional cryosurgery – Luer lock and acne aperture for cryopeel. Liquid nitrogen is the ideal cryogen due to its very low boiling point of −196 °C (Table 114.2). The maximum storage

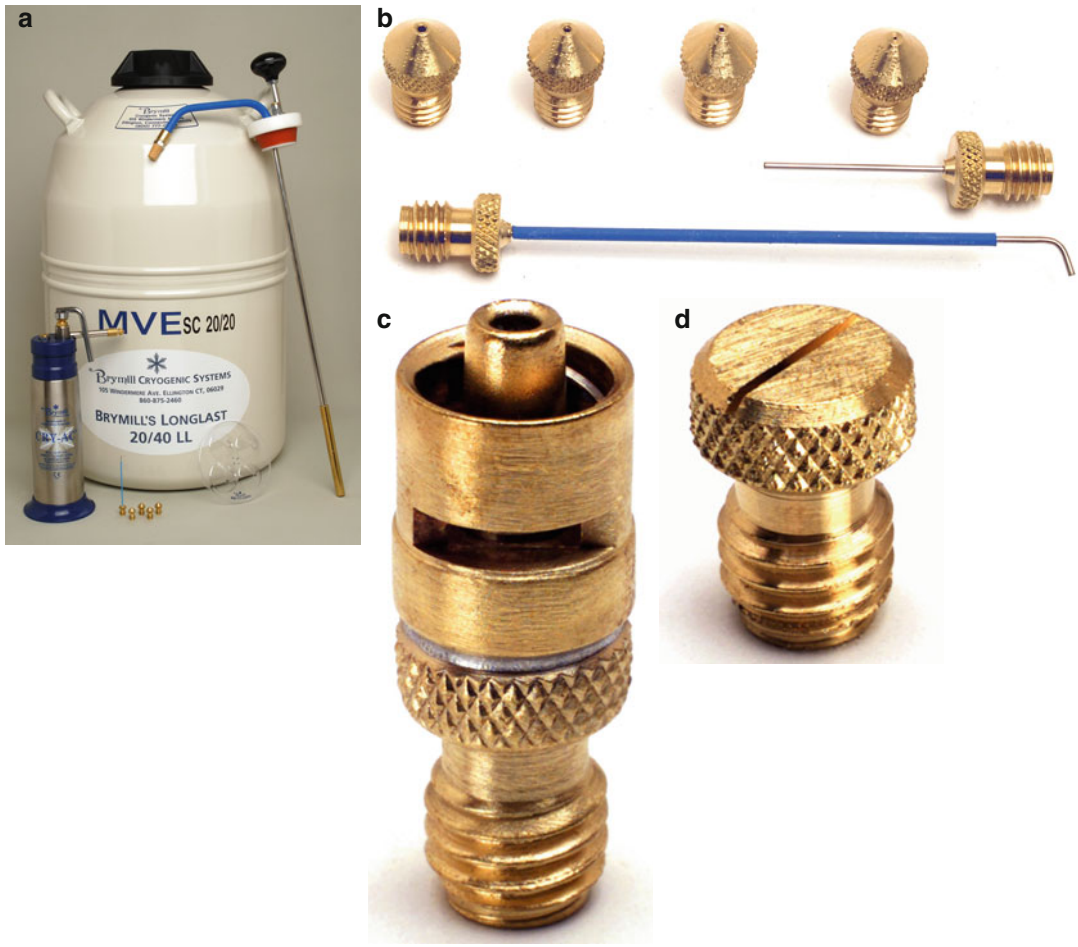

Fig. 114.1 Cryosurgery equipment. (**a**) Cryogun, withdrawal tube and container, (**b**) extensions for open spray, (**c**) Luer lock for intralesional cryosurgery, (**d**) acne aperture for cryopeel

Table 114.2 Cryogens and boiling points

Liquid nitrogen	−196 °C
Carbon dioxide	−70 °C
Nitrous oxide	−60 °C
Fluorocarbon liquids	−90 °C

capacity for containers used in skin surgery procedures is up to 50 l and for the time period of up to 300 days. The liquid nitrogen is poured into the cryogun, i.e., spray unit by using withdrawal tube (fills one bottle at the time) or withdrawal device (fills several bottles at the time). Simple decanting is to be avoided due to the risk of cryogen spillage and burns. Liquid nitrogen is odorless, inert, noncorrosive, noninflammable, and colorless and, at the room pressure of 1 atm, has temperature of 195.8 °C. Cryoguns can vary in volume from 300 to 500 ml and can store liquid nitrogen from 12 to 24 h. Simple Q-tips and plastic containers could be used for spot freeze technique with a cotton ball. This method is not precise and often does not produce complete freezing beyond desirable plateau for the treatment of benign tumors, which is below −15 °C. The used cotton ball should never be redipped into the spray bottle due to the risk of the contamination. The cryogen should be poured in the plastic/paper container to be discarded after each patient. The nozzles sizes for the spray bottle range from A through F, with F representing the smallest aperture. Different cryochambers, cryocones, and cryoprobes are used for more focused freezing when limited effect of the spray bottle is desired, without risk of damaging the sensitive surrounding skin. Bended extensions are attached to the spray nozzle to provide focused and precise application of the cryogen to cavities like the oral cavity, lips, ears, or nostrils. The variety of cryoprobes used for contact cryosurgery should be matched with the size of the treated lesions. Finally, Luer lock adapter serves for the attachment of the 16 or 18 G needle for intralesional cryosurgery mostly for keloids and some tumors. The last part of the equipment are tissue temperature monitors, obligatory with cryodestruction of malignant tumors, which work based on temperature change, electrical impedance, or ultrasound transmission. Finally, the invention of a new device – Cry-Ac Tracker (Fig. 114.2) – facilitated the controlled timely destruction of the target tissue by using the infrared monitoring method.

Fig. 114.2 Cry-Ac Tracker with infrared monitoring device

Techniques (Fig. 114.3)

The dose of liquid nitrogen and the choice of delivery method depend on the size, tissue type, and depth of the lesion. The area of the body on which the lesion is located and the required depth of freeze also should be considered. Additional patient factors to consider include the thickness of the epidermis and underlying structures, the water content of the skin, and local blood flow.

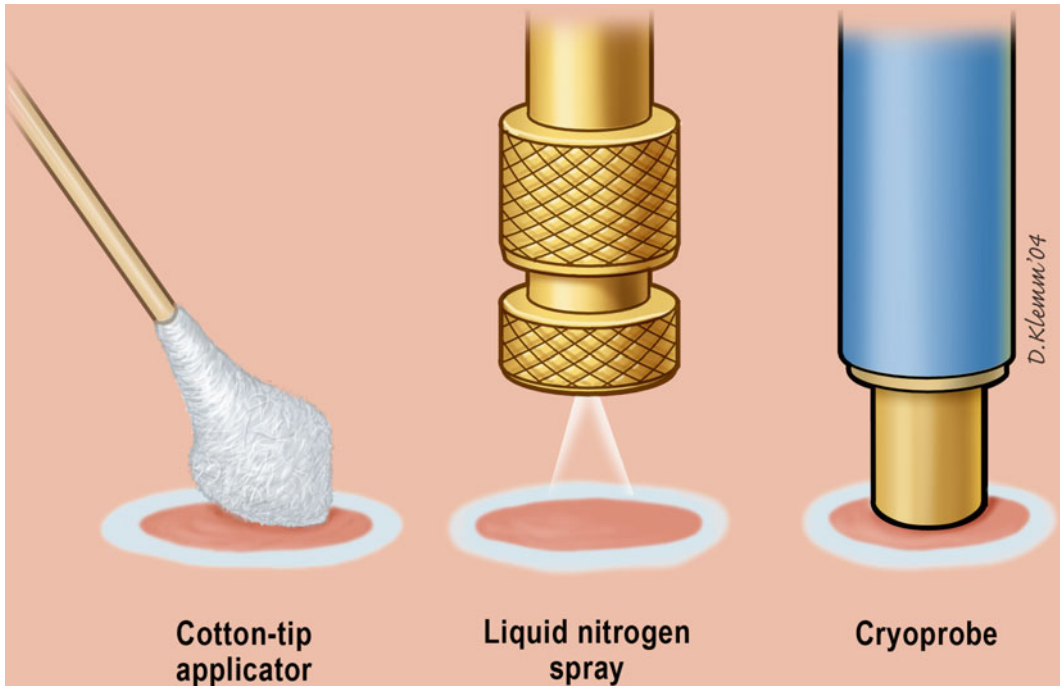

Fig. 114.3 Cryosurgery techniques (Printed with permission – Copyright David Klemm)

Liquid nitrogen spray methods for lesions of different sizes include the timed spot freeze or direct spray technique, the rotary or spiral pattern, and the paintbrush method, confined spray technique, and contact and intralesional cryosurgery (Fig. 114.4a–c). Each modality has different maximal freezing temperatures achieved in the treated tissue and should be used according to the desired depth of freeze (Table 114.3).

(a) *Timed Spot Freeze (Open Spray Technique)*. It may be the most appropriate method for physicians who are learning to perform cryosurgery. Use of this technique maximizes the ability to destroy a lesion with minimal morbidity. The freezing time is adjusted according to variables such as skin thickness, vascularity, tissue type, and lesion characteristics. Nozzle sizes B and C are suitable for the treatment of the most benign and malignant lesions; they are the apertures most frequently noted in case reports.

For the standard spot freeze technique, the nozzle of the spray gun is positioned 1–1.5 cm from the skin surface and aimed at the center of the target lesion. The spray gun trigger is depressed, and liquid nitrogen is sprayed until an ice field (or ice ball) encompasses the lesion and the desired margin. The designated ice field may need to be delineated in advance with a skin marker pen, because freezing may blur pretreatment lesion margins. The margin size depends primarily on the thickness of the lesion and whether the lesion is benign or malignant. Margins for most benign lesions are 1–2 mm beyond the visible pathologic border. Premalignant lesions need margins of 2–3 mm, while malignant lesions require margins of 5 mm of clinically normal skin to ensure adequate removal. These margin sizes allow enough depth of freeze to ensure temperatures of −50 °C to a depth of 4–5 mm. For benign/premalignant lesions freezing down to −25 °C is sufficient (Table 114.4). Once the ice field has filled the specified margin, the spray needs to be maintained (intermittently pressing/depressing the trigger) with the spray canister trigger pressure

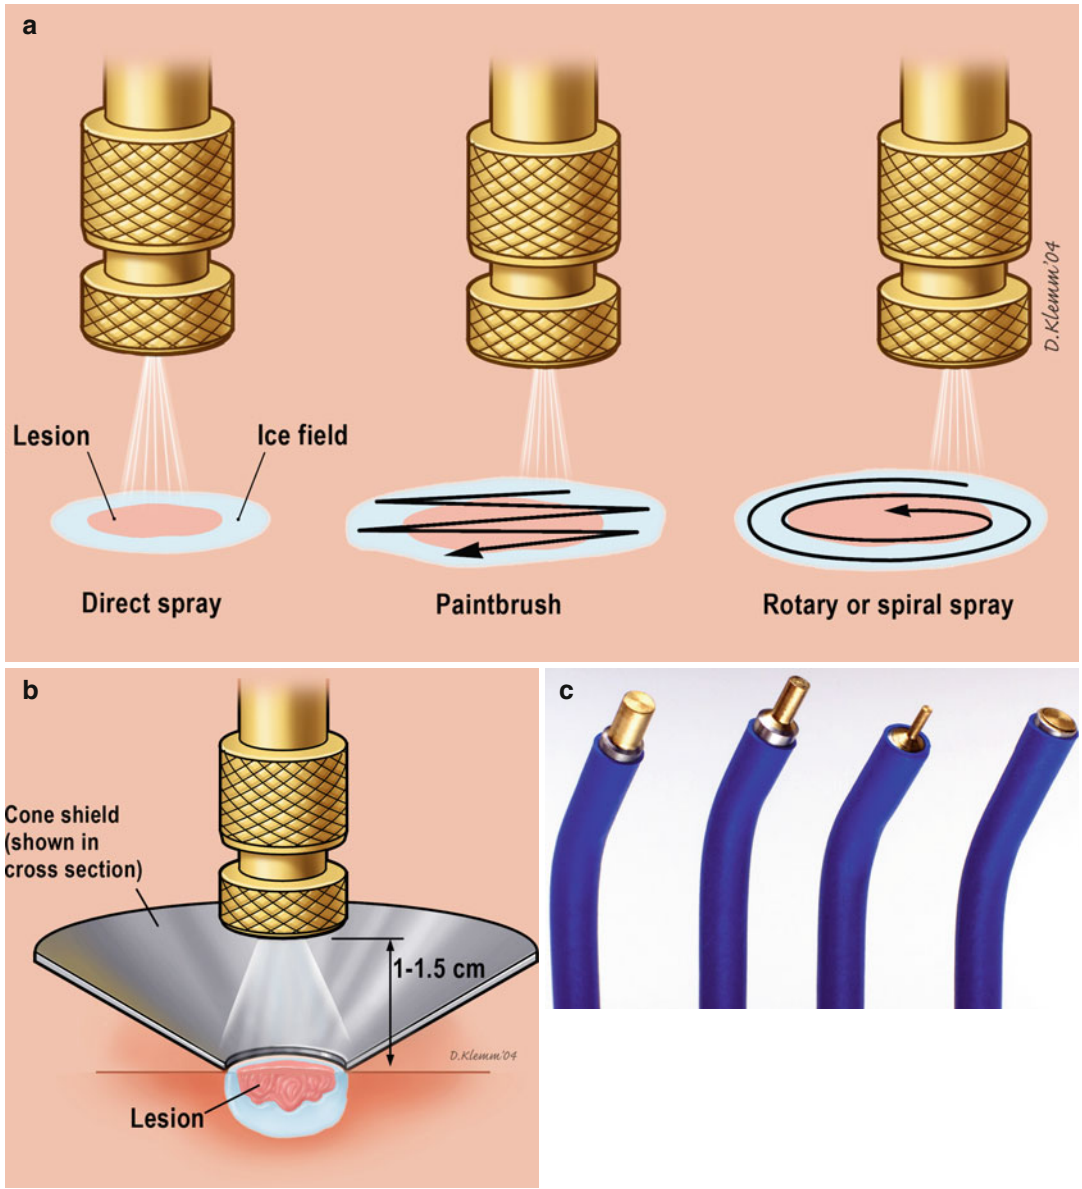

Fig. 114.4 (**a**) Spray patterns for larger lesions, (**b**) confined spray technique, (**c**) cryoprobes for contact cryosurgery (Printed with permission – Copyright David Klemm)

Table 114.3 Surface tissue temperatures attainable with various cryogens

Cryogen	Temperature (°C)
Carbon dioxide snow	−79
Nitrous oxide	−75
Liquid nitrogen Q-tip	−20
Liquid nitrogen spray	−180
Liquid nitrogen probe	−196

and, thus, the liquid nitrogen spray flow adjusted to keep the target field frozen for an adequate time. This time may vary from 5 to 30 s (60 s for malignant tumors) beyond the initial time for the formation of the ice field. If more than one freeze-thaw cycle is required for lesion destruction, complete thawing should be allowed before the next cycle. The

Table 114.4 General cryosurgical settings for skin tumors

Parameters	Benign	Malignant
Freezing speed	Moderate (≤100 °C) or rapid (≥100 °C)	Rapid (≥100 °C)
Thawing speed	Slow (10 °C/min) or spontaneous	Slow (10 °C/min) or spontaneous
Osmotic phenomena	Homogeneous and heterogeneous nucleation	Homogeneous nucleation
Probe temperature	−86 to −196 °C	−196 °C
Duration	30 s	60 s
Repetition of freeze-thaw cycles	No	Yes (twice)
Vascular reaction	Yes	Yes
Immunological reaction	Probable	Probable

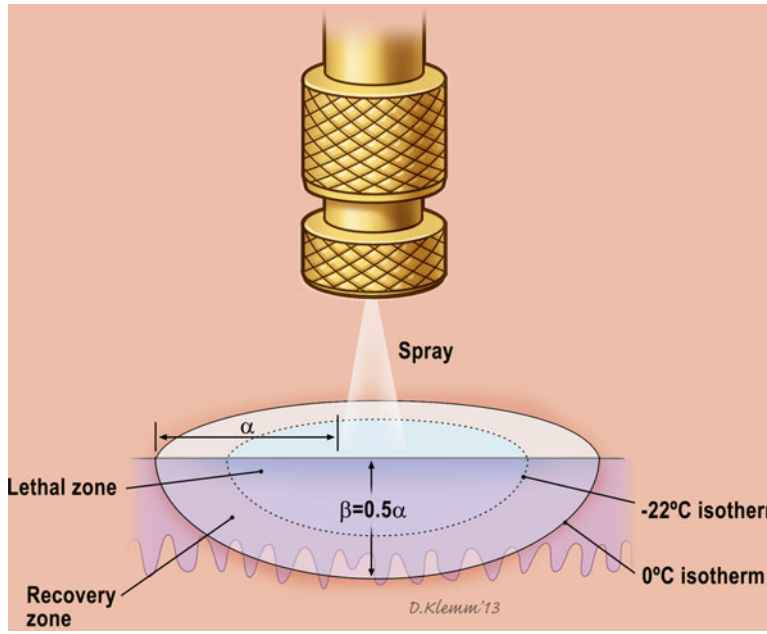

Fig. 114.5 Depth of freeze in open spray technique (Printed with permission – Brymill Corporation Inc.)

depth of freeze is approximately half of the lateral ice ball radius (Fig. 114.5). The thawing time is usually 2–3 min, i.e., 1.5 to two times longer than the freezing time. For lesions bigger than 2 cm in size, the open spray technique can be modified into the *rotary, spiral, or paintbrush pattern* to allow complete freezing.

(b) *Contact Cryosurgery*. Cryoprobes attached to liquid nitrogen spray gun can provide additional versatility especially when dealing with smaller and delicate lesions where deeper penetration is necessary (hemangiomas) or when surrounding skin is to be minimally affected like eyelid margins. The cryoprobes can vary in shape and size and are applied directly to the skin, ablating the lesions with contact exchange of the heat, and can be used with contact gel. The separate small hose is releasing liquid nitrogen from the side of the probe and should be kept away from the skin to avoid spillage of cryogen to nondesirable areas. Contact cryosurgery can penetrate up to 20 mm in depth and requires double freezing

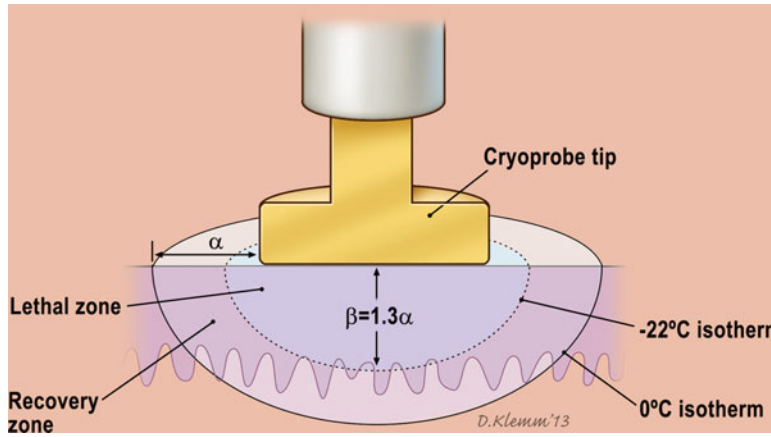

Fig. 114.6 Depth of freeze in contact cryosurgery (Printed with permission – Brymill Corporation Inc.)

times compared to spot spray freeze technique. The depth of freeze is approximately 1.3 times the radius of the ice ball (Fig. 114.6).

(c) *Intralesional Cryosurgery*. Needles for intralesional cryosurgery are applied to the nozzle using Luer lock adapter. A sprayed cryogen is then passed through the needle forming the ice cylinder. The distance of freeze can be estimated by monitoring the degree of extension of the whitish ice ball around the points of contact between the skin surface and the visible part of the needle. Depending of the size of the lesion, the needle can be reintroduced several times in order to provide more complete freezing. The main advantage of intralesional technique is the ability to freeze deeper than 20 mm, which is the maximal limit for spray and contact methods.

Clinical Applications

Most benign skin lesions can be treated successfully with any of several treatment modalities (excision, cryosurgery, electrodesiccation, and curettage). However, cosmesis, cost, and patient convenience may make one treatment modality more desirable than another. Patients should be informed about all treatment options and should be allowed to choose from the reasonable alternatives. Cryosurgery has advantages over the other modalities. Preparation time is short, and treatment requires no expensive supplies or injectable anesthesia. In addition, the risk of infection is low, wound care is minimal, and suture removal is not needed. Correct clinical diagnosis and lesion selection are as critical as the timing of the liquid nitrogen spray in producing a favorable outcome. Depending on the type of lesion, standard technique may need to be modified. Smaller flatter lesions require only 5–10 s of freezing and one cycle only. Larger thicker lesions may require longer duration of freeze up to 20 or even 30 s. Superficial keratin, especially in plantar warts, is a good insulator and should be removed by paring the lesion or application of keratolytics like salicylic acid in 2 weeks prior to cryosurgery. Before deciding about the length of freeze, one should always keep in mind the individual sensitivity of the different cell types to low temperature and adjust the duration of destruction (Table 114.5). Table 114.6 summarizes cryosurgery techniques for a variety of skin lesions.

Table 114.5 Sensitivity of different cell types to cryoinjury

Melanocytes	−4 to −7 °C
Sebaceous glands and hair follicles	−20 °C
Keratinocytes	−20 to −30 °C
Fibroblasts	−30 to −35 °C
Benign tumors	−20 to −25 °C
Malignant tumors	−50 to −60 °C

Table 114.6 Cryosurgery indications and techniques

Indications	Freeze time (seconds)	Number of freeze-thaw cycles	Margin (mm)	Typical treatment regimen	Technique
Benign lesions					
Acne	5–15	1	1	Once	Cryopeel
Angioma	10	1	<1	Once	P
Cutaneous horn	10–15	1	2	Once	OS
Dermatofibroma	20–60	1–2	2–3	Twice, bimonthly	P/OS
Hypertrophic scar	20	1	2	Once	OS/P
Ingrown toenail	30	1	2	Twice, bimonthly	OS

Lentigo maligna	60	2	5	Usually once	OS
Squamous cell carcinoma	60–90	2–3	5	Usually once	OS

By convention, freeze time is given as the interval following visible white ice formation
OS open spray, *P* cryoprobe, *F* forceps

Malignant conditions (mostly superficial basal cell carcinoma) require 60 s of freeze, tissue temperature monitoring, and two freeze-thaw cycles (Table 114.7).

Complications, Side Effects, and Contraindications

Contraindications

The relatively few contraindications to cryosurgery generally are related to concomitant illnesses in which excess reactions to cold may occur or delayed healing may be anticipated (Table 114.8). Some relative contraindications may make alternative treatment modalities more suitable. Physicians often do not perform cryosurgery in the pretibial areas, especially in elderly patients, because of slow wound healing.

Complications and Side Effects

Common complications and side effects of cryosurgery are listed in Table 114.9. Skin discomfort, generally a burning sensation, occurs with cryosurgery, but intensity is variable. The most sensitive areas are the fingertips, ears, and temples. Freezing of lesions on the forehead or temple may produce headaches. Treatment in hair-bearing areas can result in permanent hair

Table 114.7 Features of squamous cell carcinoma and basal cell carcinoma amenable to cryosurgery

Depth <3 mm
Diameter <2 mm
Low-risk site (e.g., trunk, extremity, cheek, forehead, neck, scalp)
Nodular or superficial basal cell carcinoma subtype (not sclerosing)
Not fixed to deeper structures
Primary lesion (not recurrent)
Well-defined margin
Well-differentiated squamous cell carcinoma

Table 114.8 Contraindications to cryosurgery

Absolute contraindications	Relative contraindications (perform with caution)
Agammaglobulinemia	Anticoagulant use
Cold intolerance	Blistering disorders
Cold urticaria	Dark-skinned person
Cryofibrinogenemia (large areas)	Infants
Cryoglobulinemia (large areas)	Older persons
Immunosuppression	Sensory loss
Impaired vascular supply	Sun-damaged or irradiated skin
Multiple myeloma	Therapy overlying a bony prominence
Pyoderma gangrenosum	
Raynaud disease (digital cryotherapy most concerning)	
Unexplained blood dyscrasia	

Table 114.9 Complications of cryosurgery

Type	Adverse effect
Immediate	Bleeding, blistering, edema, nitrogen emphysema, pain, vascular headache, vasovagal syncope
Delayed	Bleeding, excessive granulation, infection, tendon rupture, ulceration
Temporary	Altered sensation, hyperpigmentation, hypertrophic scarring, milia, pyogenic granuloma
Permanent	Alopecia, atrophy, cartilage necrosis, hypopigmentation

loss. Hypopigmentation is common, especially with longer freeze times, but is less noticeable in light-skinned patients and improves within several months. Hypopigmentation is caused by the greater sensitivity of melanocytes to freezing, a situation that can be used to advantage in the treatment of dermatofibromas, which frequently have some mild overlying hyperpigmentation. Feathering of the freeze margin (lighter freeze area) often results in a better transition of pigmentary changes. Freezing for less than 30 s beyond initial freeze ball formation does not result in scarring because of the preservation of fibroblasts and the collagen network of the dermis, which allows migration of the cellular components in the healing process and rebuilds the normal integrity of the skin layers. Although rare and usually temporary, sensory nerve damage has been reported occasionally in large case series, which may sometimes take 12–18 months to resolve.

Conclusions

If performed properly, cryosurgery is a relatively safe and simple procedure with few contraindications and low complication rate (Table 114.10). It provides good to excellent cosmesis, short duration, low cost, and high healing rate in difficult areas. It is also suitable

Table 114.10 Advantages of cryosurgery vs. conventional surgical techniques

Anesthesia optional
Excellent cosmetic results
Low cost
Low risk of infection
Minimal wound care
No need for suture removal
No work or sport restriction
Portable to multiple treatment settings
Safe procedure
Short preparation time
Useful in pregnancy

for use with no general or local anesthesia in wide population of patients including older, nonoperable, or pregnant individuals.

Dermoscopy of Nonmelanocytic Skin Tumors

115

Aimilios Lallas, Zoe Apalla,
Giuseppe Argenziano, and Iris Zalaudek

Key Points

- Dermoscopy is a widely accessible, inexpensive, and reliable noninvasive diagnostic tool that improves the accuracy of the clinical diagnosis of skin tumors.
- Most dermoscopic patterns correlate with specific histopathologic substrates. Accordingly, dermoscopy allows a better differentiation between specific subtypes of skin tumors.
- The common benign epithelial skin tumors, such as solar lentigo and actinic keratosis, typically display specific dermoscopic criteria, which allow their clinical recognition.
- The dermoscopic hallmark of all vascular tumors is a mixture of red-purple-blue at times black colors, which however present with different patterns.
- Adnexal tumors are generally considered as dermoscopic mimickers of basal cell carcinoma, but specific clues exist, facilitating the differential diagnosis.
- The sensitivity and specificity rate of dermoscopy in the diagnosis of basal cell carcinoma is reported to be 9 and 93 %, respectively.
- Dermoscopy reaches 98 % sensitivity and 95 % specificity in the diagnosis of actinic keratosis.
- Dermoscopy reaches 79 % sensitivity and 87 % specificity in the diagnosis of squamous cell carcinoma.

General Principles

Dermoscopy has become an integrative part of the clinical examination of skin tumors, since most dermoscopic patterns correlate with specific histopathologic substrates. The dermoscopic patterns of several benign and malignant nonmelanocytic tumors have been described in the literature. Some dermoscopic criteria are considered specific for one diagnosis, while some others can be found in more than one entity. Overall, dermoscopy, by revealing morphologic structures

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_115, © Springer-Verlag Berlin Heidelberg 2015

invisible to the naked eye, allows a better differentiation between specific subtypes of skin neoplasms. The dermoscopic patterns of the most common benign and malignant nonmelanocytic tumors are described below.

Dermoscopy of Common Benign, Epithelial Skin Tumors

Solar Lentigo

Solar lentigo (SL, synonyms: actinic lentigo, senile lentigo) is commonly regarded as the initial presentation of seborrheic keratosis (SK), based on the frequent clinical and histopathologic association between these two entities.

SLs typically present as multiple, variably large (up to few cm), light to dark brown, irregularly outlined macules, on chronically sun-exposed body sites such as the face, dorsum of the hands, and extensor surface of the forearms. They are commonly seen in severely sun-damaged skin of elderly individuals, but may also appear at a younger age.

Dermoscopic Pattern

Although the clinical diagnosis of SL usually does not prompt diagnostic difficulties, differentiation from early lentigo maligna (LM), which also arises on sun-damaged skin, might occasionally be challenging. In such cases, the dermoscopic examination might aid the accurate diagnosis.

The dermoscopic features of SL are site-dependent, with extrafacial lesions displaying frequently densely arranged, roundish to oval brown circles, reminiscent of a delicate reticular pattern. Other features include curved parallel, brown lines (fingerprint-like structure) or a structureless brown pattern with a sharp convex-concave demarcation ("moth-eaten").

In contrast, facial SLs less frequently exhibit a structureless pattern or circles but are typified by a light to dark brown pseudonetwork pattern with sharp demarcation. The pseudonetwork pattern is caused by a structureless brown pigmentation, which is interrupted by numerous nonpigmented follicular openings. The recognition of SL is easier when the brown pseudonetwork is combined with parallel curved lines, brown elongated circles (fingerprint-like structures or fat fingers), and sharp demarcation (jelly sign or moth-eaten borders).

The dermoscopic discrimination from LM is facilitated by the characteristic patterns of SL as well as on the absence of gray structures (gray circles within the hair follicle, gray dots around the hair follicles or within the hair follicle, or gray-brown lines), which are, with only few exceptions (regressing SL), more frequently observed in LM.

Ink-Spot Lentigo

Ink-spot lentigo represents a heavily pigmented reticulated type of SL, which typically develops as a solitary, bizarre outlined, black macule on the shoulders of persons with a freckling phenotype and fair skin and with a history of severe sunburns.

In the surrounding skin, numerous additional brown freckles (solar freckles) are usually seen. Because of its irregular clinical shape and the strikingly black color, ink-spot lentigo is considered a simulator of melanoma in situ.

Dermoscopic Pattern

Ink-spot lentigo is typified by a unique dermoscopic pattern, consisting of dark brown to black and interrupted (broken up) pigment network with thick lines and wide meshes.

Mucosal Lentigo

Mucosal lentigines (also called mucosal macules or melanosis) of oral and genital mucosal membrane are benign, pigmented, nonmelanocytic macules. They may develop as solitary or multiple lesions with a tendency to confluence. Clinical differentiation between mucosal melanosis and mucosal melanoma may be troublesome, and histopathologic examination is often required to establish a definite diagnosis.

Labial lentigo of the lips commonly develops on the lower lip of fair-skinned individuals after sun exposure and appears as a small, round to oval, light brown to brown-gray macule. Importantly, the macule is strictly located to the mucosa and does not extend to the normal skin.

Genital melanosis can occur as a solitary, brown to brown-gray macule of variable size or as diffuse, multifocal, irregularly outlined, brownish-grayish confluent macules forming a speckled pattern.

Dermoscopic Pattern

The most characteristic findings of mucosal lentigines are variable shades of brown-gray color and parallel curved lines and roundish to oval circles or a structureless pattern.

Detection of blue-white, blue-gray, or white-red color in association with structureless areas, atypical pigment network, white network (syn: reticular depigmentation, inverse network), or irregular black dots and globules should always raise the suspicion of melanoma and warrant a biopsy and histopathologic examination.

A potential clue for the differential diagnosis of multifocal, genital melanosis from mucosal melanoma is based on the palpability of the lesion. While mucosal melanosis is always flat, multifocal melanoma can be regarded as advanced at time of presentation and therefore often reveals nodular, invasive areas with a dermoscopic blue-black coloration.

Seborrheic Keratosis

SK is a common, benign epithelial skin tumor, which develops commonly on the face and the trunk, but may involve any body site except the palms and soles. SKs appear as solitary or multiple, slightly raised to nodular, well-demarcated lesions with a keratotic, papillomatous, or smooth surface.

Lesions typically have a "stuck on" appearance. The color of SK varies from yellowish to opaque brown black or gray. A sharp demarcation, a dull and verrucous surface, and the prominent follicular orifices represent useful clinical signs that allow a straightforward diagnosis in most cases. At times, irritated SKs or peculiar histopathologic variants such as melanoacanthoma or clonal SK may cause diagnostic difficulties.

Dermoscopic Patterns (Definitions of Dermoscopic Criteria Are Shown in Table 115.1)

The most classical dermoscopic features of SK are multiple milia-like cysts, multiple comedo-like openings, a sharp demarcation of the border, and a brain-like pattern. In irritated SK, hairpin vessels and thick dotted vessels surrounded by a whitish halo are commonly seen. These vessels correspond to long capillary loops and can be seen in other keratinizing tumors such as squamous cell carcinoma, where they are located at the periphery of a keratotic structureless center.

Acanthotic Type

Among various histopathologic variants of SK, acanthotic, reticulated, and verrucous subtypes represent the majority of lesions, and each one of them displays a distinctive dermoscopic pattern, consisting of different combinations of the aforementioned criteria.

Acanthotic SK is the most frequent subtype and reveals upon dermoscopy multiple milia-like cysts and comedo-like openings. Its color varies from yellow to light brown to black gray. A brain-like appearance is very common in acanthotic SK, especially when located on the face. Hairpin vessels, exophytic papillary structures, and a peripheral delicate pigment network may also be seen. Fingerprinting, a sharp demarcation, and a moth-eaten border represent additional characteristics of initial SK developing from SL.

Reticulated Type

Reticulated SK usually presents as small (<6 mm) slightly raised, uniform colored, and sharply demarcated lesion. Dermoscopically, it exhibits a network structure, composed by densely aligned, brown round or oval circles or thick lines. Dermoscopic clues for differentiating the network structures of reticulated SK from the network of melanocytic tumors are based on the striking sharp

Table 115.1 Definition of dermoscopic criteria associated with seborrheic keratosis

Dermoscopic criterion	Description	Diagnostic significance
Milia-like cysts	Numerous, variously sized, white or yellowish, roundish structures	Acanthotic SK
Comedo-like openings	Brown-yellowish to brown-black, round to oval, sharply circumscribed keratotic plugs in the ostia of hair follicles	Acanthotic SK
Brain-like (cerebriform) pattern	Dark brown fissures between ridges typifying a brain-like appearance	Acanthotic SK
Network-like structures	A peculiar type of pigment network with thick, hyperpigmented lines that may end abruptly at the periphery and large grids with holes corresponding to keratin-filled structures	Reticulated SK
Fingerprint-like structures	A peculiar type of delicate pigment network consisting of curved, light brown, parallel lines	Reticulated SK
		SL
Hairpin vessels	Linear, looped vessels, usually regularly distributed and monomorphous, but sometimes elongated or twisted. Often surrounded by a whitish halo, they are typically seen in elevated or nodular area of the lesion while appearing as thick red dots in flat portions of the lesion	Irritated acanthotic SK
		Irritated keratotic SK
Sharp demarcation	Abrupt cutoff of pigmentation at the border of the lesion	Acanthotic SK
		Reticulated SK
		Keratotic SK
		SL
Moth-eaten borders	Sharp convex-concave demarcation in some parts of the lesion	Reticulated SK
		SL
Wobble pattern	The lesion follows the movement of the dermatoscope, but the static image does not change because the stiff, papular component cannot be dissociated from the surface of the lesion itself	Acanthotic SK
		Keratotic SK

Abbreviations: *SK* seborrheic keratosis, *SL* solar lentigo

demarcation of the network-like structure in SK, whereas the network of a melanocytic tumor often shows a fading towards the periphery.

Keratotic Type

Dermoscopy of SK of this type reveals only white to yellow horn masses which impede the visualization of underlying structures. As at times melanoma may reveal a similar pattern, histopathologic confirmation of solitary lesions with this pattern is generally recommended.

Lichen Planus-Like Keratosis

Lichen planus-like keratosis (LPLK) refers to an SL or an SK undergoing spontaneous regression. Clinically, LPLK presents as flat gray to gray-brown macule. The discrimination between LPLK and regressive LM is feasible only if areas of the preexisting benign lesion (SK or SL) are still preserved.

Dermoscopic Pattern

Dermoscopically, fully or nearly fully regressed LPLK is characterized by diffuse brownish-gray granules, which may coalesce to form globules, streaks, or even structures similar to rhomboids. Since LM may exhibit the same features, a lesion dermoscopically characterized by signs of evident regression (i.e., localized or diffuse gray granules) should be always biopsied, unless criteria of a preexisting SL or SK are clearly evident.

Dermoscopy of Vascular Tumors

Benign Vascular Tumors

Among a range of benign vascular tumors, herein only the most common ones, namely, hemangioma, angiokeratoma, pyogenic granuloma, Kaposi sarcoma, and angiosarcoma, will be discussed.

Dermoscopic Pattern

The dermoscopic hallmark of all vascular tumors is a mixture of red-purple-blue at times black colors, which however present with different patterns among the above referred entities.

Hemangioma

The term hemangioma in the daily practice is commonly used to refer to cherry (also called) senile angiomas. Their dermoscopic hallmark is red to purple lacunas (globules), which are well-circumscribed, round to oval, structures, histopathologically corresponding to dilated, blood-filled vessels in the papillary dermis. A white veil or white line is frequently seen among the lacunas. Cherry angiomas typically exhibit the above described lacunar pattern, which allows a safe dermoscopic diagnosis, even when the lesion is clinically equivocal.

Angiokeratoma

Angiokeratoma dermoscopically displays more commonly red-purple, purple-blue lacunas or structureless areas and sharply circumscribed black lacunas (globules), frequently associated with whitish-yellowish keratotic areas. The black globules thereby correspond to congealed blood in the stratum corneum of thrombotic vascular lacunas.

Pyogenic Granuloma

In contrast to hemangioma or angiokeratoma, pyogenic granuloma rarely shows black or purple-blue globules but is characterized by bright red, structureless areas, which are commonly associated with white intersections (white lines) and a whitish peripheral rim (collarette). Because thick, amelanotic melanoma may reveal similar features, the diagnosis of pyogenic granuloma should be always confirmed by histopathologic examination.

Subcorneal and Subungual Hemorrhage

Subcorneal hemorrhage (also called black heel due to the striking black color of congealed hemoglobin in the stratum corneum) is a result of trauma, typically developing on the heels of young athletes and less frequently on the palms. Similarly, subungual hemorrhage occurs following a nail trauma.

While patients usually recall the painful trauma of the nail, patients with subcorneal hemorrhage after sportive activity are usually highly concerned and seek urgent consultation.

Clinically, subcorneal and subungual hemorrhages appear as asymptomatic, sharply circumscribed, homogeneous, red-black macules.

Dermoscopic Pattern

Dermoscopy typically reveals a sharply demarcated dark red to black structureless pigmentation. Adjacent to the main body of pigment, which is commonly sharply demarcated, satellite red-black dots or globules are often present (corresponding to blood spots), facilitating the accurate diagnosis.

An important clue for the differential diagnosis of subungual hemorrhage from melanoma is based on the fact that subungual hemorrhage usually does not extend from the proximal to the distal nail plate but presents as partial nail pigmentation with a roundish border at the proximal end and streaks or lines along with blood spots at the distal end.

Subcorneal hemorrhage may occasionally exhibit a parallel ridge pattern, which is an important criterion in the early diagnosis of acral melanoma. In this scenario, a sharp demarcation of the lesion and presence of blood spots may be important clues for the correct diagnosis. Moreover, the positive scratch test (i.e., removal of pigmentation by scratching the stratum corneum) with a needle or scalpel aids the correct diagnosis of subcorneal hemorrhage.

Malignant Vascular Tumors

Cutaneous Angiosarcoma

Cutaneous angiosarcoma is an aggressive neoplasm that is generally divided into three clinical variants: angiosarcoma of the head and scalp (AS), lymphedema associated angiosarcoma (LAS) arising typically in the context of Stewart-Treves syndrome, and radiation-induced angiosarcoma (RIA) arising in previously irradiated skin areas. The classic AS is characterized by a tendency to metastasize to regional lymph nodes and lungs and is associated to a 5-year survival rate of 12–33 %.

Clinically, early AS develops as ill-defined, violaceous to bluish areas with an indurated border. At more advanced stages, the lesions become elevated or nodular and occasionally ulcerated. Extensive local growth is common, and margins are difficult to define surgically. In approximately half of the patients, the disease manifests with multiple separate foci. RIA and LAS tend to present as reddish to purple plaques with ill-defined borders.

Dermoscopic Pattern

On dermoscopy, the classic AS exhibits the typical colors of vascular tumors, namely red, purple, and blue. If nodules are present, white lines, corresponding histopathologically to fibrous septa between enlarged neoplastic vascular spaces, can be detected. In contrast to spontaneous AS, RIA appears to exhibit a more homogeneous pinkish-white pattern, which may be related to the high amount of fibrosis usually associated with these lesions.

Kaposi Sarcoma

Kaposi sarcoma (KS) can be categorized into four clinical and epidemiological variants: classic, endemic, epidemic, and iatrogenic. Classic KS shows a predilection for elderly men living in Eastern Europe and the Mediterranean. The early lesions of classic KS appear most commonly on the toes or soles as reddish, violaceous, or bluish-black macules and patches that spread and coalesce to form nodules or plaques. The course is slowly progressive and may lead to great enlargement of the lower extremities as a result of lymphedema.

Dermoscopic Pattern

Dermoscopically, Kaposi sarcoma usually lacks specific structures but is characterized by structureless areas of confluent red, purple, blue, yellow, and green color. This pattern has been also called "rainbow pattern."

Dermoscopy of Tumors of the Fibrous Tissue

Dermatofibroma

Dermatofibroma (DF) is a very common benign skin tumor which is considered to represent a reactive process to various causes, such as injuries, insect bites, or ruptured follicles. It most often develops on the lower legs, but may appear anywhere on the body. Clinically, DF is a firm plaque or nodule with a diameter ranging from 0.5 mm to 1 cm and a color varying from light brown to dark brown, purple, red, or yellow. A dimple-like depression following lateral compression represents a useful clinical sign for the recognition of DF. Differential diagnosis comprises a wide spectrum of benign and malignant tumors, including dermatofibrosarcoma protuberans.

Dermoscopic Pattern

The dermoscopic hallmark of DF is a sharply demarcated central white (scar-like) patch, surrounded by a delicate, regular, usually light brown pigment network. Sometimes within the central white patch several, small, roundish to oval globules of light brown coloration may be seen. A white network has also been described to occur within the central white patch, especially in large DFs. A reddish halo around the lesion may also be found, possibly reflecting external injury. Vascular structures can be found in approximately half of DFs, with erythema and dotted vessels representing the most common vascular dermoscopic criteria. In total, ten different global dermoscopic patterns have been described to characterize DF.

Atypical Fibroxanthoma and Malignant Fibrous Histiocytoma

Atypical fibroxanthoma (AFX) and malignant fibrous histiocytoma (MFH) are related tumors, sharing similar histopathologic characteristics, but differ significantly concerning their prognosis. The former, despite of its tendency to recur after incomplete excision, has an excellent prognosis, whereas MFH possesses a considerable metastatic potential, being associated with an overall survival rate of 50 %. AFX occurs mainly on the sun-exposed parts of elderly individuals. Clinically, it manifests as a rapidly enlarging, reddish, dome-shaped nodule, often with an eroded or crusted surface. MFH develops as an enlarging subcutaneous nodule that may acquire significant size and ulcerate.

Dermoscopic Pattern

Dermoscopically, AFX and MFH display reddish and whitish areas in combination with a polymorphous vascular pattern, consisting of various combinations of linear, dotted, hairpin, and highly tortuous vessels, irregularly distributed over the surface of the lesion. Ulceration, crusting, and keratin masses may also be detected. Although the findings of AFX and MFH cannot be regarded as specific, the detection of a polymorphous vascular pattern should raise the suspicion of a malignant tumor, warranting complete surgical excision.

Dermatofibrosarcoma Protuberans

Dermatofibrosarcoma protuberans (DFSP) is a relatively uncommon soft tissue neoplasm, characterized by a low-to-intermediate malignant potential, characterized by a locally aggressive biologic behavior and a high recurrence rate. Clinically, it initially presents as one or multiple erythematous, firm nodules or plaques that may suppurate or ulcerate. The primary lesions gradually enlarge and become confluent, forming characteristic bulky, protuberant neoplastic masses.

Dermoscopic Pattern

Dermoscopy might facilitate the clinical recognition of early lesions, by revealing a reddish background color in conjunction with fine linear vessels. A delicate pigment network has also been described in DFSP, but it lacks the characteristic peripheral arrangement observed in DF (Fig. 115.1).

Dermoscopy of Adnexal Tumors

Adnexal tumors are classified according to their differentiation as follicular, sebaceous, eccrine, and apocrine. Their natural course is generally favorable, although for several "benign" adnexal tumors, a "malignant" counterpart also has been described. Adnexal carcinomas are associated with a poor prognosis, which is, at least partially, related to their delayed recognition.

Sebaceous Tumors

Although consistent criteria for the diagnosis and nomenclature of sebaceous tumors are lacking, they are traditionally classified into benign sebaceous hyperplasia, sebaceous adenoma, sebaceoma (sebaceous epithelioma), and sebaceous carcinoma. Apart from sebaceous cysts and sebaceous hyperplasia which are common entities, sebaceous tumors are generally rare and typically occur in the context of Muir-Torre syndrome.

Dermoscopic Patterns

Sebaceous hyperplasia is dermoscopically typified by a whitish umbilicated, polylobular or structureless center, surrounded by elongated, scarcely branching vessels (crown vessels). A similar pattern consisting of central whitish/yellowish structures and crown vessels characterizes sebaceous cysts.

Two main dermoscopic patterns of sebaceous adenoma and sebaceoma have been described: first, tumors with a central crater, dermoscopically characterized by crown vessels surrounding an opaque structureless ovoid white-yellow

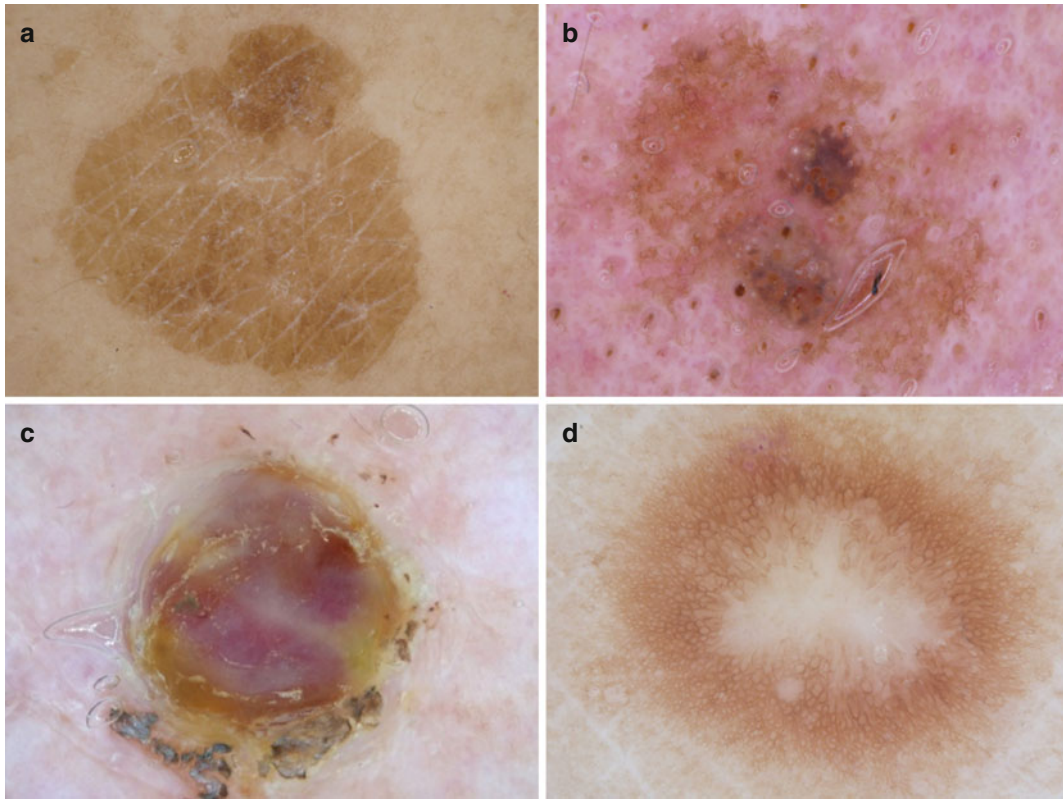

Fig. 115.1 (**a**) A solar lentigo dermoscopically typified by a structureless brown pigmentation and a sharply demarcated border. (**b**) Multiple milia-like cysts, comedo-like openings, and fingerprint-like structures are the dermoscopic hallmarks of seborrheic keratosis. (**c**) The "rainbow pattern" of Kaposi sarcoma, consisting of areas of confluent red, purple, blue, yellow, and green color. (**d**) The dermoscopic hallmark of dermatofibroma is a sharply demarcated central white (scar-like) patch, surrounded by a delicate, regular, light brown pigment network

center, which is at times covered by blood crusts, and, second, tumors without a central crater, which reveal branching but unfocused arborizing vessels over a white to yellow background and few loosely arranged yellow comedo-like globules.

Tumors of the Hair Follicle

Dermoscopic Patterns

In general, the dermoscopic pattern of follicular tumors displays overlapping features with basal cell carcinoma (BCC), namely, linear branching vessels and blue-gray dots or globules. The common presence of "white structures" has been suggested as a dermoscopic clue, suggestive of the diagnosis of a follicular tumor. Specific dermoscopic criteria are associated with some tumors, such as the unique ivory-white background color that typifies desmoplastic trichoepithelioma. Pilomatrixoma or calcifying epithelioma of Malherbe represents the commonest follicular tumor, usually affecting children and adolescents. Irregular white and/or yellow structures, white streaks, reddish homogenous areas, and linear vessels represent the most frequent dermoscopic criteria of pilomatrixoma, while ulceration and blue-gray areas are common additional findings. The white structures, histopathologically corresponding to calcification or keratin masses, represent the most useful single criterion for differentiating pilomatrixoma from melanoma and BCC.

Sweat Gland Tumors

Dermoscopic Patterns

Eccrine poroma is the most extensively studied sweat gland tumor, concerning its dermoscopic pattern. It is characterized by a high degree of dermoscopic variability, which is possibly explained by the existence of distinct histopathologic subtypes, depending on the location of the basaloid aggregations in relation to the epidermis.

Eccrine poroma may be pigmented or nonpigmented. In the former case, it may show overlapping dermoscopic features with BCC, such as blue-gray globules and arborizing vessels. Nonpigmented variants are composed by a polymorphous vascular pattern of coiled, hairpin, or linear vessels and represent important simulators of amelanotic melanoma and vice versa.

Mucinous carcinoma is characterized by eccrine sweat gland differentiation and represents a low-grade malignant tumor with a potential of local recurrence. Dermoscopy of mucinous carcinoma has been reported to mirror its peculiar histopathology, revealing a whitish network and light brown globules, which histopathologically correspond to fibrous septum and mucinous deposition, respectively.

Dermoscopy of Nonmelanoma Skin Cancer

The term nonmelanoma skin cancer (NMSC) encompasses basically all cutaneous malignancies that are not melanoma. However, it is mainly used to define BCC and SCC. With some exceptions, most BCC and SCC will not spread to other body sites, but may cause, if left untreated, significant morbidity including functional and cosmetic disfigurement. Early diagnosis and adequate treatment represent therefore key strategies in reducing BCC- and SCC-related morbidity and costs. Within the spectrum of NMSC, we also include Merkel cell carcinoma (MCC), which is a less common, but highly aggressive skin neoplasm, characterized by a rapidly increasing incidence.

Basal Cell Carcinoma

BCC accounts for approximately 80 % of all skin cancers, and its incidence has doubled over the past 25 years. Although BCC is observed in people of all races and skin types, dark-skinned individuals are rarely affected, and it is most often found in light-skinned individuals, particularly among those with a very fair skin color and red or blond hair. There are several histopathologic subtypes of BCC, which differ also with respect to their dermoscopic patterns.

Dermoscopic Patterns (Definitions of Dermoscopic Criteria Are Shown in Table 115.2)

The reported diagnostic accuracy of dermoscopy to recognize BCC ranges from 95 % to 99 %. The hallmark of nodular-cystic basal cell carcinoma is focused, bright red, and branching arborizing vessels. Although also sclerodermiform BCC reveals branching vessels, they are usually finer and more scattered and show fewer branches compared to the classic vessels of nodular BCC. In addition, the underlying fibrosis of sclerodermiform BCC results in a dermoscopically whitish background, whereas dermoscopy of nodular BCC typically reveals a translucent pinkish tumor. The most classical presentation of superficial BCC is that of a red, translucent, or opaque structureless plaque with multiple small erosions which are at times associated with short focused "microarborizing" fine telangiectasias with relatively few ramifications. Dermoscopy of pigmented nodular and superficial BCCs reveals different pigmentation patterns. Pigmented nodular BCC exhibits loosely arranged blue-gray globules that differ in size and number. These features are typically combined with arborizing vessels.

Instead pigmented superficial BCC tends to display translucent light brown to grayish finger-like projects (leaflike areas) which are typically located at the border of a nonpigmented center. Other features that are seen in pigmented superficial BCC are concentric structures composed by oval areas with a darker center and spoke wheel

Table 115.2 Definition of dermoscopic criteria associated with different subtypes of BCC

Dermoscopic criterion	Description	Diagnostic significance
"Classical" arborizing vessels	Stem vessels of large diameter branching irregularly into finest terminal capillaries. The vessels' color is bright red, being perfectly in focus in the images due to their location on the surface of the tumor (just below the epidermis)	Nodular-cystic BCC
Fine arborizing vessels	Scattered, fine, focused, elongated telangiectasias with fewer ramifications compared to the classic, thick arborizing telangiectasias	Sclerodermiform BCC Infiltrating BCC Nevoid BCC
Short arborizing vessels	Short, focused telangiectasias with very few branches. In FeP they are often associated with dotted and glomerular vessels	Superficial BCC Sclerodermiform BCC FeP
Large blue-gray ovoid nests	Well-circumscribed, confluent or near confluent pigmented ovoid or elongated areas, larger than globules and not intimately connected to pigmented tumor body	Nodular-cystic BCC
Multiple blue-gray dots and globules	Numerous, loosely arranged round to oval well-circumscribed structures, which are smaller than the large gray blue ovoid nests	Nodular-cystic BCC Nevoid BCC FeP
Focused dots	Loosely arranged well-defined small gray dots which appear sharply in focus	Nevoid BCC Infiltrating BCC
Concentric structures	Irregularly shaped globular-like structures with different colors (blue, gray, brown, black) and darker central area; they represent variations of the leaflike areas	Superficial BCC
Spoke wheel areas	Well-circumscribed radial projections, usually tan but sometimes blue or gray, meeting at often darker (dark brown, black, or blue) central axis	Superficial BCC
Leaflike areas	Translucent brown to gray/blue peripheral bulbous extensions that never arise from pigmented network and from adjacent confluent pigmented areas	Superficial BCC
Ulceration	Large structureless areas of red to black-red color	Nodular-cystic BCC
Small erosions	Small brown-red to brown-yellow crusts	Superficial BCC
Pink-white areas	Areas of structureless pink to white color	Superficial BCC FeP
Short white streaks (chrysalis)	Orthogonal short and thick crossing lines that are seen only by polarized dermoscopy	Superficial BCC FeP

Abbreviations: *BCC* basal cell carcinoma, *FeP* fibroepithelioma of Pinkus

areas (central darker globule surrounded by lighter, peripheral fingerlike projections).

Other variants of BCC including FeP and nevoid BCC may mimic a range of benign skin tumors such as dermal nevus, skin tag, or seborrheic keratosis, which are not routinely excised. As it became a rule to examine almost all skin lesions by dermoscopy irrespective whether they look clinically benign or malignant, these rare subtypes of BCC can be however easily identified by dermoscopy. This is because they reveal classical BCC-specific vascular or pigmented patterns. Finally, in patients with Gorlin–Goltz syndrome, dermoscopy allows the rapid identification of palmar pits by disclosing dotted vessels (Fig. 115.2).

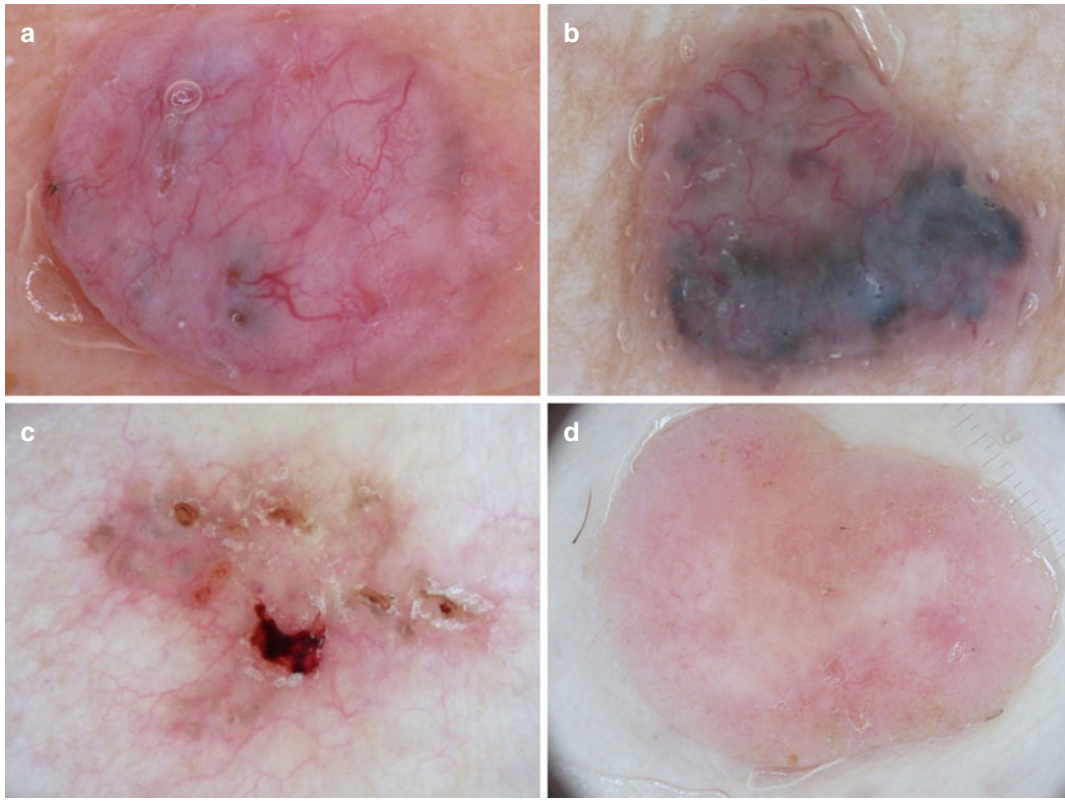

Fig. 115.2 (**a**, **b**) The dermoscopic prototype of nodular BCC, characterized by prominent, focused arborizing vessels and blue-gray ovoid nests. (**c**) A superficial BCC exhibiting short fine superficial telangiectasias, multiple small erosions, ulceration, and small foci of pigmentation. (**d**) A FeP dermoscopically displaying a white-pinkish background color with fine arborizing vessels in the center and dotted vessels at the periphery

Keratinocyte Skin Cancer

The term keratinocyte skin cancer refers to actinic keratosis (AK), intraepidermal carcinoma (IEC), and invasive squamous cell carcinoma (SCC).

Actinic Keratosis

Actinic keratoses (AKs) are the most common neoplasms within the continuum of keratinocyte skin cancer. They are nowadays defined as the earliest form of squamous cell carcinoma. AKs rarely develop as single lesion; effectively multiple lesions affecting an entire field of chronically actinic damaged skin are commonly present. This has lead to the concept of "field cancerization," which refers to the presence of genetically altered cell clones in normal appearing skin contiguous to fields of neoplastic cells, which have the potential of clonal expansion and thus give rise to locally recurrent skin cancer.

In 2007, a clinical classification for grading AK (grade 1, 2, and 3) was developed; grade 1 describes slightly palpable AK (better felt than seen), grade 2 shows moderately thick AK (easily felt and seen), and grade 3 is very thick, hyperkeratotic, and/or obvious.

Dermoscopic Patterns (Definitions of Dermoscopic Criteria Are Shown in Table 115.3)

The three different clinical grades of AK correspond dermoscopically to three different patterns. Grade I AKs are dermoscopically typified by red pseudonetwork pattern and discrete white

scales; grade II corresponds to an erythematous background intermingled by white to yellow, keratotic and enlarged follicular openings (these features are reminiscent of the surface of a strawberry; therefore, this pattern has been termed strawberry pattern). Grade III AK exhibits either enlarged follicular openings filled with keratotic plugs over a scaly and white-yellow appearing background or marked hyperkeratosis seen as white-yellow structureless areas. The diagnostic sensitivity and specificity of dermoscopy in the diagnosis of AK have been reported to reach 98 % and 95 %, respectively.

Intraepidermal Carcinoma and Bowen's Disease

IEC and Bowen's disease (BD) refer to an SCC in situ (SSCIS) with full-epidermal thickness dysplasia that has the potential for significant lateral spread before invasion. IEC and BD are often named synonymously to describe SSCIS. Clinically, lesions may be solitary or multiple and appear as slowly enlarging, erythematous, well-demarcated scaly patch or plaque.

Dermoscopic Patterns (Definitions of Dermoscopic Criteria Are Shown in Table 115.3)

Dermoscopically, BD is typified by the presence of dotted and/or glomerular vessels, white to yellowish surface scales, and a red-yellowish background color. Glomerular vessels represent a variation of dotted vessels but are larger in size and characterized by tortuous capillaries. Both dotted and glomerular vessels often appear within the same lesion and are distributed in small, densely packed clusters or groups or as lines at the periphery.

In cases of pigmented BD, in addition to the above-described criteria, small brown/black globules arranged either in a patchy distribution or in peripheral lines are seen. Dermoscopy was also shown to be useful for follow-up of a case of pigmented BD treated with laser ablation. Disappearance of disease-specific dermoscopic criteria was shown to predict a histopathologic clearance of the disease.

Squamous Cell Carcinoma

Primary cutaneous SCC is a malignant tumor that may arise from the keratinizing cells of the epidermis or its appendages. It is locally invasive and has the potential to metastasize to the regional lymph nodes and to other organs of the body.

SCC is the second most common skin cancer after basal cell carcinoma and causes the majority of deaths among the nonmelanoma skin malignancies. When detected and treated early, (less aggressive) SCC has a 95 % cure rate. However, if neglected, SCC may cause local tissue destruction and may metastasize. In the latter occasion, prognosis is extremely poor. Clinically, SCC usually presents as an indurated hyperkeratotic nodule with or without ulceration, or it may manifest as an ulcer without evidence of keratinization. Since SCC commonly develops on the background of AK, presence of the latter on the surrounding or neighboring skin may be clinically evident.

Dermoscopic Pattern (Definitions of Dermoscopic Criteria Are Shown in Table 115.3)

Dermoscopically, SCC is characterized by targetoid-appearing follicular openings (white circles) over a structureless white background. Additional features that are commonly seen are amorphous masses of white-yellow keratin (often located in the center) and polymorphic vessels consisting of peripheral hairpin, dotted/glomerular, and/or linear-irregular vessels.

This variability of vascular structures, along with more recently described criteria related to keratinization, may be useful to discriminate invasive SCC from in situ variants (AK and BD). In detail, according to a recently proposed model, progression from AK into invasive SCC is characterized by dermoscopically evident increase in vascularization and keratinization structures. The former is reflected by the development of initially dotted/glomerular vessels and latter, hairpin and linear/irregular vessels. Instead, keratinization is characterized by the early appearance of diffuse yellow-whitish opaque scales, followed by the development of white structureless areas or a central mass of keratin, associated with ulceration.

Table 115.3 Definition of dermoscopic criteria associated with actinic keratosis, intraepidermal carcinoma, and invasive squamous cell carcinoma

Dermoscopic criterion	Description	Diagnostic significance
Erythema	Structureless pale red areas without any recognizable areas of hypopigmentation or morphology	AK I
Red pseudonetwork	Structureless red areas which, intermingled with small roundish white areas, resemble a network structure; the small white areas correspond to the follicular openings of the skin	AK I
Strawberry pattern	Structureless red areas which, intermingled with evident, targetoid inner yellow and outer white roundish structures, resemble the surface of a strawberry; the targetoid areas correspond to keratin-filled follicular openings	AKII
Red starburst	Radial-arranged structureless red lines or hairpin vessels that surround a yellow to white structureless scaly center and which resemble overall a starburst appearance	AK II IEC
Dotted vessels	Tiny red dots densely aligned next to each other	IEC
Glomerular vessels	Variation on the theme of dotted vessels; they are larger than dotted vessels, have a convoluted morphology, and are often distributed in clusters	
Hairpin vessels	Vascular loops sometimes twisted and bending, usually surrounded by a whitish halo when seen in keratinizing tumors	SCC
Linear-irregular vessels	Linear or slightly curved, irregularly shaped, sized, and distributed red structures	SCC
Targetoid hair follicles	Variably large roundish structures composed of a yellow to light brown structureless center and a white outer structureless rim; this pattern corresponds to keratotic plugs within the follicular openings of the skin	AK II SCC
Rosettes	Four closely aggregated white, small dots in correspondence to the follicular opening and resembling a 4-leaved clover; if one imagines connecting the four dots with a line, a geometrical figure of a rhombus can be formed	AKI I–II
White structureless areas	White structureless areas in the absence of any structure; they may cover large areas of the tumor and may be associated with large targetoid hair follicles	SCC
Yellow to light brown opaque scales	Yellow to light brown opaque structureless areas with a scaly or keratotic aspect that do not cover large areas of the tumors surface	IEC
Erosions	Small and irregularly distributed orange to red to red-brown structureless areas; they correspond to superficial hemorrhages and are usually associated with yellow opaque structures	IEC SCC

In addition, keratin masses and white circles surrounding follicles have been recently proposed to specifically predict the diagnosis of SCC or KA among nonpigmented tumors.

Similarly, whitish background and keratin have been suggested to discriminate invasive SCC from amelanotic melanoma, which commonly exhibits a polymorphic vascular pattern associated with a pinkish background hue. Taken all the above into consideration, white structures and keratin represent valuable dermoscopic clues for diagnosis of invasive SCC.

It should be noted that well-differentiated SCC often presents as a rapidly growing nodule, which dermoscopically exhibits structureless white areas, central masses of keratin, and elongated

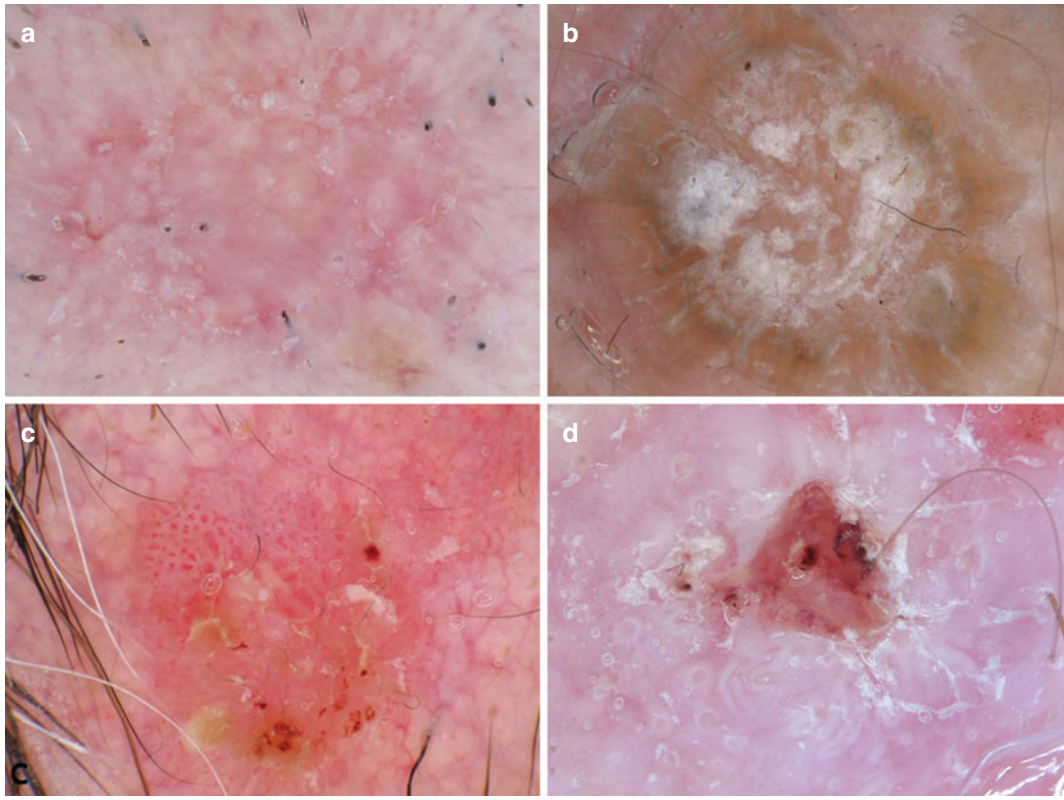

Fig. 115.3 (**a**) Grade I actinic keratosis is dermoscopically typified by the "strawberry pattern," consisting of a reddish background interrupted by whitish follicular openings. (**b**) A grade III actinic keratosis exhibiting marked hyperkeratosis seen as white-yellow structureless areas. A few dilated follicular openings filled with keratin plugs are visible. (**c**) Bowen's disease is dermoscopically characterized by glomerular vessels and white to yellowish surface scales. (**d**) A typical example of SCC, exhibiting white perifollicular circles, whitish structureless areas, and a large ulceration

peripheral vessels that remind to the arborizing vessels of BCC. Instead, poorly differentiated SCC lack signs of keratinization both dermoscopically and histopathologically and presents often as ulcerated plaque (endophytic growth) showing only polymorphous vessels (Fig. 115.3).

Merkel Cell Carcinoma

MCC is a very aggressive neoplasm, associated with a high risk of locoregional and distant spread and poor survival. Clinically, MCC most commonly develops as a persistent, asymptomatic, red/pink nodule that rapidly increases in size over a period of weeks to months. The most common sites of presentation are the head/neck region and extremities, followed by trunk and oral and genital mucosa. Because of its unspecific clinical presentation, the differential diagnostic spectrum of MCC is broad. Diagnosis is often delayed, since more than half of MCCs are thought to be benign at the time of biopsy.

Dermoscopic Pattern

Dermoscopy of MCC typically reveals a milky red background and a polymorphous vascular pattern, comprising dotted, arborizing, linear–irregular and glomerular vessels. This dermoscopic pattern cannot be considered as specific, since similar findings characterize amelanotic melanoma and other malignant tumors. However, dermoscopy may enhance the discrimination of MCC from benign tumors by

revealing features predictive of malignancy. Specifically, milky red areas, which represent the commonest criterion of MCC, are very rarely present in benign lesions (with the exception of pyogenic granuloma), whereas they are frequently detected in AM. Additionally, the synchronous presence of more than one morphologic type of vessels (forming the so-called polymorphous vascular pattern) is also suggestive of a malignant tumor, such as AM or squamous cell carcinoma (SCC). Effectively, detection of one or both of the above criteria should warrant complete surgical excision.

Future Perspectives

Up to date, much research has concentrated on the identification of criteria that aid the clinical diagnosis of skin, whereas only few well-designed and prospective studies focused on the impact of dermoscopy in the management. However, there is an increasing trend towards conducting such studies, and it can be expected that more evidence on the real value of dermoscopy in the treatment decision process and in the follow-up will be available in the next few years.

Dermoscopy of Pigmented Skin Lesions

116

Silvija Duma

Key Points

- Dermoscopy (epiluminescence microscopy) is a non-invasive diagnostic method. Apart from dermoscopy, digital dermoscopy and videodermoscopy are used to monitor the patients, as well as teledermoscopy, which provides new opportunities in this field.
- The first step in dermoscopy is determining melanocytic or non-melanocytic lesions, while the second one requires the use of some of the dermoscopic algorithms (pattern analysis, ABCD, 7-point checklist, Menzies analysis) for further categorization of the lesions into benign and malignant.
- The melanocytic as well as the non-melanocytic lesions present their own specific dermoscopic structures.

General Principles

Dermoscopy (also known as epiluminescence microscopy, dermatoscopy and amplified surface microscopy) is an in vivo non-invasive method for observation of pigmented skin lesions.

Dermoscopy requires optical magnification and liquid immersion. With dermoscopy, we can visualize the structures which are not visible to the naked eye, like structures in the epidermis, dermoepidermal junction and superficial and reticular dermis.

These morphological features (dermoscopic structures) have specific histopathological correlation. By understanding the histopathological equivalents of such structures, the investigators are able to understand the dermoscopic structures better and to make a distinction between benign vs. malignant pigmented skin lesions.

History of Dermoscopy

- Kolhaus started skin surface microscopy (1663).
- Ernst Abbe described the use of immersion oil in light microscopy (1878).
- Una introduced the term “diascopy” (1893).
- Zeiss created the first binocular dermatoscope (1916).
- Johann Saphier introduced the term dermoscopy and first published an article on dermoscopy (1920).
- Goldman was the first dermatologist who used a sophisticated dermoscopy technique (1950).

- Rona Mackie was the first to write about the preoperative use of dermoscopy and the benefit of it (1971).
- H. Pehamberger et al. introduced pattern analysis for the diagnosis of pigmented skin lesion (1987).
- H. P. Soyer et al. discussed that dermoscopic criteria are correlated with underlying histopathological structures.
- J. Kreusch and G. Rassner published the first atlas of dermoscopy in literature.
- W. Stolz et al. discussed that the application of the ABCD rule of dermoscopy represents a new practical method for early recognition of melanoma malignum.
- G. Argenziano et al. discussed the introduction of an algorithm for the detection of melanoma called 7-point checklist (1998).
- Consensus net meeting in Rome (2001).

Technique and Instruments

The technique consists of placing mineral oil, alcohol or even water on the skin lesion that is subsequently inspected by using a hand-held lens, a hand-held scope, a stereomicroscope, a camera or a digital imaging system. The magnification of the instrument ranges from 6× to 40× and even up to 100×. The widely used dermatoscope has a tenfold magnification permitting sufficient assessment of the pigmented skin lesions in daily routine.

The diagnostic instruments commonly used for dermoscopic examination and image acquisition are

1. Dermatoscope
2. Dermaphot
3. Stereomicroscope
4. Stereomicroscope according to Kreusch
5. Videodermatoscope
6. Teledermatoscope

Two-Step Dermoscopy Algorithm

The first step in performing a dermoscopic evaluation of a lesion is to determine whether it is melanocytic or non-melanocytic (not all pigmented lesions are melanocytic).

The classification is based on certain structures (network, pseudonetwork, globules, streaks, homogeneous blue pigmentation and parallel pattern). If the lesion does not have any positive criteria for a melanocytic lesion, it needs to be considered, by default, to be melanocytic/non-melanocytic.

If the lesion meets the criteria for melanocytic lesion, the second step in the two-step algorithm can be applied. With the second step we can differentiate benign naevi and melanoma by using the dermoscopic algorithm "pattern analysis", the ABCD rule, the Menzies method and the 7-point checklist.

Dermoscopic Colours and Structures

The eumelanin pigment has a brown colour. Colours in dermoscopy depend on the location of the melanin in the skin (black, stratum corneum; brown, epidermis; grey, upper dermis; steel blue, medium dermis).

Other colours seen in dermoscopy are red (inflammation, vascularity), white (depigmentation, scarring), yellow (hyperkeratosis, sebaceous material), orange (serum) and jet black (congealed blood).

Dermoscopic Structures

1. Pigment network

   The network represents the rete ridge pattern of the epidermis. The hypomelanotic holes in the network correspond to the tips of the dermal papillae and the overlying suprapapillary plates of the epidermis.

   The pigment network is the most important morphologic structure in the pigmented lesions. It is a net-like structure with a honeycomb look.

   The typical pigment network is uniform, with regular lines and holes, homogeneous in colours and usually thinning to periphery. The melanocytic naevi usually have this kind of network.

   An atypical network is non-uniform, with darker and broadened lines and holes, with heterogeneous area. It may abrupt at the periphery – usually seen in malignant lesions.

   A negative network is a term which describes the downgrowth of hypomelanotic

rete ridges into the dermis. In dermoscopy, this element is visualized as a pale, net-like structure with a brown hue filling the holes. This is in stark contrast to what is usually seen in pigmented lesions. It could actually be a feature of invasive melanoma or Spitz naevi.

A pseudonetwork on the face, palms and soles results from junctional pigment outlining hair follicles, sebaceous glands and eccrine duct. The pigment on the palm and soles outlines linear skin markings along or across the skin furrows, resulting in a parallel, lattice-like or fibrillar pattern.

2. Dots and globules
   Dots and globules are formed when aggregation of melanocytes or melanophages in the skin arises or when pigment occurs in clumps. Dots are dark brown to black or blue-grey small spherical structures less than 0.1 mm.

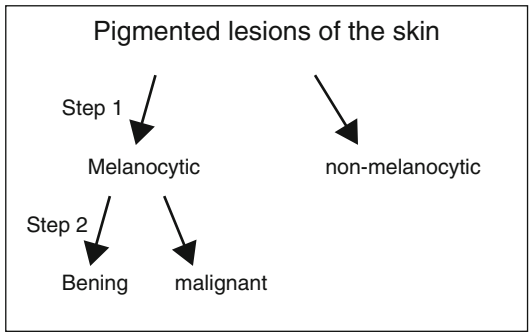
   Globules are brown, black or red spherical or ovoid structures with diameters usually greater than 0.1 mm.
3. Branched streaks and radial streaming
   Streaks are brownish-black linear structures of variable thickness found in benign and malignant lesions. They may be present at the periphery of a lesion or in the centre of the lesion. Streaks are formed by heavily pigmented, confluent junctional nests/fascicles of melanocytes that extend through the epidermis and by bridging nests of melanocytic cells within the epidermis and papillary dermis.

   Streaks at the periphery are a sign for superficial spreading melanoma and symmetric arrangement at entire lesion, seen in Reed and Spitz naevi (pigmented type).
4. Structureless areas
   Structureless areas are regions devoid of structures (e.g. globules, network) which tend to be hypopigmented.
5. Blotches
   Blotches are dark brown to black, usually homogeneous areas of pigment obscuring underlying structures. A blotch usually does not encompass the entire lesion.
6. Regression pattern
   Regression pattern is a white, scar-like depigmentation often combined with a blue-grey periphery.
7. Blue-white veil
   Blue-white veil is an irregular, indistinct, confluent blue pigmentation with an overlying white. The pigmentation cannot occupy the entire lesion.
8. Vascular pattern
   The dermoscopically visible vascular pattern includes comma vessels, point vessels, tree-like vessels and hairpin-like vessels.

   The atypical vascular pattern includes linear, dotted or globular red structures irregularly distributed within the lesions.
9. Milia-like cyst
   Small white or yellow cystic structures resemble milia, which often shines brightly. Pigmented milia-like cysts can resemble brown globules.
10. Regression pattern – it is a white, scar-like depigmentation, often combined with blue-grey peripheral zone or peppering.
11. Blue-white veil is an irregular, indistinct, confluent blue pigmentation with overlying white, ground-glass haze. The pigmentation cannot occupy the entire lesion.
12. Vascular patterns (structures) – they are dermoscopically visible vascular patterns, which include “comma vessels”, “point vessels”, “tree-like vessels”, “wreath-like vessels” and “hairpin-like vessels”.
    The atypical vascular pattern includes linear, dotted or globular red structures irregularly distributed within the lesion.
13. Milia-like cysts – they are small, white or yellow cystic structures resembling milia which often shine brightly. Pigmented milia-like cysts each resemble brown globules.
14. Comedo-like openings – they are blanched-like plugs, keratin-filled invaginations of the epidermis. They are mainly seen in seborrhoeic keratosis.
15. Fissures and ridges (brain-like appearance) are irregular, linear keratin-filled depressions, commonly seen in seborrhoeic keratosis.
16. Fingerprint-like structures – they are thin light brown parallel running lines resulting in patterns that resemble a fingerprint. They are usually seen in flat seborrhoeic keratosis.
17. Moth-eaten borders – they are concave invaginations of the lesion border resembling

defects shaped like those of the edges of a moth-eaten garment.
18. Leaf-like structures (maple leaf-like areas) – they are brown, blue-grey, discrete structures resembling a leaf-like pattern.
19. Spoke wheel-like structures – they are well-circumscribed, brown to grey-blue-brown, radial projections meeting at a darker brown central hub. In the absence of a pigment network, they are highly suggestive of a basal cell carcinoma.
20. Large blue-grey ovoid nests – they are well-circumscribed confluent or near confluent, pigmented ovoid areas, larger than globules, and not intimately connected to a pigment network. When a network is absent, ovoid nests are highly suggestive of basal cell carcinoma.

Two-Step Dermoscopic Pattern



Algorithms in Dermoscopy

Differentiate between benign naevus and melanoma
1. Pattern analysis
2. ABCD rule
3. Menzies method
4. 7-Point checklist

Pattern Analysis According to Pehamberger et al. (1993) (Modified)

Benign melanocytic lesions tend to have a few colours, architectural order, symmetry of pattern and homogeneity. Malignant melanoma often has many colours and many architectural disorders, asymmetry of the pattern and heterogeneity.

In general there are six kinds of patterns:
1. The reticular pattern is the most common in melanocytic lesions. This pattern represents the junctional component of a melanocytic naevus (Clark, dysplastic naevus).
2. The globular pattern is characterized by the presence of numerous "aggregated globules". It is usually seen in congenital naevus, superficial type.
3. The homogeneous pattern is seen like diffuse pigmentation in brown, grey-blue, grey-black or reddish black colour. An example for this pattern is the blue naevi.
4. The starburst pattern – what is specific in this pattern is the presence of the streaks in a radial arrangement, which are visible at the periphery of the lesion. This kind of pattern can be seen in Reed and Spitz naevi.
5. The parallel pattern is found on the palms and soles.
6. The multicomponent pattern refers to network, dots, globules, hyperpigmentation and hypopigmentation. This pattern is highly suggestive of melanoma.

The ABCD Rule of Dermoscopy According to Stolz et al. (2002) (Modified)

This algorithm is based on a scoring system for melanocytic neoplasms that categorizes them into benign, suspicious and malignant categories.

ABCD rule of dermoscopy according to Stolz et al. modified

Asymmetry-complete symmetry

		Points	Weight factor	Subscore range
Asymmetry	Complete symmetry	0	1.3	0–26
	Asymmetry in 1 axis	1		
	Asymmetry in 2 axes	2		

		Points	Weight factor	Subscore range
Border	8 segment, 1 point for abrupt cut-off of pigment	0–8	0.1	0–0.8
Colour	1 point for each colour	1–6	0.5	0.5–3.0
	White, red, *light b*rown, dark brown, black, blue-grey			
Dermoscopic structures	1 point for each structure	1–5	0.5	0.5–2.5
	Pigment network, structureless areas, dots, globules, streaks			
			Total score range	1.0–8.9

Benign <4.75
Suspicious 4.75–5.45
Malignant >5.45

The 7-Point Checklist (2003)

A 7-point checklist algorithm distinguishes three major and four minor criteria. These features are selected for their frequent association with melanoma. Each major criterion has a score of 2 points, while each minor criterion has a score of 1 point. A minimum total score of 3 points is required for the diagnosis of malignant melanoma.

7-Point Checklist Argenziano

The 7-point checklist according to Argenziano et al. (2003)	
Macro criteria	
Atypical pigment network	2
Blue-white veil	2
Atypical vascular pattern	2
Minor criteria	
Irregular streaks	1
Irregular pigmentation	1
Irregular dotes or globules	1
Regression structures	1

Sensitivity range 85–93 %

The Menzies Method According to Menzies et al. (2003)

This is an algorithm based on the two negative features (presence of a single colour, point and axial symmetry of pigmentation). Also, this algorithm is based on nine positive features (favouring melanoma diagnosis).

The Menzies method according to Menzies et al.
Negative features
Point and axial symmetry of pigmentation
Presence of a single colour
Positive features
Multiple brown dots, blue-white veil
Radial streaming
Pseudopods
Multiple colours (5–6)
Peripheral dots/globules
Multiple blue-grey dots
Broadened network
Scar-like pigmentation

The 3-Point Checklist

The 3-point checklist was designed to be used as a screening method.

The sensitivity is much higher than specified to ensure that melanoma is not misdiagnosed.

3-Point checklist according to Argenziano	
Asymmetry	1
Atypical pigment network	1
Blue-white structures	1

Each of these points means 1-point score. If the score is 2 or more, we must decide for further investigation (biopsy or excision).

Dermoscopic Features in Most Common Pigmented Lesions

The key points in dermoscopic diagnosis are specific dermoscopic features in each pigmented lesion.

Benign melanocytic lesions have a well-organized, tending to be symmetrical and uniform, structures. They may be flat, raised centrally or entirely elevated.

Fig. 116.1 Dermoscopic picture of benign naevi "fried egg-like" pattern

Naevi

Argenziano et al. (1999) proposed a new classification of naevi into seven categories based on specific dermoscopic features:

1. *Globular* (*congenital*) *naevus*. Specific dermoscopic features are globular pattern in children, cobblestone or fried egg pattern in adults (Fig. 116.1).
2. *Reticular* (*acquired*) *naevus*. Reticular pattern with or without hypopigmented, distributed or structureless area, sometimes atypical features (Fig. 116.2).
3. *Starburst* (*Spitz/Reed*) *naevus*. Peripheral pigmented streaks or globules, symmetrically distributed, reticular depigmentation and dot vessels in nonpigmented lesions.
4. *Blue* (*homogeneous*) *naevus*. Homogeneous structureless blue coloration, sometimes white areas of fibrosis or hypomelanosis.
5. *Site-related naevi* (acral and facial naevus). Facial naevus in children presents often pseudoreticular pattern and in adults presents remnants of pigmentation and comma vessels. Among this group we can include acral

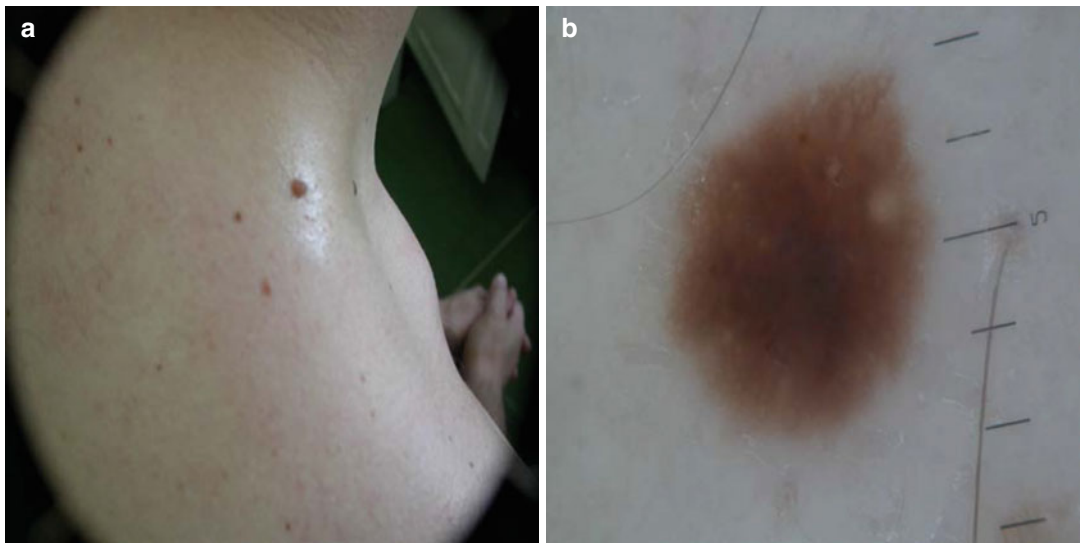


Fig. 116.2 (**a**) Clinical picture of naevi with reticular pattern. (**b**) Dermoscopic picture of naevi with reticular pattern

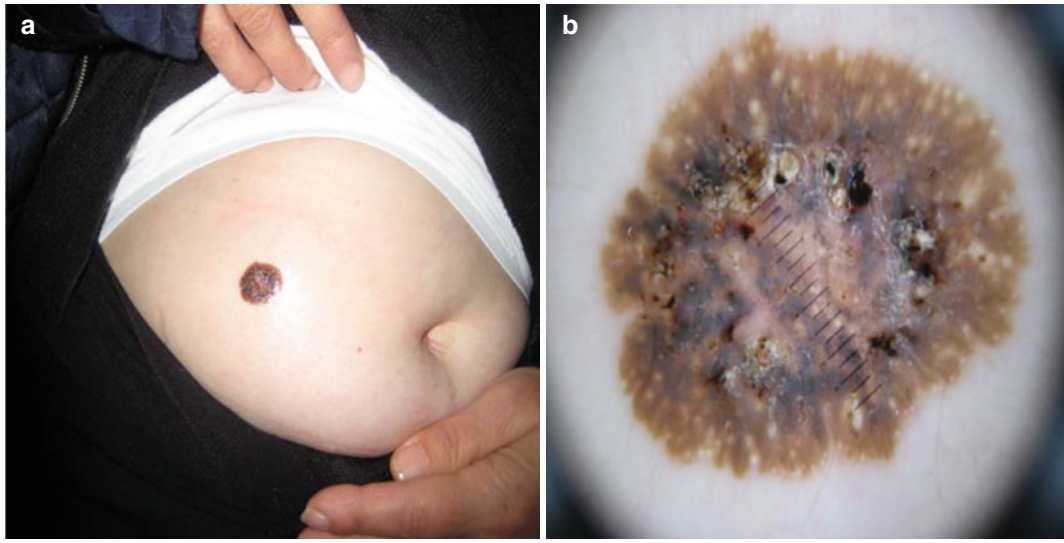

Fig. 116.3 (**a**) Clinical picture of seborrhoeic keratosis. (**b**) Dermoscopic picture of seborrhoeic keratosis

naevi – parallel, furrow pattern, lattice-like pattern and other patterns.

6. *Naevi with special features. Among this group it is possible to remember*:
   - Combined naevus – combination of globular, reticular, starburst and homogeneous patterns
   - Halo naevi – globular pattern with blue granules with scar-like areas
   - Irritated – globular, reticular or structureless with variable grey or red areas
7. *Unclassifiable melanocytic lesions*. They can have any of the previous patterns with atypical features; melanoma cannot be ruled out.

Dermoscopic Features of Seborrhoeic Keratosis (Fig. 116.3)

1. Fissures and ridges (brain-like or cerebriform appearance):
   Fissures are irregular linear keratin-filled depressions. They may also be seen in melanocytic naevi with congenital patterns and in some dermal naevi.
2. Fingerprint-like structures:
   Some flat seborrhoeic keratosis can show thin, brown, parallel lines resembling fingerprints.
3. Comedo-like openings:
   Brown-yellowish, round to oval or even irregular-shaped, sharply circumscribed structures.
4. Milia-like cysts:
   White, yellowish, roundish dots.
5. Moth-eaten border:
   Some flat seborrhoeic keratosis has a concave border.
6. Hairpin vessels:

Usually grouped together, surrounded by a whitish halo.

Dermoscopic Features of Dermatofibroma

1. Central white patch:
   Centrally situated white scar-like macule. Globule-like structures and vessels can be found. There are numerous variations of the white patch seen in dermatofibroma.
2. Peripheral thin reticulation:

Brown reticulation at the periphery of the lesion.

Dermoscopic Features of Solar Lentigo

1. Pigment network:
   The network corresponds to melanocytes and melanin-filled keratinocytes in the elongated rete ridges.
2. Moth-eaten border:

Irregular concave borders, sharply demarcated.
3. Fingerprint-like structures
4. Structureless area:
   Some lesions do not have a distinct dermoscopic structures, and they appear as light brown structureless areas.
5. Pseudonetwork

Dermoscopic Features in Malignant Pigmented Lesions

Dermoscopic Features of Basal Cell Carcinoma (BCC) (Fig. 116.4)

BCC is the most common skin cancer. It tends to be locally invasive but rarely metastasizes. In 6.5–8.5 % of the cases, it presents as a pigmented lesion. There are five distinctive types (nodular, morpheaform, fibroepithelial, infundibulocystic). Dermoscopy gives a sensitivity of 97 % in diagnosis of pigmented BCC.

Positive Dermoscopic Features of BCC

1. Leaf-like areas. Brown-grey to grey-black patches revealing a leaf-like configuration
2. Spoke wheel areas. Well-circumscribed radial projections, usually tan in colours but sometimes blue or grey, often with darker centre
3. Large blue-grey ovoid nests. Well-circumscribed, confluent or near confluent pigmented ovoid or elongated areas, larger than globules and not intimately connected to a pigmented tumour body
4. Multiple blue-grey globules which should be differentiated from blue-grey dots (melanophages)
5. Arborizing vessels. Telangiectasia with distinct tree-like branching
6. Ulceration. Absence of the epidermis, often associated with congealed blood, not due to a history of trauma

Lentigo Maligna

The main dermoscopic features of LM have been described by Stolz et al. (2002):
1. Hyperpigmentation of follicular opening (circles, semicircles, irregular circles and double circles)
2. Annular-granular structures
3. Obliterated hair follicles

Pralong et al. proposed four new dermoscopic features for LM:
1. Darkening at dermoscopic examination
2. Target-like pattern
3. Red rhomboidal structures
4. Increased density of the vascular network

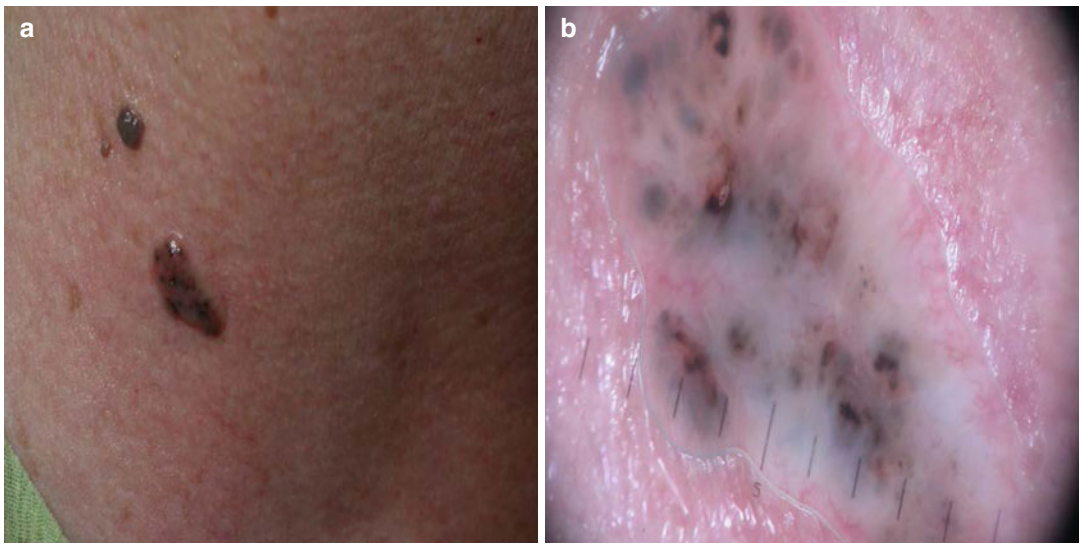

Fig. 116.4 (**a**) Clinical picture of pigmented BCC. (**b**) Dermoscopic picture of BCC

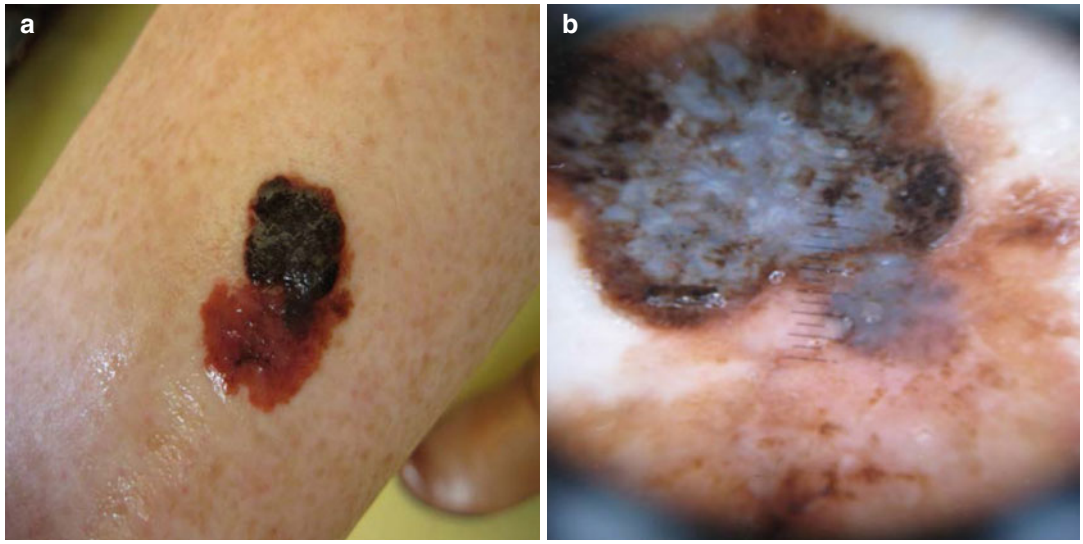

Fig. 116.5 (**a**) Clinical picture of melanoma. (**b**) Dermoscopic picture of melanoma

Melanoma (Fig. 116.5)

1. Atypical pigment network:
   Black, brown or grey network with irregular meshes and thick lines
2. Streaks:
   Irregular, linear structures not clearly combined with pigment network lines at the margins
3. Blue-whitish veil:
   Irregular, confluent, grey-blue to whitish blue diffuse pigmentation
4. Regression structures:
   White (scar-like) areas, blue (pepper-like) areas or combinations thereof
5. Dots/globules:
   Black, brown and/or grey round to oval, variously sized structures irregularly distributed within the lesion
6. Blothes:
   Black, brown and/or grey pigmentation areas with irregular shape

Nodular Melanoma

Nodular melanoma is 15–30 % of all melanomas. It is the most aggressive and has more rapid phase of growth and higher number of mitoses. It is frequently symmetric, with regular borders, often with a single colour or black/brown pigment.

ABCD algorithm is not useful, but EFG (elevation, firm on palpation, continuous growth for 1 month) is valuable. The blue-black rule recently proposed by Argenziano et.al. described a new dermoscopic feature characterized by combination of blue and black pigmented areas involving at least 10 % of the lesion surface. A blue-black colour is combined with one or more of classic dermoscopic feature, thus improving diagnostic accuracy for nodular melanoma.

Simple Rules Which Should Be Taken into Consideration in Dermoscopy

- For each change, we should make a decision in 10 s. If more time is necessary, it means that biopsy or excision is necessary.
- When dermoscopy is carried out, attention is given to what is in the focus, i.e. to what is predominant upon the basis of which decisions are made.
- Granuloma pyogenicum should not be carried out with cryo- or electrotherapy, since it does not have clear dermoscopic features and could be confused with amelanotic melanoma.

- When numerous changes are present, "the ugly duckling" should be chosen, i.e. the one which is different from the others.
- The age of the patient is crucial, since at a certain age different types of naevi are expected (children, globular; adults, reticular; elderly, papillomatous).
- The white colour in the middle of the change which is whiter than the surrounding is fibrosis. The white colour which is present in the surrounding skin is hypopigmentation.
- Lentigo maligna has specific grey granules which are located perifollicularly.
- Suspected solar lentigo means that biopsy is necessary.
- Not only is the age important, so is the skin type. With brighter phototypes, the naevi are brighter, with a possibility of a brighter area in the centre. Unlike people with darker complexion, the naevi themselves are darker especially in the central area.
- The blood vessels are different in case of different types of tumours – they are of great importance in dermoscopic diagnosis:
  - Melanoma: dots, linear, irregular, crazy vessels
  - BCC: arborizing vessels
  - Dermal naevus: coma-type vessels (Fig. 116.6)
  - SK, SCC, keratoacanthoma: hairpin vessels, with a white hue around the keratoacanthoma
- Negative network (or white network) is present in Spitz naevus and in amelanotic melanoma.
- Junctional naevi on the face do not exist, as well as dysplastic naevi. Then we go on further examination biopsy or excision.

Dermoscopy is a useful and valuable tool especially when applied by an experienced dermatoscopist. It gives us a new perspective on skin tumours, with great specificity and sensitivity. The greatest benefit is its non-invasive approach and the speed with which a diagnosis can be given.

New technologies in field of dermoscopy, high quality of digital images and teledermoscopy will offer us to communicate true dermoscopy network.

Electrosurgery

117

Eckart Haneke

Key Points

Electrosurgery comprises

- Hot electrocautery
- Electrofulguration
- Electrodesiccation
- Electrocoagulation
- Electrosection
- Electric epilation
- Radiofrequency resurfacing (coblation)

General Principles

Electrosurgery is mainly used to destroy both benign and malignant lesions, to cut and excise tissue and to control bleeding. In general, it is easy to perform, inexpensive and time honouring. The more modern radio wave surgery uses approximately 3.8 MHz as compared to the old technique using kHz electric current. Radio wave surgery allows cutting almost without thermal destruction of the margin and thus is very similar to CO_2 laser surgery. There are many different electrosurgery machines on the market permitting specific outputs to be used for various indications.

Terminology in electrosurgery is often incorrectly used. Monopolar means that the electrode has only one point, whereas bipolar means that two tips are used to coagulate or heat tissue in between them. Monoterminal refers to the use of only one electrode and biterminal when two connections or electrodes, usually an active surgical and an indifferent ground plate electrode, are used.

Table 117.1 summarizes the indications for electrosurgery.

Electrocautery

Metals are heated by electric current from a battery or an outlet-dependent device. The tip of the unit consists of a wire with high electrical resistance. When the current is turned on, the wire starts glowing. It is then gently held onto the anaesthetized lesion to be destroyed. The heat does not penetrate deeper than the papillary dermis; thus, the method is best used for superficial lesions or small pedunculated lesions, such as flat seborrhoeic keratoses or small acrochordons. When the glowing tip of the instrument touches the lesion, this starts bubbling until it becomes carbonized. A crust forms that is shed after a few days.

Table 117.1 Indications for electrosurgery

Electrodesiccation	Electrocoagulation	Electrosection
Molluscum contagiosum	Acrochordons	Condylomata acuminata
Flat warts	Telangiectasia	Hidradenitis suppurativa
Epidermal naevi	Spider naevi	pyodermia fistulans sinifica
Flat seborrhoeic keratosis	Sunburst veins	Rhinophyma
Dermatosis papulosa nigra	Venous lake	Incisions in skin and plastic surgery
Sebaceous hyperplasia Syringoma	Pyogenic granuloma	
Xanthelasma	Pyogenic granuloma	
After curettage of basal cell carcinoma	Granulation tissue	
	Bleeding vessels in surgery	
	Oozing lymph vessels in surgery	
	Hypertrichosis, hirsutism	
	Actinic keratosis	
	Nodular BCC	

Electrofulguration

An electrical spark is used to treat small superficial lesions resulting in carbonization of the skin surface. This method is often used to treat telangiectasias.

Electrodesiccation

A high-voltage, low-amperage damped current from a spark gap unit is used in a monoterminal fashion for electrodesiccation. If the electrode is held at a slight distance from the tissue, a spark is created causing very superficial destruction (electrofulguration), whereas direct tissue contact of the electrode is used for electrodesiccation. These techniques are suited for very superficial lesions such as seborrhoeic keratoses, plane warts, acrochordons and xanthelasmas, and they also provide haemostasis for small capillary bleeding after curettage.

Electrodesiccation requires local anaesthesia except for small skin tags. Alcoholic skin cleansers must be avoided as they may ignite with electrosurgery. Postoperative care includes a sterile dressing. Delayed bleeding may occur but is very rare.

Curettage and electrodesiccation (E&D) are very often combined to treat small basal cell carcinomas. This approach has a high cure rate for nodular BCCs but is not recommended for larger ones and for all aggressive BCC types.

Electrocoagulation

Electrocoagulation uses moderately damped, partially rectified current with active concentrating and dispersing neutral electrodes. The voltage is lower and the amperage higher than in electrodesiccation. It penetrates deeper, thus causing more tissue destruction.

Indications for electrocoagulation are deep tissue destruction and surgical haemostasis.

- Tissue destruction: a ball electrode is directly applied to and slowly moved over the lesion. The charred tissue is removed with a wet gauze pad or a curette. This procedure is repeated until the lesion is completely destroyed. Usually three passes are necessary for malignant tumours.
- Haemostasis: the electrode may directly touch the bleeder vessel or the vessel may be grasped with a fine pincer or clamped with a haemostat which is touched with the electrode. The power of the device should be set as low as possible in order to achieve coagulation of several millimetres which reduces the risk of delayed bleeding. Bipolar electrocoagulation with special forceps is used for less traumatizing pinpoint haemostasis. However, it requires a dry operative field.

Electrocoagulation is the most effective means for treating spider naevi. A needle electrode is lightly held on the central pulsating vessel and a nurse assistant slowly turns on the

power. The needle sinks into the tissue, gently coagulating the feeding vessel. No scarring is observed when using this technique cautiously.

Electrosection

Cutting is performed using slightly damped, fully rectified current in a biterminal fashion. High amperage and low voltage are further characteristics. Cutting and haemostasis are achieved by tissue vaporization. Lateral heat spread is low, reducing peripheral tissue damage. The higher the power, the easier the cutting and the less is the coagulation, and vice versa.

The narrow electrode passes effortlessly through the tissue leaving an almost dry cut surface. If the electrode drags, the power setting is too low. If it sparks, it is too high. For incision, a needle or blade electrode is commonly used. A thin loop electrode is optimal for removing tissue slices such as in rhinophyma and of pedunculated or protruding lesions such as condylomata acuminata or to excise small tumours with one stroke. We also use the electrical loop in chronic hidradenitis suppurativa, keloidal acne and other deep-seated infections not amenable to conservative therapy.

Radio wave electrosurgery uses higher frequencies of 1.2–4 MHz. In the cut mode, fully filtered current is used. There is minimal heat generation and therefore almost no coagulation. Specimens thus excised can be submitted for histopathological control of margins. Lateral tissue damage is even less than with the continuous wave surgical CO_2 laser. The device can also be set to fully rectified current for cutting and coagulation and to partially rectified current for coagulation. This machine is optimal for surgery of the face and for creating skin flaps.

Electroepilation

Removal of unwanted hair by electrical current is usually performed by cosmeticians. Two different techniques are available:

- Electrolysis
- Thermolysis

Electrolysis uses direct current to induce a chemical reaction in the hair bulb. The anode is inserted into the follicle and the patient holds the cathode as a moist pad. When being switched on, the current produces an electrochemical reaction generating sodium hydroxide, which is caustic. The procedure takes 30–60 s for each follicle to be destroyed.

Thermolysis is much faster, causing heat destruction of the hair root. In the slower technique, lower heat is generated for 3–20 s. In the flash technique, high temperatures are delivered for less than 1 s.

A blend of both methods was developed to speed up treatment and increase efficacy.

For all techniques, a very fine needle is inserted into the follicle down to the bulb. The needle tip is rounded to avoid puncturing through the follicle wall, and its length is insulated (Kromayer needle) in order to avoid damage to the superficial follicular portion with the risk of scarring. However, the stem cells are located in the bulge region relatively high above the hair bulb and even very efficient and precise destruction of the root may be followed by a recurrence.

Side effects are rare. Electrolysis is less painful and has probably a higher success rate when carried out by an experienced therapist. Post-treatment pigmentary disturbance depends on skin type.

Devices for home self-use are not effective. Hair shafts are not conductive for electrical current; therefore holding a hair with tweezers and applying electrical current cannot permanently destroy the hair root.

It has to be stressed that special lasers or high-energy light pulses for hair removal are now the preferred methods with at least as good results but performed with much more ease and more rapidly.

Radiofrequency Resurfacing

The removal of superficial skin layers including skin resurfacing is a new electrosurgical method although it may have been used for similar

purposes decades earlier. Whereas CO_2 laser resurfacing works by thermal damage, this is replaced by a much cooler and more controlled ablation (hence the new term 'coblation'). A fine layer of an electrically conductive solution, usually physiological saline, is sprayed on the skin. The hand-held bipolar electrode-tipped wand is set on this layer on the target. When the current is switched on, the saline between the electrodes is converted into an ionized vapour layer, called plasma. Ions accelerate across this gradient towards the skin, dissociating molecular bonds within tissue structures, thus removing tissue layers and ultimately causing collagen neosynthesis and improved skin appearance. The process runs at only 80–90 °C as compared to 300–600 °C with the CO_2 laser. Heat damage to the surrounding tissue is considerably lower, suggesting that the risk of persistent erythema and scarring is lower and wound healing considerably faster.

Risks of Electrosurgery

Preoperative discussion includes information about the procedure, healing time of at least 2 weeks for small wound, scab formation and scarring. Preoperative evaluation discusses bleeding disorders, hepatitis, human immunodeficiency virus, immune defects, individual scarring, pacemaker, prosthesis and other electronic implants.

Some risks are inherent to electrosurgery, such as ignition of inflammable gases and fluids. Therefore, preoperative disinfection requires non-alcoholic solutions. Electrosurgical electrodes are not self-sterilizing and spread of infection is possible if they are not properly sterilized. Furthermore the plume generated by the heat may contain intact virus particles and effective smoke evacuation is therefore mandatory. Smoke evacuation is also recommended for large operations such as hidradenitis suppurativa. Experience has shown that drying up the wound is easier for the patient immediately after surgery but takes longer to heal than occlusive or semi-occlusive treatment.

Delayed postoperative bleeding is due to incomplete coagulation of vessels, particularly when local anaesthesia with vasoconstrictors was used. Postoperative pain may be intense. Some reddening around the wound is frequently seen. Eschar formation and sloughing of necrotic tissue are obligatory. Electrosurgery carries the risk of delayed wound healing and hypertrophic scarring. They are dependent of the amount of tissue coagulation. Hyperpigmentation in dark-skinned and hypopigmentation in fair-skinned persons are common. Electrosurgery is thought by many to be contraindicated on the soles of the feet as it may cause very painful hypertrophic scars and even keloids. Improper contact with the ground plate electrode may cause large burns. However, also the epoxy resin of the ground plate may cause allergic contact dermatitis potentially misinterpreted as a burn. Patients with sensitive electrical facilities such as demand-dependent pacemakers or implantable cardioverter defibrillators are at risk. There may also be interference with cardiac monitoring devices in anaesthesiology.

Excimer Laser Therapy

118

Carmen Maria Salavastru

Key Points

- Excimer laser therapy is a new valuable option for treating various dermatologic conditions.
- The most part of the published results focuses on efficacy and safety in treating psoriasis and vitiligo, both in adults and children.
- New encouraging results for treating atopic dermatitis and alopecia areata, in all age groups, are under evaluation.
- The mechanism of action is similar to the UVB phototherapy; however, the cumulative dosage is lower, and the targeted area is strictly the lesional one; currently, fewer side effects are noticed.

General Principles

In addition to narrowband ultraviolet type B (nb-UVB) (311 nm), a new UVB source generated by a 308-nm excimer laser has been introduced for the treatment of various dermatological conditions.

The excimer laser is a gas laser emitting in the UV-wavelength range from 157 to 351 nm. The name excimer laser is derived from *ex*cited di*mer*. This type of laser utilizes as its active medium a mixture of a noble gas, a halogen, and a buffer gas, and the various wavelengths emitted depend on the combination of the noble gases and the halogen. In dermatologic treatments, the 308-nm laser is used and it implies a XeCl gas mixture as an active medium.

This type of laser operates at a rate pulse of 100 Hz and a pulse width of approximately 10 ns. It emits a monochrome radiation in the UVB spectrum, it does not produce heat, and the beam energy is absorbed by the tissue at most 1 nm in depth.

The size of the spot may be adjusted between 14 and 30 mm; in this way there is the possibility of treating precisely the affected area without the irradiation of the non-affected skin.

Mechanisms of Action

The 308-nm wavelength, which is very close to 311 nm, used in nb-UVB phototherapy, is considered to have a similar mechanism of action with the latter. The radiations of the UVB spectrum show immunosuppressive effects by inducing T-lymphocyte apoptosis and immunomodulatory effects, too. A single 308-nm UVB dose reduced the number of pathogenic memory/effector T cells infiltrating psoriatic lesional epidermis and dermis, and, consistent with apoptosis induction, caspase activation increased in lesional T cells

after treatment. Another interesting finding is the preferential induction of endothelin-1 in a human epidermal equivalent model by narrowband ultraviolet B light sources. This molecule is associated with UVB-induced migration of melanocytes and stimulates DNA synthesis in melanocytes.

Clinical Applications

The first use of an excimer laser was in eye surgery. In dermatology, the XeCl excimer laser, 308 nm, is used in treating inflammatory conditions: vitiligo, psoriasis, atopic dermatitis, alopecia areata, and others.

There are important advantages in using excimer lasers in dermatological treatments: the radiation is limited strictly to the affected area, and the exposure time and the cumulative dosage are lower than with the conventional UVB phototherapy.

Vitiligo

The monochromatic excimer laser has the advantage of targeted treatment with less body irradiation and less impact on non-lesional skin. It works well for patients with higher Fitzpatrick skin types. The mechanism of action is thought to be similar to conventional therapy. The xenon chloride monochromatic excimer laser (308 nm) is the most used laser therapy for vitiligo and it is approved by the FDA for the treatment of this disease.

Efficacy

When used as monotherapy, repigmentation rates higher than 75 % are seen in 16.6–52.80 %; response rates may be as high as 95 %.

It has been observed that repigmentation starts at the margins of the lesions especially for the acral ones. In the area where hair follicles are present, there is a perifollicular debut of repigmentation, too. The onset of repigmentation negatively correlates with the total number of treatments but may be sooner on the face, neck, and axillae compared to the trunk and limbs.

The face and neck respond better than the hands and feet and with less total irradiation.

Approximately 30 % of the patients may achieve repigmentation on more than 75 % of the treated area, with an average of 32 sessions. Higher Fitzpatrick skin types achieve better results. Age, skin types, duration, and evolution of the disease do not confound treatment outcomes. Even some previously nb-UVB treatment nonresponders may achieve repigmentation, and compared to nb-UVB, it shows better clinical outcomes. Most cases are stable at 1 year of follow-up. However, there are also patients who may not respond to this type of therapy.

The results improve when used in combination with other therapies. Topical tacrolimus and calcipotriol or topical hydrocortisone have been assessed for possible additive effects.

The 632.8-nm helium neon laser is used in treating patients with segmental vitiligo.

Treatment regimen and dosage for vitiligo treatment, as it is followed in our clinic, is illustrated in Table 1.

Side Effects

Side effects are minimal and local. The treatment is well tolerated with some patients experiencing mild to moderate erythema and pruritus. Vesiculation and blistering are seldom. Because of the absence of photosensitizing substances and drug-induced toxicity, patients who work outdoors, pregnant women, and patients with liver or kidney failure can also be treated.

Use in Children

In children the therapy is widely used with good results.

Psoriasis

Psoriasis is a common, chronic, inflammatory, multisystem disease with predominantly skin and joint manifestations affecting approximately 2 % of the population.

Various spectra of UVB and UVA wavelengths have been used to treat psoriasis.

Although a minimum of 10 % body surface area has been traditionally used as a prerequisite to starting ultraviolet (UV) light or systemic therapy for psoriasis, a subset of patients with limited disease have debilitating symptoms: psoriasis of the palms and soles or severe scalp psoriasis. The significant negative effect on the quality of life of this type of patient makes treatment with systemic therapies an appropriate approach.

Traditional UVB radiation has been used for the treatment of psoriasis for more than 75 years. In recent years, phototherapy has maintained its important role in the treatment of psoriasis, either as monotherapy or in combination with topical or systemic agents.

Although nb-UVB is reported to be less phototoxic than UVB in some studies, other studies failed to show this discrepancy.

Efficacy

There are several studies showing the efficacy of laser excimer therapy in plaque psoriasis; the patients treated achieve remission in a lower number of sessions and with a lower cumulative dosage compared to the patients treated by nb-UVB. The energy delivered during one session is bigger than the one delivered during the nb-UVB treatment; therefore there are a larger number of side effects: erythema, vesiculation, and hyperpigmentation.

The chromophore for the excimer laser is DNA.

The efficacy of the excimer laser in treating plaque psoriasis relies, besides the direct cytotoxic effect on DNA T lymphocytes, on lowering the TNF and IL-1 skin levels and on inhibiting the antigen presentation by the Langerhans cells.

During the past years, there are a number of papers showing the efficacy and safety of excimer laser in treating plaque psoriasis. The main drawback of the published papers is the small number of patients treated. The results are variable but generally they show a better outcome when using this method compared to nb-UVB. Fifty to eighty-five percent of the patients obtain remission (PASI 90) in 10–24 sessions, and the time needed to obtain the remission is up to 3.6 times shorter than for nb-UVB. Additionally, the cumulative dosage is significantly lower than the nb-UVB dosage, for the same clinical result. There is also an observation that the guttate type responds better than the plaque type. There are encouraging results for the difficult responding lesions of elbow and knee areas. The free disease interval ranges between 1 and 6 months.

There are some successful treated cases of patient showing predominantly skin fold psoriasis, leading up to a 6-month remission.

For the palmar and plantar forms, the efficacy is similar to PUVA therapy, with a better compliance. Up to 75 % of the patients experienced an 80 % improvement. Good results were seen in treating scalp psoriasis, too; around half of the patients experienced a 90 % decreasing of the lesional area, after an average of 21 sessions. Nail psoriasis seemed not to be influenced by this procedure.

The 308-nm excimer laser appears to be a safe and effective treatment for localized psoriasis in children as well as in adults.

Treatment Regimen and Dosage

Before starting the therapy, the minimal erythematous dose (MED) should be identified.

The treatment may be tailored either by increasing the dosage at the beginning of each session (the exposure dosage is a multiple of the MED and it is increased every other session) or by accelerated dosage increase per exposure. The second option leads to a smaller number of sessions needed and ultimately to a lower cumulative dosage.

The excimer laser therapy is well tolerated by the patients, which may experience a mild stinging sensation during exposure. Side effects depend mostly by the dosage: erythema and hyperpigmentations appear in 40 % of the patients following the increase of the dosage every other session. Erythema, vesiculation, and crusts are manifest to all the patients who experience the accelerated increase in dosage per exposure.

Recently, there is a recommendation of adjusting the dosage according to the plaque thickness and Fitzpatrick skin type. The frequency of the treatment is two to three times a week, with a minimum of 48 h between treatments.

Side Effects

Since the excimer laser therapy is delivered directly to the treated areas, the side effects are limited to the treated area: erythema, burning, and hyperpigmentations. Vesiculations and blistering may occur with higher fluences. The long-term safety remains to be fully established.

Pregnancy and Breastfeeding

There is no study conducted in pregnant patients but it is suggested that it is unlikely to have any teratogenic effects.

Pediatric Use

Data regarding the use of the 308-nm excimer in children for psoriasis are limited, but it seems to be safe, according to expert opinion.

Contraindications

Excimer laser therapy should be used with caution in patients with photosensitivity.

Atopic Dermatitis

New devices such as 308-nm monochromatic excimer light expand the therapeutic options in patients with localized and therapy-resistant atopic dermatitis, even though they can treat only limited surfaces. However, this therapeutic option has not yet been properly assessed in atopic dermatitis.

Data available at the moment refers mostly to patients with flexural lesions and moderate severity. They show decrease in pruritus, edema, and lichenification by more than 50 %, some results being noticeable after only two sessions.

The side effects are comparable with the ones experienced by the patients treated for vitiligo.

Alopecia Areata

There are only scarce data regarding the efficacy of excimer laser treatment for alopecia areata. The initial dosage is usually lower than the MED, and the dosage is increased, according to the patients' tolerability, every other session. By using this procedure, there was a regrowth of the hair in 41.5 % of the alopecia areas with the beginning of the effect during the second month of therapy. The scalp lesions respond better than the beard or acral lesions. In adults the regrowth is present in 75 % of scalp lesions and in children in 60 %. The remission lasts less than 6 months. The usual side effects, erythema, hyperpigmentation, and vesiculation, are limited but they are increased by higher dosage.

Other Skin Diseases

There is an increasing number of short reports published about the results of treatments by excimer laser therapy on skin conditions such as striae distensae, granuloma annulare, or mycosis fungoides. The gathered data indicate that excimer laser therapy is helpful in treating various chronic dermatologic conditions, with a good clinical tolerance and some advantages compared to UVB phototherapy.

Table 1: Protocol Excimer Laser Treatment Vitiligo

I. *Selection criteria*:
   (a) Inclusion criteria:
      – <20 % lesional skin of total body surface
      – Recent diagnosis (<5 years)
   (b) Exclusion criteria:

Phototherapy within the last 3 months
Any other cause of photosensitivity/photomediated diseases
Medication which forbids UV exposure
Total depigmentation of the face and/or dorsal aspects of the hands
Fitzpatrick skin phototype I
Cutaneous malignant tumors
Pregnancy and lactation

II. *Clinical type of vitiligo*
III. *Assessment of Vitiligo Disease Activity* (*VIDA*)
IV. *Assessment of Dermatology Quality of Life Index* (*DLQI*)

V. *Assessment of thyroid function* – TSH, ATPO, FT4
VI. *Signing of the informed consent by the patient/tutor*
VII. *Pictures*:
  (a) Before starting the therapy
  (b) Every other week during the therapy and by 6 and 12 months after the end of the therapy
VIII. *Therapy*:
  – Excimer laser monotherapy
  – Combined excimer laser therapy
  – Specify
IX. *Assessment of Minimal Erythematous Dosage – MED*
X. *Excimer Laser Therapy*
  (a) First exposure: 85 % of MED.
  (b) Second exposure: according to the clinical result
    – Increasing by 30–50 J/cm^2 every session if no side effects (e.g., erythema).
    – Maintain the dosage if slightly pruritus and erythema are observed.
    – Stop the treatment if important side effects develop; upon remission of the side effects, the treatment is resumed at a dosage lower than the one which induced the side effects.
    – For facial lesions, the initial dosage is 50 J/cm^2 and increases by 20–30 J/cm^2 during every session.
  (c) During the procedure, the surrounding non-lesional skin should be covered.
XI. *Frequency of the exposure*: 2–3 sessions/week, non-consecutive days
XII. *Immediately postprocedure care instruction*
  – Sun avoidance – sun blockers.
  – Makeup may be used as desired.
XIII. *In case of side effects*
  (a) Patients report any side effects immediately after their appearance.
XIV. *Total number of sessions*
  (a) Average: 20 sessions/patient.
  (b) If total repigmentation is achieved sooner, the therapy is stopped.
  (c) If after 20 sessions the doctor consider the result satisfying although not yet total repigmentation achieved, the therapy may be continued up to a total of 30–35 sessions.
XV. *Patient evaluation*
  (a) According to the degree of repigmentation:
    0 – no repigmentation
    1 – repigmentation 1–25 %
    2 – repigmentation 26–50 %
    3 – repigmentation 51–75 %
    4 – repigmentation >75 %
  (b) Assessment is scheduled by the twentieth session and/or by the last scheduled session.
  (c) Assessment of the patient by 6 and 12 months after the end of the therapy.
  (d) Assessment of DLQI by the end of therapy.
  (e) Pictures of the patient are taken at session 20 and/or last session.

Fillers and Soft Tissue Augmentation

119

Christopher M.E. Rowland Payne and Ines Verner

Abbreviations

BDDE	1, 4 butane-diol-diglycidyl ether
CHA	Calcium hydroxylapatite
HA	Hyaluronic acid
HBOT	Hyperbaric oxygen therapy
PLLA	Poly-L-lactic acid
PMMA	Polymethylmetacrylate
SILS	Serial intralesional steroid
SMDS	Serial microdroplet silicone
SOOF	Sub-orbicularis oculi fat

Key Points

- Loss of facial volume is one of the most important determinants of facial ageing.
- Facial volume loss can be partially restored by the injection of soft tissue fillers into the subcutaneous tissue. With the vast technological developments of the last few decades, many different soft tissue fillers have become available. Soft tissue augmentation has now become one of the most popular non-invasive cosmetic procedures worldwide.

I. Verner
Kiryat Ono Mall, 39 Jerusalem, Kiryat Ono, Israel
e-mail: ines.verner@gmail.com

- Fillers may be divided into inert and fibrogeneic. Inert fillers, such as hyaluronic acid (HA) and fat, are injected and remain inert until the body resorbs them. Fibrogeneic fillers, such as silicone, calcium hydroxylapatite and poly-L-lactic acid, elicit a fibrosis-granuloma host response which ensures a longer-lasting effect.
- Fillers provide many opportunities for therapeutic benefits, both medical and aesthetic. Medical indications include, for example, correction of the perioral rhitids of systemic sclerosis or creation of missing volume in patients with cleft lip or Romberg's hemiatrophy. Aesthetic indications are legion. Many relate to replacement of facial volume. As facial volume involutes with time, the overlying skin becomes less tightly stretched. Skin ptosis (e.g. lateral to the mouth) and concertina-like wrinkles (e.g. perioorally) ensue. These phenomena can all be improved using fillers.
- Fillers can be injected using needles or microcannulae. They can be implanted at the intradermal, subcutaneous and deeper levels. The most widely used filler now is HA. Fillers can be injected using a threading 'tagliatelle' technique or as multiple puncture 'pearls'. Many fillers can be used in both ways. Most

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_119, © Springer-Verlag Berlin Heidelberg 2015

fillers may be injected in aspiration bolus, in retrograde or in antegrade, sometimes perpendicular and sometimes tangential to the skin's surface. Silicone is usually only used as serial microdroplet silicone (SMDS). Subcision alone can treat very fine early lines. Intradermal subcision is often also a useful adjunctive treatment when other fillers are used at the dermosubcutaneous junction. Hypodermal or deeper subcision can be useful for more established rhitids.

- Specific injection technique at specific facial sites is discussed. Complications and their treatment and prevention are reviewed.
- Fillers and soft tissue augmentation offer enormous therapeutic opportunities.

General Principles

From time immemorial, human beings have sought to enhance natural beauty and tried to slow ageing. With the advent of anaesthesia and surgery, towards the end of the nineteenth century, more invasive cosmetic procedures became available, including soft tissue fillers. Fat was the first soft tissue filler to be used after trauma and is still widely used today. However, autologous fat transplantation is considered a relatively major procedure, as it necessitates the transplantation of fat from another site, and its results may be variable. Towards the end of the nineteenth century, paraffin oil was used for the restoration of volume and symmetry. However, its use was accompanied by a high incidence of inflammatory foreign body granulomatous nodules (*paraffinomas*) with consequent facial distortion and, occasionally, life-threatening paraffin pulmonary emboli. Hence, the use of paraffin oil was discontinued.

Liquid silicone gained some popularity in Europe in the 1940s, when thousands of patients were treated with it. Since the 1960s and through to the present day, excellent, safe and durable results have been reported with silicone, using the serial microdroplet technique. On the other hand, the use of inappropriately large volumes of silicone or impure silicone has been followed by horrific complications, such as neurological dysfunction, blindness and erysipelas-like inflammatory reactions. These problems have cast an unwarranted cloud of unease over the safe and proper use of serial microdroplet silicone (SMDS).

Injectable bovine collagen was the first biodegradable filler available. The FDA approved it in 1981 for soft tissue augmentation because of its relative safety. The minimally invasive nature of the procedure, with no downtime, led to a growing demand for soft tissue augmentation. Its very short duration in the tissue and its high incidence of allergic reactions led to the development of other fillers with enhanced longevity and safety, notably hyaluronic acid (HA). According to the annual report of the American Society of Plastic Surgeons, filler injections were the second most commonly performed minimally invasive procedure with two million injections performed in 2012, second only to botulinum toxin injections: 6.1 million in 2012 (www.plasticsurgery.org). The use of HA fillers has now become commonplace.

Facial Anatomy

Fat Compartments

Like the flesh of an orange, the facial subcutaneous fat is divided into segments or compartments (Fig. 119.1).

These compartments are separated from one another by fibrous septa, which are condensations of the retinaculum cutae. The septa arise from the superficial fascia and insert into the dermis. These septa form the interconnecting framework that limits shearing forces on the face and which helps prevent migration of skin, subcutaneous fat and injected filler (Rohrich and Pessa 2008).

Mid-facial fat is arranged in two and paranasally in three independent anatomical layers. The

Fig. 119.1 The fat compartments of the face (Courtesy of Dr R Rohrich)

superficial layer is composed of the nasolabial fat, the medial cheek fat, the middle cheek fat, the lateral temporal cheek compartment and three orbital compartments. Deep midfacial fat is composed of sub-orbicularis oculi fat (SOOF) (medial and lateral parts) and deep medial cheek fat (medial and lateral parts) (Gierloff et al. 2012).

Different compartments age differently. Some atrophy (e.g. at the temples), others bulge and sag (e.g. at the jowls). The mid-facial fat compartments migrate inferiorly.

In youth, these compartments are more or less ideally inflated. With age these various fat compartments deflate. Like the female breast, fully inflated fat compartments stand out from the underlying tissues with an anterior projection. As the fat involutes, the compartments deflate and gravity determines that anterior projection gives way to vertical descent with festooning of relatively deflated fat compartments and consequent facial ptosis. If the fat compartments have been subject to any episodes of overinflation, for example, due to obesity or periodic oedema of women, then there may also have been some stretching of the fibrous septa. In such patients, the ptosis of subsequent deflation will be aggravated by septal weakness consequent upon the physical effect of having been stretched. The pattern of inflation, stretching, deflation and puckered festooning is the same process as that which leads to cellulite in the panniculus adiposus of other parts of the body.

Facial Ligaments

Arising from the bone or from the deep fascia and inserting into the skin are various facial ligaments. These tie the skin, at various points, to the deeper structures. Since these stretch little with age, they act as fixed points and so aggravate the appearance of festooning of the intervening skin and fat. This is mostly so at the jaw line.

Skeletal Changes

Ageing of the facial bones is characterised by bony involution with concomitant morphological changes in the orbit, midface and mandible. The mandibular angle increases, whilst mandibular length and mandibular body height decrease. The maxillary angle decreases. There is widening of the orbital aperture with inferolateral and superomedial expansion. Similar to the axial skeleton, facial mineral bone density decreases (Shaw et al. 2010, 2012). These changes lead to changes in the skeletal support of the soft tissue and a consequent redraping of the soft tissue, further contributing to a sagging appearance around the eyes (Warren et al. 2011).

Facial Structure

Changes in the fat compartments together with changes in the facial skeleton lead to changes in the support of the soft tissues and thus changes in facial morphology. Gradual sagging of the soft tissues and changes in the shape of the bone result in a metamorphosis from the heart-shaped

or inverted triangular-shaped face of youth to the rectangular or 'bottom heavy' face of late middle age. When the youthful face is observed obliquely, a double ogee (an S-shaped curve) is apparent, running from the brow into the lateral orbital wall and from the upper into the lower midface. This line is considered to be the line of beauty. With age, it flattens or reverses.

Medical Indications

Fillers can be used for many different indications, not only to treat the manifestations of ageing but also to treat facial defects and asymmetry due to trauma or disease (Verner and Rowland Payne 2009).

In the upper third of the face, forehead asymmetries or depressions can be corrected, such as sunken scars or tissue loss due to certain skin diseases, such as Romberg's hemidystrophy and morphoea en coup de sabre.

In the middle third of the face, bilateral lipodystrophy is seen in patients receiving retroviral treatment for HIV disease. Lipotransfer or the use of other fillers may help greatly. Minor nasal imperfections, such as nasal tip descent or an overdeep nasal bridge, can be corrected, sparing the need for surgery (Fig. 119.2).

In the lower third of the face, lip asymmetries or defects can be corrected. Cleft lip scars can benefit from SMDS. Systemic sclerosis may result in disfiguring perioral radial rhitids and so may congenital syphilis. SMDS or HA may be

Fig. 119.2 (**a**) Post-traumatic nasal deformity. (**b**) Post-traumatic nasal deformity. After treatment by HA filler (Courtesy of Dr C Rowland Payne)

Fig. 119.3 (**a**) Prognathism. Before treatment. (**b**) Prognathism. After treatment by submucous filler in the upper lip (Courtesy of Dr C Rowland Payne. Reproduced from Shai A, Maibach HL & Baran R. Handbook of cosmetic skin care. 2nd ed. p. 196, with permission of the publishers)

very helpful in attenuating these stigmata. Acne scars can be treated by SMDS. If the chin is too small, chin augmentation can also be achieved by fillers. A prominent mandible can be made less evident by submucosal filling of the upper lip (Fig. 119.3).

Cosmetic Indications

The face, especially the central face, is well suited to the use of fillers. Tissue involution, muscular activity and gravity all take their toll in this area. Moreover, the central face is less amenable to improvement by rhytidectomy than is the lateral face, and the benefits possible from botulinum are limited by the need to preserve muscular expression and oral sphincter function.

Correction of Changes Due to Ageing

The upper third of the face ages with a loss of the convex projection of the supraorbital ridge with a consequent descent of the eyebrows. Laterally, there is loss of volume at the temporal region leading to temporal fossa hollowness and lateral brow ptosis. Fillers can also be used in these areas to elevate the eyebrows, to treat deep glabellar folds (between the eyebrows) and to treat wrinkles lateral to the eyes (crow's feet) (Carruthers and Carruthers 2010; Busso and Howell 2010). Filling the temporal fossa improves the shape of the face and lifts the lateral brow.

The middle third of the face ages by the appearance of hollows under the eyes and loss of volume in the medial and lateral cheek. By correcting the hollows under the eyes, a tired appearance can be effaced and the face can gain a smoother appearance. Fillers can restore volume loss in the medial and lateral cheeks and can accentuate the cheekbones (Montes 2012).

The lower third of the face ages with deepening of the nasolabial fold and the appearance of marionette or 'drool' lines. These lines run from the corners of the mouth down towards the sides of the chin. There are changes in the position and structure of the lips and jowling of the jaw line. The nasolabial fold is one of the most popular indications for fillers. Filling this fold can give excellent and durable cosmetic results. However, often a more natural midface appearance can be achieved by filling and correcting the medial and lateral cheek. Filling the cheek not only improves the nasolabial folds but also lifts the mid and lower face and improves a tired appearance. Treating marionette lines also helps support the sides of the mouth, but care should be taken not

to overfill this area. Ageing also leads to loss of jaw line definition with jowling. Fillers can help redefine the jawline. Ageing lips become thin and flat; fine radial or cross-hatched wrinkles develop on the upper and lower lips, and the lipstick may 'bleed' out from the vermillion into the surrounding skin, giving the lipstick a smudged appearance. Natural fullness and definition can be improved and restored. One of the most difficult aims of lip augmentation is to achieve natural looking lips. To achieve this requires a study of lip anatomy and awareness of natural lip structure (Verner 2012). The first and most important point to consider when examining lips from the anterior view is the proportion between the upper and lower lip. The lower lip should be 1.6 times taller than the upper (i.e. about one third taller than the upper). If the lower or the upper lip is too thin relative to the other, just correcting this one feature will lead to great improvement. Many times, less is more when approaching lip enhancement, and even thin lips with correct proportions can be pleasing aesthetically. In Rowland Payne's 'Mona Lisa smile' (Rowland Payne 2003), fillers are injected into the angles of the mouth to correct downturning.

Types of Fillers

Soft tissue fillers can be divided into two large groups: inert and fibrogeneic.

'Cushions or Oysters'

Inert fillers are the equivalent of stuffing a *cushion* with feathers. Fibrogeneic fillers are the equivalent of putting a grain of sand into an *oyster*, and the oyster then makes a pearl. With inert fillers, the filling effect is proportional to the amount of filler substance introduced. With fibrogeneic fillers, the filling effect is proportional to the intended foreign body granuloma reaction of the host.

The inert fillers are biodegradable. They mostly have the advantage of a high safety profile and the advantage that if a problem arises after injection (e.g. an inflammatory nodule or if the patient is dissatisfied with the result), the filler will eventually resorb and the problem will resolve. They have the commensurate disadvantage of a temporary result.

The fibrogeneic fillers, on the other hand, mostly have the advantage of long durability but carry a greater risk of long-lasting problems, such as granulomatous inflammatory nodules and the problem that misplaced injections will not disappear effortlessly in 6–12 months.

In the past, the longevity of most inert biodegradable fillers was very short (a few months), and therefore some preferred the more permanent fibrogeneic fillers (Vert 2009). Nowadays, some biodegradable fillers have enhanced longevity and remain 12–18 months in the tissues, providing a longer term result. The need for permanent fillers, with their attendant risks of permanent problems, has thus gradually lessened (Wang et al. 2007). Also faces change with ageing. What is a good result in a young person may look strange in an older face: lips that stay large, whilst the rest of the face becomes smaller due to the volume loss of ageing.

With inert fillers the result of the injection is immediately apparent so there is seldom a need for a 'touch-up' visit. Inert fillers seldom stimulate a host reaction, so unwanted granulomas are rare with inert fillers (unless they become microbiologically contaminated). The archetypal inert filler is HA. HA has the added advantage of being easily available, dissolvable with hyaluronidase and not excessively expensive.

Inert Fillers

Most of the filling effect of inert fillers stems from the volume of gel injected.

Autologous Fat: The Ideal Filler

The patient's own fat is, in many ways, the ideal filler. Transient fat has the advantage of tissue compatibility and durability, often lasting many years (Fig. 119.4).

Fig. 119.4 (**a**) Syringe lipotransfer. After 4 treatment sessions at three monthly intervals. (**b**) Syringe lipotransfer. Same patient, 15 years later (Courtesy of Dr P Fournier)

When fat is harvested with minimal trauma and handled gently and correctly, 30–70 % of the volume injected will remain long term. Therefore the injection process should be regarded as a two- or three-stage procedure, aiming for a small overcorrection at the initial treatment and, 2–3 months later, a second injection with perhaps a third a few months later. Even after that, fine-tuning with HA filler may be helpful. Many patients have faces which would benefit from enhanced volume. Sometimes they also have unwanted, diet-resistant fat pads at love handles or buttocks. This is particularly the case in obese patients who deliberately follow a weight-reducing diet: the fat is lost from the face but not from these diet-resistant fat pads. These fat pads make an ideal donor site for lipotransfer. Thin patients are unsuitable as they may have insufficient donor fat.

The processes of harvesting, washing and preparation of the fat, prior to its injection, take time and require aseptic technique. Harvesting and injection require a needle or cannula of at least 14 g diameter. Using narrower gauge instruments results in adipocyte cell wall rupture with a reduction in graft survival rates. Harvested fat may be implanted either immediately or stored in a deep freeze for later use. Ecchymosis may occur at donor or recipient sites.

Fat is best suited to a fuller face in a patient who has lost substantial amounts of weight and where several ml of filler are required. If HA was used, these volumes would be excessively expensive to repeat on an annual basis.

Hyaluronic Acid (HA)

Non-animal-derived HA fillers have come to dominate tissue augmentation. With their longer duration of action and low immunogenicity, HA, presented in a homogenous gel, has become the gold standard for soft tissue augmentation worldwide.

HA is a linear polysaccharide composed of disaccharide units (glucuronic acid and n-acetylglucosamine) which are linked together by β 1-4 glycosidic bonds forming a polymer. HA is present in the tissues of all vertebrate animals. In the skin, it is the viscous fluid in which the collagen fibres, elastic fibres and other intercellular structures are embedded. HA binds water into the tissues. Unlike collagen, its chemical structure is not specific to any particular organism; it is identical in all species. Therefore, in its pure form, it is not immunogenic. With ageing, the amount of HA in the skin decreases, which results in reduced volume and reduced intradermal hydration.

When injected into the skin, native HA will stay for only 1–2 days, making it a poor candidate for tissue augmentation. To improve the longevity of HA in the skin, cross-linking of the HA molecules was developed in the 1980s. In this process, a chemical binds single HA into large macromolecules. This makes the HA more resistant to degradation, thereby increasing its durability after injection. The first cross-linked HA preparation that was widely used for tissue augmentation was Hylaform®. This was produced from cocks' combs; it was cross-linked with divinyl sulfone. As it lasted only 3 months in the tissue after injection, it lost much of its initial appeal. The most commonly used cross-linking agent nowadays is 1, 4 butane-diol-diglycidyl ether (BDDE) (Edsman et al. 2012).

The first HA product to receive FDA approval was Restylane® (December 2003). Its results last 6–18 months. It is produced by bacterial fermentation followed by cross-linking with BDDE. Restylane® products differ according to the size of the HA particles and the number of gel particles per ml. The product with the highest number and the smallest size of particles is the least viscous product of all and is designed to correct fine lines and superficial, easily distensible defects by injection into the dermis. The product with the least number and largest size of particles is the most viscous and is designed to correct deep folds or wrinkles by injection into the subcutis.

Juvederm® is another widely used HA filler that was approved in Europe in 2001 and received FDA approval in 2006. This filler, like Restylane®, is also produced by bacterial fermentation and cross-linked by BDDE. Although many different Juvederm® products are available, all are composed of a homogeneous gel with 24 mg HA per ml. The products differ by their degree of cross-linking. The greater the cross-linking, the more viscous the product and the more deeply it should be injected. Thus, the denser product is more suitable for deeper wrinkles and folds, and the less viscous, less cross-linked product is more suitable for more superficial wrinkles.

Many other products containing HA are available in various parts of the world, such as Teosyal®, Surgiderm®, Emervel® and many others. Most HA products have a good safety profile, good viscoelastic properties and good durability in the tissue.

After injection of HA into the tissues, the process of degradation or breakdown of the polymer begins. This process includes glycosidic bond cleavage, dissociation of the chains, enzymatic degradation by hyaluronidases and free radical degradation (De Boulle 2004)

Injectable Collagens

Collagens are proteins that form the bulk of the extracellular matrix and comprise 80 % of the dry weight of the dermis of the human skin. The physiological role of collagen fibres in the skin is

to provide the tensile properties of the skin. With ageing, the amount of collagen in the dermis decreases. This contributes to the development of wrinkles.

The first biodegradable soft tissue filler was bovine collagen. It was introduced in 1951 and was the first soft tissue filler to receive FDA approval in 1981 (Zyderm I®, followed by Zyderm II® and Zyplast®). Bovine collagen was the most popular US filler until 2003, when Restylane®, an injectable HA filler, also received FDA approval. Bovine collagen is not used any more as it had a very short longevity (3–6 months) and a high level of immunogenicity. Sensitivity to bovine collagen affected 3 % of patients, and a skin test was needed prior to treatment.

Some human collagen products that were less immunogenic were produced from cadaver skin (Alloderm®, Cymetra®, Cosmoderm®, Cosmoplast®, Dermalogen®), but, owing to insufficient longevity, none is currently used anymore.

Another collagen filler was produced from porcine collagen, Evolence. Even though the allergenic part of the collagen (telopeptide) was removed, cross-linking was performed using the non-toxic sugar ribose, and its longevity was improved (12–18 months). It has now been withdrawn (for unclear reasons) from the market (Christensen 2007).

Fibrogeneic Fillers

Subcision

Subcision induces a natural filler reaction. Subcision is the act of using the bevel of a needle to divide the skin or deeper tissues in a plane parallel to the skin surface (Orentrich et al. 1995). Into the space created by the subcision, blood and serous exudate seep. Wound healing eventuates in fibroblast proliferation and collagen neogenesis, i.e. the formation of natural filler substance. Usually a yellow 30 gauge needle is used (Fig. 119.5).

Chicken pox scars and rolling acne scars are particularly well suited to treatment by subcision, and best results are achieved over two or three sessions. Two subcision treatments will achieve a two-thirds improvement in the depth of a typical facial chicken pox scar. If the chicken pox scar has an alabaster white colour, the whiteness can be improved by additional perpendicular needling. Intradermal subcision can also be used to treat fine early rhitids. Hypodermal or deeper subcision can be useful for more established rhitids.

Subcision is very easy, quick and inexpensive. It has the disadvantage of necessarily and unavoidably causing small ecchymoses. In the

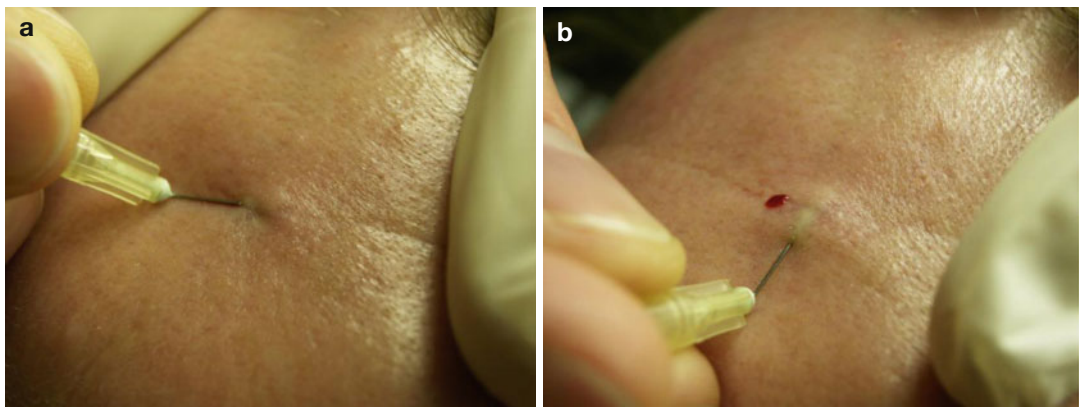

Fig. 119.5 (**a**, **b**) A chicken pox scar being treated by subcision (Courtesy of Dr C Rowland Payne)

case of intradermal subcision on the face, these bruises last up to 4 days. The alternative of treating such lesions with SMDS avoids this inconvenient ecchymotic phase.

Deep nasolabial rhitids can be helped by deep subcutaneous filler injection followed by adjuvant subcision in the same layer.

Silicone: The Queen of Fillers

Liquid silicone is the most controversial of the permanent soft tissue fillers. Its advocates are adamant that when used correctly it is extremely safe and effective. Its adversaries point out that silicone has on occasions been associated with massive, deforming and sometimes unresolvable inflammatory nodules (granulomas), sometimes developing even many years after injection (Christensen 2009, Dayan et al. 2011).

Liquid silicone is a synthetic polymer of dimethylsiloxane. Its viscosity is a function of its polymerisation and is measured in centistokes. Silicone has a product licence for long-term replacement of the vitreous humour extracted during vitreoretinal surgery. The most suitable for use as a filler is 100 % silicone oil (1,000 centistokes) injected into the deeper dermis and/or subcutis. Silicone elicits an intended fibrosis-granuloma tissue response with new collagen formatting around the injected silicone, such that tiny collagen pearls develop around each microdroplet.

Injecting silicone into the skin is like putting a grain of sand into an oyster, and the oyster makes a pearl. Injection of a tiny drop of silicone into the skin and the body will coat it with a layer of fibrosis or foreign body granuloma. These 'silicone pearls' offer possibilities for greater precision. To achieve the desired result, a series of at least four or five sessions of injections, at 4–6 week intervals, are needed – serial microdroplet silicone (SMDS) (Fig. 119.6).

In SMDS, microdroplets of silicone, 0.005–0.01 ml, are injected at 1–2 mm intervals along the length of a rhitid. Each tiny injection is made in the deep dermis or at the dermosubcutaneous border.

Silicone can reach parts that other fillers cannot reach. SMDS can do things that HA cannot do.

HA cannot easily correct deep V notch rhitids. When HA fillers are used to attempt to treat deep V notch rhitids, for example, at the angles of the mouth, the HA cannot be introduced in a sufficient amount at the very bottom of a deep V notch. The HA either passes deep, lifting proud the whole V notch, or it passes to one side of the V, resulting in a bulging V, i.e. a γ shape. On the

Fig. 119.6 (**a**) Perioral rhitids. Before treatment. (**b**) Perioral rhitids. Twelve months after ten treatment sessions of serial microdroplet silicone (SMDS) (Courtesy of Dr D Orentreich)

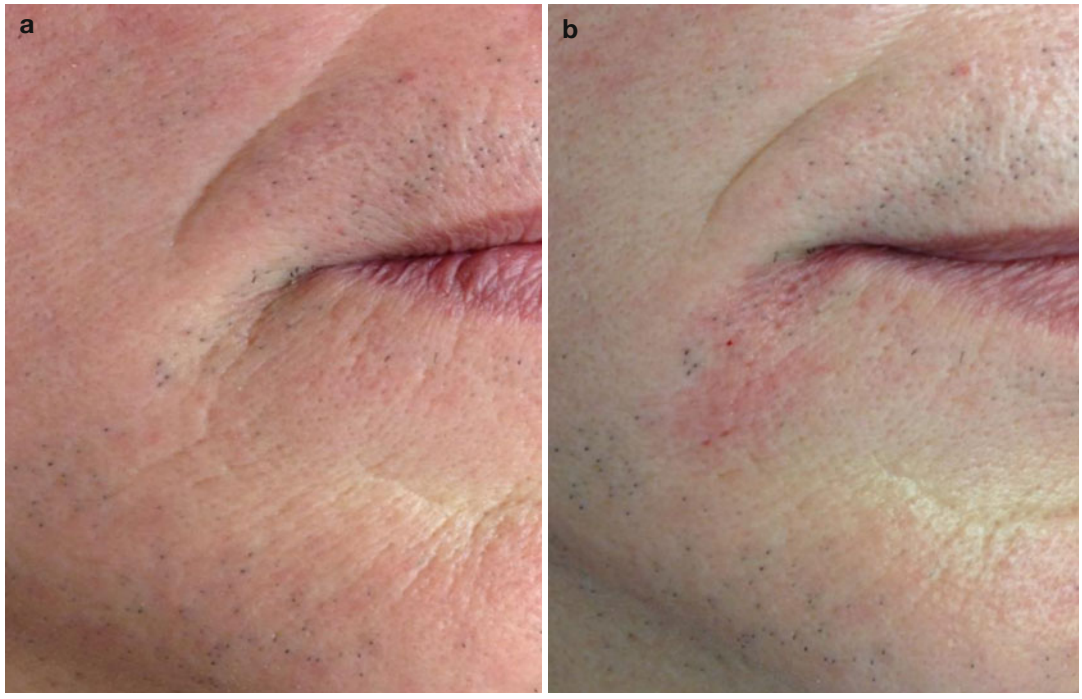

Fig. 119.7 (**a**) Deep V notch angular marionette lines in a man. Before treatment. (**b**) Deep V notch angular marionette lines in a man. After microdroplet silicone (Courtesy of Dr C Rowland Payne)

other hand, microdroplets of silicone can be seeded precisely at the bottom of a V notch rhitid. Over 4–6 weeks, the silicone will become coated by a host fibrotic reaction which will serve to blunt the bottom of the V and lift it. SMDS, repeated at monthly intervals, will go further towards effacing deep V notch rhitids than will any other filler. SMDS can achieve excellent results in these V notch rhitids at the angles of the mouth (Fig. 119.7).

HA cannot lift depressed scars like chicken pox scars. Silicone can. To do this, tiny microdroplets of silicone are serially injected into the scar. These stimulate the host tissue response which gradually, over the ensuing weeks, lifts the scar. Because of the densely fibrotic nature of the scar tissue, it is not physically possible to inject sufficient volume of an inert filler, such as HA, into a bound down scar to achieve the same effect. Worse still, the HA may enter the neighbouring skin, so potentially aggravating the 'sofa button' appearance of the scar. SMDS can lift depressed scars.

HA is short-lived. Silicone is long lasting. This is a clear advantage, but it also means that silicone is unforgiving and imperfect results, for whatever reason, will also be long-lasting. Correct injection technique is critical. It avoids 'silicone lakes' (injection of droplets that are too large) and 'beading' (the formation of palpable lumps just under the skin due to too superficial an injection). Silicone fills by inducing an intended fibrosis-granuloma host response. Since there is variability of intensity of fibrosis-granuloma response between different people and even variability within the same person over time, great care is needed to avoid overcorrection – hence the use of four or five injection sessions, SMDS. When silicone is administered as SMDS, adverse reactions are very rare (Lemperle 2009). Occasionally, unexpectedly severe granulomatous reactions occur (in perhaps 1 in 1,000 patients), even in very experienced hands using the right technique. In the hands of an inexperienced practitioner, the frequency of such events is probably higher. These reactions may even

happen many years after injection of silicone and without any obvious precipitating event (e.g. infection). At least some of these late cases may be due to the unrelated coincidental later development of sarcoidosis, since a feature of sarcoidosis is that foreign body silica granulomas and old scars may become affected by sarcoidal granulomas (Rowland Payne et al. 1983). Such reactions can be treated by serial intralesional steroid (SILS).

Calcium Hydroxylapatite (Radiesse®)

Radiesse® is a biodegradable fibrogeneic filler composed of 30 % microspheres of calcium hydroxylapatite (CHA) particles suspended in a carboxymethylcellulose gel carrier. After injection, the carrier gel is gradually absorbed by macrophage phagocytosis, and a local fibroblastic response develops around the CHA particles. These particles are gradually degraded after 12–24 months, which is the duration of action of this filler. As a more viscous filler, it is especially suitable for the deeper folds or for facial volume replacement and should be injected into the deeper subcutaneous tissue. For the same reason, it is not suitable for lip augmentation or for areas with a lot of movement and thin skin, as it may become palpable or visible in these areas. With the right injection technique, this filler has an excellent safety profile (Christensen 2009).

The *combination gels* contain microparticles (e.g. calcium hydroxyl apatite or poly-L-lactic acid) that are dissolved in a short-lived transient biodegradable carrier gel. The filling effect of these gels relies initially on the carrier gel and later on the host tissue foreign body response. The carrier gel disappears slowly (months to years after injection depending on the filler), and at the same time the host response to the remaining microparticles gradually creates its own filling effect. This host foreign body response eventuates in permanent fibrous tissue formation. As the host response continues to develop due to continuous gradual product degradation, there is a higher incidence of late granulomatous reactions (Christensen 2007).

Poly-L-Lactic Acid (PLLA) (Sculptra®)

Poly-L-lactic acid (PLLA) (Sculptra®) is considered a slowly biodegradable filler (or semi-permanent filler), as it may take up to 40 months or even longer to degrade. It works by stimulating the production of new connective tissue. In due course, the PLLA slowly breaks down to carbon dioxide and glucose. It is mainly suitable for facial volume replacement. PLLA was approved in Europe as New-Fill in 1999 and was the first filler to be used as a volumizer. Even though its clinical results were quite satisfying, about 10 % of the patients developed subcutaneous papules and nodules. Also, the product information used to state erroneously that it should be injected intradermally. Consequently, it lost popularity and was then taken off the European market (Christensen 2009). In spite of this, in 2004 the FDA approved it for the treatment of lipoatrophy in HIV patients and in 2009 for aesthetic use as Sculptra. Compared with New-Fill, Sculptra has a similar molecular composition but a larger particle size and is reconstituted using a larger volume (8–9 ml water instead of 5–6 ml in the past). With the larger particles and this higher dilution, the papule and nodule ratio is now between 0 % and 13 % according to different publications. Some clinicians state that the high rate of complications was due to wrong dilution, incorrect injection technique, incorrect injection volume or inappropriate sites of injection. Apparently, by using large dilution volumes, by preparing the mixture 12–24 h before treatment and by injection in the subcutaneous plane, the risk of complications is relatively low (Dayan et al. 2011).

Polymethylmetacrylate (Artefill® and Artecoll®)

Artefill® is composed of 20 % homogenous polymethylmetacrylate (PMMA) microspheres evenly suspended in 3.5 % bovine collagen and 0.3 % lidocaine (Lemperle et al. 2003). It was available in Europe from 1994 as Artecoll. In 2006 it was taken off of the market due to the high incidence (2.5 %) of treatment-resistant

granulomas. Interestingly, in the same year, Artefill which is a smoother product, with its negative charge removed, was approved in the USA. After this improvement in the product, the incidence of granulomas dropped from 2.5 % to 0.1 %. Nevertheless, Artefill granulomas may arise even 10 years or more after treatment and are mostly resistant to therapy. The newer HA products with their improved longevity and excellent safety record make Artefill, with its attendant risk of treatment-resistant granulomas, obsolete (Park et al. 2012).

Polyacrylamide Gels

Aquamid® is composed of 2.5 % polyacrylamide gel in water. Bio-Alcamid® is composed of 4 % cross-linked polyacrylamide with polyalkylimide. These two gels are very slowly resorbed by the body over many years. They either dissipate (like Aquamid®) or are kept in place (like Bio-Alcamid®) by a fibrous capsule. When injected in large quantities, these gels have a relatively high incidence of complications. Their use is obsolete (Christensen 2009; Dayan et al. 2011).

Filler Selection

Which Filler for Which Indication?

HA is the most widely used filler. Experience is enormous. Its molecular size, its rheological properties and its water holding capacity can be manipulated to tailor it to its various therapeutic indications and to modify its durability. Its adverse effects are well known, well understood and fortunately relatively rare. The existence of hyaluronidase is another factor in favour of HA. HA is usually the filler of choice but not in every case.

For deeper HA injections, such as deep zygomatic region injections, water retention and lack of deformability are advantages. Water retention provides greater volume correction. Lack of deformability means that the position of the filler is less likely to be modified by external forces, such as sleeping on the cheek.

For superficial HA injections, such as infraorbital injections, water retention and stiffness (lack of deformability) are disadvantages. After infraorbital injections, water retention may cause unsightly 'puffiness', and lack of deformability may be regretted if the filler leaves ridges just beneath the surface that are resistant to digital compensation.

Fat is the ideal filler for a fallen or drawn face in a patient who has lost weight but who still has diet-resistant areas of body fat suitable for use as donor material.

SMDS and/or subcision are the only fillers that can treat chicken pox scars and deeper V notch fine-line rhitids, e.g. at the angles of the mouth. SMDS is the ideal filler to treat small-volume lifelong defects, such as post cleft lip surgery. SMDS requires four or five treatment visits, and then the benefits are lifelong without the need for further treatment visits.

Not all fillers are suitable for all indications, and different fillers may be used in the same patient. For example, it may be better not to use the same filler in the cheeks as in the lips or in fine rhitids at the angles of the mouth or in chicken pox scars. In the cheeks, a large particle stiffer HA filler may provide more and longer-lasting volume enhancement. In the lips, a finer particle HA filler with greater deformability may allow more precision of placement and also the use of a finer, and therefore less uncomfortable, needle. At the angles of the mouth and in chicken pox scars, SMDS may be a better choice.

Injection Technique

Needles or Microcannulae

A needle or a cannula may be used to introduce filler. Needles and microcannulae are available in a wide range of gauges. The finest gauges are reserved for needles and the widest for cannulae.

For needles, typically a 30 gauge needle is used. For microcannulae, typically a disposable 27 gauge microcannula of 37 mm length (e.g. Magic Needle) is selected. Most types of HA filler can pass through this very useful instrument.

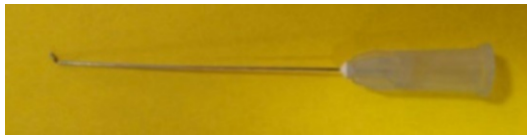

Fig. 119.8 A microcannula, whose tip was bent over by being forcibly advanced against tissue resistance

Microcannulae require a port for entry, which is swiftly made using a needle of a slightly broader gauge.

Advantages of needles include availability, ease and speed of use, lack of dead space, low cost and accuracy of placement of filler.

Advantages of microcannulae include the reduced risk of accidental intra-arterial injection and filler embolisation, and the requirement for fewer cutaneous piercings owing to the length and flexibility of microcannulae, as all parts of the face, is easily attainable through relatively few points of entry. Disadvantages of cannulae include the possibility of a bending over of the tip, if it is forcibly advanced against resistance (Fig. 119.8).

Fine needles and fine microcannulae are probably both capable of inadvertently entering a small artery of the face, and so neither tool is exempt from the risk of filler embolisation, though it is less likely with cannulae.

Level of Filler Implantation

Fillers may be used at any level from intradermal to supraperiosteal.

Superficial injections require smaller volumes, allow greater precision and are well suited to finer work, such as V notch fine lines. They need to be made with greater accuracy.

Deeper injections (and other types of implants) require greater volumes, are more forgiving and are well suited to the treatment of broader contours, such as wide U-shaped trough defects.

Pearls or Threads

Fillers can be injected in pearls or threads.

A pearl may be large or small, e.g. a bolus of 0.1–0.5 ml or a microdroplet of 0.005–0.01 ml.

Bolus injection lends itself to deeper injections. Using a needle or a cannula, a relatively large volume of filler may be introduced relatively swiftly through a single injection point. It has the advantage of minimising the risk of intra-arterial injection by allowing for aspiration prior to injection. Its large volume retains a centre that is relatively far from the microvasculature and therefore the macrophage system, so ensuring enhanced durability of the implant. On the other hand, a lake of filler may migrate more easily than threads of filler which have been interlaced into the recipient tissues, and, if a bolus is microbiologically contaminated, its distance from the blood stream will impair the efforts of host immunity and of antibiotics.

Microdroplet injection lends itself to superficial injections. Using a fine needle, repeated microinjections may be made with great precision. Intradermal and just subdermal microdroplet injections are relatively safe from embolic risks. Microdroplets are of such small volume that, even if injected intra-arterially, they are highly unlikely to cause embolic sequelae. Moreover, the intradermal plane is entirely safe from risk of embolisation as its vessels are of such fine diameter. The subdermal plane is also relatively safe.

Threads may be very fine if a 30 g needle is used or relatively thick, like tagliatelle, if a 14 g needle or cannula is used.

Fine threads are suitable for subdermal injection into the white line roll of the lip. Layered fine threads suit the nasolabial folds.

Tagliatelle-like threads are the ideal form for fat injections. The diameter of the threads should be at least 14 gauge which is wide enough to contain a core of intact, and therefore viable, adipocytes and yet thin enough to allow adequate diffusion of oxygen, nutrients and metabolites to facilitate graft survival until revascularisation has been achieved.

Injection Method: Bolus, in Retrograde or in Antegrade?

Classic teaching advises insertion of a needle, aspiration to check if the tip is not in a vessel and

then a bolus injection which may be a very small dot bolus or a more substantially large bolus.

The aspiration-bolus injection technique comprises injection of the needle into a given site; this is immediately followed by aspiration, to check that the needle tip is not within a vessel; then a bolus of filler is injected. Aspiration-bolus injection avoids retrograde or antegrade injection. It avoids injection from a moving needle tip. The aspiration-bolus needle injection technique may be preferred when injections are made by needle into zones where arteries are plentiful because at these sites there is a greater risk of accidental intra-arterial injection, with its attendant hazards of ischaemic necrosis or distant embolisation. The zones that are rich in blood vessels of sufficiently wide diameter include the subcutaneous and muscle layers (but not the dermal, immediately subdermal or immediately submucosal layers). This is especially so at the glabella, the ala nasi and the modiolaris. These are not the only zones of the face that are at risk of accidental intra-arterial injection. Caution needs to be exercised in all zones.

Retrograde injection is when the needle is first advanced to the farthest part of the injection site and then a threading injection is made in retrograde. This assists the formation of a very evenly formed thread of filler. This is very suitable for the white line of the lips or for injection deep to the eyebrows.

Antegrade injection, by contrast, is when the needle is inserted and then a threading injection is made in antegrade. This helps to push vessels away from the tip of the advancing needle, so minimising bruising. This is very suitable in the tissue of the infraorbital skin where small vessels are plentiful.

Perpendicular or Tangential

The needles through which the filler is injected can pass through the skin perpendicularly or at an angle which is so oblique that it is almost parallel ('tangential') to the surface of the skin.

Perpendicular injection is less uncomfortable and quickly passes deep, eventually, in many places, reaching periosteum. Perpendicular injection can only easily be done by needle, not by cannula. The periosteum is well innervated, and touching it with a needle is therefore somewhat uncomfortable. Touching the periosteum almost always also means touching the bone itself which blunts the needle tip. Thus a new needle is needed for each supraperiosteal injection. The periosteum also has a good blood supply, so the aspiration-bolus technique is needed at this anatomical level.

Tangential injection (whether by needle or cannulae) maintains a relatively superficial plane of implantation carrying with it the commensurate advantages of implants made in the superficial plane.

Pretreatment Considerations

As with all elective procedures, the good physician needs to remember that patient selection, mutual trust and good communication are at the heart of a successful doctor/patient relationship which itself is an important determinant of patient satisfaction with treatment. Verbal exchange and eye contact are essential steps in this process. All of this is much more easily achieved if the initial consultation follows the classical medical model with a clinical history, physical examination, a diagnosis and a discussion with the patient of the treatment options. All the better for the patient and the patient's confidence in you if your consultation reveals other matters of a non-cosmetic nature that you can help with. If there is depression or anxiety, these are best treated before filler treatment is undertaken.

During the preoperative consultation, the patient will usually indicate which area of their face they wish to have improved. The patient should be observed at rest and in animation. Before treatment, it is helpful to demonstrate in a hand mirror to the patient any facial asymmetries. Often patients are entirely unaware of quite major facial asymmetries.

It is very important for the patient to have realistic expectations of the treatment. Using the mirror, the physician discusses the face with the patient before treatment, so that the patient understands what can and what *cannot*

be corrected by fillers. Patients with severe photo-ageing and disseminated wrinkles are not such good candidates for fillers and may be better treated in other ways, e.g. ablative resurfacing by a deep chemical peel (Verner 2014). Patients with wrinkles that are caused by excessive muscular movement (e.g. deep glabellar furrows) will only achieve a transient improvement from the injection of a filler, unless the muscles that cause the wrinkling are also relaxed by botulinum.

Once the choice of treatment has been decided upon, the patient needs to give verbal and possibly written informed consent. Patient advice sheets may be useful. The more that can be explained to a patient preoperatively about what they can expect, the less that needs to be explained postoperatively.

Preoperative explanation is '*knowledge*'. *Postoperative explanation is an* '*excuse*'.

Attention to all of these steps increases patient confidence. The patient who is confident and positive in their approach to treatment will find the experience of the treatment session easier and often less uncomfortable than the patient who is more diffident or doubtful. A patient who has confidence in the doctor is more likely to tolerate well any minor inconveniences of the treatment, such as small bruising.

Pretreatment Preparation

To minimise bruising, patients are asked to avoid aspirin and other nonsteroidal anti-inflammatories for 14 days preoperatively. For 2 days before treatment, patients may also avoid ginkgo, vitamin C, vitamin E and supplements of fish oil or garlic (cooked garlic in food need not be avoided). If pain relief is needed during 14 days prior to treatment, patients are asked to use only paracetamol or codeine or co-codamol 30/500 (which is a combination of both paracetamol 500 mg and codeine 30 mg).

It is very helpful to have an assistant who can exert pressure as soon as any bleeding is observed and who can also make detailed contemporaneous notes.

Analgesia

A relaxed, unhurried and trusting patient will tolerate filler treatment well. Topical anaesthetic, such as EMLA, is applied when the patient arrives in the waiting room and then again 2–5 min before treatment. During treatment, the patient should be kept at their ease by talking. Vocal anaesthesia, especially if it is the patient who is talking, will help. Oral anaesthesia is usually not required but, if it is, co-codamol 1–2 tablets 1.5 hours before treatment is helpful (patients should be advised to avoid driving for a few hours after the first time of taking codeine as it makes some patients drowsy or nauseous). Anxious patients may also benefit from diazepam 5–10 mg 1.5 hours before treatment.

Discomfort and the risk of bruising are also related to the number of injections, the depth of the injections, the angle of the injections and the sharpness of the needle. To avoid the increased discomfort that would come from using a dulled needle, no one needle should make too many injections.

Injection Technique for Specific Facial Anatomical Sites

The facial region offers many opportunities for filler treatment.

Nasolabial filler treats nasolabial rhitids. Nasolabial fillers can be introduced in the deep dermis, at the dermosubcutaneous junction or in the upper subcutis. The latter is particularly useful for 'U'-shaped rhitids. It is a good site to gain experience.

The Paris lip is the standard filling technique around the mouth. As lips age, full lips with a smooth vermillion surface and a well-defined vermillion border gradually become less full, their surface becomes cross-hatched, and radial rhitids begin to traverse the vermillion border into which the lipstick 'bleeds'. Thinning of the lips, cross-hatching of the surface, lipstick 'bleeding' and radial rhitids can all be corrected by fillers. Radial rhitids at the lip are usually best filled not by direct injection into the rhitids but by

injection perpendicular to the rhitids running parallel to the vermillion border either inside the white line roll of the lip or within the pulp of the vermillion. Filler is introduced into the anatomical potential tunnel which lies beneath the white line (the border between vermillion and glabrous lip) (Fig. 119.9).

A refinement of this technique includes a threading intradermal injection into the philtrum. An excellent indication for the Paris lip is radial 'bleeding' of lipstick. Patient anxiety is greater with injection in the lips than at any other site. Many fear the 'trout pout'. Any injections made at this site will be scrutinised particularly closely by the patient. The Paris lip should not be the first filler injection made by a tyro.

The Mona Lisa smile (Rowland Payne 2003) lifts the angle of the mouth. A point is chosen on the white line of the *upper* lip 3 mm superomedial to the existing angle of the mouth. The needle is inserted at this point into the white line space and passed inferolaterally towards the angle of the mouth and on along 0.5 cm, still in the white line space of the lateral part of the *lower* lip. Filler is injected in retrograde. To further enhance the effect, a little extra filler is injected into the body of the vermillion part of the lower lip, just medial to the angle of the mouth. Downturning of the angle of the mouth can be corrected in this way (Fig. 119.10).

Fig. 119.9 The white line of the lip being injected by HA (Courtesy of Dr C Rowland Payne)

Wet line injection produces a fuller lip. Wet line injection increases the visible vermillion, 'the kissable surface'. The wet line of the lip is where the vermillion changes from mucous membrane to stratified epithelium. The wet line injection is made deep to the wet line. If HA is used, the injection is a threading injection along the length of the lip. If SMDS is used, it is as microdroplets. Either way, the filler is deposited deeply in the lip, ¼–½ cm deep to the wet line.

Submucosal lip injection displaces the lip anteriorly. Microdroplets of HA filler are introduced just submucosally opposite the teeth. Threading submucosal injections carry a high risk of ecchymosis, and so pinpoint submucosal microdroplets of HA are best. The lips drape over the teeth. As the lips involute and become thinner, the skin of the lips lies in closer relation to the teeth themselves. Any dental asymmetry results in lip asymmetry which becomes more obvious with age. Asymmetrical submucosal injection can compensate for dental asymmetry, a common problem in the middle aged British mouth. Submucosal injection opposite the upper

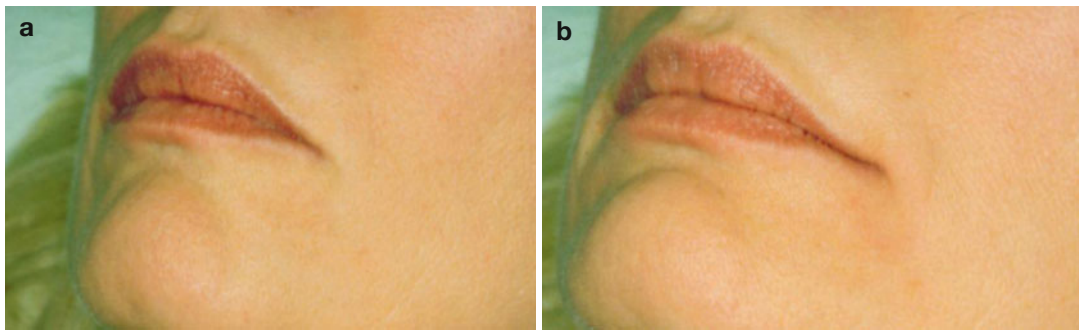

Fig. 119.10 (**a**) The Mona Lisa smile. Before HA treatment. (**b**) The Mona Lisa smile. After HA treatment (Courtesy of Dr C Rowland Payne. Reproduced from Shai A, Maibach HL, Baran R. Handbook of cosmetic skin care. 2nd ed. p. 195, with permission of the publishers)

dentogingival line can also be used to offset maxillary bone resorption. Submucosal injection behind the lateral parts of the lower lip improves the shadowing that occurs inferolateral to the angles of the mouth. Prognathism can be treated by mandibular surgery, but it can also be disguised by submucous filler injections in the *upper* lip (Fig. 119.3).

Marionette line injections help efface shadowing inferolateral to the angles of the mouth. They also improve the rhitids that run out inferolaterally from the angles of the mouth. When the rhitids are U shaped, they can be filled directly by a threading injection of HA, best made with a cannula inserted at their inferolateral end. If there is notable shadowing at their superomedial end, i.e. at the angle of the mouth, some HA is also implanted perpendicularly into the body of the glabrous part of the lower lip, just inferolateral to the angle of the mouth. This inferolateral injection can be made subdermally, subcutaneously or submucosally or all three. At this site the arterial supply is rich and tortuous providing a theoretically enhanced risk of accidental intra-arterial injection during subcutaneous injection. For subcutaneous injection at this site, the aspiration-bolus technique is therefore advised. Fine deep V notch angular marionette rhitids are very common in men. They are not easily amenable to HA. SMDS offers precision of filler placement precisely into the bottom of these V notches (Fig. 119.7).

The tribolus technique provides anterior projection to the medial cheek (Carey 2012). Two perpendicular aspiration-bolus injections are made in the upper medial cheek. To avoid the neurovascular bundle that exits the maxillary foramen, one is made just medial and the other just lateral to the midpupillary line. The third injection is made paranasally, 1–2 cm inferior to the upper medial injection.

Zygomatic injection improves anterolateral projection of the zygomatic part of the cheek which serves also to improve nasolabial folds and jowls. It can be achieved by aspiration-bolus injection or by cross threads introduced by microcannulae.

Ala nasi injection restores support for the inferior part of the nose. Imagine a person lying on their back, the nose is the 'tent pole' of the supine face, not only holding up the nose itself but also supporting the neighbouring structures. In a person standing erect, this 'tent pole' provides anterior projection not only for the nose itself but also for the ala nasi fossa and the superior part of the nasolabial groove as well as the cheeks as far laterally as the pupillary line and as far superiorly as the tear trough. All this is evident if a small amount of HA (0.05–0.1 ml each side) is injected deep to the ala nasi. In the ala nasi injection, the needle enters the skin 0.5 cm inferior to the ala nasi running in a slightly superior direction to reach a point lying deep (i.e. posterior) to the ala cartilage. Using the aspiration-bolus technique, 0.05–1 mm of HA is implanted. The technique is repeated on the contralateral side. With the ala nasi injection, aspiration should always be performed before injection to avoid compression of the angular artery. If, instead of this anterior approach, a lateral approach is used, the risk of intra-arterial injection is greater as this is where the tortuous facial artery runs, just before it splits into the lateral nasal artery and the terminal branch of the facial artery itself, known as the angular artery.

Medical rhinoplasty can supplant the need for aesthetic surgical rhinoplasty. The bridge, the dorsum and the tip can be filled, usually using HA (Fig. 119.2). The tip can be lifted by a filler injection in the columella. A point is selected two-thirds of the distance from the nasolabial angle to the tip of the nose. Pointing tipward, the needle is inserted almost parallel to the surface of the skin; HA 0.05–0.1 ml is injected in antegrade which serves to lift the tip of the nose (Fig. 119.11a, b).

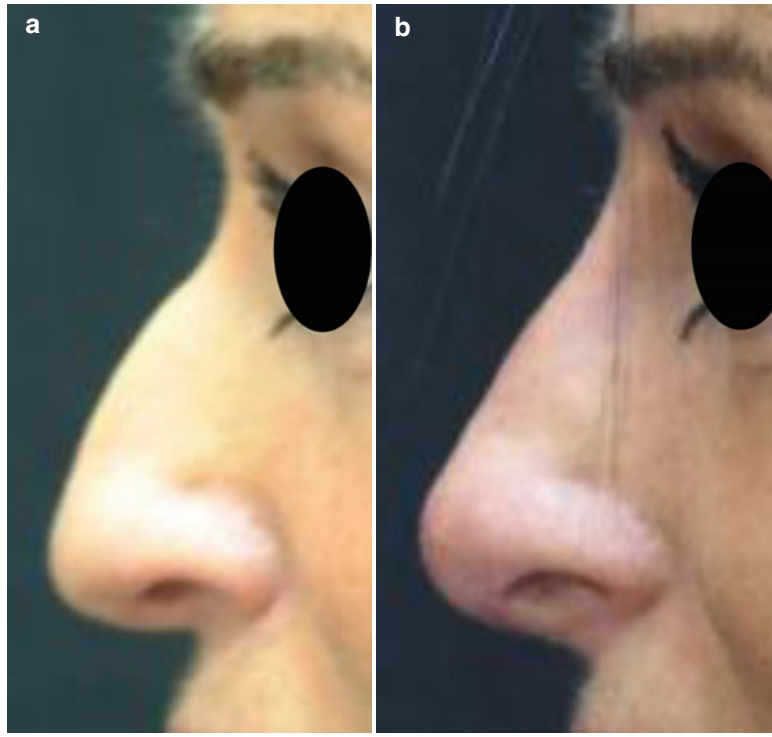

Fig. 119.11 (**a**) Medical rhinoplasty. Before filler treatment. (**b**) Medical rhinoplasty. After filler has been implanted at the bridge of the nose and at the nasal tip (Courtesy of Dr J-P Amsellem)

Temporal injection fills the temporal fossa. The convex temporal fullness of youth imperceptibly gives way to a concave temporal skeletalization that characterises old age. The point of maximum hollowness at the temple is selected. A perpendicular 'pistol shot' injection is made. The periosteum is reached. Using the aspiration-bolus technique, 0.2–0.5 ml is injected slowly.

The eyebrow injection raises the eyebrow 1–2 mm and so also raises the upper lid fold. If a cushion is put behind a curtain, the bottom of the curtain rises (i.e. the distance between the bottom of the curtain and the floor increases). The eyebrow injection is made deep to the eyebrow. If HA is used, the injection is a threading injection along the length of the eyebrow. The filler is deposited either just subdermally or on the periosteum. Between the two planes there are many vessels and nerves. If SMDS is used, the microdroplets are best placed subdermally or within the layer of the subcutaneous tissue where the roots of the eyebrow hairs lie. The eyebrow lift is much appreciated by the patient who will notice an opening of the orbit and hence a brightening of the face. After this injection there may be a temporary post-injection oedema.

Ear lobe injections reflate the ear lobes and efface ear lobe rhitids.

Prejowl bolus injection masks the mandibular line (Verner and Rowland Payne 2009).

Retromandibular injection (Rowland Payne) helps improve jowls by drawing them back posteriorly which also improves the prejowl

sulcus somewhat. By aspiration-bolus technique, 0.2–0.5 ml HA is placed on the periosteum of the posteroinferior aspect of each mandibular ramus.

Injection Technique for Full Face Treatment

In any particular patient, any or all above site specific techniques can be employed piecemeal, according to aesthetic good taste. Alternatively, a more global approach may be employed alone or in combination with the site specific technique.

Lipostructure. Coleman (2006) developed the principle originally espoused by Fournier (1986), in which tagliatelle-like threads of fat are intricately transplanted all over the face to restore the smooth and softly rounded curves of youth. This is a major procedure usually performed under general anaesthetic.

SoftLift. Luigi Polla's SoftLift (Fig. 119.12) employs the principles of Coleman's lipostructure technique in an ambulant outpatient procedure that is virtually painless. A microcannula delivers superficial subcutaneous retrograde threading injections of HA. These radiate out, like the spokes of a wheel, from each skin puncture in a clock face fashion: 1 o'clock, 2 o'clock, 3 o'clock, etc. Multiple puncture points enable the threads to cross-cross one another to produce a very even and smooth result.

Extrafacial Uses for Filler

Other non-facial sites can be treated by filler, including the hands, breasts and external and internal genitalia. Filler can also be used in the feet to treat corns and metatarsalgia.

Complications

Filler-Induced Arterial Occlusion

In the absence of a sufficient collateral circulation, intra-arterial injection of filler will result in distal ischaemia. The first sign is an immediate and transient greyish discolouration, often accompanied or followed by pain. Some minutes later, there may be a phase of reactive hyperaemia. A couple of hours later, reticulate livedo supervenes (Fig. 119.13). If the collateral circulation has not taken over, next comes scattered pustules followed by an eschar and/or ischaemic ulceration and later cicatrisation (Lazzeri et al. 2012). Vulnerable sites on the face include the glabella and the ala nasi.

Ala nasi or nasal tip necrosis may be caused by vascular embolization into the lateral nasal artery, which is a branch of the angular artery. This complication has also been reported after injection into the upper nasolabial area (Kang et al. 2011). Patients after nasal surgery have a higher risk of this complication due to their

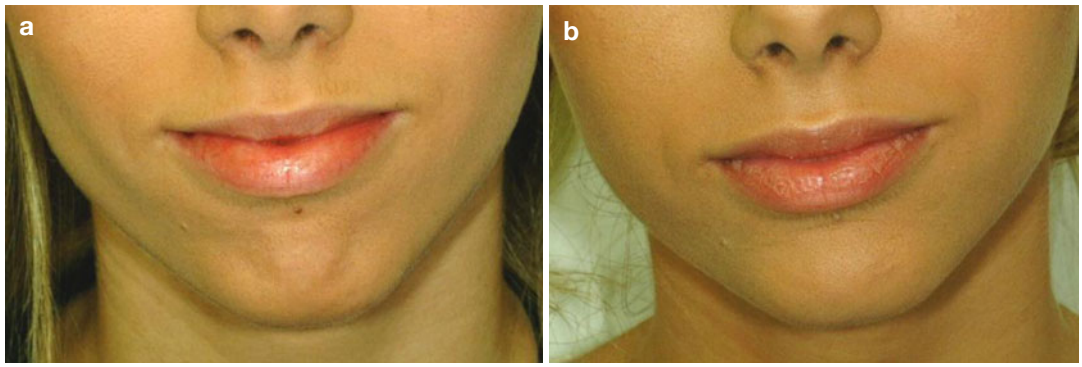

Fig. 119.12 (**a**) SoftLift. Before filler treatment. (**b**) SoftLift. After filler treatment (Courtesy of Dr L Polla)

Fig. 119.13 Filler-induced occlusion of the facial artery at the ala nasi fossa. This reticulate livedo resolved spontaneously over the next week

compromised blood supply (Grunebaum 2009). Injection of hyaluronidase (in the case of HA injection) as soon as possible after the filler injection is the first treatment whether the HA is believed to be intra- or peri-arterial. Attempts should also be made to increase blood flow to the area to assist the collateral circulation both physically and pharmacologically. Physical methods include warm/hot compresses and massaging or tapping the affected area. Pharmacological methods include application of nitroglycerine ointment and oral glyceryl trinitrate spray. An oxygen mask may be helpful. In severe cases, hyperbaric oxygen therapy may be considered. Some authors also advise aspirin and/or low-molecular-weight heparin.

Filler-Induced Pulmonary Embolism

Barlow's group have had one death from fat embolisation after lipotransfer (Gleeson et al. 2011).

Ocular Embolisation

A particularly feared complication of filler treatment is embolisation of the retinal artery or one of its branches with consequent retinal ischaemia. Like the brain's circle of Willis, the face has a circular network of arteries that are in direct communication with one another and through which blood can flow in either direction. The major phylogenetic advantage of these circular networks is that blockage at any particular point is not disastrous, as the direction of blood flow in the residual network has the capacity to reverse. Consequently ischaemic necrosis of that part of the brain or face is avoided. Unfortunately, the corollary of this safety system is that filler injected inadvertently intra-arterially may travel, by retrograde flow, from any of the smaller arteries of the face into the arteries of the facial circle and thence into the central retinal artery before the embolus lodges in the retinal circulation resulting in ischaemic damage to that part of the retina with consequent loss of that part of the visual field of that eye.

To help protect against this possibility, cannulae are preferred, which are practical over needles; where possible, the syringe should be aspirated before injection; injection pressure should be as low as possible; injections should be performed slowly; volumes used should be as small as possible, and the patient's eyes are usually best kept open during injections. Retrograde and antegrade threading injections by needle are best avoided in the danger zones. These zones include the subcutaneous and muscle layers (but not the dermal, immediately subdermal or immediately submucosal layers), especially at the glabella, the ala nasi and the modiolaris. These parts of the face carry a greater risk, but no part of the face can be regarded as truly exempt of this risk.

Fortunately this complication is extremely rare. Between six and 40 cases of partial or complete loss of sight in one eye are believed to have occurred worldwide over about 10 years. In that time, approximately about 20–40 million filler treatments have been performed. It is deduced that the risk of ocular embolisation is of the order of one in a million.

If ocular embolisation does occur, attempts should be made to help shift the embolus more distally, so reducing the ultimate size of the field of ischaemia and the consequent size of the area of visual impairment. This is attempted by vasodilatation. Vasodilatation can be induced directly

by pharmacological means. Vasodilatation can be induced indirectly as a consequence of reducing intraocular pressure. Immediate ophthalmological help should also be sought.

Vasodilatation can be induced pharmacologically. This can be achieved by increasing the partial pressure of CO_2 through rebreathing and also by administration of glyceryl trinitrate.

Vasodilatation can be induced by reducing intraocular pressure. This can be achieved by bidigital orbital compression and by acetazolamide.

The role of oxygen is more debatable. Oxygen is a vasoconstrictor, but it is oxygen that the retina needs. Hyperbaric oxygen therapy (HBOT) facilitates increased partial pressure of oxygen, such that not only haemoglobin but also plasma oxygen saturation rises. Oxygen carried by plasma better penetrates marginally perfused areas. The benefits of HBOT may outweigh the unwanted vasoconstrictory effects of oxygen. HBOT can only be regarded as a temporary measure but may provide time for some collateral circulation to take over. Some authors also advise aspirin and/or low-molecular-weight heparin (Box 119.1).

Box 119.1. Emergency Treatment for Filler-Induced Ocular Arterial Embolisation

1. Rebreath into a bag for 20–30 min.
2. Firm and repeated bidigital compression of the eyeball for 20–30 min.
3. Glyceryl trinitrate spray 800 μg sublingually.
4. Acetazolamide 500 mg by mouth.
5. Seek ophthalmological assistance.
6. Consider oxygen mask.
7. Consider hyperbaric oxygen therapy.
8. Consider aspirin.
9. Consider low-molecular-weight heparin.

Fibrosis

Fibrosis is a physiological aspect of wound healing. A filler treatment is, in a certain sense, a wound, and some fibrotic reaction would not therefore be unexpected. Indeed the fibrogeneic fillers, such as silicone, rely upon this tissue response for their therapeutic activity. Nodules may develop due to fibrosis arising from a stimulatory filler as PLLA, CHA or silicone. Fibrosis is very rare after HA injection (Lemperle et al. 2003). Fibrosis responds well to SILS.

Granulomas

Any foreign bodies, and thus all fillers, may sometimes elicit a foreign body reaction in human tissue. In this kind of reaction, macrophages and foreign body giant cells surround the implanted material.

Granulomas mostly have a late onset, are tender and swollen and occasionally may suppurate or ulcerate. It has been proposed that granulomas may occur due to protein impurities in the product, irregularities of filler particle surface or biofilm activation (Hall-Stoodley et al. 2009).

Any filler may induce a granuloma. Indeed, the mode of action of fibrogeneic fillers, such as silicone or polylactic acid, is by deliberate induction of a controlled and limited host fibrosis-granuloma response.

A granuloma is a host tissue response. It is part of the physiological repertoire of the inflammatory reactions of the innate immune system. The capacity to form granulomatous inflammation varies from one individual to another and varies within an individual over time. This is best illustrated in tuberculosis or leprosy. Some patients readily entrap these bacilli in tuberculous granulomas. Other less lucky patients, in the absence of treatment, develop disseminated tuberculosis (‘galloping consumption’) or lepromatous leprosy. Changes in the general health or nutrition of a patient can result in a major modification to their capacity to form granulomas.

Granulomatous inflammation may also occur as a physiological inflammatory response to a foreign body. The intensity of this response may also vary over time. It also varies with disease. For example, longstanding silica foreign body granuloma reactions may later become more

severe if the patient later develops sarcoidosis (Rowland Payne et al. 1983).

In the same way, *unwanted* granulomatous reactions around filler implants may occur 4–6 weeks after injection or at any time, even many years later. At their worst, such granulomas may be complicated by calcification. Factors favouring the development of unwanted filler granulomas can be divided into host-related factors and filler-related factors.

Host-related factors include genetic factors and probably the development of sarcoidosis.

Filler-related factors include the nature of the filler and any microbial contamination. The mechanism of the therapeutic action of fibrogeneic fillers harnesses their capacity to induce fibrosis and granulomas, e.g. silicone. When silicone is used as SMDS, *unwanted* granulomas are most exceptional. If silicone were injected as a bolus (or 'lake') or as a thread (as HA might be injected), then unwanted granulomas would be very likely. This 'lake' method of injection of silicone is entirely outdated and is now merely of historical and theoretical note. Paraffin is no longer used as a filler, and so paraffin granulomas ('paraffinomas') are also fortunately now no longer seen. In recent years, some particular fillers have been notorious in having induced unwanted granulomas. These include New-Fill, now reissued as Sculptra with altered product preparation and usage advice. Microbial contamination of filler implants also increases the risk of subsequent granuloma formation. This can occur by contamination of the injection by skin flora or possibly by haematogenous spread from a focus of injection elsewhere, such as dental caries or sinusitis.

If granulomas occur, SILS injections are almost always successful in controlling them. In rare cases, intralesional bleomycin or oral agents, such as prednisolone or methotrexate, may be needed. Surgery, even biopsies, should in most cases be avoided as granulomatous material, especially if complicated by microcalcification, is not only likely to be difficult to remove in its entirety but also any residual elements have a high likelihood of continuing to discharge to the surface by way of a non-healing sinus. The ostium of such a sinus so often remains situated at the very point of the surgical incision, where it persists as a lasting reminder to the patient of the name of the surgeon whose well-meant incision is now the portal of a chronic weeping sinus, a sinus which remains open as long as the body attempts unsuccessfully to discharge the remains of the granuloma.

Infections

Cellulitis may result from contamination of filler by pathogenic bacteria and is associated with the appearance of red, painful swelling around sites of injection. This is extremely unusual and responds to antibiotics with or without incision and drainage of any contaminated lake of filler. A 10- to 14-day course of antibiotics, such as penicillin V 500 mgs with flucloxacillin 500 mg qd or erythromycin 500 mgs qd alone, will usually suffice. Moreover, as HA is slightly acidic, bacterial infection is relatively rare. Good aseptic technique makes cellulitis an unlikely hazard.

Subacute cellulitis is more common than frank acute cellulitis. It is characterised by tender lumps, which may be reddish, at sites of injection. Injections in the subcutaneous plane require careful aseptic technique to avoid this. Deep in the subcutaneous fat layer, the body's immune defences are less efficient than in the subdermal layer. Sometimes antibiotics are required. If penicillin V with flucloxacillin or erythromycin is not successful, a prolonged course of minocycline may be considered.

Subacute inflammatory reactions may occur when filler is used in the deeper fat. These are probably caused by contamination of the injection by skin commensal microbes. In most of these cases, an oral antibiotic will solve the problem, indicating that imperfect aseptic technique may be the cause of this subacute cellulitis.

Biofilm is the development of a microbial coating of the surface of a bolus of filler. It is most likely to occur with deeper subcutaneous injection as the host immune defences are less strong at this level owing to its poorer blood supply. A biofilm may induce the host inflammatory

response, sometimes causing erythema or a fibrotic shell around the bolus of filler. A biofilm may lie relatively dormant, potentially flaring up when the patient's general health becomes impaired. A biofilm or other subclinical infection may cause delayed or late reactions. Many complications that, on the basis of negative bacterial cultures, were previously assumed to be foreign body granulomas or allergic reactions are now thought to be due to biofilms (Nusbaum et al. 2012). Careful aseptic technique is required to avoid this complication (Hall-Stoodley 2009, 2004). A biofilm is an aggregation of microorganisms that excrete an extracellular polymeric substance (EPS) matrix composed of polysaccharides (especially HA), proteins and extracellular DNA. This framework of EPS facilitates surface attachment and increased antibiotic resistance. A biofilm can form when a foreign body (e.g. a filler) is contaminated. It can happen days or weeks or even months after injection and may be due to inoculation during the procedure, direct spread from another focus or haematological spread (De Boulle 2004; Dayan et al. 2011).

Haematogenous cellulitis is a dubious entity. Patients with chronic dental problems, sinusitis or other infections may have a greater tendency to develop an infection after filler injection. They may present as cellulitis with redness, tenderness and swelling. Mostly, an oral antibiotic will solve the problem.

Other Complications

Minor injection site reactions. Injection site reactions are the most common adverse events. These include pain, swelling, redness, bruising, itching and tenderness. These reactions (mostly mild) may occur to some extent after any filler injection and mostly subside in less than 10 days. No treatment is necessary.

Injection-induced oedema may follow injection, especially into the loose adventitial tissue of the lips, eyebrows and infraorbital skin, exactly the same areas which are most susceptible to angiooedema. Some people are more susceptible at certain times and to a variable degree to angiooedema from a variety of causes. Multiple needle punctures are one such cause. This post-traumatic angiooedema may develop in minutes or hours, even up to 24 h after injection. Typically, it lasts 2–20 min, occasionally 2 h to 2 days.

Deep ecchymosis may follow deeper injections. Typically, a day or two after the procedure, the patient will notice a deep and slightly tender nodule or a degree of asymmetry. There may be no colour change if the ecchymosis is deep. It resolves within 2–3 weeks. No treatment is required.

The Tyndall effect describes the apparently bluish hue of colourless transparent material (e.g. HA) seen through a thin layer of skin. It occurs after too superficial injection of filler. Needle puncture and expression will express the excess filler.

Beading describes small papules of filler near the surface of the skin. Needle puncture and expression will express the excess filler.

Visible lumps. Overcorrection or too superficial placement of a filler may lead to visible lumps under the skin. This problem is mainly seen in areas of thin skin with a lot of movement, such as around the lips or the eyes or in the nasolabial grooves. These lumps may be treated either by firm compression between finger and thumb or by aspiration or, in superficial cases, by puncture incision and expression. Injection of hyaluronidase (an enzyme that breaks up hyaluronic acid) may be used when the problem arises after injection of HA. When a temporary biodegradable filler is used, any unwanted lumps are usually temporary and treatable.

Prolonged infraorbital swelling is a result of water absorption by HA. It is a particular risk in the infraorbital skin. It may last a year. It can be avoided by using HA in only small quantities at this site and by choosing less hydrophilic preparations of HA.

Inert filler lakes may sometimes be unsightly. They respond to incision and expression.

Migration may occur if lakes of filler are implanted. It requires incision and expression. It is extremely unlikely if filler is threaded into the host tissues.

Facial lipoatrophy is a rare complication of filler use (Andre et al. 2002).

Conclusions

The use of soft tissue fillers is increasing rapidly. In part this is due to the development of fillers with better longevity and a higher safety profile. Now there are different fillers for different indications. Any former social pressure against fillers has been replaced by a peer pressure that encourages their use.

Though the complication rate with most fillers is very low, it is usually preferable to begin by using an inert biodegradable soft tissue filler of temporary duration, such as HA. Moreover, in due course most HA-related complications resolve spontaneously.

Hair Examination

120

Bianca Maria Piraccini, Francesca Bruni, and Michela Starace

Key Points

- The methods for the study of hair include noninvasive and invasive techniques, with different difficulty of execution.
- A correct assessment of the patient requires a good knowledge of the physiology of the hair to correctly interpret the results.
- The new diagnostic instruments, such as the videodermatoscope, permit to reduce the necessity to utilize invasive techniques.

General Principles

The hair is formed by two parts: a visible part, the shaft, and a non-visible part, the hair follicle. The latter is further divided into upper segment, or permanent, and a lower segment, or dynamic, for the changes they have during the follicular cycle. The follicular cycle causes the production of the hair from the follicle, and it is not continuous but cyclic, with a succession of the three stages: growth (anagen), regression (catagen), and resting (telogen).

The daily "normal" hair loss is 50–70 hairs a day. These percentages vary in different periods of the year. In our climate, the peak of hair loss occurs between August and September. The follicular cycle is the result of a complex interaction of signals between epithelium and mesenchyme. It is influenced by environmental factors, such as the duration of the day that acts on the hypothalamus-pituitary axis with the production of melanin and prolactin and by systemic and local factors largely unknown.

Diagnostic methods in hair diseases are:

1. Pull test
2. Trichogram
3. Videodermatoscopy
4. Wash test
5. Modified wash test
6. Biopsy of the scalp

Hair diseases can be divided into two categories:

1. Associated with diffuse hair loss with no hair thinning
2. Associated with patchy hair loss

This classification is very important for the choice of the method to make a diagnosis. In fact, according to the clinical manifestation of diseases, it is possible to choose the instrument and the position where to perform the diagnostic method.

Pull Test

The pull test allows to evaluate the phase in which the hair is located at the time of fall. It is simple to perform, and it allows an immediate assessment of the phase. Using the thumb and index, the physician exerts a pull, slight but steady, of a tuft of 10–20 hair and evaluates the type of the root and the number of hairs that are extracted. Once the hairs are extracted, they are mounted on a slide with a gel or oil solution, covered with a cover glass, and analyzed by light microscopy.

In cases of diffuse hair loss, the test is usually performed in four to six areas of the head: the frontal, parietal, and occipital part of the scalp, and usually it detaches some roots in telogen. In case of patchy hair loss, the test is performed at the margin of the alopecic area.

The hair can be extracted in various stages of the hair cycle:

1. Anagen: it shows a pigmented dark bulb, often with a triangular shape. It's possible to identify both the external and internal epithelial sheaths.
2. Catagen: extracted very rarely, are similar to the hair in telogen with some pigment and a tiny epithelial "tail."
3. Telogen: typically club shaped and more or less pigmented. The presence of a lot of transparent epithelium around the bulb identifies a telogen hair extracted before the end of the cycle.

In normal conditions, the pull test extracts hairs in the telogen phase, and the number is the equivalent of the daily fall that is about 50–70 hairs/day and becomes 100–150 during washing. The extraction of more than six hairs in the telogen phase, from 4 to 5 days after the last washing, is considered pathological.

It is important to remember that the result of the pull test can be influenced by many external factors, such as the frequency of brushing, the distance from the last wash, and the traction force of the physician. The number of hairs that is extracted with the pull is in fact reduced by shampooing, brushing, and combing. We prefer to perform the pull test the same day or 1 day after shampooing.

Fig. 120.1 Dystrophic hair roots in alopecia areata

- A pull test revealing too many telogen hairs or hair in another phase of the hair's cycle is considered abnormal.
- Pull test extracting anagen roots with thickened sheaths is typically seen in cicatricial alopecia.
- Pull test extracting anagen roots devoid of sheaths and with rugged cuticles (loose anagen hair, LAH) is typical of the loose anagen hair syndrome (LAHS).
- Pull test extracting dystrophic anagen hairs (broken at the level of the keratogenous zone and present a fractured proximal end) is diagnostic for alopecia areata. These hairs correspond to the distal part of the exclamation mark hairs. They are also typical for anagen effluvium (Fig. 120.1).

Trichogram

The trichogram is a technique now disused, because it's not easy, it does not give objective data, and it is painful for the patient.

The trichogram is a forced tear of about 50–100 hair of a scalp area with klemmer forceps with the ends covered with rubber pads: it extracts by plucking all the hair in that area. You have to "clamp" the hair between the forceps ends 1 cm from scalp emergency and make a firm tug, pulling in the direction of hair's emergency from the scalp. Once extracted, the hairs are positioned side by side with the roots at the

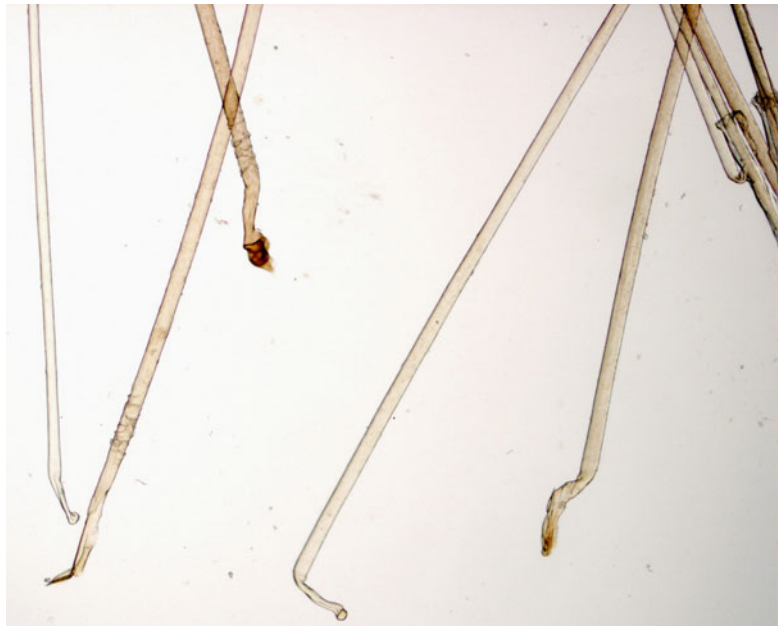

Fig. 120.2 Trichogram in an LAHS

center of the slide. The different hair roots are then counted. The normal percentage of telogen hair is less than 15 %.

The trichogram is important if you suspect a loose anagen hair syndrome, even if the pull test is negative (Fig. 120.2). Both the absence of pain during trichogram and the presence of more than 70 % of hair in the anagen phase with cuticles "ruffled" are diagnostic. In all the other hair disorders, the trichogram can only give information on anagen to telogen ratio but is not diagnostic.

In hair shaft diseases, the hairs analyzed are not extracted with plucking, but they are directly cut with scissors from the emergency of the scalp and then observed with a light microscope at high magnification and/or with an electronic microscope.

Videodermoscopy

Dermoscopy and videodermatoscopy (VDS) are useful techniques for the evaluation of the physiology and pathology of the hair and scalp. Several videodermatoscope devices, at different magnifications (from 20× to 70×), are available. The images are digitized, stored, and observed in a high-resolution monitor in real time.

The technique has been applied to the scalp, in order to study its skin, vessels, and hair shaft, and allows a noninvasive diagnosis, often avoiding the biopsy. Because of its complexity, however, this methodology is reserved for experienced dermatologists.

VDS allows to evaluate several basic parameters such as the density, the diameter, the diversity of the diameter of the hair, the appearance of the skin, and other specific signs of hair disorder (Fig. 120.3).

- Hair density (number of hairs per cm^2) is classified on a scale ranging from 1 (less than 4 hair) to 6 (more than 40).
- Hair diameter that indicates the size of the hair is classified as 1 (thin), 2 (medium), and 3 (large).
- The diversity of the diameter of hair indicates the presence of hair with varying diameter. A normal scalp has hairs of similar diameter and thinner hairs, which are less than 20 %. In androgenetic alopecia there is more than 20 % variability in the hair shaft diameter.
- Peripilar sign, which appears as brown halos around the follicular ostia, is a sign of perifollicular inflammation which is often associated with androgenetic alopecia.

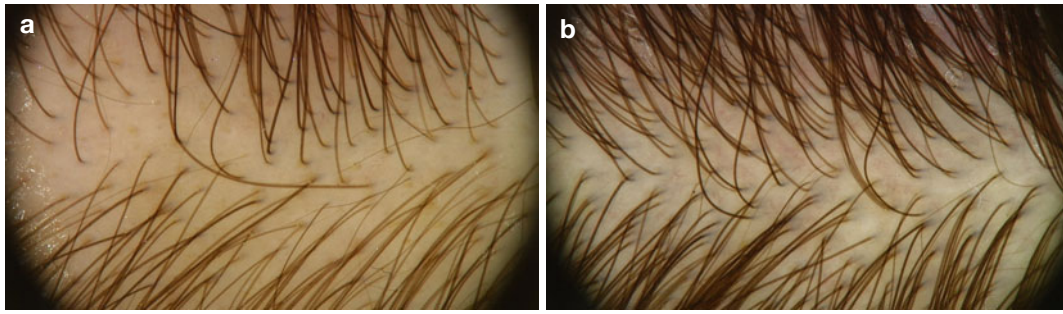

Fig. 120.3 Dermoscopy of the scalp in androgenetic alopecia: comparison of hair density (anterior lower than 20 % (**a**) vs posterior more than 20 % (**b**)) in central part line

- "Empty follicles" are the follicles that have already lost their hair in telogen but have not started to produce a new hair (kenogen stage) yet, as they have an abnormal hair cycle.
- Loss of follicular ostia is a diagnostic sign of cicatricial alopecia.
- Scalp vessels: dermoscopy permits to distinguish psoriasis and sebopsoriasis from seborrheic dermatitis. In psoriasis and sebopsoriasis, dermoscopy shows tightly coiled capillary loops.
- Hair shafts: the hair shaft abnormalities are easily recognized in vivo at high magnification.

Wash Test

The wash test is a noninvasive procedure, proved to be a reliable and useful tool for monitoring hair shedding. The wash test consists in weekly counting the hair that remains in the sink after washing. Washing must be performed at a distance of 5 days from the last shampooing. The test consists in the washing of the head in the sink with the drain hole covered with gauze and then counting the hair lost. In order to obtain an average of the situation, it is necessary to perform two washes at 15 days from each other (with always a 5-day interval).

Modified Wash Test

The modified wash test is a noninvasive and nonexpensive procedure, which can be employed with confidence in the office. It permits to distinguish telogen effluvium from androgenetic alopecia and patients with both diseases. The modified wash test also provides an estimate of the severity of the three conditions. In telogen effluvium the shed hairs are increased in number, but longer than 3 cm (hair with the tip of hair not previously cut) hairs; instead in the case of androgenetic alopecia, the hair count includes a prevalence of vellus and intermediate hairs, shorter than 3 cm. The test reveals the presence of both patterns when telogen effluvium and androgenetic alopecia occur. This technique allows the dermatologist to decide which condition is actually prevalent and which should be treated first.

The modified wash test is based on the wash test technique, added by the observation of the type of hair. In this simple way, it is possible to do a differential diagnosis between telogen effluvium and androgenetic alopecia.

Histology

Scalp biopsy is indicated in all cases of suspected cicatricial alopecia, in diffuse hair loss diseases, and in all cases of diagnostic doubts. When performing a skin biopsy in hair diseases, the choice of the place plays a key role. It depends on the disease involved and on the stage of the disease itself: an active inflammation area with hair follicles is better. A wrong choice may not be diagnostic and also requires the repetition of the biopsy.

The scalp biopsy requires a punch of 4 mm, which scans an area of 12.6 mm^2; the 4 mm piece

Table 120.1 Evaluation of hair's diseases

<table>

</table>

LAH loose anagen hair, *LAHS* loose anagen hair syndrome

is then divided longitudinally into two identical parts: one for the vertical sections and the other for the horizontal ones.

Whiting studied the normal parameters of a healthy scalp, studied with a 4 mm punch biopsy:

1. Terminal hairs: 33; 2 in telogen (6 % with a range between 0 and 15 %), 31 in anagen, and 0 in catagen
2. Telogen terminal units: 5
3. Vellus hair: 5
4. Follicular count: 38 (range 19–59)
5. Follicular unit: 1/mm^2 that is made up of about 12 2/5 terminal hairs and 0/2 level hair, similar to each other in size and number
6. Anagen/telogen ratio: 85 %:15 %

The best way to do a diagnosis of hair diseases is presented in Table 120.1.

After collecting a good personal history, the physician approaches the patient with the scalp examination. In case of diffuse hair loss, the first step is to look for the presence of widening of the central hair line; if it is positive, it's possible to suspect androgenetic alopecia and perform a videodermoscopy that observes more than 20 % variability in the hair shaft diameter. This confirms the diagnosis.

If there is the absence of widening of the central part, it's possible to perform a pull test in all the scalp. The pull test is positive when you extract more than six hairs and then observe the roots under the microscope.

In case of dystrophic roots, it's possible to suspect alopecia areata and perform the videodermoscopy in order to observe the activity of the disease. With dermoscopy it's possible to view dystrophic hair, exclamation hair, and black dots during the acute phase and yellow dots in the chronic phase.

In case of telogen roots, the diagnosis can be directed to telogen effluvium but not forgetting alopecia areata incognita, a type of alopecia areata with a diffuse hair loss and not a patchy pattern. In this case videodermoscopy shows diffuse yellow dots, and a scalp biopsy is mandatory to confirm the diagnosis.

Otherwise, when you have a patchy hair loss, you perform a pull test at the patch margin to understand the activity of the disease; in these diseases the hair's extract can be dystrophic in case of alopecia areata or anagen with sheaths in case of a cicatricial alopecia. In this last case, a scalp biopsy is mandatory.

Lasers: Ablative

121

Leonardo G. Marini and Aleksandar L. Krunic

Key Points

- Ablative lasers are, without any doubt, the mainstay of laser technology in dermatologic surgery today.
- A relatively simple, touch-free, highly modulable tissue photothermal vaporization can be generated, either in full-beam or fractional mode with conventional surgical infrared lasers (CS-IRL).
- When performed properly, using the right laser equipment and delivery accessories, setting the appropriate parameters, and last, but not least, selecting the patients to be treated, ablative laser procedures will produce excellent clinical results with few contraindications and low complication rates.

Abbreviations

AFR	Ablative fractional resurfacing
CS-IRL	Conventional surgical infrared lasers
HSP	Heat shock protein
IR	Infrared
MMP	Matrix metalloproteinase
PIH	Postinflammatory hyperpigmentation
PRL	Platelet-rich plasma
QS-IRL	Q-switched infrared lasers
RTD	Residual thermal damage
TRT	Thermal relaxation time

General Principles

Ablative lasers are, without any doubt, the mainstay of laser technology in dermatologic surgery today. A relatively simple, touch-free, highly modulable tissue photothermal vaporization can be generated, either in full-beam or fractional mode with conventional surgical infrared lasers (CS-IRL). This effect is based on the well-known physical process where light energy is absorbed by tissue chromophores resulting in heat formation leading to local temperature increases (Table 121.1). Intraoperative immediate results are clearly visible, and final clinical improvements – after wound healing – are quite predictable. Recently another type of tissue ablation has been introduced focusing on nonthermal photomechanical effects produced by Q-switched infrared lasers (QS-IRL) (Fig. 121.1). Modern laser systems can consistently rely on effective and efficient technical solutions able to facilitate operators in the performance of otherwise complicated surgical procedures, thanks to a better spatial control on degree and extent of tissue

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_121, © Springer-Verlag Berlin Heidelberg 2015

Table 121.1 Terminology used to describe ablative laser effects in biology and medicine

Cold photothermal ablation	Photothermal effects obtained by short pulse (≤1 ms) and relative high fluence on living tissue
Hot photothermal ablation	Photothermal effects obtained by long pulse (≥1 ms) and relative low fluence on living tissue
Photoacoustic nonthermal ablation	Photomechanical effects obtained by extremely short pulse (≤10 ns) and relative high fluence on living tissue
Full-beam ablation	Effects of intact laser beam produced on the surface of living tissue
Fractional beam ablation	Effects of micro-fragmented laser beam produced on the surface of living tissue

injury. Today ablative lasers can be effectively used to rejuvenate skin and mucous tissues through careful modulation of cellular destruction and tissue regeneration (Fig. 121.2), improve scars through precise severing of thick collagen bundles leading to their subsequent qualitative and quantitative regenerative rearrangement (Fig. 121.3), increase transcutaneous penetration of topical actives, precisely eliminate epithelial growth, and finely "sculpt" dermal irregularities (Fig. 121.4). Ablative lasers can be effectively combined with other technologies like radio frequency and different non-ablative light sources besides being integrated with more complex combined treatments as advanced PDT (Fig. 121.5) and regenerative platelet-rich plasma (PRP).

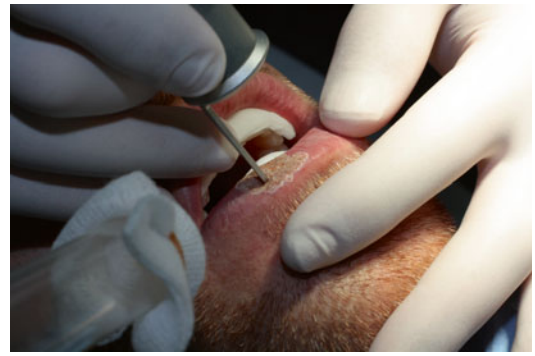

Fig. 121.6 CW CO_2 laser focused beam controlled-speed scanner-assisted ablation

History

The history of laser ablation begins with the birth of laser itself. The discovery of unique light-tissue interaction induced by lasers led to confirm that high-density light energies were able to spatially confine tissue heating resulting in controlled thermal injury, tissue removal, and coagulation. It became immediately evident that the choice of light wavelengths and their specific tissue interactions were fundamental in determining their optical penetration depth and thus their ability to influence the interplay between tissue removal and haemostasis. Throughout the 1960s, a surprisingly rich array of studies appeared in the scientific literature which presaged most modern applications of ablative lasers. The number of studies grew linearly in the 1970s but exploded around 1985 with the reinvigorated diffusion of laser applications in medicine and surgery, as well as in other biological fields, due to the publication of the theory of selective photothermolysis presented by Rox Anderson and John Parrish in 1983. Medical laser companies constantly struggled to provide dermatologists with progressively more sophisticated technologies aiming at efficiently controlling photothermal tissue effects and modulating tissue destructive vaporization and coagulation (Fig. 121.6). The development of short-pulsed, high-energy carbon dioxide laser systems in the 1990s led to the emergence of

Fig. 121.7 Variable pulse modulation 2940nm Er:YAG laser-controlled photothermal ablation

precise laser skin resurfacing, clearly improving clinical outcomes from those induced by previously available continuous and pulsed laser mode (Hobbs et al. 1987). In the same timeframe, the advent of pulse modulation technologies allowed 2,940 nm Er:YAG laser systems to reach an optimal compromise between vaporization and coagulation previously unthinkable for this highly water-selective wavelength

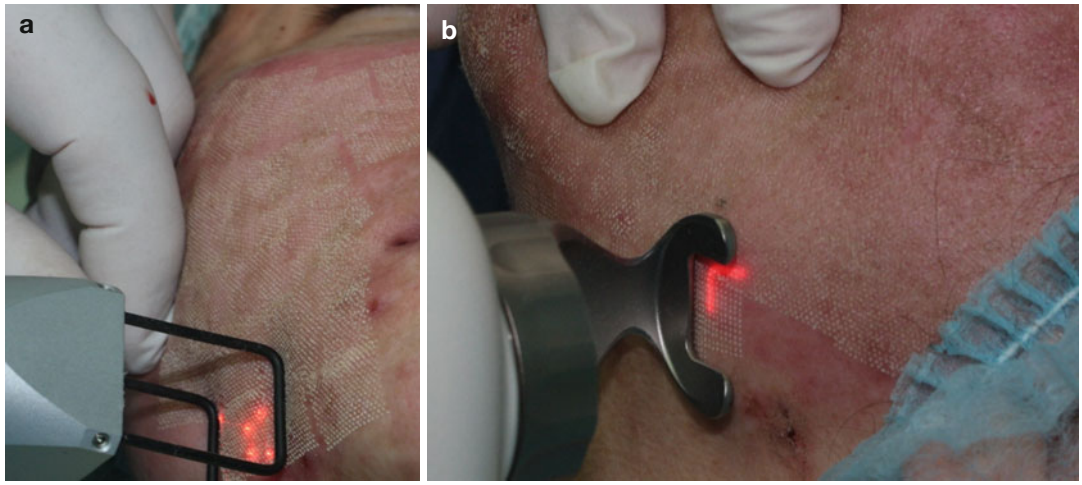

Fig. 121.8 Scanner-assisted ablative fractional remodelling/resurfacing: (**a**) random-pattern CO_2 variable pulse modulation photothermal micro-drilling and (**b**) sequential-pattern Er:YAG variable pulse modulation photothermal micro-drilling

(Fig. 121.7). Pulse modulation was immediately adopted also by CO_2 laser systems improving their biological interactions. Dieter Manstein and the group of Rox Anderson introduced the innovative concept of fractional thermolysis, originally applied to non-ablative lasers in 2003, with the specific aim of decreasing post-operative downtime and side effects produced by ablative full-beam skin resurfacing procedures. This technology, allowing controlled thermal destruction of microcolumns of epidermal and dermal tissue, in regularly spaced arrays over a fraction of skin surfaces, was successfully applied to ablative laser systems in 2007, changing forever the operative approach of ablative skin resurfacing (Fig. 121.8).

Short-pulsed, high peak power QS photoacoustic skin microablation was described by Leon Goldman and co-workers in 1965 after tattoo pigment removal using a 695 nm ruby laser. Randall Lane and Roy Geronemus further described the microablative properties of QS lasers on skin tissues using a 193 nm Ar:fluoride and a Kr:fluoride systems working at 14 ns pulsewidth in 1985. This nonthermal type of ablation has proven effective in skin rejuvenation as well as in controlled destruction of skin alterations such as xanthelasma palpebrarum.

Mechanism of Action

Conventional photothermal ablative lasers are confined within the mid-IR spectral band light emission. Their specific wavelengths are able to be selectively absorbed by water which is ubiquitously distributed within biological tissues. Photothermal effects induced by mid-IR lasers are mostly independent from the presence of other chromophores such as haemoglobin, melanin, and dermal cytochromes. Ablative lasers can be therefore considered virtually colour blinded. As in all kinds of light-tissue interactions, clinical effects are produced only when proper light absorption is guaranteed. Laser radiation generates heat precisely and selectively only where light absorption takes place. At least two processes occur during laser irradiation of biological tissues: the first is a thermodynamic heating process which results in a local temperature rise. The second is a complex chemical process whereby heated proteins reversibly or irreversibly modify their tertiary structure resulting either in biomodulational rearrangements or progressive loss of integrity within involved tissues. The rate of protein functional response is a complicated function of temperature, time, local pressure, and various different environmental parameters. Slow

Table 121.2 Photobiological light-tissue interactions in photomedicine

Photothermal mode	Photothermal effects obtained by short pulse (≤1 ms) and relative high fluence on living tissue (cutting, vaporization, coagulation)
Photobiological mode	Photobiological effects obtained by long pulse (≥1 ms) and relative low fluence on living tissue (photobiological effects)
Photomechanic (elecromechanic) mode	Photomechanical effects obtained by extremely short pulse (≤14 ns) and relative high fluence on living tissue (highly spatially confined nonthermal destruction)

Table 121.3 Sensitivity of tissue proteins to temperature and relative biological consequences

Temperature (°C)	Tissue proteins effects
43–45	Proteins conformational changes – retraction – hyperthermia (slow cell mortality after prolonged exposures)
50	Enzyme activity reduction
60	Protein denaturation – coagulation
80	Collagen denaturation – cell membrane permeabilization
100	Vaporization – ablation
>100	Desiccation – carbonization

heating will cause progressive reversible or irreversible tissue alterations below water boiling point (<100 °C), while rapid heating (>100 °C) immediately destroys tissue within confined microanatomical areas (Table 121.2). Thermally induced structural and functional modifications of human cells start at temperatures as low as approximately 43 °C (Table 121.3).

Ablative lasers are named so since their photothermal effects are evident immediately at their primary impact on biological tissue. Their optical penetration depth is confined to the first water-containing layers encountered by their light beams. Their specific secondary thermal action continues to be produced beyond the primary site of light impact, at its immediate or distant periphery, as long as tissue water is available. Ablative lasers are also known as "surgical lasers" since they are able to cut, photovaporize, and coagulate biological tissues. They can produce different photothermal effects on the skin depending on the particular absorption characteristics peculiar to their specific wavelengths as was clearly demonstrated by Kaufmann in 1994 (Table 121.4). 10,600 nm CO_2 lasers, for example, have a water absorption coefficient of 800 cm^{-1}. With a pulse duration of less than 1 ms and a fluence of 5–7 J/cm^2, its light penetrates approximately 20–30 μm, and peripheral residual thermal damage (RTD) is confined between 100 and 150 μm of peripheral tissue. 2940 nm Er:YAG lasers have a better water absorption coefficient, very close to the peak absorption for this chromophore, which is 16 times than CO_2 lasers. Its penetration depth is limited to 1–3 μm per J/cm^2 of fluence. Its estimated RTD is 10–40 μm. Laser skin ablation typically induces four concentric micro-zones of thermal damage. Starting from the centre, corresponding to the core of laser irradiation, it is possible to recognize an area of missing tissue ablation – maximal thermal effect (1), progressively surrounded by a variable thickness of tissue necrosis – direct protein thermal damage (2), an adjecent micro-zone of coagulation – indirect irreversible protein thermal damage (3), and a peripheral hyperthermia-related photo-thermal biomodulation (4). When ablative fractional photothermolysis is considered, well-defined histologic findings have been clearly documented. Ablative microcolumns are associated with eschar layers confined within corresponding micro-cavities. Annular coagulation zones are evident at their immediate periphery. Re-epithelization occurs rapidly, within 48 h.

Table 121.4 Ablative photothermal lasers commonly used in dermatology

Laser	Wavelength (nm)	Absorption peak of water (nm)
Nd:YAG (Q-switched)	1,064	3,000
Tm:YAG	1,927–2,010	
Ho:YAG	2,100	
Er:YAG	2,790	
Er:YAG	2,940	
CO_2	10,600	

The biological changes occurring during mid-IR laser-tissue interaction can be divided into three phases: (a) direct tissue injury, (b) photothermal biomodulation of perilesional cells due to residual thermal damage (RTD), and (c) inflammatory response.

(a) **Direct tissue injury** – the initial rise of temperature by rapid heating (100 °C), produces an immediate vaporization of intracellular and extracellular water associated with irreversible proteins denaturation within skin layers exposed to laser irradiation.
(b) **Photothermal biomodulation** of perilesional cells is mainly due to RTD insufficient to induce tissue vaporization (43–80 °C). Cellular dehydration induces an upregulation of aquaporins, special channels located within cell membranes to improve water balance, as well as more or less reversible structural modification of proteins.
(c) **Inflammatory response** induces selective release of biologically active cytokines able to initiate and modulate wound healing response within, and immediately around photothermally exposed tissue (increased production of collagen III, heat shock protein HSP70, and alpha smooth muscle actin).

Recently gene expression analysis performed 2 h after CO_2 ablative fractional resurfacing (AFR) has shown threefold upregulation on 38 genes including CYR61, HSP90, aquaporin 3, HSP27, and HSP40, whereas 68 revealed a threefold or more downregulation. The same analysis performed 24 h posttreatment confirmed an upregulation of 53 genes including Wnt5a, matrix metalloproteinase (MMP)-19, and histone deacetylase 7A (Kim et al. 2013).

Given that targeting skin with colour-blinded mid-IR lasers induces a sudden increase of tissue temperature, it is very important to remember that thermal surge starts always at its primary impact site and spreads subsequently to deeper layers. When laser parameters are properly selected, cells and extracellular matrix can be immediately and precisely vaporized. Modulation of laser parameters is crucial to produce different immediate photothermal tissue modifications and delayed thermally induced biological effects. Power density (irradiance: W/cm^2), fluence (J/cm^2), spot size, pulse duration, pulse "shape", and pulse stacking are extremely important parameters to be chosen by operators. Each of them should be precisely tailored according to the photothermal and photobiological effects useful to treat different skin alterations located on selected anatomical areas. The main goal of ablative laser treatments is to attain effective clinical results without excessive heat production at the immediate periphery of treated targets. Modern laser dermatology applications are based on the fundamental theory of "selective photothermolysis" originally proposed by Anderson and Parrish in 1983. According to this theory, each biological target has a specific thermal relaxation time (TRT, the time taken for a heated tissue to lose 50 % of absorbed heat through diffusion). Should laser irradiation last longer than target-specific TRT, heat diffusion will be inevitably conducted to surrounding tissue, leading to extended thermal effects and thermally induced biological alterations. Surgical lasers usually operate within continuous and millisecond light emission range. Longer laser exposures lead to tissue desiccation (complete subtraction of biological tissue water) and eventually to carbonization. Short exposures allow precise tissue destruction with controlled thermal effects within peripheral tissues. Lower fluences subtract water from biological tissue without reaching a thermal threshold sufficient to induce vaporization. Higher fluences reach water vaporization threshold immediately. Ablation depth depends on **fluence**; coagulation thickness is related to **pulse duration**. Modulating laser energy and pulse duration influences tissue vaporization efficiency and peripheral coagulation zones thickness, allowing "simulation" of photothermal tissue interactions produced by different IR wavelengths.

Nonthermal QS laser ablation is relatively independent from optical penetration depth of laser wavelengths since it mainly relies on the propagation of photoacoustic waves typically generated by short-pulsed ($\leq$14 ns) lasers within biological tissues. Cellular and extracellular tissue damage is immediate and not associated with any significant "thermal" tale. Penetration of photoacoustic waves is proportional to laser pulse intensity and not to the total energy dose accumulated in residual tissue.

Equipment

Ablative lasers consist of a main laser unit and its accessories: laser case, delivery systems, control panel, electric wires, activation switches, and key (Fig. 121.9) (Table 121.5). Further laser-independent accessories consist of a properly filtered smoke evacuator and primary eye and respiratory individual protections. Laser beams can travel a long distance and can be reflected by polished surfaces; therefore, laser rooms and surgical tools should be designed to prevent inadvertent photothermal effects on biological tissue different from the ones being treated. Laser room access should be restricted to authorized staff

Fig. 121.9 Operational control panel of a modern laser system

Table 121.5 Ablative laser accessories

Laser accessories	Specifications	Ergonomic/functional efficiency
Laser case	Wheeled container hosting laser unit and its primary accessories	Compact, highly movable, sturdy, smooth angle frame, handy positioning of electric switches and key, easily cleanable
Delivery systems 1	Articulated arm	Sturdy, highly movable, weight balanced, effortless return to resting position, smooth hand-piece change operation, position as close as possible to operating area, easily cleanable
Delivery systems 2	Full-beam hand-pieces and spacers – focused or collimated	Sturdy, smooth hand operational, non-slip surface, easily cleanable
Delivery systems 3	Fractional beam hand-pieces (focused or collimated), pixel or stamping mode or true fractional mode	Sturdy, smooth hand operational, non-slip surface, easily cleanable
Delivery systems 4	Full-beam scanners	Sturdy, smooth angle frame, built-in digital controls, easily cleanable
Delivery systems 5	Fractional beam scanners	Sturdy, smooth angle frame, built-in digital controls, easily cleanable
Control panel	Full function or hybrid touch screen to interact with laser unit	Sturdy; easily accessible operation; standardized colour-coded operational settings, acoustic warning, and operational signals; position as close as possible to operating area; easily cleanable
Electric wires	Wires connecting laser case to electric sockets	Built-in plug-socket securing system to avoid accidental interruption of electric supply during operation, relatively long, colour coded, easily cleanable
Activation switches 1	Primary and secondary operational switches, built-in laser case	Easily accessible, colour coded, smooth operation
Activation switches 2	Foot pedal activation of operational laser emission	Remote control (wire independent)
Activation key	Laser system activation	Easily accessible, colour coded

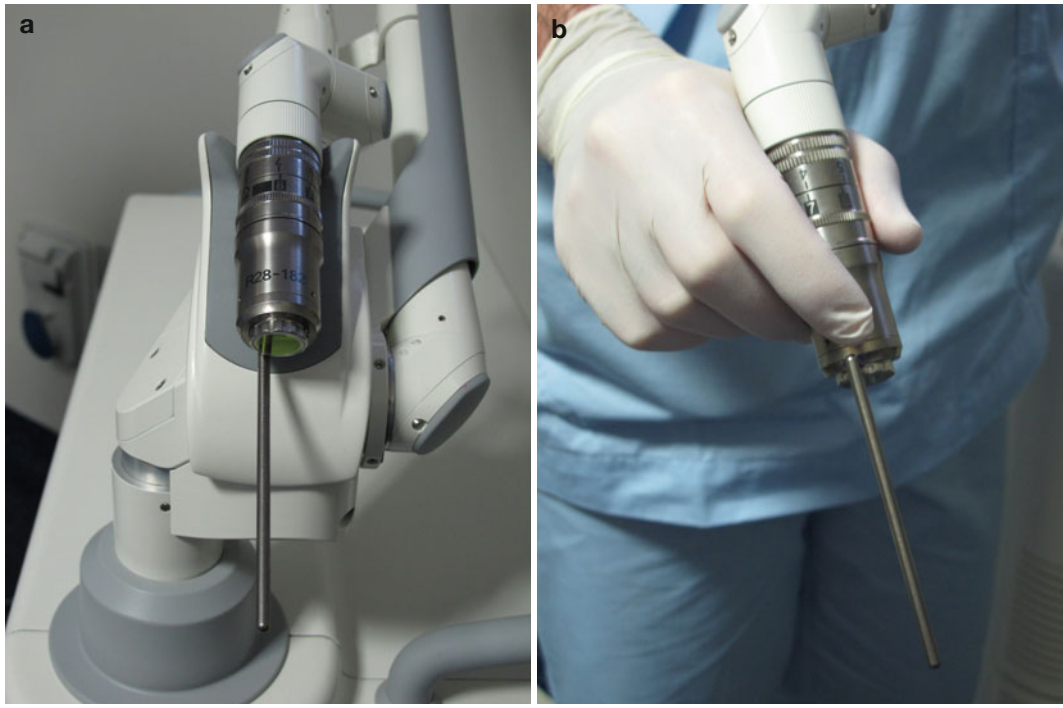

Fig. 121.10 Free-hand ergonomic hand-piece of a Q-switched laser system: (**a**) hand-piece in its protected resting position with articulated arm at rest and (**b**) hand-piece perfectly adapting to surgeon's hand

only, and warning signs should be placed outside the entrance door. Controlled door locking systems should be activated during laser operation in order to avoid unauthorized access to laser room without proper primary eye and respiratory individual protections.

Choosing the right accessories when performing ablative laser surgery is very similar to choosing proper surgical instruments when planning to perform an invasive procedure. Anatomical location, type, and extension of surgical procedures imply specific selection of scalpel shapes and sizes, as well as all necessary instruments to fulfil all operating requirements. Ablative laser accessories should be selected according to the same general requirements. Well-designed, ergonomic, relatively small focused beam hand-pieces should be chosen for precise photothermal cutting and small spot full-beam photovaporization. Collimated beam hand-pieces should be chosen when planning relatively large full-beam resurfacing to be performed on complex anatomical areas. The choice of fractional beam hand-pieces should follow the same criteria. Full-beam (Fig. 121.9) and fractional beam scanners (Fig. 121.10) should be used when large anatomical areas are to be treated (Fig. 121.11).

Techniques

The choice of primary photothermal and secondary bio-thermal thermal actions induced by conventional ablative lasers depends on the size and depth of lesions to be treated, as well as on specific tissue characteristics related to anatomical locations. Mid-IR lasers can be used either in full-beam mode (all irradiated surface is thermally affected) or in fractional beam mode (partial irradiated surface is thermally treated). Photothermal and thermal tissue interaction varies according to pulse shape (energy distribution during ablation time), total energy delivered per pulse (mJ/pulse – J/cm^2 irradiation dose), pulse

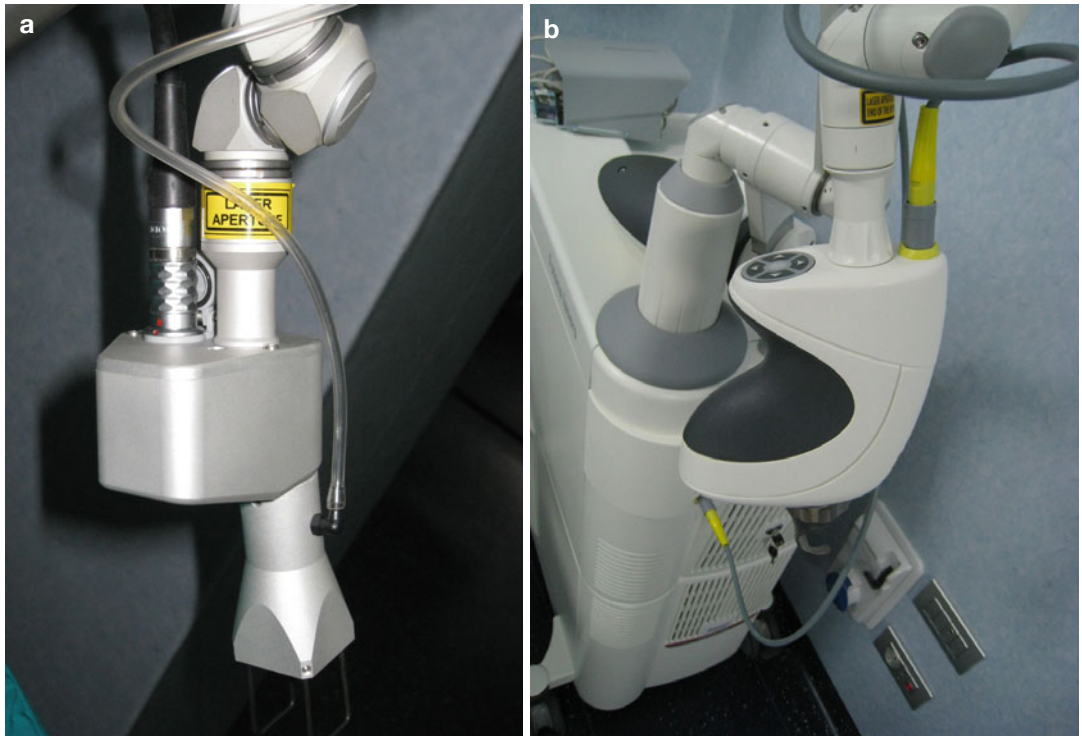

Fig. 121.11 Examples of ablative fractional laser scanners: (**a**) CO_2 laser scanner and (**b**) Er:YAG laser scanner

duration or action time, pulse diameter, pulse density (percentage of laser spot overlapping in full-beam mode or micro-spot spacing in fractional mode), pulse stacking, pulse layering, and sequential or random spot/micro-spot delivery. Full-beam mode was the first option available to operators and can be used either in a continuous emission (CW) or pulsed emission (chopped pulse, superpulse, ultrapulse, variable pulse) allowing variable degrees of thermal control on irradiated tissue. Full-beam delivery is usually performed free-hand and can be used according to a micro-focused mode (Gaussian energy distribution with maximum concentration of laser irradiation on the centre of laser spots – useful for cutting and vaporization resurfacing of small areas), variable spot size collimated mode (square pulse energy distribution evenly covering full laser spot surfaces – useful for full-beam resurfacing of variably sized anatomical areas) (Fig. 121.12), and defocused mode (diluted laser

Fig. 121.12 Full-beam random-pattern, variable pulse modulation Er:YAG laser-controlled photothermal resurfacing

irradiation insufficient to induce vaporization, useful for tissue coagulation). Fractional beam delivery can be technically divided in two beam-splitting modes: (*a*) pixel or stamping mode and (*b*) true focused fractional mode. In the first case, laser beams are split by metal grids located along their paths within specific surgical hand-pieces – resulting microdots carry just a fractional part of the pulse energy selected on the control panel. True fractional mode implies the generation of complex sequences of focused microdots, each carrying the same energy selected on the control panel. When scanners are used, different photothermal effects can be achieved with proper selections of scanning sequences of microdots. Higher localized temperatures can be reached when uninterrupted sequential linear patterns are selected, while more gentle heating can be produced when interrupted, random-pattern microdot sequences are chosen. Maximum localized thermal effects are achieved when laser beams are directed perpendicularly to the skin surface, while variable thermal effects are produced when angling laser beams at different degrees. This simple manoeuvre can be quite useful in producing "feathering" effects to avoid demarcation lines in complex anatomical areas. Partially overlapping, full-beam spots can avoid skip areas when planning a full, conventional resurfacing, while stacking fractional microdots allows to reach deeper ablation depths – particularly useful in complex scar remodelling procedures. Anatomical tissue thickness variations should be taken into proper account when selecting ablative parameters, particularly when working on the face. Combinations of fractional and full-beam laser modes can be used either sequentially, according to more or less complex laser layering techniques, or fragmentally, according to different photothermal clinical end results planned for specific patients (mosaic resurfacing). Sequential combinations of photothermal ablative fractional resurfacing and Q-switched photoacoustic destruction have been successfully used in advanced tattoo removal procedures (Fig. 121.13). Q-switched photoacoustic ablation can be achieved according to both full-beam and fractional mode (Fig. 121.14). Due to the extremely high energies delivered by Q-switched laser systems, a flat-top beam, which allows an almost uniform laser energy distribution over the entire spot area, is highly recommended.

Fig. 121.13 Er:YAG ablative fractional resurfacing immediately performed before Q-switched photoacoustic destruction of tattoo pigments – note the transepidermal escape of photoacoustic-induced tissue vapour on Er:YAG laser treated side (*left*) compared to vapour "entrapment" in pure Q-switched laser treated side (*right*)

Clinical Applications

Most benign and superficial precancerous and cancerous lesions can be treated successfully with any of the several treatment modalities available to modern dermatologic surgery (excision, cryosurgery, electro-assisted destruction and curettage, dermabrasion, chemical peels). The choice depends on many different factors including aesthetic and economical considerations and including patients' specific attitude to accept or refuse specific treatment modalities. In any case patients should be informed about all treatment options and should be allowed to choose from the reasonable alternatives. Ablative lasers, even if more expensive and technically demanding, have specific advantages over other treatment modalities. Touch-free laser treatments allow to reach any anatomical area of the body, including the most delicate. Precise "deposition" of laser energy allows to finely modulate surgical ablation providing excellent visual control of surgical field. The risk of infection depends on the size and

Hypotrophic scars	Fractional beam ablation	Scanner assisted
Keloids[d]	Fractional beam ablation	Scanner assisted
Topical drug delivery	Fractional beam ablation	Scanner assisted
Enhanced PDT	Fractional beam ablation	Scanner assisted
Enhancer PRP	Fractional beam ablation	Scanner assisted
Tattoo pigment removal[e]	Fractional beam ablation	Scanner assisted
Facial rejuvenation	Fractional/full-beam ablation	Free-hand/scanner assisted
Surgical incisions	Full-beam ablation	Free-hand linear

[a]Preliminary shave biopsy and histological analysis are advised for nevomelanocytic and not clear-cut clinical diagnosis
[b]Preliminary shave biopsy and histological analysis are always advised – associated curettage is advised
[c]Preliminary biopsy and histological analysis are always advised – associated curettage is advised (older patients, superficial lesions)
[d]Adjuvant topical or intralesional pharmacologic treatment usually associated
[e]Indicated for allergic reaction to tattoo pigment or ablative "priming" before Q-S laser photo-ablation (Ibrahimi et al. 2011; Marini and Crisman 2013)

site of treated areas; post-operative wound care is reasonably simple. Proper clinical diagnosis and lesion selection are as critical as the choice of laser parameters and light delivery systems in producing a favourable outcome. Considering that each patient is different and each lesion is unique, there are many variations to the so-called "standard" treatment protocols (Table 121.6).

Both conventional surgical infrared lasers (CS-IRL) and Q-switched infrared lasers (QS-IRL) trigger dermal nociceptors, inducing a pain response during ablative procedures. Proper topical and locoregional anaesthesia should be

Table 121.7 Stabilized Kligman's formula

Hydroquinone 5 g
Retinoic acid 0.1 g
Dexamethasone 0.125 g
Stabilizing excipient 100 g (vit. C 20 g)

performed before every ablative laser procedures in order to provide a comfortable experience for both patients and operators. Topical skin antisepsis should be performed without alcohol-based solutions in order to avoid possible explosive ignition. Ablative laser procedures can induce activation or deactivation of skin melanocytes; therefore, proper preoperative preparation and post-operative skin care should be implemented, particularly when sun-exposed skin is to be treated. Usually a modified Kligman's formula is prescribed 2 weeks prior to laser procedures (one application every day at bed time), associated with a balanced, high-SPF sunscreen during daytime (Table 121.7). The same formula is resumed 1 week post-treatment and continued for two more months. Darker skin types (Fitzpatrick 3–4) are at major risk for postinflammatory hyperpigmentation (PIH); therefore, it is strongly advisable to use class 1 topical steroids during the first 4–5 days after ablative laser procedures. Steroids should be continued according to a personalized pulsed regimen to be continued following a pulsed regimen usually (one application, two consecutive night per week) during the subsequent 2–4 months.

Complications, Side Effects, and Contraindications

Contraindications

The relatively few contraindications to ablative laser procedures are generally related to concomitant pharmacological regimes and selected skin alterations which may delay or jeopardize wound healing (Table 121.8).

Complications and Side Effects

Common complications and side effects of ablative laser procedures are listed in Table 121.8.

Table 121.8 Contraindications to ablative laser surgery

Absolute contraindications	Relative contraindications
Oral isotretinoin treatment	Pregnancy
Impaired vascular supply	Anticoagulant use
Agammaglobulinemia	Blistering disorders
Active bacterial/viral infection	Dark skin (Fitzpatrick 5–6)
Immunosuppression	Diabetes
Unexplained blood dyscrasia	Melasma

Table 121.9 Complications of ablative laser surgery

Complication type	Adverse effects
Immediate	Bleeding, edema, pain, vasovagal syncope
Delayed	Prolonged erythema, infection, altered sensation
Temporary	Postinflammatory hyperpigmentation (PIH), milia, acne reactivation, textural changes
Permanent	Hypopigmentation, demarcation lines, textural changes, and hypertrophic scarring

Moderate skin discomfort, generally a hot, burning sensation, occurs immediately after ablative laser procedures. Intensity varies according to extension and anatomical location of laser treatments. The most sensitive areas are the face, genitalia, and digital extremities. Postinflammatory hyperpigmentation (PIH) is quite common but improves within several months with proper topical treatments. Postinflammatory hypopigmentation is rare and maybe sometimes permanent. Textural changes associated with hypertrophic or hypotrophic scarring may occur after too aggressive ablative treatments. Reactivation of herpetic infections may be triggered by ablative procedures. Proper antiviral prophylaxis can effectively control this kind of complications (Table 121.9).

Conclusions

When performed properly, using the right laser equipment and delivery accessories, setting the appropriate parameters, and last, but not least, selecting the patients to be treated, ablative laser procedures will producing

excellent clinical results with few contraindications and low complication rates. Constant technical innovations surely contributed to expand the use of ablative lasers in modern dermatologic practice including procedures never thought before. Enhanced topical drug delivery, enhanced PDT, advanced tattoo pigment removal, and hypertrophic scar remodelling are just some of them. The future of ablative lasers is quite bright, and dermatology will certainly be at the forefront of its further developments.

Mohs' Surgery

122

António Picoto, Jose Manuel Labareda,
Rui Themido, and Fernanda Coelho

Key Points

- Micrographic surgery is a method where a skin tumour is excised in horizontal successive layers followed by immediate preparation of frozen sections for histological examination.
- For the treatment of skin cancer, Mohs' micrographic surgery is currently the method that achieves the best cure rate.
- Preservation of healthy tissues is another great advantage of this method.
- Mohs' surgery is not indicated for multicentric tumours, patients unable to follow post-operative rules and cope with local anaesthesia and cases with bone invasion or invasion of natural cavities of the human body.

General Principles

Mohs' micrographic surgery was created in 1930 by Dr. Frederic Mohs, a North American surgeon working on his thesis in Madison, Wisconsin. He found that if a paste of zinc chloride was applied to tumours in vivo, for 24 h he would have a slice of "controlled" necrosis. "Controlled" because after separation of the necrotic tissue with a scalpel, histological slides could be prepared because the typical architecture was preserved. This method involved successive in vivo fixation followed by a deeper horizontal layer being taken from the patient each time. The fixation in vivo was painful for the patient and in certain locations could not be used because of the risk involved. If used on the eyelids, a spillage of the paste onto the eyeball could lead to serious lesions of the cornea. Therefore when treating the eyelids, Mohs did not use the paste but made the excisions similarly in horizontal succession under local anaesthesia. Then he made the histological preparations using a cryostat to obtain frozen cuts. He realized that this "fresh tissue technique" enabled him to reach the tumour-free plane much faster so that immediate surgical reconstruction was possible. He published his preliminary results in the book *Skin Surgery* edited by Epstein in 1956.

In 1970, Dr. Tromovitch showed his results with the "fresh tissue technique" applied to the treatment of tumours in different locations other than the eyelids in a Meeting of the American College of Chemosurgery. Dr. Tromovitch and Dr. Stegman promoted the diffusion of this technique that became widely used.

Another important step in the dissemination of this therapeutic modality for the treatment of skin cancer was the initiation by Professor Perry Robins in New York of the first 1-year chemosurgery education programme in the USA.

In 1990, the authors and other European doctors founded in Estoril (Portugal) the European Society for Micrographic Surgery. This Society gets together Mohs' surgeons from Europe and Israel and tries to make the method familiar to European doctors. In a so-called millennium paper, Brodland et al. (2000) write about the American history and evolution of Mohs' micrographic surgery.

Technique

Mohs' micrographic surgery is a method where a skin tumour is excised in horizontal successive layers followed by the immediate preparation of frozen sections for histological examination. Because a thin and horizontal piece of tissue is controlled, the bottom and lateral borders are controlled, and theoretically if the tumour persists, it will show in the histological slides. Simultaneously a map is drawn where the division of the tissue is marked and the anatomical orientation is indicated. At each stage, the tissue provided by the surgeon's excision, with the scalpel held at approximately 45° in relation to the skin plane, is divided into pieces preferably not more than 1 cm in diameter. The pieces are marked on faces opposing the skin edge with ink markers, normally black and green or red. Each stage is repeated until a plane free of tumour is reached. After that, immediate reconstruction can be done (Figs. 122.1, 122.2 and 122.3).

Because there are many methods for controlling skin tumour excision, the American College of Mohs' Micrographic Surgery and Cutaneous Oncology published a "position paper" where the principles are very clearly stated. The uniqueness of the method and base of its excellency is the horizontal control of the tissue with all its margins included – lateral and bottom.

The mapping should be accurate and we use xerocopies of anatomical drawings and measure exactly the pieces of tissue extracted so that we can exactly situate the tumour nests that we find after microscopic examination. Joseph Alcalay described a very interesting way to do the mapping with extreme accuracy. He has called it digital computerized mapping in Mohs' micrographic surgery.

The pieces of tissue are embedded in OCT compound and cut in a cryostat. It is very important that the first or second cut is obtained in perfect condition; otherwise, we will be marching towards the surface and abandoning the real margins.

The cryostat should be able to keep a low temperature (between −26 and −30 °C), and the cutting blade should be very sharp – preferably using a disposable blade. After cutting the tissue, we move to the staining of the frozen sections. The most common method is haematoxylin and eosin (H & E) or toluidine blue. Recently a variation has been described using haematoxylin and safranin instead of H & E

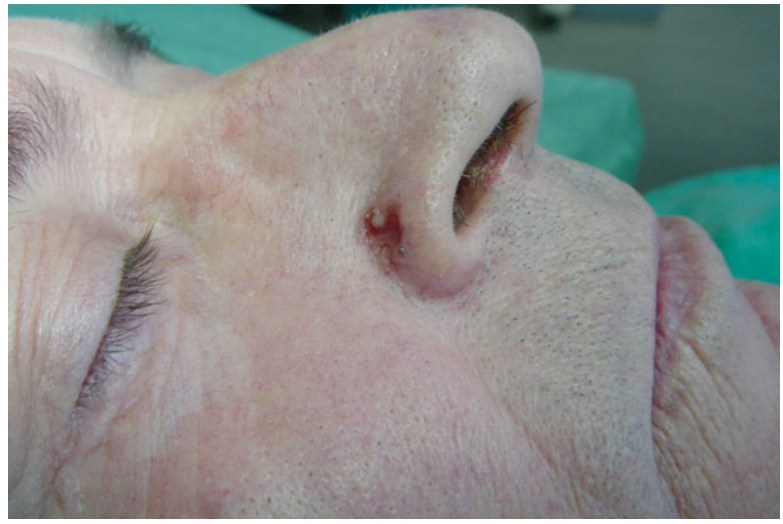

Fig. 122.1 A recurrent basal cell carcinoma

Fig. 122.2 The defect after Mohs' surgery

Fig. 122.3 Reconstruction done

apparently with superior results in basal cell carcinoma (BCC) and squamous cell carcinoma (SCC).

In the last years, much investigation has been done on the use of special stains that could help detect tumour cells of difficult tumours among dense infiltrates or around nerves. One can use either immunohistochemical techniques as described by Jimenez et al. and Ramnarain et al. or immunoperoxidase techniques as described by Mondragon et al.

Indications for Mohs' Micrographic Surgery

For the treatment of skin cancer, Mohs' micrographic surgery is currently the method that achieves the best cure rate. Another advantage to consider is the preservation of healthy tissue because in Mohs' micrographic surgery, there is no "blind" margin of security. This can be of great value for the reconstruction of defects on the face, extremities and genitals.

Mohs' micrographic surgery is indicated for basal cell carcinomas and squamous cell carcinomas:

- That are recurrent
- That are more than 2 cm in diameter
- With histologically demonstrated perineural invasion
- With poorly defined borders
- That are persistent after previous surgery
- That are located near the orifices of the face, ears, scalp, extremities and genitals
- That are invasive histological types
- In immunocompromised host
- To check and ensure if excision was complete

Other cutaneous tumours:

- Bowen's disease and erythroplasia of Queyrat
- Dermatofibrosarcoma protuberans
- Merkel carcinoma
- Atypical fibroxanthoma
- Other uncommon tumours (microcystic adnexal carcinoma, sebaceous gland carcinoma, extramammary Paget's disease, angiosarcoma, malignant fibrous histiocytoma)

Some indications are debatable, in particular melanoma. In the case of melanoma, a complete excision block is the only sound basis for good histological examination as it is so important for establishing what further treatment and follow-up guidelines are required and to determine the prognosis. Difficulty in distinguishing melanoma cells from benign melanocytes in frozen sections was overcome with melanoma immunostaining techniques, namely, HMB-45, Mart-1 and Melan-A. Mohs' surgery may be useful for melanomas in areas where it is necessary to conserve tissue, namely, the head, neck and extremities.

The drawback is the increase in expense and time needed in between Mohs' stages.

It is also important to know what should not be referred for Mohs' micrographic surgery:

- Multicentric tumours
- Patients unable to follow the post-operative rules and to cope with the local anaesthetic in successive stages – cooperation of the patient in this is essential
- Patients with bone invasion or invasion of natural cavities

Conclusions

Mohs' micrographic surgery is a specific surgical method for the treatment of aggressive skin cancers and so far achieves the best cure rates with maximum spared tissue of all therapeutic modalities.

It is not an expensive method – the cryostat is the only expensive tool and most dermatology services have their own cryostat or easy access to one in general pathology. Proper training and appropriate referral of patients are essential elements for excellent performance; cooperation with other medical specialists is desirable.

Mohs' micrographic surgery should only be used when necessary, and recent studies have found that the referral rate for the treatment of nonmelanoma skin cancer will be approximately 20 % of all cases seen in a clinic.

In some rare cases, Mohs' surgery can be incomplete, either because the cancer has proved to be unresectable or the patient has been unable to tolerate further surgery. In a study published by Madaniet al. (2000), this happened only in 14 out of 10,346 procedures (0.15 %).

Asgari et al. (2009) compared patient short-term and long-term satisfaction before and after treatment of skin cancer with other therapeutic modalities and Mohs' micrographic surgery.

Patients treated with Mohs' surgery are more satisfied in the long term compared to patients submitted to other treatments.

Mycological Examination

123

Laura Atzori, Monica Pau, and Nicola Aste

Key Points

- Mycoses are diseases caused by fungi, present in the soil, air, contaminated food, animals, and humans. Fungi are classified according to the microscopy appearance and by the method of reproduction in culture. Therefore, laboratory testing is necessary to confirm the diagnosis in all conditions.
- Superficial localized infection can be diagnosed rapidly by taking fresh unstained material (skin, nails, hairs) to be examined by *direct microscopy* after potassium hydroxide (KOH) clarification. This procedure is usually rapid and easy to handle even in general practice, if provided with a light microscopy.
- *Fungal culture* is necessary to identify the fungus and to confirm the vitality of the strain. When a local or systemic antifungal treatment is performed, culture is necessary to assess effective recovery or current infection. It requires specific training and great expertise, reserved to specialized mycology laboratories.
- False-negative results are possible; therefore, *biopsy and histology* are indicated if direct microscopy and culture are negative and clinical suspicion is high.
- *Wood's lamp examination* has very limited indication, detecting the natural luminescence of only few pathogens, mainly *Microsporum spp.*, *Malassezia furfur*, and *Corynebacterium minutissimum*.
- *Molecular techniques*, such as DNA hybridization and PCR, are useful to prompt diagnosis, detecting even small amounts of fungi, but are expensive procedures, limited to the research or reference laboratories for the diagnosis of rare fungal infections, which are difficult or dangerous to cultivate in vitro.
- Great simplification of the fungal identification process is expected from the introduction of the *assay mass spectrometry* in routine laboratory.

DOI 10.1007/978-3-662-45139-7_123,

General Principles

Mycological examination is the diagnostic procedure necessary to confirm a fungal disease, from the Greek word "mykes" meaning mushroom. The mycological test is also necessary to document the complete cure response to treatment, as clinical recovery is often followed by a relapse if the fungus has not been completely eliminated from the skin (mycological cure). The diagnosis of a fungal infection is considered simple from a clinical point of view, but the report of unusual presentations, misdiagnosed or sometimes neglected, has increased worldwide causing extensive and long-standing disease. General immunosuppressive treatment for inflammatory chronic diseases and acquired immune depression syndrome are frequently complicated with fungal superinfections, both from common strain and rare or opportunistic fungal species, such as cryptococcosis, histoplasmosis, sporotrichosis, blastomycosis, and aspergillosis. In the immunocompetent patient, dermatophytes are the main fungal infection, being the primary pathogen. Clinical presentation has also changed with time, from the classic ringworm appearance (tinea) to more veiled eczematous undefined patches, simulating more frequent diseases, such as atopic or contact eczema, seborrheic dermatitis, impetigo, rosacea, and lupus erythematosus. A general common attitude to prescribe combination treatments and/or corticosteroid topics before confirming the diagnosis ("ex adjuvantibus") is one of the possible causes of further dermatophyte pathomorphosis and misdiagnosis, named tinea incognita or tinea atypica.

The etiology of a fungal infection is rapidly proved with laboratory testing and possible in a general office if provided with very basic light microscopy. Besides, few dermatologists and laboratory physicians are trained to recognize dermatophytes. Final identification of the species requires culture facilities and further expertise, which should be referred to a mycology laboratory.

False-negative results are possible, especially if the specimen is not correctly taken, and more invasive assessment should be performed before ruling out the diagnosis of a fungal disease. Biopsy specimens for histopathology examination with PAS or silver staining are indicated when clinical suspicion is high. Sensitivity of culture alone is about 32 %, while histology reaches 85 %, especially in onychomycosis.

A specific fluorescent dye named calcofluor-white might be used, because it binds selectively to the fungal cell wall chitin (apple green fluorescence), but a fluoroscope is necessary.

A molecular approach has been proposed, but the tool is expensive; a plethora of different methods has been proposed without conclusive validation and therefore has never gained much popularity. Direct staining with monoclonal antibody labeled with fluorescent dyes has been proposed to detect rare and small amounts of fungi in the clinical specimens, mainly *Pneumocystis carinii* in bronchoalveolar lavage.

The perspective in clinical mycology laboratories is the fast fungal identification by assay mass spectrometry (matrix-assisted laser desorption ionization time-of-flight (MALDI-TOF) mass spectrometer (MS)) from clinical cultures. Spectral databases (biotype library) of different fungal species have been realized by several independent researchers, and preliminary results confirm the usefulness of the tool, with a sensitivity of 91.9 % on skin isolates, which is hoped to become routine in the immediate future.

Biology and Morphology of the Fungi

Fungal microscopy identification requires an extensive knowledge of fungi biology as a whole, whose principles are magisterially described in the reference book by Grigoriu et al. (1987) and are somewhat synthesized as follows.

Fungi are classified with the lower plants (category, cryptogams; phylum, thallophytes), although devoid of chlorophyll and incapable of photosynthesis, and they are:

- *Heterotrophic*, meaning they subside on organic substances for survival and are unable to directly elaborate mineral elements, such as green plants. They are provided with several

enzyme systems able to digest organic substances (keratin) and to de novo synthesize toxins and antibiotics.
- *Aerobic*, developing at different temperatures varying from one species to another, but usually ranging between 20 and 37 °C, preferring neutral pH and several degrees of humidity, while dryness is poorly tolerated. Direct light exposure has different effects among species, fostering or inhibiting growth.
- *Eukaryotes*, with well-differentiated cytoplasm and nuclei. They consist of a thallus or aerius mycelium, which is a matted network of branching tubes called hyphae, filled with the living substance, continuously expanding with growing tips. The thallus accomplishes both vegetative and reproductive functions: from the central starting point of the colony, the hyphae develop centrifugally in all directions obtaining nourishment from the environment, with the young elements at the periphery and aging dead elements at the center. When the vegetative expanding apparatus has accumulated sufficient nourishment and the environment is favorable, the reproductive phase might take place, which can be either sexual (*perfect fungi*) or asexual. A limited number of fungal species do not have a documented sexual way of reproduction and for this reason are called *imperfect fungi*.

A number of *classifications* have been proposed on the basis of the thallus' different characteristic and sexual reproduction ways, to consent a precise nomenclature and identification, whose simplest ones are illustrated in Table 123.1.

- On the basis of thallium morphology, it is possible to distinguish among septate and not septate fungi. A single cell generates a type of thallus with intercommunicating filaments (hyphae), named coenocytic filaments, without subdivision and therefore called aseptate hyphae. Other thalli are made of septated hyphae, which indicate the presence of regular periodical septal division in the filaments, provided with central pores allowing the passage of nutrients from one segment to the other. Another type of thallus consists of isolated cells, solely and elongated or attached one to the other, forming fragile, eventually branching chains but without intercommunication, therefore called pseudomycelium.
- The principal way of fungal reproduction in pathologic material is asexual, producing a variety of spores (Table 123.2) responsible for fungal dissemination in the environment. The aspect of pathogenic fungi might differ from the parasitic state to the culture optimal saprophytic state. In fact, mycelia fungi do not usually deserve fruiting bodies in the pathologic materials, and species identification is possible only in culture specimens. Yeasts might bud in vivo, while the so-called dimorphic fungi are typically found as yeast cells in pathologic material, producing mycelia filaments in cultures.

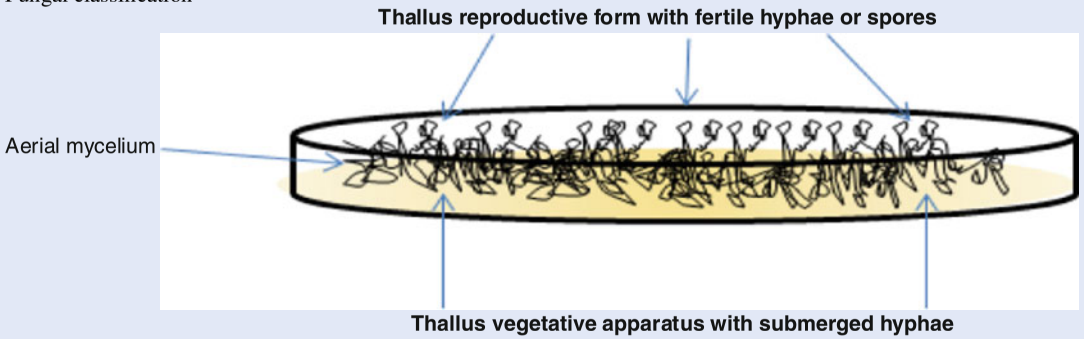
Basic Concepts Related to the Pathogens

From a practical medical point of view, the pathogenic fungi for humans are:
- Dermatophytes (whose mycological diagnosis is extensively treated in this chapter)
- Yeasts and yeastlike fungi (whose laboratory diagnosis requires specialized equipment and expertise, and only basic concepts are expressed in this chapter)
- Some dimorphic and opportunistic fungi, becoming pathogen under peculiar circumstances (whose diagnosis is not developed in this chapter)

Dermatophyte Infections

Dermatophytes are actually classified among the ascomycetes and represent a closely related group of fungi, whose main pathogens for humans are the *Trichophyton*, *Microsporum*, and *Epidermophyton* genera. They are ubiquitous and are characterized by the ability to use keratin as a nutrient source, therefore evolving a dependency on humans and/or animals for the survival and dissemination of their species. They are noninva-

Table 123.1 Fungal classification based on the thallus characteristics and type of sexual reproduction

Fungal classification		Type of sexual reproduction
		


Nonseptate hyphae  The thallus is characterized by continuous filaments, without any septa, forming the coenocytic thallus or coenocytes. The cellular multiple nuclear divisions are not followed by the cytokinesis, resulting in single coordinated unit composed of multiple cells linked structurally and functionally	Zygomycetes 	The name comes from the type of sexual reproduction, taking place in a specialized organ named zygosporangia, forming resistant spherical spores. They live in soil, on decaying plant, or on animal material

Septate hyphae  The thallus is characterized by regular interruption of the filaments (hyphae), called septate provided with central pores allowing the passage of nutrients from one segment to the other	Ascomycetes 	The sexual reproduction takes place in a specialized ovum structure (ascus), formed by the fusion of a male and female gamete, inside which successive divisions of the zygote produce unicellular endospores (ascospores)
	Basidiomycetes 	Similar sexual reproductive process, but the ovum makes peculiar extrusion towards the external space, called basidiospores, keeping them attached to the central core by minute arm called sterigmata
	Imperfect fungi	The thallus produces septate hyphae in the vegetative state, but the sexual reproduction modality has never been documented

Table 123.2 Distinctive morphological characteristics of fungal spores

Arthrospores	Formed by septated hyphae fragmentation, at the tip of the filaments, maintaining a rectangular shape	
Blastospores	Budding cells, the bud separating from the parent cell or keeping the linkage for a certain time and yet continue budding to produce extensive branching (pseudomycelia)	Chlamydospores	Swollen portion of the hypha or pseudohypha, with a very thick double wall (intercalary or terminal), which ensures resistance to many adverse conditions	
Aleuriospores	Lateral budding of the hypha, disposed like a Cross of Lorraine or bunches, which remains attached to the hypha axis	
Microconidia	They are identical to aleuriospores but are deciduous and detach from the hypha immediately after their formation	Macroconidia or fuseaux	Very voluminous and elongated septated budding, with the same significance of microconidia	Dictyospores	Multicellular digitiform or globular elements	

sive, as they colonize the keratinized stratum corneum, which is a nonliving tissue. However, the presence of the fungus and its metabolic products usually induces an inflammatory eczematous response in the host, counteracting the parasitism. More severe reactions might be related to the species and strain of dermatophyte causing the infection, but also from host predisposing condition, such as skin barrier alterations or previous skin diseases.

- The superficial dermatophyte infections affect the outer layers of the skin, the nails, and hairs. Growing fungi produce typically branched and compartmented septate filaments (hyphae) and arthrospores, which break off from the hyphae at the septate level and represent the main ways of propagation and species conservation. Each segment forms a physiological unit.
- In culture, the characteristic morphology of the reproductive spores (micro- and macroconidia) and accessory features consent species identification.

Guidelines for Proper Specimen Collection in Dermatophyte Infections

Specimen collection is a delicate moment and is the first cause of false-negative results. It should be adapted to the site affected and type of material, including skin scrapings, broken hairs, nail clippings, corneal scraping, and body fluids such blood, CSF, urine, sputum, as well as discharge or pus from lesions.

All specimens must be transported to the laboratory without delay to prevent bacterial overgrowth. Some laboratories suggest refrigeration if a long delay is expected, especially for body fluids and discharged materials, but it is recommended only for a short period.

Skin scales scrapings are best taken from the leading edge of the rash, after the skin has been cleaned with soaks of 0.9 % saline solution to remove cream residuals. Disinfection with alcohol or ether is often advocated but is not necessary and might remove the upper scales which are the most infested. Gently remove the surface skin using a blade or curette and place the material in a sterile container or a black paper envelope (Fig. 123.1).

Hairs should be gently pulled out with a pair of tweezers, choosing those broken off at the surface (black dots) or few millimeters from the follicle, discolored and lusterless, surrounded by a whitish sheath, or covered by scales (Fig. 123.1). Parasitized hairs are removed easily and painless. A toothbrush can be used to collect scales from the infected scalp.

Nail clippings are usually taken from the ventral surface scaly deposits, using a blunt curette or a blade. If the nail plate is widely detached and full of debris, the distal end should be cut with a pair of scissors and discarded to find the fresh infected nail. Depending on the site of involvement, the lateral and/or proximal surface of the nail plate should also be scraped (Fig. 123.2).

Examination by Direct Microscopy

The most common and first step laboratory examination is to examine fresh unstained materials (*native preparation*), such as scales, hairs, and nails. Part of the material is placed on a clean slide and eventually split to very fine dust with the aid of a blade. Body fluids, content of vesicles, and pustules can be also directly placed on the smear. Keratinized material and cell walls are opaque at microscopy, and some chemical solutions (Table 123.3) must be added to dissolve keratinocytes and make the material transparent, a process that is called "clearing." Certain laboratories add glycerin to delay the preparation drying out and have more time to perform the slide lecture. One or two drops of the clearing agent is put on the collected material on the slide and then covered with a cover slip (Fig. 123.1). The most used clearing solution is potassium hydroxide (KOH) in 10–40 % concentrations. It is very cheap and stable on light and does not

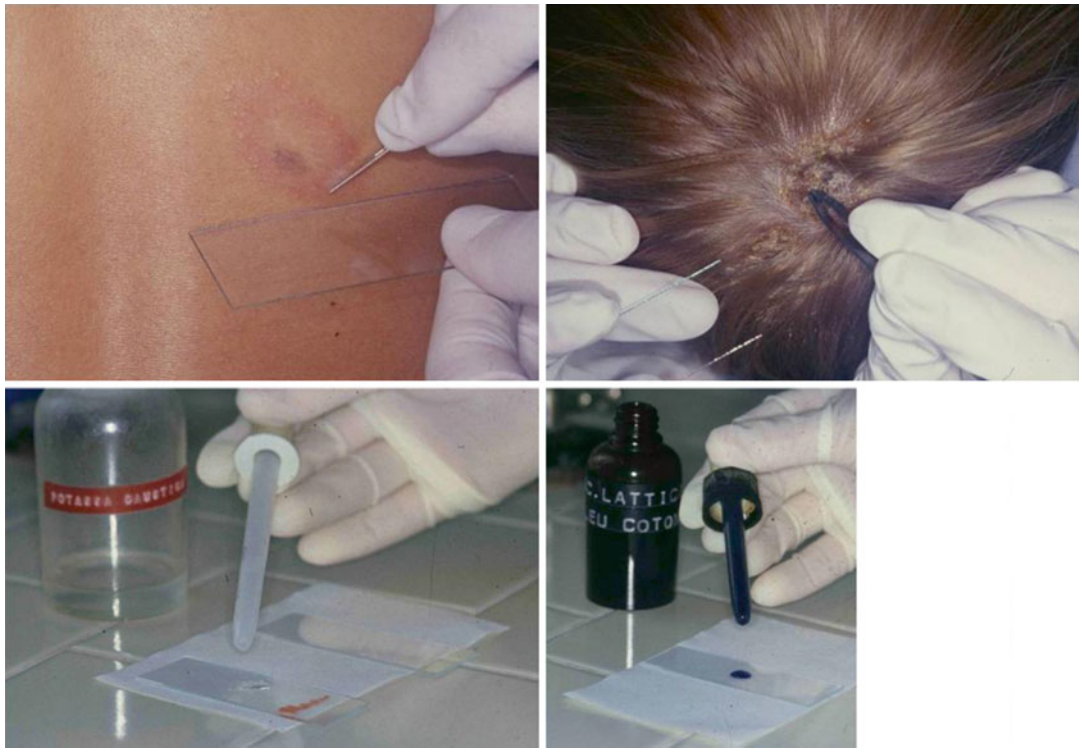

Fig. 123.1 Correct execution of the scales sample from the active borders of an erythematous scaling round-shaped lesion (*top-left* inset); correct execution of the hair sample from discolored and few millimeter broken-off hairs plucked with a pair of eyebrow tweezers (*top-right* inset). The native preparation is put on a smear and a drop of a clearing solution is added (*down-left* inset); staining with blue or black ink preparations might be useful to highlight hyphae and arthrospores or yeasts presence (*downright* inset)

need particular conservation or caution, and the preparation is rapidly ready. Time to clearing depends on the material type and thickness, the hairs being rapidly destroyed by KOH and therefore examined in 20 min, 1 h at most; the skin scales usually are examined within 3 h, while the nails are more resistant, sometimes requiring 24 h and addition of new clearing solution or physiologic solution, because one of the major disadvantages with KOH is precipitation and formation of crystals. Additional staining with methylene blue, Parker blue, or black ink do not replace direct examination (Fig. 123.1), but it is sometimes useful to highlight the chitin in the fungal cell walls. Fixation and staining with lactophenol cotton blue (LPCB) is preferred to observe yeasts, fungal accessories, and fruiting structures, especially from culture specimen.

The microscopic examination is first performed under a low-power lens (100×) run carefully along the slide to find fields of interests (Fig. 123.3). Once the fungus is detected, the high-power lens (200 or 400x) observation allows for true hyphae confirmation and distinction from pseudohyphae, as well as arthrospores selection from yeasts.

Fungal elements are sometimes difficult to find, and a negative result does not rule out fungal infection. Microscopy should be repeated, possibly with fresh material or giving more time to clearing and repeating the observation with great perseverance.

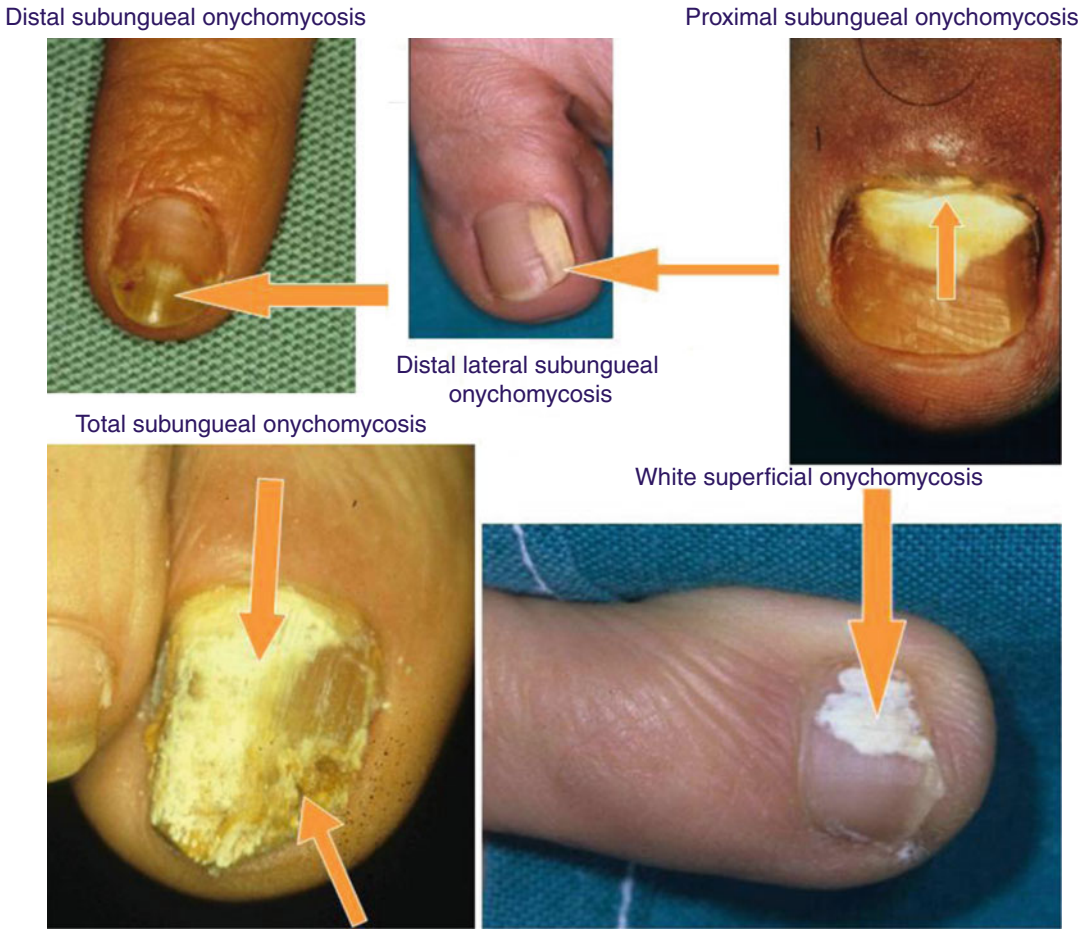

Fig. 123.2 Correct site of sampling depending on the clinical form of onychomycosis

Table 123.3 Clearing solutions for direct microscopic examination

Chemical solution	Preparation
KOH	Potassium hydroxide 10–40 % concentration
Amann's chlorallactophenol	Equal parts of chloral hydrate + lactic acid + phenol
Sodium sulfide	10 % sodium sulfide in a solution made of ¾ distilled water and ¼ 80 % alcohol
Sodium lauryl sulfate	5 % in distilled water

Direct Microscopic Examination Pitfalls

Specific training is necessary to avoid the many possible sources of errors in mycology, as in any other laboratory procedure.

- Mistakes in sample collection: insufficient material, inadequate site of sampling, and contamination.
- Insufficient clearing and hasty observation yield most false-negative results.
- Artifacts (Fig. 123.4): the mycelia filaments and arthrospores have to be distinguished from:
  - Fungus mosaics: a network made of refractive small filaments or crystals, irregular in shape and diameter, whose chain arrangement is very similar to the mycelia and might mislead a nonexpert investigator. They are cell debris containing cholesterol crystals due to a reaction of the intercellular substance with potassium hydroxide. Usually the mosaics are located at the limits of the cells and disappear if a drop of

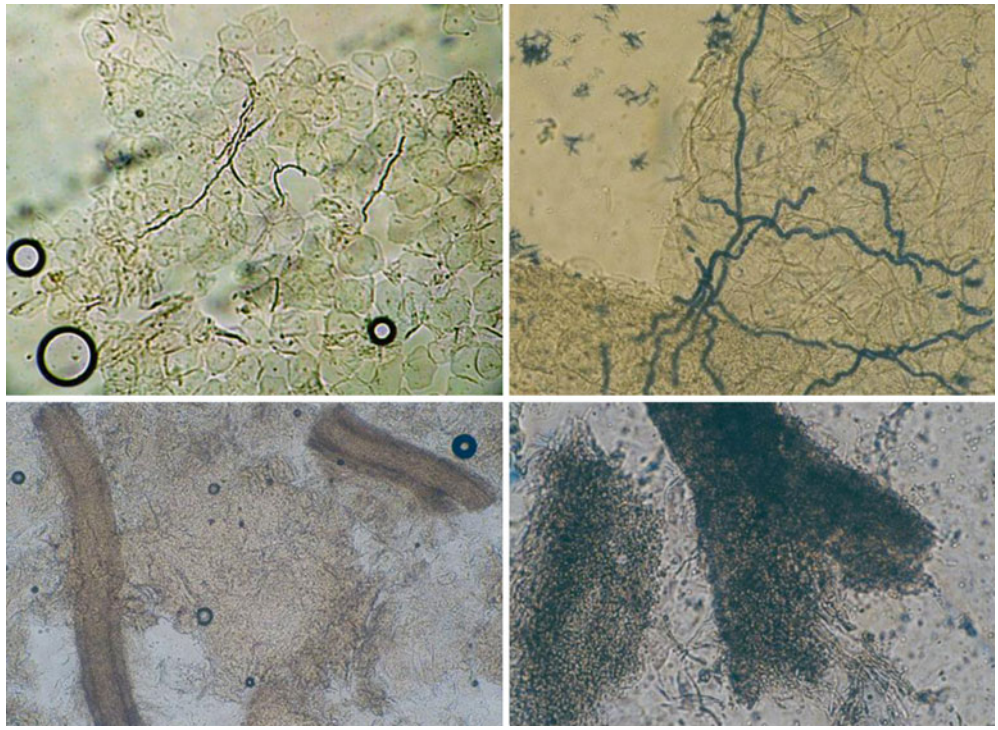

Fig. 123.3 Skin scraping: under low-power light microscopy, selection of a field of interest (*top-left* inset; 100×); major definition of hyphae and arthrospores characteristics at higher power observation (*top-right* inset; 400×). Parasitized hairs: sheath of arthrospores surrounding the hair shaft in an ectothrix arrangement and hyphae presence in the scales (*bottom-left* inset; 100×); hyphae and arthrospores inside the hair root and shaft in endothrix parasitism (*bottom-right* inset; 400×)

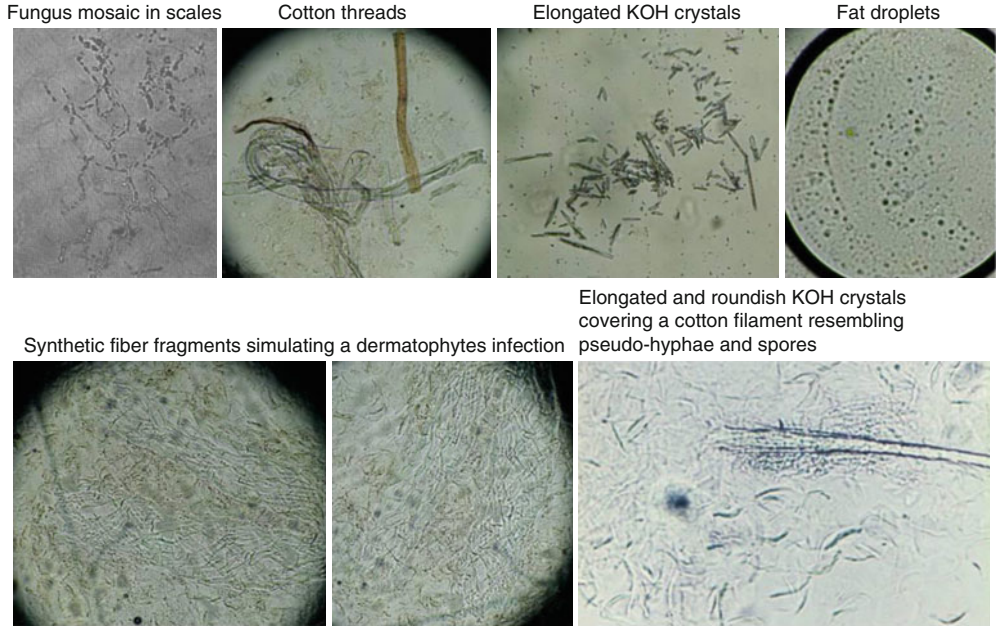

Fig. 123.4 Microscopic examination artifacts

glycerol or physiologic solution is added to the preparation. The higher-power observation (100×) enables the distinction from the fungal hyphae, which are regular in caliber and shape, septated, connected together continuously.
  - Cotton threads, other vegetal filaments and fur brittles, which are usually woven or twisted on their axis and irregular in caliber, tufted at the extremities.
  - Polyhedral or elongated crystals: refractive bodies differing in appearance one from the other and not connected together. It is the dehydrated clearing agent that usually causes this artifact, and a drop of distilled water added directly to the smear makes them to disappear.
  - Fat droplets, refractive roundish or oval bodies, enclosed by a double membrane frequently due to the previous use of cosmetic creams, persisting on the skin although disinfected. Cleaning with water and soap before examination is advisable.
- Filamentous bacteria: some *Actinomycetales* bacteria and particularly the *Streptomyces* genus are able to produce a network of branching filaments very similar to the fungal mycelia, but smaller in dimensions (0.5–0.8 μm).

Yeast Infections

Yeasts and yeastlike are a subtype of fungal species characterized by clusters of round or oval cells. They divide and propagate budding out similar cells from their surface. Some yeasts are capable of producing filaments, which remain part of the single original cell, not connected with other elements and called pseudohyphae. They are usually saprophytic, but a pathogenic potential might arise in the presence of several favoring conditions. The main yeasts causing human superficial skin infections, whose diagnosis might be confirmed in a general laboratory provided with a light microscopy, are:

- *Candida* species and *Torulopsis glabrata*
- *Malassezia* species

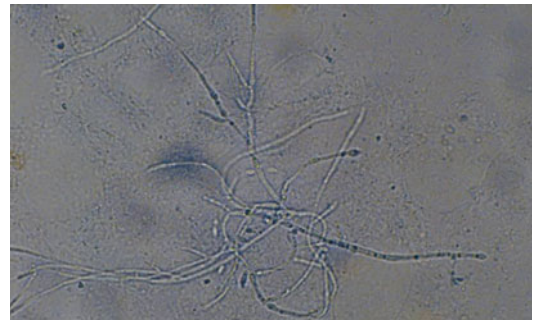

Fig. 123.5 *Candida* yeast cells and pseudohyphae in a groin intertrigo (400×)

Specimen Collection and Examination by Direct Microscopy

Basic concepts and procedures are similar to dermatophyte mycological examination, and only useful additional information for the general practice is addressed in the following paragraphs.

Candida spp. *infection* can be confirmed by swabs and by scrapings. The pathologic material (scales, pustules, white deposits, and secretions) is cleared with KOH between the slide and the cover slip. Urine can be examined without clarification, and blood is seeded directly on the medium for culture. Under the microscope, the presence of pseudohyphae and round, oval yeasts forms might be sufficient to confirm the type of infection (Fig. 123.5), but when dealing with opportunistic infections, culture execution is recommended to confirm pathogenicity instead of simple colonization. Detection of yeasts should be interpreted in close cooperation with clinicians, and equivocal or unusual findings should be verified by repeated laboratory tests. Superinfection of skin lesions in the course of several diseases is very frequent, and *Candida* detection is not sufficient to ascribe its etiologic role. Histology is sometimes necessary to distinguish primary infection from superinfection.

Malassezia spp. *infection* is better documented by stripping off the skin surface with an adhesive tape (scotch test), as the scales are very subtle and superficial. The scotch is then stuck on

a glass slide and examined using potassium hydroxide (KOH), eventually stained with blue or black ink preparation. The abundant presence of the fungal filamentous form budding from the yeast cells in a pattern called "spaghetti with meatballs" is very peculiar and diagnostic (Fig. 123.6).

Fig. 123.6 *S*kin scotch test after KOH + Parker's blue clarification positive for *Malassezia furfur* pseudohyphae and clusters of yeastlike cells (400×)

Fungal Culture

General Principles of the Correct Procedure and Fungal Identification

Culture is necessary to correctly identify most of the fungal species but requires great expertise, and only very specialized laboratories are reliable.

Specimen collection is similar to the previously described technique for direct examination, but sterile materials should be used, because the transferring process of the pathologic samples (scales, hairs, nails) is a delicate moment, at high risk of contamination. Every subsequent passage should be performed under sterile conditions. The specimen must be placed on a sterile plate, subdivided into small particles with the aid of a sterile dissecting needle or a razor blade and collected with a previously flamed platinum loop to be seeded on the culture medium (Fig. 123.7). A distance of about 1 cm should be maintained

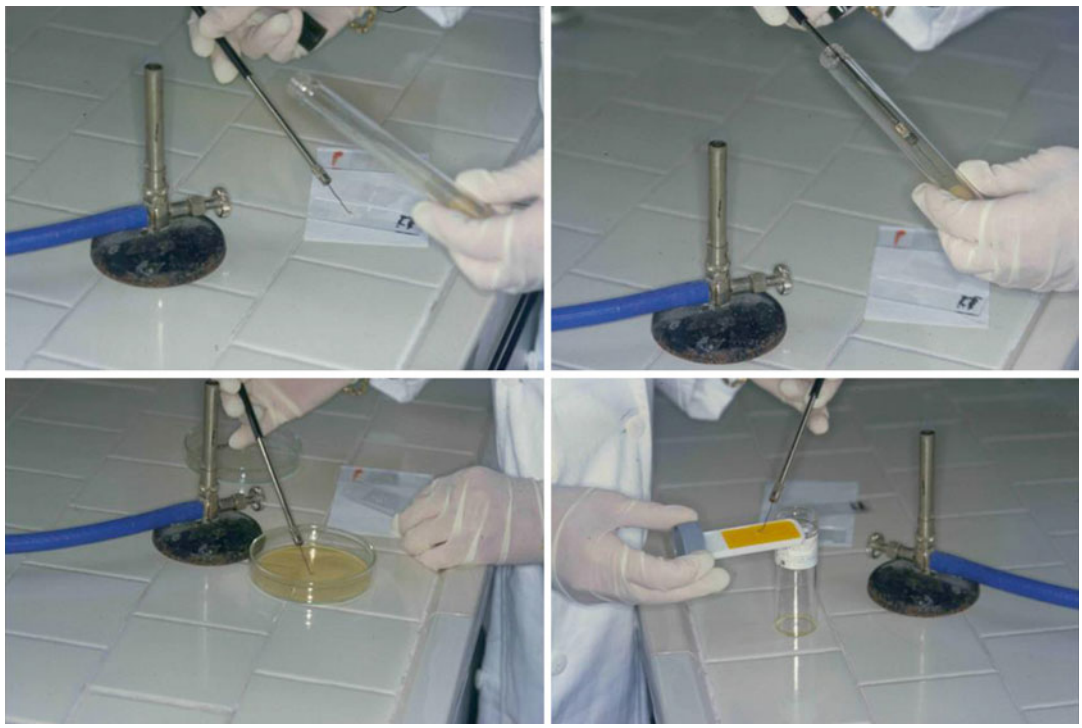

Fig. 123.7 Culture technique: transferring process of the pathologic material on different medium containers

between each inoculum on the medium surface. The test tubes or Petri dishes must be taken from fridge cool to room temperature, and the mouth of the tube or the dish plate must be flamed with a Bunsen burner to sterilize it.

The most commonly used culture medium is Sabouraud's dextrose agar added with cycloheximide and chloramphenicol to avoid mold contamination. Time to colony growth on Sabouraud's agar is a first discrimination of the type of fungus: filamentous fungi grow very slowly, along several weeks (3 weeks or more), incubated at 25–30 °C. Yeasts produce fast growing colonies (24–48 h). A number of other organic and synthetic culture media have been proposed (Table 123.4), whose laboratory preparation has been simplified by the use of prompt dehydrated media, which only need the addition of a fixed amount of distilled water, sterilization, and portioning on test tubes or Petri dishes.

A selective dermatophytes medium (DTM) is available for practitioner's use in the office, which does not require special conservation or care. Dermatophyte growth is indicated from the medium's color change to orange. Unfortunately, this kind of test is expensive and does not allow for subsequent fungal identification.

Table 123.4 Some examples of fungal culture media composition

Medium denomination	Composition	
Agar Sabouraud's medium	Crude glucose	40 g
	Granulated peptone	10 g
	Agar	20 g
	Tap water	1,000 ml
Emmons' variant	+ chloramphenicol	0.5 g
	+ cycloheximide (actidione)	0.5 g
Sabouraud's liquid medium	Same composition without agar	
Vanbreuseghem's variant	20 % earth + agar + tap water	
Rice medium (to favor dermatophytes fruiting)	Gelose	20 g
	Husked rice	20 g
	Peptone	2 g
	Tap water	1,000 ml
Potato-carrot medium (to favor *Candida albicans* chlamydospores formation)	Chopped potatoes 20 g	
	Chopped carrots 20 g	
	Macerated in 1 l tap water for 1 h; boiled for 5 min, filtered, and added with powdered agar g 20; the whole brought up to 1,000 ml	
Marcelou-Kinti's medium (used for the rapid sugar fermentation test)	Agar	9 g
	Peptone	10 g
	Bromocresol purple	0.04 g
	Chloramphenicol	0.5 g
	Tap water	1,000 ml
	+10 % sodium bicarbonate solution to adjust the pH	
	To this base, several sugars are added in separated 30 % solution: glucose, maltose, raffinose, galactose, lactose, saccharose, trehalose. Each sugar final solution is used to impregnate a disk of blotting paper, placed in hemolysis tubes and finally added with the fungal culture inoculum suspended in physiological solution. After 24–48-h incubation, the fermented tubes have discolored medium	
Lodder's medium (to study the assimilation of sugar and nitrogen)	Potassium dihydrogen phosphate	1 g
	Magnesium sulfate	0.5 g
	Ammonium sulfate	5 g
	Agar	20 g
	Distilled water	1,000 ml

Once the colonies have grown, identification relies on both gross and microscopic features. Colony morphology and growth dynamics may vary considerably with the culture medium used (type of glucose, peptone, pH) and other conditions such as the degree of humidity and temperature. It is therefore essential to maintain constant conditions in the laboratory and to use the same components for the media preparation. Well-established and reference features are based on Sabouraud's medium, and it is advisable to always perform at least one culture on that medium when other culture media are used.

Candida species cannot be identified either by direct microscopy or by culture macro- and microscopic features. The final species determination relies on the germ tube tests (rapid production of chlamydospores) and on sugar fermentation and assimilation tests, as well as nitrogen utilization (Table 123.5).

Candida strains resistant to antifungals have been detected (35–39); therefore, the antifungal susceptibility test should be performed, especially in nosocomial settings and in immunocompromised patients.

Culture of *Malassezia species* is not easy to obtain and usually not necessary. The Sabouraud's agar medium is added with a layer of olive oil to favor *Malassezia* caramel-colored colonies growth.

Gross Morphology Examination

The colony morphology examination has a relative value, because gross features are changeable and similar to related fungi (Figs. 123.8 and 123.9). Observation includes the reverse side of the tubes or Petri dishes, because some features may differ greatly.

Surface of the colony: convex or flat; elevated with a central button, convoluted with regular folds or vermiculate, with radial branching.

Aspect of the colony: plaster-like or waxy, glabrous or wooly, granular, dusty, creamy.

Color: grayish or creamy, orange, red, purple, pink, cafè au lait, dark brown, black, dark or olive green. The pigmentation density usually varies as it diffuses in the medium and might greatly change on the reverse side of the colony.

Consistency: soft and friable or so hard that it is difficult to detach with the platinum loop.

Culture Microscopic Examination

Once the gross morphology observation is completed, a specimen of the culture is taken with a platinum loop and put on a slide, cleared with one or two drops of KOH or stained with lactophenol cotton blue, which stains the fungal elements in blue, and covered with a cover slip.

The first step of the culture microscopic examination is to reveal if the specimen contains hyphal fungi (septate or not septate) or yeasts (pseudohyphae, budding cells). In the case of yeasts, it is not usually possible to complete identification under the microscope, and therefore a switch to other techniques is necessary, as previously mentioned (implantation on selective medium, sugar fermentation and assimilation test, nitrogen utilization).

The *second step* is the detailed description of the mycelia elements configurations (Tables 123.6 and 123.7). Some hyphae are very straight, others sinuous, slender, or thick, with periodical enlargement of single enchained elements and/or swelling at the tips of the filaments. These specialized, ornamental or accessory structures, arising from a single cell modification into a thick-walled resting cell, with a very peculiar morphology aid in species identification: spiral and racquet hyphae are commonly seen in *Trichophyton mentagrophytes*; pectinate body occurs in *Microsporum audouinii*; chandelier hyphae occur in *Trichophyton schoenleinii* and *Trichophyton violaceum* infections, and nodular organ characterize *Trichophyton mentagrophytes* and *Microsporum canis*.

Although suggestive, the accessory structures are changeable, and the most important elements to note are the presence of fruiting bodies (spores, chlamydospores, asci, aleuriospores, etc.). In the case of dermatophytes, the micro- and macroconidia configurations, arrangement, and shape make identification certain. Additional biochemical tests

Table 123.5 Additional tests to discriminate the main pathogen *Candida species*

	Fermentation test (zymogram)						Assimilation test (auxanogram)

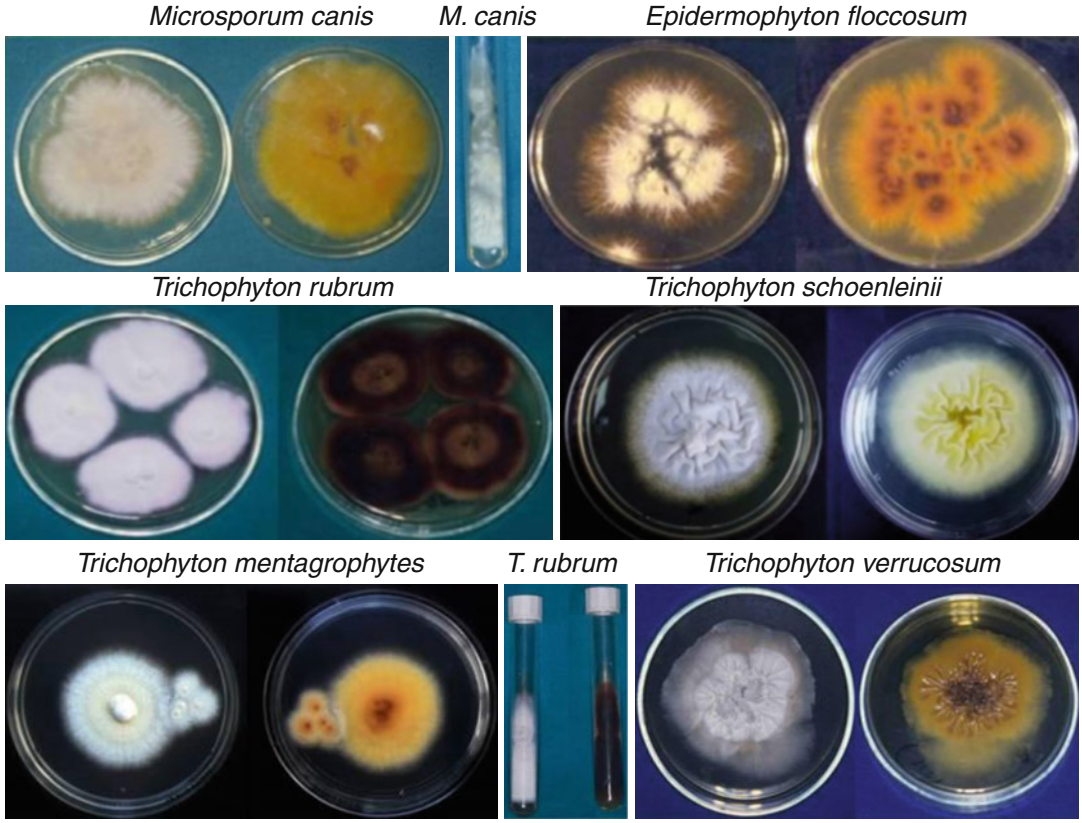

Fig. 123.8 Gross morphology of *dermatophyte* colonies

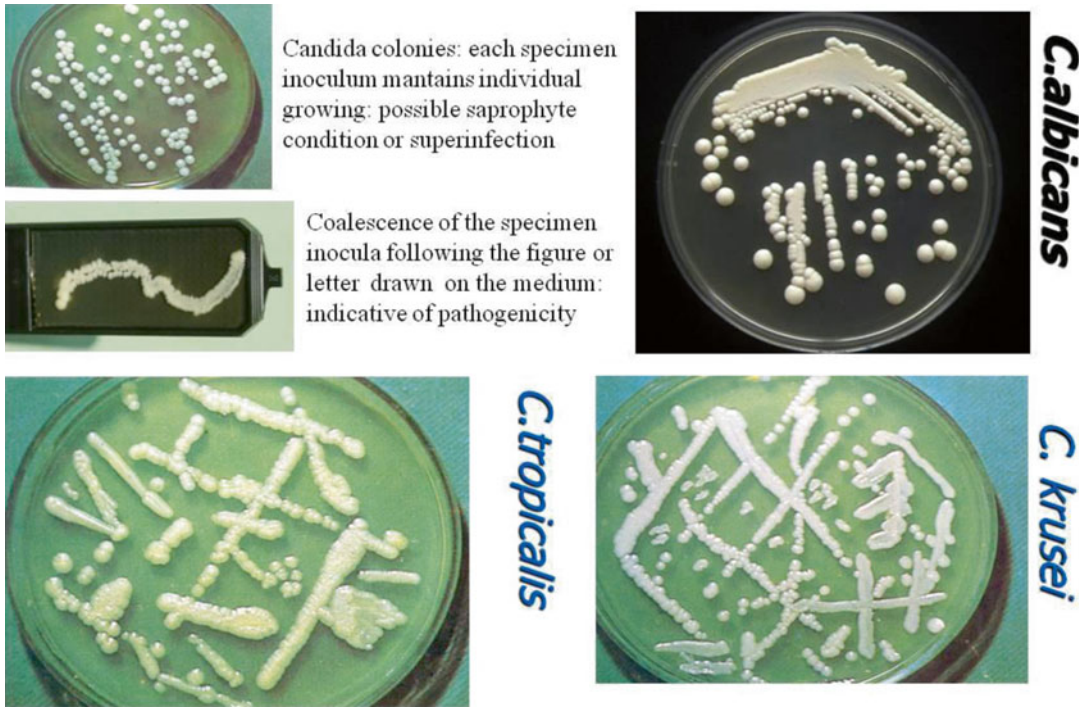

Fig. 123.9 Gross morphology of *Candida* colonies on Sabouraud's agar

Table 123.6 Some examples of the main dermatophyte species characteristics on culture identification process

Dermatophyte	Culture morphology	Accessory structures and fruiting bodies
Microsporum canis (zoophilic fungus)	Colonies grow at moderate rates and are cottony or wooly with whitish center and lemon-yellow pigment at the periphery; radial grooves may also be present. The reverse is lemon-yellow, becoming yellow-brown with age	Few pyriform microconidia; numerous large macroconidia with thick rough walls, spiky, boat-like septate (navicular) with more than 6 cells (multilocular) 
Microsporum gypseum (geophilic fungus)	Colonies grow moderately rapidly with dusty granular to sugar texture, whitish surface darkening to cinnamon brown, especially on the reverse	Macroconidia are more numerous than *M. canis*, but ellipse-like shaped, less spiky with rounded tips, and fewer cells Microsporum audouinii (anthropophilic fungus)	Colonies grow at moderate rates and are gray-white, flat, or velvety, with a characteristic light pink to brown reverse	Usually no microconidia are present, but the presence of pectinate hyphae and terminal chlamydospores suggests the identification. Macroconidia are fusiform, beaked, and septated, with irregular intervals
Trichophyton mentagrophytes (zoophilic fungus)	Colony grow slowly, with variable appearance, usually white-creamy with a shielded center and dusty periphery; the reverse may be tan-brown, yellow, or red similar to *T. rubrum*	Numerous round or pyriform microconidia arranged in grape-like clusters, presence of spiral hyphae. Macroconidia are cylindrical and septate

Table 123.6 (continued)

Dermatophyte	Culture morphology	Accessory structures and fruiting bodies
Trichophyton rubrum. (anthropophilic fungus)	Colonies grow slowly; with a convex central surface (like a shield boss or umbo) and dusty periphery; the colonies are white pigmented with a characteristic wine red reverse	Numerous grape-like microconidia and aleuriospores arranged along thick unbranched hyphae; macroconidia are rare, cylindrical or clavate, and multiseptate Trichophyton schoenleinii (anthropophilic fungus)	White shielded surface, with yellow pigment on the reverse	There are no micro- or macroconidia; divergent branching and swellings at the hyphae tips producing chandelier or favus accessory structures are useful for the identification
Trichophyton verrucosum (zoophilic fungus)	Colonies with a velvety convoluted surface, creamy to ochre in tan; the reverse may be colorless or yellow	Hyphae with swollen tips, and symmetrical arthrospores arranged like a string of beads. True pyriform microconidia and rattail macroconidia are rare Trichophyton tonsurans (anthropophilic fungus)	Colonies mature slowly and have variable color, texture, and shape; usually yellow-brown tan	Clavate to elongate microconidia; some are usually swollen and attached to conidiophores by short stalks. Macroconidia are rare
Epidermophyton floccosum (anthropophilic fungus)	Colonies are yellow-khaki or olive green with flat aerial surface conveying a soft leather appearance (suede)	Microconidia are absent; very numerous bunches of clavate or club-shaped macroconidia (banana-like) with 2–6 cells and smooth walls 

Table 123.7 Specialized accessory features help to further distinguish several dermatophyte species

Accessories structure	Morphology	Dermatophyte species
Spiral hyphae: subtle filaments coiled on their axis spirally		*Trichophyton mentagrophytes*
Pectinate body: short, unilateral projections from the hyphae that resemble a broken comb		*Microsporum audouinii*
Favic chandelier: hyphal tips grouped to resemble a chandelier or the antlers of the deer (antler hyphae)		*Trichophyton schoenleinii and Trichophyton violaceum*
Nodular organ: enlargement in the mycelium that consists of closely twisted hyphae		*Trichophyton mentagrophytes and Microsporum canis*
Racquet hyphae: regular enlargement of one end of each segment with the opposing end remaining thin		*Epidermophyton floccosum, Trichophyton mentagrophytes*

may be helpful in distinguishing *T. rubrum* from *T. mentagrophytes*: milk agar medium favors *T. mentagrophytes* growth, while *T. rubrum* is restricted; *T. mentagrophytes* is urease positive while *T. rubrum* is urease negative.

Culture Pitfalls

A negative culture may arise because:

- The condition is not due to fungal infection.
- The specimen was not collected properly, especially as regards sterile procedure and eventual bacterial contamination.
- Antifungal treatment had been used prior to collection of the specimen.
- There was a delay before the specimen reached the laboratory.
- The laboratory procedures were incorrect.
- The organism grows very slowly.

It is advantageous to collect several samples from the patient, to eventually repeat the cultural examination when a fungal infection appears likely, preferably prior to treatment.

Another major problem is false-positive results due to contamination, especially *molds development* in nail specimens. Molds are ubiquitous and their etiologic role in onychomycosis is very controversial. Onychomycosis due to opportunistic fungi, especially *Scopulariopsis brevicaulis*, have no specific clinical features, and simple isolation from the nails is not sufficient to assess infection. As a general rule, the suspected pathogen fungus must be detected at least in three different samples of the pathologic material, obtained from several different sites, plated out on at least three different media, including Sabouraud's agar + actidione.

Other Complementary Examinations in Mycology

Wood's Lamp Examination

This very simple examination introduced in medical mycology in 1925 by Margarot and Devèz is no more very popular in routine use, requiring a source of ultraviolet rays filtered with a 9–10 % nickel salt sheet of glass (366 nm wavelengths allowed to pass). The examination is performed in a dark room and natural luminescence phenomenon is limited to *microsporum species (*green fluorescence*)*, *pityriasis versicolor* (yellow green), and erythrasma (reddish fluorescence). It is otherwise useful to rapidly distinguish the malassezia infection from other skin coloring changes such as vitiligo and to detect tinea capitis during epidemics, especially in schools.

Histological Examination

Biopsy and histological examination does not replace native preparation and usually is unnecessary in superficial fungal infections, but it is sometimes performed to exclude major skin diseases and superinfections, especially if dealing with yeasts. Histological examination allows for primary candidiasis to be distinguished from superinfection, by the presence of a parakeratotic horny layer, stuffed with PAS-positive yeast cells and pseudohyphae.

It is otherwise mandatory to confirm the clinical suspect of rare deep-seated or disseminated fungal diseases, such as actinomycosis, cryptococcosis, histoplasmosis, and other infections. It is also effective to confirm a pathologic role of opportunistic fungi and their relation with the infected tissue. Histology is superior to the other methods in its negative predictive value. The combination of direct microscopy plus histology was 97.8 % sensitive with 98 % negative predictive value and remains the most sensitive diagnostic approach for onychomycosis.

The specific request must be clearly indicated to the pathologist, because simple hematoxylin-eosin stains give more information on the tissue reaction pattern than on the fungal presence and require a very careful examination. It rarely enables a more precise diagnosis than simple mycosis and the fungus cannot be identified as a rule. The most used stains are Hotchkiss-McManus stain (Periodic Acid Schiff reagent, PAS) in all conditions, May-Grunwald-Giemsa and Gram stain to visualize very fine Gram-positive filaments (actinomycosis, nocardiosis), and methenamine silver nitrate staining by Gomori's method, which is particularly useful to fungal membrane detection.

Electron Microscopy

The extensive use of both transmission and scanning electron microscopy is devoted to research on the morphology and physiology of the various pathogenic fungi. It does not play a role in diagnostic procedures.

Future Perspectives

Mycology is sometimes considered an obsolete assessment, because clinical diagnosis is usually simple and antifungal treatment highly efficacious. Laboratory exam has relied on direct examination for such a long time that interest on research and implementation has been limited for decades. The sensibility of the traditional mycological examinations is not very high and conditioned from the investigator's expertise. The diagnostic error accounts for about 30 % of the cases. Therefore, last decade's research has devoted a certain interest to faster, more sensitive, and culture-independent techniques. The molecular biology techniques, especially the *polymerase chain reaction (PCR)* and *in situ hybridization* for fungal identification, are highly sensitive but expensive and require complex post-amplification procedures to differentiate relevant fungal types. At the moment, research is limited to deep-seated and disseminated fungal infections (blood infections, drug-resistant *Candida* and *Aspergillus* species) or to severe special site infections (fungal keratitis). Preliminary data using real-time polymerase chain reaction high-resolution melting analysis (PCR-HRM) suggest the capacity to detect and differentiate yeasts from filamentous fungi and to discriminate among relevant species of yeasts.

Current limitation of the molecular assays is the lack of methodological standardization and validation, with continuous new method proposals whose results interpretation are not always clear and reproducible.

New impulse to collect samples and make correct fungal identification arises from the *assay mass spectrophotometry*, which seems to be a cost-effective rapid tool and will probably be largely adopted as routine laboratory determination in an immediate future.

Wide consensus and validation from large prospective studies are necessary to allow widespread adoption of these assays into the clinical setting, but the basic approach with direct microscopy remains the clue to the diagnosis of superficial skin fungal infections.

Patch Testing

124

Anna Tagka and Alexandra Katsarou

Key Points

- Patch testing is a well-established practical method to diagnose and evaluate allergic contact dermatitis. The main indication is persistent eczema.
- The International Contact Dermatitis Research Group (ICDRG) contributed to the standardization of patch testing procedures and methodology.
- These guidelines include recommendations for the test systems, the site, the technique of patch testing, the concentration of allergens and vehicles.
- The method includes the application of a certain antigen in standard concentration under occlusion. We usually prefer the upper back and white petrolatum as a vehicle.
- It is necessary to give special instructions concerning to medication and activities of the patient in order to perform patch testing.
- The procedure to evaluate the relevance between the reaction to the specific allergen and the present case of eczema is usually the most difficult and interesting part.

General Principles

Josef Jadassohn (1895) is considered as the first scientist who established the procedure of patch testing. He first reported a patient suffering from an eczematous reaction to mercury. Bruno Bloch later followed and expanded the clinical and experimental work of Jadassohn.

Patch testing is now a well-established practical in vivo method to diagnose and evaluate allergic contact dermatitis. According to Gell and Coombs classification, we study a type IV reaction of delayed-type hypersensitivity in patients previously sensitized and presenting clinical signs of contact dermatitis. In the past, because patch test techniques varied, it was difficult to compare results from different dermatology centers. Over the last few decades, much work has been done worldwide, in order to determine the optimal concentration of materials and to standardize allergens, vehicles, tapes, technique, and scoring of reactions. The International Contact Dermatitis Research Group (ICDRG) has set specific guidelines for patch testing that include recommendations for test systems, the test site, the technique of patch testing, the concentration of allergens, the vehicles, the components of a standard test series, and the interpretation of results.

This has greatly facilitated comparisons of patch test reactivity and conclusions about allergic contact dermatitis between centers in different geographic areas.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_124, © Springer-Verlag Berlin Heidelberg 2015

Indications

The patch test provides objective information about contact allergy. Without it, the diagnosis and management of contact dermatitis are based only on clinical criteria. The socioeconomic and medical consequences of contact allergy are so important that proving the presence or absence of allergy is essential. Thus, patch testing is indicated:

1. In patients with a recurring, eczematous, pruritic dermatitis that is clinically diagnosed as contact dermatitis. In these cases, patch testing can:

   Determine the actual allergens among many clinically suspected allergens. Detect relevant, but clinically unsuspected, contact sensitizers. Determine the safety of materials for the patient.
2. In patients with aggravation of other dermatoses, particularly psoriasis, endogenous eczema, or leg ulcers, where superimposed contact dermatitis needs to be excluded
3. As part of a thorough workup in a patient with a puzzling diagnostic problem

Test Systems

Two types of patch tests are used, the original system and the ready-to-use system, where only a covering membrane has to be removed before the test is performed.

Original System

In the original system, the allergens, patches, and tapes are supplied separately.

Allergens

Contact allergens are simple chemical substances with low molecular weights (<1,000 Da). The allergens should be as pure and well defined as possible. According to de Groot, more than 4,350 chemicals are identified as sensitizers. Of these, approximately 300 are commercially available from the various suppliers (Trolab/Hermal, Kurt Herrmann, Chemotechnique Diagnostics AB, Lofarma and others), and the most frequently encountered allergens are included in standard batteries. The present European Standard Series includes 28 substances. The choice of allergens in the standard series is based on the experience of the members of the ICDRG and on the frequency of positive reactions. If the incidence of positive reactions to an allergen falls to less than 1 %, it can be removed from the series. Therefore, the composition of the standard series is not constant.

Several additional series are available for patch testing patients with different medical histories and occupations. Thus, series are available for hairdressing chemicals, metal compounds, cosmetics, medicaments, antimicrobials, preservatives, plants, plastics, glues, and rubber chemicals, for example.

The most commonly used vehicle for allergens is petrolatum, although a few substances are incorporated in water or other vehicles (ethanol, acetone). White petrolatum has good occlusion, keeps the allergens stable, and is inexpensive. Commercially available allergens are dispensed in individual syringes. Packaging should protect against air, humidity, mechanical damage, and radiation. In general, test allergens should be kept in the refrigerator to minimize degradation.

The Patches

Commercially available patches have a test area that is circular with a diameter of 8–10 mm. The AL test has been a standard method for patch testing for several years. It consists of a filter paper disk of cellulose (10 mm) attached to a strip of plastic-coated aluminum foil and is available in rolls. The Finn Chambers is the most widely used method, and it employs 8 mm aluminum and polypropylene cups is an alternative option.

Large firm chambers (12 mm) may be useful for the detection of weak responses and are usually recommended for experimental studies.

The Tape

The modern polyacrylate-based adhesive tape (Scanpor) eliminates irritant and allergic reactions.

Concentrations

In textbooks of patch testing and suppliers' catalogues, the concentration of an allergen is given as a percentage. In TRUE test concentration is given in milligrams or micrograms per square centimeter.

Ready-to-Use Systems

The TRUE test is a system in which a measured amount of allergen is included in a gel printed on a polyester patch of 9×9 mm. These patches, containing different allergens, are mounted on acrylate tape covered with a siliconized protection sheet and packed in an airtight, light-impermeable envelope. Epiquick is another ready-to- use patch test system that consists of Finn Chambers, on Scanpor tape, that contain allergens of the standard series in petrolatum.

The advantages of these systems are the constant volume of allergen in the chamber, uniformity in materials and procedure, and savings in test performance time. However, the cost is higher. Ready-to-use systems are especially recommended for use in children.

Test Sites

The midportion of the upper back is the site of patch test application. The skin must be hairless and normal. If even a trace of dermatitis is present on the test site, the patient should not be tested at that time, in order to avoid false-positive reactions. If the skin is not hairless, shaving should be done with an electric razor in order to avoid abrasion, soap, and shaving cream. In certain instances, the upper, outer arm can be used to isolate a test allergen when a strong positive reaction is expected, as, for example, with nickel.

False-negative results can be observed on the lower back or on the volar arms.

Technique of Patch Testing

Patch tests should be applied to the upper back on intact skin, without prior use of alcohol or soap. The amount of test material used is an important point. Twelve to fifteen microliter of test material, or slightly more than half of the chamber area (for Finn chambers), should be applied. For materials in solution, it is sufficient to place one drop onto the filter paper disk, and this should be done a few minutes before applying the test in order to avoid evaporation. The physician or technician that is handling the allergen-filled syringes must wear a protective glove to prevent contact allergy.

The tape strips are applied from below with slight pressure so as to remove air bubbles and obtain uniform and complete contact. In cases of oily or hairy skin, sweating, or high humidity, the ends of the strips require additional tape.

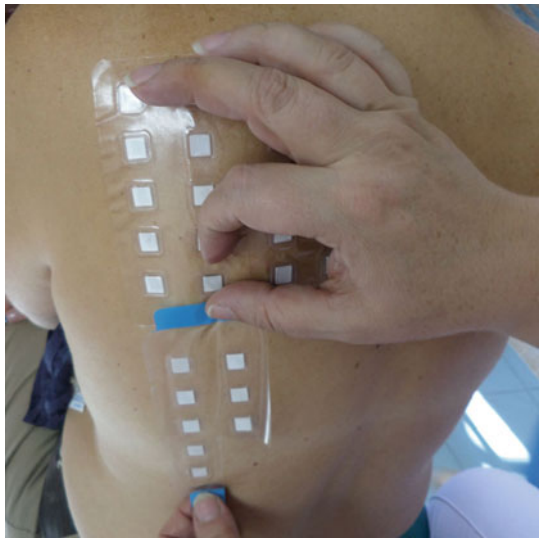
The type of series and representative (i.e., top) numbers of the set should be labeled on the tape. Before removing the patch tests, it is important to mark the skin outlining the test area using a water-resistant marking pen that will not stain clothing (Figs. 124.1 and 124.2).

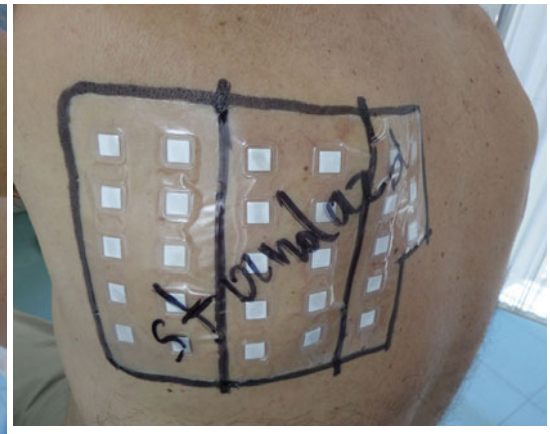
Instructions for the Patient

There is special recommendation to avoid washing the upper back and scratching the area.

It is inconvenient for the patient exposing to heat, the outside activities, and sports.

We strongly recommend avoiding systemic treatment that interferes or topical treatment, especially used on the upper back. Patients must be given written instructions to keep the patches dry, to diminish work activity, to avoid vigorous exercise, and to fix any area that becomes loose with additional tape. If excessive itching





Figs. 124.1 and 124.2 Application of patch test (standard series) usually on the upper back

or burning occurs at a certain area, the patch may be carefully removed, but all other patches should be left in place to be removed at 48 h.

Baseline and Additional Series in Patch Testing

There are four proposals concerning the baseline series in patch testing:

- The updated 2011 European baseline series from the European Society of Contact Dermatitis (ESCD) and the European Environmental and Contact Dermatitis Research Group (EECDRG)
- The updated 2011–2012 North American baseline series from the North American Contact Dermatitis Research Group (NACDG)
- The updated 2011 Japanese baseline series from the Japanese Society for Contact Dermatitis (JCDS)
- In 1997 the ICDRG (International Contact Dermatitis Research Group) group published a short list with 20 allergens used internationally performing the rule of 1 %. A new revised recent approach was lately published by Alikhan et al. (2011).

These series are in a dynamic status with several additions and removals according to the rules of ICDRG.

We perform the standard series and supplementary available additional series according to the medical history of the patient (Tables 124.1 and 124.2). There are available additional series for hairdressers, chemicals, metal compounds, cosmetics, medicaments, antimicrobials, preservatives, plants, plastics, glues, rubber, and other substances (Table 124.2). We choose the proper additional series on the basis of clinical relevance.

There is a list with chemicals that are not available in commercial lists of allergens and have been collected in de Groot's textbook, which proposes the proper vehicle and concentration of several allergens. It is of great importance to avoid patch testing with unknown products because of adverse effects.

Nickel is the most frequent allergen of baseline series among children and adults, remarkably high in young women.

Table 124.1 Standard series of allergens

	Allergens	ECDRG[a] (%)	NACDG[b] (%)
1.	Potassium dichromate	0.5	0.25
2.	Neomycin sulfate	20	20

Interpretation of Patch Tests

The optimal exposure time is 2 days (48 h). A first reading takes place 30–60 min after the removal of a patch test. At this time, many irritant reactions can be noticed, caused by occlusion and reactions to allergens or tape. If only a single reading at 48 h is performed, 30 % of positive reactions will be missed. Therefore, it is recommended that two readings are performed, the first after the removal of the patches (48 h) and the second 2–4 days later. A positive

Table 124.3 Interpretation of patch test reactions according to the ICDRG (International Contact Dermatitis Research Group)

?+	Doubtful reaction
+	Weak positive reaction, non-vesicular; erythema, infiltration, papules
++	Strong positive reaction; erythema, infiltration, papules, and vesicles
+++	Extreme positive reaction; intense erythema and infiltration, coalescing
–	Negative reaction
IR	Irritant reactions (of different types)
NT	Not tested

reaction on day 2 that is negative on day 4 is usually considered to be an irritant reaction. Certain common allergens such as neomycin, organic dyes, and corticosteroids may only show late reactions.

The system for interpreting patch test reactions as recommended by the ICDRG is shown in Table 124.3.

The doubtful and weak reactions are the most difficult to interpret. Irritant responses can be characterized by erythema without infiltration, papules in follicular distribution, pustular reactions, wrinkling, bullae, or necrosis.

Reading only at 48 h may show irritant reactions that disappear within 24 h.

There are difficulties in distinguishing weak allergy and irritant lesion. In such cases we have to perform supplementary test with different dose and dilution of allergens, ROATS (repeated open application test), and get access to the clinical history of the patient (Fig. 124.3).

Accuracy of Patch Testing

Patch tests, like all biologic tests, have inherent errors. False-negative or false-positive reactions may occur, and the experience of the dermatologist is a very important factor that helps distinguish false reactions.

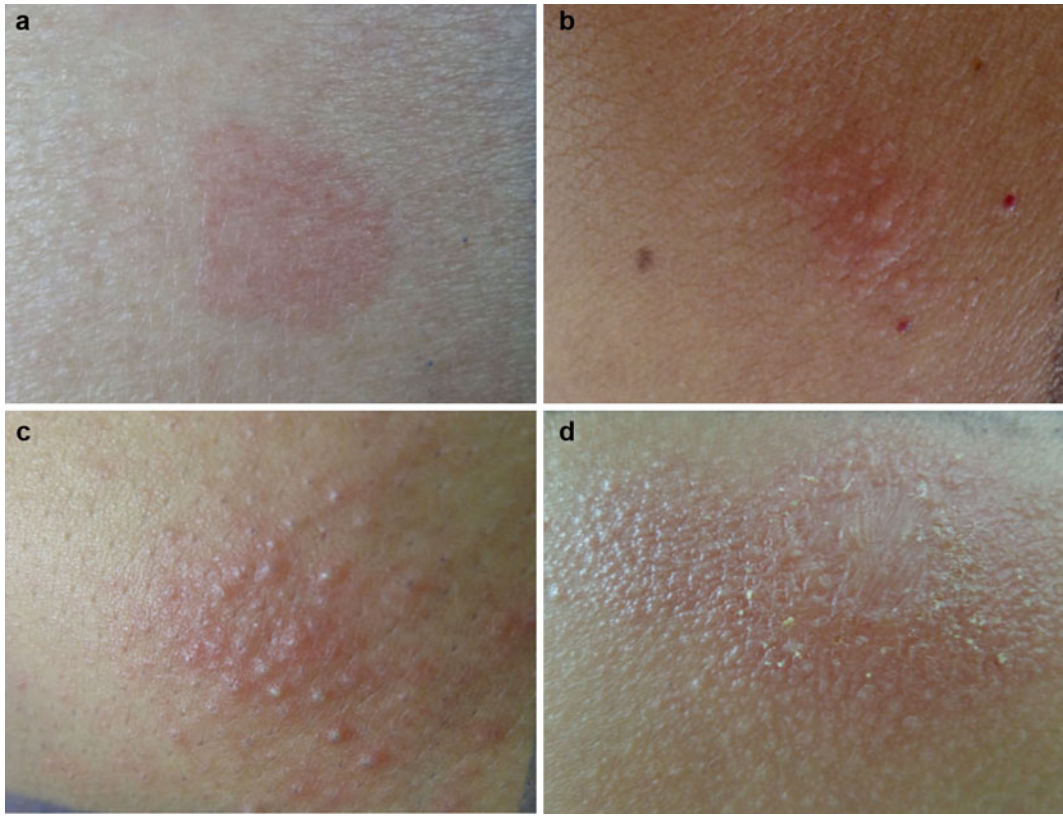

Fig. 124.3 Allergic Contact Dermatitis. Scoring of positive patch test reaction (72 h). (**a**) +, (**b**) ++, (**c**) ++, (**d**) +++

Causes of false-positive patch test reactions are:

1. *Test system factors*
   Test concentration is too high (i.e., with substances of unknown composition).
   Impure or contaminated test substances.
   Mechanical irritation (pressure, friction, soluble substances).
   Pustular reactions to metal salts.
   The vehicle is irritant (irritates the skin or enhances allergen penetration).
   Adhesive tape reaction.
   Reaction to the patch (pressure, friction, irritant or allergic reactions).
2. *Personal factors*
   Presence of dermatitis at test site, or elsewhere
   Lowered natural resistance
   High skin temperature, sweating
   Previous exposures to alcohol solvents, topical cosmetics

Causes of false-negative patch test reactions are:

1. *Test system factors*
   Test concentration is too low.
   Allergen is not in active form (i.e., degraded).
   Insufficient amount of occlusion.
   The vehicle prevents the substance from penetrating the skin.
2. *Methodology factors*
   Patch applied to site other than upper back (leg, lower arm).
   Test read too early (48 h); some substances give delayed reactions (i.e., neomycin).
3. *Personal factors*
   Prior treatment of test site with topical corticosteroids or UV irradiation (even 10–15 days earlier)
   Systemic medications: corticosteroids (prednisolone >15 mg/day), cytostatic agents, cyclosporine A
   Anergic phase (available T lymphocytes are involved in clinical reaction)

Complications

The most common complications of patch testing are irritant reactions from products of unknown composition brought in by the patient, active sensitization, aggravation of previous existing dermatitis due to percutaneous absorption of allergen (excited skin syndrome), alterations in pigmentation (hyperpigmentation, hypopigmentation), scarring, necrosis, bacterial and viral infection, and anaphylactic reactions (penicillin).

Excited Skin Syndrome The phenomenon is characterized by the presence of several strong positive reactions on the skin which is in status of hyperreactivity. These multiple strong reactions to several allergens are not reproductible. This situation is alternatively described by the use of the term angry back. The pathogenesis has not yet been evaluated. This occurs often in patients with active atopic dermatitis or other type of dermatitis. This status eczematicus makes reading impossible. The procedure has to be continued with additional tests.

Irritant Patch Test Reactions

This type of reaction is related to the chemical nature of substance and the high concentration of the allergen. It is often when we use an inappropriate procedure.

Irritant responses usually present as:

- Erythema without infiltration
- Papules in follicular distribution
- Pustular reactions especially in atopic patients (metallic salts)
- Wrinkling or bullae or necrosis

There are difficulties in distinguishing weak allergy from irritancy.

The clinical pattern of irritant reactions usually presents a number of clinical signs as an erythematous reaction, which is strictly limited to the site of application, usually not edematous (usually related to fragrance mix, parabens, thiuram mix). Purpuric reactions are common in some allergens like metals (particular in cobalt chloride), also in paraphenylenediamine, IPPD, and drugs. Soap-like effect reactions are often. Soap and detergents are involved in skin disease related to irritant reaction. The skin is red, wrinkled, usually with no vesicles. Blistering (or bullous reaction) occurs after testing with nondiluted or high concentrations of caustic substances as turpentine. Pustular reactions are mainly related to metallic salts (chromate, cobalt, nickel, mercury) in atopic patients. Necrotic reactions are often described as a sign of strong irritancy (caustic soda, kerosene).

In cases of irritancy, we have to perform patch testing again in order to reproduce the result, to use controls and serial dilution of the allergen with further investigation.

Cross-Reactions

Sometimes, the contact allergy of a primary allergen is connected with the allergy to another substance with related chemical structure. These patients who are sensitized to the first chemical are more likely to present contact dermatitis to the second allergen. Chemically similar materials may be immunochemically indistinguishable for the skin. Thus, cross-reacting substances (i.e., para-substances) may give a weaker reaction than the primary allergen. This is an indication to search for the responsible allergen.

Examples of cross-reaction are:

- *P*-phenylenediamine which is related to the amino group in para position, local anesthetics, azo compounds, and sulfonamides.
- Some antibiotics like neomycin, kanamycin, gentamicin, and framycetin.
- Nonsteroidal anti-inflammatory drugs, like ketoprofen and tiaprofenic acid.
- Plant dermatitis presents true examples of cross-reaction.

Relevance

The procedure to evaluate the relevance between the reaction to the specific allergen and the present case of eczema is usually the most difficult and interesting part. In order to decide about the relevance of our results and patient history, we are obliged to study the chemical properties of

Table 124.4 The relevance scoring system of positive patch test reactions (adopted from Lachapelle 1997)

Past relevance (PR)	
PR 0	Not traced
PR 1	Doubtful
PR 2	Possible
PR 3	Likely
Current relevance (CR)	
CR 0	Not traced
CR 1	Doubtful
CR 2	Possible
CR 3	Likely

the allergen, the aspects of patient's probable exposure to the substance during his/her professional and personal habits (hygiene, aesthetic procedures, clothing, etc.), and the course and recurrence of current episode of dermatitis.

A positive skin reaction can be related to an allergen that presents an etiologic relevance (present relevance) with the present episode of dermatitis (Table 124.4).

In some other cases, a positive skin reaction can be related to a previous episode of allergic contact dermatitis (past relevance) with no clinical significance concerning to the present case of dermatitis.

The most difficult part of evaluation is an unexplained positive skin reaction (unexplained positive) and lack of etiologic relevance, until the patient is able to recognize the allergen during his/her personal habits.

Medical history, clinical examination, accessing of exposure and chemical analysis of the substance may contribute to a detailed analysis of the clinical relevance between positive allergens and the current episode of dermatitis.

Considerations About the Effect of Systemic or Topical Treatment in Patch Testing

Corticosteroids

The oral administration of corticosteroids has an influence in patch tests results. Oral dose of 20 mg of prednisone has been acceptable and is considered as a safe solution in order not to miss any important allergies. Application of topical corticosteroids in the area of patch testing is not recommended. The interpretation of patch test results in patients with oral administration of corticosteroids is difficult. Sometimes in doubtful results, it is necessary to repeat patch testing after treatment discontinuation.

Antihistamines

Generally, it is recommended to discontinue antihistamines. Sometimes a low dose is acceptable.

Immunomodulators

It is unclear the effect of these drugs in patch testing. Generally we prefer to perform patch testing without the administration of these agents. Sometimes, cyclosporine is acceptable in dose of 25–50 mg/day. Topical immunomodulators (tacrolimus, pimecrolimus) could influence the results of atopy patch test.

Irradiation

There is an effect to patch testing related to treatment with UVB and Grenz rays. This is a result of the reduced number of Langerhans cells. We have to avoid performing the test in darkly tanned patients and directly after sun exposure, at least for 4 weeks.

Pregnancy and Patch Testing

There is no evidence that allergens could influence the fetus. The general rule indicated by the members of ICDRG is not to test pregnant women because in case of miscarriage or deformity it is likely to blame the doctor.

Patch Test in Children

There is the same indication for patch testing as in adults. The procedure is similar and it is considered to be safe for children. There is only a

technical problem related with the small surface for patch testing in children's back. It is usually advised to use 8 mm Finn Chamber. There is a general consensus of using the same concentration of allergens as in adults. Irritant reactions are not rare in children. Usually the classical standard and additional series are applied to the children according to their medical history. A number of authors propose to use limited number of allergens and specific series according to children's environment.

Photopatch Test (PPT)

Photopatch test is of main importance when we suspect photoallergic contact dermatitis for patients presenting dermatitis with distribution mainly in the exposed sites of the body in order to indentify the responsible allergen. Further indications for the use of PPT are photoallergic contact dermatitis, photoallergic drug reaction, photosensitive eruptions (lupus erythematosus), and idiopathic reaction (polymorphic light eruption, chronic actinic dermatitis).

This is patch testing with the addition of UV radiation in order to induce formation of photo allergens. It is necessary additional equipment of a light source for UVA. The method of application of the test and the scoring criteria are the same. The action spectrum for most photoallergies is included in UVA rays (315–400 nm). Allergens are applied to the upper back using standard series and photopatch series twice. The one set is removed after 24 h (or preferably 48 h) and is irradiated with ultraviolet UVA (5 J/cm^2).

We read the test according to the ACDRG scoring system in preirradiation, immediately postirradiation, and 48 h postirradiation. Further evaluation at 72 and 96 h postirradiation is recommended. PPT is positive when reaction is present only in irradiated area of allergens. A true positive photopatch test persists and increases the reaction between 24 and 72 h. Phototoxic (false-positive) reactions are common.

UV filters are the most frequent photoallergens, drugs like ketoprofen, diclofenac, ibuprofen, naproxen topical antihistamines like promethazine and others.

Atopy Patch Test (APT)

Patch test can reproduce of contact skin reaction using allergens that elicit IgE-mediated reactions, and the evaluation is performed after 24–72 h. The method is called atopy patch test (APT). This test represents a diagnostic tool for patients suffering from atopic dermatitis triggered by allergens. APT is indicated in children and adults. Positive reactions in APT are associated with allergen-specific T-cell responses.

APT results are graded according to ICDRG guidelines.

The performance of APT test has to identify aeroallergens and food allergens connected with the occurrence or exacerbation of atopic dermatitis (AD). The APT value in diagnosis of food allergy,associated or not with AD, is limited.

Positive reactions are frequent in patients with persisting dermatitis, increased total IgE, increased specific serum IgE, positive skin prick test reaction, and rhinoconjunctivitis. The main allergens identified include aeroallergens (with house dust mites and grass pollen) and food allergens, specially in children (cow's milk, eggs, soy, wheat flower). Allergen-specific avoidance strategies are recommended in certain cases of patients presenting positive APT reactions.

The diagnostic validity of APT in routine diagnosis of aeroallergen triggered atopic dermatitis has to be evaluated in further controlled studies.

Conclusions

Patch testing is a well-defined method to diagnose contact allergy.

Recognizing and avoiding the responsible allergens are of great importance for the prognosis of allergic contact dermatitis.

Photodynamic Therapy for Benign Lesions

125

Marita Kosmadaki

Key Points

- Acne can be improved with long photosensitizer application and high fluences of light or with shorter application time and/or lower light exposure. Concentration of the drug, application time, and light fluence and wavelength need to be further studied to determine an optimum protocol. With longer photosensitizer application time and higher provided energy, the severity of side effects is increasing.
- PDT seems to improves signs of photoaging, fine wrinkles, mottled hyperpigmentation, roughness, and sallowness that appear to ameliorate after PDT sessions. Different light sources, energy fluences, different photosensitizers at varying concentrations, and shorter or longer application times are being used. It is not known which the optimum protocol for the improvement of photoaging is.

M. Kosmadaki
Department of Dermatology, University of Athens, Athens, Greece
e-mail: kosmadaki@gmail.com

General Principles

Topical PDT involves the application of a precursor of a photosensitizer on the skin (typically aminolevulinic acid (ALA) or its methylated ester, MAL) which are converted by the heme biosynthetic pathway mainly to protoporphyrin IX (PpIX). PpIX is the photosensitizing substance and is preferentially accumulated in rapidly proliferating tissues, such as tumors or sebocytes. PpIX is activated during illumination with visible light, and as a result reactive oxygen species are produced. They trigger apoptosis and/or necrosis of target cells and immunological changes in the target tissue.

Over the years, PDT has expanded to several off-label applications, most responsive of which appear to be acne and photoaging. The method probably offers improvement of different diseases like granuloma annulare, necrobiosis lipoidica, viral warts, onychomycosis, cutaneous leishmaniasis, leg ulcers, lichenoid dermatoses (the erosive and scleroatrophic variant). However, no well-controlled clinical trials have been performed to precisely assess the efficacy of PDT for off-label applications. Pretreating the skin with CO2 fractional laser or other ablative methods may increase ALA/MAL penetration and enhance the therapeutic results.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_125, © Springer-Verlag Berlin Heidelberg 2015

Acne

The photosensitizer precursor is applied for 1–3 h, then it is gently removed, and the area to be treated is irradiated with light of varying wavelength (blue to red) and of varying fluence. Lower drug concentrations, low light doses, short incubation, and less penetrating blue light are termed "low-dose" PDT. "High dose" involves long incubation times and delivery of more energy of deeper penetrating red light. There is no consensus about optimal light dosimetry and irradiance and no consensus about optimal photosensitizer, its concentration, and the time it should be applied for. High-dose PDT appears to have more long-lasting results but also is associated with more side effects and a longer-lasting phototoxic reaction that limits patient for several days. The ideal effective protocol for PDT treatment of acne must balance efficacy with tolerability. Interestingly, novel photosensitizers, like indocyanine green and indole-3-acetic acid, are also being tested for acne.

PDT for acne is often painful. The treated area should be protected from the sun for at least 24 h after treatment to avoid further exposure to photoactivating wavelengths. Sunscreens are usually of very little help for the initial post-treatment period (hours) since the action spectrum of porphyrins extends into the visible range. However, they should be applied later to avoid post-inflammatory hyperpigmentation.

Mechanisms

Photodynamic therapy is believed to have a role in acne treatment due to different mechanisms. Reactive oxygen species (ROS) produced with PDT cause a direct destruction of sebaceous glands (shown for high-dose red light ALA-PDT). PDT-produced ROS also induce immunologic changes: they promote inflammation increasing pro-inflammatory cytokines like TNF-alpha, IL-6, and IL-1. PDT may also decrease the expression of TRL-2, which is implicated in mediating inflammatory response in acne, and thus have an anti-inflammatory action. The precise mechanism by which PDT modulates inflammation and improves acne remains unknown.

Further, PDT probably enhances epidermal cell turnover, reduces the hyperkeratosis in the hair follicle, and thus blocks the triggering mechanism in acne formation.

Propionibacterium acnes involved in the pathogenesis naturally produce small amounts of porphyrins, especially coproporphyrin III. Topical photosensitizers may promote its accumulation and render the propionibacteria more sensitive to light. However, consistent reduction of propionibacterium acnes population has not been described after PDT of acne patients.

PDT for acne has not been optimized. It is not clear which is the optimal ALA/MAL concentration, for how long it should be applied, and which irradiation dose of which wavelength the patient should receive. Therefore, PDT may be used as an alternative treatment for selected cases. It seems to have little or no effect on non-inflammatory lesions.

Side Effects

Erythema that usually lasts 3–5 days, edema, blisters, and crusts may appear. A pustular sterile eruption may appear on the second to third day post-treatment that typically lasts 3 days (reported with high fluences of red light). Post-inflammatory hyperpigmentation and herpes simplex may also occur.

Photorejuvenation

Topical photodynamic therapy appears to be effective for the improvement of several aspects of skin aging. Fine wrinkles, mottled hyperpigmentation, tactile roughness, and sallowness appear to ameliorate after PDT sessions. Red light, blue light, pulsed dye laser, and high-energy flash lamps with different cutoff filters all appear to be inducing good results. However, there are no well-controlled studies comparing the efficacy of different light sources with each

other, so it remains unknown which is the most effective. Short pulse durations used with IPL and PDL have a role in reducing pain (in comparison to continual irradiation with red/blue light). Moreover, similarly to acne, no consensus exists regarding the optimal irradiance the light sources should deliver, the photosensitizer, its concentration, and time it should be applied for. Both ALA (concentration varying from 0.5 % to 20 %) and MAL (16 %) are being used with different incubation times (1–3 h). Lower MAL concentrations are being tested. A single treatment appears not to be enough for significant improvement of photoaging – a second or third treatment at intervals of 2–4 weeks is recommended.

Mechanisms

The mechanism by which PDT improves photoaging appears to be related to enhanced collagen production and remodeling after treatment. Specifically, biopsies taken before and 1 month after ALA-PDT with red light showed an increase of collagen and procollagen types I and III in the upper dermis. TGF-b, which stimulates fibroblast proliferation and thus increases collagen synthesis, was upregulated. The expression of collagen- and elastin-degrading matrix metalloproteinases (MMP-1, MMP-3, and MMP-12) was decreased. Increase of collagen fibers was also observed in biopsies taken 6 months after MAL-PDT.

There are no clear indications of when to use PDT for rejuvenation and no clear data on which protocol to use. However, patients with actinic keratosis seem to be good candidates for the unmodified protocol used for precancerous lesions. Patients with telangiectasias/erythema may benefit more from pulsed dye laser or IPL using appropriate filters.

Side Effects

Erythema that usually lasts several days or weeks, edema, blisters, crusts, and scaling may occur. A pustular sterile eruption may appear on the second to third day post-treatment that typically lasts 3 days (reported with high fluences of red light). Post-inflammatory hyperpigmentation and herpes simplex may also occur. Lower photosensitizer's concentration, shorter incubation time, and low fluences result in milder side effects.

Contraindications

Photosensitivity to visible light used for the procedure, to the photosensitizer, or photoaggravated dermatoses. PDT is not licensed for use during pregnancy or lactation.

Photodynamic Therapy for Malignant Skin Lesions

126

Edidiong Celestine Ntuen Kaminska, Susan Pei, and Maria M. Tsoukas

Key Points

- Photodynamic therapy (PDT) is a form of phototherapy involving a photosensitizer, a light source, and tissue oxygen.
- Aminolevulinic acid (ALA) and its ester derivative methyl aminolevulinate (MAL) are commonly used photosensitizers acting as prodrugs for protoporphyrin IX (PpIX). PpIX accumulates in abnormal epidermis and upon subsequent exposure to and activation by the appropriate light source generates reactive oxygen species that selectively destroy diseased lesions.
- PDT has been established to be a safe and effective treatment for superficial skin cancers and premalignant skin lesions. Pain is the most severe adverse effect but can be effectively managed. Porphyria is an important contraindication.
- Common approved PDT protocols include Levulan 20 % solution ALA-PDT activation with blue light for treatment of actinic keratosis (AK) in the USA and Metvix/Metvixia MAL-PDT for treatment of AK, Bowen's disease, and basal cell carcinoma in Europe.
- Off-label, ALA-/MAL-PDT have been reported to treat invasive squamous cell carcinoma, cutaneous T-cell lymphoma, Kaposi's sarcoma, Paget's disease, and various benign inflammatory disorders and to prevent recurrence of squamous cell carcinoma in organ transplant recipients.
- Combination therapy of PDT with other treatment modalities such as cryotherapy, surgery, and field therapies is being explored with preliminary data suggesting improved efficacy, tolerability, and long-term results.
- In addition, PDT offers enhanced cosmetic outcome compared to cryotherapy or surgery. PDT can also be used for skin photorejuvenation.

General Principles

Photodynamic therapy (*PDT*) is a form of phototherapy using a light-sensitive compound that upon exposure to the appropriate light source will become activated. The byproducts of this activation produce targeted toxic effects on abnormal cell types (i.e., malignant and other diseased cells). Three necessary components are required

DOI 10.1007/978-3-662-45139-7_126, © Springer-Verlag Berlin Heidelberg 2015

for PDT applications. These include a photosensitizer, a light source, and tissue oxygen. The combination of these three components leads to the chemical destruction of tissue that has selectively taken up the photosensitizer and has been exposed to light. Activation of the photosensitizer requires a suitable wavelength of the light that will excite the photosensitizer to produce reactive oxygen species (ROS) and free radicals. These ROS are generated by the targeted tissue's oxygen supply through PDT. Specifically, cells become overloaded with the activated photosensitizer via light, and the activated molecule transfers energy to tissue oxygen in close proximity. This creates excited singlet state oxygen molecules and free radicals that accumulate within the affected tissue and ultimately result in lesion destruction by direct cellular damage by apoptosis or necrosis and indirect stimulation of inflammatory cell mediators. Therefore, PDT causes selective destruction of targeted abnormal premalignant or malignant cells with the simultaneous preservation of surrounding normal structures.

Photodynamic Therapy: Basic Concepts

Evolution

At the end of the nineteenth century, Oscar Raab, a student of von Tappeiner, observed a toxic effect of acridine dye on paramecia cultures and recognized that light was required for the killing of paramecia cultures to take place (Raab 1900; Kick et al. 1996). Von Tappeiner and colleagues further explored this concept and discovered, in addition to a photosensitizing compound and light, importantly that oxygen was also essential for the photodynamic effect (Jodlbauer and Von Tappeiner 1904). These scientists expanded the application of the photodynamic effect clinically by applying 1 % eosin solution as a photosensitizer to patients with facial basal cell carcinoma followed by exposure to either sunlight or to an arc-lamp light. Many of these patients demonstrated complete tumor resolution and a relapse-free period of 12 months (Jesionek and Von Tappeiner 1905). Almost a century later, Thomas Dougherty and colleagues used PDT with a hematoporphyrin derivative (HpD) as a photosensitizer to treat cutaneous and subcutaneous malignant tumors and observed a total or partial resolution of these tumors (Dougherty 1987; Dougherty et al. 1978). Thus, the first clinical applications of PDT were used for dermatology.

Kinetics

Topical exogenous porphyrin (aminolevulinic acid (ALA) and methyl aminolevulinate (MAL)) administration results in the stimulation of the heme synthesis pathway, thereby culminating in the accumulation of protoporphyrin IX (PpIX) in cells (Fig. 126.1). Normally, the rate of heme synthesis and the intracellular concentration of different porphyrin intermediates are under negative feedback heme control of the ALA synthase activity. This limits the concentration of endogenous ALA. By supplying the cells with exogenous porphyrins, the normal regulatory control is lost and overproduction of endogenous porphyrins results. Malignant tumor cells have abnormal porphyrin metabolism because of disturbed enzyme activity, and therefore the accumulation of PpIX is enhanced in these lesions (Orenstin et al. 1997). Although PDT is dependent on the concentration of photosensitizer in the tumor, adequate light irradiation is also important (Dougherty 1987; Dougherty et al. 1978). Incubation and irradiation times are discussed in the "General principles of treatment" section below.

Photosensitizers

In PDT, photosensitizers allow for the transfer and translation of light energy into a chemical reaction that produces ROS leading to tissue destruction. In clinical practice, photosensitizers arise from three major groups—porphyrins, chlorophylls, and dyes. Each photosensitizer needs to be reliably activated at a high enough light wavelength useful for therapy. Porphyrin species

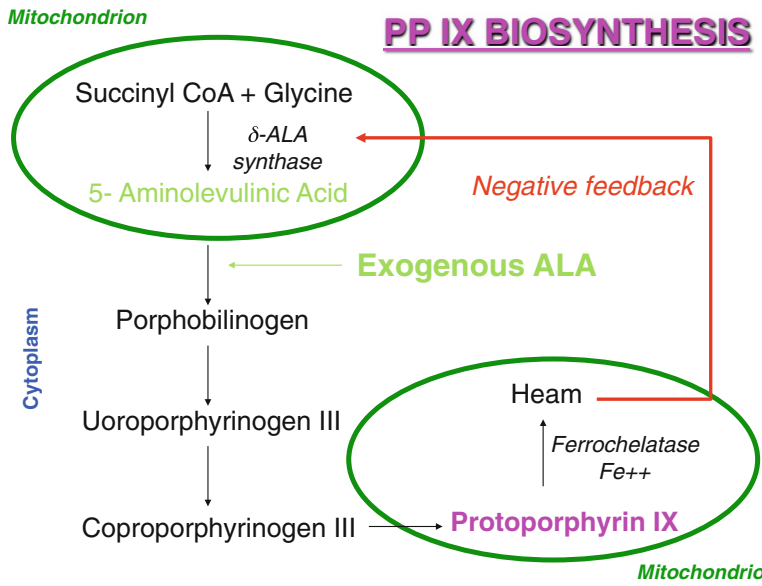

Fig. 126.1 Pathway of protoporphyrin IX (PPIX) biosynthesis. PPIX is produced in excess amounts in mitochondria as a result of exogenous photosensitization due to ALA topical application, utilizing the same cellular pathway for heme production

derived from hematoporphyrin have long been recognized as demonstrating preferential uptake by cancerous cells since these cells exhibit a significantly greater uptake and affinity for porphyrins compared to normal quiescent tissues (Lipson and Baldes 1960; Lipson et al. 1961). As such, refined topical exogenous porphyrin derivatives are currently used and absorbed by rapidly proliferating cells utilizing the heme synthesis pathway to produce PpIX, which is the photosensitizing agent. An additional benefit of porphyrin-derived products is that PpIX fluoresces during photoirradiation allowing for margin identification of human skin tumors. The most characterized and broadly applied in dermatology agents are 5-ALA and MAL. Other topical compounds will be briefly mentioned.

Aminolevulinic Acid (ALA)

In 1990, Kennedy and co-workers introduced 5-ALA with PDT for the treatment of skin disorders (Kennedy et al. 1990). ALA is the first compound in the porphyrin synthesis pathway, and it serves as a prodrug for the active photosensitizing compound, PpIX which is synthesized in vivo after exogenous application of ALA. Pp IX photosensitization is induced in cells of the epidermis and its appendages, but not in the dermis. Kennedy et al. found that ALA in aqueous solution passes readily through abnormal keratin, but not through normal keratin. Therefore, photosensitivity is restricted primarily to the abnormal epithelium (such as in nonmelanoma skin cancer and premalignant conditions like actinic keratoses (AK)). Subsequent exposure to photoactivating light selectively destroys such lesions. Several studies after these initial findings have confirmed the mechanism of ALA-PDT. ALA is presently available in the USA in the form of reconstituted hydroalcoholic solution (Levulan Kerastick) and in Europe as Alacare skin-colored patch facilitating occlusion, as well as BF-200 ALA nanoemulsion for increased stability and penetration.

Methyl Aminolevulinate (MAL)

MAL is a more recent ester derivative of ALA, with a similar mechanism of action. However, MAL may offer advantages over ALA including deeper skin penetration depths due to potentially enhanced lipophilicity and greater specificity for neoplastic cells (Peng et al. 1997, 2001). Although MAL was FDA approved in the USA, it is mostly applied in Europe (Metvixia).

Other Topical Photosensitizers

Although ALA and MAL are most commonly used, other porphyrin molecules such as benzoporphyrins and porphycenes may potentially play a role in PDT (Szeimies et al. 1996). Additionally photosensitizers from the chlorophyll and dye families may also be used for treating premalignant cutaneous lesions with topical PDT and have excellent photosensitizing properties (Allison et al. 2004). Chlorophyll-derived and degradation photosensitive products include temoporfins, purpurins, mono-L-aspartyl chlorin e6 (NpE6), LS11, and HPPH. Dyes have been used as early in the twentieth century as photosensitizing products (Raab 1900). The dyes most commonly reported to include phthalocyanines and their relatives are the naphthalocyanines. Although data is promising, there is still a need for comparative studies and standardized therapeutic protocols to define the place of these other agents and topical PDT in dermatology.

Fig. 126.2 Activation of PPIX during photodynamic therapy with BLU U light source (blue light, 417 nm). Eye protective goggles are utilized during exposure to visible light

Light Source

The administration of a photosensitizing drug and its subsequent activation by irradiation with a light source at wavelengths matching the absorption spectrum of the photosensitizer is important for clinical efficacy. The absorption spectrum of PpIX includes the blue light range (the main absorption peak) and the red light range; these are the most commonly used light sources for PDT. In the USA, Levulan 20 % solution ALA-PDT activation with blue light (417 nm Blu U, Levulan Kerastick, DUSA Pharmaceuticals, Inc) is FDA approved for the treatment of AK (Fig. 126.2). Whereas in Europe, practitioners frequently use 16.0 % cream Metvix/Metvixia MAL-PDT (Galderma) for the treatment of AK, Bowen's disease (BD), and basal cell carcinoma (BCC). Light activation is with red light (~630 nm) because it allows greater optical penetration depth (8–10 mm at 630 nm compared with 1–2 mm at 400–500 nm (Wolf et al. 1993)) and permits shorter illumination times.

Several small studies have investigated intense pulsed light (IPL) and pulsed dye lasers (PDL) as possible light sources for PDT in the treatment of AK (Peng et al. 1997; 2001; Haddad et al. 2011; Alexiades-Armenakas and Geronemus 2003). IPL emits a broad spectrum of visible to near-infrared light. Infrared irradiation causes hyperthermia, and it has been suggested that mild hyperthermia may act synergistically with PDT (Peng et al. 1997; 2001). The combination of ALA-PDT with an IPL source has been shown to improve AK clearance compared to IPL alone (Haddad et al. 2011). Long pulsed PDL (595 nm) in combination with ALA-PDT also has proven efficacy for eradicating AKs compared to PDL (Alexiades-Armenakas and Geronemus 2003). The advantages of using other light sources even with broad-emitting radiation spectrum are that (a) they eradicate the need to have a dedicated PDT light source, (b) they activate PpIX at different absorption maximal wavelengths, (c) they may increase PDT efficacy per each treatment, (d) they may require lower light doses, and (e) they can be better tolerated with decreased recovery time or discomfort.

Table 126.1 ALA-PDT vs. MAL-PDT

	ALA-PDT	MAL-PDT
Exogenous porphyrin	5-aminolevulinic acid	Methyl aminolevulinate
Strength and formulation	20 % alcohol-water solution[a]	16 % oil in water cream[b]
Indication	Actinic keratoses of face and scalp (USA)	Actinic keratoses of the face and scalp (USA and Europe), Bowens disease, superficial and nodular basal cell carcinoma (Europe)
Light source	Blue fluorescent light	Red and blue light
Incubation	14–18 h FDA approved[c]	3 h under occlusion
Efficacy	Reports vary ~80 % up to over 90 %	Same as ALA-PDT
Safety	Photosensitivity and dermatitis	Same as ALA-PDT
Pain	Variable	Unclear compared to ALA-PDT but more intense if red light used

[a]Metvix®/Metvixia®, Galderma
[b]Levulan Kerastick™; DUSA Pharmaceuticals
[c]Although many investigators are now using 1–3-h protocols, based on similar efficacy at these shorter incubation times

General Principles of Treatment

Pretreatment

Usually prior to treatment with ALA-/MAL-PDT, the superficial crust and scale of skin lesions, such as moderate thickness or hyperkeratotic AK, and nonmelanoma skin cancers (NMSC) are gently removed with light curettage or scalpel removal, occlusion with a keratolytic the night before treatment, tape-stripping, microdermabrasion, or laser ablation (Morton et al. 2013a). A topical acetone solution may also be used to decrease oils on the skin surface. These pretreatment techniques may improve efficacy of medication uptake and optical penetration.

Incubation and Exposure

Although Levulan ALA-PDT is approved for a 14–18-h incubation followed by activation with blue light (417 nm Blu U, Levulan Kerastick, DUSA Pharmaceuticals, Inc), expert consensus recommends shorter incubation times with intervals around 1–3 h (Nester et al. 2006). These were derived from the results of several studies demonstrating comparable efficacy with reduced incubation time. Patients are then treated with an appropriate light source. For Levulan ALA, a 1,000-s exposure to BLU U, 417 nm, is suggested (*Figure—consider image of patient sitting under blue u*). Repeat treatment may be performed after 8 weeks as clinically indicated. This protocol is generally accepted in the USA and Europe for the treatment of AK. Metvix/Metvixia MAL-PDT (Galderma) is typically applied for 3 h under occlusion, followed by red light irradiation (570–670 nm or narrower spectrum) for a total light dose of 75 J/cm^2. Two treatments separated 1 week apart for BD/BCC or one initial treatment repeated at 3 months, only if required for AK, may be performed (Morton et al. 2013a) (Table 126.1). Although these are the most common protocols, there are many off-label uses of ALA-/MAL-PDT for malignant skin lesions; please see section "Photodynamic therapy of malignant skin lesions."

Photodynamic Therapy of Malignant Skin Lesions

Several clinical studies have established PDT as a safe and effective treatment for superficial skin cancers and premalignant skin lesions. We review key studies below and as reported in the recent 2013 European guidelines for topical photodynamic therapy.

Actinic Keratoses

AK on the face and scalp tend to respond well to topical ALA-/MAL-PDT, with typical clearance rates of 89–92 % 3 months after therapy,

and 1 year clearance rates of 63–69 % (up to two treatments) (Piacquadio et al. 2004; Tarstedt et al. 2005; Morton et al. 2006a, b; 2008). Clearance rates of AK on acral sites are reduced by ~10 % likely because lesions tend to be thicker on these sites. Comparing MAL-PDT with cryotherapy for facial and scalp AK, after the initial therapy, PDT cleared more lesions (87 % vs. 76 %); however, the outcome was equivalent after nonresponders were retreated (89 % vs. 86 %) (Morton et al. 2006a, b), and for acral AK, PDT was less effective in clearing lesions, 78 % vs. 88 % at 6 months (Kaufman). Guidelines identify ALA-/MAL-PDT as an effective treatment option for focal and field AK. PDT may also serve as an alternative treatment option for patients that cannot tolerate multiple cryotherapy treatments or session, prolonged irritation from topical therapy such as 5-fluorouracil or imiquimod, or that may not respond to immunomodulators.

Squamous Cell Carcinoma

Bowen's Disease

ALA-/MAL-PDT clearance rates of 82–100 % have been reported for BD lesions. For the ALA-PDT studies, a single treatment or two treatments (separated by 1 month based on incomplete response at follow-up) were used (Dijkstra et al. 2001; Varma et al. 2001). In the MAL-PDT studies, clearance rates were determined at 3 months beyond one or two cycles (two treatments 7 days apart defined as one cycle). Sustained clearance rates of 68–71 % at 24 months were observed. These rates were similar to conventional therapy with cryotherapy of 5-flurouracil, but with superior cosmesis (Morton et al. 2006a, b; Calzavara-Pinton et al. 2008). Another study demonstrated a 76 % clearance rate of BD after two sessions of MAL-PDT and a median follow-up of 16 months (Truchuelo et al. 2012).

Similar to AK therapy, guidelines identify ALA-/MAL-PDT as an effective treatment option for BD. Some guidelines recommend PDT as the treatment of choice for BD on poor-healing sites and for large lesions (Cox et al. 2007).

Invasive Squamous Cell Carcinoma

Currently, MAL-PDT clearance rates of 57 and 26 % have been reported for microinvasive and nodular invasive SCC at 24 months (Calzavara-Pinton et al. 2008, 2013a, b). Cellular atypia and poorly differentiated keratinocytes are negative prognostic factors for invasive SCCs, and these cells may be less sensitive to PDT. Another potential concern is that PDT may not reach adequate depths to treat deeply invading tumors. Because of the metastatic potential and the reduced efficacy rates of invasive SCC, European guidelines do not recommend PDT use for these tumors (Morton et al. 2013a).

Basal Cell Carcinoma

Superficial Basal Cell Carcinoma

MAL-PDT studies have demonstrated a clearance rate of 73–97 % at 3 months for sBCC (Basset-Séguin et al. 2008; Szeimies et al. 1996, 2008, Arits et al. 2013). In one randomized study, sBCC was treated with either a single baseline MAL-PDT application or cryotherapy (Basset-Séguin et al. 2008). In a second study, sBCC was treated with either two MAL-PDT applications 7 days apart or surgery (Szeimies et al. 1996, 2008, 2013). In both MAL-PDT protocols, two additional treatment cycles were applied as needed at 3 months. Both studies reported 1-year recurrence rates of 9 % and 5-year recurrence rate of 22 % following MAL-PDT. In addition, both studies reported equivalent clearance efficacy and superior cosmetic outcome following MAL-PDT compared to either cryotherapy or surgery. In a single-blind, randomized study comparing sBCC clearance following MAL-PDT to either topical fluorouracil or imiquimod, fluorouracil was observed to be non-inferior, while imiquimod was superior to MAL-PDT (Arits et al. 2013).

A review of 12 ALA-PDT studies published between 1990 and 1995 reported an average weighted clearance rate of 87 % for sBCC (Peng et al. 1997, 2001). ALA-PDT efficacy is comparable to cryotherapy and yields superior cosmesis (Wang et al. 2001). In a longitudinal study of

BCC treated with curettage and one or two sessions of dimethyl sulfoxide-supported ALA-PDT, 81 % of lesion sites were disease-free at 6 years (Christensen et al. 2009) and 75 % at 10 years (Christensen et al. 2012).

Lesion thickness and location predict therapeutic response to PDT, with thicker tumors and those in the H-zone less responsive (Morton et al. 1998; Vinciullo et al. 2005). Therefore, current guidelines recommend topical PDT for sBCC (Morton et al. 2013a).

Nodular Basal Cell Carcinoma

Studies yield mixed results regarding treatment of nBCC with PDT. One study demonstrated 91 % clearance at 3 months and 76 % clearance at 5 years following MAL-PDT (applied twice at 7 days interval with retreatment at 3 months as needed; Rhodes et al. 2004; 2007). A different study reported an overall response rate of 73 % for nBCC following MAL-PDT with prior minor tumor debulking, though clearance for facial lesions was higher at 89 % (Foley et al. 2009). Fantini et al. report a more modest response rate of 33 % for nBCC compared with 82 % for sBCC with no prior debulking of tumor mass. Specifically, nodular subtype and lesions located in the limbs were the least responsive. Compared with surgery, MAL-PDT yields comparable clearance at 3 and 12 months though a trend towards higher recurrence emerges at 24 months (Rhodes et al. 2004). However, MAL-PDT resulted in superior cosmetic outcomes at all time points. A recent study showed that fractional carbon dioxide laser pretreatment increases clinical effectiveness of MAL-PDT compared to curettage pretreatment (Lippert et al. 2013).

A phase III clinical trial found similar clearance efficacy following ALA-PDT (25 % recurrence at 12 months verified histopathologically) compared to cryosurgery (15 % recurrence), with no significant difference between the superficial and nodular subtypes (Wang et al. 2001). ALA-PDT produced superior cosmetic results. However, a smaller randomized pilot study comparing nBCC clearance and cosmesis following ALA-PDT with prior minimal curettage to surgery did not find any difference in either clearance or cosmesis (Berroeta et al. 2007). Fractionated ALA-PDT is comparable to surgery in clearing nBCC. However, failure rates during long-term follow-up vary between 20 and 31 % at 2–5 years depending on fractionated dosing protocol and debulking pretreatment (de Haas et al. 2007, 2008; Mosterd et al. 2008; Roozeboom et al. 2013).

Current guidelines recommend PDT for thin low-risk nBCC, especially in cases where surgery is contraindicated or a preference for superior cosmesis exists (Telfer et al. 2008). Patients treated with PDT should be monitored for recurrence for at least 1 year.

Nevoid Basal Cell Carcinoma Syndrome

Patients with NBCCS may benefit from PDT. In one cohort study, 33 patients were treated with either topical PDT for superficial lesions (<2 mm thick) or systemic PDT for lesions >2 mm as assessed by ultrasound with overall local control rates of 56 % at 12 months (Loncaster et al. 2009). In a case report of seven patients, including two children, treated with MAL-PDT, 60 % of lesions were cleared after one session and 78 % after three sessions (Girard et al. 2013). MAL-PDT treatment also resulted in excellent cosmetic outcome. In addition, MAL-PDT may improve patient satisfaction and lower the need for surgical procedures (Pauwels et al. 2011).

Other Cutaneous Malignancies

The following diseases have no standardized protocols given the lack of well-controlled high-power studies.

Cutaneous T-Cell Lymphoma

Topical ALA- and MAL-PDT have both been used in localized cutaneous T-cell lymphoma

(CTCL), and evidence is derived from case reports and series. The most promising data has been observed in thin plaque cutaneous B-cell lymphoma using PDT with ALA ($n=2$) and MAL ($n=1$) where patients achieved clinical and histological remission after one or two treatments with clearance maintained over 8–24 months (Mori et al. 2006). Other small studies have shown that multiple treatments may be necessary (1–11) to improve or clear patients with unilesional disease, plaque-stage CTCL, and extensive erosive facial mycosis fungoides (Zane et al. 2006; Edstrom et al. 2001; Debu et al. 2010). Topical hypericin in under occlusion for 24 h followed by administration of visible light has also been described as partially efficacious for CTCL (Rook et al. 2010).

Kaposi's Sarcoma

Case reports and case series of PDT have demonstrated PDT as an effective modality for AIDS-related Kaposi's sarcoma (Sk-AIDS). In 1995, Hebeda et al. described treatment with laser-based Photofrin-PDT (Ph-PDT) protocols in homosexual men with HIV ($n=8$). The response rates by patient for all treated lesions were 50–100 % with a median duration of 3 months. However, cosmetically, there was a high prevalence of scars and long-lasting hyperpigmentation. Based on this, the authors could not recommend Photofrin-PDT for Sk-AIDS (Hebeda et al. 1995). Bernstein et al. published a comprehensive study with 25 patients and concluded that Ph-PDT was effective as palliative treatment for Sk-AIDS; however, cutaneous phototoxicity reactions were seen in 27 % of the patients (Bernstein et al. 1999). In 2006, Tardivo et al. injected phenothiazinium compounds (methylene blue and toluidine blue) and used PDT with a noncoherent light source (RL50) to treat Sk-AIDS in a single patient. The patient was reported to have complete remission with an excellent cosmetic result although the patient required five PDT sessions to confirm histological clearance (Tardivo et al. 2006).

Paget's Disease

Case reports and small series of PDT in extramammary Paget's disease (EMPD) demonstrate that it may not be as effective in treating NMSC such as SCC and BCC. There may be some short-term improvement. ALA-PDT and MAL-PDT have been used with clearance rates of 50–100 %, but some cases have been complicated by recurrence less than 6 months after treatment (Shieh et al. 2002; Mikasa et al. 2005; Zawislak et al. 2004; Rapagliesi et al. 2006.).

Photodynamic Therapy of Other Skin Lesions

Several benign and inflammatory disorders have been treated with ALA-/MAL-PDT with remarkable preliminary clinical results. These include acne, cutaneous infections (i.e., atypical mycobacteria, leishmania), granuloma annulare, hidradenitis suppurativa, keloids, lichenoid dermatoses, lymphadenosis benigna cutis, necrobiosis lipoidica, psoriasis, rosacea, and several others (Morton et al. 2013b; Calzavara-Pinton et al. 2013a, b; Nie 2011; Takeda et al. 2005; Rose and Stables 2008). Most findings are based on anecdotal, observational, or small case series data. Protocols are still being refined, and larger studies are needed to confirm these findings. In-depth discussion of these lesions is outside of the scope of this chapter.

Photodynamic Therapy Combined with Other Modalities

Prevailing topical AK and NMSC therapies include destructive modalities, such as cryosurgery and electrodessication and curettage (ED&C), and topical regimens such as fluorouracil, diclofenac sodium, imiquimod, and PDT. Destruction by cryotherapy and ED&C is suitable and highly effective for treating a few lesions; however, these procedures may require local anesthesia and can result in scarring and pigmentary alterations. On the other hand, field

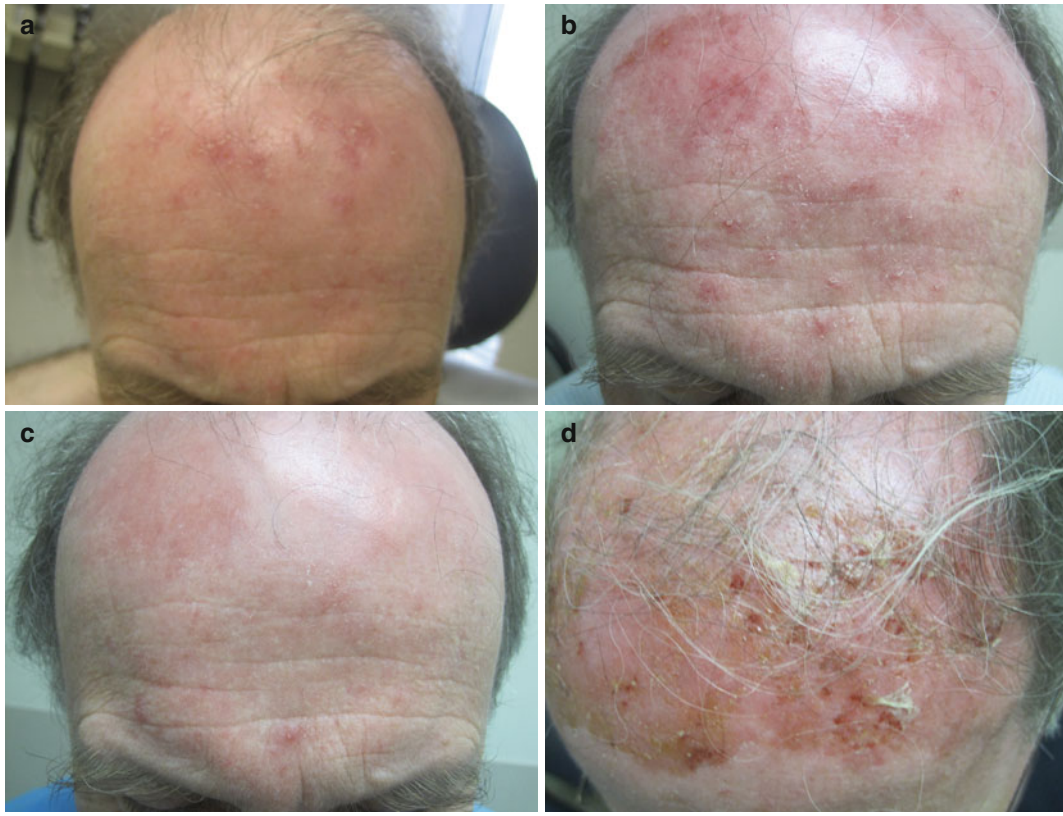

Fig. 126.3 ALA-PDT responses for actinic keratosis, post short 5 FU pretreatment: clockwise: (**a**) before treatment, (**b**) immediately after light exposure, (**c**) 3 days post light therapy with significant crusting, (**d**) 1 month following PDT

therapies including topical chemotherapy, nonsteroidal anti-inflammatory agents, immunomodulators, chemical peels, lasers, or photodynamic therapy (PDT) are suitable for treating multiple lesions. Singly, these treatment modalities have shown to be effective; however, each of these may require application over several weeks or multiple sessions. Additionally, immunomodulator response is variable from individual to individual, and a given response cannot be generalized.

Few sequential therapy studies with PDT have been derived from small pilot studies, case series, anecdotal evidence, or individual preference. Published combination therapies for AK include pretreatment with topical tazarotene gel, diclofenac gel, or 5-fluorouracil followed by ALA-PDT, ALA-PDT followed by topical imiquimod, and ablative fractional laser resurfacing-assisted MAL-PDT; detailed findings can be found in a review by Kaminska and Tsoukas (2013). Although data exploring combined field therapy with these modalities are limited, preliminary findings suggest that these may offer improved efficacy, tolerability, and long-term results compared with monotherapy (Fig. 126.3).

Organ Transplant Recipients

The management of AK and NMSC in solid organ transplant recipients (OTRs) presents many clinical challenges for physicians and bears special mention since this population is at a 65-fold increased risk for developing cutaneous SCC. This is the most common NMSC that develops after transplantation. These SCCs can be associated with significant morbidity, particularly in patients who develop multiple tumors. Risk factors that lead to an increased risk of NMSCs

include a past medical history of any previous cutaneous malignancy, a personal history of significant sun exposure, a fair skin complexion, and/or greater immunosuppressive medication levels. Field decancerization has enabled physicians to treat large affected areas quickly and effectively. PDT is often used in OTRs according to individual patient tolerability (Bangash and Colegio 2012).

In a recent study by Willey et al., high-risk OTRs ($n=12$) received cyclic ALA-PDT (every 4–8 weeks for 2 years) for the prevention of cutaneous SCCs. The study demonstrated a significant reduction of SCCs at the end of 24 months of treatment (95 % reduction) when compared to the baseline number of SCCs (the number of SCCs developed during the year before initiation of cyclic PDT). These data suggest that cyclic ALA-PDT could potentially prevent new SCCs in this high-risk patient population (Willey et al. 2010) and therefore decrease morbidity and mortality.

Cosmesis

The ultimate goal of PDT is for long-term treatment and prevention of large cutaneous areas of premalignant and malignant lesions. An additional benefit is excellent cosmetic results, superior to other modalities such as cryotherapy or surgery, which can leave scars and result in dyspigmentation. In a study using broad-area application of δ-ALA-PDT for treatment of AK and diffuse photodamage, improvement in Griffiths score, sallowness, and fine wrinkling accompanied reduction in AK (Touma et al. 2004).

PDT is also effective for skin photorejuvenation, with improvement in fine wrinkles, mottled hyperpigmentation roughness, and sallowness (Kohl et al. 2010; Alster and Surin-Lord 2006). Split-face studies demonstrated that adjunctive use of 5-ALA with intense pulsed light for photoaging (IPL) results in greater improvement in overall photodamage, mottled pigmentation, fine lines, crow's feet, tactile skin roughness, and telangiectasias compared with IPL alone (Dover et al. 2005; Gold et al. 2006). Split-face studies also demonstrated efficacy of MAL-PDT plus red light in improving fine lines, tactile roughness and skin tightness (Ruiz-Rodriguez et al. 2008), global photodamage, coarse lines, mottled pigmentation, sallowness, erythema, and sebaceous hyperplasia (Sanclemente et al. 2011). Combined fractional resurfacing and MAL-PDT has been reported to improve superficial wrinkles (Ruiz-Rodriguez et al. 2007). PDT combined with various pretreatment modalities (such as microneedling, microdermabrasion, fractional lasers) allows for synergist results and improved cosmesis on different anatomical sites (Szeimies et al. 1996, 2008, 2013).

Adverse Effects and Management

Adverse effects of PDT include induction of burning and stinging during light exposure. Clinically, crusting, peeling, erythema, edema, pigmentation, pustules, and pain may be noted. Of these, pain is the most severe of the adverse effects, sometimes resulting in treatment interruption and termination. Although uncomfortable, these side effects are not contraindicated and can be managed. Contraindications for ALA, MAL, and PDT are outlined in Table 126.2.

While the definitive pain mechanism of PDT is not yet fully understood, several modalities

Table 126.2 Contraindications for PDT

	Skin disease	NMSC	Hypersensitivity	Pregnancy class
ALA-PDT	Any photosensitive disorders such as porphyria	Morpheaform basal cell carcinoma[a]	Porphyrins, sensitivity to any component in product	C[b]
MAL-PDT	Same as above	Same as above	Porphyrins, arachis oil, peanut, soya to or any other component in product	Same as above

[a]Insufficient data to use PDT
[b]Off-label PDT for acne management has been practiced in later stages of pregnancy

may help prevent or decrease discomfort during therapy. Thermal spring water is thought to have anti-inflammatory activity in vitro. Cooling the skin with cold air may reduce metabolism, which decreases the effects of tissue damage. Infiltration anesthesia and nerve blocks without vasoconstrictor are useful in the management of pain in PDT. Lower irradiances are related to lower levels of pain. However, one therapy that has not proven efficacious is topical anesthetics in PDT. It is postulated that since both ALA and MAL have an acidic pH and the majority of the topical anesthetics have an alkaline pH, their combined use is incompatible (Chaves et al. 2012).

Future Perspectives

Investigators are currently studying ways to improve PDT outcomes. From combination therapies as mentioned above to refining the topical product (i.e., a patch ALA formulation that does not require pretreatment lesion preparation (Hauschild et al. 2009) or nanoemulsion ALA that increases ALA stability and skin penetration (Dirschka et al. 2012)) or optimizing the light protocol (i.e., a fractionated illumination scheme, in which two light fractions are delivered separated by a 2-h dark interval, following a single ALA application (de Haas et al. 2007, 2008)), PDT continues to evolve. Additionally, daylight PDT is practiced in Europe and can increase efficacy and compliance of the modality (Braathen 2012). As such, one can expect guidelines to adjust as the technique is perfected.

Conclusion

Aggressive nonsurgical treatment of precancerous lesions and NMSC may prevent the rate of conversion to more advanced tumors. Since PDT is an evidence-based treatment modality, it is appealing to both prospective patients and physicians alike. Its advantages include decreasing treatment costs and improving cosmetic outcomes. As more information becomes available on how to increase the absorption of the exogenous porphyrin prodrug (thereby amplifying PpIX production in lesional skin), enhance light penetration, and improve patient tolerability by decreasing pain, in the future, PDT may become the gold standard for field decancerization of AK and NMSC.

Phototherapy

127

Marita Kosmadaki and Christina Antoniou

Key Points

- Phototherapy is the use of ultraviolet radiation or visible light for therapeutic purposes. When artificial photosensitizers are used in combination with light, the appropriate term is *photochemotherapy*.
- Narrowband and broadband UVB, UVA as part of photochemotherapy (PUVA), UVA1, and targeted phototherapy (excimer lasers and nonlaser monochromatic excimer light sources) are in use today with success in dermatologic therapy.

General Principles

The different wavelengths of ultraviolet radiation penetrate the skin in different depth and interact with different molecules in the skin. As a consequence, each form of phototherapy has unique effectiveness for different diseases and unique side effects.

UVB radiation (290–320 nm) is absorbed in the epidermis and superficial dermis. Its absorption results in many different types of DNA damage but mainly pyrimidine dimers and 6,4 pyrimidine–pyrimidone photoproducts. UVB activates a series of signal transduction pathways and results in the generation of reactive oxygen species. These have DNA-damaging effects, activate other signal transduction pathways, and stimulate cytokine production.

UVA radiation (320–400 nm) reaches deeper than UVB in the mid- or lower dermis. The major biological effects of UVA radiation are due to the generation of reactive oxygen species, although direct DNA damage has also been shown after UVA irradiation. UVA-induced ROS are capable of harming DNA, lipids, proteins, and various cellular organelles.

Psoralens used in photochemotherapy intercalate with DNA, and following UVA exposure results in cross-linking of DNA strands in the double helix. This signals a DNA damage response, suppressing DNA synthesis and cell division, and is thought to contribute to the therapeutic response of psoriasis. Psoralens also react with RNA, proteins, and other cellular components and indirectly modify cellular components via ROS-mediated reactions.

In general, the therapeutic action of photo(chemo)therapy may fall into three major categories:

1. Effects on production of soluble mediators from skin cells
2. Modulation of the expression of cell-surface-associated molecules
3. Direct action on cells/apoptosis in pathogenetically relevant cells

1. Soluble mediators induced by photo(chemo) therapy are thought to have anti-inflammatory, immunosuppressive, or both properties. The production of soluble, immunomodulatory mediators is well proven for UVB, for UVA, and for UVA1 radiation. In contrast, less is known about the effects of PUVA on the release of molecules from skin cells. Keratinocyte-derived cytokines of particular therapeutic relevance are IL-10 and prostaglandin E2, both of which have been shown to diminish the capacity of dendritic cells to present antigen to effector T cells and to suppress T-cell responses. Other immunosuppressive mediators that have been reported to be increased following UVB exposure include agonists of the platelet-activating factor receptor, alpha-MSH, cyclooxygenase-2, and calcitonin gene-related peptide.
2. UVB, UVA, and PUVA treatment can directly affect the expression and function of cell-surface receptors. Adhesion molecule intercellular adhesion molecule-1 (ICAM-1) is rarely expressed on the surface of normal human keratinocytes. However, it is greatly upregulated in inflamed skin (psoriasis, atopic dermatitis, T-cell lymphoma). This molecule serves as a counter-receptor for the lymphocyte function-associated antigen-1 (LFA-1), which is present on the surface of leukocytes. The ICAM-1-/LFA-1-mediated keratinocyte–lymphocyte adhesion is important for the generation and maintenance of different inflammatory and immune reactions in the skin. UVB and PUVA therapies are shown to decrease ICAM-1 expression. The mechanisms responsible for this effect are not known.
3. Induction of apoptosis. T cells have an increased susceptibility toward UV radiation-induced apoptosis compared to other cell populations such as monocytes or keratinocytes. This provides a partial explanation of the responsiveness of T-cell-dependent diseases to phototherapy and has been demonstrated for UVA1 phototherapy in the lymphocytic infiltrate in atopic dermatitis and for narrowband UVB in psoriasis. UVA1 radiation, but not PUVA, is capable of inducing apoptosis in skin-infiltrating mast cells of patients with urticaria pigmentosa and is associated with mast cell depletion from the skin and longer-lasting remission periods in patients with urticaria pigmentosa.

Effects on Melanocytes

Ultraviolet radiation is known to induce melanogenesis, which is at least in part a consequence of DNA damage and/or its repair. Gradual exposure to UV (artificial or not) and possibly the consequent tanning response may increase the tolerance of patients with certain photosensitivity disorders to ambient sun exposure. UV-induced tanning also decreases the efficacy of phototherapy unless the dose of ultraviolet radiation is gradually increased. For the same reason, darker phototypes (V–VI) are frequently poorer responders to phototherapy for certain diseases.

Narrowband UVB and PUVA are effective in repopulating vitiligo-affected skin with melanocytes. The mechanism underlying this observation may involve stimulation of hair follicle melanocyte proliferation and migration.

Effects on Collagen

One of the major consequences of UVA exposure of the skin is the activation of matrix metalloproteinase-1 (MMP-1), the major biologic activity of which is degradation of collagen. Collagen degradation is the aim of phototherapy use in sclerotic skin diseases.

Phototherapy in Daily Praxis

Prior to phototherapy initiation, patients should undergo detailed dermatological examination to assess the extent of skin lesions and any contraindications to treatment. Absolute contraindications are photoactivated disease photosensitivity, history of phototoxic drugs, history of skin cancer, prior exposure to ionizing radiation or arse-

nic, dysplastic nevus syndrome, and genetic defect in DNA repair mechanisms. On the other hand, the relative contraindications include the phototype I, age less than 10 years for UVB and 16 years for PUVA, the presence of actinic keratoses, and prior or concurrent administration of immunosuppressive drugs. Pregnancy and breastfeeding are contraindications for PUVA. Also, history of cataract, liver enzyme abnormalities, and renal failure should be taken into consideration prior to PUVA initiation.

Prior to PUVA initiation, blood tests including transaminase, creatinine, and antinuclear antibodies are desirable. During the treatment, it is necessary to cover the eyes with goggles, and for 12 h after taking psoralen, patients should protect their eyes from sunlight.

UVB

Ideally, minimal erythema dose (MED) of each patient should be calculated before treatment initiation in order to determine the optimal dose regimen (MED is defined as the minimum dose that causes erythematous reaction 24 h after exposure to radiation). The initial dose should be equal to 70 % of MED. If this dose is well tolerated, each session can be increased by 20 %. However it is noted that increasing the dose by 5 or 10 % per session may be equally effective. If the patient develops erythema, the next session should be canceled or delivered at a reduced dose (50 %). The sessions are conducted two to five times a week. In broadband UVB phototherapy, initial dose is equal to the MED and further increased by 50 %, 40 %, 30 %, etc. It is recommended that patients do not undergo more than 300–450 treatment sessions in their lives.

PUVA

The UVA doses depend on patients' phototype or on the minimum phototoxic dose (MPD), defined as the minimum dose of UVA radiation that causes the least erythema on skin surfaces exposed to increasing doses of UVA radiation after ingestion of psoralens. The test is read after 72 h. To achieve a good therapeutic result, multiple sessions with gradually increasing dose are required. When the desired effect is reached, the frequency of sessions is decreased, and the last dose of UVA is used as a maintenance dose in maintenance therapy if required.

To minimize the risk of carcinogenicity, patients should not exceed throughout their life the 150–200 PUVA sessions and the total dose of 1,200–1,500 J/cm^2. Thirty phototherapy sessions should not be exceeded per treatment cycle with an upper total radiation limit of 100–150 J/cm^2.

Psoralens may be administrated as a topical agent, a bath, or oral agents. The topical application of 8-MOP in the form of a cream, lotion, or ointment has several disadvantages. The uneven distribution of psoralen to the skin can cause severe phototoxic reactions and uneven pigmentation. Additionally, if there are numerous lesions, topical application is laborious and delicate while it does not prevent the appearance of new lesions in previously healthy skin. Thus, the use of topical PUVA with psoralens is indicated only in cases of limited disease or involvement of the palms and soles.

The use of psoralens to bath form offers uniform distribution on the skin surface, with very low levels of drug absorption and fast elimination of free psoralen to the skin. In this way gastrointestinal and ophthalmological side effects are not observed since there is no systemic photosensitization. The process involves immersing the entire body in a solution of 0,5–5 mg 8-MOP per liter of water. The radiation exposure is carried out immediately after the bath.

Systemic PUVA. The 8-MOP is administered orally (0,6–0,8 mg/kg body weight) 1–3 h prior to UVA exposure. The liquid form is absorbed faster than the microcrystalline form. For the 5-MOP, the usual dosage is 1,2–2,8 mg/kg.

Side Effects

Itching, burning sensation, nausea, and phototoxic erythema may result after PUVA treatments. Very rarely eruptions similar to the polymorphous light eruption, subungual hemorrhages, and facial

hirsutism may be seen but resolve after discontinuation of therapy. Long-term PUVA therapy can lead to solar elastosis, lentigines, actinic keratosis, and increased risk of developing skin cancer, especially SCC. The risk of melanoma also seems to be increased for individuals with at least 250 treatments and at least 15 years from the first PUVA treatment. Cutaneous carcinogenicity is a major concern with long-term high cumulative UVA doses. Both DNA damage and PUVA-induced immunosuppression are implicated in the PUVA-induced cutaneous carcinogenicity.

With respect to UVB and nonmelanoma skin cancer, most studies have shown that there is no or little risk beyond that associated with habitual sun exposure with either BB-UVB or NB-UVB phototherapy. Greater than 300 treatments BB-UVB is associated with a modest but significant increase in SCC and BCC.

Reported side effects of UVA1 phototherapy include intense tanning, erythema, pruritus, urticaria, tenderness, a burning sensation, polymorphous light eruption, eczema herpeticum, and bacterial superinfection. The long-term effects are still under investigation.

Diseases

The skin diseases that are amenable to phototherapy are summarized in Table 127.1.

Psoriasis

The narrowband UVB phototherapy is an essential treatment option for moderate to severe psoriasis. It has been shown that narrowband UVB radiation is clearly more effective than broad spectrum, as narrowband-treated patients have faster healing of skin lesions and longer periods of disease remission. On the other hand, the effectiveness of narrowband UVB seems to be comparable to oral PUVA and superior to bath PUVA. Thus, narrowband UVB is preferable than PUVA as it does not involve the use of psoralens, does not require eye protection after treatment, costs less, and can be used during pregnancy and childhood.

After achieving a good therapeutic result with photo(chemo)therapy, patients are often treated with maintenance sessions (twice a week for 1 month and then weekly for 1 month). Some authors, however, suggest maintenance therapy only in cases of known short relapses.

A combination of phototherapy with topical or systemic factors in order to achieve higher cure rates, longer disease-free intervals, and less risk of carcinogenesis is often used in psoriasis patients.

Local agents that can be used are anthralin, vitamin D analogues, retinoids, glucocorticoids, and emollients. The vitamin D analogues have anti-inflammatory action and also slow down cellular growth rate. The surface being treated should not exceed 30 % of the total body surface to avoid systemic side effects of the percutaneous absorption

Table 127.1 Phototherapy-amenable diseases and the type of phototherapy they are responsive to

	PUVA	UVB	NB-UVB	UVA	UVA1	Excimer
Psoriasis	+	+	+			+
Vitiligo	+		+			+
Atopic dermatitis	+		+		+	
T-cell lymphoma	+		+		+	
GVHD	+					
Pruritus		+	+			
Morphea						
Urticaria pigmentosa	+				+	
PLE	+		+			
Pityriasis lichenoides	+	+	+			

of the drug (such as hypercalcemia with accompanying nephrocalcinosis). The combination of vitamin D analogues with UVB phototherapy is more effective than phototherapy alone. Tazarotene is a topical retinoid effective in plaque psoriasis. Its use in combination with UVB phototherapy seems to improve the efficacy of treatment and to contribute to a rapid improvement. Topical corticosteroids may be useful in areas not reached by UV radiation, such as the head, the perineum, and the navel or on areas resistant to phototherapy. Furthermore, they can be used in particular inflammatory lesions, in order to achieve a rapid improvement.

Systemic factors that are administered in combination with phototherapy are retinoids, methotrexate, and rarely glucocorticoids. Retinoids increase the effectiveness of phototherapy acting synergistically and reduce the risk of carcinogenesis. Their administration starts 5–10 days before the initiation of photo(chemo)therapy and continued throughout the course of treatment. Methotrexate can reduce the required length of treatment with UV, the number of sessions, and the total dose of UV. Moreover, it may be effective in cases that do not show improvement only with PUVA or UVB phototherapy. However, methotrexate can act synergistically with UV to increase the risk of skin cancer and therefore should not be used for long periods. The use of oral corticosteroids is restricted only in special severe cases such as generalized pustular psoriasis. The combination of phototherapy with cyclosporin is not recommended since both substances increase the risk of developing skin cancer from UV radiation.

Excimer laser and nonlaser (MEL) light sources (308 nm) are also used for treatment of mild to moderate localized psoriasis. This localized phototherapy is indicated for patients with lesions localized in places difficult to access in other treatments (elbows, knees, palms, soles) or persistent psoriatic plaques that do not respond to other treatments. It cannot be used for large surfaces as the spot is small (2 cm^2). Advantages include using only the affected area and thus possibly reducing the cumulative dose of UV and the smallest number of sessions required.

Cutaneous T Lymphoma

The UV radiation causes apoptosis of T lymphocytes. Thus, phototherapy plays an important role in the treatment of diseases with involvement of T lymphocytes. UVA1, PUVA, and narrowband UVB may be used. The first appears to be as effective as the second but with fewer side effects, while the third is less effective and appropriate for the early stages of mycosis fungoides (IA, IB, IIA). Regimens with high and medium doses of UVA1 are effective in the treatment of stages IA and IB of mycosis fungoides. For the treatment of erythrodermic form (stages IB, IIB, III), high doses are required. PUVA dosage and frequency of sessions for cutaneous T-cell lymphoma are similar to psoriasis. The initial treatment sessions are followed from a 2-month maintenance therapy (two sessions per week for a month and one session per week for the next month). Subsequently, the patient is monitored once a month and then every 2 months. Treatments can be repeated. PUVA is an excellent treatment option for early-stage disease and achieves long disease-free periods. In more advanced stages, PUVA appears to improve quality of life and prolong survival when combined with other factors such as retinoids, bexarotene, and interferon-A2A.

Vitiligo

PUVA was the most common treatment for vitiligo in the past. However, studies have shown that the narrowband UVB phototherapy achieves repigmentation of vitiligo lesions to many patients, even in those with phototypes IV and V, as well as children. If no improvement is seen within 6 months, the narrowband UVB phototherapy should be discontinued. It should be noted that as in trials with PUVA, some body parts like the fingers and the tips of the hands and feet had poor response. Targeted phototherapy devices (excimer laser or lamp) with irradiation peak at 308 nm are particularly suitable for treating localized disease.

Atopic Dermatitis

The UVA1 phototherapy is effective as monotherapy in atopic dermatitis, particularly in acute, severe forms of the disease. UVA1 phototherapy appears superior to the combined UVA/UVB radiation. Moreover, it is significantly more effective than topical corticosteroids in comparison made the tenth day of treatment. The effectiveness of the treatment is dose dependent. Regarding the chronic form of the disease, UVA1 low-dose radiation may be used; however the narrowband UVB and the combined UVA/UVB give better results. The broadband and narrowband UVB phototherapy, combined UVA/UVB, and UVA broad spectrum seem to be effective in mild and moderate forms of atopic dermatitis used in combination with topical corticosteroids. The narrowband UVB phototherapy appears to have similar efficacy with PUVA. PUVA often requires greater number of sessions for complete healing of atopic dermatitis compared with other skin diseases. There is a high rate of early relapse indicating the importance of maintenance therapy. The combination of PUVA with local corticosteroids appears to be more effective than PUVA alone in maintaining remission.

Urticaria Pigmentosa

UVA1 phototherapy ameliorates urticaria pigmentosa, reducing urticarial lesions and pruritus. Urinary histamine levels also decrease in response to UVA1. PUVA leads to improvement of skin sessions, and possibly improvement of systemic symptoms. Recurrences respond to phototherapy as well as the original lesions. Since treatment of cutaneous mastocytosis has been unrewarding with other modalities, phototherapy, although not curative, is a good choice when patients' quality of life is impaired.

Polymorphous Light Eruption

For polymorphous light eruption, PUVA and narrowband UVB are effective in preventing the appearance of the disease. Sessions are held three to four times a week for 3–4 weeks, at the beginning of spring. The effect appears to last 2–3 months after loss of tanning. In order to maintain the therapeutic effect of phototherapy, patients should be regularly exposed for short periods in the sun.

Pruritus

Both the narrowband and the broadband UVB phototherapies appear to be effective in various types of pruritus, especially in cases related to diabetes, liver disorders, and idiopathic.

Lichenoid Pityriasis and Lymphomatoid Papulosis

Both UVB phototherapy and PUVA seem to be effective for the treatment of lichenoid pityriasis and lymphomatoid papulosis. PUVA is most probably superior to UVB and its use is recommended in chronic forms of the disease, resistant to UVB.

Localized Scleroderma (Morphea)

UVA1 for localized scleroderma significantly reduces the thickness of skin lesions and increases the elasticity of sclerotic plaques. The efficiency is dose dependent. PUVA is also effective. Both treatments may be applied to sclerotic lesions of chronic graft-versus-host disease. Narrowband UVB is also effective for superficial widespread lesions.

Chronic GVHD (Graft-Versus-Host Disease, GVHD)

Both chronic and acute forms of the disease seem to respond positively to PUVA. An improvement of lichenoid rash even in patients who have not improved with immunosuppressive therapy is expected. Sclerotic lesions appear more resistant.

Gradual increase in dose should not exceed 0,5 J/cm^2 every second to fourth session. The sessions are conducted three to four times a week.

Sclerotherapy

128

Simone Napoli, Matteo Zanardelli,
Angelo Massimiliano D'Erme, and Torello M. Lotti

Key Points

- *Sclerotherapy* consists of intravenous injection of sclerosing agents for the treatment of cosmetic leg veins.
- Clinical examination of patients is fundamental before beginning sclerotherapy in order to determine the feasibility of this treatment as a primary mode.
- By understanding venous pathology and aetiology and by choosing the proper sclerosant and right technique for the vein being treated, a successful outcome will be achieved.
- Sclerotherapy agents can be divided in three classes: hyperosmotic agents, detergents and chemical irritants.
- In order to minimize side effects and reduce their incidence, it is necessary for physicians to understand the potential causes, to advice the patients and to be able to treat.

General Principles

Sclerotherapy consists of intravenous injection of sclerosing agents for the treatment of cosmetic leg veins. Several studies have reported that sclerotherapy has been successfully used for the treatment of minor branch vein varicosities not associated with saphenous incompetence.

Varicose veins are enlarged, tortuous veins that have lost their elasticity. They have a calibre greater than normal (more than 2 mm in diameter) and are placed in the deep derma and in the subcutaneous tissue. It is possible to distinguish primary and secondary varicose veins. The latter originate from a thrombotic occlusion of one or more deep veins and are often associated with abnormal valvular function.

The superficial veins of the legs are the most frequently involved. Telangiectases are small (diameter less than 2 mm), with visible blood vessels placed in the dermis that are permanently

dilated. Women suffer more from vein problems: it has been estimated that more than half of European and American women are affected by telangiectases.

Varicose Veins and Telangiectases

The aetiology is multifactorial: various factors could be responsible for their pathogenesis such as hormones, pregnancy, obesity, frequent constipation, prolonged standing and individual problems, i.e. sex, hereditary, etc. For example, in pregnancy venous relaxations due to increased hormone levels, expansion of blood volume and increased venous pressure especially in the limb where the iliac vein is compressed by the enlarged uterus are causes of varicosity.

Thrombophlebitis leads to formation of varicose veins by destroying venous valves. Studies have suggested that an increase of venous pressure can induce leucocyte accumulation and subsequent free radical production and inflammatory response. Pathogenesis of telangiectases is related to many different pathological processes affecting the blood vessel endothelium and its supporting structures. Some situations are often connected with telangiectases such as the presence of varicose veins, hormonal factors and physical factors.

Clinical Features and Course

Superficial venous insufficiency is a common problem in young and working people.

Clinical examination of patients is fundamental before beginning sclerotherapy in order to determine the feasibility of this treatment as a primary mode.

Varicose veins are visible as dilated, tortuous, superficial veins, often thick walled. Most patients with varicose veins and chronic venous insufficiency have specific symptoms and signs as chronic pain, oedema, inflammation and/or ulceration.

However, in most patients, telangiectases may be the only abnormality noted on clinical examination, and they are not associated with symptoms. They appear on the skin as red, small, linear, stellate or punctate markings, usually treated for aesthetic purpose.

Diagnosis

Diagnosis of superficial venous insufficiency is usually based on clinical observation.

The need for laboratory data should be assessed on an individual basis. They are necessary usually in patients with hypercoagulability or severe venous symptoms.

The most commonly used tests to investigate the blood flow in the superficial and deep venous system are duplex scanning and venous Doppler study. Phlebography, photoplethysmography and light reflection rheography are other investigations usually reserved for those patients with venous symptoms and/or large vessel incompetence or large numbers of spider telangiectases indicating venous hypertension.

Instrumental examinations became useful in order to find a correct therapeutic strategy and to follow up the treatment.

General Principles of Treatment

The recommended approach to the sclerotherapy should be the following:

- If the patient reports symptoms as leg pain, itching and heaviness, vascular testing is indicated.
- Vascular testing is also indicated if the patient does not refer symptoms but has at least two of the following signs: oedema, vessel diameter greater than 4 mm, corona of lower extremities, changes of pigmentation, dermatitis, ulcer and fibrosis.

The treatment of varicose and telangiectatic leg veins can be approached in a logical and systematic way. Venous regions or entire abnormal superficial venous networks related to incompetent perforators should be injected in a single session, instead of randomly injecting as many veins as possible in a given period of time. Each patient

requires differing amounts of time for this systematic approach.

It is important not to limit treatment to telangiectatic veins but to consider the complete system.

Sclerosing Solutions

In the literature several studies dealing with the use of different sclerosing solutions for the treatment of both functional and cosmetic vein disorders are present. Each solution has a unique safety and efficacy profile. The type, concentration and quantity of solution selected are determined by the type and/or site of varicose vein injected.

There are three classes of sclerosant agents based on their mechanism of action: hyperosmotic agents, detergents and chemical irritants.

The purpose of sclerotherapy is not merely to achieve thrombosis of the vessel, which per se may be amenable to recanalization, but definitive transformation into a non-recanalizable fibrous cord.

The other depends on the endothelial cell surface alterations with direct damage of the endothelial cells resulting in inflammation and thrombus formation. They have the ability to denature biological molecules irreversibly within the vein wall.

Hyperosmotic agents as hypertonic saline (23.4 % sodium chloride) with or without lidocaine and heparin are dehydrating sclerosing agents commonly used. Hypertonic saline causes dehydration of endothelial cells by osmotic action with resultant injury, inflammation and thrombus formation. At the recommended dose of 10 mL per treatment session, it is effective and extensively used in Europe for the treatment of minor varicosity and telangiectases. The Food and Drug Administration (FDA) of the USA has approved it only as an abortifacient rather than a sclerotherapy agent. It may cause moderate pain on injection with occasional muscle cramps and risk of ulceration at the site of extravasation. One of the major advantages of this agent, when used pure, is the absence of adverse allergic reactions.

Sclerodex (10 % sodium chloride, 25 % dextrose and 1 % phenylethyl alcohol) is a dehydrating agent that is very effective and often used in Europe for the treatment of minor varicosity and telangiectases. The low concentration of chloride, associated with anionic dextrose, decreases injection pain and muscle cramps.

Sodium morrhuate derived from cod liver oil and sodium tetradecyl sulphate (STS) are other sclerosing solutions also approved by the FDA. They belong to the detergent class and cause vascular injury through the alteration of the surface tension around the endothelial cells. The first is rarely used because of its side effects (among which are anaphylactic reactions). The sodium tetradecyl sulphate (STS) is often used for varicose veins under ultrasound guidance. Furthermore it can be used in a dilute form for the treatment of telangiectases. The use of STS in a sclerosing foam (Tessari method) mixing 1 part liquid STD and 5/6 parts air was recently indicated to give good results.

A recent study of Subbarao et al. (2013) evaluated the safety and efficacy of STS sclerotherapy in the treatment of varicose veins and its dermatological complications.

The sclerosant was diluted to required concentrations using 0.9 % normal saline. Commonly used concentrations were 0.3–0.5 % of STS depending on the size of the veins. 0.75 % STS was used to inject the perforators.

In the study, 50 patients were included. At the end of the treatment, pain improved in 29 patients out of 38 cases (76 %), dilated veins reduced in 45 (90 %) out of 50 cases, oedema reduced in 7 of 15 patients (46 %), ulceration reduced in 10 (66 %), pigmentation responded poorly with 8 cases showing response out of 42 cases and eczema showed a good response in 33 (82.5 %).

Polidocanol (hydroxy-polyethoxy-dodecane) (POL) (0.25 %) is a surface tension-acting agent, with the same mechanism of action of sodium morrhuate and STD.

Lastly, chemical irritants, as chromated glycerine (72 % glycerine mixed with 1 % lidocaine and 1:100,000 epinephrine combined 2:1), which injure cells by causing a corrosive secondary to

the metal component, are indicated for the treatment of fine leg telangiectases (up to 1 mm of diameter) (Zaulyanov-Scanlan 2009).

Interestingly, an Italian–American study proposed a new therapeutic approach consisting in the use of polymerized hyaluronic acid (HA) mesotherapic injections following sclerotherapy in the areas of the skin affected by telangiectasia in patients without major vein insufficiency (Iannitti et al. 2012).

This pilot study suggests that the prolonged persistence of cross-linked HA, across the microvascular venous areas, is able to induce a stronger stromal tissue, thus preventing relapse.

The optimal sclerosant concentration may vary with the diameter of the veins being treated. In fact if the concentration is too weak, it can cause an insufficient damage to the endothelium followed by a thrombus that eventually may recanalize. If the concentration is too strong, side effects, as ulceration and hyperpigmentation, can occur.

In case of pregnancy, sclerotherapy should never be used. These agents are at least locally toxic, and no studies have been done to prove their safety in pregnant women.

Technique

With the patient standing, the veins must be carefully marked out and the needles inserted into the varicosities.

The sclerosing solution is injected into the vessel with a 30-gauge or smaller needle to maintain the needle parallel to the skin surface. The vessel is carefully cannulated under magnification. Then a small amount of sclerosing solution is injected until the vessel and interconnecting vessels are filling. In order to assess whether the vessel has been cannulated, it is recommended to inject a small amount of air before the sclerosing solution. The site of injection depends on individual experience. Normally, two or three points are selected on a very long anterolateral thigh vein, whereas one injection will suffice for short tributaries. The sclerosant quantity per injection should be no more than 0.1–1.0 mL.

Concentrations utilized range from 0.2 to 3 %, depending on the vein size and on the volume injected: when a higher concentration is injected, a smaller volume would be used.

Zummo (1991) tried to standardize quantities and concentrations of different sclerosing agents depending on the type of vein malformations to treat, suggesting that therapy must be adapted for each patient. The Tessari and Tessari/double-syringe system methods are recommended for the generation of foam sclerosant. Air is the most accepted gas component for the generation of foam sclerosant for all indications. A mixture of carbon dioxide and oxygen may also be used. The preferred ratio of liquid sclerosant and gas for the generation of a foam sclerosant is 1:4. The recommended maximum foam volume per leg and session (given in a single injection or in several injections) is 10 mL. The viscosity of the foam should be directly proportional to the calibre of the varicose veins.

Empty Vein Technique

The empty vein technique is used in the sclerotherapy of varicose veins. Firstly patient should be placed supine. Then the leg should be kept up until the complete emptying of the veins. A major advantage of this technique is the minimal dilution of the sclerosant agent.

Post-sclerotherapy Compression

In general telangiectases less than 1 mm in diameter may require no compression. However some veins may be more effectively treated with compressive dressing.

This may be accomplished by multiple techniques including bandaging and stockings. Bandage dressing could be elastic or not. The nonelastic are more commonly utilized. Compression bandages are recommended for patients with oedema. Graduated compression stockings are available in different models wherein the choice depends on the physical attributes of the injected leg as well as the type of varicosity

treated. The most important part of the stocking is below the knee, where the standing venous pressure is the highest. Although effective for symptom control, stockings may not be practical in elderly persons, for whom the application can be difficult; in obese patients, in whom fitting can be problematic; and in patients with skin damage.

Graduated stockings are usually left on the leg during the entire time of treatment or removed when the patient is lying down.

Immediate and sustained compression has considerable advantages: decrease of the volume of intraluminal thrombus and minimization of the duration required for complete resorption of the vein. In fact when a vein has undergone mural disruption, it still has enough intact long intraluminal space to be distended by blood which rapidly becomes coagulated.

The duration of compression depends on the size of the vein as well as its intraluminal venous pressure. Normally, the time of compression ranges from 2 to 8 weeks after treatment. However compression enhances the results of sclerotherapy that are directly correlated with duration of compression. Further it leads to a reduction of post-sclerotherapy hyperpigmentation.

The degree of compression applied can vary from 30 to 50 mmHg and is evaluated on the basis of hydrostatic pressure within the vein: the greater the hydrostatic pressure, the greater must be the externally applied compression. Although the evidence is limited, patients with uncomplicated varicose veins are prescribed stockings that compress at 20–30 mmHg to help with pain and oedema control. Patients with venous stasis ulcers need 30- to 40-mmHg stockings.

Complications

Managements of side effect can be challenging. Complications of sclerotherapy are partly drug specific and include allergic reaction. Some of them are acute, as pain and cramping, and resolve also quickly. Other common and cosmetically significant side effects of sclerosing agents, as hyperpigmentation, telangiectatic matting and cutaneous necrosis, are more chronic.

Hyperpigmentation is caused by haemosiderin extrusion, from an ectatic blood vessel treated by sclerotherapy. It is not caused by melanocytic deposition and it thus does not respond to topical bleaching agents.

It appears related to solution strength, vessel fragility, site of vessel treated, injection pressure and the type of solution used. The role of elevated serum ferritin level in post-sclerotherapy pigmentation is a matter of debate. Scott and Seiger (1997) consider the ferritin levels irrelevant. Further studies are needed to better understand it.

The general incidence of hyperpigmentation ranges from 10 to 30 %. Although it may persist for months, its presence rarely deters patient from continuing treatment. Spontaneous resolution occurs in 70 % at 6 months and 99 % within 1 year.

Telangiectatic matting is a recognized complication occurring in 15–20 % of patients treated. It represents a revascularization in the treated area, with vessels much smaller than the original sclerosed vessel. The exact mechanism of the phenomenon remains unknown. However it seems to play an important role in reactivation of inflammation and/or a neo-angiogenic mechanism. Telangiectatic matting is usually not permanent and resolves spontaneously within 3–12 months.

Both hyperpigmentation and telangiectatic matting may benefit from the treatment with intense pulsed light (IPL) (Zaulyanov-Scanlan 2009).

It is possible that under ideal circumstances or in the absence of error operator, cutaneous necrosis may occur with the injection of any sclerosing agent. It has been hypothesized that this phenomenon could be due to the presence of arteriovenous shunts under telangiectases. To prevent skin ulceration, it is suggested to administer to a single site a maximum of 0.2 mL of sclerosant.

When sclerosant extravasation occurs, dilution is needed immediately. However with careful technique and appropriate treatment of extravasation, necrosis can almost be avoided.

Thrombi may be seen within 1 week of injection, especially in larger (1–4 mm) treated vessels. They may produce pain that can be relieved by incising the vessels and expressing the thrombus.

Small ulcers develop in approximately 1 in 70,000 patients but are usually seen only when

skin is already damaged. The only systemic reactions that have been seen are allergic, such as urticaria, but also anaphylactic reactions. Sodium morrhuate and Sotradecol have significant allergenic potential, while polidocanol has only a 0.01 % reported rate of allergic reaction, and with Sclerodex and hypertonic saline, no allergic reactions have been seen yet.

In order to minimize side effects and reduce their incidence, it is necessary for physicians to understand the potential causes of complications following sclerotherapy:

- To advise patients prior to beginning the treatment on the common risk involved in sclerotherapy and on the relative incidence
- To understand the concept of minimal sclerosant concentration and how it can help to choose sclerosing solution concentrations to minimize risks

Skin Resurfacing with Carbon Dioxide Laser

129

Stefanie Luebberding
and Macrene Alexiades-Armenakas

Key Points

- Skin aging manifested by rhytides, laxity, and photoaging has been treated by laser skin resurfacing using a large variety of modalities, with carbon dioxide (CO_2) laser proving to be the gold standard for the past few decades.
- Standard ablative CO_2 laser resurfacing, while still the most highly effective, is associated with a greater side effect profile and risk of complications. For these reasons, fractional ablative CO_2 laser resurfacing has emerged as a highly effective, yet far safer, top tier treatment for rhytides and photoaging of the aging skin.
- In this chapter, we will address background information on standard and fractional CO_2 laser resurfacing; proper patient selection; pre-, peri-, and postoperative instructions; treatment, prevention, and management of complications; and clinical efficacy.

General Principles

A beautiful face is considered to possess smooth and flawless skin, an even complexion, and firm facial features. Beauty is strongly associated with healthy and youthful skin. Nevertheless, over the course of a lifetime, the body's outer shell changes significantly; genetics, aging, sun exposure, and lifestyle factors including nutrition, alcohol consumption, and smoking habits, as well as skin diseases and lesions, may contribute to visible skin changes. Consequently, wrinkles, brown spots, blotchy skin coloring, skin laxity, and scars become visible. However, since the desire for eternal youth and beauty is high and still increasing worldwide, the market for cosmetic and aesthetic treatment modalities is booming also.

In the past three decades, numerous techniques have been developed including chemodenervation with botulinum toxins or skin augmentation using injectable soft tissue fillers. Whereas these methods treat certain areas of the skin specifically, including wrinkles or volume

loss, they do not achieve a uniform improvement to the entire facial skin surface. In contrast, skin resurfacing procedures globally improve the overall appearance of the entire face.

Skin resurfacing employs a variety of techniques, ranging from laser-, light-, to other energy-based treatments, but may be considered to also encompass chemical peels or dermabrasion. Common to all these techniques is that they use either thermal, mechanical, or chemical methods to induce a controlled dermal injury on the skin surface, prompting it to heal itself by creating new skin cells. The skin-rejuvenating effect therefore depends on the method used. Among the various skin resurfacing options, carbon dioxide (CO_2) lasers have long been established as the gold standard. CO_2 lasers are one of the highest-power lasers available on the market and have evolved since their inception in the 1990s into ultra-pulsed and fractional varieties.

Mechanism of Light: Tissue Effect

Skin resurfacing with CO_2 lasers, as well as other laser- and light-based modalities, is effective in skin rejuvenation and induces skin remodeling with subsequent new collagen fiber formation. It is also theorized that collagen shrinkage and wound-healing-induced fibroplasia are mainly responsible for the cosmetic improvement of the skin.

The biological effect of laser light can therefore be achieved by heating the skin tissue. While heating, light energy is absorbed within the chromophore and converted into thermal energy. This process of deep tissue heating results in a provoked dermal injury. Thereby, the total depth of dermal injury is the sum of the ablated skin area plus the depth of the RTD. Depending on the energy density, the pulse duration, and the heat conduction within the target, various effects, such as coagulation, vaporization, or shrinkage, can occur.

The photothermal effect results further in water vaporization and denaturation of collagen fibers followed by a wound-healing process. Recently, it has been shown with real-time temperature feedback experiments that denaturation temperature of collagen ranges between 65 and 70 °C but is also dependent on the time of laser light exposure; in general, for every 5 °C decrease in temperature, a tenfold increase in time is needed to achieve the same degree of denaturation (Alexiades-Armenakas et al. 2013). However, once collagen fibers have been denatured by laser-generated heat, collagen rapidly contracts as fibers shrink to one-third of their length resulting in immediate skin tightening.

Thermal injury of deep dermal collagen induces a vigorous healing process leading to dermal remodeling. Wound healing is initiated characterized by extremely high levels of collagenases, which degrade the fragmented collagenous matrix. This process is followed by proliferative phase including angiogenesis, collagen deposition, granulation tissue formation, and a rapid reconstruction of the epidermis. A prolonged period of dermal neocollagenesis of up to at least 6 months follows.

Laser Skin Resurfacing with CO_2 Laser

In 1964 Kumar Patel invented the carbon dioxide laser (CO_2), one of the earliest gas lasers developed. The CO_2 laser emits a 10,600 nm wavelength and operates in the infrared spectrum which is highly absorbed by intra- and extracellular tissue water allowing the vaporization of living tissue at the focal point. The CO_2 lasers of the 1960–1970s emitted a continuous and uninterrupted wave light which made these lasers highly usable for virtually bloodless photo-excision and coagulation of superficial skin lesions, such as warts, actinic cheilitis, or keloids.

The use of CO_2 laser technology for cosmetic and aesthetic indications was then introduced in the 1980s, when continuous-wave CO_2 lasers were first used to resurface photodamaged skin in a procedure named “thermabrasion.” However, early continuous-wave CO_2 laser technology was very effective in rejuvenating aged skin; the

continuous emitted and uninterrupted beam of light also led to an imprecise ablation and dermal heating of the skin tissue consequently increasing the risk for unwanted side effects, such as severe thermal damage and scarring.

The theory of selective photothermolysis, proposed by Rox Anderson and John Parrish in 1983, revolutionized the use of lasers in dermatology. The theory refers to the precise heating of chromophores, such as melanin, water, or oxyhemoglobin, using a specific wavelength of laser light with the intention of absorbing light into the specific target area and destroying structures within the skin, without affecting the surrounding tissues. However, in order to successfully conduct selective photothermolysis, the parameter wavelength, pulse duration, and fluence need to be tailored to the specific properties of the target chromophore and the clinical indication to obtain optimal outcomes with minimal effects on surrounding tissue (Bogdan Allemann and Kaufman 2011).

Based on the concept of selective photothermolysis, two CO_2 laser approaches were developed at the end of the 1980s/beginning of the 1990s utilized for the purpose of a safer and precisely controlled skin resurfacing, the high-energy pulsed CO_2 laser that delivers energy in individual pulses and the second type, the scanned CO_2 laser, that achieves well-controlled tissue ablation by rapidly scanning the focal spot of a focused CW CO_2 laser over the skin using an opto-mechanical flash scanner.

Fully Ablative CO_2 Laser

The CO_2 laser emits a monochromatic 10,600 nm wavelength, which is strongly absorbed by water, resulting in full ablation of the epidermis and part of the dermis. The penetration depth for CO_2 waves is dependent upon the water content in the dermal tissue. The beam diameter plays a role; with pulse duration of less than 1 ms and an energy fluence of 5 J/cm^2, approximately 90 % of carbon dioxide laser energy is absorbed in the initial 20–30 μm of skin, and residual thermal damage (RTD) can be confined to a layer of about 100–150 μm of tissue (Alexiades-Armenakas et al. 2008). At these settings, the skin temperature reaches approximately 120–200°°C and produces a thermal necrosis that is sufficient to seal small dermal blood vessels and lymphatics but yet narrow enough to reduce the prevalence of scarring. Smaller beams of 100–300 μm in diameter achieve high fluences and more rapid tissue vaporization, whereas larger beam sizes of greater than 2 mm induce non-vaporization heating and increase the risk of deep thermal damage.

Fully ablative CO_2 laser skin resurfacing treats mild, moderate, and severe signs of photoaging of the skin. Clinical rating by investigators shows a significant improvement of photoaged skin up to 86 %. Wrinkle reduction assessed with optical profilometry and microscopy confirms these results and found significant reduction in mean wrinkle depth of 91 %. In accordance to evaluate long-term results, Manuskiatti et al. and Ward and Baker examined and interviewed up to 104 subjects. With an average follow-up period of 24 months (range 12–44 months), the researchers observed high patient satisfaction ratings and significant persistence of wrinkle score improvement. Long-term histologic features confirm the long-lasting nature of the clinical improvement and demonstrated continuing, progressive improvement in solar elastosis deep in the dermis.

While fully ablative CO_2 is very effective in treating all signs of photoaging, it is also known for a significant risk of severe side effects such as permanent dyschromia, infections, hypertrophic scarring, as well as downtime and pain. About 100 % of patients further experience edema, burning, crusting, and erythema lasting up to 12 months after treatment.

The knowledge about these possible adverse events combined with further innovations in laser-based treatment technologies significantly changed skin resurfacing procedures in recent years. Fully ablative CO_2 laser skin resurfacing has lost its importance in the treatment of skin aging in the past decade and is currently used mainly in the removal of benign skin lesions and carcinomas, nevi, rhinophyma, keloids, or scars.

Fractional Photothermolysis Using CO_2 Lasers

In 2004, Manstein and colleagues introduced a dramatic improvement in laser resurfacing, called fractional photothermolysis (FP). Unlike conventional lasers, FP treats only a fraction of the skin, leaving up to a maximum of 95 % of the skin uninvolved. This is achieved by inducing small three-dimensional microscopic thermal zones (MTZ) of epidermal and dermal tissue by thermal damage or ablation. Depending on wavelength and pulse energy, the micro-columns can penetrate the skin to varying depths of up to 1,300 μm with a diameter usually smaller than 400 μm. The chosen parameters of energy per MTZ and the density of MTZs per square centimeter further influence the treatment coverage of the skin which can be anywhere from 3 to 40 %.

In 2007 Hantash et al. first described the use of fractional CO_2 on human skin in vivo and explained histological changes due to fractionated thermal damage. Immediately after FP treatment, MTZs appear as distinct columns of thermal coagulation surrounded by undamaged tissue permitting a rapid repair of the affected skin. Epidermal coagulation then activates epidermal stem cells that transiently increase proliferation for a rapid replacement of the damaged epidermal tissue which is completed about 3 days post treatment. Approximately 1 week after FP, collagen type 3 synthesis begins promoting dermal remodeling until MTZs are completely replaced after approximately 3 months.

Similar to fully ablative CO_2 laser skin resurfacing, fractional ablative CO_2 lasers also target the chromophore water, allowing selective thermal damage to various water-rich targets such as epidermal keratinocytes, collagen, and blood vessels throughout the skin (Geiges 2011). The first fractional CO_2 laser entered the market in 2007, promising a more rapid repair of the affected skin resulting in an optimized ratio of efficacy, downtime, and side effects.

Procedure

Patient Selection

As with any cosmetic treatment, successful outcome relies on proper patient selection. The ideal candidate for CO_2 laser skin resurfacing should be healthy and with lightly pigmented skin (Fitzpatrick's skin types I–III). However, since the wavelength of CO_2 laser is not absorbed by melanin, it has been used to treat darker skin types with effective and safe results. However, the possibility for postinflammatory hyperpigmentation should be discussed with the patient and may be averted by the use of lower treatment settings. In managing patient expectations, the reported studies demonstrate that the most superficial wrinkles and photodamage are usually eliminated with fully ablative and greatly improved with fractional CO_2 laser resurfacing, while the more severe aging signs are improved. It is imperative to modulate the patient's expectations and to convey a full understanding of the potential risks, complications, and side effects of the procedure and the requirement for postoperative care.

Contraindications to any version of CO_2 laser resurfacing include: active bacterial or viral infections, the use of isotretinoin within the last 12 months, pregnancy and breastfeeding, as well as ablative or invasive procedures in the treatment area within the prior 3 months (Alexiades-Armenakas et al. 2008; Manstein et al. 2004). Additional contraindications include patients with a history of hypertrophic or keloidal scarring, increased photosensitivity, and disturbed wound-healing process (e.g., patients with diabetes mellitus) or an immunosuppression.

Preoperative Care

All patients should be premedicated with oral antiviral medications (e.g., famciclovir) for *Herpes simplex* prophylaxis starting 1 day

prior to the procedure and for 5 days post treatment. Additionally, the author (MAA) recommends also prescribing antibacterial antibiotics (first- or second-generation cephalosporin such as cephalexin) starting 1 day prior and continuing for 5 days post treatment. One report suggests that prophylactic facial cleansing with chlorhexidine twice daily for 3 days preoperatively may further decrease the incidence of postoperative infection; however, such infections are exceedingly rare in the author's (MAA) experience. Patients should be advised to stop taking anticoagulants at least 2 weeks prior to treatment.

General Principles of Treatment

Prior to CO_2 laser skin resurfacing, the skin area is cleaned with a mild cleanser before baseline clinical photographs are taken. Topical anesthetic (lidocaine/prilocaine) is applied for a duration of 1 h. Following removal of the topical anesthetic, the treatment area should be cleansed with 70 % alcohol. In addition to topical anesthesia, forced cold air provided by a Zimmer Cooler (LaserMed, Monroe, CT) or similar device is recommended for perioperative pain control (Manstein et al. 2004). Immediately post treatment, cold compresses are applied.

Numerous fractional CO_2 devices are available on the market, each with recommended parameters. With increasing power or energy, the ablative depth increases (see (Manstein et al. 2004)). The spacing of the micro-columns should be placed conservatively to avoid the rare instances of hypopigmented scarring that may occur. In addition, the pulse duration will impact the degree of collateral thermal damage. It is prudent to be very familiar with the recommended energy settings recommended for each grade of skin aging severity (see reference (Alexiades-Armenakas 2006)), with the understanding that the time needed for postoperative recovery will increase with increasing parameter intensity.

Postoperative Care

Postoperative care is of the utmost importance and significantly lowers the risk infections and scarring and will promote rapid healing. The standard therapy advises patients to use a topical wound healing, in most cases petrolatum ointment, for up to five times a day for at least 5–7 days after treatment to promote the skin barrier function. Reepithelialization is usually completed after 3–6 days, after which patients may apply makeup or sunscreen. Patients are advised to avoid significant sun exposure for at least 30 days post-procedure to avoid pigmentary changes. Although it is generally accepted that the use of SPF can significantly reduce the risk for postinflammatory dyschromia, the conventional treatment concept does not recommend patients to apply sunscreen from day 1 due to the potential risk for allergic irritations. However, a recently published meta-analysis indicates a relatively lower risk for SPF-related reactions, and yet Wanitphakdeedecha et al. recommend using SPF at day 1. They were able to show that the use of a sunscreen starting on the first day after ablative fractional skin resurfacing can decrease the incidence of postinflammatory hyperpigmentation after laser treatment. However, the author (MAA) avoids sunscreen application until reepithelialization is complete (Figs. 129.1, 129.2, 129.3, and 129.4).

Besides conventional treatment options, recently published study indicates that the injection of platelet-rich plasma (PPR) immediately after treatment might be beneficial to improve the wound-healing process and to reduce the risk for transient adverse effects. However, the effectiveness has to be proven in large randomized controlled trials.

Clinical Efficacy

Numerous clinical studies have demonstrated CO_2 laser resurfacing to be effective in treating all signs of photoaged skin, such as fine lines and

Figs. 129.1, 129.2, 129.3, and 129.4 CO_2 laser skin resurfacing: pre and post treatment

coarse wrinkles, pigment changes, sallow complexion, as well as skin roughness. Preferred treatment area is the face, but also more sensitive areas such as neck and chest may be treated with lower settings with fractional CO_2 laser resurfacing with excellent outcomes. Hands with photoaging may be treated as well with moderate improvement.

Investigator scoring of a 32-patient study by the author using a quantitative grading system demonstrated a greater than 50 % improvement after fractional CO_2 treatment on the face in the vast majority of subjects at 6-month follow-up. Those with the categories of photoaging of dyschromia and solar elastosis and rhytides demonstrated the greatest improvement.

Alexiades-Armenakas and colleagues subsequently conducted a multicenter trial of fractional CO_2 laser resurfacing for the treatment of rhytides, photoaging, and acne scars on the face. Evaluations

were conducted using a quantitative comprehensive grading scale (Table 129.1). The clinical findings demonstrated a 0.42- to 1.63-grade improvement on a 4-point grading scale, which correlated in direct proportion with power, pitch, and dwell time. Recovery time ranged between 3 and 10 days, also proportionate to laser parameter intensity. No adverse events were observed. In that study, striae albae were also treated with variable results (Tables 129.1 and 129.2).

A study from Kohls et al. confirms these results and further indicates that the best results regarding wrinkle size and depth were found for the cheeks (−58.3 %, $p = .018$, and −51.3 %, $p = .018$) and the periorbital area (−35.1 %, $p = .000$, and −31.1 %, $p = .001$). The homogeneity of melanin distribution in the skin was improved by 21.4 % on the cheeks ($p = .012$) and by 24.0 % in the periorbital area ($p = .000$), as well as the mottled pigmentation (51–75 %) (Kohl et al. 2014).

Long-term efficacy was assessed by Ortiz et al. (2010) who evaluated 10 subjects at 1 and 2 years after fractional CO_2 treatment of acne scarring and photodamage in the face. Investigators graded maintenance of improvement on a quartile scale based on clinical photography and found that subjects maintained 74 % of their overall improvement at their long-term visits compared to 3-month follow-up visits. However, while clinical improvement was maintained long term, the results were not as remarkable as those seen at 3-month visits.

Overall, patient satisfaction is generally high. At 3 months post treatment, subjects reported 67–80 % improvement in skin texture, facial wrinkles, and laxity, as well as in skin pigmentation. In a study of Clementoni et al., 40 patients (75.47 %) would recommend fractional CO_2 treatment to others because they had obtained an overall improvement greater than 75 %.

Stebbins and Hanke treated the skin of the dorsal hand of ten patients, each receiving three treatments to only one hand at 4–6-week intervals with fractional CO_2. At 1-month follow-up after final treatment, investigators rated mean improvement of 26–50 % for wrinkles, 51–75 % for pigment, and 26–50 % for texture. Participants rated mean improvement after final treatment as 26–50 % for wrinkles, 51–75 % for pigment, and 51–75 % for texture. Similar efficacy was assessed by Tierney and Hanke for the treatment of age-related changes on the neck. For skin texture, the mean score improved 62.9 %, skin laxity 57.0 %, and rhytides 51.4 %. For overall cosmetic outcome, the mean score improved 59.3 % (55.1 %, 63.5 %) at 2 months post treatment.

Side Effects

Frequent short-term side effects evolving with FP treatments are pain, facial edema, dry skin, flaking, pruritus, bronzing, and increased sensitivity. The procedure is usually reported as painful, however tolerable. Mild to severe transient erythema immediately after treatment is reported in 100 % of the patients treated. Unlike transient erythema, which usually resolve in 3–4 days, prolonged erythema is defined as post-treatment redness that persists longer than 1 month with ablative treatment. The occurrence of side effects highly correlates with higher density and treatment settings.

The rate of herpes simplex virus (HSV) infection, the most common type of infection after fractional laser skin resurfacing, has been reported in 0.3–2 % of cases. However, antiviral prophylaxis 1 day prior to treatment and continued for 5–7 days post treatment lowers the risk. The chance for bacterial infections, primarily *Staphylococcus aureus* and *Pseudomonas aeruginosa*, is generally low (about 0.1 % after FP). However, increased pain, focal intense erythema, increased exudate, and erosions with crusting should alert the physician to the possibility of bacterial superinfection that usually presents 1–3 days after treatment (Stebbins and Hanke 2011; Metelitsa and Alster 2010). Especially in the first postoperative week, the risk for viral, bacterial, and fungal infections is generally high. In this critical phase the proper identification and treatment is essential to avoid further complications, including delayed wound healing, scarring, coinfection with other pathogens, and systemic dissemination.

Table 129.1 Quantitative comprehensive grading scale of rhytides, laxity, and photoaging (Alexiades-Armenakas et al. 2008)

Categories of skin aging and photodamage								
Grading scale	Descriptive Parameter	Rhytides	Laxity	Elastosis	Dyschromia	Erythema–Telangiectasia (E-T)	Keratoses	Texture
0	None	None	None	None	None	None	None	None
1	Mild	Wrinkles in motion, few, superficial	Localized to nasolabial (nl) folds	Early, minimal yellow hue	Few (1–3), discrete, small (<5 mm) lentigines	Pink E or few T, localized to single site	Few	Subtle irregularity
1.5	Mild	Wrinkles in motion, multiple, superficial	Localized, nl and early melolabial (ml) folds	Yellow hue or early, localized periorbital (po) elastotic beads (eb)	Several (3–6), discrete, small lentigines	Pink E or several T localized 2 sites	Several	Mild irregularity in few areas
2	Moderate	Wrinkles at rest, few, localized, superficial	Localized, nl/ml folds, early jowls, early submental/submandibular (sm)	Yellow hue, localized po eb	Multiple (7–10), small lentigines	Red E or multiple T localized to 2 sites	Multiple, small	Rough in few, localized sites
2.5	Moderate	Wrinkles at rest, multiple, localized, superficial	Localized, prominent nl/ml folds, jowls and sm	Yellow hue, po and malar eb	Multiple, small and few large lentigines	Red E or multiple T, localized to 3 sites	Multiple, large	Rough in several, localized areas
3	Advanced	Wrinkles at rest, multiple, forehead, periorbital and perioral sites, superficial	Prominent nl/ml folds, jowls and sm, early neck strands	Yellow hue, eb involving po, malar and other sites	Many (10–20) small and large lentigines	Violaceous E or many T, multiple sites	Many	Rough in multiple, localized sites
3.5	Advanced	Wrinkles at rest, multiple, generalized, superficial; few, deep	Deep nl/ml folds, prominent jowls and sm, prominent neck strands	Deep yellow hue, extensive eb with little uninvolved skin	Numerous (>20) or multiple large with little uninvolved skin	Violaceous E, numerous T little uninvolved skin	Little uninvolved skin	Mostly rough, little uninvolved skin
4	Severe	Wrinkles throughout, numerous, extensively distributed, deep	Marked nl/ml folds, jowls and sm, neck redundancy and strands	Deep yellow hue, eb throughout, comedones	Numerous, extensive, no uninvolved skin	Deep, violaceous E, numerous T throughout	No uninvolved skin	Rough throughout

This 4-point grading scale has been extensively tested and employed for evaluating laser- and energy-based cosmetic treatments

Scan areas	Square	Round	Round	Adjustable shape, size, ratio	Square	Round or square	–

The use of occlusive moisturizers and dressings can increase the risk for acneiform eruptions; the risk for acne is about 2–10 %, while the development of milia occurs in about 19 % of the treated patients. The avoidance of petrolatum-based healing ointments or a change to noncomedogenic equivalents can help to prevent acneiform eruptions. In moderate to severe breakout, short courses of oral tetracycline-based antibiotics are the treatment of choice.

Delayed purpura which may develop more than 3 days after skin resurfacing has been reported in some cases. Previous reports assume that the avoidance of nonsteroidal anti-inflammatory drugs and anticoagulants after treatment may decrease the risk for delayed purpura.

Pigmentary changes, hyper- and hypopigmentation, are much less frequent with fractional CO_2 than with fully ablative CO_2 but are still observed in 1–32 % of patients, depending on the system used, parameters applied, and skin phototypes treated. To minimize the risk, patients should avoid sun exposure for at least 2 weeks post-procedure and are advised to use sunscreen on a regular basis for at least 30 days after treatment. Special attention should be given when treating darker skin types due to their higher risk for developing any dyschromia (Clementoni et al. 2007). In general the use of higher fluencies, lower density settings, and longer treatment intervals can help to decrease this potential risk. In most cases postinflammatory hyperpigmentation resolves spontaneously without treatment; however, topical lightening agents, mild peeling agents, and protection can accelerate the resolution. Hypopigmentation, although rather uncommon, often has a delayed onset (6–12 months postoperatively) and frequently occurs in darker skin. In the author's (MAA) experience, patients have presented who have been treated repeatedly with fractional laser resurfacing and developed subtle hypopigmented patches and textural changes. It is therefore advised to space treatment intervals to allow for complete wound healing prior to repeating the treatment.

Scarring is a potential side effect after fractional CO_2 which may be due to overly aggressive treatments in those sensitive areas (including excessive energy, density, or both), lack of technical finesse, associated infection, or idiopathic (Manstein et al. 2004; Metelitsa and Alster 2010). However, the incidence for scarring increases with the area treated. Therefore, special care should be taken, when fractional CO_2 is used in areas other than the face, such as the neck and chest, or in location with very thin skin, such as the eyelids.

Conclusions

A half-century after the CO_2 laser was developed, the device remains a top tier form of therapy for rhytides and photoaging of the skin. The technological progress of the past decade in the form of fractionated delivery has helped to transform this laser procedure to an effective and safe approach for skin rejuvenation. When first used for resurfacing in the early 1990s, pulsed CO_2 lasers were revolutionary; never before it had been possible to apply such high energy to human skin to achieve both physiological and aesthetic changes. For a long period of time, the fully ablative CO_2 laser, although associated with serious side effects, was the gold standard and the treatment of choice for many physicians to rejuvenate aged skin. With the introduction of the fractional photothermolysis, it was possible to significantly lower recovery time and the risk for serious side effects while maintaining an acceptable clinical outcome.

In addition to the 10,600 nm CO_2 laser, the Er:YAG 2,940 nm and YSGG 2,790 nm lasers have also been used to perform fractional ablative resurfacing. While these newer technologies exist, the fractional CO_2 laser has maintained its preeminence as the first choice for ablative resurfacing. The efficacy of clinical outcomes from the fully ablative and fractional CO_2 laser has been well demonstrated owing to its high absorption spectrum for water in the living tissue, penetration depth, and collateral thermal injury which serve to induce neocollagenesis and skin rejuvenation.

Surgery

130

Myrto Trakatelli and Elena Rossi

Key Points

- The first principle of skin surgery is that appropriate margins should always be respected according to the type of the tumor excised.
- A preoperative evaluation of the patient is necessary to make the right choice about the type of reconstruction and to prevent complications such as bleeding or infections.
- One of the key steps in planning the elliptical excision is determining the proper placement and orientation.
- The ideal closure provides the best esthetic and functional results while avoiding potential complications.
- Alternatives for closure of a defect include primary closure, second-intention healing, skin grafting, or local tissue transfer with flaps.

General Principles

Before any surgical decision, for any skin lesion we must respect the fundamental oncologic principle: "*Tumor removal first*, *reconstruction second*." This is particularly relevant when the lesion is malignant. The best-designed flap reconstruction is a failure if performed without complete tumor clearance. One should respect the margins both lateral and deep and in case of doubt perform two-stage surgery or Mohs surgery to be able to guarantee complete extraction of the lesion.

Several factors must be evaluated before determining a method of reconstruction:

1. Patient considerations include patient needs, general medical condition, and psychosocial factors.
2. Defect considerations include the size, depth, and location of the defect. The location of the defect influences structure, function, and the availability of adjacent tissue reservoirs.
3. The surgeon's experience and personal preferences play a role.

The ideal closure provides the best esthetic and functional result while avoiding potential complications, accommodating the patient's needs, and incorporating the patient's ability to participate in postoperative care. Alternatives for closure of a given surgical defect include primary closure, second-intention healing, skin grafting, or local tissue transfer with flaps.

Defect Closure

Closure is the process of joining the edges of a wound. It can be done through the use of different materials. The suture with the needle and the thread is the most used one, but also sterile skin-closure strips, cyanoacrylate glue, and staples are available. The choice of the material and the type of stitches depend on several factors such as anatomical site, dimension, and tension of the wound. Atraumatic sutures are defined as needle-suture combinations, where the needle is firmly attached to the suture in order to reduce tissue trauma.

Material for Closure

Needle

Today it can be assumed that, at least with respect to European manufacturers, stainless steel needles are generally used for surgical suture materials. There are different needle shapes (fishhook-shaped, three eighth circle, five eighth circle, straight, one half circle, semi-curved, spoon-shaped, one fourth circle, etc.), types (round-bodied or reverse cutting), points, radius, and lengths. In dermatology we mostly use the reverse cutting ones.

Suture Material

The "thread" can be of various dimensions from 3 to 12-0 (the number itself means an increasing order, whereas if the number is followed by 0, it means a descending order so thinner suture). The most used sizes in dermatologic surgery are from 3-0 to 5-0. It is best to use fine sutures on the face while on areas where cosmetic concerns are less important, sutures 3-0 or 4-0 are best, because the larger size makes the technique easier and the thicker sutures are stronger.

The suture material can be classified in natural (silk and catgut) and synthetic (such as polyamide, polyesters and polymers derived from polyglycolic acid).

According to the material absorbability in human tissue, suture material can be classified as absorbable or nonabsorbable. Absorption can occur enzymatically, or hydrolytically, as with the absorbable synthetic polymers: the latter is less reactive because the polymeric chain of the material is hydrolyzed by water that breaks it. The nonabsorbable material is permanent and if not removed will last in the tissue.

According to the structure, the material can be either monofilament or multifilament (composed of many fine individual threads either twisted or braided together). The single filament is less traumatic for the tissue but less resistant and more difficult to handle when compared to a braided thread. Monofilaments are less involved in infections. An increased adherence of bacteria to braided sutures has been demonstrated: this is correlated with higher infection rates (Katz et al. 1981).

Suture Technique

Sutures can be divided in buried (strong, tough, and effective) or superficial (less visible as possible: the opposite edges should be juxtaposed without differences of level), interrupted, or continuous.

The most used suture in dermatologic surgery is the *simple interrupted suture* (Figs. 130.1, 130.2, and 130.3). It consists of a series of single

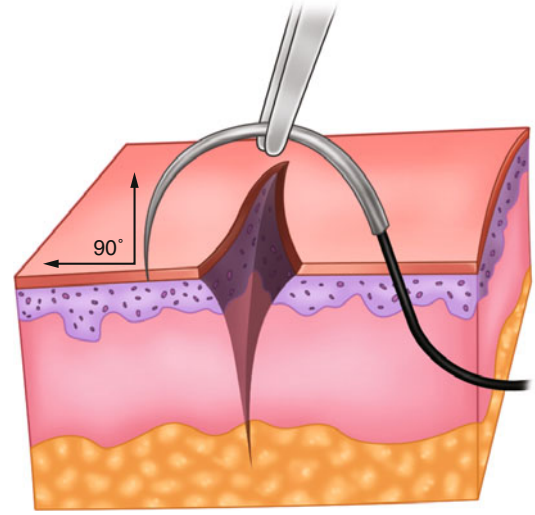

Fig. 130.1 Simple interrupted suture

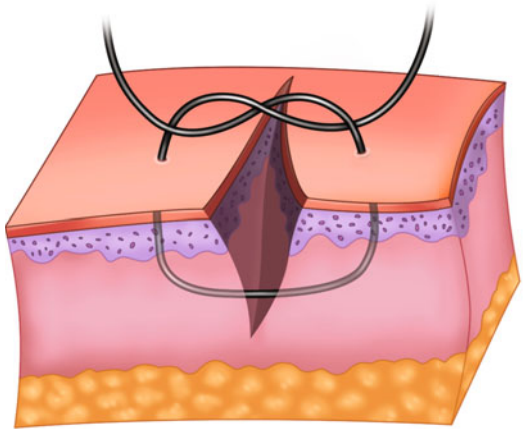

Fig. 130.2 Simple interrupted suture

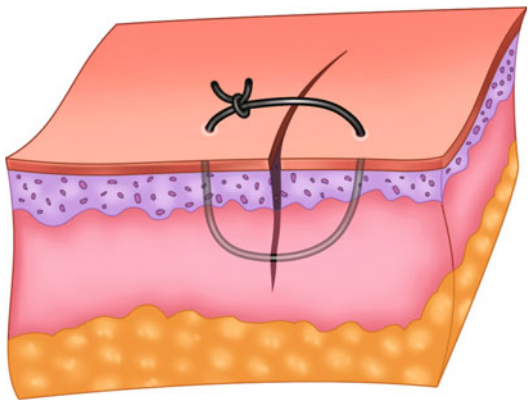

Fig. 130.3 Simple interrupted suture

stitches individually placed and tied. To perform an optimal stitch, the needle must be correctly positioned within the holder, with the first third of the needle within the jaws so that the curve of the needle can be used to advance. The same amount of tissue has to be taken in each margin, at the same depth of the wound. The orientation of the needle to the skin should be perpendicular (Fig. 130.1), 3–5 mm from the wound edge, in order to take enough tissue and properly evert the wound edge. The tip of the needle is retrieved using tissue forceps; the thread is pulled through leaving 2–3 cm at its tail, to guarantee the possibility to knot it (usually with the needle holder, but also hand tying can be performed). The closure is ensured by a squared knot: the long end

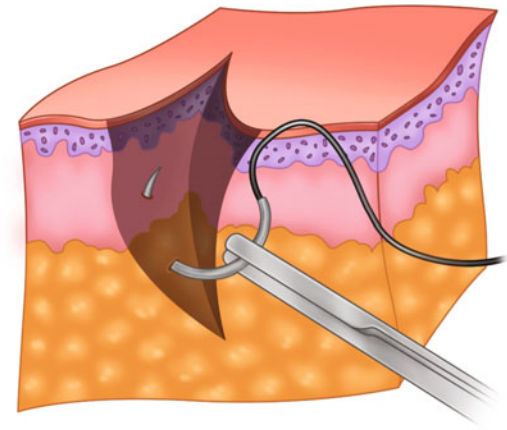

Fig. 130.4 Buried intradermal suture

of the suture is wrapped around the tip of the closed needle holder twice and anticlockwise before grasping the short end of the suture with the needle holder; then, it is pulled gently tight. The second loop is locking clockwise and it determines the tension of the stitch. That has to be sufficient to ensure the juxtaposition of the margins but not too tight so that it causes tissue bunching or an ischemic area. The third loop is single and anticlockwise: it is placed to secure the knot. When using monofilament material, more knots can be placed in order to prevent the slipping. All the knots should lie on the same side of the wound, and not on the wound itself. If the knots are too tight, this could lead to tissue ischemia, whereas if they aren't properly locked, there could be wound dehiscence. The distance between the single stitches should be about 1 cm in the body while in the face it should be about 0.5 cm.

When the injury is deeper and wider, it is useful to perform the *buried intradermal suture* (Figs. 130.4, 130.5, and 130.6). It lines up the dermis in order to help the skin closure and it spreads the tension of the wound in the deep dermis. The suture is done with absorbable material; the beginning is at the subcutaneous level, the needle comes out below the epidermis (going from deep to more superficial tissues). The needle then enters the same dermal level on the opposite side of the wound and exits in the same subcutaneous level as it was initially entered into on the first side of the wound. The knot is tied

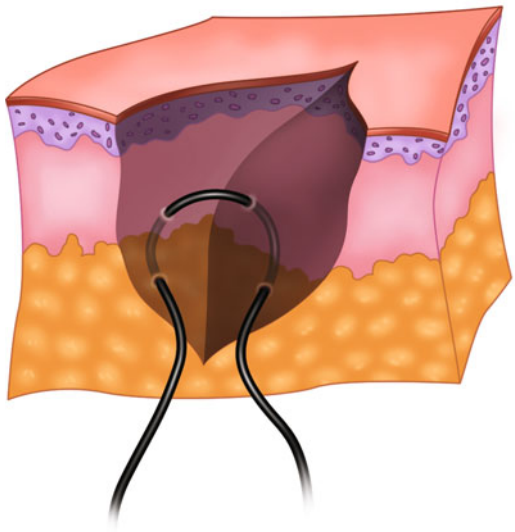

Fig. 130.5 Buried intradermal suture

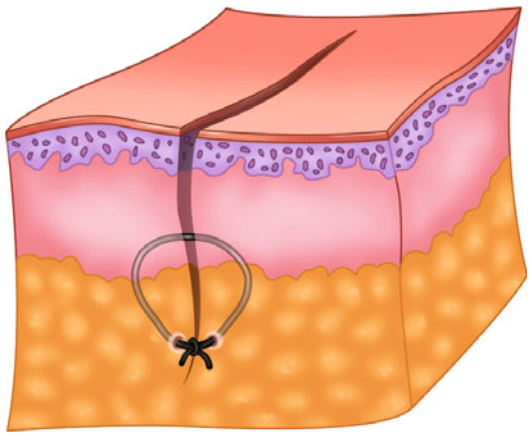

Fig. 130.6 Buried intradermal suture

deep at the subcutaneous level. The knot can be correctly buried in the wound only if the two ends of the thread are put at the same side of the stitch and not over the stitch.

When there is asymmetry of the anatomic layers, irregularity of the edges, dead spaces to be closed, it is difficult to evert the edges, or hemostatic effect is needed, *mattress suture* can be performed. It is especially helpful when the excision leads to the formation of dead space (i.e., when excising cysts, lipomas, etc.)

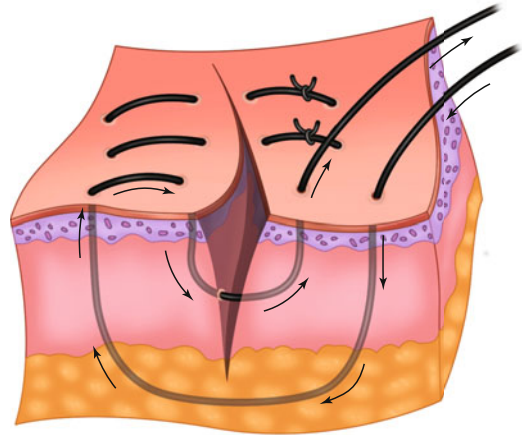

Fig. 130.7 Blair-Donati suture

This suture can result in tissue ischemia or bad cosmetic result: so it should be used only when necessary and simple interrupted sutures should be positioned between mattress sutures to improve the final result.

The *vertical mattress suture* (Zitelli and Moy 1989) is a two-row suture: the first stitch is placed wide and deep, and then a smaller and superficial reverse stitch is placed above the first one, in the same vertical plane, perpendicular to the wound. A square knot is then tied. It has the shape of a vertical U.

The *Blair-Donati suture* (far-far, close-close, and deep-deep-superficial-superficial) is a particular vertical mattress suture: after the first stitch, the second, reverse one is very superficial and close to the edge (Figs. 130.7 and 130.8). The first part of the stitch ensures the juxtaposition of the deeper layers and closes the wound. The second part of the stitch allows a correct position of the dermis and the epidermis thus providing a better cosmetic result.

Another variation is the *Allgöwer suture* that is a half-buried vertical mattress suture: on one side of the wound, the thread does not come out from the skin but is passed under the epidermis (Fig. 130.9). It minimizes the scar and can be properly placed at the border of the scalp to hide the scar between the hair.

The *horizontal mattress suture* is performed by the placement of the first stitch and then the second one in parallel in the same layer

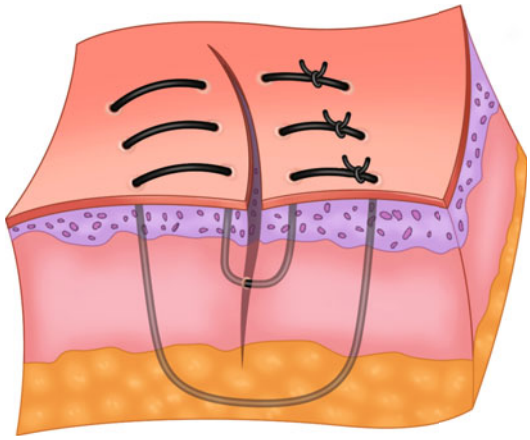

Fig. 130.8 Blair-Donati suture

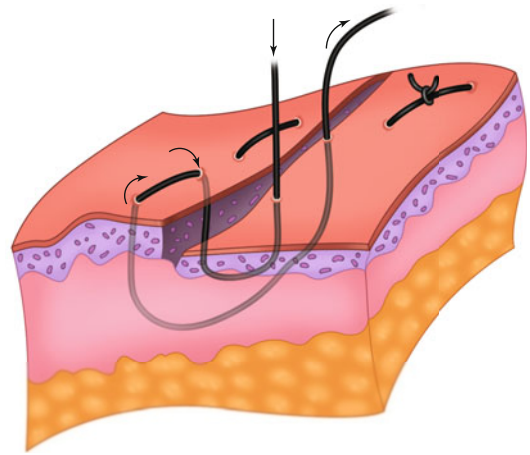

Fig. 130.10 Horizontal mattress suture

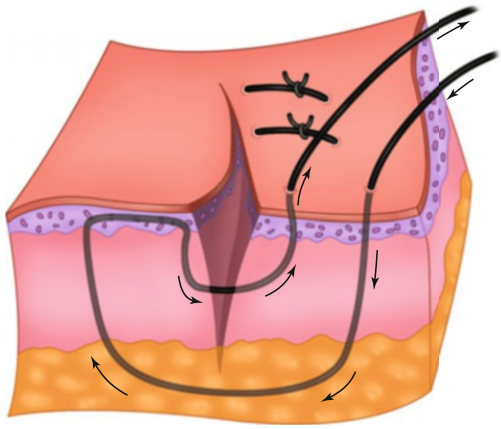

Fig. 130.9 Allgöwer suture

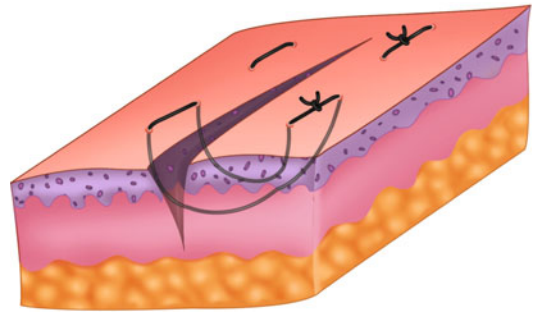

Fig. 130.11 Horizontal mattress suture

(Figs. 130.10 and 130.11). It has the shape of a horizontal U.

The *angle* (*or corner*) *stitch* (Figs. 130.12 and 130.13) is a particular horizontal mattress suture used to close wounds that are angled or Y-shaped without compromising blood supply to the wound tip. It begins on the side of the wound on which the flap is to be attached. The needle is introduced into the skin 3 mm away from the defect, and then it passes through the dermis of the wound edge to the dermis of the flap tip. The needle is passed horizontally staying in the same dermal plane in the flap tip, exits the flap tip, and reenters the other side of skin to which the flap is to be attached. The needle is directed perpendicularly and exits the skin; then, the knot is tied. It is important that no part of the suture must overlie the tip as this may reduce its viability.

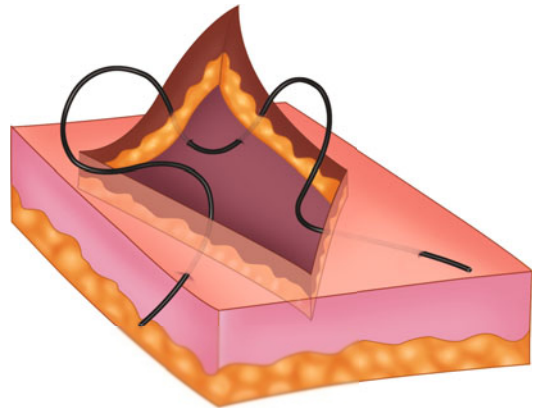

Fig. 130.12 Angle (or corner) stitch

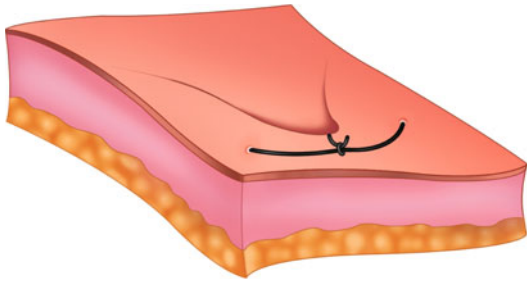

Fig. 130.13 Angle (or corner) stitch

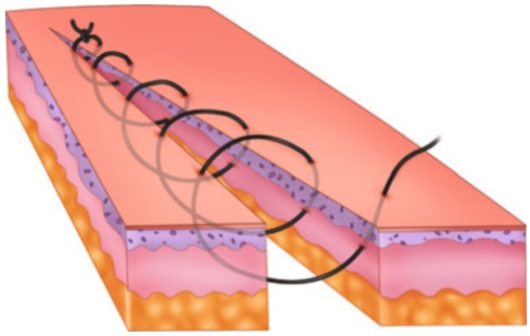

Fig. 130.14 Running or continuous suture

The *running or continuous suture* (Fig. 130.14) starts with a single stitch at the beginning of the wound; then, once the knot is tied, the thread is not cut but is used to make a series of loops through the skin running the length of the wound. The suture is pulled until the edges oppose but not too tight. The end is tied to the final loop. This suture is useful for long wounds and flaps on the face. It can be performed very quickly and leads to good cosmetic result. It is better to use this suture only when associated with buried intradermal suture in order to avoid tension on the edges of the wound as it is less resistant than the single interrupted suture. A variation is the locked running suture: every time the needle emerges from the skin, it is hooked under the previous loop. It induces greater suture marks but can be useful to obtain hemostasis especially in the scalp.

The *running subcuticular suture* (Cordova et al. 2013) (Fig. 130.15) creates a very fine scar but needs no tension of the wound; it must be always associated with a buried suture. The epidermis is pierced only at the beginning and end of the suture line, and then the suture is not visible. The needle enters in the skin at about 1 cm from the end of the wound; the needle is driven through the dermis parallel to the skin taking small bites alternately on one side of the wound and then the other. It exits the skin surface approximately 1 cm from the wound end and is pulled gently to approximate the wound sides. At both ends, the thread can be tied or taped to the skin.

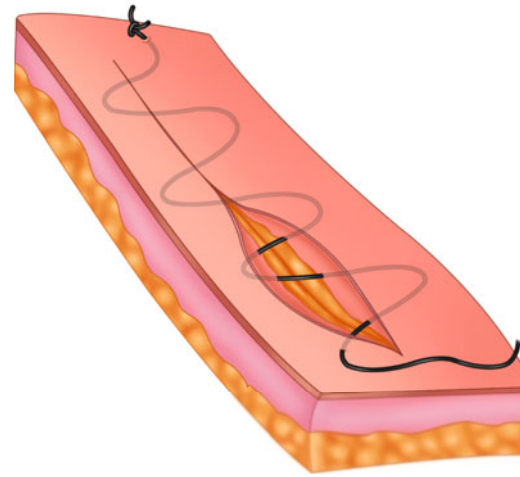

Fig. 130.15 Running subcuticular suture

Table 130.1 Average time for stitches removal depending on the area

Area	Removal time (days)
Face	5–7
Eyelid	4–5
Ear	14–21
Scalp	7–10
Arms and legs	10–14
Trunk and limbs	8–12
Palms and soles	14–21

Suture Removal

Depending on the area, the stitches can be removed at varying times (Table 130.1). Common periods of time for removal are listed above. These are general indications: the surgeon will evaluate the wound itself and the general condition of the

patient that sometimes could delay the process of healing. Moreover, sutures may be taken out all at one visit, or sometimes, they may be taken out over a period of days if the wound requires it.

Other Wound-Closing Methods

Metal clips (Biancari and Tiozzo 2010) (staples) made of stainless steel or titanium can be used for the approximation of the skin. The application is fast and good wound eversion can be reached, the risk of infection is decreased. Special tools for removal are needed. These are often used on the scalp and on the back.

Surgical adhesives (Coulthard et al. 2010) are better used to close lacerations in emergency departments, above all in children. These can't be used if the wound has tension and they will not evert the wound edges. The cosmetic result is often less favorable than with traditional suture (Patel and Price 2011).

Sterile skin-closure strips can be used alone or associated with suture (Duscher et al. 2013). When placed without suturing, they can be used only when there is no tension. They do not evert the edges (so a depressed scar is possible). It is better to associate them with the running subcuticular suture or place them after the removal of the stitches.

Primary Closure: The Fusiform Excision

The primary closure refers to the direct side to side apposition of a skin defect: the skin edges of the wound are sutured together to close the defect.

An excisional biopsy is commonly done in a fusiform or elliptical shape. The proper planning of this procedure will help the surgeon to avoid or to minimize the formation of puckering of the skin at each end of the wound called tissue cones or dog-ears.

The dog-ear formation depends on several factors (Weisberg et al. 2000):

- Tissue dynamics: the skin is an elastic structure and its elastic properties vary according to several factors (age, location, scarring from prior surgery, etc.). The excessive tension on a wound might cause a depression of the central portion that will lead to the formation of "pseudo-dog-ears" at the end of the wound (Rohrer et al. 2009).
- Geometry of the wound: shape, correct length-to-width ratio, apical angles.
- Surface contour: wounds on convex surfaces are prone to develop dog-ears at the distal margins (mandible, chin)
- Surgical technique: the correct blade angle, the shape of the specimen.

First of all it is important to make a preoperative evaluation of the patient: drug allergies, systemic medications (Kearon and Hirsh 1997) (MAO, aspirin, warfarin, etc.), presence of any electronic devices (i.e., pacemaker or defibrillator), mitral valve prolapse, endocarditis, prosthetics, lifestyle (i.e., smoke, alcohol), and other pathologies (Otley 2006). This allows the correct pre-, intra- and postoperative care for every situation to maintain the patient's safety, to make the right choice about what type of reconstruction will be used, and to prevent any complications such as bleeding or infections.

One of the key steps in planning the elliptical excision is determining *the proper placement* and *orientation*. It is better to orientate the long axis of the ellipse following the long axis of the lesion. More specifically the incision should be placed following relaxed skin tension lines and in the face, bearing in mind the concept of *cosmetic units*.

It is an incontroversible fact that there is a naturally occurring tension (and thus extensibility) within the skin, which varies at different sites. Relaxed skin tension lines are fictitious lines "drawn" on the skin that correspond to the lines created by underlying muscle activity and are often visible in older patients; these lines are parallel to dermal collagen bundles and lie perpendicular to the long axis of the underlying muscles. An ellipse placed parallel to these lines leads to a fine linear scar as the maximum traction is exerted in the direction of these lines; if it is placed perpendicular to these lines a widened scar may result, as the distraction forces are maximal at the widest part of the wound. So the right orientation

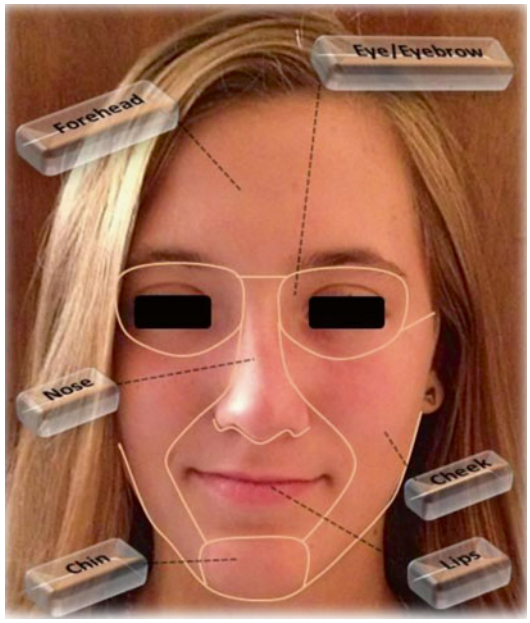

Fig. 130.16 The main cosmetic units of the face

of the ellipse should never be in an angle of more than 20° from these lines (Bush et al. 2007).

The face consists of six major esthetic units (Fig. 130.16): forehead, eye/eyebrow, nose, lips, chin, and cheek. The borders of the esthetic units are important in facial surgery and are natural lines separating distinct anatomic units. Every cosmetic unit can be divided in other smaller units. When possible, the placement of a scar along the border of a unit will give optimal esthetic results. This concept is very important for surgery performed on the face and plays an important role when planning flaps.

An important point that must always be considered when planning the orientation of an excision is that the vectors of tension of the planned closure will not pull on a freely mobile skin structure such as the eyelid, the eyebrow, and the lip. Also, proper orientation of a fusiform excision on the extremities will avoid contracture of an underlying joint.

Once the correct orientation of the wound (Fig. 130.17a) is determined, the ellipse is drawn on the skin. This procedure is done with the patient in the upright position and before the administration of anesthesia as a horizontal position and a large amount of anesthesia can interfere with the placement and orientation of relaxed skin tension lines. It is better to first mark a circle around the lesion itself, and then define with a second marking the recommended oncologic margins according to the diagnosis.

A lot of different excision shapes have been described in the past years; the best and simplest approach is the fusiform shape. To minimize the formation of dog-ears, the length should be three times the width, but the ratio of length to width may vary from 3:1 to 4:1 (Fig. 130.17b). The length of the short axis of the ellipse is predetermined by the size of the lesion being removed. For instance, an 8-mm malignant tumor to be excised with 5-mm margins will have a short axis of 18 mm, and the long axis will be approximately 38 mm in length. It is important to recognize that even a proportionate and properly designed ellipse may produce a closure with small standing cones or "dog-ears," at each pole that must be removed. Each tip of the wound should create a 30-degree angle. If the length-to-width ratio is reduced, the ellipse is not symmetrical, or its angles are greater than 30°, then the possibility of tissue cones formation is increased (Goldberg et al. 2004). If an anatomical landmark must be avoided, the ellipse may be asymmetric and the tissue cone will result more in the opposite tip to the landmark.

After the preoperative evaluation is done, the surgeon has to explain carefully to the patient everything about the surgical act. It is important to enlighten him about the geometry of the excision (even using some images) so as to clarify why the incision line will be certainly longer than the lesion being removed. Informed consent should then be obtained.

Once the preparation and the draping of the surgical site are performed, anesthesia is done. The choice of the right scalpel blade is important. There are disposable scalpels or stainless steel handles designed for smooth, reliable loading of surgical blades; different sizes are available, but for cutaneous surgery, the most used ones are numbers 15, 11, and 22/23 that have all different shape, dimension, and sharpness. The number 15 blade has a small curved cutting edge with an unsharpened back edge and is the most frequently

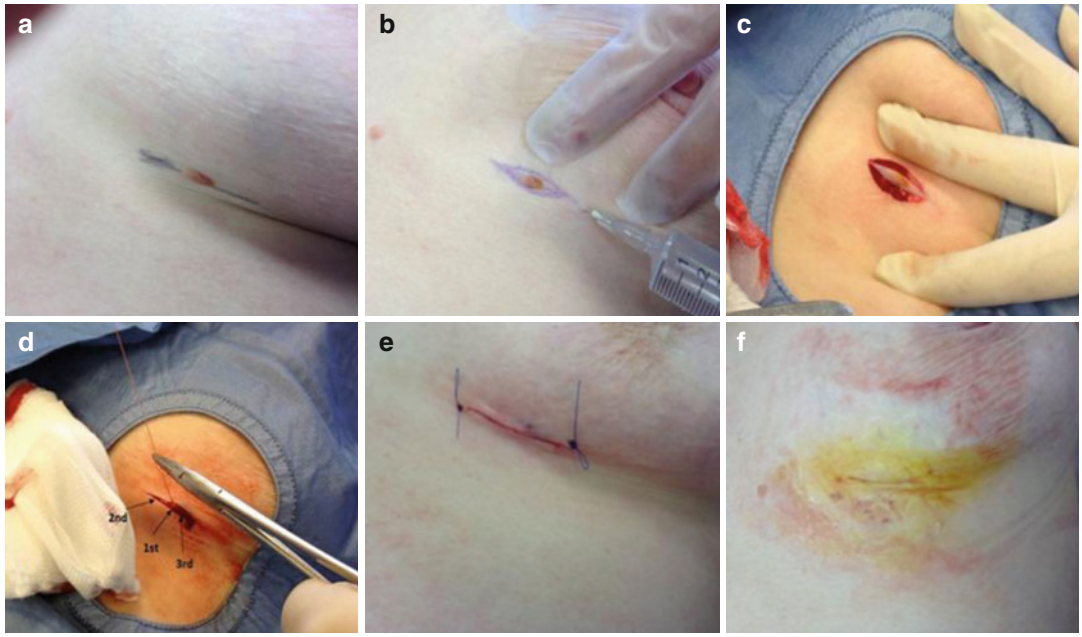

Fig. 130.17 (**a**) The ellipse is planned respecting relaxed skin tension lines that can be marked on the skin. (**b**) Then the ellipse is drawn respecting the ratio of length to width from 3:1 to 4:1 and both the tips of the wound are at a 30-degree angle; anesthesia is performed. (**c**) The incision is continued along the designed lines with constant pressure and minimizing the passes of the scalpel. (**d**) Once the lesion has been excised, hemostasis and undermining are done, the key point is placed, buried suture is the first to be placed proceeding with the rule of the halves. (**e**) If there is low wound tension, a running subcuticular suture can be done. (**f**) After 1 week the suture can be removed. Steri-strip are applied for one more week. Note the presence of contact dermatitis caused by adhesive

used one, mainly for facial defects. The number 11 is an elongated triangular blade sharpened along the hypotenuse edge and with a strong pointed tip: it is ideal for excising very small lesions. The number 23 is a leaf-shaped blade sharpened along its leading edge, similar to 15 but larger: it is required for making long incisions through thick skin (i.e., on the back).

The correct position of the blade on the skin is usually perpendicular. Only in hair-bearing regions, it is better to angle the incision lines so that they are parallel to the hair follicles.

The incision is initiated from the one tip of the drawn fusiform excision, with the scalpel held perpendicular to the skin. After the entry of the blade in the skin, the scalpel is then gently tilted to a 45° angle for incising the remaining margin until the other tip is reached. At that point the blade is then returned again to the perpendicular position. The same procedure is done on the opposing side (Kaufmann and Landes 1994). To avoid unnecessary injuries, it is desirable that the tips of the ellipse meet at a fine point, without unnecessary extension of the incision beyond that point. The incision has to be continuous along the designed lines so that there are less nicked edges. The amount of pressure or force used when incising the skin is learned only by experience, but the force depends on the thickness of the dermis and it is very important to try to be the most constant possible. Minimizing the number of passes of the scalpel through the dermis (Fig. 130.17c) avoids «stair casing» wound margins that would hamper the correct juxtaposition of the margins (Leshin).

The ellipse is excised through full-thickness skin to the appropriate depth with either a scalpel or scissors. The specimen should be of uniform thickness and wedge shaped. A common mistake is to leave more fat and dermal tissue at the tip and tail of the ellipse than at the center. This "boat-shaped" specimen will lead to redundancies and elevation of the end of the ellipse.

More importantly, the tissue left in the defect may cause protrusions at the two tips creating pseudo-dog-ears.

The process of undermining adjacent tissue, once the specimen is excised, avoids unnecessary vascular compromises, facilitates the eversion of the margins and the closure, and enhances the cosmetic outcome after scar contraction because it minimizes the tension. It can be done both with scissors or blade (but more often with scissors), and while executing this procedure, the wound margins are gently handled with forceps or hook. Undermining if needed should be carried out using blunt-tipped scissor as superficially as possible to avoid unnecessary damage to blood vessels and nerves. The depth varies with the anatomic area: on the scalp it is best carried out below the galea to avoid transection of hair follicles. The forehead is best undermined in the deep subcutaneous tissue to avoid damage of the sensory innervation of the scalp. To avoid injury of the superficial motor nerves, undermining on the temple, cheeks, and chin should be carried out in the superficial subcutaneous tissue. On the trunk, undermining can be carried out at any level above the muscle fascia. At sites of minimal subcutaneous tissue such as the hands and the feet, undermining should be done just below the dermis.

Before proceeding to suture the wound, hemostasis (stopping of the bleeding) must be done: achieving hemostasis is an essential component of all surgery. The goal of hemostasis in surgery is to control bleeding while avoiding unnecessary tissue destruction. Hemostasis can be reached by chemical agents that produce superficial hemostasis or by electrocoagulation (monopolar or bipolar) for deeper hemostasis. Hemostasis may also be done by physical methods that involve pressure, sutures, or gelatin sponges.

Depending on the dimension and the depth of the wound, the suture can be on only one layer or on more layers. Usually a double-layered suture is performed: the deeper one is placed in the dermis and allows spreading the tension of the wound, then the surface one is more superficial and is done only to ensure the juxtaposition of the edges.

To avoid the formation of dog-ears, it is important, as a general principle, to follow the rule of the halves while suturing. The "key point," that is, the one that carries the most tension, is usually positioned at the widest part of the ellipse (i.e., in the middle): this is the first stitch to be placed (Fig. 130.17d). Then the surgeon proceeds toward each tip of the wound placing every stitch in the middle of the remaining defect. This helps the spreading of the eventual exceeding tissue to both the extremities of the wound.

If one of the ends of the excision is better suited to be the location of any tissue cone formation, suturing from the opposite end first will push the tissue cone to the desired end.

Sometimes, the surgeon can decide first to excise the lesion, then to manage independently each tissue cone resulting after the placement of the key point. This allows many different orientations of the scar.

To perform a linear repair, the surgeon hooks the tissue cones (Fig. 130.18a) and makes the first incision along the line of the initial excision (Fig. 130.18b). The hook placed in the end of the wound defines the geometry of tissue protrusion in the shape of a standing cone. Then the base of the triangle is incised and undermined. The triangle-shaped tissue is then moved toward the other side of the previous incision (Fig. 130.18c) and then removed on the same line of the initial excision (Fig. 130.18d). This procedure is a simple way to remove puckering tissue, resulting in a lengthened linear scar (Petres et al. 1996).

At each tip of the ellipse, the first cut performed to remove the puckering tissue is the one giving the direction of our final scar: there are very different shapes such as linear repair, hockey-stitch repair, curved repair, L-shaped repair, and T-repair (Fig. 130.19).

Dealing with tissue cone repair is fundamental in every type of dermatologic surgery, from the primary closure to flaps and more complex reconstructions. Every surgical planning has to consider and to manage the puckering tissue.

Ellipse Variations

According to the location, the orientation, and the anatomy of the region, there are some variations of the classic ellipse that can improve cosmetic and functional results. The most used variations are:

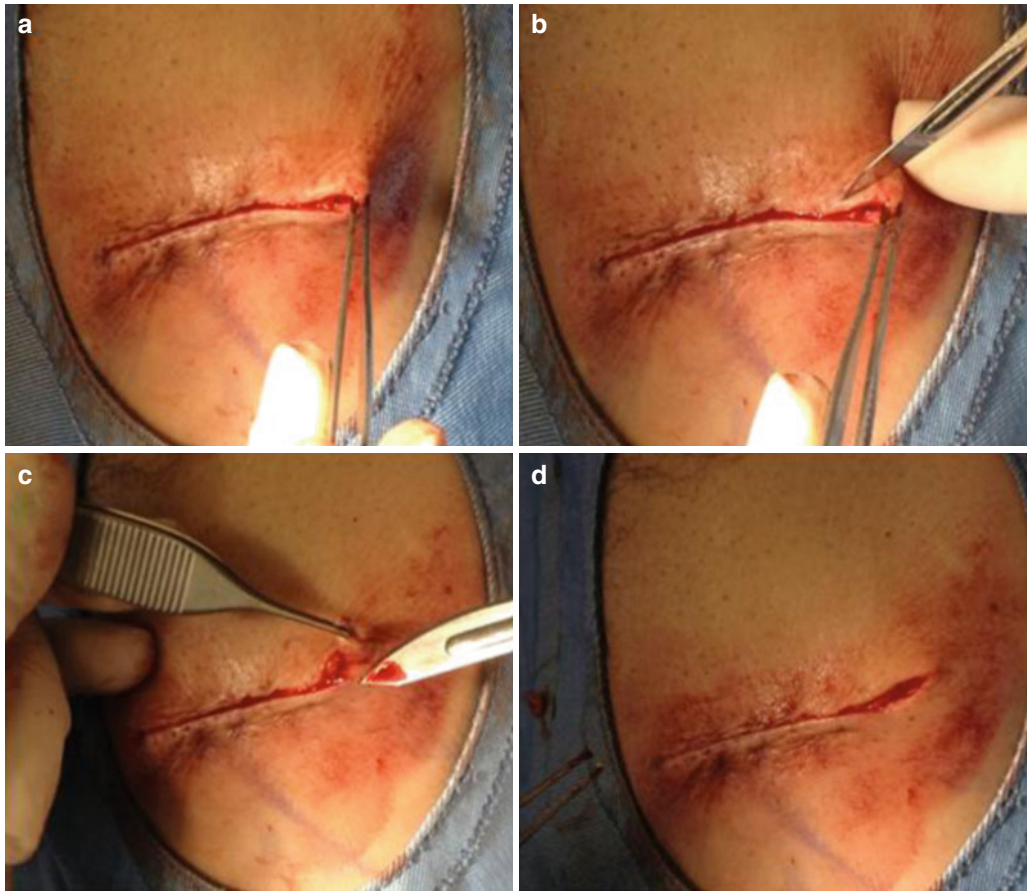

Fig. 130.18 Linear repair of tissue cone

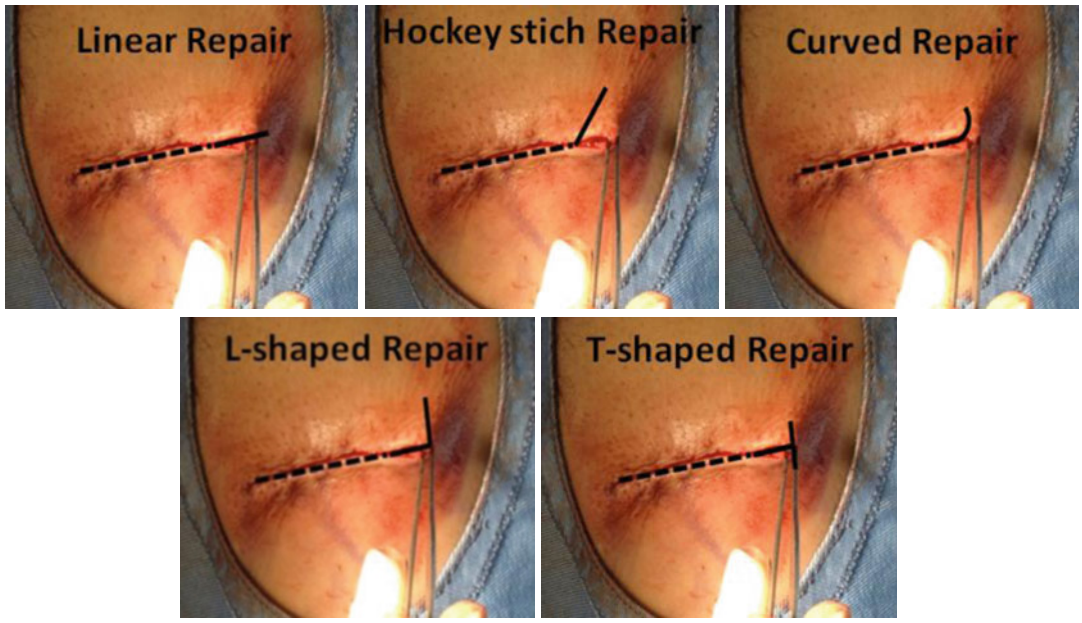

Fig. 130.19 Modification of tissue cone repair

Fig. 130.20 Crescentic ellipse

Fig. 130.21 Lazy S-shape

- Crescentic ellipse
- S-plasty
- M-plasty
- Relaxing incision
- Serial excision
- Wedge excision repair.

The *crescentic ellipse* (Fig. 130.20) is a curved ellipse: in some areas such as the mid cheek, the nipple, or the melolabial fold, it is preferred to obtain a curved scar. The sides of the ellipse are not of the same length. This difference is spread in the whole wound while suturing: the vector of the stitches is not perpendicular, but every stitch takes a little more tissue in the longer side. The difference between the two sides must not be too large (Goldberg and Alam 2004) to prevent dog-ear correction.

On convex areas or if the skin elasticity is low, the shape of the ellipse can resemble a *lazy S-shape* (Fig. 130.21). This varies the distribution of the vectors of tension of the wound: in the classic fusiform excision, they are oriented perpendicularly to the wound, when performing a lazy S-plasty, these vectors are diagonally oriented. This improves the central scar depression. When this alternative plastic reconstruction method is chosen, the suture is reduced in length by approximately one third and assumes a curved profile, which is better esthetically. This technique is simpler than a flap and shorter (and more esthetic) than a simple elliptical excision (Boggio et al. 2003).

The *M-plasty* can be used to shorten the scar, to avoid crossing an esthetic boundary, or to accommodate the anatomy of a special area (i.e., lateral canthus). It is a tissue-sparing dog-ear repair. The classic fusiform excision can be drawn while planning an M-plasty, but the end of the excision is incised inward, toward the center of the ellipse, creating an M in one or both the sides of the wound (Fig. 130.22). The angles of the limbs of the M-plasty should not be greater than 30° to avoid the formation of a standing cone deformity.

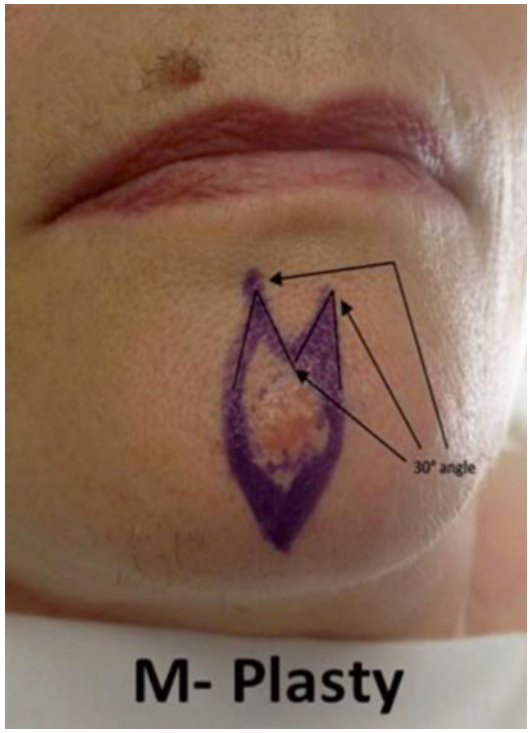

Fig. 130.22 M-plasty

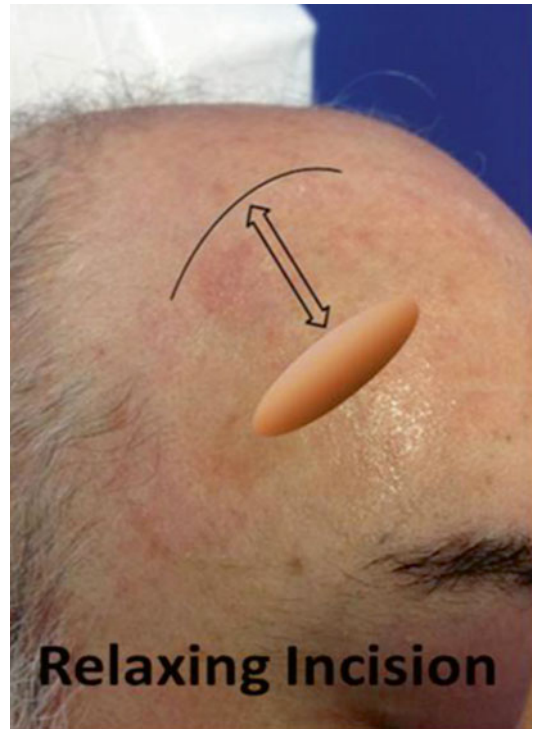

Fig. 130.23 Relaxing incision

The *relaxing incision* is an incision made to allow movement of skin for closure of a wound of a parallel incision: it allows primarily closure of wounds that would need more complex surgery. It can be used for wounds placed on the forehead: a full-thickness incision (including galea) is made near the defect, hiding the second incision behind the hairline (Fig. 130.23). This allows the spreading of a defect of two different sites of closure, allowing primary closure of both regions.

For benign lesions (i.e., congenital naevi), the complete removal of the whole lesion in one-time surgery could mean a very large ellipse or a complex reconstruction with a large resulting scar. *The serial excision* allows for a better cosmetic result even if more surgical time is needed. The elasticity of the skin, after the first partial excision with primary closure, allows subsequent re-excision at least few months later with a smaller resulting scar (Fig. 130.24).

Wedge excision is a surgical procedure to remove a full-thickness triangle-shaped slice of tissue (Fig. 130.25). It is applied on the free margins of the skin. Ideally, the inner corner of the wedge is 30° to minimize the formation of a dog-ear. Small defects on free margins such as the eyelid (one fourth), helix (one third), and of the lip (one third lower, one fourth upper) can be repaired with a wedge excision.

Wound Dressing and Follow-Up

Covering a wound with a dressing mimics the barrier role of epithelium and prevents further damage. Furthermore, the application of compression provides hemostasis and limits edema. A primary dressing is placed directly on the wound and may provide absorption of fluids and prevent desiccation, infection, and adhesion of a secondary dressing. A secondary dressing is one that is placed on the primary dressing for further protection, absorption, compression, and occlusion. To protect the stitches, steri-strip

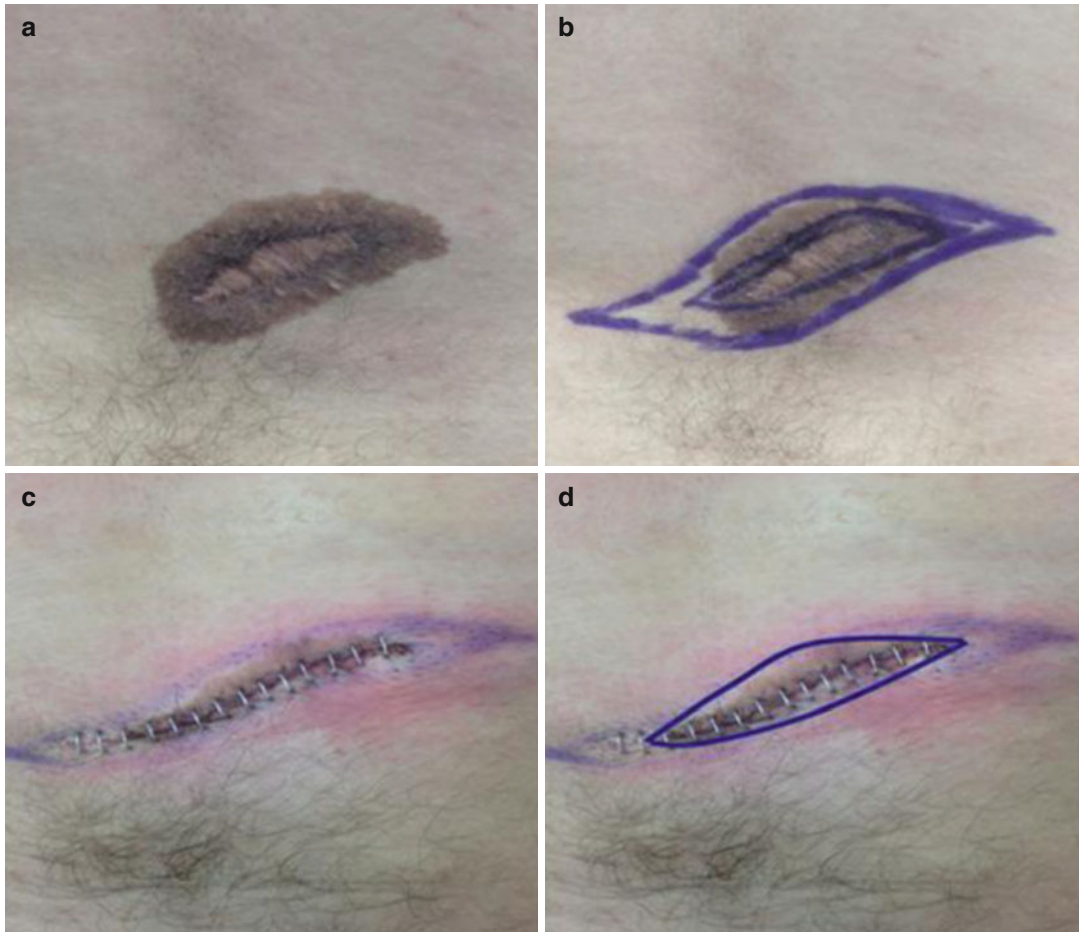

Fig. 130.24 (**a**) On the central area of the congenital nevus, there is a visible scar of the previous first excision. (**b**) Difference between the lengths of the scar if the lesion was totally excised, or if we plan another re-excision. (**c**) Final scar of partial excision. (**d**) Part of the lesion remaining to be excised: the scar won't be longer than the existing one

Fig. 130.25 Wedge excision

can be applied on the dry wound after thorough cleaning and topical antiseptic application. The wound is covered when it is still sterile in the operative field, so if there isn't any complication, it can remain closed for some days. Oral antibiotics therapy is usually not necessary: it should be reserved for clinically suspected and swab-proven infections rather than being prescribed empirically (Cherian et al. 2013). The surgeon has to inform carefully the patient and the caregiver about the changing of the dressing and explain the possible risks to facilitate early recognition and reporting of potential adverse events (Fonder et al. 2008). The patient should have a follow-up visit. Topical application of antiseptic (povidone-iodine solution or chlorhexidine) is useful to prevent infection (Milstone et al. 2008): after the removal of the first dressing, it should be changed once a day until the stitches are removed. Sterile skin-closure strips after the removal of the stitches can help to prevent wound dehiscence.

Postoperative Complications

Most surgical wounds will heal without causing any problems. The prevention of surgical complications depends on correct preoperative evaluation, proper surgical technique, postoperative care, and follow-up care. Even if all precautions have been taken, some complications might occur (Table 130.2). The important role of the surgeon is to assume responsibility and manage correctly any situation. The early identification will allow a correct approach to the complication, adjusting any possible worsening.

Infection: It is uncommon but is usually heralded by pain on days 4–8. It is managed by prescription of topical and systemic antibiotics and wound care.

Seroma: It is the deposit of serous fluid under the wound. It can occur after the excision of large lesions such as lipomas or cysts or in areas of wide undermining. The body is simply reacting to the presence of a dead space. When occurring,

Table 130.2 Postoperative complications

Complication	Prevention	Treatment
Infection	Sterile surgery Management of dressing	Topic and systemic antibiotics Wound care
Seroma	Accurate buried multilayer suture Compression	Aspirate with a needle Puncture with a lancet
Bruising, bleeding or hematoma	Systemic therapies adjustment Hemostasis Pressure dressing	Drainage Remove of hematoma Ligation or cauterization of the vessel
Tissue necrosis	Undermine at correct depth/avoid wound tension	Keep wound moist but not wet Remove necrotic tissue Perform debridement
Contact dermatitis	Accurate anamnesis	Topical steroid Avoid exposure to the allergen Patch test
Nerve injury and alteration of specific anatomical sites	Surgical anatomy knowledge	Surgical correction if possible
Hypertrophic scarring and keloid formation	Accurate evaluation before surgery Follow-up	Medication Topical or intralesional steroid Laser treatment Needling
Dehiscence	Sutures into multiple tissue layers Undermining to allow minimal tension Don't remove sutures too early	Scar revision

this could resolve spontaneously in some days or some drainage could be necessary to alleviate pain and tension on the wound.

Tissue necrosis can occur if the undermining is too superficial or if there is too much tension on the wound. If the skin is left too thin, it may not have enough blood supply from deeper tissues and some tissue could start to suffer or to necrose. If the tension is more than moderate, the lack of vascularization could occur in the central area of the wound: this is due to the fact that the blood flow in a random flap decreases in an inverse manner with increased tension.

Bruising, *Bleeding, or Hematoma*: Patients on anticoagulants (Bordeaux et al. 2011) or aspirin may be associated with increased intraoperative bleeding in dermatologic surgery (Shimizu et al. 2008). To prevent it, an accurate hemostasis must be achieved, and if needed, compression should be applied after surgery to stop the bleeding.

Nerve Injury and Alteration of Specific Anatomical Sites: Mainly the cervicofacial region requires a good knowledge of the surgical anatomy of the area with special attention to known danger zones. A nerve transection may result in sensory (trigeminal nerve and its branch) or motor (cranial nerve VII and its branch or the spinal nerve in the neck) deficits. When performing surgery in special areas such as the eyelid or lip, the preoperative planning must respect the correct position of the free skin margin. Ectropion, lagophthalmos, or eclabium are all conditions that could result from inappropriate surgery: they often require another surgical intervention to restore functionality and if possible the cosmesis.

Contact Dermatitis: This inflammation is caused by irritation or delayed-type hypersensitivity to any topical agent that is part of the dressing (ointments, bandages, topical antibiotics, or adhesives). This clinically appears with erythema, sometimes associated with vesicles, and it is often shaped like the part of the dressing responsible.

Hypertrophic Scar and Keloid: Scarring is an inevitable part of wound healing. In most people, if the wound is closed properly, the scars are small and barely visible. The size of the scar varies by location on the body and the individual person. Some people are genetically predisposed to formation of large hypertrophic scars particularly for surgery on the chest and back. The hypertrophic scars do not grow beyond the boundaries of the original wound and arise within a month of surgery; they can spontaneously regress. Keloids may arise from 3 month to years after surgery, they do not regress spontaneously, and they frequently recur. The primary risk factor for keloids is darkly pigmented skin (Murray 1994), but a familial predisposition is recognized.

Dehiscence: For reasons such as high tension or poor surgical closure, the wound edges can come apart. The term for that is wound dehiscence. In order to avoid this wound complication, sutures should be placed into multiple tissue layers to hold the wound together under minimal skin tension: to achieve this result, the correct undermining of adjacent tissue and a proper knotting technique are important. Wound dehiscence can also be caused by increased stress to the wound area as a result of trauma, strenuous exercise, and heavy lifting: this has to be explained to the patient.

Pigmentary or surface alterations of the wound or suture granulomas can occur sometimes.

Other Reconstructive Options

As mentioned already every single wound has to be individually considered: the surgeon should make the right choice by evaluating different options (Table 130.3) and carefully explaining the benefits and the risks of any different surgical approach. Primary approximation, flaps, grafts, and secondary healing all have an appropriate indication. The decision depends on several factors: the nature of the lesion to be excised, the functional and esthetic result desired, the patient's status and wishes, as well as the surgeon's experience.

A *flap* consists of skin and subcutaneous tissue only partially removed from one part of the body so that it retains its own blood supply during transfer to another site. There are many classifications of flaps, but the most used ones

Table 130.3 Options for closure of cutaneous surgical defects

SURGICAL OPTIONS			
PRIMARY CLOSURE	SECOND INTENTION	FLAP	GRAFT

are the ones based on blood supply and on tissue movement. According to vascularization, flaps can be divided in arterial (or axial) flaps and random flaps. Most of the flaps used in dermatologic surgery are random, that means they are vascularized by the perforating subdermal plexus. The axial flap takes its blood supply from a specific artery. The classification based on the tissue movement distinguishes advancement, rotation, and transposition flaps.

A *skin graft* is constituted by epidermis and varying amounts of dermis. It is excised from a donor site and placed on a recipient site (bed). The graft has no vascularization: the new blood vessels will arise from the recipient site. Grafts are classified in terms of thickness or depth: a split-thickness graft (further classified as thin or thick) takes the whole epidermis and a portion of the dermis, whereas a full-thickness graft contains the entire epidermis and dermis.

During the process of *secondary intention healing*, the wound is left open: it heals by contraction, granulation, and epithelialization. The healing duration will depend on the amount of tissue that must be replaced. The resulting scar may be quite extensive but an adequate alternative especially on concave areas of the head and neck. The esthetic and functional result even if it is not perfect could represent a good compromise that can spare the patient more complex procedures such as flaps or skin grafts reconstruction. The final scar is less noticeable in older patients with skin laxity and in lighter-skinned patients.

Part III

Drugs

Antibacterial Agents

131

Maria Souli and Helen Giamarellou

Key Points

- *Staphylococcus aureus* and streptococci are the most common pathogens in SSTIs.
- The global emergence of community-acquired methicillin-resistant *S. aureus* (MRSA) is responsible for a change in the current treatment algorithm of SSTIs. Risk factors for this pathogen should always be pursued before prescribing empirical treatment for SSTIs.
- The current evidence on the limitations of the glycopeptides for the treatment of severe MRSA infections and the introduction of some newer antimicrobials in the market necessitate an update in the treatment of SSTIs.

General Principles

The contemporary dermatologist quite often confronts bacterial skin and/or soft tissue infections (SSTIs). Therefore, he should be familiar with antibacterial agents, particularly with newer antibiotics and their role in modern chemotherapy. Classification of cutaneous infections according to morphological and clinical criteria is helpful in providing initial clues regarding the most likely responsible pathogens, which will lead to the appropriate antimicrobial chemotherapy.

Furthermore, in the past decade there has been a global increase in the burden of staphylococcal SSTIs due to the increase in dissemination of specific clones of methicillin-resistant *Staphylococcus aureus* (MRSA), which are genetically and epidemiologically distinct from hospital-acquired clones, designated community-acquired MRSA, CA-MRSA. These clones carry smaller staphylococcal chromosomal cassette *mec* (SCC*mec*) elements, mostly type IV or V, frequently carry genes for virulence determinants such as Panton-Valentine leucocidin (PVL), and they are susceptible to many non-β-lactam classes of antimicrobial agents including many oral agents (clindamycin, minocycline, trimethoprim/sulfamethoxazole, fusidic acid, etc.). Also, they typically affect groups lacking risk factors for exposure to health-care system. The modern dermatologist should be able to recognize and to adequately treat this pathogen.

Finally, and despite the scope of the present manual, it was considered appropriate to also include some clinical data on the common streptococcal and staphylococcal skin infections, which will help the dermatologist to choose rationally from among the available antimicrobial agents. Emphasis will be placed on the newer

antibacterial agents, while for the older ones the discussion will be confined mainly to their indications in current dermatological therapy.

Common Bacterial Infections in Dermatology

The commonest bacterial skin and soft tissue infections in the immunocompetent host are those in which staphylococci and streptococci are implicated. However, in immunocompromised patients, several *Enterobacteriaceae*, *Pseudomonas aeruginosa* and a variety of fungi (yeast and moulds) are implicated. The common SSTIs are represented by the following entities.

Folliculitis

This consists of small erythematous papules topped by a central pustule located within hair follicles; *S. aureus* is the main cause, but *P. aeruginosa* has been implicated in 'swimming pool' folliculitis attributed to inadequate chlorination. Folliculitis may extend to the deeper structures creating a furuncle which is a deeper inflammatory nodule occurring in areas of the skin subjected to friction and perspiration like the neck, axillae, buttocks and face.

A more extensive process is a 'carbuncle', which extends into the subcutaneous fat whenever the involved skin is inelastic and thick. In the latter case, multiple abscesses develop draining along hair follicles. Diabetes mellitus is considered a predisposing factor. *S. aureus* is the unique aetiological agent. Invasion of the blood stream by staphylococci may result in endocarditis, osteomyelitis or other serious infections, while location at the upper lip and nose may spread staphylococci via the facial and angular veins to the cavernous sinus.

Impetigo

This is a superficial, infection of the skin appearing initially as vesicular and rapidly as thick, golden-yellow-crusted lesions in the exposed areas of the skin. In 90 % of the cases, group A streptococci are involved and rarely group B (in the newborn) as well as group C and G. In 10 % of the cases, a bullous form of impetigo is observed due to *S. aureus*.

Erysipelas and Cellulitis

This refers to superficial skin infection with distinctive lymphatic involvement. In 70–80 % of cases, the lower extremities are affected and only in 5–20 % the face. In almost all cases, group A streptococci and uncommonly group C and G are implicated. However, in the neonate, group B is also involved. Patients with diabetes mellitus, venous stasis, nephritic syndrome or lymphatic obstruction (as after radical mastectomy) are vulnerable to erysipelas. Portals of entry for streptococci are skin ulcers, abrasions, postoperative wounds, eczematous or psoriatic lesions and even skin fungal infections. Erysipelas is painful with a red 'peau d'orange' picture and a characteristic raised border which is sharply demarcated from the surrounding normal skin. As a rule, streptococci cannot be cultured from the skin lesions. The infections can be complicated with cellulitis, subcutaneous abscesses and even necrotizing fasciitis. However, cellulitis can appear as an acute infection extending from the beginning into deep subcutaneous tissues. Cellulitis may be caused by numerous organisms, indigenous to the skin or to particular environmental niches.

Cellulitis associated with furuncles, carbuncles or abscesses is usually caused by *S. aureus*. In contrast, cellulitis that is diffuse or unassociated with a defined portal is most commonly caused by streptococcal species. Important clinical clues to other causes include physical activities, trauma, water contact, and animal, insect or human bites.

Staphylococcal Scalded Skin Syndrome

This represents a severe *S. aureus* infection characterized by widespread large flaccid clear bullae, which promptly rupture resulting in

exfoliation that exposes large areas of bright red skin. It starts with fever, skin tenderness and a scarlatiniform rash. The early stage should be differentiated from 'toxic shock syndrome', which is characterized by hypotension or shock, functional abnormalities of at least three organ systems and desquamation of the skin lesions. *S. aureus* strains, with the capacity to produce exotoxins, are the main cause; however, group A streptococci are also implicated.

Necrotizing Infections

Necrotizing fasciitis (NF) may be monomicrobial and caused by *S. pyogenes*, *Vibrio vulnificus* or *Aeromonas hydrophila*. Recently, necrotizing fasciitis was described as a complication of MRSA infection. Polymicrobial NF may occur following surgery or in patients with peripheral vascular disease, diabetes mellitus, decubitus ulcers and spontaneous mucosal tears of the gastrointestinal or gastrourinary tract (i.e. Fournier gangrene). As with clostridial myonecrosis, gas in the deep tissues is frequently found in these mixed infections.

Gas gangrene is a rapidly progressive infection caused by *Clostridium perfringens*, *Clostridium septicum*, *Clostridium histolyticum* or *Clostridium novyi*. Severe penetrating trauma or crush injuries associated with interruption of the blood supply are the usual predisposing factors. *C. perfringens* and *C. novyi* infections have recently been described among heroin abusers following intracutaneous injection of heroin. *C. septicum* may cause spontaneous gas gangrene in patients with colonic lesions (such as those due to diverticular disease), adenocarcinoma or neutropenia.

Necrotizing fasciitis and gas gangrene may cause necrosis of skin, subcutaneous tissue and muscle. Disproportionate pain as compared to initial clinical findings should always prompt to this diagnosis. Cutaneous findings of purple bullae, sloughing of skin, marked oedema, crepitus, foul odour and systemic toxicity mandate prompt surgical intervention because necrotizing skin infections represent a medical-surgical emergency and they are life threatening.

Hidradenitis Suppurativa

This is a chronic suppurative subcutaneous process that results from occlusion of follicles, secondary inflammation and sometimes infection of the pilosebaceous and apocrine glands of the genital, perianal and axillary regions. Recent investigations suggest that the interleukin-12-interleukin-23 pathway and tumour necrosis factor α (TNF-α) are involved in the pathogenesis of hidradenitis suppurativa, supporting the suggestion that it is an immune or inflammatory disorder. Red nodules that become fluctuant and drain are the initial lesions, which result in chronic draining sinuses and cicatricial scars. Secondary infections involve staphylococci, streptococci, Enterobacteriaceae, *Pseudomonas* spp. and anaerobes. Therefore, a therapeutic decision should not be empirical but based on 'pus' culture results. For severe and refractory disease, TNF-α inhibitors, oral retinoids, immunosuppressants and other therapies are used.

Antibacterial Agents

Penicillin G

Today this is still the drug of choice for streptococcal infections as well as for anthrax and *Erysipelothrix* infection (soft tissue and/or systemic infection after exposure to domestic or marine animals and seafood). Depending on the severity of the infection, it is given either orally as penicillin V, in case of impetigo (1.5 million IU every 6 h) with an empty stomach (at least for an hour) or parenterally as i.v. penicillin G (3–4 million IU every 4–6 h, over 30 min). Oral penicillin (1.5 million IU every 12 h with empty stomach) or i.m. benzathenic penicillin G (2.4 million IU every 20 days) given for a period of 12–18 months is effective as prophylaxis for recurrent cellulitis (for patients with a history of two or more episodes).

The major side effects of penicillins in general are hypersensitivity reactions, which range in severity from rash to anaphylactic shock and death. While allergic rash reactions occur

in 4–7/1,000 penicillin treatment courses, immediate anaphylactic reactions occur mostly with penicillin G from 0 to 1 h post administration and are expressed as urticaria, angiooedema, laryngeal oedema, bronchospasm and shock. They occur in 4/100,000 penicillin treatment courses with fatalities reported once in every 32,000–100,000 treatment courses. Late allergic reactions observed after 72 h of β-lactam administration are manifested by morbilliform rash, Stevens-Johnson syndrome, exfoliative dermatitis, drug fever, serum sickness, neutropenia, thrombocytopenia, haemolytic anaemia, interstitial nephritis, vasculitis, pruritus and contact dermatitis.

The detection of anaphylactic reactions to penicillin requires skin testing using minor antigenic determinants, a test not available in several countries. However, a negative result when testing with the major antigenic determinants, available commercially as the Pre-pen test, does not exclude the possibility of an anaphylactoid reaction, while skin testing with diluted penicillin G is very dangerous in individuals prone to express an anaphylactoid reaction. Therefore, whenever the appropriate tests are not available, a careful history of any potential for previous allergic reactions should be noted. In cases of an immediate reaction, adrenaline solution (1:1,000) should be given i.m. and repeated every 15 min until recovery, followed by corticosteroids.

Antistaphylococcal Penicillins

Oxacillin, dicloxacillin, cloxacillin, flucloxacillin and nafcillin, either orally at a dose of 1 g every 8 h for mild infections or parentally at a dose of 3 g every 6–8 h for serious infections, are still the drugs of choice for staphylococcal infections. However, it should be seriously considered that 20–50 % of *S. aureus* strains are now resistant to them (methicillin-resistant *S. aureus*, MRSA). Interestingly such infections, although mostly hospital acquired, are also encountered in the community (community-acquired MRSA, CA-MRSA). Therefore susceptibility tests, at least in serious infections, are required. It should be pointed out that MRSA strains are obligatorily resistant to any type of β-lactam antibiotic including the inhibitor combinations, the cephalosporins and the carbapenems.

The remaining group of penicillins, i.e. aminopenicillins (ampicillin and amoxicillin), carboxypenicillins (carbenicillin and ticarcillin), ureidopenicillins (mezlocillin, azlocillin, piperacillin) as well as the β-lactam group of monobactams (aztreonam) and carbapenems, will not be included since they are out of the scope of this handbook.

β-Lactamase Inhibitors

These compounds, which are by themselves weak antibiotics, are potent inhibitors of many plasmid-mediated, and also of some chromosomal, β-lactamases, produced by *S. aureus* and several Enterobacteriaceae. Three derivatives are in clinical use, clavulanic acid, sulbactam and tazobactam. These restore the antibacterial activity of amoxicillin and ticarcillin (when combined with clavulanic acid), ampicillin (combined with sulbactam), piperacillin and cefoperazone (combined with tazobactam) against Gram-positive cocci, including staphylococci (but not MRSA strains) and several common Gram-negative species. Ticarcillin and piperacillin combinations are also active against *P. aeruginosa*.

Clavulanic acid and sulbactam bind primarily to plasmid-encoded β-lactamases, while tazobactam binds also to chromosomally encoded enzymes, produced mainly by *Klebsiella* and *Bacteroides* species.

The pharmacokinetics of clavulanic acid and sulbactam in humans are similar to those of amoxicillin and ampicillin. They are both available in oral and parenteral formulations with a weight ratio of inhibitor to the relevant β-lactam of 1:5 and 1:2, respectively. When clavulanic acid is combined with ticarcillin, the ratio is 1:25, and for tazobactam-piperacillin is 1:8. With the exception of clavulanic acid, the excretion of which is influenced in renal failure (and therefore amoxicillin plus clavulanic acid should not be administered in patients with renal insufficiency)

the dose of the remaining combinations should be reduced proportionally to the decrease of the relevant β-lactam dose. Tissue kinetics of the inhibitors are compatible with those of the combined β-lactam.

Clavulanic acid plus amoxicillin is given in adults orally at a dose of 1 g every 12 h, while i.v at a dose of 1.2 g every 6 h. An oral extended release (XR) formulation is available, which is administered at a dose of 1.25 g every 12 h. Sulbactam plus ampicillin is given orally at a dose of 3.75 g every 8 h and i.v. at a dose of 3 g every 6–8 h. Clavulanic acid plus ticarcillin is given only i.v. at a dose of 3.2 g every 4 h or 5.2 g every 6 h, while tazobactam plus piperacillin is given at a dose of 3.375 g every 6 h or 4.5 g every 6 h (depending on the available formulation).

As with any β-lactam antibiotic, allergic reactions are the main threat, and they are mainly attributed to the combined β-lactam and very seldom to the inhibitor itself. Diarrhoea with the oral compounds exceeds in some series 10 % of the treated cases.

Because of their very wide spectrum of activity, which disturbs gastrointestinal tract flora and destroys colonization resistance, the inhibitors should not be given for the common streptococcal or staphylococcal infections, taking also into consideration that MRSA strains are by definition resistant. On the contrary, when SSTIs are likely to be polymicrobial such as surgical site infections of the abdominal wall, or in proximity to the genital tract or rectum, diabetic foot infections and human or animal bites, β-lactam/β-lactamase inhibitor combinations should be among the preferred treatment options.

Table 131.1 Classification of cephalosporins with half-lives and daily dosage schedules

Generic name	Half-life (h)	Daily dosage regimen and route of administration
First generation		
Cefazolin	1.8	1 g every 8 h i.v. or i.m.
Cephradine	0.7	0.5 g every 6 h orally or 1–2 g every 4–6 h i.v.
Cephalexin	0.9	0.5–1 g every 6 h orally
Cefadroxil	1.2	0.5–1 g every 12 h orally
Second generation		
Cefamandole	0.8	2 g every 4–6 h i.v.
Cefoxitin	0.8	2 g every 4–6 h i.v,
Cefuroxime	1.3	1.5 g every 6–8 h i.v.
Cefotetan	3.5	2–3 g every 12 h i.v.
Ceforanide	3.0	1–2 g every 12 h i.v.
Cefuroxime axetil	1.3	0.25–0.5 g every 12 h orally
Cefaclor	0.8	0.5–1 g every 8 h orally
Cefprozil	1.2	0.5–1 g every 8 h orally
Loracarbef	1.1	0.4 g every 12 h orally
Third generation		
Cefotaxime	1.0	2 g every 6–8 h i.v
Ceftriaxone	8.0	2 g every 12–24 h i.v.
Ceftazidime	1.8	2 g every 8 h i.v.
Ceftizoxime	1.7	2 g every 8–12 h i.v.
Cefoperazone	2.0	2 g every 8–12. h i.v
Cefixime	3.7	0.4 g every 24 h orally
Cefpodoxime proxetil	2.2	0.4 g every 12 h orally
Cefetamet	2.2	0.5 g every 12 h orally
Cefditoren pivoxil	1.6	0.4 g every 12 h orally
Ceftibuten	2.5	0.2 g every 12 h orally
Fourth generation		
Cefepime	2.1	1–2 g every 8–12 h i.v.
Cefpirome	1.0	1–2 g every 8–12 h i.v.
Anti-MRSA		
Ceftaroline fosamil	2.6	0.6 g every 12 h i.v.
Ceftobiprole	3.0	0.5 g every 8–12 h i.v.

Cephalosporins

Based on their in vitro activity and their stability to β-lactamases, cephalosporins are divided into four generations (Table 131.1). They represent broad-spectrum antibiotics, the first and second generation being more potent against the Gram-positive cocci, the third and fourth against the nosocomial Gram negatives, including the various Enterobacteriaceae and *P. aeruginosa*. Also, the fourth generation has greater coverage against Gram-positive organisms than the third-generation agents.

Cephalothin, cephradine, cefazolin, ceforanide and cefamandole possess the highest activity against staphylococci; cefoxitin and cefotetan are the only ones active against *Bacteroides fragilis*, but acquired resistance is increasing. Ceftazidime is the most potent against *P. aeruginosa*. The

latter compound, however, is practically not active against streptococci and staphylococci. None of the first-, second-, third- or fourth-generation agents are active against methicillin-resistant staphylococci.

The pharmacokinetic properties of the parenteral compounds differ in that the half-life ($t_{½}$) can range from 30 min to 8 h, mandating the frequency of administration (Table 131.1). Based on the much lower minimal inhibitory concentrations (MICs) for Gram-negative bacteria as well as the addition of different side chains at position 3 of their nucleus, which modifies their kinetic properties, third- and fourth-generation cephalosporins in comparison with earlier compounds have kinetics which are particularly advantageous when treating infections in the cerebrospinal fluid or the prostatic and bone tissues.

Adverse effects associated with the cephalosporins are similar to those from other β-lactams and concern mainly allergic reactions. However, anaphylaxis/angiooedema reactions are rare relative to the frequency of 0.04 % associated with penicillin. Allergic cross-reactions with the penicillins are expected at a range of <7 %. Haematological adverse effects and coagulation abnormalities (hypoprothrombinaemia) have been reported mainly with moxalactam (which has been removed from the market), while gastrointestinal reactions such as antibiotic-associated diarrhoea including pseudomembranous colitis occur at a frequency of 1–7 %.

Like the β-lactam/β-lactamase inhibitor combinations, cephalosporins should not be given for common SSTIs since their extremely broad spectrum of activity disturbs the normal flora, facilitating colonization with enterococci and fungi. Additionally, cephalosporin use favours selection of resistant clones, especially Gram-negative species producing extended-spectrum β-lactamases (ESBLs) in normal floras. Furthermore, these agents do not provide coverage against MRSA, so if this pathogen is a concern, empiric coverage with another active agent is recommended pending culture results. The appropriate dosage regimens for adults are shown in Table 131.1.

Ceftaroline

Ceftaroline fosamil is the prodrug of the active metabolite ceftaroline. Ceftaroline is a novel agent that belongs to the antimicrobial class of cephalosporins. Because of its unique spectrum of activity, which includes methicillin-resistant staphylococci, it has been described in the literature as a 'fifth-generation' cephalosporin.

Like other β-lactams, ceftaroline exerts its rapid bactericidal effect by binding to key penicillin-binding proteins (PBPs). It has a high affinity against MRSA PBP 2A and against penicillin-resistant *Streptococcus pneumoniae* PBPs.

Ceftaroline has a broad-spectrum activity against Gram-positive and Gram-negative organisms including *S. pneumoniae*, *S. aureus* (methicillin-resistant as well as vancomycin-intermediate and – resistant isolates), *Streptococcus pyogenes* and other Streptococci and Gram-negative species (*Haemophilus influenzae*, *Moraxella catarrhalis* and Enterobacteriaceae non-ESBL producers). The majority of MRSA isolates are inhibited by ceftaroline concentration ≤1 mg/L (MIC range, ≤0.12–2 mg/L). Similarly, ceftaroline MIC_{90s} for hetero-resistant vancomycin-intermediate *S. aureus* (hVISA), vancomycin-intermediate *S. aureus* (VISA) and vancomycin-resistant *S. aureus* (VRSA) strains are ≤2 mg/L (MIC range, ≤0.25–4 mg/L).

Ceftaroline fosamil is dosed at 600 mg i.v. every 12 h (infusion over 1 h) in adults. Dosage adjustment is necessary in patients with moderate to severe renal impairment. Ceftaroline is well tolerated. The most common adverse events reported in clinical trials were diarrhoea, nausea and headache. The most common adverse event leading to discontinuation of ceftaroline was hypersensitivity (0.3 % of patients).

In 2010, ceftaroline fosamil was approved by the FDA for the treatment of acute SSTIs and community-acquired pneumonia. In cases where coverage for MRSA is necessary but *Pseudomonas* and *Acinetobacter* are not among the possible pathogens, ceftaroline is an attractive option because of its favourable safety and

tolerability profile. The lack of activity against non-fermenters is another positive characteristic since the use of ceftaroline is not expected to increase the burden of selective pressure against these problematic nosocomial pathogens.

Aminoglycosides

They are represented by tobramycin, netilmicin, amikacin and isepamicin for systemic use, neomycin for topical application and gentamicin for both. It should be pointed out that all aminoglycosides are inactive against streptococci as well as against anaerobes, while despite their in vitro activity, they do not behave as bactericidal agents against staphylococci. However, after combination in vitro with antistaphylococcal penicillins and/or rifampicin, they exhibit a synergistic result. Therefore, the dermatologist at least for the common streptococcal or staphylococcal infections should not prescribe any aminoglycoside either systemically or locally, as solutions or as ointments. Aminoglycosides are by definition ototoxic and nephrotoxic agents. Local application facilitates development of resistance among the Gram negatives and particularly in *P. aeruginosa* strains (which serve as colonizers and future pathogens) since the exposed skin area favours transfer of resistance genes. It should also he considered that various non-antimicrobial ointment ingredients are capable of inducing allergic skin reactions aggravating inflammatory signs.

Tetracyclines

The tetracyclines currently in use for systemic administration are the short-acting compound, tetracycline ($t_{½}$, 8–9 h) and the long-acting derivatives, doxycycline and minocycline ($t_{½}$, 16–18 h).

Tetracycline should be administered on an empty stomach to increase absorption, while doxycycline and minocycline are absorbed almost completely, achieving high serum levels with relatively small doses. Despite their broad spectrum of activity covering both Gram-positive and several Gram-negative aerobic and anaerobic species, acquired resistance has emerged both among *S. pyogenes* and among *S. aureus* strains. In particular, minocycline is the most effective against *S. aureus*, including both MRSA and CA-MRSA strains.

The long-acting tetracyclines are lipophilic, and they are diffused in many tissues and fluids. However, they all cross the placenta. They concentrate in fetal bone and teeth causing hypoplasia of the enamel with subsequent permanent grey-brown to yellow discoloration of the teeth and depression of skeletal growth in premature infants. Therefore, tetracyclines should not be given during pregnancy, at the breastfeeding period or to children up to the age of 8 years when tooth enamel is being formed. Tetracyclines may cause photosensitivity reactions, gastrointestinal tract disturbances and hepatotoxicity. Vertigo is a side effect unique to minocycline, usually beginning on the second or third day of therapy, and it is more frequently observed in women than in men.

Food in general decreases the absorption of tetracyclines, while all form inactive complexes with divalent or trivalent cations. Therefore, tetracyclines should not be given simultaneously with calcium, magnesium and aluminium in antacids, milk or iron-containing compounds. Also, they should not be prescribed in pre-existing renal or hepatic insufficiency.

Tetracycline is given at a dose of 500 mg every 6 h. Minocycline is given at a loading oral dose of 200 mg followed by a daily dose of 100 mg every 12 h and doxycycline at a dose of 100 mg every 12 h. Doxycycline or minocycline has been proposed by the 2011 Infectious Diseases Society of America (IDSA) guidelines as one of the options for empirical treatment of SSTIs caused by CA-MRSA in outpatients. In case coverage for both β-haemolytic streptococci and CA-MRSA is desirable, a combination with a β-lactam is recommended.

Tigecycline

Tigecycline is the first member of a new class of broad-spectrum antibiotics, the glycylcyclines. It

is a derivative of minocycline, designed to avoid both *tetK* (tetracycline-specific efflux-mediated) resistance and *tetM* (target modification) class resistance to tetracyclines. It inhibits bacterial protein synthesis by binding to the 30S ribosomal subunit but with a five times higher affinity than that for the tetracyclines. Tigecycline exhibits a bacteriostatic activity. Its antimicrobial spectrum includes staphylococci (both methicillin-susceptible and methicillin-resistant isolates), streptococci, enterococci (both vancomycin-susceptible and vancomycin-resistant isolates) and multidrug-resistant Enterobacteriaceae (with the exception of *Proteus*, *Providencia* and *Morganella* spp.), *Acinetobacter* spp. as well as anaerobes. It is not active against *P. aeruginosa*. Tigecycline is administered at a loading dose of 100 mg i.v. the first day, followed by 50 mg every 12 h from the second day on. No dose adjustment is required in renal impairment and in moderate hepatic impairment, while a 50 % reduction of the daily dose is required in case of severe hepatic impairment.

Tigecycline has been approved for the treatment of cSSTI by susceptible pathogens. Monotherapy with tigecycline could be a choice when a broad-spectrum antimicrobial coverage is indicated (for polymicrobial or mixed infections) provided that *P. aeruginosa* is not among the causative bacteria. Tigecycline has not been approved for the treatment of diabetic foot infection. Clinicians should add an antipseudomonal agent to empirical regimens in patients with risk factors for pseudomonal infections. A concern is that tigecycline has not been evaluated in randomized trials for the treatment of severely ill patients. Observational non-randomized studies have shown a clinical success rate of around 80 % in critically ill patients with cSSTI. The data from the pivotal trial with tigecycline versus vancomycin-aztreonam in cSSTI revealed a non-significant difference in mortality of 0.7 %. The bacteriostatic action of the drug and the limitations of its PK/PD characteristics, mainly a low achievable Cmax, create concerns about its use in the case of bacteraemic and septic patients.

Tigecycline is in general well tolerated. Frequently observed side effects are of gastrointestinal origin (nausea, vomiting) but the most serious ones consist of a decrease in fibrinogen and a reversible coagulopathy and thrombocytopenia.

Macrolides and Clindamycin

The macrolides (erythromycin, roxithromycin, azithromycin and clarithromycin) and the lincosamides (lincomycin and clindamycin) although chemically unrelated, they have similar properties. Among the macrolides, clarithromycin possesses the most potent in vitro action against group A streptococci and methicillin-susceptible staphylococci (MSSA) strains followed by erythromycin, while azithromycin is two- to fourfold less active than erythromycin. However, cross-resistance among macrolides and lincosamides is usually the rule. It is a matter of concern that resistance rates of *S. pyogenes* to erythromycin have been increasing. MRSA strains are almost always resistant to macrolides. Lincomycin or clindamycin resistance has been reported in 20–85 % of MRSA strains including 50 % of erythromycin-resistant strains. Clindamycin resistance among erythromycin-resistant strains could be inducible, and it may be overlooked if the laboratory does not perform a special test, called 'D test'. However, cross-resistance of *S. aureus* between lincomycin and clindamycin is complete. Clindamycin activity against streptococci is more potent than lincomycin but similar to that of erythromycin.

With the exception of azithromycin, which is better absorbed without food, all others can be taken with food. Half-lives are 1.4 h for erythromycin, 3–7 h for clarithromycin, >70 h for azithromycin and >2.5 h for the lincosamides. Therefore, erythromycin should be administered at doses of 500 mg every 8 h orally or i.v., clarithromycin at 500 mg every 12 h orally or i.v., azithromycin at 500 mg every 24 h orally or i.v., lincomycin at 600 mg every 8 h i.v. or i.m. and clindamycin at 600 mg every 8 h i.v. or orally. With the exception of CSF, all have good tissue penetration, and all are selectively concentrated in the neutrophils and the macrophages. A dose

adjustment is required for erythromycin and clarithromycin in patients with renal impairment.

Macrolides in general are safe drugs. Their main adverse reactions concern the gastrointestinal tract, more with erythromycin and much less with clarithromycin and azithromycin. However, with lincosamides, diarrhoea occurs in up to 20 % of patients, while 1.9–10 % of clindamycin-treated patients will suffer from the complication of pseudomembranous colitis caused by toxin-producing *Clostridium difficile*.

Macrolides and lincosamides can be used as alternatives to penicillin, particularly in β-lactam allergic patients when streptococci and MSSA are the potential pathogens. However, macrolides should not be used alone in the treatment of deep-seated staphylococcal infections because of the fear for the emergence of resistance during therapy. Clindamycin has been proposed by the 2011 IDSA guidelines as one of the options for empirical treatment of SSTIs caused by CA-MRSA. It can be used as monotherapy when coverage for both CA-MRSA and β-haemolytic streptococci is needed. An advantage of clindamycin is that it suppresses toxin production in toxin-producing strains of *S. aureus* or streptococci, which could be responsible for serious complications in the setting of SSTIs (necrotizing fasciitis, toxic shock syndrome, etc.).

Quinolones

The fluoroquinolones are represented by norfloxacin, ciprofloxacin, ofloxacin, moxifloxacin, levofloxacin and prulifloxacin. They represent fluorine- and piperazinyl-substituted derivatives of the original nalidixic acid structure, which is a 1, 8-naphthyridine. They are characterized by a broad spectrum of activity and good tolerability. Most are available for oral and parenteral use and possess similar bioavailability for both routes. Despite their broad spectrum of activity, the above-mentioned fluoroquinolones (with the exception of moxifloxacin) are not active against streptococci, anaerobes and MSSA, while their activity against MRSA is considered as borderline. Therefore, there is no absolute indication for their use in common dermatological infections. However, whenever *P. aeruginosa* is implicated, ciprofloxacin is an option because it is the only orally available antimicrobial agent with antipseudomonal activity. Furthermore, norfloxacin and prulifloxacin have no indication for SSTIs.

Ciprofloxacin is administered at a dose of 500–750 mg every 12 h p.o. or 600 mg every 12 h i.v. A formulation of extended release (XR) is also available, and it is given at a dose of 500 or 1,000 mg every 24 h. Ofloxacin is administered at a dose of 400 mg every 12 h p.o. or i.v. and levofloxacin at 500–750 mg every 24 h p.o or i.v. A dose adjustment is needed for ciprofloxacin and levofloxacin in patients with renal impairment.

The most important but rare adverse effects of the above-mentioned quinolones include QTc interval prolongation, central nervous system (CNS) excitatory symptoms, glucose dysregulation, hepatotoxicity, hypersensitivity, phototoxicity, peripheral neuropathy and tendonitis. Also, quinolones have been associated with *C. difficile-associated* diarrhoea.

Moxifloxacin is a novel 8-methoxyfluoroqulnolone with an improved spectrum of activity, which includes Gram-positive, Gram-negative, aerobic and anaerobic bacteria as well as intracellular pathogens. As with other quinolones, moxifloxacin acts by binding to and inhibiting bacterial topoisomerases (i.e. topoisomerases II and IV), exhibiting a bactericidal effect. It is very active against streptococci, pneumococci, irrespective of β-lactam or macrolide resistance and against MSSA. It has a more variable activity against MRSA strains. It is also active against Enterobacteriaceae, but not against *P. aeruginosa*. Its spectrum also includes several species of anaerobes: *Clostridia*, *Fusobacteria*, *Prevotella*, *Porphyromonas*, *Peptostreptococci*, *Propionibacterium* and *B. fragilis*. Moxifloxacin has also good in vitro activity against pathogens isolated from patients with animal or human bite infections and the causes of more exotic cSSTIs, such as *Bacillus anthracis*, *Yersinia pestis*, *Vibrio* spp. and *Francisella tularensis*.

It is administered orally at a dose of 400 mg once daily. It has a favourable pharmacokinetic profile with advantageous tissue penetration at

skin and soft tissue sites. It is metabolized by conjugation to inactive metabolites, and it is excreted by both renal and hepatic routes, reducing the potential for drug accumulation in patients with renal or liver impairment.

The most common, adverse events are gastrointestinal disturbances. In contrast to some other fluoroquinolones, it appears to have a low propensity for photosensitivity and CNS toxicity. As it is not metabolized by the cytochrome P450 pathway, it shows no interactions with methylxanthines, ranitidine, oral anticoagulants or contraceptives. Its bioavailability is reduced by the co-administration of antacids, sucralfate or iron preparations, but not by food.

It is licensed for the indication of respiratory tract infections, as well as for the treatment of mixed aerobic and anaerobic SSTIs from susceptible pathogens. The IDSA guidelines recommend fluoroquinolones for the treatment of infections that are likely to be polymicrobial, including surgical wound infections involving the abdominal wall, perineum and genital tract as well as animal and human bite infections.

Rifampin

Primarily used for tuberculosis, rifampin has also very promising bactericidal activity against staphylococci, including a high percentage of MRSA strains. However, it should never be administered as a single agent, because staphylococci will rapidly develop resistance in vivo even after the first dose. To protect, against this, rifampin should be combined with another agent possessing antistaphylococcal activity, like trimethoprim-sulfamethoxazole, a fluoroquinolone, a glycopeptide or daptomycin. It should not be given empirically but only in cases where MRSA strains have been isolated and their susceptibility to rifampin has been confirmed. As an extremely lipophilic substance, rifampin penetrates well into all body tissues and stains brightly red almost all body excretions.

It is given in adults as a daily dose of 600 mg plus 300 mg orally or i.v. with an empty stomach (at least 1 h before meals). Rifampin may cause hepatotoxicity, while it is one of the most potent inducers of intestinal and hepatic microsomal enzymes leading to decreased serum $t_{½}$ for several compounds, among which are digoxin, dicumarol anticoagulants, prednisone, ketoconazole and oral contraceptives, requiring dosage adjustments for the latter drugs or therapeutic drug monitoring or even drug discontinuation.

Fusidic Acid

This antibiotic, despite its advantageous properties, is not available in the USA. It is mainly active in vitro and in vivo against staphylococci, including a high percentage of MRSA strains. Fusidic acid possesses excellent tissue kinetics and has a $t_{½}$ of 14 h. With the exception of self-limited hepatotoxicity, fusidic acid is safe and well tolerated by the oral route. The i.v. formulation should be given by slow infusion (3–4 h) to avoid chemical irritation of veins and subsequent thrombophlebitis. It is administered at a dose of 500 mg every 8 h orally or i.v. Topical use of fusidic acid in the form of gauzes or ointments should be avoided since it is rapidly followed by emergence of resistance in staphylococci colonizing the skin.

Trimethoprim/Sulfamethoxazole

The combination acts synergistically against Enterobacteriaceae and staphylococci since trimethoprim potentates the sulfonamide activity by the sequential inhibition of folic acid synthesis. It is given at a dose of 980 mg every 8–12 h p.o or i.v., with a dose adjustment in case of renal impairment. The most important side effects are attributed to the sulfonamide component and include acute haemolysis related to glucose-6-phosphate dehydrogenase deficiency, haematologic toxicity (leukopenia, thrombocytopenia or pancytopenia), hypersensitivity reactions and erythema multiforme often expressed as Stevens-Johnson syndrome. The combination has bactericidal activity against staphylococci. It has proven to be in vitro active against 95–100 % of CA-MRSA strains, and although clinical studies for its efficacy in the treatment of staphylococcal

infections are limited, the 2011 IDSA guidelines recommend it as one of the options for empirical treatment of SSTIs caused by CA-MRSA in outpatients. The good tissue penetration, the availability of oral formulation and the low cost make trimethoprim/sulfamethoxazole an attractive alternative to newer more expensive drugs or drugs that require intravenous administration. Nevertheless, it should be avoided as monotherapy in cellulitis because it has poor activity versus *S. pyogenes*.

Glycopeptides

This group is represented by vancomycin and teicoplanin. They bind with high affinity to the D-Ala-D-Ala C-terminus of late peptidoglycan precursors and prevent reactions of cell-wall synthesis in Gram-positive bacteria. Glycopeptides are active against staphylococci, including methicillin-resistant strains, streptococci, enterococci, *Corynebacterium* spp. and *B. anthracis*. They are also active against Gram-positive anaerobes including *Clostridium* spp. However, some *S. haemolyticus* and *S. epidermidis* strains are resistant.

Vancomycin is administered i.v. at a dose of 15–20 mg/kg/dose every 8–12 h. Therapeutic drug monitoring is recommended, and trough levels should not be lower than 15 mg/L for a successful clinical outcome. Teicoplanin has an extremely prolonged $t_{½}$ (30–180 h); therefore, it is given both i.v and i.m. at a dose of 8–10 mg/kg twice daily for the first day and once daily afterwards.

For decades, vancomycin has been the standard therapy for patients with serious infections due to MRSA. In addition, vancomycin is the antibiotic most extensively studied in clinical trials involving patients with SSTIs, and it is recommended by the 2011 IDSA guidelines as one of the treatment options for patients with cSSTIs due to MRSA. However, its efficacy has come into question, with concerns over its slow bactericidal activity, the emergence of resistant or hetero-resistant strains and the MIC 'creep' among susceptible strains. The rate of treatment failure is high in infections caused by MRSA with MIC >1 mg/L. In this case and particularly for severe infections, antistaphylococcal agents other than the glycopeptides are recommended. Vancomycin kills staphylococci more slowly than do β-lactams in vitro and is clearly inferior to β-lactams for methicillin-sensitive *S. aureus* infections. Only in cases of serious allergy to β-lactams could the glycopeptides replace them for MSSA infections.

Rapid or bolus administration of vancomycin can cause flushing and hypotension, the so-called 'red-man' or 'red-neck' syndrome, which is not an allergic reaction. Therefore, vancomycin should always be given over a 30–60 min infusion. Vancomycin is also ototoxic and potentially nephrotoxic particularly when combined with aminoglycosides or diuretics, while drug fever is the most frequent side effect. Teicoplanin is well tolerated; it does not require slow infusion, but ototoxicity, nephrotoxicity (microscopic haematuria), thrombocytopenia and drug fever may be encountered. Allergic cross-reactions are not anticipated between the two agents.

Daptomycin

Daptomycin is a cyclic lipopeptide antibiotic that disrupts cell membrane function via calcium-dependent binding, resulting in rapid bactericidal activity in a concentration-dependent fashion. It is active against Gram-positive cocci and Gram-positive bacteria including MRSA as well as staphylococci with reduced susceptibility to the glycopeptides.

Daptomycin is administered intravenously at the dose of at least 6 mg/kg/dose once daily, which could be safely increased to 8–10 mg/kg/dose once daily in patients with serious infections such as bacteraemia or infective endocarditis. No dose adjustment is needed for patients with a mild renal insufficiency, whereas for patients with a CL_{CR} of <30 ml/min including patients in haemodialysis, administration of the same dose every 48 h is recommended.

It is approved for the treatment of *S. aureus* bacteraemia, right-sided infective endocarditis and cSSTI. It should not be used for the treatment of pneumonia, because its activity is inhibited by

pulmonary surfactant. Consequently, daptomycin is one of the preferred treatment options in patients with cSSTI caused by MRSA and a high risk or evidence for bacteraemia. Furthermore, the once-daily regimen and the advantageous safety profile make daptomycin an attractive option for outpatient treatment in cases where no appropriate oral regimen is available. The IDSA guidelines for the treatment of MRSA infections published in January 2011 recommended daptomycin as one of the first-line options (AI) for the empirical therapy of cSSTI and of bacteraemia with or without endocarditis of any site in hospitalized patients.

In phase III clinical trials for the efficacy of daptomycin for the treatment of cSSTIs, the percentage of patients with a successful outcome (clinical cure or improvement) only after 4–7 days was significantly higher in the daptomycin group than in the vancomycin group. In a prospective open-label study of patients treated for the same indication, those receiving daptomycin had a significantly shorter duration of i.v. antibiotic therapy and a shorter median length of antibiotic-related hospital stay than those treated with vancomycin.

The most serious side effects consist of creatinine phosphokinase (CPK) elevations with or without symptoms. Patients should be observed for development of muscle pain or weakness and have weekly CPK levels determined, with more frequent monitoring in those with renal insufficiency or who are receiving concomitant statin therapy. Nevertheless, this is rarely treatment limiting. Treatment discontinuation is required in case of symptomatic myopathy with an increase >5 times ULN or 1,000 units/L or in asymptomatic patients with a CPK ≥10 times ULN. Also, case reports of daptomycin-induced eosinophilic pneumonia have been described.

It should be noted that non-susceptible isolates have emerged during therapy in clinical trials, leading to treatment failure. Prior exposure to vancomycin and elevated vancomycin MICs have been associated with increases in daptomycin MICs, but analysis of data from the Cubicin® Outcomes Registry and Experience (CORE) retrospective observational study showed that daptomycin treatment for a variety of staphylococcal infections was associated with similar outcomes, regardless of the level of vancomycin MIC and multivariate logistic regression failed to identify vancomycin MIC as a predictor of daptomycin failure.

Mupirocin

Mupirocin is a locally applied agent, which is bactericidal against streptococci and staphylococci both MSSA and MRSA at concentrations achieved by topical administration (20,000 mg/mL with the 2 % formulation) after 24–36 h exposure. It was formerly called pseudomonic acid because the major metabolite responsible for most of its antibacterial activity is derived from the submerged fermentation by *Pseudomonas fluorescens*. Despite its name, it is not active against *Pseudomonas* spp. Its weak in vitro activity against normal skin flora, e.g. *Corynebacterium*, *Propionibacterium* and *Micrococcus* spp., is advantageous because it preserves the skin's natural defence against infection. Unfortunately, prolonged courses of mupirocin for chronic skin infections can lead to development of resistant staphylococci. Therefore, mupirocin should not be used for long-term therapy.

Mupirocin is used for localized impetigo and folliculitis with clinical and bacteriological cure rates of 85–100 % and 80–95 %, respectively, and it is recommended for this indication by the 2005 IDSA guidelines for the management of SSTIs. However, in cases of widespread impetigo, systemic therapy is preferable. It is also effective in the therapy of secondarily infected eczema, lacerations, burns and leg ulcers. Mupirocin can also eliminate nasal carriage of *S. aureus*. No substantial toxicity in humans has been reported.

Synercid

Synercid is a combination of two semisynthetic streptogramin molecules, quinupristin (a group B or type I streptogramin) and dalfopristin

(a group A or type II streptogramin) in a 30:70 ratio (w/w). The combination has synergistic antibacterial activity in vitro against a wide range of Gram-positive organisms, including methicillin- resistant and glycopeptide-intermediate strains of staphylococci (GISA), penicillin and macrolide-resistant strains of streptococci and multidrug-resistant and vancomycin-resistant strains *of E. faecium*, while it is intrinsically inactive against *E. faecalis*. It is also active against *S. pneumoniae*, *M. catarrhalis*, pathogenic *Neisseria* spp. and Gram-positive anaerobes such as *Clostridium* and *Peptostreptococcus* spp. Synercid exerts its activity through inhibition of protein synthesis. It is bactericidal against staphylococci and pneumococci and bacteriostatic against enterococci. The recommended dose is 7.5 mg/kg every 8 h or every 12 h for SSTIs, infused over 60 min. A dose reduction is required for patients with hepatic cirrhosis or severe renal insufficiency. The drug combination is a potent inhibitor of the cytochrome P450 enzymes, exhibiting clinically important interactions with many other drugs such as antihistamines, antiretroviral agents, antineoplastic agents, benzodiazepines, calcium channel blockers, cholesterol-lowering agents, gastrointestinal motility agents, immunosuppressive agents and steroids, as Synercid enhances their activity.

It is approved for the treatment of cSSTIs and as a salvage therapy for invasive *E. faecium* and MRSA infections in the setting of vancomycin treatment failure. The most common adverse effects are arthralgia, myalgia, gastrointestinal disturbances, rash, headache, generalized pain and pruritus and increased conjugated bilirubinaemia. Peripheral venous irritation is common and can be minimized by infusion via a central venous route.

Linezolid

Linezolid is the first member of the oxazolidinone class of synthetic antibacterial agents to be introduced into clinical practice. It has a unique mechanism of action: it inhibits protein synthesis by interfering with initiation complex formation. Cross-resistance with other inhibitors of protein synthesis (i.e. macrolides, streptogramins, aminoglycosides, fusidic acid, tetracyclines, chloramphenicol) has not been observed since the oxazolidinones act early in translation, inhibiting this process at a different stage.

Linezolid inhibits most Gram-positive organisms such as staphylococci, including methicillin-resistant, glycopeptide-intermediate (GISA) or glycopeptides-resistant (GRSA) strains; *Streptococcus* spp. including macrolide-resistant strains; *E. faecium* and *E. faecalis*, including vancomycin-resistant strains; pneumococci including penicillin-resistant strains; *Bacillus* spp.; *Corynebacterium* spp.; and *Erysipelothrix* spp. Anaerobes such as *Clostridium* spp., *Propionibacterium acnes*, *Bacteroides* spp. and *Fusobacterium* spp. are also susceptible to linezolid, whereas Enterobacteriaceae and *P. aeruginosa* are not. It has bacteriostatic activity against staphylococci and enterococci.

Linezolid is available for both oral and i.v. administrations at the same dose of 600 mg every 12 h. It is rapidly and completely absorbed after oral administration with a bioavailability of approximately 100 %, not influenced by the presence of food. It has an elimination $t½$ of 5–7 h and is excreted by both renal and non-renal routes. No dose adjustment is required for renal or liver impairment.

Linezolid is approved for adults and children for the treatment of SSTI and nosocomial pneumonia due to MRSA. It has been demonstrated to be superior to vancomycin for the treatment of cSSTI caused by MRSA on the basis of a phase IV clinical trial. For serious SSTI, such as necrotizing fasciitis or infections by CA-MRSA producing Panton-Valentine Leucocidin, linezolid may be particularly useful because of its ability to impair toxin production.

Long-term linezolid use (>14 days) is limited by haematologic toxicity (thrombocytopenia occurring more frequently than anaemia and neutropenia), peripheral and optic neuropathy (with vision loss) and lactic acidosis. Although myelosuppression and optic neuropathy are generally reversible, peripheral neuropathy is not always reversible. Linezolid is a weak, nonselective,

reversible inhibitor of monoamine oxidase and has been associated with serotonin syndrome in patients taking concurrent selective serotonin receptor inhibitors (SSRIs). For this reason, treatment with SSRIs should be discontinued during therapy with linezolid.

Linezolid offers the possibility of early switch to oral therapy and, consequently, early discharge, which may be of possible economic advantage, particularly in the field of cSSTI.

Telavancin

Telavancin is a lipoglycopeptide derivative of vancomycin. It has a dual mechanism of action; it is a potent inhibitor of peptidoglycan synthesis, with a tenfold greater activity than vancomycin but also triggers rapid concentration-dependent dissipation of cell membrane potential, which results in membrane pores and leakage of cytoplasmic adenosine triphosphate and potassium ions. This second mode of action is specific for bacterial membranes and appears to contribute to the more rapid bactericidal activity of telavancin, compared with vancomycin.

Telavancin is consistently active against *S. aureus*, including methicillin-resistant, vancomycin-intermediate, linezolid-resistant and daptomycin-non-susceptible strains, against coagulase-negative staphylococci, streptococci, vancomycin-susceptible enterococci as well as *Clostridium* spp.

The drug is usually administered intravenously at 10 mg/kg every 24 h. It is excreted by the kidneys, and thus, dosage adjustments are required in cases of renal failure. Clinical trials have demonstrated non-inferiority, compared with vancomycin, in the treatment of cSSTIs and pneumonia, but it is currently approved by the FDA for the treatment of cSSTIs only. The IDSA guidelines for the treatment of MRSA infections published in January 2011 recommended telavancin as one of the first-line options (AI) for the empirical therapy of cSSTI in hospitalized patients. Telavancin is associated with higher rates of nephrotoxicity, altered taste, nausea and vomiting but lesser rates of pruritus and infusion-related events, compared with vancomycin. Telavancin might be an alternative to vancomycin in cases of difficult-to-treat MRSA infections. The potent antistaphylococcal activity of telavancin should be weighed against the potential for nephrotoxicity.

Antifungal Drugs

132

Roderick J. Hay

Key Points

- A wide number of antifungal drugs is currently used for the treatment of skin and mucosal diseases. They can be grouped into two large families and a number of smaller ones.
- Most of them are available as either topical or systemic treatments.
- The largest family of antifungals is the azole family, a group of synthetic antimicrobials that can be further subdivided into imidazoles and triazoles. There is another family of polyene antifungals that have a large macrolide ring structure. Other important antifungal agents include the allylamine and the morpholine groups as well as griseofulvin, flucytosine and ciclopirox. The echinocandins a most recently introduced group are largely used to treat systemic infections.
- The availability of these drugs for medical use varies between different countries.

General Principles, Classification and Structure

The antifungal drugs currently used for the treatment of skin and mucosal diseases can be grouped into two large families and a number of smaller ones. Most of the antifungal drugs are broad spectrum in their antifungal activity in vitro and inhibit a wide variety of different fungi that cause superficial fungal disease. Many are available as either topical or systemic treatments. In vitro some behave as cidal compounds; in other words, the concentration at which they inhibit growth, the minimum inhibitory concentration (MIC), is the same or very close to the concentration at which they destroy the fungi, the minimum cidal concentration (MCC). In theory, this property is an advantage, as it should mean that fungal cell death depends on drug concentration alone, although in real infections other factors such as local availability and in vivo structural adaptations play a key role in determining the outcome of treatment.

The largest family of antifungals is the azole family, a group of synthetic antimicrobials that can be further subdivided into two distinct subdivisions, the imidazoles and the triazoles. The chemical structure of both is based on an azole ring with different side chains that affect the solubility, antifungal activity and antimicrobial resistance properties of each compound. There is another family of polyene antifungals that have a large macrolide ring structure. In distinction to

the azoles, the polyenes are derived from *Streptomyces* species, and although a large number of different polyene derivatives are known, there are few in clinical use.

Other important antifungal agents include the allylamine and the morpholine groups as well as griseofulvin, flucytosine and ciclopirox. The echinocandins a most recently introduced group are largely used to treat systemic infections. The availability of these drugs for medical use varies between different countries.

Azole Antifungals

Mechanism of Action

There are two distinct groups of compounds within the azole family, the imidazoles and the triazoles. The imidazoles are synthetic antifungal agents. They include miconazole, clotrimazole, econazole, isoconazole, ketoconazole, tioconazole and bifonazole. The triazole series contains two potent oral agents, fluconazole and itraconazole. Two other triazoles, voriconazole and posaconazole, are mainly used for the treatment or prevention of systemic fungal infections (Table 132.1).

Many azoles have been developed for topical use although some, particularly the triazoles, are effective in the treatment of widespread or deeply seated infection, for instance, ketoconazole (oral), itraconazole (oral and intravenous), fluconazole (oral and intravenous), posaconazole (oral) and voriconazole (oral and intravenous). The azoles are metabolised in the liver and affect fungal cell-membrane synthesis through inhibition of cytochrome P450-dependent 14β demethylation which is responsible for a key stage in the synthesis of ergosterol in the cell membrane. To some extent azoles all show some affinity for certain human cytochrome P450 isoenzymes, a property which may lead to drug interactions or competition with human metabolic processes. There is, however, considerable variation amongst the different drugs in this respect. Apart from fluconazole and voriconazole, most azoles penetrate cerebrospinal fluid and urine in low concentrations. The azoles have a broad spectrum of activity against many fungal pathogens, although fluconazole, miconazole and ketoconazole are not effective for *Aspergillus* infections. By contrast, itraconazole and voriconazole are active in vitro against a very wide variety of mould fungi including aspergilli as well as dematiaceous (pigmented) fungi. Fluconazole is less active against mould fungi, and there are instances of both primary (*C. krusei*, *C. glabrata*) and secondary (*C. albicans*) antimicrobial resistance to this compound. However, all the azoles can be used for treatment of the common superficial mycoses such as dermatophytosis, candidosis and *Malassezia* infections.

Table 132.1 Azole antifungals (only the more commonly used compounds have been shown)

Class	Oral	Topical
Imidazole	Ketoconazole	Clotrimazole, miconazole, econazole, sulconazole, bifonazole, ketoconazole, tioconazole
Triazole	Itraconazole	Terconazole
	Fluconazole	

Indications and Other Uses

Topical Azoles

Many of the imidazole antifungals are available as topical agents for the treatment of superficial mycoses such as dermatophytosis and pityriasis versicolor. Some Gram-positive bacterial infections such as erythrasma caused by *Corynebacterium minutissimum* as well as *S. aureus* may respond to many imidazoles but not triazoles. Although topical imidazole creams, ointments or powders are usually given twice daily, there is evidence that some, e.g. sulconazole, can be given once daily; it is possible that this is an appropriate regimen for many azoles, but unfortunately there is no clinical trial data to support a wider recommendation at present.

The duration of treatment using topical azoles is also variable. Most of the original clinical trials were based on a 4-week treatment duration, and

their efficacy is established on this basis. However, some topically applied compounds, such as ketoconazole, appear to be effective after shorter periods of treatment; again it is not clear whether these shorter treatment regimens would also be appropriate for other topical azoles.

Ketoconazole

Ketoconazole is an imidazole antifungal available as topical therapy or as an oral tablet (200 mg). It is active against most superficial fungi including dermatophytosis *Malassezia* infections and candidosis but not against Gram-positive bacteria, a property of most other topically active imidazole antifungals. Ketoconazole is used in doses of 200–400 mg daily. However, it is seldom prescribed, in long courses, due to a risk of symptomatic hepatic reactions in some patients. There is also a shampoo formulation of ketoconazole used for the treatment of seborrhoeic dermatitis of the scalp or the management of the carrier state in tinea capitis.

Drug resistance of yeast species to ketoconazole can occur (see below).

Itraconazole

Itraconazole is an orally active triazole. Its mode of action, as with all azoles, is through the inhibition of the formation of ergosterol in the fungal cell membrane via inhibition of the 14β-demethylase enzyme. Itraconazole is fungistatic in vitro but is active against a wide range of organisms including dermatophytes, moulds such as aspergilli and dimorphic fungi such as *Histoplasma* and *Penicillium marneffei*; it is also active against yeasts including *Candida albicans*. Most countries do not have a product licence for the use of itraconazole in children. Itraconazole comes in two main formulations: a capsule containing pelleted itraconazole and an oral solution containing itraconazole in cyclodextrin. A new formulation (SubaCap) with better absorption has been approved for use, but it is not currently marketed. The oral solution is designed for the treatment of severe oropharyngeal and oesophageal candidosis in severely immunocompromised patients.

Itraconazole is also effective in dermatophyte infections. The daily doses in adults are 200 mg daily for 1–2 weeks for tinea corporis but 200 mg twice daily given each day for 1 week every month for 2–3 months in onychomycosis. This approach to treatment is known as pulse(d) therapy (De Doncker et al. 1999). Doses of 200 mg twice daily for 1 week are appropriate for dry-type tinea pedis. For tinea capitis in children, itraconazole is generally given in 3–4 mg/kg daily doses. The regimens used vary between 3 and 5 mg/kg daily for 4–6 weeks which is effective in over 80 % of children with tinea capitis due to *T. tonsurans*. A pulsed regimen using 5 mg/kg for 1 week every 3 weeks has been evaluated in a small number of children. There is no ideal therapeutic formulation for children at present.

The use of itraconazole extends to superficial candidosis, particularly to proven cases of *Candida* onychomycosis and oropharyngeal candidosis. Like ketoconazole, it is mainly used at higher dosage in AIDS patients (e.g. 200 mg daily), but the oral solution formulation can be given at 100–200 mg daily in such patients. *Malassezia* infections including pityriasis versicolor and *Malassezia* folliculitis respond to itraconazole, which is also used in severe cases of seborrhoeic dermatitis.

Itraconazole is useful in some deep mycoses such as sporotrichosis, chromoblastomycosis and subcutaneous zygomycosis. It is used as primary or secondary treatment in histoplasmosis, paracoccidioidomycosis and blastomycosis and also coccidioidomycosis and infections due to *Penicillium marneffei*. In HIV/AIDS patients, suppressive therapy in histoplasmosis and *Penicillium* infections after initial treatment is used in many countries for several months until there is evidence of cure and/or restoration of CD4 counts to prevent recurrence of infection.

Drug resistance to itraconazole is not common, but some fungi develop multiple resistance to azoles (Vanden Bossche et al. 1998) (see below).

Fluconazole

Fluconazole is an orally active triazole antifungal. As with other triazoles, the main site of action is through the inhibition of the 14α-demethylase enzyme. There are both oral

and liquid formulations of fluconazole as well as an intravenous form for deep infections.

The drug is active against a range of fungi including yeasts such as *Candida albicans* and *Cryptococcus neoformans*, as well as some mould fungi including dermatophytes. It is less active in other mould infections such as aspergillosis and zygomycosis.

Fluconazole is effective in superficial candidosis, including oropharyngeal candidosis, and dermatophytosis in doses of 100–200 mg daily. In practice, it is often given as a 150 mg weekly treatment for 2–8 weeks in tinea corporis. In onychomycosis, it is given in weekly doses of 150–300 mg and the duration monitored by clinical and mycological recovery. Fluconazole is effective against a range of different dermatophytes including both *Trichophyton* and *Microsporum* species. It has been used in tinea capitis in doses ranging from 1.5 to 6 mg/kg daily up to 8 mg/kg weekly (Scher et al. 1998).

Fluconazole is very active against *Candida* species apart from *Candida krusei* and *Candida glabrata*. However, there is a risk of resistance developing if the drug is continued in the presence of persisting infection. Resistance to fluconazole is now seen mainly in chronic vaginal infections where *C. glabrata* has become more common and in some oropharyngeal *Candida albicans* infections in AIDS patients. There are at least four different mechanisms for drug resistance including increased efflux from the fungal cell, changes in the site of action of the drug, decreased binding at the active site and the existence of supplementary paths of ergosterol biosynthesis. Drug resistance to ketoconazole and to a lesser extent itraconazole may also occur. There is no evidence that resistance may also occur among dermatophytes. Fluconazole is used for oropharyngeal candidosis and can be given at the same dosage (50–200 mg daily) to all patients. It is active against vaginal candidosis where a single oral treatment of 150 mg is given.

Fluconazole is also widely used for systemic candidosis as either oral or intravenous therapy and in the primary or secondary treatment of cryptococcosis at higher doses, e.g. 400–600 mg daily.

Newer Azoles

Neither voriconazole nor posaconazole is much used in superficial infections as their main targets are internal or systemic mycoses. Posaconazole has been found to be effective in onychomycosis and both drugs in oropharyngeal candidosis. Their high cost is at present likely to limit their use for fungal diseases seen in dermatology. Other new azoles such as albaconazole and pramiconazole of potential value in onychomycosis have not been developed to marketing.

Side Effects, Contraindications and Drug Interactions

Most of the topical azoles can occasionally cause mild stinging and, exceptionally, allergic contact dermatitis. Oral azoles have a low frequency of adverse reactions such as nausea, dyspepsia and gastrointestinal discomfort or headache. The frequency of severe adverse events is low. However, these are important to note. Ketoconazole causes hepatitis in a small proportion of cases estimated to be approximately 1:7,000. The risk factors for this are not well understood, although patients with a previous history of liver disease may be at risk. For this reason, the drug is rarely used long term for, for instance, the management of fungal nail disease. Ketoconazole may also cause gynaecomastia in males and menstrual irregularities in women when used in doses over 400 mg daily, problems associated with interferences with androgen metabolism. With itraconazole and fluconazole, the incidence of symptomatic hepatitis is much lower; in the case of itraconazole, for instance, less than 1:100,000 cases. With fluconazole, it is more difficult to estimate the frequency of adverse reactions as the cohort of patients treated with this drug has been different and includes many with severe systemic disease; attributing hepatic dysfunction in such cases to a single cause is correspondingly difficult. Exceptionally rare adverse events include angioedema (itraconazole), thrombocytopenia (fluconazole) and toxic epidermal necrolysis (fluconazole). Voriconazole has been associated with hepatotoxicity, transient visual disturbances

Table 132.2 Main drug interactions and oral antifungals

Drug name	Interaction
Terbinafine	Terbinafine serum levels reduced by *rifampicin*
	Terbinafine increases levels of *nortriptyline*, *warfarin*
Itraconazole, *fluconazole*, *ketoconazole*	Azole serum levels may be reduced by *rifampicin*, *rifabutin*, *phenytoin*, *phenobarbitone*, *carbamazepine*
The breadth of the data provided depends on reports of clinical interactions. These vary between the different drugs and between patients	Azoles may increase levels of: *terfenadine*, *astemizole*, *digoxin*, *cyclosporin*, *tacrolimus*, *midazolam*, *triazolam*, *warfarin*, *loratadine and tolbutamide*. This varies between drugs and is more prominent with itraconazole
	Azoles may also reduce serum levels of some drugs such as *oestrogens*, *cisapride* (mainly itraconazole), *busulfan*
	Itraconazole interacts with statins such as *lovastatin* and *simvastatin* to cause rhabdomyolysis
Griseofulvin	Griseofulvin serum levels reduced by *phenytoin*, *phenobarbitone*
	Griseofulvin may reduce levels of *oestrogens* and *warfarin*

Many of these drug reactions depend on interactions between drugs and cytochrome P450 isoenzymes such as P3A4. Unfortunately, these are not necessarily either predictive of the likelihood of reaction nor can they always explain the mechanisms of drug interaction. Those listed here are the commonly reported or potentially dangerous reactions. Theoretically terbinafine can interact with P2D6, but only one report of a reaction with nortriptyline is associated with this mechanism

and photosensitivity. It is also known to cause rapid onset non-melanoma skin cancers in patients on chronic treatment, e.g. after bone marrow grafting.

There is an important list of drug interactions with the azoles that should be remembered. As a general principle, itraconazole is more likely to be associated with drug interactions, but those that may cause serious consequences, e.g. terfenadine, astemizole and digoxin, are seen with all azoles. In addition, statins, e.g. somatostatin, appear to interact with itraconazole to cause rhabdomyolysis.

Table 132.3 Drug combinations that are contraindicated with the azoles – ketoconazole, itraconazole and fluconazole

Terfenadine, *astemizole*, *azolam compounds*, *cisapride* (*particular caution with digoxin*)
In addition, statins such as lovastatin should not be given with itraconazole

These interactions and those of other oral antifungals are summarised in Table 132.2. Contraindications of the use of azoles are shown in Table 132.3.

Polyene Antifungals

Mechanism of Action

The polyenes antifungals have been known for longer than the azoles. They are macrolide substances derived originally from *Streptomyces* species. Although comprising a large family, only three polyenes, amphotericin B, nystatin and natamycin, are in current use for treatment. More recent experimental additions to this group were partricin and mepartricin, but neither has been developed further. Amphotericin B, which is derived from *S. nodosus*, is the only polyene widely used as a parenterally administered drug; it is also available as an oral tablet or pastille. Nystatin and natamycin are purely topical, either creams, pastilles, suspensions or, in the case of nystatin, as a vaginal tablet, although vaginal preparations are difficult to obtain in some countries. Amphotericin B is metabolised in the liver and penetrates body cavities, cerebrospinal fluid and urine poorly. The polyenes have a broad in vitro spectrum of activity against a wide range of fungi including the major systemic pathogenic fungi such as *Aspergillus* and *Candida* species. Amphotericin B is widely used for the treatment of deep mycoses. The mode of action of the polyenes appears to involve inhibition of sterol synthesis in the fungal cell membrane. Polyenes function, though, by binding onto the sterol membrane and causing cell leakage.

Combinations of amphotericin B with a lipid, for instance, in a liposome, have been developed as a means of reducing the nephrotoxicity of the intravenous drug. The main commercial "lipid-associated amphotericins" are AmBisome (a true liposome), amphotericin B lipid complex (ABLC) or Abelcet (a ribbon-like lipid binding amphotericin B). It does not appear that these combinations have different modes of action, but in the case of AmBisome, there is evidence that the active drug, i.e. amphotericin B, is directly transferred from the lipid droplet to the fungal cell membrane. These formulations are comparatively expensive and are not used for superficial infections.

Indications and Other Uses

The polyene antifungal, amphotericin B, is widely used as a systemic agent for the treatment of systemic mycoses such as aspergillosis and candidosis. The newer lipid-associated amphotericins are used for similar indications including the treatment of the febrile neutropenic patient.

Amphotericin B is also used in the topical treatment of oropharyngeal candidosis as a lozenge; this treatment is not available in certain countries. It is given four times daily for 7–19 days.

Nystatin likewise is used for topical treatment generally for oral candidosis in lozenge or suspension form or as a vaginal tablet, where available, for vulvovaginal candidosis. It is also available as an ointment for skin disease. It is used twice daily for at least 14 days for these indications.

Natamycin is not used for the treatment of skin disease.

Side Effects, Contraindications and Drug Interactions

It is beyond the scope of this article to discuss the side effects of intravenous amphotericin B although it is recognised that the use of this drug is associated with a high frequency of side effects such as potassium loss, renal failure and renal tubular necrosis as well as anaemia. By contrast, the use of the topical preparations, either on the skin or orally, is seldom associated with any problems apart from the bitter taste of some of the oral preparations.

Allylamine Antifungals

Mechanism of Action

The allylamine drugs comprise a smaller group of compounds. There are two related compounds naftifine and terbinafine. There is also a related compound, the benzylamine, butenafine, which is available in some countries. These drugs inhibit squalene epoxidase which is active in the early part of the pathway for the biosynthesis of ergosterol in the fungal cell membrane. They are fungicidal compounds. The antifungal activity appears to depend on two events – the accumulation of squalene, which disrupts intracellular membranes, and the depletion of ergosterol in the membrane. Cidal activity resides mainly with the former property. The allylamines are available as topical agents (naftifine, terbinafine), but terbinafine is also an oral drug. Terbinafine has a very high level of in vitro activity against a number of different fungi such as dermatophytes where minimum inhibitory concentrations (MICs) lie between 0.01 and 0.001 μg/ml. The minimum fungicidal concentrations (MFCs) are usually at the same or within a single dilution of these MICs which explains the high fungicidal activity in vitro. Terbinafine is also very active against some mould fungi such as aspergilli, dimorphic pathogens, e.g. *Sporothrix schenckii*, and pigmented fungi. It is somewhat less active against yeasts such as *Candida* species and is only fungistatic against *C. albicans*. Terbinafine is lipophilic and well absorbed (70 %) after oral administration. After oral administration, it has a large peripheral volume of distribution and is bound in tissue rich in lipid or keratin. This provides a great advantage for dermatophytosis but less for yeast infections such as those caused by *Malassezia* species where terbinafine is active clinically after topical administration but not after oral treatment.

Indications and Other Uses

Terbinafine is mainly used against all dermatophyte infections, and it also has activity against a range of infections due to mould fungi including some superficial *Aspergillus* infections, chromoblastomycosis and sporotrichosis; it is less effective against yeasts such as *Candida albicans* although it can be used topically to treat superficial candidosis. Terbinafine is available as a cream or in tablet form (250 mg). The topical preparation can be used for the treatment of dermatophytosis such as interdigital tinea pedis, superficial candidosis of the skin and pityriasis versicolor. It is clear that treatment periods may be very short, and there is a single application film forming topical treatment for tinea pedis.

Oral treatment is mainly aimed at dermatophyte infections including onychomycosis due to dermatophytes. The oral compound is not clinically effective at normal doses in superficial *Candida* or *Malassezia* infections. The dose is 250 mg for adults. In some countries, a paediatric tablet is available (125 mg). In children, the regimen used is based on weight: <20 kg 62.5 mg/day, 20–40 kg 125 mg/day and >40 kg 250 mg/day. The responses of dermatophyte infections to oral terbinafine are excellent. In most tinea infections, the duration of oral treatment is 1–2 weeks. In onychomycosis, the drug is given for 6 weeks for fingernail infections and 12 weeks for toenails (Evans and Sigurgeirsson 1999). The results are good with remission rates of 70–80 % being achieved even after long-term follow-up of over 1 year (De Cuyper and Hindryckx 1999). There has been some work carried out on reducing drug exposure by using a pulsed course of treatment with 1 month on terbinafine, 1 month off and then a second month on with good results. In tinea capitis, it is effective against a range of organisms, and there are a number of studies comparing terbinafine with griseofulvin. However, there are several points to note. The treatment period is usually 4 weeks – although there are some data to show that shorter periods of treatment may be effective, e.g. 2 weeks for infections due to *Trichophyton* species. The responses of *Microsporum* species causing scalp disease are generally slower than those of *Trichophyton*, and in some patients, there is treatment failure; often a doubling of the normal dose is advised. A new granule form terbinafine has been assessed in scalp disease and has also been shown to be effective, again with the best responses in *Trichophyton* infections (Gupta et al. 2009). Terbinafine is also used in some deep infections notably sporotrichosis and chromoblastomycosis in doses of 250 mg daily.

Naftifine is a related allylamine similar to terbinafine but only available for topical usage in some countries. It is effective is dermatophytosis and other superficial mycoses. It has a similar spectrum and mode of action as terbinafine and is given for 1–2 weeks.

Side Effects, Contraindications and Drug Interactions

Terbinafine is associated with a low level of adverse effects after topical use – occasional reports of irritation. After oral treatment a variety of minor problems may occur such as nausea and dyspepsia. More serious events are occasionally seen. For instance, alteration of taste or even loss of taste may occur. It is expected to return to normal after 4 weeks. Rare instances of hepatic dysfunction presenting with jaundice have been reported. Other very rare drug side effects such as erythema multiforme, including major forms, have also been reported. Drug interactions are shown in Table 132.2; they are not common.

Griseofulvin

Mechanism of Action

Griseofulvin is an orally active compound derived from the organism, *Penicillium griseofulvin*. It is fungistatic in vitro, and its mode of action is through the inhibition of intracellular microtubules. This prevents the formation of the mitotic spindle. Griseofulvin is active in vitro against dermatophyte fungi, but few other organisms respond to the drug. In addition to its antifungal properties, it inhibits leucocyte movement.

Indications and Other Uses

The traditional treatment for many dermatophyte infections was oral griseofulvin given in a dose of 500–1,000 mg daily (adults) or 10 mg/kg daily for a period of 4–8 weeks for superficial infections apart from nail disease and for 6–18 months for onychomycosis. The drug is ineffective in *Candida* or *Malassezia* infections, and it cannot be given by topical route. There are both tablet and, in some countries, liquid formulations of griseofulvin. Griseofulvin appears slower in action than the newer azole and allylamine antifungals and, in most instances, has been superseded by the newer compounds such as itraconazole or terbinafine. However, it is effective for most organisms causing tinea capitis, although there are some patients with *M. canis* infections who require longer courses of treatment, e.g. 12 weeks. Since the earliest clinical studies, patients with *T. tonsurans* infections have been reported to have a variable response to griseofulvin, and, again, the duration of therapy may have to be increased. In some countries, griseofulvin is not available either as a tablet or as a paediatric liquid formulation.

Side Effects, Contraindications and Drug Interactions

Some patients experience gastrointestinal discomfort or nausea on griseofulvin, but generally these are tolerable. But occasionally headache may be chronic and severe, and it may be necessary to stop the drug. Other side effects include urticaria and photosensitivity – the latter may present with onycholysis. Griseofulvin may also precipitate systemic lupus erythematosus and acute intermittent porphyria. As it may cause abnormalities in sperm, its use is not advised in adult males of reproductive age in many countries. Griseofulvin may also cause hepatic dysfunction such as cholestasis. A number of interactions are described which include phenobarbitone and phenytoin that inhibit absorption (Table 132.2).

Amorolfine

Amorolfine is a morpholine antifungal available as a topical treatment for nail disease in a specially formulated nail lacquer. It has broad-spectrum antifungal activity and is fungicidal in vitro. Its mode of action is via inhibition of two enzymes, 14-reductase and the β 7, 8-isomerase, involved in ergosterol biosynthesis in the cell membrane. It is not clear how this leads to cidal activity. Amorolfine nail lacquer has been assessed as a once or twice weekly treatment for dermatophyte nail infection of limited extent and not involving the nail matrix. Treatment results suggest that it is effective as sole therapy in a smaller proportion of nail infections than would be expected with oral therapy but that it is effective as an adjunct to oral treatment. Studies show that the combination with terbinafine or pulsed itraconazole is as or more effective in onychomycosis particularly where there is nail matrix involvement.

Side effects are seldom problematic. Itching and local irritation occur in a small proportion of treated cases.

Ciclopirox Olamine (Ciclopirox)

Ciclopirox olamine is a hydroxy-pyridone derivative. It functions probably through inhibition of iron-containing mitochondrial enzymes. It has broad antifungal activity, particularly against dermatophyte fungi as well as some non-dermatophyte mould fungi, and is active topically. As with amorolfine, its minimum cidal concentrations are close to the minimum inhibitory concentrations. As ciclopirox, it has been developed as an antifungal nail lacquer; the drug is incorporated at a strength of 8 % into a transungual delivery system which allows evaporation of the solvent to provide a much higher terminal drug concentration in contact with the nail plate. While cure rates are lower than with oral therapies in nail disease, some studies indicate that it is effective in about 50 % of cases (Seebacher et al. 1993).

Flucytosine

Flucytosine (5-fluorocytosine) functions through the inhibition of fungal thymidylate synthetase. It is active against yeast fungi including *Candida glabrata* and is chiefly used with amphotericin B as a combination therapy because of its high level of synergistic activity with this polyene drug. It has been used in chromoblastomycosis in this combination. It is more generally given as treatment in systemic mycoses such as cryptococcosis. The drug is excreted in urine, and dosage should be reduced in patients with renal impairment. Resistance is also seen amongst *Candida* and *Cryptococcus* species.

Other Topical Antifungals

A number of other antifungal compounds are used in many European countries. Their availability will vary, though, across the continent. Most are sold as over-the-counter (OTC) preparations. Some of these antifungal preparations are listed here.

Tolnaftate is a tolcyclate compound used topically as a treatment for dermatophytosis. It is active against a range of dermatophyte species but cannot be used for scalp or nail disease. Undecenoic acid and zinc derivatives are used either alone or in combination as topical treatments for dermatophytosis. Whitfield's ointment, a combination of salicylic acid (keratolytic) and benzoic acid (antifungal), is available for dermatophyte infections in many European countries. The relative proportions of these two main ingredients used in the formulation may vary between countries.

Despite a number of studies aimed at evaluating new topical agents either for use in superficial mycoses (e.g. abafungin) or new formulations of topical agents for nail disease (e.g. terbinafine nail lacquer), at present none has been approved for therapeutic use. Amongst the new nail treatments is a new product combining urea ointment followed by topical bifonazole and topically applied terbinafine in transfersomes.

Treatment Regimens

General Guidelines

As a general principle, it is important to select an appropriate formulation and drug for each purpose. In practice, superficial infections of limited extent and not involving structures such as hair can be treated with topical therapy, but where the infections are more extensive or more severe oral therapy is given. It is important when giving an oral treatment to ensure that the infection is likely to be responsive. In fact the majority of superficial infections are easily treated with most of the oral agents apart from griseofulvin which is only active in dermatophytosis. Terbinafine is not active clinically in *Candida* or *Malassezia* infection by oral route although it works when given topically. For many oral compounds, it is important to understand the potential interactions and to ask patients about any concomitant medications. These interactions are listed in Table 132.2.

Adjunctive Treatments

Surgical removal of whole or parts of fungal infected nails either by laser or chemical ablation has been recommended. The usual approach to chemical nail removal has been to treat the affected nail under occlusion with topically applied urea 40 % paste for 7–10 days before removing the softened nail segments with clippers. A formulation combining urea and bifonazole is available in some countries, and the treatment pack contains a scraper for removing the soft nail. At present, there is little comparative or scientifically assessed data on laser treatment of nails, including long-term relapse rates, and reaching a valid judgement on its efficacy is not possible at present (Kimura et al. 2012; Landsman et al. 2010).

Dosages

The dosages of the main antifungal preparations are listed in the table below (Table 132.4).

Table 132.4 Antifungal drugs and their dosages

Family of antifungals	Name	Route of administration	Suggested dose
Polyenes	Amphotericin B	Oral (lozenges)	1–2 qid
		Intravenous	1 mg/kg/day
	Lipid-associated amphotericin B		3 mg/kg/day
	e.g. AmBisome (liposomal AMB)		
	Nystatin	Oral (pastilles)	1–2 qid
Azoles	Azole antifungals topical (bifonazole, clotrimazole, econazole, miconazole, sulconazole, ketoconazole, tioconazole)	Topical	Twice daily (for some once-daily therapy has been shown to be sufficient). 2–4 weeks
			Bifonazole/urea preparation is available for nail disease
	Ketoconazole	Oral	200 mg daily
	Itraconazole	Oral	200 mg bid for 1 week in tinea corporis/cruris but repeat ×2 for fingernail, ×3 for toe nails
			100–200 mg daily oropharyngeal candidosis
	Fluconazole	Oral	100–200 mg daily for continuous therapy or 150–300 mg weekly pulses
Terbinafine		Oral	250 mg daily
		Topical	Usually 7 days once daily
Griseofulvin		Oral	500–1,000 mg daily or 10 mg/kg/day
			20 mg/kg daily in *T. tonsurans* infections
Topical nail treatment	Ciclopirox nail lacquer	Topical	Daily (some studies suggest 2–3 times weekly)
	Amorolfine nail lacquer	Topical	2–3 times weekly
Flucytosine		Oral/intravenous	Daily. In patients with normal renal function, 120 mg/kg daily in four divided doses. Check serum levels in patients with renal impairment (normal 40–60 g/l)
Other antifungal compounds	Undecenoates	Topical	Different compounds usually containing zinc undecenoate/undecenoic acid. Daily use for dermatophytosis
	Benzoic acid compound (Whitfield's ointment)	Topical	Daily treatment for dermatophytosis. As it is irritant, care should be taken in using in the groin area

Antihistamines

133

Angelo Massimiliano D'Erme, Serena Gianfaldoni, Andreas D. Katsambas, and Torello M. Lotti

Key Points

- The anti-H1 antihistamines are one of the most commonly used drugs in dermatology, especially for itching dermatitis.
- Antihistamines inhibit the effects of histamine, e.g., localized vasodilation and transudation of fluid.
- They represent the first-line treatment for urticaria-angioedema, pruritus, allergic rhinitis, allergic conjunctivitis, mastocytosis, itch from mosquito bites, and prevention of adverse reaction to insect venous immunotherapy.
- The second-generation antihistamines have replaced the first ones in the dermatological treatment due to their more safe profile and their lack of both sedative and anticholinergic effects.
- The most common side effect of first-generation H1 antihistamines is drowsiness. This side effect is much lower during the therapy with the second-generation H1 antihistamines.
- A patient suffering from urticaria may profit from up-dosing of second-generation H1 antihistamines.

General Principles

The function of histamine and its receptors are known from several times.

The histamine receptors can be classified into four types: H1, H2, H3, and H4.

The H1 receptors mediate the following effects: vasodilatation of small blood vessels resulting in increased permeability and pruritus. The H2 receptors are known for mediating the effects on gastric acid production. The H3 receptors have been found in the brain and peripheral neurons and are responsible for autoregulation of histamine production and release.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_133, © Springer-Verlag Berlin Heidelberg 2015

The H4 receptors have been discovered recently. They are expressed in the skin from Langerhans cells, DCs, fibroblasts, and T cells.

Classification

The antihistamines have been used in the dermatological practice since the 1950s.

The histamine-receptor antagonists or antihistamines are classified into two classes:

- H1-type antihistamines
- H2-type antihistamines

The H1-type antihistamines can be further divided into:

- First generation – sedating, old, or classic H1-type antihistamines
- Second generation – low-sedating or new H1-type antihistamines

The H1- and also H2-type antihistamines are considered as first-line medication and can be used either in children or in adults.

The role of H3 and H4 receptors has been investigated in the last years. No agents are approved to date yet but some clinical studies are in progress. There is a considerable interest and optimism on efficacy and safety of H3 and H4 antihistamines in allergic disorders as allergic rhinitis, asthma, pruritus, atopic dermatitis, and other chronic inflammatory disorders.

The first-generation H1 antihistamines have in common with histamine a substituted ethylamine moiety as an integral part of their molecule (Fig. 133.1).

The activity of an H1 antihistamine is increased if a halogen is substituted in the *para* position of the phenyl or benzyl group of R1.

The first-generation H1 antihistamines have been divided into six chemical classes on the basis of a substitution at the X position with the nitrogen, oxygen, or carbon. The six chemical classes (and the corresponding most commonly used antihistamines) are shown in Table 133.1.

The first-generation H1 antihistamines are the first ones commercialized. They are widely used in the treatment of allergic and nonallergic

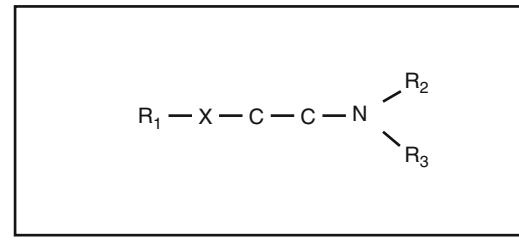

Fig. 133.1 Ethylamine moiety of H1 antihistamine

Table 133.1 Different chemical classes of first-generation antihistamines. Some of them either are not yet approved or have never been approved. Some others, such as astemizole and terfenadine, have been withdrawn from the market in the 1990s because of rare but potentially fatal side effects

	Molecules	
Chemical class	First-generation (old) H1 antihistamines	Second-generation (new) H1 antihistamines
Alkylamine (propylamine)	Brompheniramine maleate, chlorpheniramine maleate, dexchlorpheniramine maleate, dimethindene, pheniramine, triprolidine	Acrivastine
Aminoalkyl ether (ethanolamine)	Celestamine, diphenhydramine hydrochloride, carbinoxamine, doxylamine	–
Ethylenediamine	Tripelennamine citrate, tripelennamine hydrochloride, antazoline,	–
Phenothiazine	Methdilazine, methdilazine hydrochloride, promethazine hydrochloride	–
Piperidine	Azatadine maleate, cyproheptadine hydrochloride, ketotifen, diphenylpyraline	Astemizole, bilastine, desloratadine, ebastine, fexofenadine, loratadine, mizolastine, rupatadine, terfenadine, levocabastine
Piperazine	Hydroxyzine hydrochloride, hydroxyzine pamoate, oxatomide, cyclizine	Cetirizine, levocetirizine
Others	Doxepin	Azelastine, emedastine, epinastine, olopatadine

Doxepin has dual H1- and H2-antihistamine activities and it is classified as an antidepressant

disorders. These drugs, binding also other receptors such as muscarinic, serotonin, and α-adrenergic, are associated with diverse side effects. Moreover they can cross the blood-brain barrier causing sedation of varying intensity. These well-known effects can be results useful in the management of itching diseases, for example, in the nocturnal pruritus that annoys the sleep of patients suffering from atopic dermatitis.

The introduction of second-generation or low-sedating H1 antihistamines in the late 1980s was marked by significant improvements in pharmacology and safety. Their pharmacokinetics and pharmacodynamics have been investigated extensively in healthy adults as well as in elderly people, in children, and in patients with severe hepatic or renal dysfunction. Second-generation H1 antihistamines have improved tolerability and drug/food interaction profile versus the first-generation antihistamines. Thus, they have replaced the first-generation antihistamines in the dermatological treatment due to their better binding to peripheral H1 receptors, more safe profile, and lack of both sedative and anticholinergic effects. They minimally cross the blood-brain barrier and they are extensively distributed in body fluids.

Some of the second-generation antihistamines are related with the first-generation antihistamines and each other: for example, cetirizine is a metabolite of hydroxyzine and levocetirizine is an enantiomer of cetirizine.

The second-generation antihistamines are divided into classes according to their chemical structure (Table 133.1). Not all these drugs are available in all European countries.

H2-type antihistamines, as cimetidine, ranitidine, famotidine, and nizatidine, possess an imidazole ring and lack the aryl ring of H1 antihistamines. These therapeutic agents are less lipophilic, which presumably accounts for their lack of central nervous system (CNS) effects. They were developed for use in peptic ulcer diseases and they are used less than H1-type antihistamines in dermatology. However the presence of H2 receptors in the cutaneous microvasculature justified their use. Clinical trials with H3 and H4 antihistamines are in progress.

Most Commonly Used Antihistamines

- First generation – sedating, old, or classic H1-type antihistamines H1 antihistamines:
  - Dexchlorpheniramine, oxatomide, hydroxyzine, and chlorpheniramine maleate
- Second generation – low-sedating or new H1-type antihistamines:
  - Bilastine, desloratadine, ebastine, fexofenadine, loratadine, mizolastine, rupatadine, levocabastine, cetirizine, and levocetirizine
- H2-type antihistamines:
  - Cimetidine and ranitidine
- No H3 and H4 antihistamines are approved to date, yet but some clinical studies are in progress.

Mechanisms of Action

Antihistamines competitively inhibit the action of histamine by blocking its receptors on the vascular endothelial cell surface. As a result, antihistamines prevent the effects of histamine, e.g., localized vasodilatation and transudation of fluid, leading to the formation of a typical weal.

Moreover histamine is one of the mediators in the pruritus signal.

Indications and Other Uses

Antihistamines are usually used for itching dermatitis. They represent the first-line treatment for urticaria-angioedema, allergic rhinitis, allergic conjunctivitis, mastocytosis, pruritus from mosquito bites, and adverse reaction to insect venous immunotherapy. The recommendation regarding the last three is supported by smaller randomized controlled trials. Comparative studies of the subgroups of traditional H1 antihistamines have shown the drugs to be almost of equal efficacy. Their use is going to decrease. Their side effects (mainly sedation) can be useful in the management of itching disease. They can be combined with other H1 antihistamines, mainly with the low-sedating ones.

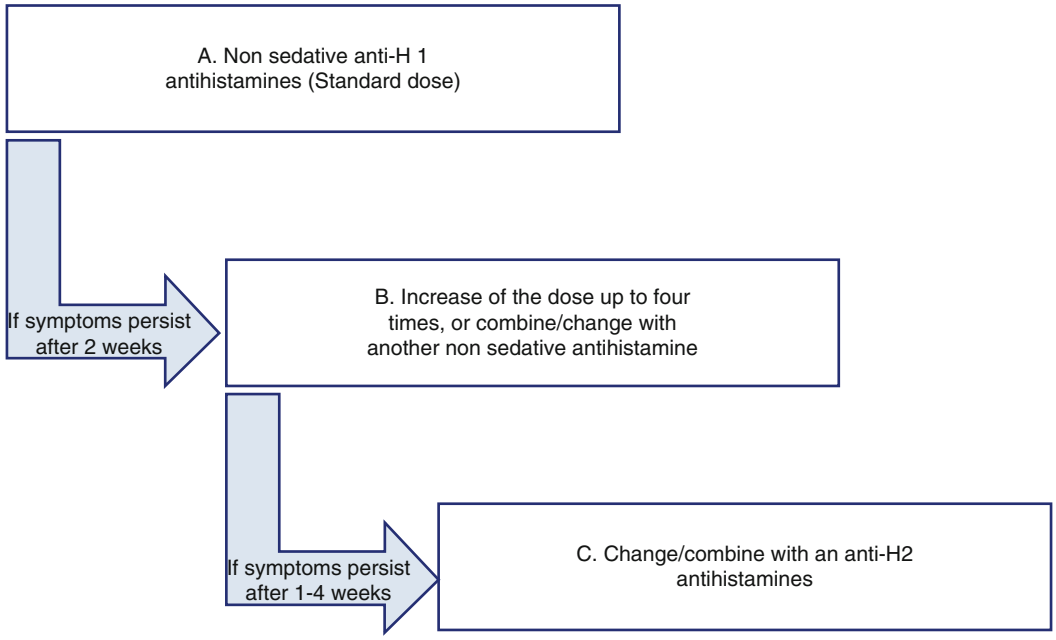

Fig. 133.2 Treatment algorithm for the use of antihistamines in urticaria (From Zuberbier et al. (2009a, b), modified)

The latter have been studied longer in the treatment of acute and chronic urticaria and angioedema and a lot of their use recommendations are derived from urticaria and pruritus guidelines.

In randomized studies, in which low-sedating H1 antihistamines have been compared with each other and with sedating H1 antihistamines, no statistically significant differences in efficacy have been proven. However, due to some important differences between all these agents in terms of dosing, convenience, and side effects, the guidelines for diverse diseases have suggested to use a class respect to another. For example, the European guidelines (Zuberbier et al. 2009a, b; Maurer et al. 2013) on urticaria highlighted the use of low-sedating antihistamines in the treatment of the diseases (Fig. 133.2). Due to the sedation and anticholinergic effects, the guidelines strongly discouraged the use of sedating H1 antihistamines in the treatment of urticaria-angioedema (Church et al. 2010).

Pruritus of various causes and atopic dermatitis are commonly treated with H1 antihistamines, both the first and second generations. In these diseases, even if a rationale of the use of antihistamines has been documented, evidence base for efficacy and safety is missing. As reported by recent atopic dermatitis guidelines (Ring et al. 2012a, b), there is not enough evidence to support the general use of both first- and second-generation antihistamines for treatment of pruritus in atopic eczema.

Molecules as hydrochloride, doxepin, and ketotifen have dual H1 and H2 activities and are classified as tricyclic antidepressant drugs. They have been used successfully to relieve the symptoms of pruritus, diffuse cutaneous mastocytosis, and asthma. Their sedation and other adverse effects are comparable with those of first-generation antihistamines.

Indication of Use

- Allergic diseases in which H1 antihistamines are medications of choice:
  - Urticaria, allergic rhinitis, allergic conjunctivitis, mastocytosis*, pruritus from mosquito bites*, and to reduce adverse reaction to insect venous immunotherapy* (*supported by smaller randomized controlled trial)
- Diseases in which H1 antihistamines are not medications of first choice:
  - Atopic dermatitis, asthma, anaphylaxis, and nonallergic angioedema

Side Effects

The most common side effect of first-generation H1 antihistamines is drowsiness. It is common, varies from patient to patient, and interests mainly the first days/weeks of the therapy; during the continuation of the therapy, it can completely disappear. If the classic H1 antihistamines are given in the evening, the resulting somnolence can be adequately tolerated.

This side effect is much lower during the second-generation H1-antihistamine treatment. The use of first-generation H1 antihistamines can be particularly useful when an itching dermatitis disturbs the sleep of the patient.

Moreover the majority of first-generation H1 antihistamines show an accentuation of the central depressive effect.

Due to their anticholinergic effect, the first-generation and not the second ones should not be administered to patients with glaucoma or urinary retention.

Prolongation of the cardiac QT interval and arrhythmias, mainly ventricular, have been reported after standard or higher doses of first-generation H1 antihistamines for their binding with muscarinic, α-adrenergic receptors and for the blockade of ion currents.

Convulsions, appetite stimulation, weight gain, dry mouth, blurring of vision, difficulty in micturition, and impotence are rare side effects with the sedative ones.

It has well-known the photo-contact dermatitis due to the application of topical antihistamines, as topical promethazine.

An overdose can cause drowsiness, confusion, hallucinations, respiratory depression, cardiotoxicity, and fatality.

Contraindications

In patients with hepatic or kidney dysfunction, epilepsy, prostatic hypertrophy, glaucoma, porphyries, urinary retention, and cardiac diseases, the use of antihistamines should be limited/avoided, especially the first-generation ones. Patients should not drink alcohol after their drug intake.

Drug Interactions

The ingestion of first-generation H1 antihistamines in combination with central nervous system antidepressant may determine an accentuation of the central depressive effects. In particular they should not be administered with the monoamine oxidase inhibitors: their anticholinergic side effects (e.g., dryness of mucosae, urinary retention) may be prolonged and accentuated.

Side Effects

- Common: drowsiness
- Less common: decrease of alertness, dry mouth, glaucoma, urinary retention, arrhythmias, and appetite stimulation (especially the first-generation antihistamines)
- Contact dermatitis (when applied topically)
- Hyperdosage: confusion, hallucinations, convulsions, blurring of vision, difficulty in micturition, impotence, respiratory depression, cardiotoxicity, and fatality
- Drug interaction: central nervous system antidepressant, mainly monoamine oxidase inhibitors

Pregnancy and Breast-Feeding

The first and second generations seem to be quite safe in pregnancy. If possible, the avoidance of all antihistamines is suggested in pregnancy, especially during the first trimester, although none of them have been shown to be teratogenic in humans. No relation between the H1 antihistamines and the development, even minor, of fetal malformations has been established. It is worthy to remember their wide use in allergic disease also in women before discovering to be pregnant.

First-generation H1 antihistamines (chlorpheniramine and diphenhydramine) and second-generation H1 antihistamines (loratadine) have a favorable category B rating.

First-generation H1 antihistamines should be avoided before parturition because they can cause contractions because of oxytocin-like effects. Moreover the neonate may exhibit withdrawal symptoms, as irritability and tremulousness,

when a large dose has been taken before the delivery.

Extremely small amounts of loratadine are excreted in breast milk.

Pregnancy and Breast-Feeding

- First-generation H1 antihistamines (chlorpheniramine and diphenhydramine) and second-generation H1 antihistamines (loratadine) have a favorable category B rating.
- The use of antihistamines should be limited in pregnancy.
- First-generation H1 antihistamines should be avoided before parturition because they can cause contractions because of oxytocin-like effects.

Use in Infants and Children

Most of the antihistamines are allowed to be used in infants and children. Some others have indications in patients older than 12 for the lack of study in this age. It has been recently shown that the first-generation H1 antihistamines can cause in infant and children drowsiness and diminution of REM phase. Recently a lot of pediatric oral formulations containing first-generation H1 antihistamines have been withdrawn from the market.

For these reasons a recent GA^{2}LEN position paper (Church et al. 2010) strictly discourages the use of the first-generation antihistamines in this age, especially in the treatment of urticaria-angioedema.

Use in Elderly People

The use of H1 antihistamines should be limited in elderly people because they often have cognitive dysfunction and they are particularly vulnerable to the adverse effects of these drugs.

Use in Infants and Children

- Most of antihistamines are allowed to be used in infants and children.
- First-generation H1 antihistamines can cause in infant and children drowsiness and diminution of REM phase, and their use is discouraged in this age.

Treatment Regimen and Dosage

The dosage and frequency of administration of antihistamines are recommended by the manufacturers and are usually based on the inhibition of experimental histamine weal.

However recent studies in urticaria-angioedema have shown that the single dose is not sufficient to treat efficiently the diseases.

In these cases, after an insuccess of 15-day treatment of single dose, patients with urticaria may profit from up-dosing with second-generation H1 antihistamines up to four times.

Studies on loratadine, desloratadine, and rupatadine have shown an increase of the efficacy of the drug in the treatment of urticaria without an increase of the side effects. Further researches are needed for predicting markers in different subtypes of urticaria.

It is worthy to remember that this recommendation represents an off-label use of the drug: it is also true that physicians are becoming familiar with an increase of the antihistamines dose.

In the urticaria treatment, when an increase of the antihistamines dose is not sufficient to treat sufficiently the disease, a combination of non-sedative H1 antihistamines and H2 antihistamines is beneficial in patients with (chronic) urticaria-angioedema.

The urticaria guidelines do not suggest the use of first-generation antihistamines (Zuberbier et al. 2009a, b; Maurer et al. 2013). Their use may be useful for some forms of urticaria (e.g., cholinergic or solar urticaria) when the cholinergic receptors are involved (Fig. 133.2).

A lot of suggestions for the use of antihistamines in other itching skin diseases are derived from the urticaria guidelines. In many itching diseases, the evidence base for the efficacy and safety of antihistamines is weak, and it is not supported by large and randomized study. Similarly, there are no data regarding the efficacy and safety of up-dosing of antihistamines. Patients with pruritus or with atopic dermatitis may benefit from the treatment with the first generation of sedative antihistamines. These drugs may allow a better sleep pattern in acute situations with exacerbations of eczema. The evidence of this recommendation is low. The dose and the period treatment have to be personalized to the patient and his/her skin disorder.

Dosage

Traditional H1 antihistamines		
Drug	Adult dose	Children dose
Dexchlorpheniramine	6 mg every 12 h	
Diphenhydramine hydrochloride	25–50 mg every 4 h	Under 12 years of age: 5 mg/kg per 24 h in divided doses
Tripelennamine hydrochloride	25–50 mg every 6 h	Under 12 years of age: 5 mg/kg per 24 h in divided doses
Promethazine hydrochloride	25 mg 3 times a day	Under 12 years of age: 6.25–12.5 mg three times a day and 25 mg at bedtime
Cyproheptadine hydrochloride	4 mg 3 times daily	7–14 years: 4 mg 3 times a day
		2–6 years: 2 mg 2–3 times a day. (0.25 mg/kg daily)
Oxatomide	30 mg 2 times a day	Older than 1 year: 1 drop (2.5 mg)/2 kg two times a day
Hydroxyzine hydrochloride	25 mg 2–3/day	Older than 12 months: 10–20 mg/day in divided doses
Second-generation (new) H1 antihistamines		
Cetirizine	10 mg daily	2–12 years: 5 mg daily
		1–2 years: 2.5 mg daily
Loratadine	10 mg daily	2–12 years: 5 mg daily
Fexofenadine	180 mg daily	–
Mizolastine	10 mg daily	–
Ebastine	10–20 mg daily	–
Bilastine	20 mg daily	–
Desloratadine	5 mg daily	1–5 years: 1.25 mg daily
		6–11 years: 2.5 mg daily
Levocetirizine	5 mg daily	Children 6–12 years: 5 mg daily
		2–6 years: 1.25 mg twice a day
Rupatadine	10 mg daily	–
H2 antihistamines		
Cimetidine	200 mg two to three times daily	Intramuscularly, 2 mg/kg every 6 h
Ranitidine	150 mg twice a day or 300 mg daily	2 mg/kg twice a day
Famotidine	20–40 mg daily	–

Antiviral Drugs

134

Mihael Skerlev, Ivana Čulav-Košćak, Jane Basarovski, and Andrija Stanimirović

Abbreviations

5-FU	5-Fluorouracil
HHV	Human herpesvirus
HPV	Human papillomavirus
HSV	Herpes simplex virus
IN	Intraepithelial neoplasia
MC	Mollusca contagiosa
MMRV	Measles, mumps, rubella and varicella
STI	Sexually transmitted infection
TCA	Trichloroacetic acid
VZV	Varicella-zoster virus

Key Points

- In spite of some recent advances, the treatment of viral diseases in dermatology and venereology sometimes remains quite challenging and frustrating for both patients and physicians.
- Herpes simplex virus (HSV) infections belong to the rare group of viral diseases with efficient antiviral drugs available. Thus, antiviral (especially oral) treatment should be provided to the patients with HSV infections to a greater extent than it has been generally advised in the "usual and traditional manner".
- The oral treatment for HSV infections can sometimes be initiated whenever the symptoms exist, no matter if this period might be longer than 72 h (as traditionally believed) from the clinical onset of disease.
- Providing the protection against the most common four human papillomavirus (HPV) DNA types, the quadrivalent vaccine has a great target and potential in dermatovenereology. The HPV has overcome the "only sexually transmitted infection (STI)" limitation, and this virus has been associated today with the great spectrum of cancers (not only cervical, but also anal, penile, vulvar, pharyngeal, oral, tonsillar, etc.). Thus, the HPV vaccine might be one of the first

examples how the oncologic disease might be successfully prevented!

- Treatment of mollusca contagiosa (MC) from dermatovenereological point of view depends on the size, number and site of lesions, convenience, cost of treatment, patient discomfort and preference as well as physician's experience. Given the self-limiting course of disease in immunocompetent patients, the span of therapeutic options ranges from attentive "wait and see" approach, assuming patient education and reassurance, to decisive acts directed to destroy cutaneous lesions induced by *Molluscipoxvirus*. The adult patients with MC should be definitely screened for other STIs!

General Principles

In spite of some recent advances during the past few decades, the treatment of viral diseases in dermatology and venereology remains quite challenging on one side and frustrating on the other side for both patients and physicians. However, due to the better insight into the pathogenesis and principles of molecular biology of viral infections, there are ongoing investigations and clinical trials concerning new therapeutic agents and vaccines which would hopefully change current unrewarding state and prognosis of viral diseases. In this chapter, we will primarily focus on antiviral drugs that are most frequently used in dermatovenereological practice.

Classification

Drugs for the Treatment of Human Herpesvirus Infections

Herpesviridae family comprises eight viruses, *human herpesvirus* (HHV) (1–8) which all have double-stranded linear DNA molecule and are capable of causing several different mucocutaneous disorders (Table 134.1). *Herpes simplex virus* (HSV1) (HHV1) and HSV2 (HHV2) infections, either in the form of orofacial or genital herpes and varicella-zoster virus (VZV) (HHV3) known to cause varicella (chickenpox) with primary infection and herpes zoster with recurrent infection, are all rather frequent in dermatologic practice. However, other types of HHV (4–8) infections are less frequently recognized as the aetiological agents in dermatologist's office. In scientific terms, rather than practical aspects in treating patients so far, a special attention should be given to HHV 6 and 7 and their association with pityriasis rosea and exanthema subitum (roseola infantum), as well as to the HHV 8 and its association with Kaposi sarcoma (KS).

Indications and Other Uses

Treatment of HSV infections remains symptomatic in many cases in the everyday practice. We must say that we do not completely agree with such attitude providing that HSV infections belong to the rare group of viral diseases with efficient antiviral drugs available. Thus, antiviral (especially oral) treatment should be provided to the patients with HSV infections to a greater extent than advised in the "usual and traditional manner", so far. It has been generally recommended to treat, first of all, those infections which are protracted, complicated, recurrent and/or affecting the immunodeficient host or a neonate. It is also recommended as prophylactic treatment from 36 weeks' gestation since it has been documented to reduce recurrences, viral shedding and the need for caesarean deliveries.

Acyclovir (9-2-hydroxyethoxymethyl guanine or acycloguanosine) is an acyclic guanosine analogue which in its active form inhibits viral DNA polymerases resulting in highly selective inhibition of further viral DNA synthesis. It is a widely used and well-tolerated drug which can be administered topically, orally and intravenously. In topical preparations, it is available as 5 % ointment with very little systemic absorption resulting in low efficacy; especially in the cases of genital herpes (topical acyclovir has not

Table 134.1 Schematic overview of the treatment dosing regimen for *human herpesvirus* infections in dermatology and venereology

	Acyclovir	Valacyclovir	Famciclovir
First episode of genital herpes	5×200 mg daily for 10 days OR	2×500 mg daily for 10 days	3×250 mg daily for 10 days
	3×400 mg daily for 10 days		
Recurrent genital herpes	5×200 mg daily for 5 days OR	2×500 mg daily for 3–5 days	2×125 mg daily for 5 days OR
	3×400 mg daily for 5 days OR		
	3×800 mg daily for 2 days		2×1 g daily for 1 day
Suppressive therapy	2×400 mg daily	<10 episodes per year: 500 mg daily	2×250 mg daily
		>10 episodes per year:	
		2×500 mg daily OR 1 g daily	
Orolabial herpes	5×200 mg daily for 5 days	2×2,000 mg daily or 1 day	1×1,500 mg single dose OR
			3×250–500 mg daily for 5 days
Herpes zoster	5×800 mg daily for 7–10 days	3×1,000 mg daily for 7 days	3×500 mg daily for 7 days
Chickenpox	4×20 mg/kg (800 mg max) daily for 5 days	3×20 mg/kg (1 g max) daily for 5 days	
Suppressive therapy in pregnancy	3×400 mg daily from 36 we eks' of gestation		

been recommended for genital herpes at all!). Oral formulations are most frequently used and are characterized by low bioavailability (15–30 %). Intravenous administration of acyclovir is indicated in immunocompromised patients and severe illness such as disseminated HSV infection, complicated primary infection, neonatal infection, eczema herpeticatum (eruptio varicelliformis Kaposi) and herpes encephalitis. Indications approved by the FDA for the use of acyclovir in the context of dermatovenereology are: symptomatic primary or recurrent HSV infections in immunocompetent and/or immunocompromised patients, suppression of recurrent HSV infections, prevention of perinatal transmission, treatment of VZV infections (herpes zoster and chickenpox) in immunocompetent or immunocompromised patients and treatment of recurrent erythema multiforme which is most frequently preceded by HSV infection. Acyclovir is approximately ten times more potent against HSV1 and HSV2 than against VZV (due to its more efficient phosphorylation by the viral thymidine kinase). Adverse effects of oral acyclovir reported in clinical trials include malaise, headache, dizziness and lethargy, while other neurologic adverse effects were less frequently reported. Dermatologic adverse effects have been reported for topical, oral and intravenous formulation, including local pruritus, erythema, unspecified rash, hives, Stevens-Johnson syndrome (!) and toxic epidermal necrolysis. The most frequent adverse effect for parenteral acyclovir is inflammation at injection site, also known as phlebitis. Cases of thrombotic thrombocytopenic purpura and haemolytic-uremic syndrome have occurred in immunocompromised patients.

When given for primary genital HSV infection, recommended dose is 200 mg five times daily for 10 days or alternatively 400 mg three times daily for 10 days, whereas for recurrent

genital HSV infection the dose is usually 200 mg five times daily for 5 days or alternatively 400 mg three times daily for 5 days. This alternative therapeutic regimen has, understandably, better compliance rate. However, there are some "shortcuts" in dosing regimen recommendations for genital herpes suggesting that a time shorter than usual 5 days might be as effective. Therapy of HSV infections in general terms should be adjusted to each patient individually, since studies have not shown significant advantage of one therapy over another in terms of drug choice or duration of therapy. Some patients with recurrent genital herpes will benefit from one of short-course therapeutic regimes such as 800 mg of acyclovir three times daily for 2 days or famciclovir 1 g twice daily for 1 day or valacyclovir 500 mg twice daily for 3 days. For others, prolonged treatment will be needed. Nevertheless, we would feel very happy if even "classical" dosing regimen described above would have been largely accepted for the benefit of the patient him/herself and for the benefit of his/her partner(s). Oral acyclovir has also proven effective when administered early in the course of orofacial HSV infection in doses of 200 mg five times daily for 5 days. It has been usually accepted that oral treatment for either oral or genital herpes should be given up to 72 h after the first signs of infection. The usual (but not clearly evidence-based) practice is that "there is no point" of prescribing the oral treatment afterwards. We do not think that this should be so strict, and such an approach should be individualized; the oral treatment can sometimes be initiated whenever the symptoms exist, no matter if this period might be longer than 72 h from the clinical onset of disease. Suppression of recurrent HSV infections can be achieved with 400 mg of acyclovir twice daily and is generally indicated in patients with frequent recurrences, in immunocompromised patients, in recurrent ocular HSV disease and also in patients with recurrent erythema multiforme. In order to prevent perinatal transmission of HSV, daily dose of acyclovir 400 mg three times should be given from 36 weeks' of gestation (Patel et al. 2010). Suppressive oral treatment turned out to be one of the greatest achievements in improving the quality of life of patients with recurrent genital herpes, as well as in significant decreasing of the viral shedding, and such a treatment might be given for several months up to 1 or 2 years.

Therapeutic regime for first episode of VZV in immunocompetent adults is 800 mg five times daily for 7–10 days, whereas primary varicella in children is 20 mg/kg (800 mg max) four times daily for 5 days.

Valacyclovir 2 [2-amino-1,6-dihydro-6-oxo-9H-purin-9-yl-methoxy] ethyl-L-valinate hydrochloride is the valine ester of acyclovir and is, in fact, its oral prodrug sharing the identical mechanism of action, clinical spectrum and similar side effects. The crucial difference between the acyclovir and valacyclovir is greater bioavailability of valacyclovir (55 %) which is also considered generally safe and well-tolerated drug.

Valacyclovir is indicated in treatment of primary and recurrent HSV infections, both in immunocompetent and immunocompromised patients, chronic suppression of HSV infection, herpes zoster in both immunocompromised and immunodeficient patients and recurrent erythema multiforme.

First episode of genital HSV is treated with 1,000 mg of valacyclovir twice daily for 10 days, while the dose for recurrent episodes of genital HSV is 500 mg twice daily for 3 days. For the purpose of suppressive therapy of recurrent HSV infections (<10 episodes per year), valacyclovir is given 500 mg daily, whereas for ten or more episodes dosage is upgraded to 1 g daily or 500 mg twice daily (Corey et al. 2004). Orofacial HSV infection is treated with 2,000 mg twice daily for 1 day.

Dose of valacyclovir for chickenpox when administered orally is 20 mg/kg (1 g max) three times daily for 5 days. For the treatment of herpes zoster, valacyclovir is administered in doses of 1,000 mg three times daily for 7 days. It has also proven to be more effective than acyclovir in relieving postherpetic neuralgia, though certain cases of postherpetic ("postzosteric") neuralgia remain still very resistant to almost any treatment modality whatsoever.

Famciclovir [9-(4-hydroxy-3-hydroxy-methylbut-1yl) guanine is the oral prodrug of an acyclic nucleoside penciclovir. In its active form, famciclovir has 10–20 times longer intracellular half-life than acyclovir and greater bioavailability (around 77 %). It has identical clinical spectrum to valacyclovir, which is, again, very similar to acyclovir.

When given for the first episode of genital herpes, the dose of famciclovir is 250 mg three times daily for 10 days, and the dose for episodic genital herpes is 125 mg twice daily for 5 days. Suppressive therapeutic regimen for recurrent HSV disease which proved to be efficient is 250 mg twice daily. Several other schemes exist for orofacial HSV infections, such as famciclovir given at 1,500 mg single dose or 250–500 mg three times daily for 5 days.

Therapeutic effectiveness of famciclovir in the treatment of herpes zoster in adult immunocompetent patients was demonstrated for doses of 500 mg three times daily for 7 days, with the same dosing regimen prolonged for 3 days more in an immunocompromised patients.

Topical agent *penciclovir*, the active metabolite of the oral drug famciclovir, is approved for topical treatment of HSV infections on the lips and face. Its use on mucous membranes has not been established so far. Main advantage of topical penciclovir over topical acyclovir is the longer intracellular half-life in infected cells. Recommendation is to apply topical preparation of penciclovir every 2 h from the beginning of the symptoms, avoiding area around the eyes. There is lack of data confirming its safety and efficacy in children younger than 12 years and in immunocompromised patients.

In order to summarize the therapeutic options in HHV infections, we would like to acknowledge that all of the three drugs mentioned above are equivalent in their safety and efficacy profile as well as the clinical spectrum. Each of them is declared as category B for use in pregnancy. Nevertheless, clinical practice has not documented any related fetal risk so far. Drug interactions in this drug group are few since none of them is metabolized by hepatic microsomal enzymes. In general terms, the acyclovir and its derivates mentioned above are effective in HSV and VZV infections in both immunocompetent and immunocompromised patients, with the latter group being more likely to develop resistance against acyclovir in which case it can be substituted with intravenous foscarnet or cidofovir. Among other reasons, viral resistance against acyclovir is most commonly caused by loss of thymidine kinase activity. Since both foscarnet and cidofovir display more toxicity, they are not recommended as first-line therapy in HSV infections (Mendoza et al. 2012). There are, however, some new and potentially effective drugs on the horizon, currently under investigations. These include helicase-primase inhibitors which seem to be capable of addressing the emerging resistance to oral nucleoside analogues. Efficacy of treatment with acyclovir, valacyclovir and famciclovir is demonstrated in several clinical studies where it was measured by shortening of duration of disease and its overall severity, by their ability to inhibit viral shedding and frequency of outbreaks as opposed to placebo.

Vaccine for varicella-zoster virus has been on the market for 18 years since its first official approval, and since then, this live attenuated VZV vaccine has significantly improved quality of life around the world. Varicella vaccine is indicated for all adults without evidence of immunity to varicella, and it is given in two doses. Children receive the first dose of vaccine at the age of 12–15 months and the second at the age of 4–6 years. At age of 12–47 months, either a dose of combined measles, mumps, rubella and varicella (MMRV) vaccine or separate MMR vaccine and varicella vaccine can be given as the first dose. If the first dose is given at ≥48 months of age, CDC recommends combined MMRV vaccine (Klein et al. 2010). Second dose is also preferably combined MMRV vaccine at any age (15 months–12 years). Vaccine is, however, contraindicated for use in pregnancy and immunosuppressed patients. For these groups of patients, there is varicella-zoster immune globulin that can be given within 96 h postexposure to varicella as a passive prophylaxis aid (Marin et al. 2007). Year 2006 remains

important in the history of VZV vaccine since it then became the first approved vaccine for prevention of herpes zoster in patients who are 60 years old or older (Harpaz et al. 2008). It is recommended as a single dose for immunocompetent individuals 60 years of age or older regardless of their history of varicella or herpes zoster. Important contribution of this vaccine is its ability to reduce the incidence of herpes zoster and the severity of postherpetic neuralgia, while those unfortunate patients who still develop the disease after vaccination displayed less pain and discomfort. Although the duration of this vaccine has not been established yet, it is perceived to last for at least 5 years.

Unlike vaccine for VZV, the ongoing search for effective and safe vaccine for HSV has not been completely successful so far. Despite the fact that several different formulations of vaccine have been offered, yet none of them has managed to meet the requirements. Given the impact this vaccine would have on medical practice, global economy and society in general, great efforts are currently being implemented in its development.

Drugs for the Treatment of Human Papillomavirus (HPV) Infections

Treatment of HPV infections to date remains symptomatic since there is no real causative therapeutic option. Bearing that in mind, it is implied that such therapeutic approach to infection as common as HPV in general population is subjected to frequent and multiple doctor's office visits, repeated trials of accessible therapeutic options and at times dissatisfying results. The recurrence rate is generally significant, and the majority of treatment options for the HPV genital infections is associated with pain, discomfort and irritation and can be sometimes very frustrating for both patient and physician. However, given that most HPV infections are self-limited in nature and general lack of evidence to support favourable long-term outcome of treatment, it is considered unjustified to treat them overagressively (Wolf et al. 2007) (Table 134.2).

Indications and Other Uses

Physical destruction of HPV-induced lesions is one possible approach. Purpose of these methods is to voluntarily inflict injury to the skin infected by the HPV with the goal of eliminating the viral-induced skin or mucosal lesion. *Cryotherapy*, perhaps the most frequently tried and inexpensive method, is applied in weekly or biweekly intervals and still remains the mainstay of the routine treatment. Other approaches include surgical removal by tangential excision, *curettage* and/or *electrosurgery*, photodynamic therapy with topical aminolevulinic acid and laser vaporization which is especially suitable for certain localizations of typical lesions such as nailbed (common warts) or urethral meatus (genital warts). Keratolytic agent trichloroacetic acid (TCA) or bichloroacetic acid 70–90 % is also included in the spectrum of local destructive measures, whose topical application results in tissue destruction without systemic toxic effects making it thus applicable for use in pregnancy. TCA can be applied once a week with strict precautions concerning its caustic properties. Various salicylic acid preparations, another yet milder keratolytic agent, for local use can also be tried. It is, of course, possible and often seen in clinical practice that some of these methods are used in various combinations (sometimes following each other after a few minutes) for better clearance rate. There are reports of effectiveness of 5 % potassium hydroxide solution, a strong alkali agent, for at home use as another locally destructive approach.

Cytotoxic therapy both local and intralesional assumes application of several different agents. Podophyllin is used as 10–25 % solution for genital lesions once weekly or once biweekly, often in combination with cryotherapy. It should be washed off 1–4 h after application to avoid local irritation and treating large areas and at once should be avoided. Also, it is recommended for use up to 6 weeks. Due to its sometimes low efficacy, potential systemic toxicity and unstable formulation, it has been slowly replaced by other options, and it has been omitted from certain guidelines. However, we think that it should not be completely banned providing that if only

Table 134.2 Schematic and simplified overview of the treatment options for HPV genital infections and common warts

Regimen	Physical destruction	Cytotoxic therapy	Topical immunomodifiers	Antiviral drugs	Vaccines
Office therapy	Cryotherapy once weekly or biweekly	Podophyllin solution 10–25 % once weekly or biweekly up to 6 weeks (*rarely, but still possible*; *please, see in the text*!)			Gardasil™, Silgard™ quadrivalent (HPV6/11/16/18) for females and males 9–26 years of age at 0, 2 and 6 months
	Tangential excision				
	Curettage				
	Electrosurgery				
	PDT (ALA)				Cervarix™, bivalent (HPV 16/18) for females 9–26 years of age
	Laser therapy				
	Bichloroacetic/trichloroacetic acid once weekly or biweekly				
Patient-applied therapy		Podophyllotoxin solution or gel 0.5 % twice daily for 3 consecutive days followed by 4 days break up to 4 cycles	Imiquimod cream 5 % 3 times weekly up to 16 weeks	Cidofovir gel, cream or ointment 1–3 %	
	Salicylic acid	5-FU 5 % cream or solution 1–3 times weekly for several weeks	Sinecatechins ointment 10–15 % 3 times daily for 16 weeks		

For use in pregnancy

office applied by a skilled professional, and properly washed out, it might be still sometimes an efficient option, especially if the other treatment modalities could not be afforded. Podophyllotoxin, a podophylline derivative known as an antimitotic agent that arrests mitosis in metaphase, used by patient at home as a 0.5 % solution or gel twice a day for three consecutive days followed by 4 days break has proven to be more effective and less toxic according to some trials. This scheme can be repeated for up to four cycles. Both podophyllin and podophyllotoxin are contraindicated in pregnancy. Another cytotoxic agent less frequently used is 5-fluorouracil (5-FU) in formulation of 5 % cream. It is known to interfere with DNA and RNA synthesis resulting in cellular death. 5-FU cream is effective when used one to three times weekly for several weeks especially for troublesome intraurethral (meatal) or perianal condylomata or intraepithelial neoplasia (IN) of external genitalia. It should be washed off 3–10 h after application. When used on genital area, it (often) causes inflammation accompanied by pain, burning and possibly ulceration. However, for cutaneous warts, it can be used daily under occlusion and/or in combination with up to 10 % salicylic acid.

Antiviral agent cidofovir has been used as intralesional injection or 1–3 % topical preparation (gel, cream and ointment) for both cutaneous and genital (especially hyperkeratotic) lesions as well as intraepithelial neoplasia. Its systemic use for HPV mucocutaneous manifestations is, even though proven successful, limited by its toxicity and reserved for immunocompromised patients.

Topical immunomodifiers are another group of drugs used for HPV infections in dermatovenereology that has imposed itself among other therapeutic options. Most commonly used agent in this group is *imiquimod* which will be discussed in more details in separate chapter. The use of *sinecatechins*, extracts derived from green tea leaves, as 10 % (Europe) or 15 % (USA) ointment three times daily for 16 weeks in treatment of anogenital condylomata, offers yet more reason for excitement since clinical studies have demonstrated their ability to induce complete clearance with a low recurrence rate. Adverse effects include erythema, pruritus and pain. The use of *interferons*, topical, intralesional and systemic, has displayed contradictory results so far. Systemic therapy, burdened by high cost and adverse effects, is not recommended for routine use (Kirnbauer et al. 2012). Studies demonstrating satisfying results of *zinc sulphate* 10 mg/kg up to 600 mg daily have been published but still awaiting confirmation from clinical practice (Yaghoobi et al. 2009).

Topical (tretinoin, tazarotene) and systemic (acitretin, isotretinoin) *retinoids* seem to interfere with HPV replication and virions assembly through their effect on keratinocyte proliferation and differentiation, thus expanding their clinical spectrum.

Immunotherapy in the context of HPV infections has not been routinely used, but evidence of its efficacy is well documented. Agents such as diphenylcyclopropenone 0.5–4 % and squaric acid dibutyl ester were given intralesionally at various interval rates producing high percentage of clearance rate. Intralesional application of *Candida*, *Trichophyton* and/or mumps skin test antigens has also been used with certain success in immunocompetent patients.

Recommended approach for the treatment of genital warts in pregnancy includes cryotherapy, trichloroacetic acid, surgical and laser treatment since all of these options are considered generally safe. Several therapeutic modalities are, as mentioned, designed for at home use by patient alone in cases/circumstances where compliance is expected and lesions clinically visible and accessible. These modalities include podophyllotoxin 0.5 % solution or gel, imiquimod 5 % cream and sinecatechins 15 % ointment. Same therapeutic regimes, with perhaps some minor modifications, are foreseen both for immunocompetent and immunocompromised patients regarding HPV infections, although closer monitoring of precancerous lesions is mandatory in the latter group of patients. However, despite seemingly broad therapeutic options, recurrence rate remains relatively high and further aggravated by the questionable reduction of transmission to new sexual partners.

Currently there are two *HPV vaccines* commercially available on the market: quadrivalent vaccine (Silgard™, Gardasil™, Merck, MSD) and bivalent vaccine (Cervarix™, GlaxoSmithKline). These vaccines consist of the virus-like particles of the L1 major capsid protein, but do not contain viral DNA, and so far extensive studies have proven their efficacy in inducing high-titre, long-lasting and type-specific neutralizing antibodies. Their (primary) role is prophylactic as quadrivalent vaccine prevents HPV types 6, 11, 16 and 18, whereas bivalent vaccine prevents HPV types 16 and 18. Providing the protection against the most common four HPV DNA types, the quadrivalent vaccine has a greater target in dermatovenereology. It has been licenced for use in females and males 9–26 years of age, preferentially before beginning of sexually active period, hence before exposure to HPV. Vaccines are administered as intramuscular injections given in three series at 0, 2 and 6 months. Adverse effects include erythema, oedema, itching and pain at the site of injection. These types of vaccines have not been theoretically designed as therapeutic measures since they have no ability to prevent disease progression nor induce disease regression. However, there have been some anecdotal reports about the therapeutic efficacy of the quadrivalent HPV vaccine suggesting that immunity induced by vaccination is four to five times superior to that induced by natural infection, but, definitely, more consistent studies are required. Therapeutic success of Gardasil has also been demonstrated in conjunction with local application of imiquimod. In spite of the fact that the vaccines have been commercially available for relatively short period of time (depending on the geographical distribution and the economy income of the different countries worldwide), quite encouraging conclusions can be made (so far, of course) about the great impact of the HPV vaccine on the reduction of HPV-induced anogenital diseases and the HPV oncogenic potential. Moreover, the HPV has overcome the "only sexually transmitted infection (STI)" limitation, and this virus has been associated today with the great spectrum of cancers (not only cervical but also anal, penile, pharyngeal, oral, tonsillar, etc.). Thus, the HPV vaccine might be one of the first examples how the oncogenic disease might be successfully prevented! Future perspective concerning HPV infection seems to be grounded on further development of preventive and curative vaccines, as currently several such vaccines are being engineered.

Drugs for the Treatment of Mollusca Contagiosa

Treatment of mollusca contagiosa from dermatovenereological point of view depends on the size, number and site of lesions, convenience, cost of treatment, patient discomfort and preference as well as physician's experience. Given the self-limiting course of disease in immunocompetent patients, the span of therapeutic options ranges from attentive "wait and see" approach, assuming patient education and reassurance, to decisive acts directed to destroy cutaneous lesions induced by *Molluscipoxvirus*. Former approach is seldom accepted by patients and potentially complicated by the autoinoculation, increasing contagion, risk of scarring and further patient distress. On the other hand, overaggressive treatment is not eligible approach in this case either.

Indications and Other Uses

Local therapy, with its modalities almost identical to those used for treatment of HPV infection, includes mechanical methods such as curettage, cryotherapy, with or without the prior use of local anaesthetic cream (EMLA), and pulsed dye or carbon dioxide laser. Topical application of keratolytics such as bi- and trichloroacetic acid, salicylic, glycolic and lactic acid is also effective approach. Cantharidin solution 0.7–0.9 %, a type of terpenoid known for its chemovesicant properties, is usually applied at 3–4 week intervals, and the area is thoroughly washed 30–60 min after application. It is generally considered safe, effective and well tolerated when used properly even though it has not warranted FDA approval for this indication (Mathes and Frieden 2010). Precaution should be made since its application can be accompanied by pain and skin erosion. Topical application of cidofovir gel 0.1 %, an

antiviral drug, has been reported to inhibit *Molluscipoxvirus* DNA polymerase activity (Skerlev et al. 2011). Cytotoxic therapy is based on successful usage of 0.5 % podophyllotoxin cream. Imiquimod cream, either 1 % applied three times daily or 5 % applied once a day for 4 weeks, is a relatively new therapeutic option representing the topical immunomodifying method by stimulation of cell-mediated immunity. However, significant irritation can sometimes be observed, which together with its (relative) cost makes this therapeutic option less used for this indication. Sinecatechins 15 % ointment is also effective, albeit off-label, approach within the group of topical immunomodifiers. Other options include tretinoin cream 0.05 % or gel 0.025 % applied once or twice a day. Intralesional interferon alpha once a day for 4 weeks is a therapeutic option in immunocompromised (AIDS) patients, in whom satisfying results can be achieved also by laser therapy together with highly active antiretroviral therapy which itself is known to improve mollusca.

Systemic therapy of mollusca contagiosa with retinoids or cimetidine (30–50 mg/kg of cimetidine daily in divided doses for up to 3 months) is supported by the assumption that it stimulates cell-mediated immunity by increasing the number of CD4+ lymphocytes. For the same reason, it can be used for HPV infection.

Beta-Blockers for Hemangiomas

135

Carlo Gelmetti and Riccardo Cavalli

Key Points

- Infantile hemangiomas (IHs) are the most common tumors of infancy. Their typical natural history is characterized by an early rapid growth in the first months of life and by a slow spontaneous involution in the first years of life.
- Even though spontaneous regression of IHs could suggest therapeutic abstention, systemic treatment is the therapy of choice in many patients in which these situations occur: (1) rapid growth of IHs; (2) location of IHs in aesthetically critical areas; (3) recurrent hemorrhages, ulcerations, or infections of IHs; (4) IHs interfering with important physiological functions (breathing, feeding, vision, hearing, etc.); and (5) large or multicentric IHs that can cause heart failure.
- Since 2008, systemic administration of propranolol, an old nonselective beta-blocker, was found, serendipitously, to improve the treatment of IHs replacing older and more dangerous therapies like oral steroids, vincristine, interferon-alpha, or vascular lasers. At present, oral propranolol has dramatically changed the approach of IHs because its efficacy is almost 100 % and its action is rapid, without important side effects. The formal approval by the FDA and EMA has been declared in 2014.

General Principles

Infantile hemangioma (IH) is the most common tumor of infancy ranging from a tiny red papule to a giant mass. Its typical natural history is characterized by an early rapid growth following birth and a slow spontaneous involution which is complete before puberty but almost complete within the first 3–6 years of life. The cause underlying IH is still unknown, but the role of fetal hypoxic stress is strongly suggested as a triggering signal. A different hypothesis suggests that IH can be derived from embolized placental progenitor cells that lodge in privileged sites of the developing embryo. Alternatively, IH has been reported as an aberrant proliferation and differentiation of a primitive mesoderm-derived hemogenic endothelium regulated by the renin-angiotensin system

(RAS) leading to propose angiotensin-converting enzyme (ACE) as a potential therapeutic target. While some angiogenic factors have been identified (e.g., mast cells, heparin), there are no data demonstrating a hereditary component. Immunohistochemical studies of IH confirm their vascular origin. During the proliferative phase, IH shows a high expression of cell proliferation nuclear antigen, vascular endothelial growth factor (VEGF), type IV collagen, urokinase, basic fibroblast growth factor (bFGF), and von Willebrand factor. These data demonstrate active angiogenesis and are not observed in vascular malformations.

IHs occur in up to 4–5 % of neonates, although up to 30 % in premature babies with low birth weight (<1 kg). They are significantly more frequent in females, with a 3:1 to 5:1 female/male ratio. The majority of IHs are noticed in the postnatal period more often during the first to second week, even though few of them may already be visible at birth, although usually with very different clinical features. IHs are distinguished from other less common vascular malformations of infancy by their characteristic clinical course. Although each lesion may have a distinct growth pattern, most follow a typical course divided into four stages: (1) nascent, (2) proliferative, (3) steady state, and (4) involution.

The first stage is the newborn stage prior to emergence of lesions, which typically lasts a few days. In fact, when IH is present at birth as a precursor, it is very small and flat, usually represented by an erythematous dot or patch or, paradoxically, by an ischemic patch ("herald patch") mimicking "nevus anemicus," or by telangiectasias surrounded by an ischemic halo. The majority of IHs appear as a single lesion; although there is no limit to their numbers, it is very rare to see more than five or six lesions. Equally rare are visceral IHs, usually hepatic. Topographically, the head is the most affected region, accounting, alone, for about 50 % of total lesions. History and phenotype allow, in most cases, diagnosis of IHs without the need for additional intensive investigations.

During the following 3–6 months, proliferation occurs in an early proliferative stage which brings rapid growth in the first few months of life, followed by a late proliferative stage with less rapid growth. As compared to superficial or localized lesions (the so-called "strawberry angiomas"), deep or segmental lesions, as those affecting the parotid region, appear to have a mysterious and prolonged proliferative phase extending beyond 6 months and rarely beyond the first year of life; in addition, in these phenotypes, the precursors and the first steps of the proliferative phase cannot be clinically observed. However, most lesions still cease growth by 9 months of age. The steady state or stabilization phase is of variable duration, usually a few months. Involution is typically heralded by a change in color from bright red to gray or purple, as well as a softening texture and flattening or diminution in size. Thermographic studies show a higher temperature of IHs, rising in the proliferative phase and fading in the evolution stage. Approximately most of IHs involute by 5–7 years of age, but smaller lesions are not noted any more at the time of primary school.

It should be noted that the deep localization of IHs, in the absence of a superficial "sentinel" IH, delays greatly the observation of the lesion, which is not usually discovered until after its full proliferative stage. The spontaneous regression of IH leaves minimal sequelae in about half the cases; it can result in various degrees of lesions (scars, telangiectasias, yellowish hypoelastic patches, etc.), especially on the head. It is difficult to predict the quality of the final regression, which is not influenced by gender, race, site or size of the lesion, presence or absence at birth, and duration of the proliferating phase. Of course, usually, smaller lesions have a better outcome and deeper lesions more rarely produce sequelae that alter the skin surface.

In addition to the aesthetic changes, IHs may ulcer, producing hemorrhages that can obstruct the respiratory and digestive tract. Big IHs with rapid regression may form a scab with cicatricial sequelae. In periocular localizations, impaired vision may occur. Amblyopia and astigmatism are the most common ophthalmic complication of IHs. Orbital lesions are less common, but, secondary to their mass effect, they may result in

strabismus, proptosis, exposure keratopathy, or compressive optic neuropathy.

Histologically, IHs are composed of a complex mixture of cells including multipotent stem cells, a majority of immature endothelial cells, pericytes, dendritic cells, and, in the late stage, adipocytes. In the proliferating phase, there is a new production of capillaries, sometimes mixed with larger vascular lacunae due to proliferation and swelling of endothelial cells, and mast cells are greatly increased in number. In the involuting phase, the cellular component becomes scarce, and vascular lakes regress and are replaced by fibroadipose structures. In the stable phase, under electron microscopy, the endothelial cell shows swollen mitochondria and activity of the rough endoplasmic reticulum; additionally, there is thickening of the basement membrane.

A critical consideration concerns the treatment of IH. Spontaneous regression of IHs could suggest therapeutic abstention but this attitude is not wise in the majority of cases. We agree with those authors who recommend therapeutic abstention, but only for very small IHs (<3 cm by the 3rd month of age, <6 cm by the 6th month of age) and for those whose locations do not create problems either objectively or subjectively. Otherwise, we recommend treating IHs, because, first, by limiting the expansion we can limit the symptoms, and, second, a small IH will have, in any case, a negligible fibroadipose residue. Finally, it should be considered that even a small IH located in an exposed site can cause variable psychological damage from the time of socialization onward. An early intervention is, therefore, recommended also in this case. In short, and especially after the rediscovery of propranolol, the sentence: "Leave it alone; it will go away" is no longer a universally acceptable advice for IH (Requena and Sangueza 1998). It is, however, better to continue to follow up the patients and their parents, reassuring them of the favorable outcome, with the aid of illustrations and photographs that show the evolution of these lesions. Local treatments (e.g., elastic compression, cryotherapy, laser therapy, ultra-potent topical corticosteroids, etc.) are often disappointing or impossible for various practical reasons, so that systemic treatment remains the therapy of choice in some situations: (1) rapid growth of the lesion; (2) location of the lesion in aesthetically critical areas; (3) recurrent hemorrhages, ulcerations, or infections; (4) in lesions interfering with important physiological functions (breathing, feeding, vision, hearing); and (5) large or multicentric IH that can cause heart failure.

To answer the question that parents have regarding the current stage of IH growth or involution, it is important to consider all available data: anamnestic, photographical, morphological (usually, IHs that are easily and frequently compressed against a bony surface, such as the back, stop earlier, while those that occur in very extensible areas, such as parotid, lateral-cervical, or mammary regions, expand much more), and especially the three parameters of color, temperature, and consistency. The color (not detectable only in subcutaneous IH) is connected with the temperature (that is related with metabolic activity) and with the consistency (in the proliferating phase, most of the mass is formed by endothelium that proliferates and forms solid cords with a small lumen and therefore difficult to compress). The increase of color, temperature, and consistency therefore indicates the proliferating phase of IH, while their reduction indicates the beginning of the involuting phase.

Infantile Hemangiomas and Beta-Blockers

Infantile hemangiomas (IHs) are vascular tumors expressing intrinsically benign proliferations with a spontaneous tendency to regression. So, when lesions are small and located in body regions that are aesthetically indifferent, a "wait-and-see" policy is the best management (Chandran et al. 2013). In many cases, the size and/or the localization of the lesion cause significant cosmetic deformity or functional compromise requiring a prompt treatment. Unfortunately IHs are mainly located in the head and neck area. In any case, besides aesthetic risks, the main indications for treatment of IHs are: life-threatening conditions (heart failure, respiratory distress),

functional risks (amblyopia, swallowing disorders, etc.), and painful ulcerations.

For almost half a century, corticosteroids have been the first-line therapy for complicated IHs. Fortunately, this treatment was effective in the majority of patients affected by IHs and led to a progressive disappearance of older and more dangerous treatments like radiotherapy, cryotherapy, chemotherapy (like vincristine or cyclophosphamide), interferon-alpha 2a, therapeutic embolization, laser, and surgery.

Systemic corticosteroids, however, have a low safety profile, especially in infancy. Parents of children with IHs under treatment with systemic steroids are more worried during treatment and perceive a negative impact on normal life issues, including work and vaccination of their child. Not enough, the response to treatment is not homogenous, and rebound growth upon cessation of treatment is quite common.

At the end of 2007, by serendipity, the pediatric dermatologist Christine Léauté-Labrèze who works in the team of Professor Alain Taïeb in Bordeaux (France) realized that a common beta-blocker, the propranolol, could be used in the treatment of IHs. Indeed the propranolol was prescribed to treat hypertrophic obstructive cardiomyopathy, in a young infant with coexisting nasal IH, and the IH regressed rapidly. In the following year, she published the first two observations together with nine additional cases. Let's quote the original text (Leauté-Labrèze et al 2008):

> The first child had a nasal capillary hemangioma. Despite corticosteroid treatment, the lesion was stabilized but obstructive hypertrophic myocardiopathy developed, so the patient was treated with propranolol. The day after the initiation of treatment, the hemangioma changed from intense red to purple, and it softened. The corticosteroids were tapered, but the hemangioma continued to improve. When the corticosteroids were discontinued, no regrowth of the hemangioma was noted. When the child was 14 months of age, the hemangioma was completely flat. The second child had a plaque-like infantile capillary hemangioma involving the entire right upper limb and part of the face. At 1 month of age, a subcutaneous component developed, and despite corticosteroid treatment, the hemangioma continued to enlarge. Magnetic resonance imaging revealed intraconal and extraconal orbital involvement, as well as an intracervical mass causing compression and tracheal and esophageal deviation …. Ultrasonography showed increased cardiac output, and treatment with propranolol, at a dose of 2 mg per kilogram of body weight per day, was initiated. Seven days later, the child was able to open his eye spontaneously, and the mass near the parotid gland was considerably reduced in size. Prednisolone was discontinued …. without any regrowth of the hemangioma; at 9 months of age, the eye opening was satisfactory, and no major visual impairment was noted. After …, propranolol was given to nine additional children who had severe or disfiguring infantile capillary hemangiomas….. In all patients, 24 hours after the initiation of treatment, we observed a change in the hemangioma from intense red to purple; this change was associated with a palpable softening of the lesion. After these initial changes, the hemangiomas continued to improve until they were nearly flat, with residual skin telangiectasias. Ultrasound examinations in five patients showed an objective regression in thickness associated with an increase in the resistive index of vascularization of the hemangioma…

Mechanism of Action, Indications, and Other Uses

Propranolol is a member of a class of medications called beta-blockers. It works by relaxing blood vessels and slowing heart rate to improve blood flow and decrease blood pressure. Propranolol is an old drug classically used for decades to treat high blood pressure, abnormal heart rhythms, heart disease, pheochromocytoma, and certain types of tremor but also to prevent angina and migraine headaches and to improve survival after a heart attack. Several mechanisms may be involved in the control of IH growth by propranolol. Propranolol is responsible for a vasoconstriction of the microvessels of the IH resulting in a rapid change in color and softening. It lowers the rate of renin and thus has a modulating effect on angiotensin II. In addition, β-adrenergic receptors belong to the family of G-protein-coupled receptors, which, when activated by adrenergic catecholamines, can promote a series of intracellular signal transduction pathways including that of angiogenic factors such as VEGF or bFGF and some metalloproteinases such as

MMP2 and MMP9. Finally, propranolol could lead to an early apoptosis of endothelial cells that make up the majority of IHs.

Propranolol seems to act with a dose-dependent cytotoxic effect in IH endothelial cells with decreased cell viability, migration, and tubulogenesis. This cytotoxic effect has shown to be VEGF dependent. Decreased VEGF activity is mediated through the hypoxia-inducible factor (HIF)-1α pathway but not through NF-κβ signaling. Alternatively, propranolol may suppress IH growth by inhibiting expression of eNOS (endothelial nitric oxide synthase) protein and subsequent production of nitric oxide.

More recent investigations (Tu et al. 2013) demonstrated that propranolol induces apoptosis of IH endothelial cells through typical apoptotic changes, including shrinkage, formation of apoptotic bodies, and retention of plasma membrane integrity. The molecular and genetic mechanisms underlying the therapeutic effects of propranolol revealed that this beta-blocker drug led to a marked increase in the expression of caspase-8, cytochrome *c*, apoptosis-inducing factor, caspase-3, and poly(ADP-ribose) polymerase 1, as well as a concomitant reduction in lamin B1 expression. In short, these data demonstrate that propranolol induces apoptosis of IH endothelial cells through activation of the intrinsic and extrinsic apoptotic pathways, explaining its therapeutic effects against IHs. Nevertheless, some molecular mechanisms that could induce resistance to apoptotic stimuli and, therefore, justify the possible insensitivity of some IHs to propranolol have already been described (Caussé et al. 2013).

Treatment Regimen and Dosage

Most of the patients with IHs respond to propranolol more satisfactory and more quickly than systemic corticosteroids at 2 mg/kg per day in two divided doses. The average treatment duration with beta-blockers is 6 months continuously. However, the treatment can be more prolonged when the situation of the IH is problematic (Parikh et al. 2013). The latest available meta-analysis (Lou et al. 2014) concerning the efficacy of propranolol for IHs reviewed 35 studies involving 324 patients and 248 controls, comparing propranolol with steroids, vincristine, and laser in treating cutaneous IHs, periocular IHs, infantile airway hemangiomas, and infantile hepatic hemangiomas. The conclusions of these studies provide a strong evidence for propranolol as a first-line therapy for IHs.

Rebound growth, although mild, can occur in some patients. Late rebound can also be observed indicating a prolonged proliferation IHs even after the first year of age. Late proliferation can occur also after several months of a positive response to propranolol. However, a second course of propranolol is readily able to control the recurrence (Shehata et al. 2013).

In addition to propranolol, which is a lipophilic nonselective beta-blocker, other beta-blockers have been used in the treatment of IHs. Oral atenolol, a hydrophilic selective beta-1 blocker, compared with a control group treated with propranolol, seems to be equally effective and safe (de Graaf et al. 2013).

Topical propranolol in ointment or in gel and topical timolol have also been used with satisfactory results on superficial IHs (Mouhari-Toure et al. 2013).

In the last 5 years, some authors are evaluating whether IH treated with pulsed dye laser (PDL) and propranolol displayed more rapid and complete clearance than IH treated with propranolol alone. In a retrospective and blind review of facial-segmental IHs, those cases treated with a combination of propranolol and PDL displayed more rapid and complete clearance and required a lower cumulative propranolol dose to achieve near-complete clearance (Vigone et al. 2012).

Contraindications and Side Effects

While cardiovascular diseases and asthma are absolute contraindications for propranolol therapy, relative contraindications include: hypersensitivity to propranolol in first-degree relatives, diabetes mellitus, chronic renal insufficiency, and cerebrovascular anomalies. Adverse events

(hypotension, somnolence, wheezing, insomnia, agitation and/or nightmares, hypoglycemia) are rare and uneventful and do not require, usually, treatment suspension. As far it concerns the frequency of side effects, a systematic review of 1,264 patients treated with propranolol for IHs showed (besides a high rate of efficacy) a low rate of serious adverse events with reports of symptomatic hypotension in five patients (0.39 %), hypoglycemia in four (0.31 %), and symptomatic bradycardia in one (0.079 %). The milder and most common adverse events were changes in sleep ($n=136$; 10.75 %) and acrocyanosis ($n=61$; 4.8 %) (Marqueling et al. 2013).

Propranolol has also been proposed as a first-line therapy of thyroid dysfunction associated with IHs. Consumptive hypothyroidism is a rare condition related to massive IHs producing an excess of the thyroid-hormone-inactivating enzyme type 3 iodothyronine deiodinase. While corticosteroid treatment showed only partial benefit in a large parotid IH, introduction of propranolol instead led to normalization of thyroid hormones along with a dramatic involution of the hemangioma (Vigone et al. 2012). A similar positive result was observed in thyroid dysfunction associated with severe infantile hepatic hemangiomas (Vergine et al. 2012).

Discussion and Final Remarks

Even though some authors think that, despite the numerous papers already published, more reliable prospective studies are still needed in the field of IHs treated with beta-blockers, we think that the efficacy coupled with the safety of oral (and probably topical) beta-blockers in the treatment of IH is now a matter of fact: propranolol is the first-line treatment of most IHs.

We are aware that the vast majority of the published literatures concern case reports and that there is a lack of well-designed, high-quality randomized control trials (e.g., beta-blockers versus corticosteroids), and we consider also that the updated knowledge of the broad spectrum of vascular anomalies described by Mulliken and Glowacki (1982) and Enjolras et al. (2007) and better detailed by the International Society for the Study of Vascular Anomalies (ISSVA) in 2014 is not universal. In other words, it is likely that, in some cases, the selection of the patients has not been optimal or it will not be optimal in the next future. However, we agree that the present availability of the big international study on propranolol in IH (the HEMANGIOL® study; ClinicalTrials.gov Identifier: NCT01056341) will confirm the experience of hundreds of doctors that treated thousands of patients. The final approval of beta-blockers for the treatment of IH by the FDA and EMA in 2014 has been a major step for the medicine, allowing all the physicians and the pediatricians (not only the academic doctors!) to prescribe this treatment for the most common tumor of infancy: the IH. In addition, it is not surprising that beta-blockers have already been used successfully in other vascular proliferations such as pyogenic granulomas (Wine Lee et al. 2014).

Our protocol for the management of complicated IHs is summarized in Table 135.1a–c. Obviously, when a complex syndrome is suspected, e.g., PHACES and PELVIS or SACRAL or LUMBAR,[1] additional investigations should be considered such as eye examination, head ultrasound, MRI/CT scan of the brain, etc. Ultrasound examination of the abdomen for hepatic hemangiomas should be advised in case

1 PHACES is an acronym: P, posterior fossa malformation (brain); H, hemangiomas; A, arterial anomalies; C, coarctation of the aorta along with cardiac defects; E, eye abnormalities; and S, sternum and/or supraumbilical abdominal raphe clefts. PELVIS, SACRAL, and LUMBAR are acronyms that denote the association of local hemangioma and malformation in the pelvic region, e.g., PELVIS = perineal hemangioma, external genitalia malformations, lipomyelomeningocele, vesicorenal abnormalities, imperforate anus, and skin tag. SACRAL = spinal dysraphism, anogenital anomalies, cutaneous abnormalities, renal and urologic anomalies, and angioma of lumbosacral localization. LUMBAR = lower body hemangioma and other cutaneous defects, urogenital anomalies, ulceration, myelopathy, bony deformities, anorectal malformations, arterial anomalies, and renal anomalies.

Table 135.1 Practical approach to treatment of IHs with beta-blockers

(a) Inclusion criteria
Patient with IH in cosmetically or functionally relevant areas
Patient with IH in growing or stable phase
Normal lab tests: full blood count, blood glucose, and urea
Normal pediatric evaluation
Normal cardiac evaluation
Parent counseling and consent for propranolol treatment
Direct access to the hospital in case of any emergency
(b) Exclusion criteria
Patient
Cardiovascular disorders
Asthma
History of transient or prolonged hypoglycemia in neonatal period
History of seizures, dizziness, somnolence, and/or restless sleep or nightmares
Severe atopic disorders
Children with low caloric intake
Known allergy to the drug
Coexisting treatments[a]
Family
History of cardiac arrhythmia
Autoimmune disease, i.e., SLE
(c) Dosing oral propranolol
Initial dose – 0.5 mg/kg every 12 h for the first week
If vital signs and general mood are not affected, the dose can be doubled – 1 mg/kg every 12 h for 6 months (average)
If vital signs and general mood are not affected but IH does not respond in 1 week's time, the dose can be raised up to 1.5 mg/kg every 12 h
Follow-up – first review after 1 week and subsequent visits every month
Final dose – 0.5 mg/kg every 12 h for the last week of treatment

This protocol does not apply to complex and/or multisystemic syndromes

[a]Theoretically cimetidine and other medications for heart disease or high blood pressure such as reserpine are contraindicated. In practice, given the typical age of patients with IHs, this event does not occur. For the same reasons, other recommendations concerning propranolol ("Do not drive a car or operate machinery" or "do not take alcohol" until you know how this drug affects you) do not apply to infancy

of neonatal diffuse hemangiomatosis or when cutaneous IHs are more than five.

In the meantime and in the next future, besides for a formal approval of the use of beta-blockers for the treatment of IHs by health authorities, we must always consider the potential side effects of this class of drugs. Thus, parents and caregivers should check the possible appearance of the following items:

- Allergic reactions such as skin rashes (itching or hives), swelling in the face or hands, swelling or tingling in the mouth or throat, and chest tightness
- Mood change, unusual tiredness or weakness, trouble sleeping (nightmares), trouble awakening, or losing consciousness
- Cold sweats and/or bluish-colored skin
- Slow, fast, or uneven heartbeat

In order to prevent hypoglycemic status (check: coldness, shakiness, and sweating), it is wise to give propranolol during mealtime or right after your child has eaten. In our experience (more than 200 children with IHs treated with oral propranolol from 2008 to 2013 – unpublished data), the side effects have always been mild, and in just two cases, the treatment has been stopped prudently and in no case severe side effects have been observed while the efficacy has always been good and, in some cases, spectacular (Fig. 135.1a–d). In addition, we were able to rule out hyperkalemia from the list of possible side effects. Indeed hyperkalemia and hyperphosphatemia observed in a 33-day-old female with an ulcerated IH undergoing oral therapy with propranolol were finally linked with tumor lysis syndrome that was diagnosed after excluding other causes of electrolyte imbalance in the diagnostic workup (Cavalli et al. 2012).

Conclusion

The serendipitous discovery of the efficacy of beta-blockers in the treatment of IHs has been a milestone in pediatric and in dermatologic practice and has revolutionized the approach to these neoplasms. Fortunately, this drug is

Fig. 135.1 (**a**) This newborn, 17-day-old girl, presented with a large plaque-like IH showing a rapid enlargement with the involvement of the first trigeminal branch causing eye obstruction. (**b**) A cycle of oral corticosteroids for 1 month was almost ineffective and the left eye was still closed. (**c**) A cycle of oral propranolol was greatly effective within the first week of treatment. (**d**) At 6 months of life, the IH showed a complete regression with mild slack skin and fine telangiectasias

now an approved therapy for IHs. There is great debate regarding appropriate monitoring protocols for initiating and maintaining propranolol therapy in infants with IHs as well as right parameters to follow, including the possible hospitalization of the patient. We are happy that precise treatment guidelines have recently come to help doctors and caregivers in this field. However, we strongly suggest, for the present time but also for the future, the constant need of a multidisciplinary approach for all vascular anomalies.

Key Points

- Biofeedback is a process that enables an individual to learn how to change physiological activity for the purposes of improving health and performance.
- Biofeedback training may resolve dysfunctional thought patterns, actions, or habits that may damage the skin or interfere with dermatologic therapy.
- Dermatologic disorders that have an autonomic nervous system component can be successfully diagnosed and improved using biofeedback as a complementary approach.
- Biofeedback is an active training, not a passive treatment.
- Biofeedback is a nondrug, noninvasive, and side effect-free approach.

General Principles

In 2008, the Association for Applied Psychophysiology and Biofeedback (AAPB), Biofeedback Certification International Alliance (BCIA), and International Society for Neurofeedback and Research (ISNR) – three international biofeedback organizations – reached a consensus definition of biofeedback: "Biofeedback is a process that enables an individual to learn how to change physiological activity for the purposes of improving health and performance. Precise

instruments measure physiological activity such as brainwaves, heart function, breathing, muscle activity, galvanic skin resistance, and temperature. These instruments rapidly and accurately 'feed back' information to the user. The presentation of this information – often in conjunction with changes in thinking, emotions, and behavior – supports desired physiological changes. Over time, these changes can endure without continued use of an instrument."

Biofeedback (BFB) is the process of gaining greater awareness of many physiological functions primarily using instruments that provide information on the activity of those same systems, with a goal of being able to manipulate them at will. Some of the processes that can be controlled include brainwaves, muscle tone, skin conductance, galvanic skin resistance, heart rate, and pain perception.

BFB may be used to improve health, performance, and the physiological changes that often occur in conjunction with changes to thoughts, emotions, and behavior. Eventually, these changes may be maintained without the use of extra equipment, even though, once the know-how is learned, no equipment is necessarily required to practice biofeedback.

Classification: Disciplines and Approaches Behind Biofeedback

Biofeedback (BFB) is a procedure – still considered experimental, even after 50 years from its invention – that consists mainly in providing the subject with information, with the assistance of appropriate instruments, regarding neurovegetatively (autonomic nervous system) controlled biological functions. The procedure provides a sort of biological mirror insofar as it furnishes the conscious mind with an idea of the functioning or misfunctioning of certain "visceral activities." For a long time, experimental and clinical psychology taught that learning through "operant conditioning" was possible only in relation to behavior therapy or, in any case, through the mediation of behavioral conditioning. Learning related to visceral functions controlled by the neurovegetative system was considered possible only via "classic conditioning."

The essential difference between the two above theories is that operant conditioning requires the active intervention of the individual. It is inherent in the learning scheme of this method that when there exist different possible alternative responses to a particular stimulus, then by rewarding a certain response one increases the possibility that this response will follow when the specific stimulus presents. A well-known example is Pavlov's dog, who salivated whenever he saw food; by ringing a bell when the food appeared, Pavlov managed to condition the dog to salivate when the bell was rung, even if no food appeared.

In the 1960s, a group of investigators furnished "experimental proof" that visceral control could be learned, thus opening new roads for the systematic application of methods for learning operant conditioning of functions considered autonomous in humans (Miller et al. 1960) .

These studies stimulated research leading to elaboration/development of reliable methods, using appropriate instruments, to render sensorially perceptible changes in functions controlled by the autonomic nervous system (Miller et al. 1960). Thus it became possible to reward a specific response such that the subject was able to associate with certainty the reward with that specific response. In such cases the recompense was symbolic and consisted in the individual's capacity to influence an autonomous organic function.

The new technique was called biofeedback, a combination of the words biology and feedback, meaning literally "biological return information." The biological information, regarding vital functions, such as heartbeat, muscle tone, skin temperature and resistance, electric potential of the brain registered by electroencephalogram, and others, are recorded by special instruments and evidenced to the subject in the form of visual signals or sounds with parallel indications for any variations in the emotional state, all in real time. In very few years the use of BFB spread rapidly in the United States and then in Europe, and it soon became one of the most important new methods of investigation and treatment in psychophysiological medicine and psychiatry.

The rapid development and diffusion of BFB were due principally to the progress in electronics, with the continual production of more precise, reliable, and inexpensive instruments, associated with the affirmation of a new concept of many diseases that have been traced back to functional disturbances rather than to precise anatomic-pathological substrates (Sarti 1998).

Neither the technique nor the underlying BFB concept has been fully developed and classified. In fact, they are the objects of both facile and extreme enthusiasm and equally unjustified skepticism. Biofeedback proposes two very distinct subjects to psychiatrists and psychologists: one is the speculative and heuristic concept/subject involving relevant problems of self control, mind-body equilibrium, and individual responsibility in recovery or maintenance of someone's health; the other is the more practical aspect regarding the actual clinical efficacy of BFB training. In regard to the former, biofeedback as a concept is of undeniable importance, whereas the efficacy of clinical BFB training depends largely on the preparation and skill of the BFB operator who applies the technique, just as the actual therapeutic effects of a drug depend in each case upon both the drug's intrinsic pharmacodynamics and pharmacokinetic properties and, above all, its correct administration in the treatment strategy. The international literature on this topic allows us to conclude that, when correctly applied in the proper setting and in appropriate cases, BFB is a reliable and efficacious therapeutic measure. Cognitive-behavioral methods may resolve dysfunctional thought patterns (cognitive) or actions (behavioral) that damage the skin or interfere with dermatologic therapy. Responsive diseases include acne excoriée, atopic dermatitis, factitious cheilitis, hyperhidrosis, lichen simplex chronicus, needle phobia, psoriasis, onychotillomania, trichotillomania, prurigo nodularis, and urticaria.

BFB is a procedure of training as opposed to a treatment. Much like being taught how to tie their shoes or ride a bicycle, individuals undergoing biofeedback training must take an active role and practice in order to develop the skill. Rather than passively receiving a treatment, the patient is an active learner. It's like learning a new language.

The protocol calls for a preliminary meeting between the patient and the BFB operator before the first treatment session to identify the type of disturbance, establish the appropriate procedure, and explain it and its aims to the patient. During the first session the therapist records the patient's baseline psychophysiological parameters.

Mechanism of Action

Instrumentation that can measure manifestations of autonomic nervous system activity in the skin and then display it in a visual, auditory, or kinesthetic mode gives the individual sensory biofeedback. With training, individuals may learn consciously how to alter the autonomic response and with enough repetition may establish new habit patterns. Components of the instrumentation include detectors, amplifiers, processors, recorders, and visual displays, auditory tone or signal devices, or tactile signal devices.

The most commonly used biofeedback techniques measure and provide auditory or visual feedback of galvanic skin resistance (GSR), skin temperature, electromyography (EMG), and electroencephalography (EEG). The polygraph is a combined instrument that can measure these simultaneously along with heart rate variability (HRV) and respiratory rate.

Cutaneous problems that have an autonomic nervous system component can be improved by biofeedback. Examples include biofeedback of GSR for hyperhidrosis and biofeedback of skin temperature for Raynaud's disease. With training, individuals can learn how to consciously alter the autonomic response and with enough repetition may establish new habit patterns.

A young man with hyperhidrosis, described in Panconesi (1998) as reported by Sarti, had a very low initial GSR at the beginning of treatment and improved slowly over 20 sessions combining GSR biofeedback with autogenic relaxation training. Follow-up at 3 and 6 months after treatment, during which the patient continued to practice the autogenic training exercises, showed a continued reduction in palmar sweating (GSR) to near-normal levels. Systemic sclerosis patients with Raynaud's disease have been able to increase

finger skin temperature by an average of about 4 °C. Two of six patients using autogenic training in addition to biofeedback reported that they could shorten the duration of Raynaud attacks by autogenic training. Measurement of finger blood flow in another study with venous occlusion plethysmography, finger temperature, and GSR in patients with Raynaud's disease showed significant elevations in finger blood flow, finger temperature, and GSR conductance level in those given finger temperature biofeedback compared with those who received autogenic training but no biofeedback. A recent large study of Raynaud's patients compared learned hand-warming results using different biofeedback methods and found that attention to emotional and cognitive aspects of biofeedback training was important (Shenefelt 2003).

The opinion that biofeedback, hypnosis, and cognitive-behavioral techniques are branches of alternative medicine in this particular case in dermatology is surely debatable, but also interesting. We believe that these techniques are now a well-accepted part of official, evidence-based medicine, even in relation to dermatology.

Leaving aside discussion of the boundaries between "official" and "alternative" medicine, let us focus on the main problem, the patient, in our case the dermatologic patient who, in cases involving psychosomatic affections, can benefit greatly from the techniques outlined in this section.

Counseling is a task for and must be undertaken by the dermatologist (in the case of skin disorder patients): he/she is the partner and caretaker chosen by the patient who, at least initially, does not want to be referred to other specialists.

Indications and Other Uses

The use of biofeedback to investigate and complementary treat dermatologic problems is quite recent, being dependent on instrumentation to measure such parameters as galvanic skin resistance (GSR), muscular tension (EMG), heart rate variability (HRV), and skin temperature. Skin problems that have an autonomic nervous system component can be successfully assisted by biofeedback. Numerous dermatologic disorders may be improved using biofeedback as a complementary treatment, for example, acne excoriée, alopecia areata, atopic dermatitis, congenital ichthyosiform erythroderma, dyshidrotic dermatitis, erythromelalgia, glossodynia, recurrent herpes simplex, hyperhidrosis, ichthyosis vulgaris, lichen planus, nummular dermatitis, postherpetic neuralgia, pruritus, psoriasis, rosacea, trichotillomania, urticaria, viral warts, and vitiligo (Shenefelt 2002).

Using biofeedback, individuals may learn to consciously change their autonomic responses. In one report, a man increased his galvanic skin resistance after 20 sessions of biofeedback with autogenic relaxation training (Shenefelt 2005). Cognitive-behavioral therapy (CBT) plays a role in skin conditions that involve dysfunctional thought patterns that result in actions that cause skin damage. Examples include atopic dermatitis, factitious cheilitis, lichen simplex chronicus, prurigo nodularis, and acne excoriée. The therapy is designed to break the cycle of anxiety associated with the dysfunctional thought that is relieved by the destructive action. In one study, patients with atopic dermatitis scored higher in levels of anxiety and suppressed hostility compared with control patients with normal skin (Jordan and Whitlock 1972). In a variety of studies, CBT appears to be beneficial when used in combination with other therapies. One patient with acne excoriée improved with CBT, biofeedback, minocycline, and sertraline (Fried 2002). Factitious cheilitis responds to a combination of topical anti-inflammatory medications with CB. A 6-year-old child with vulvar lichen simplex chronicus improved within 13 weeks when the mother rewarded non-scratching behavior and ignored scratching (Bar and Kuypers 1973). These psychocutaneous therapies are all noninvasive and given their potential for efficacy may be beneficial when used in combination with other therapies (See Table 136.1).

In 2001, a Task Force of the Association for Applied Psychophysiology and Biofeedback and the Society for Neuronal Regulation outlined criteria for levels of evidence-based clinical efficacy of psychophysiological interventions (Moss and Gunkelman 2002). More recently, Yucha and

Table 136.1 Cutaneous affections reported to have high incidence of psycho-emotional factors (Panconesi 1998)

	Warts
Acne	
Rosacea	
Perioral dermatitis	Vitiligo

Montgomery rated the current evidence on the efficacy of biofeedback training on various diseases and reported this in 2008. These ratings are summarized in Table 136.2 (See Table 136.2).

It appears that if a condition has a lower efficacy rating, this does not suggest that biofeedback is not helpful in that condition, but rather that relevant research has not yet been conducted. Also, when combined with conventional medical management, an individual may very much benefit from a "possibly efficacious" biofeedback application.

Table 136.2 Efficacy ratings for biofeedback training on various medical conditions (ratings were made by Yucha and Montgomery (2008) based on data from the cited references)

Level of evidence	Diseases	References
Level 5 Efficacious and specific	Urinary incontinence (females)	Burgio et al. (1998)

	Syncope	McGrady et al. (2003)

An initial evaluation can usually reveal whether physiology monitored by biofeedback is outside normal limits and whether correcting it is likely to help the symptoms or disorder. In the latter case, BFB is used as a diagnostic tool to quantify the gap between standard values in body-mind relax condition and patient recordings. The more measured values are far from standard ones, the higher the probability that skin disorder has a psychophysiological component.

Conclusion

Skin disorders can have a significant effect on the psyche, and the psyche through psycho-neuro-immuno-endocrine and behavioral mechanisms can have a significant effect on skin disorders.

Because many inflammatory dermatologic disorders are triggered or aggravated by stress and/or anxiety, investigation and teaching patients to practice safe stress using non-pharmacological methods deserve more attention in treatment planning. Adding nondrug physiological awareness training such as biofeedback often enhances the effectiveness of pharmaceutical, psychiatric, or psychological treatment. A multidimensional approach often enhances and optimizes the treatment response. Much additional research is needed to compare the single mode and multimodal treatment effectiveness of drugs, drug combinations, and non-pharmacological methods for modulating and improving skin disorders that have a significant psychological component.

Biologic Agents for Psoriasis

137

Marina Papoutsaki and Christina Antoniou

Key Points

- The choice of treatment for psoriasis depends on the severity of the disease.
- The severity of psoriasis is not always easy to define as it depends both from the extension of the disease as well as its impact on the quality of life of the patients.
- The main target of almost all systemic treatments for psoriasis is the immune system.
- The introduction of biologics has brought an important therapeutic improvement for psoriasis.
- Biologics are a heterogeneous group of monoclonal antibodies, fusion proteins, and recombinant cytokines that modify and regulate pivotal and specific mechanisms involved in psoriasis' immunopathogenesis.
- At present, there are four biologics available for the treatment of psoriasis: three antitumor necrosis factor alpha (TNFα) agents, namely, adalimumab, etanercept, infliximab, and one anti-IL12/23 monoclonal antibody (mAb), ustekinumab.
- Patient candidates for a biological treatment need to undergo a detailed screening and a regular follow-up, in order to guaranty a good safety profile.
- Biologics show high efficacy both in the short and in the long term and a good safety profile.
- The better understanding of the pathogenetic mechanisms of psoriasis leads to continuous development of new therapeutic agents with very promising results.

General Principles

The choice of treatment for psoriasis depends on the severity of the disease; nevertheless, the evaluation of its severity may result difficult in some cases as not only objective parameters (extension, erythema, infiltration, etc.), but also the impact on the quality of life of the patients must be taken into consideration. Indeed smaller lesions may cause a higher psychological or physical discomfort for the patient depending on their localization.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_137, © Springer-Verlag Berlin Heidelberg 2015

Given the well-established role of the immune-mediated inflammation in the pathogenesis of psoriasis, the immune system is the main target of almost all systemic treatments available for this disease.

Systemic agents, including cyclosporine, methotrexate, and acitretin, or phototherapy, are usually prescribed in patients affected by moderate to severe plaque-type psoriasis or psoriatic arthritis. However, various factors may limit their long-term use, in particular the risk of serious cumulative organ toxicity and the lack of efficacy over time. Furthermore, underlying diseases, such as hypertension as well as renal and/or hepatic alterations, may represent contraindications to the abovementioned systemic treatments. Thus, effective drugs with less long-term toxicity are needed.

An excellent therapeutic improvement has been recently obtained by the introduction of the "biological response modifiers" or more commonly defined as "biologics." Biologics are a heterogeneous group of monoclonal antibodies, fusion proteins, and recombinant cytokines, designed to modify and regulate pivotal and specific mechanisms involved in psoriasis immunopathogenesis. To date, biologics have been suggested to have a more favorable side effect profile than conventional treatments.

Biological Agents for the Treatment of Psoriasis

Numerous biologics are approved by FDA or EMA and are actually being used for the treatment of psoriasis. These biologics include three antitumor necrosis factor alpha (TNFα) agents, namely, adalimumab, etanercept, infliximab, and one anti-IL12/23 monoclonal antibody (mAb), ustekinumab. All three anti-TNFα agents and the anti-IL12/23 agent, ustekinumab, are now commercially available for the treatment of both psoriasis and/or psoriatic arthritis.

Anti-TNF-a Agents

Etanercept

Mechanism of Action

Etanercept is a dimer of a chimeric protein genetically engineered by fusing the extracellular ligand-binding domain of the human TNF receptor 2 and the Fc domain of human IgG1 antibody (including the hinge and CH2 and CH3 regions but not the CH1 region). Because of its structure, etanercept binds and neutralizes the inflammatory cytokines TNF-α and lymphotoxin-alpha (TNF-beta). As a soluble receptor, etanercept binds free but not transmembrane TNF-α and therefore blocks the inflammatory cascade triggered by TNF-α leading to anti-inflammatory and immunosuppressant activity.

Its terminal elimination half-life is about 4–5 days.

Indications

Etanercept has been approved for moderate to severe plaque-type psoriasis and psoriatic arthritis, in whom other systemic therapies and phototherapy have failed, are contraindicated, or not tolerated. Moreover, etanercept is the only anti-TNFα agent approved for the treatment of childhood psoriasis (in children over 6 years of age) and psoriatic arthritis (in children over 12 years of age) nonresponsive or intolerant to traditional systemic therapies or phototherapy.

Dosage and Mode of Administration

Etanercept is self-administrated subcutaneously.

Initial dose: 25 mg twice weekly or 50 mg once weekly or 50 mg twice weekly for the initial 12 weeks and then reduce to 25 mg twice weekly or 50 mg once weekly. However, the 50 mg/twice weekly seems to have stronger clinical activity. Pharmacokinetic modeling and simulation, as well as clinical studies, suggest that the systemic exposure is equivalent for the 25 mg twice weekly and the 50 mg once weekly regimens. Its efficacy and safety for the different dosing have been demonstrated in several randomized clinical trials.

For childhood psoriasis, the suggested dosage regimen is 0.8 mg/kg (up to a maximum of 50 mg of a single dose) once weekly.

Maintenance dose: 25 mg twice weekly or 50 mg once weekly after 12 weeks of treatment.

Combination Therapy

Etanercept is usually used in monotherapy. Nevertheless, the concomitant use of topical antipsoriatic therapies (topical steroids, vitamin

D_3 derivatives, tazarotene, dithranol) may be feasible and advisable especially in the early stages of treatment or in the cases of mild recurrences of the disease during the maintenance period.

Regarding its combination with other systemic antipsoriatic agents, MTX is an established association in the treatment of psoriatic arthritis, and it can be used also in plaque-type psoriasis. Successful association also with acitretin has been reported in the literature, while there are as yet no validated data on combination therapy with fumaric acid esters or cyclosporine.

Side Effects

The most commonly reported side effects reported are local reactions in the injection site. In patients receiving anti-TNFα agents, as etanercept, there is a higher risk of developing infections. The most common infections observed are these of the upper respiratory tract, bronchitis, and skin infections. Severe infections including sepsis, tuberculosis, demyelinating processes, vasculitis, pancytopenia, anemia, leukopenia, lupus erythematosus, thrombocytopenia, and urticaria are rare.

Drug Interactions

The use of etanercept is not advised in patients who are treated with anakinra (IL-1 R antagonist) or abatacept as an increased number of serious infections and neutropenia have been reported.

Infliximab

Mechanism of Action

Infliximab is a chimeric (25 % mouse, 75 % human) monoclonal IgG1 antibody able to bind TNF-alpha (transmembrane and soluble form) and, consequently, to inhibit TNF-alpha activity. In particular its binding blocks soluble TNF-α, neutralizing this way its proinflammatory activity, while binding to membrane cell-bound TNF-α leads to cell elimination, possibly as a result of complement activation and/or antibody-dependent cellular toxicity or induction of apoptosis.

Infliximab was the first anti-TNF-alpha therapy successfully used in psoriasis, in a woman affected also by refractory inflammatory bowel disease, and therefore treated with infliximab 5 mg/kg. Several studies show that infliximab acts on multiple steps of the pathogenic process of psoriasis.

Indications

Infliximab is approved for the treatment of psoriatic arthritis and plaque-type psoriasis.

Dosage and Mode of Administration

Infliximab is administered intravenously, and the dosage used for the treatment of plaque-type psoriasis is weight dependent.

Initial dose: There is an induction period with the dose regimen of 5 mg/kg at weeks 0, 2, and 6, followed by a maintenance dose.

Maintenance dose: The dose regimen is of 5 mg/kg every 8 weeks. This interval may be temporarily shorten up to every 6 weeks in these patients that present a time-related recurrence of the disease, in order to regain the efficacy.

The efficacy and safety of infliximab has been evaluated in several clinical trials. Infliximab shows a fast efficacy in the treatment of plaque and psoriatic arthritis.

Combination Therapy

Infliximab is usually used in monotherapy in plaque-type psoriasis. Nevertheless the concomitant use of topical antipsoriatic therapies (topical steroids, vitamin D_3 derivatives, tazarotene, dithranol) may be feasible and advisable especially in the early stages of treatment or in the cases of mild recurrences of the disease during the maintenance period.

Regarding its combination with other systemic antipsoriatic agents, MTX is an established association in the treatment of psoriatic arthritis, and it can be used also in plaque-type psoriasis. There are reports in the literature regarding its association also with acitretin (in particular in the case of recurrence of pustular forms of psoriasis) and cyclosporine.

Side Effects

Acute infusion reactions are a commonly reported side effect of infliximab, but usually these reactions are mild and transitory and

include chills, headache, flush, nausea, dyspnea, or infiltration at the infusion site. Due to this, it is advisable to monitor carefully the patient during the infusion and for 1 h afterward. Serum sickness may occur 3–12 days following the infusion. The probability of an infusion reaction is higher in patients that have developed infliximab-specific antibodies and in patients receiving the drug after a long treatment-free interval. The administration of an antihistamine can help reduce or prevent a moderate infusion reaction. Other common reactions are exanthema, pruritus urticaria, and increased liver transaminase. In patients receiving anti-TNFα agents, as infliximab, there is a higher risk of developing infections. The most common infections observed are these of the upper respiratory tract, bronchitis, and opportunistic infections. Severe infections including sepsis, tuberculosis, demyelinating processes, vasculitis, pancytopenia, anemia, leukopenia, lupus-like syndrome serum sickness, onset or exacerbation of psoriasis (often pustular forms of the disease), thrombocytopenia, anaphylactic shock, and liver cell damage are rare.

Drug Interactions

Based on the present information, no drug interactions of infliximab with other medications have been described. Nevertheless based on the reports that combination of etanercept with anakinra leads to a higher rate of serious infections, the combination of infliximab and anakinra is not advised.

Adalimumab

Mechanism of Action

Adalimumab is a fully human monoclonal antibody, genetically engineered using phage display technology, and it is structurally and functionally analogous to naturally occurring human immunoglobulins G1 (IgG1). This monoclonal antibody demonstrates a high specificity and affinity for TNFα but not other cytokines, such as lymphotoxin (LTβ).

Indications

Adalimumab is approved for the treatment of psoriatic arthritis and plaque-type psoriasis.

Dosage and Mode of Administration

Adalimumab is self-administrated subcutaneously.

Initial dose: The recommended dosing of adalimumab for the treatment of plaque-type psoriasis and psoriatic arthritis is an initial dose of 80 mg, followed by 40 mg the week after.

Maintenance dose: The maintenance dose is 40 mg/every other week starting from week 2. In some high-need patients, a dose regimen of 40 mg/weekly may be considered in order to enhance its efficacy.

The efficacy and safety of adalimumab has been evaluated in several clinical trials. Moreover, adalimumab was the first biological drug for which a comparative study with a conventional drug (methotrexate) has been performed.

Combination Therapy

No controlled studies on combination therapy have been performed, and adalimumab is usually used in monotherapy in plaque-type psoriasis. Nevertheless the concomitant use of topical antipsoriatic therapies (topical steroids, vitamin D_3 derivatives, tazarotene, dithranol) may be feasible and advisable especially in the early stages of treatment or in the cases of mild recurrences of the disease during the maintenance period.

Regarding its combination with other systemic antipsoriatic agents, MTX is an established association in the treatment of psoriatic arthritis, and it can be used also in plaque-type psoriasis. There are anecdotal reports in the literature regarding its association also with acitretin (in particular in the case of recurrence of pustular forms of psoriasis) and cyclosporine.

Side Effects

The most common adverse event reported from placebo-controlled clinical trials was injection site reactions, such as erythema, itching, pain, and swelling. Adalimumab can be associated with infectious adverse events, mainly of the upper respiratory tract, bronchitis, and urinary tract infections. Severe infections such as pneumonia, septic arthritis, postoperative infections, erysipelas, phlegmonous infections, diverticulitis, and pyelonephritis have also been described.

Thrombocytopenia and leukopenia have been rarely reported. Treatment with adalimumab may result in the formation of autoantibodies and infrequently in the development of lupus-like syndrome. Severe allergic reactions are rare and include exanthem, urticaria, pruritus, respiratory distress, tightness in the chest, as well as swelling of the mouth, face, lips, or tongue. Malignancy, especially lymphoma, is a very rare side effect.

Drug Interactions

The combination therapy with anakinra and abatacept may lead to serious infections, without any additional clinical benefit; therefore, their combination is not recommended.

Anti-IL12-23 Agents

Ustekinumab

Mechanism of Action

Ustekinumab is a human monoclonal antibody that binds to the shared p40 protein subunit of human interleukins 12 and 23 with high affinity and specificity, thereby preventing interaction with their surface IL.12Rβ1 receptor. In a population pharmacokinetic analysis based on data obtained from two pivotal large-scale phase III studies (PHOENIX 1, PHOENIX 2), different factors such as body weight, diabetes, and positive immune response (antibodies to ustekinumab) seem to be important covariates affecting the apparent clearance and/or apparent volume of distribution of ustekinumab.

Indications

Ustekinumab is approved for the treatment of psoriatic arthritis and plaque-type psoriasis.

Dosage and Mode of Administration

Ustekinumab is self-administrated subcutaneously at a dose of 45 or 90 mg according to the patient's weight (<100 kg or ≥100 kg).

Initial dose: The recommended dosing of ustekinumab for the treatment of plaque-type psoriasis and psoriatic arthritis is an initial dose of 45 or 90 mg, according to the patient's weight, at week 0 and 4.

Maintenance dose: The maintenance dose is 45 or 90 mg, according to the patient's weight, every 12 weeks.

The efficacy and safety of ustekinumab has been evaluated in several clinical trials.

Combination Therapy

There are no controlled studies on combination therapy; nevertheless, combination with topical antipsoriatic agents may be beneficial for the patient.

Side Effects

Infections are the most important side effect occurring with this drug. The most common infections observed were nasopharyngitis and upper respiratory tract infections, while the rate of severe infections was low. The data from the main clinical studies of ustekinumab (PHOENIX-1 and PHOENIX-2) show no association with lymphocytopenia nor any toxic cumulative effects. Moreover, the rate of reported malignancies was low and comparable either with the ones of the placebo population or the general population. The same applies also to the serious cardiovascular events observed, mainly during the first phase of the studies.

Drug Interactions

No chemical or via the cytochrome P450 system interactions are expected for ustekinumab.

Patient Candidates for Biological Treatments

Candidates for biological treatments are patients affected by moderate to severe psoriasis (PASI >10 or BSA >10 and DLQI >10) for at least 6 months that fulfill one of the following criteria:

- Nonresponsive or intolerant to traditional systemic treatments (cyclosporine, methotrexate, acitretin, fumaric acid)
- Nonresponsive or intolerant to phototherapy (PUVA, UVB)
- Affected by instable or life-threatening forms of psoriasis

- Patients with severe impact on their quality of life
- Patients affected by psoriatic arthritis independently of the severity of their skin lesions

Nevertheless and according to the new concept of treatment goals in psoriasis, there are special clinical manifestations that may change the definition of a mild psoriasis into moderate to severe psoriasis leading to a significant impairment of their quality of life. These manifestations can include the following:

- Involvement of visible areas
- Involvement of major parts of the scalp
- Involvement of the genitals
- Involvement of the palm and/or soles
- Onycholysis or onychodystrophy of at least two fingernails
- Pruritus leading to scratching
- Presence of single recalcitrant plaques

Patient's Screening and Follow-Up

Biological treatments have demonstrated a rather good safety profile in the long-term treatment compared with the traditional therapies. These drugs seem to lack specific organ toxicity unlike conventional treatments. Nevertheless due to their mode of action, adverse events may arise. In order to minimize their side effects, a careful screening of the patient prior to treatment is required.

Patient's Screening

Medical History and Physical Examination

Prior to treatment with a biological agent, a detailed medical history needs to be taken, and the following conditions need to be investigated:

- Presence of chronic or acute infections (tuberculosis, hepatitis B, hepatitis C, HIV)
- Presence or history of malignancies or lymphomas
- Presence of other autoimmune diseases
- Signs or positive family history of demyelinating diseases (especially in candidates of anti-TNFα agents)
- Presence or history of cardiovascular events
- Presence of comorbidities such as arthritis, diabetes, hypertension, obesity, hyperlipidemia, and depression

A list of the absolute and relative contraindications is given in Tables 137.1 and 137.2.

Physical examination is important in order to evaluate the severity of the disease as well as the presence of psoriatic arthritis. In order to evaluate the severity of the disease before treatment as well as to evaluate its efficacy during treatment, the following scores need to be assessed:

- BSA (Body Surface Area)
- PASI (Psoriasis Area Severity Index)
- NAPSI (Nail Area Psoriasis Severity Index)
- DLQI (Dermatology Life Quality Index)

Table 137.1 Absolute contraindications of biological treatments

	Adalimumab	Etanercept	Infliximab	Ustekinumab
Cardiac insufficiency (III or IV)	Yes	Yes	Yes	No
Active chronic infections including TB or HBV	Yes	Yes	Yes	Yes
Pregnancy or nursing	Yes	Yes	Yes	Yes
Known hypersensitivity to mouse proteins	No	No	Yes	No

Table 137.2 Important relative contraindications of biological treatments

	Adalimumab	Etanercept	Infliximab	Ustekinumab
Demyelinating diseases	Yes	Yes	Yes	No
Malignancy (with the exception of BCC) and lymphoproliferative diseases or history of such disease	Yes	Yes	Yes	Yes
Use of live vaccines	Yes	Yes	Yes	Yes
Autoimmune diseases	No	No	Yes	No
HIV or AIDS	No	No	Yes	No

Laboratory Parameters

The laboratory parameters include the following exams:

- Full blood count
- Biochemical analysis (including liver enzymes, creatinine, uric acid, cholesterol, triglycerides, glucose)
- ESR/CRP
- Urine analysis
- Pregnancy test (urine)
- Hepatitis B (HBsAg, anti-HBs, anti-HBc) and C screening
- ANA/anti-dsDNA
- Mantoux test and/or QuantiFERON® Gold test

Imaging

The imaging should include the following:

- Chest X-ray (in order to exclude active or latent tuberculosis)

In case of latent tuberculosis, the patient is not necessarily excluded from the biological treatments. A specialist needs to be consulted and the patient put under prophylactic anti-TB treatment prior to the beginning of biologics. The time of the prophylactic therapy varies according to the drugs used.

Patient's Follow-Up

During treatment, it is very important to monitor the efficacy and safety of the therapy.

Clinical and standard laboratory evaluation needs to be repeated more closely during the beginning of the treatment (after 2 and 6 weeks for infliximab and after 4 weeks for adalimumab, etanercept, and ustekinumab) and then every 2–3 months following the administration schedule of each drug.

Chest X-ray, Mantoux skin testing and/or QuantiFERON® Gold test, and hepatitis B and C and HIV screening should be repeated once a year. Nevertheless we need to take into consideration that further specific testing might be needed according to clinical signs, risks, and exposure of each patient. Moreover, there may be some conditions that may require a more frequent laboratory monitoring. The most common of these conditions are the following:

- Presence of comorbidities
- Contemporary administration of prophylactic therapy for tuberculosis
- Contemporary administration of other systemic conventional drugs for psoriasis (methotrexate, retinoids, cyclosporine)
- Exacerbation and/or persistence of the disease

During treatment, it is also recommended to advise the patient to undergo regular cancer screening exams according to his age, sex, and family history (pap test, mammography for women, PSA for men).

Efficacy and Long-Term Treatment with Biologics

All biological therapies have shown a rather fast onset of action, and the clinical improvement is usually visible within the first 4–8 weeks of treatment. The time of evaluation of their efficacy varies from 10 weeks of infliximab to 16 weeks in case of adalimumab and ustekinumab and 24 weeks of etanercept. More detailed information on their efficacy is shown in Table 137.3.

Regarding the long-term data on psoriasis therapy, their analysis is limited mostly due to different clinical trial designs and statistical methodology used for their interpretation. Adalimumab showed (REVEAL study) that the patients who had achieved a PASI 75 response at weeks 16 and 33 maintained that response for 100 weeks in 83 % and for 160 weeks in 76 % of the patients.

Etanercept in a post hoc analysis that included patients treated with different doses over a period of up to 4 years showed that 67 % of the patients that had a good response during the induction period (PGA 0/1) maintained the response at 24 weeks and showed only a slight variation through week 48.

Infliximab has no data of open-label extension trials available. In the EXPRESS II study, 71 % of the patients maintained PASI 75 until week 50 of continuous treatment.

Table 137.3 Efficacy of different biological agents

Therapeutic agent	Dose	PASI 75/(week 12) (%)	PASI 75/(6 months) (%)
Etanercept	2×25 mg/week	34	44
Etanercept	2×50 mg/week	49	59
Ustekinumab	45 mg/12 weeks (body weight <100 kg)	67	70
Ustekinumab	90 mg/12 weeks (body weight >100 kg)	68–71	79
Adalimumab	40 mg/eow	71–80	71
Infliximab	5 mg/kg	≥80	82

Biologic agent	Dosage	PASI 75 at week 12 (%)
Etanercept	2×25 mg/week	34
Etanercept	*2×50 mg/week*	*49*
Ustekinumab	45 mg/12 weeks (<100 kg BΣ)	*67*
Ustekinumab	90 mg/12 weeks (>100 kg BΣ)	*68–71*
Adalimumab	40 mg eow	*71–80*
Infliximab	5 mg/kg	*≥80*

Ustekinumab showed (PHOENIX I study) that 79 and 81 % for the doses of 45 and 90 mg, respectively, maintained their PASI75 at 5 years (244 weeks).

Given the good safety profile of the biologics, the therapeutic schema proposed is that of a continuous treatment, and treatment discontinuation is not advised with the exception of etanercept where also a discontinuous schema is also proposed.

According to the "new" for dermatology concept of treatment goals, a treatment is successful and should be continued if it results in a reduction of PASI ≥75 % or PASI ≥50 to <75 % combined with a DLQI ≤5. When the reduction in PASI is <50 % or PASI ≥50 to <75 % combined with a DLQI >5, treatment modifications should be considered. These treatment modifications include the following:

- Increase of drug dose
- Reduction of the intervals between drug doses
- Combination of therapies, either by adding topical treatment or a conventional systemic treatment (MTX, cyclosporine, acitretin)
- Change of the drug (usually done when all the above measures fail)

New Biologics

In the last few years, a great progress has been achieved in identifying some of the risk genes for psoriasis leading to a better understanding of the pathogenetic pathways of the disease. This increased understanding of the immunogenetic pathways has led to the development of more targeted biological therapies. In fact, multiple new treatments are currently in development for the treatment of psoriasis and their preliminary data seem to be very promising.

Table 137.4 Some of the new biological treatments currently under investigation for the treatment of psoriasis

Class	Agent
Anti-TNF inhibitors	Certolizumab pegol
	Golimumab
	ART621
Anti-IL23	BI655066
	SCH900222
Anti-IL-17	Brodalumab
	Secukinumab
	Ixekizumab
Anti-IL-20/22	Fezakinumab
Phosphodiesterase 4 inhibitors	Apremilast
JAK inhibitors	Tofacitinib (JAK1/JAK3)
	Baricitinib (JAK1/JAK2)
	ASP-015K (JAK3)

Among the new classes of targeted biological agents for psoriasis, the agents targeting the Th17/Il-23 axis will likely represent an important new therapeutic approach. These drugs by specifically targeting the IL-23/Th17 axis are likely to have a more targeted effect and an improved safety profile. Also the family of Janus kinases (JAK) inhibitors as well as the phosphodiesterase 4 inhibitors seems to show promising preliminary results.

An overview of some of the new biological treatments is shown in Table 137.4.

Conclusions

Psoriasis is a chronic systemic inflammatory disease with a complex pathogenetic mechanism that involves interactions between the innate and adaptive immune systems, genes, and environment. Being a systemic inflammatory disease, psoriasis is associated with a number of comorbidities that include psoriatic arthritis, cardiovascular disease, metabolic syndrome, and depression. In addition, psoriasis is also associated with a significant impairment of quality of life, as it affects relationships, social activities, work, and emotional well-being. Moreover due to the chronic nature of the disease, often treatment options can be limited either because of their efficacy or because of their safety.

The introduction of the biological agents, such as adalimumab, etanercept, infliximab, and ustekinumab, has provided dermatologists with more options for the short- and long-term treatment of patients with psoriasis. With the use of biological therapies, it is now possible to achieve and maintain effective disease control with a good safety profile in the long term compared to the conventional treatments. Nevertheless, the careful screening and regular follow-up of the patients that undergo biological treatments are of great importance in order to avoid side effects and guaranty the patient efficacy and safety in the long term.

Bleaching Agents

138

Agustin Alomar and Elena Manubens

Key Points

- Before starting treatment, the nature of lesions should be evaluated: potential malignancy, colour, size and pattern are characteristics that need to be taken into consideration.
- Not all of the hyperpigmentation disorders are candidates for bleaching treatments. Melasma, solar lentigines and postinflammatory hyperpigmentation are the most relevant indications.
- Sunscreen use during daytime is both effective for avoiding worsening of the lesions and enhancing the effect of bleaching compounds.
- Hydroquinone is the most studied and used of the bleaching agents. Several trials demonstrate its efficacy and safety.
- Retinoic acid results in good response rates; however, longer time of treatment is needed and it can induce more irritation.
- Combination formulas such as the Kligman-Willis formula have obtained better results than monotherapies or other therapies in many clinical trials.
- Other compounds used are azelaic acid, arbutin, ascorbic acid and kojic acid.

General Considerations

Hyperpigmented lesions are common in a dermatologist's practice. They are usually an important reason of concern, especially when they involve the face, but also other common areas such as the forearms and upper chest are frequent.

The first thing to evaluate is the nature of the lesion. Physicians should be able to differentiate between benign and potentially malignant conditions as the last ones should be removed and examined microscopically. Once malignancy is discarded, the next step is to decide whether bleaching is a suitable approach or not, and in order to determine that, the colour of the lesion should be examined. In general terms, skin colour is determined by several components, the main ones being: thickness, blood vessels and its oxygen concentration, pigments such as carotenes and the most important one being melanin.

Melanin can be deposited in the upper layers of the skin (epidermis) or in deeper ones (papillary and reticular dermis). The more superficial, the more susceptible to topical bleaching agents it should be. Wood light may help us localise the height of the pigment, as when it is disposed in the epidermis, the light highlights the contrast between the affected and the normal skin.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_138, © Springer-Verlag Berlin Heidelberg 2015

The size and pattern of disposal should also be evaluated as some skin problems appear as dark blotches, uneven distribution of pigment or uniform hyperpigmentation.

Finally, other conditions should be evaluated such as ethnicity, hormonal and genetic factors or sun exposure.

All of them are elements that should be taken into consideration in choosing the appropriate agent and technique.

Pigment lightening has always been a challenge for dermatologists. The wide range of treatment options and the lack of quality studies supporting their efficacy and safety make it difficult to take a decision when the patient asks for a solution for his hyperpigmentation.

Topical Bleaching Agents: Indications

Solar Lentigines

Also called "sunspots" or "old-age spots", these dark spots are one of the commonest reasons of consultation. They affect 90 % of white patients older than 50 years and their incidence increases with age and sun exposure.

They are well-defined hyperpigmented macules with sizes varying from a few millimetres to 1 or 2 cm and usually round shaped. The lightest ones are more homogeneous than the darkest ones, which tend to be spotted. They appear in severely sun-damaged areas such as the face, upper chest, back, hands and arms. They can appear at any age, normally over 40s, and can lighten with cession of sun exposure.

Microscopically they appear as ridge hyperplasia of melanocyte with or without proliferation. There is an increase of the melanogenesis that determines a rise in the number of the keratinocyte melanosomes.

This kind of pathology is so histologically structured that bleaching agents are usually not enough; they have a mild lightening effect but more invasive treatments are necessary such as chemical peelings or lasers to completely remove them.

Melasma

This hypermelanosis, commonly affecting women, is also called "chloasma" or "pregnancy mask" when it appears during pregnancy. It is defined by its characteristic pattern of distribution on the face, and it is associated with darker skin phototypes (Asian and Hispanic).

The lesions appear as light brown to grey macules in sun-exposed areas with irregular margins and shapes. We can differentiate three patterns depending on their distribution. The "centrofacial pattern" is the most common one (two-thirds of the patients), and it affects the forehead, nose, chin and medial cheeks. "Malar pattern" affects 20 % of the patients and is circumscribed to the nose and cheeks. The other 15 % of the patients have a "mandibular pattern". All of them can have macules in other sun-exposed areas. It can also be classified as epidermal, dermal or mixed melasma depending on the skin level where pigment is disposed.

Even though melasma's pathogenesis is not well known, it has been associated with many factors. Genetic predisposition and sun exposure are two of the most important ones. Hormonal factor also has to be taken into consideration as pregnancy and the use of contraceptives can also contribute to its appearance. If melasma occurs during pregnancy, it is likely that the lesions become lighter in the months following the pregnancy.

Postinflammatory Hyperpigmentation

Postinflammatory hyperpigmentation is a common disorder that may occur after practically any kind of skin inflammation, especially the ones with lichenoid pattern such as lichen planus or cutaneous lupus. Other conditions that may lead to hyperpigmentation are acne, atopic dermatitis, irritant and allergic contact dermatitis, phytophotodermatitis, pyodermas, burns and many others. Darker skin phototypes are more likely to develop more intense and durable lesions, causing important aesthetic traumas.

It presents with dark macules of irregular shapes and sizes that appear after the resolution of the inflammatory erythema and oedema. In the following months, the lesions may get lighter but sometimes they are permanent. The evolution depends mostly on the level of the pigment deposit in the skin; if it gets phagocyted by the macrophages, lesions are unlikely to disappear.

General Principles

All the treatments with any topical bleaching agent should be combined with a series of measures that may help improve their results.

The first and most important advice that should be given to the patient is to avoid sun exposure before, during and after the treatment as it stimulates melanogenesis. The bleaching agent should be applied at night and sunscreen should be worn when going outdoors; if the bleaching preparation incorporates sun protection, it could be used during daytime as well. Most physicians prefer to start the treatment after summer time, especially in sunny regions, as very little improvement may be achieved if the patient is exposed to high-intensity sun radiation.

Before starting the treatment, the patient should apply it on a small area of the skin as some of them may cause irritation that could lead to a counterproductive effect. If erythema appears, the physician should consider using a lower concentration of the bleaching compounds of the formula.

The preparation must be used on cleaned skin which is not dry, irritated or sunburnt; one should wait until inflammation goes down in order to avoid its worsening.

During the treatment, the patient must be aware that only pigmented patches need to be treated. If the preparation is used in normal skin, the contrast between normal and affected skin may not get better.

The physician must also advise that it may take months to achieve visible results. If no improvement is achieved during the first 3–4 months, he should consider increasing the concentration of the preparation if possible, as well as changing or combining its compounds.

Topical Bleaching Agents

Hydroquinone

Hydroquinone is probably the most popular and well-studied bleaching agent. It is a phenolic organic compound also known as benzene-1, 4-diol that inhibits the enzymatic oxidation of tyrosine and phenoloxidases. It also inhibits DNA and RNA synthesis of the melanosomes leading to melanocyte damage. All of these actions end up reducing gradually the melanin production.

In a 2010 Cochrane Review of the interventions in melasma treatment, hydroquinone was the one with more randomised controlled trials. Most of the trials compared hydroquinone to other bleaching agents and not placebo, making it difficult to obtain statistically significant results. Hydroquinone may be formulated at many concentrations from 2 % to 5 %, with 4 % being the most commonly used. When compared to 20 % azelaic acid, neither physicians nor patients found significant difference in skin lightening. The same happened with physicians' assessment in the 5 % ascorbic acid comparison, although patients did find significant improvement.

When lower concentrations of hydroquinone were used, other treatments such as 20 % azelaic acid got better results.

Higher concentrations up to 8 % could be used, but they are unstable formulations and get oxidised rapidly. At any concentration, darkening of the preparation reflects oxidation of the product, and if seen, it should be discarded as it may be more active and irritating.

Although it is a widely used compound, there is still some controversy around it.

The biggest one is the risk of developing exogenous ochronosis after its use for long periods of time. This side effect appears as brown, grey or blue hyperpigmentation in the areas of application of the product and has been well established in the literature. Although the exact incidence remains unknown, high rates have been reported in the South African population, with lower rates among Hispanics and Caucasians and rare cases in the USA. Physicians should also be careful

in cases of skin irritation, lack of sun protection and the use of concentrations higher than 3 % for more than 6 months.

Regarding its potential for malignancy, the higher incidence of hepatic adenomas, renal adenomas and leukaemia when applied topically in murines with large doses over extended time periods has been well established. However, in humans, absorption varied from 24 % to 45.3 % depending on the areas exposed and generating peak plasma concentrations no higher than the ones obtained after eating some foods containing arbutin (a compound that hydrolyses to yield hydroquinone in weak acid media).

Mode of Use: Hydroquinone should be applied at nights and be combined with a sunscreen agent during daytime. After 5 to 6 months of its use, further improvement should not be expected, and the physician should consider changing the compound or combining it. Patients should be advised that in some cases hydroquinone effect is only temporary and hyperpigmentation could reappear in the affected areas. Contact with nails should be avoided as it may tint them orange.

Nowadays the commercial hydroquinone formulas are always in combination with some other agents for thinning the epidermis and to enhance the action like some acids such as retinoic or glycolic acid.

Topical Retinoic Acid

Tretinoin (all-trans retinoic acid) is a first-generation topical retinoid derived from vitamin A and has been widely used in dermatology. When dermatologists started using it for acne treatment, patients reported lightening of the dark spots on their face. The mechanism of this effect is not well known, but it has been thought that acceleration of cell turnover, by binding specific nuclear proteins, may be implied. Its capacity for inhibiting the UVB-induced tyrosinase and interrupting melanin synthesis has also been demonstrated. Other generations of topical retinoid compounds such as isotretinoin or adapalene have shown milder effect but better tolerance, making them a good option in patients with poor tolerance to retinoic acid.

Many studies have demonstrated tretinoin's benefit over placebo for treating melasma and actinic lentigines at concentrations ranging from 0.025 % to 0.1 %. Creams or gels have been used, but the first ones are considered the best option as the moisturiser component may help with the irritation caused by the retinoic acid.

Tretinoin 0.1 % cream to treat melasma was evaluated in two randomised controlled trials showing a significant improvement in clinical assessment in 68 % and 32 % of the patients compared with 5 % and 10 % in the vehicle control group.

Adverse effects include dryness with light scaling, redness and slight stinging and usually improve after the first weeks of treatment. If the patient refers important discomfort, the preparation could be used on alternate nights.

It is important to note that studies show a slower response, up to 24 weeks, when using tretinoin in monotherapy in comparison with other treatments available such as hydroquinone.

Mode of Use: Treatment should be adapted to individual skin type. Physicians recommend to start with the lower concentration and to increase it gradually in order to minimise the adverse effects. A small amount of product should be applied nightly and cleaned up before sun exposure since it increases sensitivity. In cases of sensitive skin, it would be better to start applying it on alternate nights for 2–3 weeks. During daytime, sunscreen plus moisturiser should be worn, and aggressions to the skin such as smoking avoided. A physician should supervise combination with other cosmetic products, as retinoic acid is not stable when combined with some other compounds.

Kligman-Willis Formula

In 1975, Kligman and Willis published a new formula for lightening human skin. Their

research found that the combination of 5 % hydroquinone, 0.1 % tretinoin and 0.1 % dexamethasone applied twice daily was the one with better results and less irritation. It is thought that the retinoid prevents the hydroquinone from oxidising, improving its absorption through the epidermis. The point of adding a topical corticosteroid was to reduce the inflammation caused by the other two compounds for increasing tolerability and reducing possible postinflammatory hyperpigmentation.

Since then many other dual or triple combinations have been studied. Using hydroquinone plus retinoic acid alone may be a good option for long-term treatments where use of corticosteroids is generally a big concern.

There are other combined formulations that have proved efficacy. Four per cent hydroquinone, 0.05 % tretinoin and 0.01 % fluocinolone acetonide used nightly showed better results than dual-combination creams containing either hydroquinone plus tretinoin, hydroquinone plus fluocinolone, tretinoin plus fluocinolone and hydroquinone 4 % alone.

Six per cent hydroquinone, 0.05 % tretinoin and 0.05 % triamcinolone acetonide has also obtained good results in some patients.

Other Bleaching Agents

Azelaic Acid

Azelaic acid is a natural compound synthesised by *Malassezia furfur* and it is responsible for the hypopigmentation in pityriasis versicolor. As with other bleaching compounds, its mechanism of action also involves inhibition of the tyrosinase leading to a decrease in melanin production and melanosome formation.

In a randomised double-blind multicentre study comparing 20 % azelaic acid versus placebo in patients with melasma, statistically significant results were found. In comparison to hydroquinone, 20 % azelaic acid has been shown to have greater efficacy than 2 % hydroquinone in a 6-month study and to be equally as efficacious as 4 % hydroquinone in a 24-week double-blind trial.

As with other bleaching compounds, pruritus, erythema and scaling have also been commonly reported when using azelaic acid.

As azelaic acid is also useful for treating mild to moderate acne, it should be considered an interesting option for patients with postinflammatory hyperpigmentation secondary to acne spots.

Mode of Use: Preparations containing up to 20 % of azelaic acid are commonly used. It can be used as monotherapy or combined with other bleaching agents. It can be used up to twice daily, although it is recommended to start with nightly application to assess tolerability.

Arbutin

Technically known as hydroquinone-beta-D-glucoside, it is the natural compound of hydroquinone and it is extracted from the leaves of *Arctostaphylos uva-ursi* (bearberry) and other plants. It can inhibit the tyrosinase activity and the melanosome maturation and is used with concentrations of up to 3 %. Special care needs to be taken with higher doses as it can induce hyperpigmentation.

Ascorbic Acid

Also known as vitamin C, ascorbic acid is a natural compound that can be found in the dermis and epidermis with many properties that have been used for cosmetic purposes since old times.

When administrated both orally and topically, its antioxidant action helps to prevent the damage caused by the UVB-induced free radicals. It is also thought to decrease pigmentation by interacting with copper at the active site of tyrosinase and by reducing dopaquinone by blocking dihydro-chinindol-2-carboxyl acid oxidation. Additionally, it is involved in collagen synthesis, as it is an essential factor for the enzymatic hydroxylation of the amino acids proline and lysine, providing a more lightened and elastic appearance of the skin.

Kojic Acid

Kojic acid is a molecule produced by *Aspergillus oryzae* and *Penicillium* spp. that is a popular bleaching agent in Japan. Its mechanism of action is also through the inhibition of the tyrosinase and it is used at 2 % concentrations. Many studies have tried to demonstrate its equivalent effect to other compounds; however mixed results have been obtained. It is a very unstable molecule that can easily lose its efficacy when exposed to light.

Other Bleaching Techniques

Chemical peelings
Lasers

Calcineurin Inhibitors: Topical

139

Andreas Wollenberg and Jelena Peric

Key Points

- Topical calcineurin inhibitors are, together with topical corticosteroids and UV light, one of the mainstays of topical anti-inflammatory treatment in dermatology.
- Topical calcineurin inhibitors are currently licensed in Europe for treatment of atopic dermatitis only, but there is extensive off-label use in seborrhoeic dermatitis, lichen planus, lichen sclerosus, eyelid dermatitis, perioral dermatitis, vitiligo and pyoderma gangrenosum.
- Tacrolimus ointment and pimecrolimus cream are the two drugs licensed and available throughout Europe.
- Tacrolimus is also licensed for maintenance use or proactive therapy, which is defined as long-term, low-dose intermittent application of anti-inflammatory therapy to the previously affected skin, together with an ongoing emollient treatment of unaffected skin.
- Topical calcineurin inhibitors have the advantage of not causing skin atrophy, striae distensae, telangiectasia, glaucoma or cataract and are less absorbed than topical corticosteroids.
- Topical calcineurin inhibitors have the disadvantage of an initial burning sensation and a higher cost and less available galenic formulations compared to steroids.
- Legally, topical calcineurin inhibitors are not licensed for use during pregnancy. Scientifically, there is no evidence that they may have teratogenic effects or may otherwise be harmful during pregnancy. There is large experience with calcineurin inhibitors during pregnancy from the systemic use in transplantation medicine.

General Principles

Calcineurin inhibitors are a functionally defined substance class of molecules and well established as systemic agents in transplantation medicine. They block the induction of proinflammatory cytokines by the nuclear factor of activated T cells (NFAT), thus suppressing T-cell activation. Cyclosporine A is best established but has poor skin penetration and is not suitable for topical

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_139, © Springer-Verlag Berlin Heidelberg 2015

use. Tacrolimus and pimecrolimus have a smaller molecule size and are suitable for topical use in atopic dermatitis and many other skin diseases. Their main advantage is that they do not induce skin atrophy, even with long-term application, and thus they are particularly useful for facial and flexural areas where topical corticosteroids should be avoided.

Classification

The first introduced calcineurin inhibitor was cyclosporine. Although cyclosporine has revolutionized transplantation and proved efficacy in many inflammatory and autoimmune skin diseases, its use is limited by side effects. Despite the fact that it is very lipophilic, cyclosporine is almost ineffective as a topical agent, as it is not able to penetrate skin. Though cyclosporine acts as a calcineurin inhibitor, it is not regarded a member of the substance class of topical calcineurin inhibitors.

In contrast to cyclosporine, the newer calcineurin inhibitors tacrolimus and pimecrolimus have sufficiently low molecular weight to penetrate stratus corneum; thus, they are very effective when applied topically (Fig. 139.1). Tacrolimus and pimecrolimus can be roughly viewed as equivalent, as the wanted and unwanted effects of the medication are substance class effects. Tacrolimus is about fourfold more efficient than pimecrolimus, whereas pimecrolimus is more lipophilic. Pimecrolimus has a considerably higher affinity for the skin but a lower permeation potential. This explains the higher efficacy as well as the more common application site reactions of tacrolimus ointment compared with pimecrolimus cream. Tacrolimus is commercially available as 0.1 and 0.03 % ointment, while pimecrolimus is available as 1 % cream.

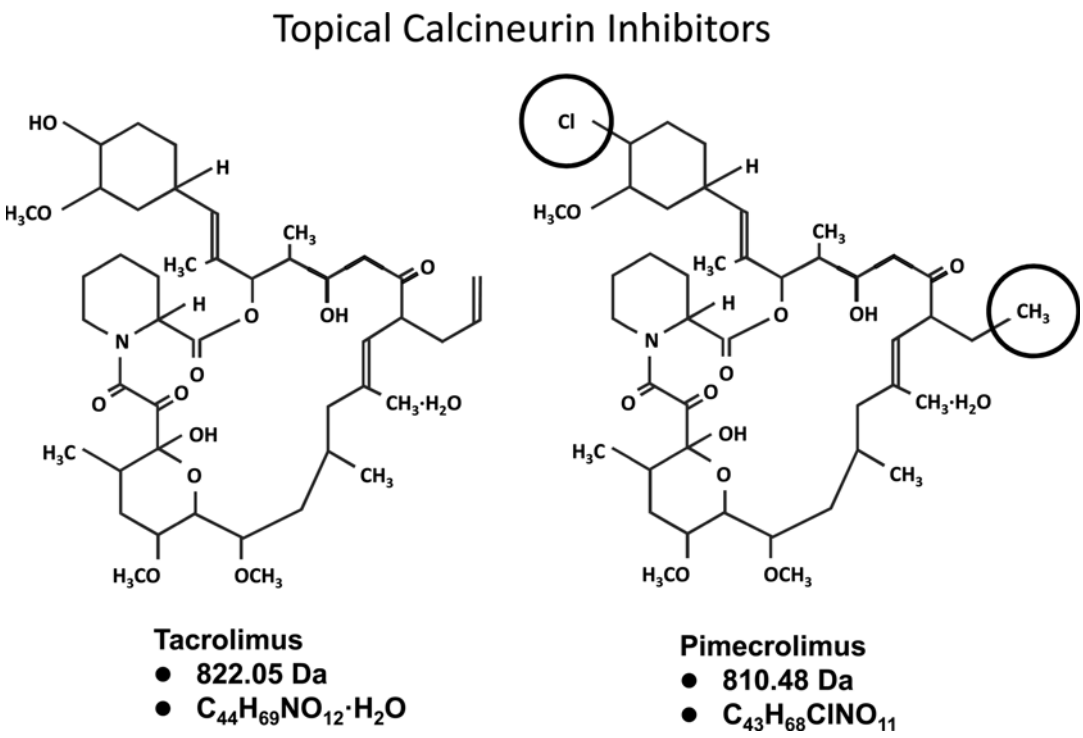

Fig. 139.1 The topical calcineurin inhibitors tacrolimus and pimecrolimus show an almost identical structure and molecular weight.

Mechanisms of Action

Calcineurin inhibitors are a functionally defined substance class of molecules, which are blocking the translocation of calcineurin from the cytosol to the nucleus, thereby inhibiting the translation of proinflammatory cytokines dependent on the nuclear factor of activated T cells (NFAT). This inhibits the activation and maturation of T cells and blocks transcription of several proinflammatory gene products in other cells. In addition, the release of histamine and other vasoactive substances from mast cells is blocked, and the expression of functionally relevant surface molecules on Langerhans cells is altered.

The main advantage of topical calcineurin inhibitors over topical corticosteroids is that they do not affect collagen synthesis by fibroblasts and therefore do not induce skin atrophy, even with long-term application. Hence, they are particularly useful for facial and flexural areas where topical corticosteroids should be avoided as the potential side effects are frequently observed.

Indications and Other Uses

Atopic dermatitis is currently the main and only licensed indication for topical calcineurin inhibitors in Europe. Numerous studies have shown the safety and efficacy in this indication. Traditional atopic dermatitis therapy follows reactive approach with an on-and-off regimen of anti-inflammatory topical treatment of visible skin lesions.

Tacrolimus 0.03 % ointment is approved for treatment of moderate to severe atopic dermatitis skin lesions in children aged 2–16 years, whereas the 0.1 % ointment is licensed for the same indication in patients older than 16 years. Pimecrolimus 1 % cream is approved for treatment of mild to moderate atopic dermatitis skin lesions in all patients aged 2 years and above. Both are routinely used twice daily on all visible skin lesions as a safe and effective therapeutic option for atopic dermatitis patients. Treatment is particularly useful in delicate skin areas where topical corticosteroid side effects are frequently observed.

The reactive treatment concept has been recently challenged by the proactive approach, which is defined as long-term, low-dose intermittent application of anti-inflammatory therapy to the previously affected skin, together with an ongoing emollient treatment of unaffected skin. The immunobiological basis for this approach is the presence of subclinical inflammation and barrier dysfunction in non-lesional atopic dermatitis skin, which is invisible to the naked eye. Proactive therapy is only performed after an intensive, twice-daily therapy has mostly cleared visible eczema. The current ETFAD position paper and EDF guideline for atopic dermatitis recommend the proactive use of tacrolimus ointment. Tacrolimus ointment, but not pimecrolimus cream, is also approved for the proactive therapy of moderate to severe atopic dermatitis to prevent relapses and extend the periods without recurrences in patients with frequent exacerbations (four or more times a year), who are initially treated with tacrolimus ointment two times a day.

Several other varieties of dermatitis and eczema including contact dermatitis, asteatotic dermatitis, irritant dermatitis, chronic actinic dermatitis, eyelid dermatitis and perianal dermatitis can effectively be treated with topical tacrolimus, whereas all topical calcineurin inhibitors are little effective on palms and soles because of the thickness of the stratum corneum in these regions.

Seborrhoeic dermatitis can effectively be treated by topical tacrolimus and pimecrolimus. Both drugs induce marked improvement of erythema and scaling with excellent tolerability in those regions where topical corticosteroid application could be potentially harmful.

Erosive mucosal lichen planus, anogenital lichen sclerosus et atrophicus and cutaneous graft-versus-host disease are other excellent indications for topical calcineurin inhibitors. Cutaneous lupus erythematosus, vitiligo, rosacea and skin lesions of dermatomyositis may also be treated with good response. In vitiligo, early lesions, children and facial lesions show a better response compared to older lesions, adults and

lesions on the extremities. As a rule, tacrolimus tends to be somewhat more effective in these off-label indications due to its higher efficacy and better penetration characteristics. Topical tacrolimus is also a good treatment option for pyoderma gangrenosum patients who are resistant to or intolerant of standard therapy, as long as the total area treated is small, e.g. less than 100 cm^2. Perioral dermatitis responds well to pimecrolimus cream.

Topical calcineurin inhibitors are worthwhile trying in virtually all inflammatory and autoimmune skin diseases in which systemic cyclosporine is effective. Though chronic plaque psoriasis does not respond well due to penetration problems, topical tacrolimus and pimecrolimus may be useful in facial and inverse psoriasis.

Side Effects

Safety data of topical calcineurin inhibitors have been reported in many clinical trials, demonstrating their safety in daily routine use. The most frequent side effect is a transient warmth and burning sensation at the application site that tends to resolve after a few days. Systemic exposition is low, and the blood levels are usually too low to be measured and significantly below the therapeutical level maintained in organ transplant patients.

A number of patients treated with topical calcineurin inhibitors experience a flush phenomenon following alcohol consumption. It is not dangerous, but may be annoying and can be prevented by 500 mg of aspirin taken 30 min before drinking alcohol.

A theoretical concern of an increased risk for cutaneous or haematologic malignancies is derived from the long-term, high-dose, systemic exposure to oral calcineurin inhibitors in transplantation medicine, where these drugs are given in spite of the known risk. Numerous clinical studies failed to demonstrate an increased risk of infections, malignancy or photocarcinogenicity, but some additional long-term safety studies are still running. It is unlikely that topical application of TCI is connected with significant systemic exposure, and they seem to have an excellent safety profile, even in small children. For safety reasons, patients are still advised to avoid excessive intentional UV exposure during the calcineurin inhibitor use.

Contraindications

Drug hypersensitivity against macrolactams and contact allergy against the components of the topical products are the main and obvious contraindications for all topical calcineurin inhibitors. The similar structure of tacrolimus and pimecrolimus may explain the cross reactivity in the patch test observed in a contact allergic patient. Treatment of patients with genetic epidermal barrier defects such as ichthyosis linearis circumflexa with topical tacrolimus may result in systemic toxicity dependent on the surface area treated, which has not been observed for topical pimecrolimus.

Drug Interactions

Treatment of atopic dermatitis with topical calcineurin inhibitors results in low systemic exposure. Those molecules reaching the systemic compartment are mostly inactivated by the cytochrome p450-3A4 isoenzyme of the liver. Known inhibitors of this enzyme such as erythromycin, itraconazole, ketoconazole, diltiazem or even grapefruit juice do increase the drug level of oral cyclosporine or oral tacrolimus, but the effect on blood levels induced by topical calcineurin inhibitor treatment is less relevant because of the generally low systemic exposure.

Use in Infants, Children and Elderly

From a scientific point of view, many published studies confirm the efficacy and safety of topical treatment with pimecrolimus cream and tacrolimus ointment in infants under the age of

2. From a medicolegal point of view, both preparations are licensed throughout Europe from the age of 2 years and above. This constellation has led to frequent off-label use in infants with atopic dermatitis. There are no restrictions or particular features for treating elderly patients.

Pregnancy and Breastfeeding

Scientifically, there is no evidence that topical calcineurin inhibitor use may have teratogenic effects or may otherwise be harmful during pregnancy. There is long-lasting experience with oral calcineurin inhibitors during pregnancy from transplantation medicine, which does not indicate a teratogenic potential for the entire substance class. The expected systemic exposure from topically applied calcineurin inhibitors is even lower, which would further lower any risk if used during pregnancy. Legally, topical calcineurin inhibitors are not explicitly licensed as safe agents for use during pregnancy. This constellation results in the need for an individual decision for each patient.

There is published data from oral tacrolimus use in transplantation medicine that tacrolimus is excreted in human milk, whereas no data is available for pimecrolimus. There is no harmful effect known for topical calcineurin inhibitors during breastfeeding. The expected systemic exposure from all topically applied calcineurin inhibitors is low, which further limits a potential risk if used during breastfeeding. This constellation results in the need for an individual decision for each patient.

Treatment Regimen and Dosage

For traditional reactive treatment, tacrolimus ointment and pimecrolimus cream are applied twice daily to all visible skin lesions of atopic dermatitis or other skin diseases. Tapering of topical calcineurin inhibitors may be helpful but is not as important as it is for topical corticosteroids.

For proactive treatment, topical tacrolimus is applied once a day twice weekly to all clinically normal but usually affected or frequently relapsing "problem zones" of atopic dermatitis. Visible lesions reappearing during the proactive treatment time must be treated twice daily, as usually done with all visible lesions, until these disappear. The frequency of applications may be adjusted according to the severity of the disease.

Corticosteroids: Topical

140

Alejandro Martin-Gorgojo, Jeanne-Duus Johansen, and Ana M. Giménez-Arnau

Key Points

- Topical corticosteroids (TCS) have a broad treatment spectrum given their multiple actions. Despite their adverse effects, including cutaneous atrophy and the possibility of systemic absorption, they are still the most potent topical anti-inflammatory agents available.
- Though their anti-inflammatory properties are the main reason for their use, other actions such as their lowering the synthesis of macromolecules that form connective tissue, their antimitotic activity, and their symptomatic relief of itching and burning can make them useful in the treatment of multiple skin conditions.
- The choice of topical steroids and their bioavailability must take into account the excipient used. Choosing one formulation or another will depend on the type of disease and on the area of the body and extent to which it will be applied.
- TCS may cause topical or systemic adverse effects, which need to be known and prevented.
- Thoughtful, individualized, and specific regimens should be advised. Combination with emollients, keratolytic agents, or regimens including corticosteroid-saving agents can be helpful.
- Long-term daily treatment of large areas of the skin should be avoided: regardless of the potency, treatment of TCS should not be maintained for more than 2–4 weeks.
- No more than 50 g per week of very potent or potent corticosteroid preparations should be used in the general population, and no more than 300 g of very potent or potent corticosteroid preparations should be administered to women during their entire pregnancy.
- Patients with preexisting renal or hepatic disease should be carefully assessed, since systemic side effects of topical administration seem to be more frequent.

General Principles, Classification, and Structure

Topical treatment with glucocorticoids began 20 years after the discovery of the basic structure of cholesterol, a precursor in the biosynthesis of

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_140, © Springer-Verlag Berlin Heidelberg 2015

all steroids. The application of cortisone directly on the skin showed disappointing therapeutic results, but the fermentation of this molecule resulted in hydrocortisone, a great therapeutic advance at the time of its introduction in 1952.

Over the years, the activity of topical corticosteroids was improved by several molecular changes, including the introduction of a double bond between the first and the second carbon (C-1 and C-2) in the molecule; the formation of esters in C-17 or C-21 position within fatty acids; the introduction of cyclical acetonides in C-16 and C-17 position, which increases the potency; and the process of halogenation (with fluorine—which tends to protect the steroid ring from being metabolized—or chlorine) in the C-9α (alpha) that enhances the effect of the preparations.

Triamcinolone acetonide was the first active halogenated topical steroid to become commercialized with success, in 1960, after showing a specific, anti-inflammatory effect that proved useful in the management of psoriasis. Flurandrenolone and flumethasone became available at the same time. All three are known as *second-generation* steroids.

The *third-generation* group of steroids includes betamethasone valerate and fluocinolone. Free betamethasone is considered as active as hydrocortisone.

The ester formation in C-17 position proved to be important: in 1962, 17-betamethasone valerate was selected from a wide range of topical steroids due to its good results obtained in the vasoconstriction test designed by Mackenzie-Stoughton. Subsequently, several simple esters in the C-17 position of hydrocortisone were developed, leading to the introduction of hydrocortisone 17-butyrate and hydrocortisone 17-valerate, two molecules designed to obtain the same efficacy as the fluorinated second-generation steroids but which minimized the systemic and topical adverse effects secondary to halogenation. The disassociation between the efficacy and adverse effects can be explained by the hydrolysis of the esters, first at skin level and afterwards in the blood. These non-fluorinated topical steroids are known as the *fourth generation.*

In the 1970s and 1980s, more potent, *fifth-generation* corticosteroids appeared: betamethasone dipropionate and clobetasol propionate. Potent compounds that could help to control certain dermatoses rapidly, they also posed a real risk for the development of topical and systemic adverse effects.

The *sixth generation* of steroids includes budesonide, specifically characterized by lateral chains of butyric acid in the C-16 and C-17 positions. This potent, non-fluorinated steroid can be used topically or inhaled. According to the vasoconstriction tests, its potency ranges between the clobetasol 17-propionate and the betamethasone-17, 21-dipropionate. Its effect on the hypothalamic-pituitary-adrenocortical axis is similar to hydrocortisone 17-butyrate.

Other formulations have aimed to minimize adverse effects while preserving the anti-inflammatory effects: mometasone furoate; prednicarbate; C-21-carboxylates such as the fluocortine-butyl-ester; the diesters 17,21-hydrocortisone aceponate, hydrocortisone 17-butyrate-21-propionate, methylprednisolone aceponate, and aclomethasone propionate; and carbothioates such as the fluticasone propionate have now been on the market for several years.

Mechanisms of Action

Glucocorticoids act on different tissues and types of cells and on tissue, cellular, or molecular levels. Some of the actions attributed to corticosteroids are not caused primarily by their pharmacological effect but by the action on a different level. Corticosteroids have specific and nonspecific actions, which can be explained by several direct and indirect mechanisms.

As small hydrophobic molecules, steroids cross the cell membranes by simple diffusion. Once inside the cell, they bind reversibly to the specific cytoplasmatic protein receptor, which is codified by the GR gene, located in chromosome 5. The glucocorticoid receptor may adopt two isoforms, depending on posttranscriptional processing: alpha, responsible for corticosteroid effects, and beta, with a regulatory role. Therefore, a rise in the beta/alpha isoforms ratio has been linked to glucocorticoid resistance.

Receptor-corticosteroid interaction activates a complex consisting of a binding protein for the hormone, two heat-shock proteins, p23 and an immunophilin. The activation causes the cleavage of these last three components and the dimerization and migration of hormone-receptor complexes into the nucleus (through the pores of the nuclear membrane), which bind to a DNA sequence and modulate the genetic transcription. This results both in the upregulation of the expression of certain molecules (interleukin-1 receptor antagonist, Iκβ-α [kappa beta-alpha], secretory leukocyte inhibitory protein, transforming growth factor-β [beta], lipocortin-1, etc.) and the downregulation of others (multiple cytokines, including interleukins 1, 2, 3, 4, 5, 6, 11, 12, and 13, tumor necrosis factor-alpha, and others; chemokines, comprising interleukin-8, C-C motif chemokine-5, and others; inducible nitric oxide synthase, cyclooxygenase 2, endothelin-I, etc.). However, several co-activators, corepressors, and other factors (such as the interaction of steroid-receptor complexes with nuclear factor-κβ [kappa beta], leading to its transrepression) should be taken into account to fully understand this genomic pathway.

Though gene modulation is considered the most important mechanism explaining the glucocorticoid effects, other mechanisms of action have been described, including a non-genomic pathway, in which corticosteroids may bind on membrane receptors linked to second messenger molecules, altering the sensitivity and activation level of target cells (such as T lymphocytes, platelets, or monocytes), with a rapid-onset effect.

These pathways have been observed and reported in the skin, helping to explain the different properties of topical glucocorticoids:

- *Anti-inflammatory effects*. Achieved by the decrease of inflammatory molecules, such as cytokines (multiple interleukins and tumor necrosis factor-alpha), chemokines (interleukin-8, C-C motif chemokine 5, and others), and inducible nitric oxide synthase, as well as the increase of anti-inflammatory molecules (such as lipocortin-1, interleukin-1 receptor antagonist, Iκβ-α [kappa beta-alpha], secretory leukocyte inhibitory protein, etc.), by modulating the transcription of their codifying genes, or by a non-genomic pathway.
- *Vasoconstrictive effects*. Capillary vasodilation is inhibited by glucocorticoids. Although not completely understood, vasoconstriction is considered to be part of the anti-inflammatory effects: the downregulation of the transcription of cytokine-inducible nitric oxide synthase may be involved in achieving this effect, given its indubitable effect on diminishing erythema and edema.
- *Immunosuppressive effects*. In addition to the inhibition of inflammatory molecules, corticosteroids inhibit leukocyte migration to sites of inflammation and interfere with the proliferation, differentiation, and maturation of all the cells that participate in the immune response. Glucocorticoids have been proven to shift the T-helper reaction pattern, favoring a T-helper type 2 response.
- *Antiproliferative effects*. Antimitotic properties of corticosteroids have been explained partially by the inhibition of the transcription and effect of several cytokines.
- *Apoptotic and antiapoptotic effects*. Glucocorticoids have proven to decrease the survival and lead to apoptosis of lymphocytes, mast cells, eosinophils, and monocytes/macrophages but to increase the survival and reduce apoptosis of neutrophils and erythrocytes.
- *Antipruritic effects*. TCS have been proven effective to alleviate pruritus and the signs of eczema, as a recent trial based on patients with induced allergic eczema to nickel sulfate (a model that has been confirmed valid to assess the efficacy and speed of action of TCS) has confirmed.

Pharmacology

The therapeutic (and adverse) effects of TCS vary according to different factors, including the potency of the molecule. The most important tests used to determine it are:

- The vasoconstriction test (or the blanching test) is based on one of the effects of TCS. Its

results correlate with drug potency, although in an unspecific manner.
- Tests to measure the suppression of the mitotic index.
- Tests for skin atrophy.

Skin pharmacokinetics and pharmacodynamics are studied together. The percutaneous absorption of steroids depends on:
- The preparation: its lipophilicity, solubility, and the drug concentration that may be reached after its application
- The patient: the anatomical location and extension on which the drug is applied, the age of the patient, and preexisting skin diseases
- The pattern of application (e.g., the number of applications per day, open or occlusive therapies, etc.)

Comparing different therapeutic studies is difficult, due to different reasons such as the lack of a standardized method to study the effect in clinical trials. Animal and human models have been used to evaluate the activity of TCS. Special methods to assess adverse effects have also been developed. Animal models include studies about the immunological and non-immunological inflammatory process and about the antimitotic and atrophogenic effects. Human models include the vasoconstriction test, non-immunological inflammatory studies (such as the ultraviolet or pyrexial erythema tests), immunological inflammatory examinations (including the ones based on allergic contact dermatitis), and studies concerning side effects (e.g., the skin atrophy induction and steroid-induced acne tests and the quantification of the endogenous suppression of cortisol).

Indications and Other Uses

There are currently numerous corticosteroid preparations, which are classified in four levels of potency (I–IV) according to the standard European classification system, with level I being the strongest. There are, however, other proposed classifications, such as the German and US systems, that may also be found in Table 140.1, along with the available marketed formulations of different topical steroids.

Table 140.1 Potency of the most commonly used topical steroids and their formulations

Very potent (*Class I Europe/IV Germany/I USA*)
Betamethasone dipropionate 0.05 % *gel* (*o.v.*), *ointment* (*o.v.*)
Clobetasol propionate 0.05 % *cream*, *foam*, *gel*, *lotion*, *ointment*, *shampoo*, *spray*
Diflorasone diacetate 0.05 % *ointment* (*o.v.*)
Diflucortolone valerate 0.3 % *cream*, *ointment*
Fluocinonide 0.1 % *cream*
Fluocinolone acetonide 0.2 % *cream*, *ointment*
Halcinonide 0.1 % *cream*, *ointment*, *solution*
Halobetasol propionate 0.05 % *cream*, *ointment*
Potent (*Class II Europe/III Germany/II/III USA*)
Amcinonide 0.1 % *cream*, *ointment*
Beclomethasone dipropionate 0.025 % *ointment*
Betamethasone benzoate 0.025 % *gel*
Betamethasone dipropionate 0.05 % *cream* (*o.v.*), *gel*, *lotion* (*o.v.*), *ointment*
Betamethasone valerate 0.1 and 0.05 % *ointment*
Budesonide 0.25 % *cream*, *lotion*, *ointment*
Desonide 0.05 %[a] *cream*, *foam*, *gel*, *lotion*, *ointment*
Desoxymethasone 0.25 % *cream*, *ointment*
Diflorasone diacetate 0.05 % *cream* (*o.v.*), *ointment*
Fluclorolone acetonide 0.025 % *ointment*, 0.2 % *cream*
Fluocinolone acetonide 0.25 and 0.2 %[a] *cream*, *ointment*
Fluocinonide 0.05 % *cream*, *gel*, *ointment*, *solution*
Fluprednidene acetate 0.1 and 0.05 % *cream*, *ointment*
Flurandrenolone 0.05 %[a] *cream*, *ointment*
Fluticasone propionate 0.05 %[a] *cream*, *lotion*, 0.005 % *ointment*
Halcinonide 0.01 % *cream*, *ointment*, *solution*
Methylprednisolone aceponate 0.1 % *cream*, *emulsion*, *ointment*
Mometasone furoate 0.1 % *ointment*
Prednicarbate 0.25 % *cream*, *ointment*, *solution*
Triamcinolone acetonide 0.5 and 0.1 % *ointment*
Moderately potent (*Class III Europe/II Germany/IV/V USA*)
Alclometasone dipropionate 0.05 %[a] *cream*, *ointment*
Beclomethasone dipropionate 0.025 % *lotion*
Beclomethasone salicylate 0.025 % *cream*, *lotion*
Betamethasone benzoate 0.025 % *cream*, *ointment*
Betamethasone dipropionate 0.05 % *lotion*
Betamethasone valerate 0.1 and 0.05 % *cream*, *foam*, *lotion*, 0.025 % *ointment*
Clobetasone butyrate 0.05 % *cream*, *ointment*
Desoxymethasone 0.05 % *cream*, *ointment*
Fluocinolone acetonide 0.1 %[a] and 0.00625 %[a] *cream*, *ointment*, *solution*

(continued)

Table 140.1 (continued)

Fluocortin butyl 0.75 % *cream*, *ointment*
Flumethasone pivalate 0.2 % *cream*, *ointment*
Flurandrenolone 0.0125 % *cream*, *lotion*
Halometasone 0.05 % *cream*
Hydrocortisone aceponate 0.127 % *cream*, *ointment*
Hydrocortisone butyrate 0.1 % *cream*, *lotion*, *ointment*
Hydrocortisone valerate 0.2 % *cream*, *ointment*
Mometasone furoate 0.1 % *cream*, *lotion*
Prednicarbate 0.1 % *cream*, *ointment*
Triamcinolone acetonide 0.2 % *spray*, 0.1 and 0.04 % *cream*, *ointment*
Mild (*Class IV Europe/I Germany/VI/VII USA*)
Dexamethasone 0.2 and 0.1 % *cream*, *gel*, *lotion*, *ointment*
Fluocinolone acetonide 0.0025 % *cream*, *foam*, *solution*
Fluocortin butyl ester 0.75 % *cream*, *ointment*
Hydrocortisone/hydrocortisone acetate 1.0 and 0.5 % *cream*
Methylprednisolone acetate 0.25 % *cream*, *ointment*
Triamcinolone acetonide 0.025 % *cream*, *lotion*

o.v. optimized vehicle
[a]Considered the next lowest level of potency according to some authors

Table 140.2 Topographical differences in the management of topical corticosteroids

Treated area	Recommended potency
Mucous membranes	Mild or moderately potent
Scrotum/genitalia	Mild (or moderately potent or potent, short periods of time)
Eyelids	
Face	
Inner thighs	
Perianal area	
Skinfolds	Mild (or moderately potent or potent, short periods of time)
Inner arms	
Scalp	
Thorax and back	Potent or very potent
Arms and thighs	Very potent (short periods of time)
Forearms and legs	
Dorsum of hands and feet	
Elbows and knees	Potent or very potent
Palms and soles	
Nails	

Topical steroids must be chosen according to the patient's age and preexisting skin conditions as well as the diagnosis (the acute or chronic character of the disease, its extent, and its location), as detailed in Table 140.2.

Table 140.3 Skin conditions susceptible to topical steroid treatment

Dermatoses requiring very potent topical corticosteroid therapy
Discoid lupus erythematosus
Granuloma annulare
Hand eczema (severe)
Hyperkeratotic eczema
Keloids
Lichen planus
Lichen simplex chronicus
Necrobiosis lipoidica
Palmoplantar psoriasis
Pompholyx
Sarcoidosis
Dermatoses requiring potent topical corticosteroid therapy
Alopecia areata
Atopic dermatitis (resistant)
Contact dermatitis (irritant or allergic)
Lichen sclerosus (skin)
Mastocytosis
Mycosis fungoides (patch stage), parapsoriasis
Nummular eczema
Subacute lupus erythematosus
Dermatoses requiring moderately potent topical corticosteroid therapy
Anal, vulvar, or scrotal pruritus
Atopic dermatitis (ideally in children)
Flexural (inverse) psoriasis
Flexural dermatitis (severe)
Lichen sclerosus (genitalia)
Perianal inflammation (severe)
Pityriasis rosea of Gilbert
Seborrheic dermatitis
Sunburns
Dermatoses requiring mildly potent topical corticosteroid therapy
Flexural, eyelids, or face dermatitis
Perianal inflammation

Though their anti-inflammatory properties are the main reason for the use of corticosteroids, other actions such as the lowering the synthesis of macromolecules that form connective tissue, their antimitotic activity, and their symptomatic relief of itching and burning can make them useful in the treatment of multiple skin conditions (Table 140.3).

The choice of topical steroids and their bioavailability must take into account the excipient

used. Choosing one formulation or another will depend on the type of disease and on the area of the body and extent to which it will be applied:

- Ointments: More occlusive than other bases, enhancing the penetration of the agent, ointments are ideal for patients with dry skin (such as those with atopic dermatitis or those who live in dry and cold areas). However, they have low cosmetic acceptability, resulting in low patient satisfaction and compliance. Ointments should not be used on hairy areas of the skin, because they can occlude the hair shaft. At the same time, they should be avoided on flexural areas, due to the risk of maceration and folliculitis.
- Creams: Cosmetically more acceptable but less potent than ointments, creams are ideal for exudative inflammatory processes, due to their drying effect, and in flexural areas.
- Lotions, solutions, and gels: Indicated on hairy locations, given their capacity to penetrate easily without leaving much residue, or on very exudative lesions, due to their drying effect. Gels are one of the most cosmetically acceptable formulations and are increasingly used in certain indications.
- Foams and shampoos: As another option for the treatment of scalp conditions, these formulations are also cosmetically very acceptable, maximizing the patient's compliance.

Finally, the combination of topical steroids with other active substances can be considered:

- Antibacterial or antifungal agents may be useful in some cases, taking into account the potential colonization of dermatitis with *Staphylococcus aureus* or *Pityrosporum orbiculare*. However, they can pose the risk of sensitization, and long-term treatment with these combinations should be discouraged.
- Salicylic acid may be another helpful association given its antiseptic and keratolytic properties, facilitating the absorption of topical steroids.
- Urea also enhances the absorption of corticosteroids, acting as a keratolytic agent and favoring water retention in the epidermis.
- The combination of betamethasone and calcipotriol has proven to be effective in the treatment of plaque psoriasis.

Side Effects

Corticosteroids are commonly metabolized in the liver. The study of glucocorticoid metabolism, of their epidermal, upper, and lower dermal concentration after topical application on intact skin, as well as the evaluation of the necessary concentrations to inhibit the synthesis of human connective tissue by the skin fibroblasts, suggests that local and systemic adverse effects could be reduced if extrahepatic transformation occurs more quickly. Therefore, the ideal glucocorticoid should be inactivated immediately after its absorption.

Steroid potency is directly related to the adverse effects; their use should be limited, and a clear and explicit treatment regimen should be indicated to the patient. Factors that may increase the risk of side effects include chronic use (especially of potent steroids), larger quantities of preparation, unclear treatment regimens or incorrect understanding of the regimen, excessive application of the preparation on the skin (which, in most of the cases, has no extra therapeutic benefit), treatment of a greater surface, or treatment of certain anatomical areas (raising the risk of systemic absorption).

Local Side Effects

Cutaneous side effects may result from the presence of corticosteroid preparations on the skin and include:

- Tachyphylaxis: Defined as the progressive lowering of the corticosteroid efficacy (or sensitivity) during chronic treatment, requiring the use of more potent topical molecules, and the subsequent increased risk of side effects.
- Skin atrophy, subsequent alterations in cutaneous mechanical properties and elasticity, and impaired wound healing: TCS can cause epidermal, dermal, and subcutaneous atrophy. Dermal atrophy is the first atrophy that can be detected. The atrophy caused by topical application of these drugs is considered reversible. Albeit less frequent than previously thought, this local side effect may be seen more among older and pediatric patients.

- Hypopigmentation: It has been postulated that melanin synthesis can be decreased in smaller melanocytes, adding up to another effect, which is the reduction amount of melanin transferred from melanocytes to keratinocytes.
- Epidermal barrier alteration: This potential effect, expressed by reduced formation of lipid lamellar bodies and an increased transepidermal water loss, seems paradoxically outweighed by aiding barrier repair and reducing inflammation in atopic dermatitis and psoriasis patients.
- Apparent skin aging, ulcerations, purpura, and stellate pseudoscars: Severe dermal atrophy, along with an increased fragility of the vessels resulting from chronic topical corticosteroid abuse, may be associated with lesions resembling actinic damage, purpuric lesions, hypopigmented and depressed stellate pseudoscars, and ulcers.
- Striae: Potentially caused by corticosteroid abuse, they should not be confused with those resulting from weight gain or pregnancy.
- Acne: Acneiform lesions can be precipitated or aggravated after topical steroid therapy. Although corticosteroids may initially diminish inflammatory papules and pustules, these lesions tend to recur and persist, giving the clinical picture of steroid-induced acneiform eruptions.
- Steroid rosacea: This is seen typically among middle-aged women with a history of rosacea-like lesions treated with mildly potent corticosteroids, which progressively lose efficacy and prompt the need of continued use of more potent steroids.
- Corticosteroid addiction: Seen among patients who, trying erroneously to control the flare-ups of several dermatoses, such as perioral dermatitis, rosacea, or acne, perform an inadvertent long-standing use of TCS mainly on the face. Some of these cases may even develop the so-called red burning skin syndrome: this erythroderma seen after steroid withdrawal can be distinguished from chronic eczema by measuring the serum nitric oxide.
- Telangiectasia: Endothelial cells from the dermal vessels may be stimulated after chronic use of corticosteroids, causing dilatation of the vessels, which can be more evident on the face.
- Perioral dermatitis: Seen mainly among female patients with continued use of potent topical steroids on the face, it is defined by the presence of an erythema along with follicular papules and pustules beginning in a perioral distribution, with a characteristic sparing of the vermilion border-adjacent skin.
- Hypertrichosis: Albeit infrequent with topical but relatively common with systemic corticosteroids, growth of villous hair by an unknown mechanism can be seen and may persist for months even after stopping the application of steroids.
- Mucocutaneous infections: Considered common during (and in some cases prior to) treatment with corticosteroids. The occurrence of the typical tinea incognito (unrecognizable cutaneous eruptions resulting from corticosteroid treatment of tinea infections) has been described, as has herpes simplex, molluscum contagiosum, scabies, reactivation of Kaposi's sarcoma, and the characteristic but rare clinical picture of granuloma gluteale infantum (consisting of persistent granulomatous papulonodular lesions on the inguinal folds, buttocks, or thighs of children that have been treated with TCS of their diaper dermatitis).
- Contact dermatitis: Incidence of contact dermatitis from TCS (excluding the excipients) is variable (ranging from 0.2 to 5 %, with 85 % of these patients having multiple steroid allergies) and depends on the molecules that are available and predominantly used in each country. Relapsing or persistent dermatitis on the face, hands, or lower legs, in older-aged patients showing signs of other side effects of chronic glucocorticoid use or with a repeated occupational exposure to TCS (e.g., nurses, pharmacists), with a lack of improvement or a worsening of the dermatitis despite of an apparently adequate corticosteroid treatment regimen, should trigger the suspicion of topical corticosteroid-induced contact allergy. Corticosteroid contact allergy testing has some specific characteristics that should be

taken into account, such as the need of a delayed reading, on the seventh day, to maximize the diagnosis.

Previously classified in five groups (A, B, C, D1, and D2), corticosteroids were reclassified in 2011 by Baeck et al. into three groups, on a clinical and molecular basis:

- Group 1: encompassing the previous group A (e.g., hydrocortisone, cortisone, prednisone, prednisolone, methylprednisolone, tixocortol pivalate), group D2 (e.g., hydrocortisone aceponate, hydrocortisone butyrate, methylprednisolone aceponate, prednicarbate), and budesonide
- Group 2: including the previous B group steroids (e.g., triamcinolone acetonide, fluocinolone acetonide, amcinonide, desonide, fluocinonide, halcinonide)
- Group 3: including the previous groups C (e.g., betamethasone, dexamethasone, desoxymethasone, fluocortolone, halometasone) and D1 (e.g., clobetasol propionate, clobetasone butyrate, beclomethasone dipropionate, betamethasone dipropionate, betamethasone valerate)

This study also confirmed that there are two usual subsets of patients with corticosteroid reactivity: patients reacting to molecules from only one group and patients reacting to the whole spectrum of corticosteroids. The European standard series of patch test allergens currently includes two markers of corticosteroid allergy: budesonide and tixocortol pivalate.

Systemic Side Effects

Normally, only 1 % of the applied topical steroid remains therapeutically active (the rest can be easily removed from the skin). Though small, this proportion of steroids may be absorbed and potentially cause systemic adverse effects, which include the following:

- Hypothalamic-pituitary-adrenal axis suppression: Short-term and early increase of plasma cortisol levels after the application of TCS has been seen. The use of more than 50 g of potent topical steroids per week, particularly in patients with impaired barrier function (such as pediatric atopic dermatitis patients), has been associated with an increased risk of iatrogenic Cushing syndrome and Addison crises.
- Hyperglycemia: Especially in patients with liver disorders, glucocorticoids may lead, through a complex mechanism, to hyperglycemia and insulin resistance.
- Other metabolic disorders: Osteoporosis in the elderly or decreased growth rates in pediatric populations, among other disorders, have been described as rare side effects of topical therapy with steroids.
- Electrolyte and water balance disorders: Due to their mineralocorticoid effect, edema, hypocalcemia, and hypertension can be triggered.
- Cataracts and glaucoma: It is possible, but not frequent, that, following long-standing topical therapy with potent preparations on the face, ophthalmologic disorders may occur.

Contraindications

TCS are contraindicated in the following situations:

- Active bacterial, fungal, or viral skin infections without applying specific antimicrobial treatment.
- Most superinfected dermatoses. However, topical steroids may be used for symptomatic relief in some situations if prescribed adequately. Furthermore, growing evidence does not contraindicate proceeding this way: a recently published study observed that, in hospitalized children with eczema herpeticum, the use of TCS during active infection was not associated with poorer outcomes.
- Long-term treatment of extensive skin areas using corticosteroids as the single topical agent for treatment.
- Past personal history of systemic or contact allergy to a molecule or the excipients of a specific preparation.

Drug Interactions

With adequate treatment regimens, it is highly unlikely that TCS could interact with systemic medications.

TCS have been combined with multiple topical treatments with no incidences. Nevertheless, possible contact allergies need to be considered when prescribing any preparation. Specifically, cross-reactions between different molecules should be taken into account when prescribing alternative preparations to patients presenting with systemic or contact corticosteroid allergy.

Use in Infants/Children and the Elderly

As previously stated, pediatric and elderly patients are more prone to suffer systemic adverse effects to TCS. Consequently, treatment regimens in this populations need to be more conservative, explicit, and clearly limited.

Regarding local adverse effects, there is no reason to sustain any concerns about the risk of cutaneous atrophy in children with atopic dermatitis exposed to appropriate long-term treatment regimens with TCS, as a recent observational study shows (in which 70 exposed versus 22 non-exposed children were evaluated for skin atrophy, finding no significant differences).

Even with reassuring evidence supporting the safety of topical corticosteroid therapy in the general population, corticosteroid phobia is a frequent concern in contact dermatitis patients and especially among the parents of these patients. A new scale has been developed to assess corticophobia in these settings.

The best practice in these population groups is described in the "Treatment and dosage" section.

Pregnancy and Breastfeeding

Growing evidence supports that adequate and limited regimens with TCS in pregnant women can be considered safe. A recent study involving 2,658 pregnant women exposed to topical glucocorticoids showed no associations with orofacial cleft, preterm delivery, fetal death, low Apgar score, or mode of delivery. However, it did show a relationship between low birth weight and the use of more than 300 g of potent or very potent TCS during the entire pregnancy. Therefore, limited use of mild to moderate corticosteroids is advised.

Extensive bibliographic searches have yielded no references concerning TCS and breastfeeding.

Treatment Regimen and Dosage

There is no standard topical corticosteroid regimen, and therefore treatments should be individualized. An appropriate treatment would be a topical corticosteroid with sufficient potency to control the disease but with as few local or systemic side effects as possible, in a formulation and excipient according to the site of the lesion, the patient's age, and past medical history.

It is essential to explain and give explicit instructions to each patient concerning the correct dosage, number of applications, and duration of the treatment.

Treatment Duration

Regardless of the potency, treatment of TCS should not be maintained for more than 2–4 weeks. Regimens exclusively with potent or very potent corticosteroids should never exceed 2 weeks and should be tapered progressively to avoid adverse effects.

Frequency of Applications

- *Acute Phase*
- One or two applications per day are recommended for most of the available preparations. Applying the product more frequently has been related with a higher rate of adverse effects, without providing better therapeutic results. However, if we take into account that the stratum corneum acts as a reservoir for TCS (animal models have proved that very potent TCS such as clobetasol propionate may persist up to 4 days in the stratum corneum, yielding a reservoir effect), every-other-day or twice-a-week regimens can be recommended.

- *Maintenance Regimen* (*If Needed*, *Mainly in Inflammatory Dermatoses*)
- Once the dermatosis is under control with the treatment, weekend application (or the minimal frequency with therapeutic effect) of topical corticosteroid along with weekday application of emollients or steroid-sparing agents (such as the calcineurin inhibitors tacrolimus and pimecrolimus) might be optimal in terms of efficacy, safety, and compliance.

Amount of Preparation Needed

The *fingertip unit* (FTU) was proposed in 1991 as a measure of the amount of cream or ointment necessary to treat a specific anatomic area. It is defined as the amount that can be squeezed with a 5 mm-diameter nozzle tube from the fingertip to the fold of the distal interphalangeal joint (with standard tubes, 1 FTU is equivalent to 0.5 g of cream/ointment). The use of FTU has been promoted worldwide to standardize recommendations and encourage compliance. Recommended FTUs depend on the anatomical site being treated (given that, as previously stated, there are certain areas more sensitive to the effects of TC). Following are the FTU recommendations:

- The face and neck would require 2.5 FTU.
- The anterior or posterior aspect of the trunk, 7 FTU.
- Each arm, 3 FTU.
- The whole hand, 1 FTU.
- Each leg, 6 FTU.
- Each foot, 2 FTU.

Specific FTU recommendations for pediatric populations were published by the same group in 1998.

Other formulations such as foam or gel are increasingly more convenient for the patient in terms of dosage, though no standardized system has been proposed to control the amount of product that needs to be applied.

General Recommendations

Though referred mainly to pediatric, elderly, and pregnant patients, the following recommendations can contribute to maximizing the therapeutic benefit and minimizing the possibilities of adverse effects:

- Thoughtful, individualized, and specific regimens should be advised. For example, alternate-day treatment (which may contribute to reducing tachyphylaxis), occlusive therapy with mildly or moderately potent corticosteroids (which has been associated with a lower risk of hypothalamic-pituitary-adrenocortical axis suppression), combination with emollients (which have been proven to reduce the amount of steroids needed), combination with keratolytic agents (lowering the need for more potent formulations), or regimens including corticosteroid-saving agents can be helpful.
- Treatment with very potent or potent corticosteroids should be done for short periods of time.
- Occlusive application of potent or very potent corticosteroids should be avoided in pediatric patients, whereas it should be used only for short periods of time in the general population.
- Long-term daily treatment of large areas of the skin should also be eluded: regardless of the potency, treatment of TCS should not be maintained for more than 2–4 weeks.
- No more than 50 g per week of very potent or potent corticosteroid preparations in the general population and no more than 300 g of very potent or potent corticosteroid preparations in women during their entire pregnancy should be used.
- Patients with preexisting renal or hepatic disease should be carefully assessed, since systemic side effects of topical administration seem to be more frequent.

TCS have a broad treatment spectrum with multiple effects. Despite their side effects, including cutaneous atrophy and the possibility of systemic absorption, they are still the most potent topical anti-inflammatory agents available.

Glucocorticoids: Systemic

141

Elisa Cinotti and Frédéric Cambazard

Key Points

- Corticosteroids (CSs) still play a major role in dermatology due to their potent anti-inflammatory and immunosuppressive properties.
- They are used as first line in most autoimmune bullous dermatoses, autoimmune connective tissue diseases, neutrophilic dermatoses and vasculitis.
- Adverse effects are mainly due to the alteration of electrolyte and water balance, the inhibition of tissue repair process, the activation of gluconeogenesis, the increase of infection risk, the inhibition of the secretion of ACTH and the risk of growth retardation in children.
- Prednisolone is commonly the oral medication of choice and its daily dose varies from 0.5 to 2 mg/kg/day, depending on the severity of the dermatological condition.
- A gradual tapering of the CSs is necessary for treatments that last longer than 4 weeks (long-term therapy) in order not to precipitate into acute adrenal insufficiency and to avoid a flare of the dermatological condition.

General Principles

Despite numerous therapeutic advances of new biologic agents and immunosuppressive drugs, corticosteroids (CSs) still play a major role in the dermatologist's armamentarium due to their potent anti-inflammatory and immunosuppressive properties.

Cortisone developed as a new compound in 1935. The Nobel Prize for Medicine and Physiology was awarded in 1950 to Edward Calvin Kendall and Tadeus Reichstein, who had independently isolated and synthesised cortisol and the adrenocorticotropic hormone (ACTH), and to Philip Showalter Hench, who had described its dramatic efficacy when injected intravenously in patients with rheumatoid arthritis. The industrial production of cortisone started subsequently.

In dermatology, CSs are widely prescribed in either topical or systemic formulations in various potencies to tailor therapy according to the severity of the underlying condition, anatomic location of application, size of the involved area and patient age. However, CSs are associated with several adverse events (AEs), particularly in cases of high doses and long-term use. The use of these drugs, therefore, requires a deep knowledge of their mechanism of action and their potential complicating factors.

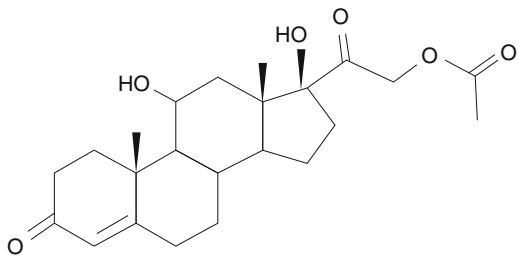

Fig. 141.1 Chemical structure of cortisol

Structure

Glucocorticoids and mineralocorticoids are collectively called CSs. CSs are basic components of the cell membrane, metabolites of the fatty acids and hormones.

The basic structure of all CSs is the cyclopentanoperhydrophenanthrene ring, composed of three hexane rings and one pentane ring (Fig. 141.1). Modifications in this steroid structure result in synthetic agents which have varying anti-inflammatory potency, mineralocorticoid effect and duration of action (related to the biologic half-life) (Table 141.1). Moreover, CSs differ for their metabolism: prednisone and cortisone must undergo conversion by the 11-hydroxylation enzyme in the liver to transform the 11-keto group in 11-beta-hydroxyl group and become activated, whereas biologically active molecules, such as prednisolone and cortisol, have already the essential beta-hydroxyl group at the 11 position. Patients with severe hepatic disease are less able to metabolise CSs, and therefore the administration of already transformed agents (prednisolone or cortisol) is recommended.

Apart from the natural steroids aldosterone, cortisone, deoxycortisone and hydrocortisone, several synthetic steroids have been produced. These analogues try to increase the potency of the drug and to separate the glucocorticoidal effect from the mineralocorticoidal effect. The determination of the potency of glucocorticoids is based on the degree of ACTH inhibition.

Table 141.1 Pharmacology of systemic corticosteroid

Drug	Equivalent dose (mg)	Mineralocorticoid potency
Short acting		
Cortisone	25	1
Hydrocortisone (cortisol)	20	0.8
Intermediate acting		
Prednisone	5	0.25
Prednisolone	5	0.25
Methylprednisolone	4	0
Triamcinolone	4	0
Long acting		
Dexamethasone	0.75	0
Betamethasone	0.6	0

Absorption and Distribution

CSs are absorbed in the jejunum. Concomitant administration with food does not decrease absorption but may delay it. Peak plasma levels are achieved within 30–100 min. Metabolised primarily by the liver, metabolites are excreted by the kidney and liver. Approximately 95 % of endogenous CSs are bound either to cortisol-binding protein (CBP), also known as transcortin, or to albumin in the circulation. The other 5 % free fraction is the steroid that is biologically active, and it is that fraction that enters cells and mediates CSs effects. Many factors influence circulating quantities of CBP. Hepatic failure, renal failure and hypothyroidism decrease CBP levels and, therefore, increase drug toxicity. Synthetic glucocorticoids have less avidity for CBP (estimated at 70 %) and, thus, have a tendency to cause side effects at low doses.

Duration of Action

The plasma half-lives of various glucocorticoids range from 1 to 5 h, but the duration of biologic effect is best assessed by the period of suppression of ACTH secretion after the administration of a single dose of the particular glucocorticoid. Short-acting glucocorticoids have an effect for

8–12 h, intermediate-acting agents for 24–36 h, and long-acting agents for 36–54 h.

Mechanism of Action

The greatest amount of cortisol is released during the early morning hours prior to waking. The basal rate of cortisol (hydrocortisone) production is 20–30 mg daily. The production may increase tenfold in stressful situations.

Cortisol enters the cellular cytoplasm by passive diffusion through the cell membrane and binds to the intracytoplasmic soluble CS receptor. This hormone–receptor complex then translocates to the nucleus either to enhance or to inhibit the expression of target genes by two independent pathways. In the first pathway, it binds to the steroid-responsive genes to induce transcription of annexin I (lipocortin-1) and mitogen-activated protein kinase (MAPK) phosphatase, limiting the formation of prostaglandins and leukotrienes. In the second one, the hormone–receptor complex binds to activator protein 1 (AP1) and nuclear factor kappa-light-chain-enhancer of activated B cells (NF-κB), two important transcription factors that play a significant role in chronic inflammation, thus inhibiting them. The end result is inactivation of cytokines, interleukins (ILs), adhesion molecules and growth factors. Glucocorticoids inhibit the production of IL-1β, IL-2, IL-3, IL-4, IL-5, IL-6, IL-8, IL-10, IL-12, gamma-interferon, tumour necrosis factor-α and the granulocyte-macrophage colony-stimulating growth factor. As a result of the intracellular effects on transcription factor activity and cytokine production, glucocorticoid administration alters the distribution and activity of each inflammatory cell. CSs affect the growth, differentiation and function of monocytes and lymphocytes, the distribution of cellular subsets and the production of cytokines. They decrease the number of circulating monocytes, eosinophils and lymphocytes and they increase the circulating pool of neutrophils by accelerating their release from the bone marrow. Moreover, they decrease some functions of macrophages such as phagocytosis and antigen presentation.

Dermatological Indications

CSs are used to treat a vast group of dermatological conditions (Table 141.2).

Table 141.2 Major indications for systemic corticosteroids in dermatology

Autoimmune bullous dermatoses
Pemphigus vulgaris (all forms)
Bullous pemphigoid
Cicatricial pemphigoid
Linear IgA bullous dermatosis
Epidermolysis bullosa acquisita
Herpes gestationis
Autoimmune connective tissue diseases
Dermatomyositis
Systemic lupus erythematosus
Mixed connective tissue disease
Eosinophilic fasciitis
Relapsing polychondritis
Neutrophilic dermatoses
Pyoderma gangrenosum
Acute febrile neutrophilic dermatoses (Sweet syndrome)
Behçet disease
Vasculitis
Cutaneous and systemic
Miscellaneous dermatoses
Sarcoidosis
Urticaria/angioedema – acute
Type I reactive leprosy
Haemangioma of infancy (in case of beta-blocker failure)
Panniculitis
Linear scleroderma
Short-term treatment for severe eczematous dermatoses
Photodermatitis
Erythrodermas
Controversial use
Erythema multiforme
Toxic epidermal necrolysis
Alopecia areata
Contact dermatitis
Atopic dermatitis
Lichen planus

Contraindications

Absolute contraindications to systemic CSs are systemic fungal infections, herpes simplex keratitis and hypersensitivity. Relative contraindications include tuberculosis, peptic ulcer disease, hypertension, congestive cardiac failure, depression or psychosis, diabetes mellitus, chronic renal failure, osteoporosis, infectious disease, cataracts and glaucoma.

Delivery

Systemic CSs can be administered orally, intravenously and intramuscularly. Oral forms are usually to be preferred.

Intravenous (IV) Therapy

IV CSs are given in two situations: in severe or life-threatening diseases to rapidly gain control and for stress coverage in patients on long-term CSs and with hypothalamic–pituitary–adrenal (HPA)-axis suppression.

Methylprednisolone, devoid of mineralocorticoid activity, is usually preferred. Two methods of administration are available: it can be given either at a total daily dose of 2 mg/kg in divided doses every 6–8 h or as pulse therapy of 500–1,000 mg daily for 1–5 days. Pulse therapy should be given in a monitored setting due to potential serious AEs (i.e. sudden death, atrial fibrillation, anaphylaxis and electrolyte imbalances). Slow administration of pulse steroids over 2 h, along with concomitant infusion of potassium and electrolytes controls before and after therapy, helps prevent these problems.

Intramuscular (IM) Therapy

IM CS therapy is not widely used in dermatology. One advantage is assured compliance since the physician administers the dose. However, there are disadvantages, including the interpersonal variability in absorption and possible lipoatrophy and sterile abscess formation at the injection site.

Choosing and Dosing the Glucocorticoids

Glucocorticoids differ in their relative anti-inflammatory and mineralocorticoid effects and duration of ACTH suppression. CSs with minimal mineralocorticoid effects and an intermediate half-life are usually selected to decrease sodium retention and reduce AEs.

Prednisolone is commonly the oral medication of choice because it has a sufficiently prolonged action (intermediate-acting CSs) to ensure the sustained effectiveness of a single daily dose, has minimal mineralocorticoid activity and is biologically active (differently from prednisone that needs to be transformed into its active form in the liver).

Cortisone and hydrocortisone have a significant mineralocorticoid effect, while prednisone and prednisolone have fewer mineralocorticoids properties. Methylprednisolone, triamcinolone, betamethasone and dexamethasone have negligible mineralocorticoid activity.

The daily dose of prednisone varies depending on the severity of the dermatological condition and ranges from 0.5 to 2 mg/kg/day. When initiating therapy, a single daily dose is preferable, given in the morning when there is maximal adrenocortical cortisol secretion. At this time, the HPA axis is least suppressed by medication since maximal feedback suppression of ACTH secretion occurs from endogenous production. To gain rapid control in severe disease, the dose can be divided and administered from two times per day (avoiding the evening) to maintain a steady plasma concentration. This increases medication efficacy but also increases HPA-axis suppression. Therefore, conversion to a single daily dose should occur as soon as possible. It should be noted that corticosteroids should be taken immediately after the meal to avoid excessive stomach damage.

The dose of systemic corticosteroids should be adapted according to the age of the patient: it should be doubled in newborns and halved in elderly

subjects. For example, a dose of 1 mg/kg/day prednisolone in adults matches to 2 mg/kg/day for a newborn and to 0.5 mg/kg/day for an elderly person.

Use of CSs can be divided into short-term (≤3 weeks) and long-term (≥4 weeks) therapy. The first one is normally reserved for acute conditions (i.e. extensive allergic contact dermatitis), whereas the long-term therapy is necessary in the majority of the other conditions. Corticosteroid-sparing agents are usually added to the regimen, in an attempt to reduce the CSs dose.

Tapering

Tapering of the CSs is necessary for treatments that last longer than 4 weeks (long-term therapy). The reduction of systemic treatment has to be gradual in order not to precipitate into acute adrenal insufficiency and to avoid a flare of the dermatological condition. Tapering should be done in decrements of 10–20 % every 1–2 weeks, taking into account the underlying disease and individual response. Tapering can be faster at the beginning and then must be slowed down with lower doses of corticosteroids. There is a lack of clinical evidence to favour a particular regimen, and various tapering durations have been studied. A peculiar method of CSs dosage tapering is to convert from daily to alternate-day therapy once prednisone dose is 15–20 mg/day. In this regimen, patients are not exposed to high daily glucocorticoid concentrations and, therefore, have less HPA-axis suppression. Conversion from a daily to an alternate-day regimen should be carried out gradually, for example, progressively diminishing the dose on 1 day while building it up the next.

Drug Interactions

Most drug interactions are due to dexamethasone and methylprednisolone, whereas prednisone and prednisolone have fewer interactions.

Inducers of the cytochrome P450 (CYP) hepatic microsomal enzyme system (CYP 3A4), such as rifampin and anticonvulsants (phenytoin and phenobarbital), may decrease serum levels of CSs. Conversely, macrolide antibiotics and azole antifungals may increase serum levels of CSs via cytochrome CYP 3A4 inhibition.

Other effects are due to the rise of intrinsic AEs rather than to true interactions. Coadministration of nonsteroidal anti-inflammatory drugs (NSAIDs) increases gastrointestinal toxicity, additive immunosuppressant drugs enhance immunosuppression, and concomitant diuretics worsen hypokalaemia. Moreover, CSs decrease effectiveness of antidiabetic agents due to induced hyperglycaemia and reduce the serum levels of salicylates so that anticoagulants, such as dicumarol, need to be increased.

Adverse Effects

CS therapy is associated with numerous AEs (Table 141.3). AEs are mainly due to the alteration of electrolyte and water balance, the inhibition of

Table 141.3 Adverse effects of systemic glucocorticoid treatment

Skeletal	Osteoporosis
Gastrointestinal	Peptic ulcer
	Intestinal perforation
Ocular	Glaucoma

	Folliculitis
	Hirsutism
Hypersensitive reactions	Anaphylaxis
	Urticaria

tissue repair process, the activation of gluconeogenesis, the increase of the risk of infection and the inhibition of the secretion of ACTH.

Short-term therapy is usually well tolerated and has fewer AEs. AEs are typically dose related. However, even low doses for prolonged periods are associated with significant AEs. Clinicians need to thoroughly monitor their patients. Low-fat, low-calorie and low-sodium diets but rich in proteins, potassium and calcium are recommended. Blood pressure should be monitored and an ophthalmologic control should be performed in case of decreased visual acuity. Osteoporosis should be prevented giving calcium and vitamin D supplements (500 mg of calcium and 400 units of vitamin D twice a day for men and for premenopausal women and up to 1,500 mg of calcium and 1,200 units of vitamin D for postmenopausal women). Gastric toxicity should be prevented with the association of proton-pump inhibitors. Moreover, tuberculosis should be excluded before establishing a long-term therapy.

In children there is a risk of growth retardation that requires height and weight chart monitoring. Moreover, parents should be informed of the increased risk of infections, especially chickenpox, and contraindication of live attenuated vaccines (Bacillus Calmette–Guérin; polyomavirus; chickenpox; MMR vaccine against measles, mumps and rubella; etc.).

Pregnancy

In general, CSs do not have teratogenic AEs on the fetus. However, delay of fetal growth and persistent ductus arteriosus have been reported. In animals adverse effects on the growth and development of immature brain and the development of cleft lip and palate have been observed, though these findings are controversial in humans. All exogenous glucocorticosteroids cross the placental barrier but each in a different degree. Prednisolone and methylprednisolone appear to cross the placenta only to a small extent in comparison with prednisone, betamethasone and dexamethasone and should therefore be preferred in pregnancy.

Conclusion

CSs remain useful molecules for the treatment of several dermatological conditions. They often provide rapid and effective response; however, in an era of steroid phobia, dermatologists should be aware of all significant AEs and monitor patients to prevent any serious complication.

Hormonal Treatment for Skin Androgen-Related Disorders

142

Francesco Lotti and Mario Maggi

Abbreviations

17β-HSD	17β-Hydroxysteroid dehydrogenase
3β-HSD	3β-Hydroxysteroid dehydrogenase
AGA	Androgenetic alopecia
DHEAS	Dehydroepiandrosterone sulfate
DHT	Dihydrotestosterone
DHT	Dihydrotestosterone
FPHL	Female pattern hair loss
MPHL	Male pattern hair loss
OC	Oral contraceptives
PCOS	Polycystic ovarian syndrome
PSA	Prostate-specific antigen
SHBG	Sex hormone-binding globulin

Key Points

- Exposure of the pilosebaceous unit to androgen excess may lead to (1) vellus to terminal/sexual hair transformation in androgen-dependent areas of the female body and hair male-like pattern in females (hirsutism); (2) reversion of terminal hair to villous-like hair (miniaturization), leading to balding scalp (androgenetic alopecia); (3) formation of sebaceous glands with excessive sebum production and, acting in combination with other causative factors, development of inflammatory skin lesions (acne).
- The most common cause of hirsutism and acne in females is polycystic ovarian syndrome.
- Androgenetic alopecia is a common cause of hair loss in both men and women. Its exact pathogenesis is not well understood. As the name implies, the role of androgens and genetic susceptibility predisposes to pattern hair loss due to gradual conversion of terminal hair into vellus hair. Male and female pattern hair loss (MPHL and FPHL, respectively) are clinically distinct entities but histologically indistinguishable.
- Skin androgen-related disorders may depend on excess of androgen: (1) production, (2) peripheral conversion, and (3) local action, alone or combined. For this reason, skin androgen-related disorders may present with high or normal androgen levels; conversely, high androgen levels may not present with skin manifestations.
- The main androgens involved in skin androgen-related disorders are testosterone and its more active metabolite,

dihydrotestosterone (DHT), formed by conversion in the pilosebaceous unit by the enzyme 5α-reductase.

- Hormonal treatments are effective in reducing the clinical expression of skin androgen-related disorders and should be started when androgen excess etiological investigations lead to a diagnosis and exclude specific causes which should benefit from other specific therapy/management.
- Hormonal therapy of hirsutism and acne is mainly based on the use of oral contraceptives (OC) and associated antiandrogens. Hormonal therapy of androgenetic alopecia mainly relies on the use of antiandrogens.
- The main difference between different OC is determined by the progestin, according to its chemical derivation and biological activity. Besides progestinic effect, different progestins may exert also antigonadotropic, antiestrogenic, antiandrogenic, or antimineralcorticoid effects or, conversely, estrogenic or androgenic effects. OC-containing progestins with antiandrogenic activity should be preferred in treating skin androgen-related disorders.
- Antiandrogens commonly used for hormonal treatment of hirsutism are competitive antagonists of the androgen receptor (spironolactone, cyproterone acetate, flutamide) or inhibitors of 5α-reductase, which decrease the conversion of testosterone to the more potent androgen DHT (finasteride).
- Spironolactone and cyproterone acetate are the most commonly used oral antiandrogens in the treatment of FPHL. Finasteride is the most commonly used oral antiandrogen in the treatment of MPHL.
- Indications and adverse effects of both OC and antiandrogens should be well known and explained to the patient.

General Principles

It is well known that the pilosebaceous unit is an elective androgen target tissue. In some areas of the skin, pilosebaceous units respond to androgens by forming sexual hair follicles, whereas in other areas they respond by forming sebaceous glands. Excessive androgen levels as well as their excessive local action on pilosebaceous units in different areas of the body may lead to different skin androgen-related disorders: hirsutism, acne, and androgenetic alopecia.

Pilosebaceous units form during fetal development, usually between 9 and 12 weeks gestation, and start producing hair by 16–20 weeks. No new hair follicles form after birth, and a decline in the number of hair follicles begins after age 40. Structurally, there are three types of hair. The first is lanugo hair, which is a soft, fine, lightly pigmented hair that covers the skin of the fetus and is shed between the first and fourth months postpartum. The second type, vellus hair, is also soft, but less fine than lanugo hair and is usually short and nonpigmented. The third type, terminal hair, is coarse, longer, and pigmented. It is the hair that comprises the scalp, eyebrows and eyelashes, and pubic and axillary areas of both sexes, and the majority of body and facial hair of men.

The growth of sexual hair is entirely dependent on the presence of androgen. Before puberty, hair is vellus (small, straight, and fair), and the sebaceous glands in androgen-sensitive follicles are small. In response to the increased levels of androgens at puberty, vellus follicles in specific areas develop into terminal hairs (larger, curlier, and darker, hence more visible), becoming sexual hair follicles; higher androgen levels are required for the growth of beard than for the growth of pubic and axillary hair. In other areas (e.g., the forehead and cheeks), the increased androgen levels dramatically increase the size of the sebaceous glands, but the hair remains vellus; the reason for this differential response is unclear.

Androgens play a major role in determining the type and distribution of hairs. Within the hair follicle, testosterone, under the influence of the enzyme 5α-reductase, gets converted to its more active metabolite, dihydrotestosterone (DHT). In

the pilosebaceous unit, 5α-reductase is expressed in two isoforms: type I, mainly located in the dermal papilla, outer root sheath, and sebaceous gland, and type II, mainly localized in the dermal papilla and inner root sheath. DHT, acting directly on dermal papilla cells and indirectly on hair epithelial cells, melanocytes, and keratinocytes, converts vellus to terminal hair. However, in some subjects, under the influence of androgens, terminal hair may gradually revert to villous-like hair, leading to balding scalp. Finally, pilosebaceous units may also respond to androgens by forming sebaceous glands. An excess of androgen action on these sites may contribute, promoting sebum production and acting together with other factors, to the onset of acne.

Among skin androgen-related disorders, the most frequent is hirsutism, followed by acne and androgenetic alopecia.

Hirsutism

Definition and Epidemiology

Hirsutism is defined as excessive terminal hair that appears in a male pattern (i.e., sexual hair) in women. About 5 % of women of reproductive age in the general population are hirsute. Racial and ethnic differences in the appearance of hirsutism are well known to exist. Especially among young women, hirsutism negatively influences psychological well-being, and this is mainly related and modulated by cultural aspects.

Basic Concepts of Pathogenesis

Hirsutism results from an interaction between the androgen level and the sensitivity of the hair follicle to androgen. Most women with androgen levels that are twice the upper limit of the normal range or higher have some degree of hirsutism. However, the severity of hirsutism does not correlate well with the level of androgen, because the response of the androgen-dependent follicle to androgen excess varies considerably within and among persons. Some women with androgen excess have no skin manifestations, or they may have seborrhea, acne, or alopecia without hirsutism. In other women, hirsutism develops without the presence of androgen excess (idiopathic hirsutism).

Testosterone is the key circulating androgen involved in hirsutism. It arises as a product of ovarian and adrenal function, either by secretion or by the metabolism of secreted precursors (mainly androstenedione or dehydroepiandrosterone sulfate, DHEAS) in peripheral tissues, such as fat. Free testosterone seems to be the main bioactive portion of plasma testosterone. The level of free testosterone is often elevated when the total testosterone level is normal in hirsute women, reflecting the relatively low levels of sex hormone-binding globulin (SHBG) in such women, which determines the fraction of plasma testosterone that is free. The SHBG levels are suppressed by hyperinsulinemia/insulin resistance and by androgen excess itself so that the total testosterone level may be normal despite androgen excess.

Variety of disorders give rises to androgen excess. In reproductive-age women, they can be classified in ovarian, adrenal, pregnancy-related, and other causes. Ovarian causes include polycystic ovarian syndrome (PCOS), hyperthecosis (a severe PCOS variant), and ovarian tumors (i.e., Sertoli–Leydig cell tumors). Adrenal causes include nonclassic adrenal hyperplasia, Cushing's syndrome, glucocorticoid resistance, and adrenal tumors. Specific conditions of pregnancy include luteoma of pregnancy, hyperreactio luteinalis, and aromatase deficiency in fetus. Other causes are hyperprolactinemia, hypothyroidism, acromegaly, idiopathic hirsutism (normal serum testosterone in an ovulary woman), and idiopathic hyperandrogenism (patients who do not fall into any of the categories listed above). In addition, several medications can induce hirsutism. In most hyperandrogenic disorders, androgen originates from more than one source. For example, testosterone secretion is increased from the ovary in PCOS, but the bulk of testosterone comes from the extraovarian conversion of significantly elevated circulating androstenedione of ovarian origin to testosterone.

The most common identifiable cause of androgen excess is PCOS. PCOS is the most common form of chronic anovulation associated with androgen excess, occurring in 5–10 % of reproductive-age women. The diagnosis of PCOS is made by excluding other medical conditions that cause irregular menstrual cycles and androgen excess and the presence of at least two of the following criteria: oligoovulation or anovulation (usually manifested as oligomenorrhea or amenorrhea), elevated levels of circulating androgens (hyperandrogenemia) or clinical manifestations of androgen excess (hyperandrogenism), and polycystic ovaries as defined by ultrasonography. Physiopathology of PCOS is complex, and the syndrome may be associated to several glicometabolic disorders.

Acne

Definition and Epidemiology

Acne vulgaris (acne) is a chronic inflammatory dermatosis that requires chronic treatment. Acne may present as a spectrum of lesions, including non-inflammatory open and closed comedones (blackheads and whiteheads, respectively) and inflammatory papules, pustules, nodules, and cysts. Lesions may be present on the face, neck, chest, or back—areas with the greatest density of pilosebaceous units.

Although often perceived as a self-limited disease of adolescence, acne's prevalence remains high into adulthood. Nearly 90 % of teenagers have acne, and half of them continue to experience symptoms as adults. By age 40 years, 1 % of men and 5 % of women still have lesions. Recent analyses show an increasing prevalence of acne in children, perhaps because of pubertal onset. Acne has clear detrimental psychosocial effects and may lead to permanent scarring.

Basic Concepts of Pathogenesis

Acne is an inflammatory disease of the pilosebaceous duct that results from four primary pathophysiologic processes: (1) abnormal keratinocyte proliferation and desquamation that leads to ductal obstruction; (2) androgen-driven increase in sebum production; (3) proliferation of *Propionibacterium acnes*; and (4) inflammation. Increased androgen production causes abnormal epithelial desquamation and follicular obstruction, which lead to the primary precursor lesion in acne—the microcomedone. Microcomedones are pathological structures not visible to the naked eye that evolve into visible lesions. An increase in circulating androgens also promotes sebum production, causing these obstructed follicles to fill with lipid-rich material and form visible open and closed comedones. Sebum serves as a substrate for bacterial growth, leading to proliferation of *P. acnes*. Finally, *P. acnes* releases chemical mediators that promote inflammation, which is propagated by traumatic rupture of comedones into the surrounding dermis. This inflammation manifests through the development of inflammatory papules, pustules, nodules, and cysts. The successful management of acne requires an understanding of these four facets of the pathophysiology of acne.

The exact mechanisms by which androgens affect sebaceous glands are unknown. There is evidence that both circulating and locally produced androgens play a role. Several, but not all, studies have reported a positive correlation between acne severity and circulating serum androgen levels. However, androgens produced and secreted locally within the sebaceous gland play a major role in acne formation. Type 1 5α-reductase isoenzyme predominately appears in sebaceous glands. Evidence has shown that there are regional differences in type 1 5α-reductase activity. The face, for example, is an area prone to acne because of increased type 1 5α-reductase enzyme activity within sebaceous glands compared to other areas of the skin.

Other enzymes have also been reported to mediate androgen activity within the skin. These include 3β-hydroxysteroid dehydrogenase (3β-HSD) and 17β-hydroxysteroid dehydrogenase (17β-HSD), both of which are part of the steroidogenic pathway that regulates conversion of

testosterone precursors. Within the sebaceous glands, the enzyme 3β-HSD converts DHEAS, the major circulating adrenal androgen precursor, to androstenedione. Subsequently, 17β-HSD controls the reversible conversion of androstenedione into testosterone. The enzyme 17β-HSD has been demonstrated in the pilosebaceous unit and epidermal keratinocytes. Greater 17β-HSD activity has been noted in sebaceous glands from the face as compared to acne nonprone areas.

Androgenetic Alopecia/Male and Female Hair Loss

Definition and Epidemiology

Androgenetic alopecia is a common cause of hair loss in both men and women. Its exact pathogenesis is not well understood. As the name implies, the role of androgens and genetic susceptibility predisposes to pattern hair loss due to gradual conversion of terminal hair into vellus hair. Male and female pattern hair loss are clinically distinct entities but histologically indistinguishable. The role of sex hormones in females is less understood.

Male pattern hair loss (*MPHL*) or *androgenetic alopecia* (*AGA*) is the most common cause of hair loss in men. The incidence of pattern hair loss in men varies from population to population based on genetic background. Hair is an important feature of self-image. Men who suffer from MPHL are 75 % less confident, especially when interacting with the opposite sex, and report loss of self-esteem and introversion. Men who seek medical help and are successfully treated reported psychological benefits with improvements in self-esteem and personal attractiveness.

MPHL occurs in the presence of androgens in genetically susceptible individuals. The disease onset and progression vary from person to person. Initial signs of MPHL usually develop during teenage years, leading to progressive hair loss with pattern distribution. Bitemporal hair loss starts at the anterior hair line, resulting in a receding hair line followed by hair loss over the vertex and midfrontal areas, with sparing of the occipital scalp.

Female pattern hair loss (*FPHL*) is the most common cause of alopecia in women. It affects 6–12 % of women between the ages of 20 and 30 years and more than 55 % of women older than 70 years. FPHL clinically presents with diffuse nonscarring loss of hair, with prominent thinning over the frontal, central, and parietal scalp. The frontal hairline is characteristically retained. A similar pattern of hair loss with follicular miniaturization is seen in male androgenetic alopecia (AGA). Because the role of androgens on alopecia in women remains uncertain, FPHL has emerged as the preferred term rather than AGA in women.

Basic Concepts of Pathogenesis

Male Pattern Hair Loss (MPHL)

Locally and systemically derived testosterone either directly binds to the intracellular androgen receptors mainly expressed within the dermal papilla and the hair bulb or is metabolized by the 5α-reductase into the more potent DHT which, in turn, binds to androgen receptors with an approximately fivefold greater affinity. It is thought DHT to be the key androgen required for the induction of MPHL. Changes in several factors along the androgen-signaling pathway possibly lead to hair follicle miniaturization, including an increase in the expression of androgen receptors, increased androgen sensitivity to bind more steroid ligand, and higher levels of 5α-reductase. The scalp has a combination of androgen-sensitive and androgen-independent hair follicles. Androgen-sensitive hair follicles are located on the frontal scalp and vertex, whereas androgen-independent hair follicles are present on the sides and back of the scalp. This distribution of androgen receptors explains the clinical presentation of pattern hair loss. The dermis of the frontoparietal scalp is derived from the neural crest, whereas the dermis of the occipital and temporal scalp is derived from the mesoderm. This difference in embryonic origin may explain the differential influence of androgens.

Table 142.1 Dosage of systemic hormonal medications commonly used for treatment of skin androgen-related disorders. Suggested duration of treatment is at least 6 months

Hormonal medication	Hirsutism	Acne	FPHL	MPHL
Oral contraceptives (OC)	OC with antiandrogenic progestins are preferred	OC with antiandrogenic progestins are preferred	OC with antiandrogenic progestins are preferred	–
Cyproterone acetate (CPA)[a,b]	50–100 mg/day	50–100 mg/day	50 mg/day	–
Spironolactone[a]	50–200 mg/day	100 mg/day	50–200 mg/day	–
Flutamide[a]	125–500 mg/day	250–500 mg/day	62.5–250 mg/day	–
Finasteride[a]	2.5–5 mg/day	2.5–5 mg/day	1.25–5 mg/day	1 mg/day
Dutasteride[a]	–	–	0.25–0.5 mg/day	0.5 mg/day

FPHL female pattern hair loss, *MPHL* male pattern hair loss
[a]Antiandrogens must be used with OC in premenopausal women
[b]In premenopausal women, CPA should be used on days 1–10 of menstrual cycle with an OC. Note that OC with CPA 2 mg are available

Female Pattern Hair Loss (FPHL)

Androgens and estrogens are the main hormonal regulators implicated in FPHL. The hair follicle is sensitive to alterations in circulating estrogen and androgen levels; these hormones are also synthesized and metabolized locally. The role of androgens in FPHL has not been clearly established, and it does not seem to be as essential as in AGA. Pattern hair loss has been described in cases with complete androgen insensitivity syndromes, suggesting that mechanisms other than androgens may be involved. Although FPHL can be associated with hyperandrogenic states, the circulating testosterone levels do not differ between patients with FPHL and normal controls. Many women with FPHL have low levels of circulating SHBG, which may increase the available free testosterone at the level of the hair follicle. Although it has been postulated that there is an increased peripheral sensitivity to androgens in FPHL, the response to treatment with 5α-reductase inhibitors is unpredictable.

The observed differences between androgen regulation in FPHL and male AGA may lie in the presence of estrogens. Estrogen signaling can modify androgen metabolism at the hair follicle, by unclear mechanisms. Estrogens may positively affect hair loss through inhibition of 5α-reductase. High systemic estrogen levels in pregnancy are implicated in the prolongation of anagen. The sudden loss of estrogen postpartum is believed to lead to shedding, known as telogen gravidarum. Conversely, lower systemic estrogen levels have been implicated in the increase of FPHL after menopause.

Hormonal Therapy: Indications and Other Uses

Hormonal therapy of hirsutism and acne is mainly based on the use of oral contraceptives and associated antiandrogens. FPHL and MPHL hormonal therapy mainly relies on the use of antiandrogens. Dosage of systemic hormonal medications commonly used for the treatment of skin androgen-related disorders is reported in Table 142.1.

Hormonal Therapy of Hirsutism

Since the cycle of the hair lasts about 3–6 months, patient should be advised that results should be observed at least 3–6 months after androgen suppression. The Ferriman–Gallwey score may be used by the clinician to objective the variation of patient's hair distribution. A score >8 indicates mild hirsutism, while a score >15 a moderate–severe form.

Oral Contraceptives (OC)

Estrogen–progestin combination therapy, mainly exerted by oral contraceptives (OC), is the

predominant treatment for hirsutism and acne in PCOS. The estrogenic component of the oral contraceptive suppresses luteinizing hormone and thus ovarian androgen production. Estrogen also enhances hepatic production of SHBG, thereby reducing the free fraction of plasma testosterone available to occupy the androgen receptor.

The main difference between different OC is determined by the progestin, according to its chemical derivation (Sitruk-Ware 2004) and biological activities (Schindler et al. 2003) (Table 142.2). Different progestins may exert, besides progestinic effect, also antigonadotropic, antiestrogenic, antiandrogenic, or antimineralcorticoid effect or, conversely, estrogenic or androgenic effect. In particular, different androgenic effects have to be known to optimize hirsutism and acne hormonal treatment. 19-Nortestosterone derivatives exert androgenic effect. Norgestimate and desogestrel are virtually nonandrogenic progestins. Cyproterone acetate exerts the maximum antiandrogenic activity. Chlormadinone acetate and dienogest exert antiandrogenic activity, as well as drospirenone, an analogue of spironolactone, which shows also antimineralocorticoid activity. Antimineralocorticoid activity is exerted also by gestodene, which however shows androgenic effect. Etonogestrel (Nuvaring) and norelgestromin (Evra patch) have androgenic activity.

The decrease in circulating free androgens results in an improvement in the hirsutism. Even if large long-term placebo-controlled RCTs assessing the actual efficacy of OC for hirsutism are lacking, subjective improvement in hirsutism with OC ranges from 60 to 100 %. Such an improvement may decrease hirsutism scores to within the normal range in women presenting with mild hirsutism, supporting the use of an OC as the single drug in these cases.

Among the different formulations, low-dose OC containing a neutral (low androgenicity) progestin, such as desogestrel or gestodene, or an antiandrogen, such as cyproterone acetate, chlormadinone acetate, or the spironolactone-derivative drospirenone, are the choice for the treatment of hirsutism because all of these drugs provide adequate normalization of testosterone levels. If the clinical response to OC containing a neutral progestin is unsatisfactory, changing the OC formulation to include an antiandrogenic progestin may be useful.

Of note, these low-dose third-generation OC formulations are not associated with the unfavorable metabolic profile of older formulations. However, a mild increase in blood pressure might occur with some of these newer OC formulations. Especially among smokers, the third-generation OC may have deleterious effects on coagulation and may increase the risk of nonfatal venous thromboembolism compared with second-generation OC containing the androgenic progestin levonorgestrel. Aside from the amelioration of hirsutism, OC provide the effective contraception recommended for the concomitant use of antiandrogens and are quite useful for the regularization of menstrual bleeding in women with PCOS, which will also reduce the risk of endometrial hyperplasia. Based on these considerations, a low-dose neutral or antiandrogenic OCP as first-line therapy for hirsutism can be useful as a single drug in women with mild hirsutism, as an adjuvant to antiandrogen administration in women with moderate or severe hirsutism and to provide adequate contraception to these patients, to guarantee regular menstrual bleeding in hirsute patients with PCOS presenting with oligo- or amenorrhea.

Antiandrogens

Antiandrogens can be classified as steroidal (cyproterone acetate and spironolactone) and nonsteroidal (flutamide, finasteride, bicalutamide, dutasteride, GnRH agonists, GnRH antagonists). Among these, cyproterone acetate, spironolactone, flutamide, and bicalutamide are competitive antagonists of the androgen receptor. In addition, steroidal antiandrogens, passing through the blood–brain barrier, exert central inhibitory action on pituitary LH release. Antiandrogens commonly used for hormonal treatment of hirsutism are competitive antagonists of the androgen receptor (spironolactone,

Table 142.2 Biological activities of natural progesterone and synthetic progestins

Table 142.3 Antiandrogen properties and adverse effects

Antiandrogen	Properties	Common adverse effects
Cyproterone acetate (steroidal)	Progestagenic properties, → decrease gonadotropins, and testosterone levels	Loss of libido in men
	Strong antiandrogen activity	Thrombophilic
	Inhibits 5α-reductase activity	Hepatotoxic
	Inhibits LH	Gynecomastia
Spironolactone (steroidal)	Weak progestagenic properties and diuretic activity	Hyperkalemia
	Androgen antagonist	Hypotension
	Inhibits 5α-reductase activity	Loss of libido in men
	Increases SHBG	Loss of erections
	Inhibits LH	Gynecomastia
	Inhibits steroidogenesis	
Flutamide	Strong antiandrogen activity	Hepatotoxic
Finasteride	Type 2 5α-reductase inhibitor	Loss of libido in men
		Loss of erection
		Gynecomastia
		Ejaculation disorders
		Depression
Dutasteride	Type 1 and 2 5α-reductase inhibitor	Loss of libido in men
		Loss of erection
		Gynecomastia
		Ejaculation disorders
GnRH analogues	Testosterone reduction	Virtually no adverse effects

cyproterone acetate, flutamide) or inhibitors of 5-α reductase, which decrease the conversion of testosterone to the more potent androgen DHT (finasteride) (Table 142.3). In particular, cyproterone acetate is a 17-hydroxyprogesterone acetate derivative with strong progestagenic properties, leading to decrease gonadotropin production and testosterone synthesis and with strong antiandrogen activity, by competing with DHT and testosterone for binding to the androgen receptor. In addition, there is evidence it inhibits 5α-reductase in the skin and increases SHBG. As an adverse effect it may reduce sexual desire, has a thrombophilic and hepatotoxic profile, and may lead to the onset of gynecomastia. Spironolactone has weak progestagenic properties and diuretic activity. It can inhibit steroidogenesis, acts as an androgen antagonist, inhibits 5α-reductase activity, and increases SHBG. Rare adverse effects are hyperkalemia and hypotension and in the male loss of libido or erection and onset of gynecomastia. It has no thrombophilic and hepatotoxic profile. Flutamide is a potent antiandrogen, which could lead to enhanced gonadotropin, testosterone, and estrogen levels and to hepatotoxicity, usually not suitable for the indication of hirsutism. Finasteride and dutasteride inhibits 5α-reductase. In particular finasteride primary inhibits type 2 isoform. As hirsutism results from a combination of effects of type 1 and type 2, this agent is only partially effective. Dutasteride inhibits the two isoforms, and anyway it has not demonstrated a positive effect on hirsutism. GnRH analogues are effective in reducing testosterone and do not have virtually side effects, but they are expensive.

Antiandrogens (androgen receptor blockers and 5α-reductase inhibitors) are possibly the most effective drugs for hirsutism, although the evidence supporting this statement is relatively weak. Several RCTs support the use of antiandrogens for hirsutism. All these drugs ameliorate hirsutism compared with placebo.

However, at present there is not enough information to establish a scale of efficacy for these drugs. Some comparative studies did not find

differences in efficacy between antiandrogen drugs, whereas in other studies flutamide appeared to have the greatest efficacy, and finasteride the lowest, of antiandrogens. Furthermore, these drugs do not appear to exert dose-dependent effects against hirsutism. Among approaches combining several antiandrogens, the combination of spironolactone with finasteride was more effective than spironolactone alone in two small 6-month studies carried out in women with PCOS or idiopathic hirsutism (Escobar-Morreale et al. 2012).

It must be stressed that antiandrogens cannot be given to pregnant women for the risk of feminization of male fetuses and should only be prescribed to women using secure contraception. Unless oral or transdermal contraceptives are contraindicated, antiandrogens should be given in combination with these drugs, especially cyproterone acetate and spironolactone. These medications may cause menstrual disturbances or even amenorrhea when given alone because of their strong progestin effects. If hormonal contraception is contraindicated, for instance, in women at risk for thrombophilia or in heavy smokers older than 35 years, contraception must be assured by the use of an intrauterine device or by surgical sterilization before using antiandrogens.

Another consideration for antiandrogens is the potential for significant side effects. In particular, flutamide is associated with an increased risk for severe or even fatal liver toxicity. In hirsute women, severe liver toxicity is anecdotic but has been reported to occur with low doses. Finally, with the exception of cyproterone acetate and spironolactone in some countries, antiandrogens are not approved for the treatment of hirsutism and are used off-label after adequate informed consent.

In summary, antiandrogen should be prescribed combined with OC in women presenting with moderate or severe hirsutism or in those with a milder hirsutism who do not reach a satisfactory control of hair growth using OC alone after 1 year of treatment or as single drugs in women in whom OC are contraindicated, warranted that a reliable contraceptive method is used.

Considering their similar efficacy and potential for side effects, we suggest prescribing finasteride, cyproterone acetate, or spironolactone instead of flutamide when an antiandrogen is needed, although the latter is apparently safe at doses below 250 mg/day.

Insulin Sensitizers

Insulin sensitizers are widely used for PCOS because insulin resistance contributes to the pathogenesis of this disorder. Insulin sensitizers improve insulin resistance and menstrual dysfunction and may decrease serum androgen concentrations; their effects on hirsutism are much less clear. Compared with OC and antiandrogens, metformin does not appear to be more effective for the treatment of hirsutism. Mixed results were observed when comparing metformin with OC. Most studies used a combination of ethinyl estradiol and low-dose cyproterone acetate, and in approximately half of them, the OC was more effective compared with the insulin sensitizer. However, the short length of these studies precludes reaching any definite conclusion on the possible long-term effects of both families of drugs.

A few trials compared antiandrogens with metformin for hirsutism. Overall, metformin was less effective compared with flutamide and spironolactone. Also, compared with antiandrogens, the effect of metformin on hirsutism may require longer periods of therapy to be noticeable. Very few studies compared the effects on hirsutism of the different insulin sensitizers that are available. Therefore, we recommend against the use of metformin or other insulin sensitizers as therapy for hirsutism as its possible effects are unconvincing and possibly not superior to placebo.

Other Drugs

There are inconsistent reports regarding the role of glucocorticoids in the treatment of hirsutism and concerns about their safety. In addition, there is considerable controversy about the

regimen and the most appropriate dosage. The studies currently available in patients with adrenal or unselected hyperandrogenism and in women with idiopathic hirsutism suggest that glucocorticoids are less effective on hirsutism compared with OC or antiandrogens. However, in women with nonclassic adrenal hyperplasia, prolonged remission after withdrawal of antiandrogen therapy may be obtained by the addition of glucocorticoids.

The adrenal enzyme inhibitor ketoconazole ameliorates hirsutism, but its frequent side effects limit its use to subjects with Cushing's syndrome while waiting for definite therapy.

GnRH analogues are potent inhibitors of ovarian steroidogenesis, but experience with these drugs in the management of hirsutism is quite limited.

So far, recommendation is against the use of glucocorticoids, ketoconazole, and GnRH analogues for first-line therapy of hirsutism because their effects are generally limited. In addition, other drugs are safer and/or more cost-effective.

Hormonal Therapy of Acne

Antiandrogens are usually used to block the effect of androgens on the sebaceous gland and the infundibulum of the hair follicle. In fact, androgen receptors are present on sebocytes and sweat gland cells along with epidermal and follicular keratinocytes, dermal papilla and fibroblasts, endothelial cells, and melanocytes.

Spironolactone may be more effective in adult women with acne as compared to OC. It competitively inhibits the androgen receptor at higher doses and inhibits 5α-reductase activity to a lesser extent. In a Cochrane review, spironolactone 100 mg/day was found to be superior to finasteride 5 mg/day and low-dose CPA 12.5 mg/day (first 10 days of cycle). Oral contraceptives and spironolactone are synergistic, and response rates can increase by 75 % with the use of this combination. Orally, the recommended dose is 50–100 mg after food, but many patients show the response with a lower dose of 25 mg once or twice daily. It inhibits type 2 17-β HSD and also reduces sebum secretion. It is contraindicated in pregnancy since it has been reported to cause hypospadias in the male fetus. Topical 5 % spironolactone has been used in Europe in acne and seborrhea.

Cyproterone acetate is reported to be effective as monotherapy in more than 75 % of women. It is commonly combined with estrogens in the OC. It is very effective in recalcitrant acne associated with PCOS. Topical CPA in a novel vehicle (solid lipid nanoparticles) having enhanced follicular penetration may be useful when systemic medication is unacceptable and can be used in both men and women. Drospirenone, in combination with lower doses of estrogen (drospirenone 3 mg/ethinyl estradiol 20, 30 μg), is reported to have a beneficial effect in acne vulgaris, hirsutism, and the OC-induced fluid retention caused by the estrogen component.

Hormonal Therapy of Hair Loss in Women and Men

Female Pattern Hair Loss (FPHL)

Spironolactone and cyproterone acetate are the most commonly used oral antiandrogens in the treatment of FPHL. The effects of these agents are comparable, with 44 % of patients with FPHL experiencing regrowth.

Topical spironolactone 2 % solution exists and has been used in combination with minoxidil with variable success. Spironolactone alone in pregnancy should be avoided.

Treatment with cyproterone can improve hair growth in patients with FPHL, alone or in combination with ethinyl estradiol or spironolactone. Cyproterone has shown efficacy in treating patients with FPHL with both increased and normal androgen levels. It is approved for use in Europe and Canada to treat hirsutism, acne, and female alopecia, while it is not available in the United States.

5-α reductase inhibitors work by inhibiting the conversion of testosterone to DHT and result in increased hair growth and halt progression of hair loss. Their use in women is limited because they

are contraindicated in women of childbearing age. Finasteride has not shown the same efficacy in FPHL as seen in male AGA. In postmenopausal women, a 1-year course of finasteride 1 mg daily failed to improve hair loss over placebo. In premenopausal women, finasteride has shown benefit in treating FPHL associated with hyperandrogenism. In normoandrogenic women, it seems to be efficacious when used in higher doses (5 mg) or in combination with drospirenone and ethinyl estradiol OC. The specific subset of women who respond well to finasteride may have an excessive activity of the 5-α reductase enzyme. Topical preparations of finasteride 0.05 % have a potential role in the treatment of FPHL. Finasteride is metabolized in the liver, and it should be used with caution in patients with liver abnormalities. It is a pregnancy category X medication, associated with feminization of a male fetus. Women of childbearing age should use strict birth control and should not handle crushed or broken pills.

Dutasteride is a 5-α reductase inhibitor with superior antiandrogenic effects to finasteride. It can decrease serum DHT levels by more than 90 %. Dutasteride is not currently approved by the FDA for the treatment of hair loss. The off-label use of dutasteride (0.25–0.5 mg/day) has led to resolution of FPHL in postmenopausal women. This medication should not be administered to women of reproductive age. Liver function needs to be monitored in all patients.

Fulvestrant is a pure estrogen receptor antagonist that was developed as a treatment of estrogen-sensitive breast cancer. In vitro studies have shown that fulvestrant can increase hair growth in mice, by stimulating telogen hair follicles to reenter anagen. In human studies, topical fulvestrant preparations have not been shown to be superior over control vehicle in the treatment of FPHL.

Ketoconazole is an antifungal used in the treatment of seborrheic dermatitis. The use of ketoconazole shampoo, especially in combination with finasteride, results in increased hair growth in FPHL. The mechanism by which it can improve hair growth is unclear. It has anti-inflammatory properties, and it reduces colonization of the skin by *Malassezia*. Ketoconazole also affects steroidogenesis locally, and it decreases DHT levels at the hair follicle. It should be part of the treatment regimen in women with FPHL who have accompanying inflammatory seborrheic dermatitis or sebopsoriasis. Hyperandrogenic women with FPHL can benefit from the antiandrogenic mechanism of ketoconazole.

Male Pattern Hair Loss (MPHL)

At present, minoxidil and oral finasteride are the only treatments approved by the FDA for MPHL. Both these drugs stimulate hair regrowth in some men and are more effective in preventing progression of hair loss. Minoxidil monotherapy in MPHL may not halt the process of miniaturization under the influence of androgens. Finasteride is a potent and highly selective inhibitor of 5α-reductase type 2. Taken orally it reduces DHT levels in serum and in scalp by up to 70 %. In 1993 it was registered in the United States for the treatment of mild to moderate MPHL.

Finasteride is quickly absorbed after oral intake, with peak plasma level occurring 1–2 h after drug intake. The serum half-life is about 6 h; the biological effect persists much longer. Recommended dosage is 1 mg once daily taken with or without food. If a patient forgets a tablet, taking the double dosage the next day is not recommended. Dosage need not be adjusted in the case of renal insufficiency. Finasteride has been shown to increase both total and anagen hair counts. Finasteride prevents or slows the progression of MPHL, and about two-thirds experience some improvement. The improvement peaks at around 12 months. Finasteride has been shown to produce significant and durable increase in hair growth in men with pattern hair loss. The previously miniaturized hair becomes longer and thicker. Finasteride is more effective over the vertex and superior frontal region of the scalp, compared with a minimal response over the temporal and anterior hairline region. Treatment should be continued because the benefits will not be maintained after ceasing

therapy. Baseline photographs of the vertex and frontal hairline are helpful and are repeated at six monthly to yearly intervals to monitor treatment response. Patients are able to observe their regrowth, which serves as a motivating factor in improving long-term compliance to medical treatment.

Patients should be made aware of the pros and cons prior to treatment. Finasteride can cause loss of libido, ejaculatory dysfunction, gynecomastia, and potential depression in a small number of individuals. In a small number of patients, adverse sexual effects have been reported to be persistent. Finasteride reduces the level of prostate-specific antigen (PSA). If treatment is started after age 45 years, monitoring of the PSA level should be considered. The PSA level should be doubled to compensate the reduction caused by finasteride, resulting in an interpretation of the test remaining accurate.

The level of finasteride in the semen of treated men is very low even with regular intake of finasteride 5 mg/day, and there is no risk in the case of sexual relations with pregnant women. Use of a condom is not necessary for this reason. Finasteride-treated men should avoid donating blood. Women who are or potentially may be pregnant should not handle crushed or broken tablets. Finasteride tablets are coated to prevent contact with the active ingredients during manipulation.

Dutasteride has similar characteristics to finasteride but is a more potent, selective inhibitor of the enzyme 5α-reductase types I and II. Dutasteride has been shown to significantly increase hair counts and hair weight, improve the ratio of anagen and telogen hairs, and improve scalp coverage based on assessment of global photography. Oral dutasteride 0.5 mg/day can be considered to improve or prevent progression of MPHL in male patients older than 18 years with mild to moderate pattern hair loss. Dutasteride significantly reduces the progression of hair loss in men with pattern hair loss. Adverse effects of dutasteride are impotence, decreased libido, breast tenderness and enlargement, and ejaculation disorders. These side effects are more common with dutasteride than with finasteride. Dutasteride is not FDA approved for MPHL. However, it is approved for men in Korea. More studies are needed comparing the efficacy of dutasteride, 0.5 mg, with finasteride, 1 mg.

Conclusions

Hormonal treatments are effective in reducing the clinical expression of skin androgen-related disorders. Hormonal therapy of hirsutism and acne is mainly based on the use of oral contraceptives (OC) and associated antiandrogens. Hormonal therapy of androgenetic alopecia mainly relies on the use of antiandrogens. Indications and adverse effects of both OC and antiandrogens should be well known and explained to the patient.

Imiquimod

143

Mihael Skerlev, Ivana Čulav-Košćak,
Suzana Ljubojević Hadžavdić,
and Maja Sirotković-Skerlev

Key Points

- Imiquimod has revolutionized not only the therapeutic protocols but also our understanding of the immunogenetic properties of some of the most frequent dermatovenereological disorders.
- Imiquimod's first official approval was for use in external genital and perianal warts.
- Meanwhile, imiquimod 5 % cream has been also officially approved for treatment of superficial small (<2 cm) non-facial basal cell cancer (BCC) and actinic keratoses on the face and scalp.
- However, the list of off-label indications continues to expand offering potential cost-effective and more elegant treatment options, including anal and vulvar intraepithelial neoplasias (AIN/VIN), common warts, mollusca contagiosa, Bowen's disease, etc.
- Imiquimod is available as a 2.5 %, 3.75 % (Zyclara™) and 5 % (Aldara™) cream.
- Future perspective lies upon further investigations of imiquimod and newer generation of imidazoquinolines such as resiquimod, an imiquimod analogue and agonist of toll-like receptors (TLR) 7 and 8. This will hopefully contribute to the extension of (often somewhat narrowed) therapeutic modalities in dermatovenereology.

General Principles

Imiquimod (1-[2 methylpropyl]-1 H-imidazo [4, 5c] quinolin-4 amine), a non-nucleoside heterocyclic amine of the imidazoquinoline family, is a synthetic compound known as the first member of a new class of immune response modifiers (Sheth et al. 2013; Schön and Schön 2007; Garland 2003). It enhances innate and acquired immune pathways resulting in antitumourous, antiviral and immunoregulatory activities (Schön and Schön 2007; Garland 2003). Since its first official approval for use in external genital and perianal warts 16 years ago, it has revolutionized not only the therapeutic protocols but also our

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_143, © Springer-Verlag Berlin Heidelberg 2015

understanding of the immunogenetic properties of some of the most frequent dermatovenereological diseases (Sheth et al. 2013; Garland 2003; Gaspari et al. 2009). Besides the aforementioned external genital and perianal warts, imiquimod 5 % cream is officially approved for treatment of superficial small (<2 cm) non-facial basocellular carcinoma (BCC) and actinic keratoses on the face and scalp (Sheth et al. 2013; Jackson et al. 2012). However, the list of off-label indications continues to expand offering potential cost-effective treatment options (Sheth et al. 2013; Gaspari et al. 2009; Jackson et al. 2012).

Mechanisms of Action

Although the exact mechanism of action against HPV infection has not been fully explained so far, imiquimod is generally recognized to operate on several levels which interact synergistically/mutually with the resultant antitumourous activity (Sheth et al. 2013; Schön and Schön 2007). Imiquimod displays effects on both innate and acquired immune response (Garland 2003; Gaspari et al. 2009; Jackson et al. 2012). Innate immune response enhancement by imiquimod is manifested by the increased production of cytokines, such as IFN-α, IL-6 and TNF-α, secretion of nitric oxide from macrophages and upregulation of natural killer (NK) cell activity (Schön and Schön 2007; Miller et al. 1999). Its stimulation of acquired immune pathways is documented by increased production of Th1 cytokine IFN-γ together with the ability to activate and enhance the migration of Langerhans cells (antigen-presenting cells) to regional lymph nodes (Schön and Schön 2007; Garland 2003; Suzuki et al. 2000; Prins et al. 2006). Imiquimod is also well known as the agonist of toll-like receptor (TLR) 7 since some of its major biologic effects are explained through this particular activity (Sheth et al. 2013; Schön and Schön 2007; Garland 2003; Gaspari et al. 2009; Jackson et al. 2012). TLR 7 is localized on the intracellular endosomal membranes of cells involved in both innate and acquired immune responses such as Langerhans cells, other dendritic cells, and macrophages (Schön and Schön 2007; Gaspari et al. 2009; Jackson et al. 2012). Imiquimod acts by reprogramming of gene expression mediated by the TLR 7 signalling pathways, resulting in movement of the transcription nuclear factor kappa B (NF-κB) to the nucleus (Schön and Schön 2007; Gaspari et al. 2009). Activation of the NF-κB induces the production of proinflammatory cytokines, chemokines and other mediators, especially IFN-α, IL-12 and IL-18, which in turn induce CD4+ T cells to produce IL-12 β2 receptor and IFN-γ, thus enhancing the cell-mediated immunity (Schön and Schön 2007; Jackson et al. 2012). It has also been proposed that imiquimod interferes with adenosine receptor signalling pathways and receptor-independent reduction of adenylyl cyclase activity which may amplify its proinflammatory activity (Schön and Schön 2007). Several studies have demonstrated increased apoptosis through decreased Bcl-2 expression after imiquimod treatment of basocellular carcinoma (Schön and Schön 2006; Vidal et al. 2004).

Pharmacokinetics

Imiquimod is applied topically, and its percutaneous absorption is minimal with very small amounts found in urine and faeces (Jackson et al. 2012; Zyclara 2012). The potential site of its metabolism as well as protein binding is unknown (Jackson et al. 2012). Some observations regarding its apparent half-life after topical and subcutaneous application led to conclusion that it has prolonged retention in the skin (Zyclara 2012).

Indications for Use of Imiquimod in Dermatovenereology

Imiquimod is available as a 2.5 %, 3.75 % (Zyclara™) and 5 % (Aldara™) cream (Imiquimod; Aldara, Zyclara; Zyclara 2012). As a topical preparation for external use on the skin, it is officially approved for the following indications with certain modifications in therapeutic schemes depending on the formulation type:

external genital and perianal warts, actinic non-hypertrophic keratoses on the face and/or balding scalp and superficial small (<2 cm) non-facial basal cell carcinoma (Sheth et al. 2013; Jackson et al. 2012; Imiquimod; Aldara, Zyclara; Zyclara 2012) (Table 143.1). Its use on ocular, nasal, oral, intravaginal and intra-anal areas has not been comprehensively evaluated and is therefore not officially recommended, so far (Zyclara 2012). However, the authors' personal, off-label experience is rather encouraging. Regardless the formulation and indication, the cream should be applied in a thin layer over the skin lesion, left on for 6–10 hours and washed off with water and mild soap after each application, especially in the case of genital warts in penile region (Imiquimod; Aldara, Zyclara; Zyclara 2012; Aldara 2013). Occlusive dressing should be avoided since it may cause irritation (Sheth et al. 2013). Hands should be washed before and after application of the cream (Imiquimod; Aldara, Zyclara; Zyclara 2012; Aldara 2013). Imiquimod 5 % cream (Aldara™) is packed in packets containing 250 mg of cream or 12.5 mg of imiquimod (100 mg of cream contains 5 mg of imiquimod) (Aldara 2013). Packets are designed for single use and should be disposed after use. Imiquimod 3.75 % and 2.5 % creams (Zyclara™) are packed in packets and pumps with the recommended dosage of 250 mg of cream (one packet) at each application or one full actuation of the pump (Zyclara 2012).

For the treatment of *external genital warts*, imiquimod 5 % cream is used topically three times per week until complete clearance of clinically visible lesions or for a maximum of 16 weeks (Imiquimod; Aldara, Zyclara; Zyclara 2012). The cream should be applied on three nonconsecutive days, e.g. Monday, Wednesday and Friday or Tuesday, Thursday and Saturday with the days of drug application preferably determined by the patient herself/himself at the beginning of therapy for better compliance and avoidance of confusion (Aldara 2013). Another formulation of imiquimod, the 3.75 % cream, is also approved for this indication and applied once daily for up to 8 weeks (Imiquimod; Aldara, Zyclara; Zyclara 2012). Special care should be applied in uncircumcised males with genital warts under the foreskin; to avoid irritations, the foreskin should be pulled back and cleaned daily (Imiquimod; Aldara, Zyclara; Aldara 2013).

Therapeutic modalities for treatment of non-hyperkeratotic *actinic keratoses* of the face and/or balding scalp include all three formulations of imiquimod. Imiquimod 5 % cream is applied three times weekly on nonconsecutive days (e.g. Monday, Wednesday, Friday) for 4 weeks (Aldara 2013). After that period, decision about prolonged therapy for 4 weeks more is brought based on thorough clinical inspection and evaluation by the dermatologist (Aldara 2013). Imiquimod 3.75 % and 2.5 % creams for this indication should be applied once daily for two 2-week cycles separated by 2 weeks without therapy (Jackson et al. 2012; Imiquimod; Aldara, Zyclara; Zyclara 2012).

Imiquimod is relatively novel therapeutic option for treatment of *small* (*<2 cm*) *superficial non-facial basal cell carcinomas*. Efficacy of imiquimod in the treatment of other types of basal cell carcinomas has not been completely

Table 143.1 Schematic overview of dermatovenereological treatment with imiquimod

	External genital and perianal warts	Actinic keratoses	Basal cell carcinoma
Imiquimod 5 % cream (Aldara™)	3 times weekly for up to 16 weeks	3 times weekly for 4 weeks (+/– 4 weeks more)	5 times weekly for 6 weeks
Imiquimod 3.75 % cream		2 cycles once daily for 2 weeks separated by 2 weeks with no treatment	
Imiquimod 2.5 % cream (Zyclara™)	Once daily for 8 weeks		

evaluated and is therefore not officially recommended, so far (Imiquimod; Aldara, Zyclara). Before beginning of therapy, the diagnosis should be confirmed histopathologically. For this indication, imiquimod is used in the formulation of 5 % cream which is applied five times per week (e.g. Monday–Friday) for up to 6 weeks. Cream should be applied across the lesion and within 1 cm diameter around the lesion in a thin layer avoiding the periorificial areas (Imiquimod; Aldara, Zyclara; Aldara 2013). Patients should be re-examined 12 weeks after treatment at which point clinical inspection is made with, preferably, biopsy as the only reliable method to ensure the complete clearance of tumour (Sheth et al. 2013; Imiquimod; Aldara, Zyclara).

Off-Label Usage of Imiquimod and Future Perspectives

Owing to the better understanding of diverse potentials of TLR 7 and more precise insight into molecular biomechanisms that have been accumulated in recent years, several new potential approaches for imiquimod have been suggested and investigated. Since this issue still awaits clinical and scientific approval for use, these alternative treatment options remain classified as "open-label" or "off-label".

Reports of successful treatment of common warts, periungual and plantar as well as flat facial warts have been submitted although the efficacy of imiquimod 5 % cream in these cases is inferior to its efficacy in genital warts (Gaspari et al. 2009; Jackson et al. 2012; Grussendorf-Conen et al. 2002; Micali et al. 2003).

Mollusca contagiosa are another open-label indication for the use of imiquimod 5 % cream confirmed by several studies and clinical trials. Frequency and duration of application of imiquimod varied between the reports (Sheth et al. 2013; Gaspari et al. 2009; Jackson et al. 2012; Imiquimod; Aldara, Zyclara; Myhre et al. 2008; Syed et al. 1998; Theos et al. 2004; Skerlev and Husar 2011; Husar and Skerlev 2002).

Acyclovir-resistant herpes simplex virus (HSV) infections can be managed with topical application of imiquimod according to some reports (Imiquimod; Aldara, Zyclara; Centers for Disease Control and Prevention (CDC) 2010; Bernstein et al. 2005). Still, one double-blind placebo-controlled study questioned these results (Schacker et al. 2002).

Efficacy of imiquimod 5 % cream in the treatment of keloids following surgical excision has been reported as well (Berman and Kaufman 2002). However, results of some later reported studies failed to confirm it (Cação et al. 2009; Berman et al. 2009).

Imiquimod 5 % cream has also been proven efficient against lentigo maligna (melanoma in situ) (Sheth et al. 2013; Gaspari et al. 2009; Jackson et al. 2012; Imiquimod; Aldara, Zyclara; Naylor et al. 2003; Powell et al. 2004; Ahmed and Berth-Jones 2000; Erickson and Miller 2010; Rajpar and Marsden 2006). Regardless the clinical studies confirming success of such treatment, it remains experimental and is generally regarded with great caution. Good therapeutic results with topical imiquimod were achieved for cutaneous melanoma metastases (Jackson et al. 2012; Florin et al. 2012; Wolf et al. 2003).

Bowen's disease (cutaneous squamous cell carcinoma in situ) is another potential indication for use of imiquimod which lacks solid evidence so far (Gaspari et al. 2009; Jackson et al. 2012; Patel et al. 2006; Rosen et al. 2007). Reports concerning its use in invasive squamous cell carcinoma also exist (Peris et al. 2006; Huang et al. 2009; Ahn et al. 2012).

Imiquimod has been used successfully also against anal and vulvar intraepithelial neoplasias (AIN/VIN) in both immunocompetent and immunodeficient (HIV/AIDS) patients (Imiquimod; Aldara, Zyclara; van Seters et al. 2008). In this context, imiquimod has also been used with success in combination with HPV vaccination (Daayana et al. 2010).

Other indications for off-label use of topical imiquimod include extramammary Paget's disease (Gaspari et al. 2009; Jackson et al. 2012; Cohen et al. 2006; Badgewell and Rosen 2006), mycosis fungoides (Deeths et al. 2005; Suchin et al. 2002; Martínez-González et al. 2008), Kaposi sarcoma (Gaspari et al. 2009; Celestin

Schartz et al. 2008; Babel et al. 2008), infantile superficial haemangioma (Ho et al. 2007) and cutaneous leishmaniasis (Jackson et al. 2012; Arevalo et al. 2007).

Future perspective lies upon further investigations of imiquimod and newer generation of imidazoquinolines such as resiquimod, an imiquimod analogue and agonist of TLR 7 and 8. This will hopefully contribute to the extension of (often somewhat narrowed) therapeutic modalities in dermatovenereology. Aiming for the better compliance, newer formulations of imiquimod and/or its analogues adjusted for daily application instead of three or five times per week is another potential direction on which future development would rely on (Gaspari et al. 2009).

Adverse Effects and Contraindications

Imiquimod is generally considered a safe drug. Contraindications for its use include hypersensitivity to its components, but absolute contraindications are not known (Sheth et al. 2013; Jackson et al. 2012; Imiquimod; Aldara, Zyclara). The most common adverse effects are restricted to the application site and include erythema, oedema, desquamation and ulceration, often accompanied by pruritus, burning, tenderness or scabbing (Sheth et al. 2013; Jackson et al. 2012). Their frequency is related to the frequency of application of the drug. However, they tend to subside once the use of drug is stopped. In cases of intense local reaction, application of imiquimod should be temporarily aborted and continued once the skin has recovered (Imiquimod; Aldara, Zyclara). Some unusual adverse effects of imiquimod have also been described such as psoriasis induced de novo or exacerbation of psoriasis (El Malki et al. 2013; Shibata et al. 2013; Gilliet et al. 2004), lichen planus and lichen sclerosus (O'Mahony et al. 2010), lupus-like skin reactions (Barr et al. 2011; Chan and Zimarowski 2011) and/or subacute lupus erythematosus (Burnett et al. 2010), erosive pustular scalp dermatosis (Vacarro et al. 2009), erosive cheilitis (Campanelli and Lubbe 2007) and aphthous ulcers (Chakrabarty et al. 2005). Systemic adverse effects are reported in 1–2 % of cases and include flu-like symptoms such as fatigue, fever, headache, diarrhoea and myalgia (Jackson et al. 2012). Serious systemic adverse effects have not been reported. Laboratory monitoring is not necessary (or cost-effective) during treatment with imiquimod (Imiquimod; Aldara, Zyclara).

Safety and efficacy of imiquimod has not been evaluated neither for children <12 years nor for immunosuppressed patients (Imiquimod; Aldara, Zyclara). During application of imiquimod on sun-exposed areas, sun-protective measures primarily sun avoidance and protective clothing (as well as avoidance of artificial UV sources) should be encouraged (Imiquimod; Aldara, Zyclara). Also, it is advised that any kind of skin disease or condition is healed before beginning of treatment with topical imiquimod (Imiquimod; Aldara, Zyclara; Aldara 2013).

Imiquimod is classified as pregnancy category C, and the data regarding its excretion in breast milk is limited (Jackson et al. 2012; Imiquimod; Aldara, Zyclara). Thus, its use in pregnant and lactating women should be carefully considered.

Insect Repellents

144

Stefania Motta and Marcello Monti

Key Points

- Insect repellents are chemical substances that, when applied to the skin, are able to repel insects and block their attack on man.
- These compounds can block the insect's approach phase to the host by deviating the flight and hence taking the insect far from the target. Insect repellents exploit their action on many insects such as mosquitoes, flies, sandflies, horseflies, fleas, mites and ticks.
- There are three categories of insect repellents: physical repellents, synthetic repellents and natural-origin repellents.
- The insect repellents marketed in Europe possess a high level of safety due to especially low concentrations of the active ingredient. However, to increase the safety profile, dermatologists should suggest to their patients the following guidelines.
- The use of insect repellents is to be reserved to adults who, for professional or recreational activities, are at risk of contracting diseases transmitted by insect bites. Other forms of protection (e.g. the mosquito net) are recommended in common situations and for children.

General Principles and Classification

Insect repellents are chemical substances that, when applied on the skin, are able to repel insects and block their attack on man. These compounds can block the insect's approach phase to the host by deviating the flight and hence taking the insect far from the target. Insect repellents exploit their action on many insects such as mosquitoes, flies, sandflies, horseflies, fleas, mites and ticks. There are three categories of insect repellents:

- Physical repellents
- Synthetic repellents
- Natural-origin repellents

Physical repellents are instruments, usually employing ultrasound and claiming to modify insect flight and host identification. High-frequency sounds are used also in many smartphone applications. Their efficacy is questionable, so they will not be considered in this chapter.

Synthetic and natural repellents are particularly effective when directly applied onto the skin. Therefore there is an interaction between human skin and the repellent substance that may

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_144, © Springer-Verlag Berlin Heidelberg 2015

cause cutaneous and/or systemic toxicity by absorption. From the dermatotoxicological point of view, insect repellents have to be considered as 'leave on products', though they can be absorbed if applied frequently for a long period. These products, which are available over the counter, are indiscriminately used nowadays, so it is necessary to consider them with particular concern for the possible risks of their use, misuse or abuse.

The substance most used as an insect repellent since World War II is a synthetic molecule called N,N[1]-diethyl-m-toluamide (DEET), chemically belonging to the diethylamide family.

Natural-origin repellents are essential oils derived from different plants. These products, unlike the synthetic insect repellents, have been relatively poorly investigated.

In this chapter, insect repellent compounds and their mechanism of action and toxicity will be considered.

The Ideal Insect Repellent

The perfect topical repellent would repel multiple species of biting arthropods, remain effective for at least 8 h, cause no irritation to mucous membranes, possess no systemic toxicity, be resistant to washing off and be greaseless and odourless. No available insect repellent meets all of these criteria.

Mechanism of Action of Repellents

The relationship between chemical structure and repellent effectiveness has not been completely clarified, thus insect repellents cannot be classified on the basis of their mechanism of action. However, the most active repellents belong to the following chemical moieties: amides, imides, alcohols and phenols. There is also a kind of relationship between vapour-producing property and the level of repellency. The repellency activity is somehow related to the olfactory receptors of insects via:

- A block of neurons which sense attractive chemical stimuli
- Activation of receptors which promote inappropriate behaviour
- Activation of receptors for noxious odours
- Activation of too many receptors and loss of attractive messengers

Factors Affecting Effectiveness of Repellency

Multiple factors play a role in how effective a repellent is; these factors are product dependent, product independent and user dependent as listed in Table 144.1.

Repellents form a barrier between the skin and mosquito receptors, and this barrier extends to 4 cm from the skin when the repellent is freshly applied. Apart from some individual host characteristics, repellents are inactive due to excessive evaporation when the temperature exceeds 30 °C. In sweaty areas such as the forehead, the duration of protection is significantly decreased. Moreover, for unknown reasons some insect species are more sensitive to repellents than other related species, which remain unaffected. Among mosquito species, *Aedes taeniorhynchus* and *Culex pipiens* are more sensitive than *Aedes aegypti* and *Anopheles albimanus*.

Table 144.1 Factors affecting repellent effectiveness

Product-dependent factors	Product-independent factors	User-dependent factors
Evaporation rate from skin surface	Species of the biting insect	Activity level of the host
Absorption rate	Density of the biting insect	User attractiveness
Resistance to abrasion	Wind velocity	Frequency of application
Resistance to wash off	Air temperature	Uniformity of application
	Wet environment	Anatomical site

Factors Attracting Insects

Mosquitoes use visual, thermal and olfactory stimuli to locate a host. Visual stimuli are important for in-flight orientation, whereas olfactory stimuli are more important as a mosquito nears its host. Even host movement and wearing of dark-coloured clothing may promote orientation. Investigations about host-attracting factors have pointed out that some body odours may attract insects. These are eccrine sweat because of the presence of amino acids, urea and ammonia and apocrine sweat and sebum secretion due to the presence of cholesterol. Urine, carbon dioxide and sexual hormones are considered as attractants. In particular carbon dioxide is a long-range attractant, whereas at close range skin moisture and warmth are attractants. Body temperature is a discriminating factor: mosquitoes choose hosts with higher body temperatures. Body humidity is also a discriminating factor due to mosquitoes having hygrometric sensors (see Table 144.1).

Types of Insect Repellents

Synthetic Insect Repellents

Thousands of chemical compounds have been demonstrated to have repellence activity. However, only few of these are considered suitable for human use. These are:

- Dimethyl phthalate (DMP)
- Ethylhexanediol
- Diethyltoluamide (DEET)
- Ethyl butylacetylaminopropionate
- Picaridin

The discrepancy between the number of active substances and the registered ones is mainly due to skin absorption toxicity.

Dimethyl Phthalate (DMP)

This compound, registered in 1929, has been the reference repellent for many years. It is an oily, colourless, water-insoluble liquid with an aromatic odour. DMP has a mean protective duration of 80 min, and its effectiveness is variable among different insect species. It is used at 40 % preparation. The minimum amount of DMP necessary to inhibit mosquito biting has been determined to be 8–8.15 mg/square inch. The toxicological data available indicate that over a 40 % concentration, DMP exerts eye, mucous and skin irritation; by ingestion it is a central nervous system and respiratory depressant. Nowadays DMP is used exclusively in association with other repellents. Recently DMP was mentioned for its efficacy against ixodid ticks and advocated for the prevention of Lyme disease.

Ethylhexanediol

This compound was patented in 1935. It is an oily, colourless, water-insoluble, chemically stable liquid. It has a protective duration ranging from 1 to 8 h depending on the different insect species. Its repellency decreases as the temperature increases due to rapid evaporation. It is used from 30 to 50 % and at these concentrations is a mild skin irritant. The only data available on the toxicity of ethylhexanediol cites suspected teratogenicity via skin absorption.

Diethyltoluamide (DEET)

This compound was patented in 1943 and marketed since 1956. It is considered the reference repellent since it still remains the best one in thousands of comparative tests with other compounds. Today DEET is distributed worldwide, and it is estimated that 200 million people use DEET each year. The repellency of this compound covers a wide range of insect species: mosquitoes, biting fleas, gnats, chiggers, ticks and others. It is oily, colourless, odourless, water and glycerin insoluble, and soluble in alcohol, ether and polyethylene glycols. It has a protective duration of about 4 h. The protectiveness

decreases to 24 min at 40 °C. Of the marketed products, DEET concentration has a wide range (from 7 to 100 %). As opposed to the previously cited repellents, a great bulk of literature on DEET toxicology is available. DEET toxicology may be subdivided into: general, systemic and skin toxicology.

Pharmacology

Human studies show variable penetration of DEET ranging from 9 to 56 % of topically applied dose. Absorbed DEET is metabolized completely within 12 h with 99 % urinary elimination. Hepatic microsomal cytochrome P450 enzymes are involved in DEET metabolism. There is no evidence of stratum corneum or systemic accumulation.

General Toxicology

DEET applied to skin is absorbed in about 20 min. The systemic LD_{50} is 2 mL/kg in rats and 10 mT Ikg in rabbits. The poisoned animals manifested laboured respiration, ataxia and convulsions.

Human Systemic Toxicity

Some cases of encephalopathy in children after the application of DEET were reported in 1961. After this, several reports on systemic toxicity after DEET application were published. Among these, the most frequently described symptoms were encephalopathy ataxia, seizures, bradycardia and hypotension. Severe toxic reactions and death after the ingestion of repellents containing DEET were also reported. In 1988, an editorial in the *Lancet* suggested that products containing less than 50 % DEET were safe; however, in children even preparations containing 20 % DEET, applied to large areas repeatedly, caused slurred speech, agitations, tremors and convulsions.

A comprehensive review of side effects due to DEET was published in 1994 (Veltri et al. 1994).

Skin Toxicology

There are several reports on specific skin sensitivity to DEET, while some reports refer to skin irritation, contact urticaria, generalized urticaria and vesiculobullous reactions (Amichai et al. 1994; Von Mayenburg and Rakoski 1994; Wantke et al. 1996).

No photosensitivity has been reported. DEET is considered a substance with a high profile of safety.

Ethyl Butylacetylaminopropionate

Ethyl butylacetylaminopropionate was synthesized by Merck and was registered as IR3535 compound.

The structure of ethyl butylacetylaminopropionate is based on alanine and beta-alanine, and the *Environmental Protection Agency* (EPA) has classified it as a biochemical substance based on the fact that it is 'functionally identical' to beta-alanine: both repel insects and the end groups are not likely to contribute to toxicity.

Picaridin (1-Piperidinecarboxylic Acid 2-(2-Hydroxyethyl)-1-methylpropyl Ester)

Picaridin, synthesized by Bayer, is an insect and acarid repellent in the piperidine chemical family. The chemical name is 1-piperidinecarboxylic acid 2-(2-hydroxyethyl)-1-methylpropyl ester.

Mode of Action

Picaridin both repels and deters insects, so that insects move away from the chemical and do not feed if they encounter skin or clothing that has been treated. Insects appear to detect the chemical through olfactory sensing.

Toxicity

Picaridin is not considered a skin irritant and is not a sensitizer, but it can cause slight to moderate eye irritation and is considered to be slightly toxic for acute dermal and ocular exposure.

Insect Repellents of Natural Origin

All substances with repellent activity not produced by chemical synthesis are considered natural-origin insect repellents. Among these, some are of historical value such as smoke, plant

derivates, tars and animal urine. Plants whose essential oils have been identified as having repellent activity include cedar, citronella, clove, coconut, eucalyptus, geranium, lavender, menthe, onion, rosemary and thyme. Plant-derived insect repellents have been poorly studied, and when tested most of these tend to give short-lasting protection.

Oil of Citronella

Oil of citronella is the most studied and utilized essential oil as a repellent. Oil of citronella is extracted from *Cymbopogon nardus*, a Gramineae native to tropical Asia (Sri Lanka and Java). The active component is the aldehyde citronellal, present in the plant from 20 to 60 %, which gives the characteristic scent. The protective duration is variable from 40 to 90 min. Citronella at 10 % has been proved to repel flies but not mosquitoes.

Skin Toxicity

There are no scientifically trusted data on systemic toxicity due to absorption of essential oils. Citronella as with other essential oils is a mild irritant or rubefacient over 20 % concentration. Some reports indicate that essential oils are sensitizers and photosensitizers. Contact urticaria has also been reported.

Pyrethrum

Pyrethrum is derived from *Chrysanthemum cinerariaefolium* and the terms pyrethrum powder and extract are used to describe the crude products obtained from the crushed dried flowers. The pyrethrins are the active components. These substances are valid insecticides but weak insect repellents and thus no longer used in commercial repellents.

Permethrin

Permethrin, a pyrethroid synthesized in 1973, is mainly an insecticide four times as effective as natural pyrethrins. It also possesses some repellent activity, and for this reason it is included in many textbooks among insect repellents. Permethrin is considered a valid tick repellent. Systemic and skin toxicity of this compound is minimal. Permethrin should be applied directly to clothing or to tent and mosquito net fabrics. Permethrin is nonstaining, odourless and resistant to degradation by heat or sun and maintains its potency for at least 2 weeks.

The best barrier against biting insects is considered the combination of permethrin-treated clothing and skin application of DEET.

Indications for Safe Use of Insect Repellents

The insect repellents marketed in Europe possess a high level of safety due to especially low concentrations of the active ingredient. However, to increase the safety profile, dermatologists should suggest to their patients the following guidelines:

- Verify that the product has been registered.
- Read the label information.
- Use the repellent only as suggested by the manufacturer.
- Use the repellent only for the insects it claims to be effective against.
- Keep repellents out of the reach of children.
- Apply repellents only to body parts suggested by the manufacturer.
- Avoid use of repellents on or near wounds or on inflamed skin.
- Avoid use around the eyes and mouth.
- Wash repellent off skin with soapy water when protection is no longer needed.
- Contact the local poison control centre if repellent-induced toxicity is suspected.

Insect repellents are useful compounds to avoid the annoyance of many insects or to prevent the transmission of some infectious diseases. In Table 144.2 insect repellent sensitivity and infectious diseases transmitted by principal arthropods are summarized. However, the insect repellents are far from being the ideal product from a pharmacological point of view. The correct use of these products is fundamental to their safety (see Table 144.2).

Table 144.2 Insect repellent sensitivity and infectious diseases of principal arthropods

Class	Common names	Species	Blood sucking	Repellent sensitivity	Vectors for
Acars	Ticks	*Ixodes*	+	+	Borrelia, rickettsiae, arbovirus
	Trombidium larvae	*Trombidium*	+	+	Rickettsiae
Insects	Lice	*Pediculus*	+	+	Rickettsiae, borrelia
	Human fleas	*Pulex*	+	+	Yersinia, rickettsiae
	Bedbugs	*Cimex*	+	–	Nothing
	Deerflies	*Chrysops*	+	+	Filaria
	Tsetse flies	*Gliossina*	+	+	*Trypanosoma*
	Houseflies	*Musca*	–	+	
	Black or buffalo flies	*Simulium*	+	+	*Onchocerca*
	Biting midges or sandflies	*Phlebotomus*	+	+	Leishmania
	Mosquitoes	*Anopheles*	+	+	*Plasmodia*
		Aedes	+	+	Arbovirus, yellow fever virus
		Culex	+	+	Arbovirus
		Mansonia	+	+	Filaria
	Ants	*Formica*	–	+	Nothing
	Bees	*Apis*	–	–	Nothing
	Wasps and hornets	*Vespula*	–	–	Nothing
		Vespa	–	–	Nothing

Relief from Arthropod Bites

Skin responses to arthropod bites range from wheal-and-flare reactions to delayed papules to rare systemic Arthus reactions and anaphylaxis. Several strategies may be considered for the relief of the itch of insect bites. Topical corticosteroids may reduce erythema, induration and itching, but the time of effectiveness after skin application is considered too long (about 20 min) for relief of wheal-and-flare reaction that usually lasts 20 min.

Diphenhydramine and benzocaine should be avoided due to allergic contact sensitivity. Oral antihistamines are effective in reducing the symptoms of insect bites, but they are poorly employed due to the delay in reducing symptoms.

Ammonium solution 3.6 % is used after bite treatment to relieve symptoms, but caution should be adopted due to causticity of the product.

Aluminium chloride hexahydrate hydroalcoholic gel 5 % (see Chap. 152) is effective in suppressing itching and burning and possesses a good safety profile.

Aluminium chloride 5 % gel is at the same time astringent and antiseptic.

Controversies in Insect Repellents

Risk Assessment

One of the main problems in the use of insect repellent is the risk of toxicity via transcutaneous absorption. Regarding this topic, toxicological studies have been performed only for the DEET molecule, while for the other insect repellents, present studies about absorption must be considered insufficient. For this reason we can say prudentially that insect repellents are not suitable for their use in children, although they are the main victims of insect bites.

Application on Clothes

Efficacy studies of insect repellents are performed on forearm bare skin placed in cages containing insects; on the other hand there are no conclusive studies on the application of the same insect repellent on clothes in the same conditions and the relationship between application on clothes and its effectiveness.

Long-Lasting Protection

Some studies have related the long-lasting protection with the repellent concentration as Fradin and Mittal. This relationship, however, is not supported by conclusive studies. Moreover no studies can confirm a night-lasting protection.

For the above considerations, we believe that the use of insect repellents is to be reserved to adults who, for professional or recreational activities, are at risk of contracting diseases transmitted by insect bites. Other forms of protection (e.g. the mosquito net) are recommended in common situations and for children.

Phytotherapeutic Approaches

145

Corrado Giua Marassi and Annalisa Rossi

Key Points

- Ever since, a large number of plants are used for their therapeutic properties within the healthcare.
- The set of substances that have physiological action and with determined pharmacological effect is defined as phytocomplex.
- Natural remedies and herbal preparations, such as tea tree oil, borage oil and aloe vera gel, are found to be useful in the treatment of dermatologic disorders; these products can be administered orally, externally or by inhalation and can be used alone or in combination with classical dermatological preparations.

Phytotherapy: From Tradition to Evidence-Based Medicine

Ever since, a large number of plants are used for their therapeutic properties. The use in all cultures throughout history of these compounds has been one of the first concrete forms of healthcare known to humanity.

Over the years we have witnessed a change in the usage of medicinal plants handed down from ancient uses to named extracts of active ingredients supported by scientific evidences.

In order to be considered effective, any remedy, medicinal plant or traditional therapeutic practice should fulfil the basic requirements of being safe and effective and it should be determined whether they have any therapeutic effect.

Phytotherapy (from the Greek *python* or plant and *therapeia* or cure) is a discipline that involves the use of medicinal plants and their derivatives for the prevention and treatment of diseases, with regard to the pharmacological properties of the chemical constituents present in the plant. As a matter of fact, products can offer efficacy, safety and repeatability of results only through the use of selected and calibrated extracts in active molecules. We would like to stress out that phytotherapy does not follow particular philosophies or religious beliefs as well as diagnostic or therapeutic methods other than those of scientific medicine.

Phytotherapy uses vegetable drugs from the plant that has therapeutic or preventive activities taking advantage of their active ingredients. Vegetable drugs can present different types of active compounds that may perform several functions and others that modulate the effect. The set of substances that have physiological action and with determined pharmacological effect is defined as phytocomplex.

The phytocomplex distinguishes the herbal compound from the synthetic drug, providing a multiplicity of pharmacological actions and lower toxicity. The phytocomplex has two main advantages compared to synthetic drugs: a pharmacological activity obtained through the interaction of different receptors with a lower risk of adverse events and a better tolerability. This means that a phytocomplex can be used alone or in combination with other phytocomplexes to treat different diseases and can be extracted from one or more vegetable drugs. The phytocomplex represents the core of the clinical phytotherapy.

Modern methods of extraction and analysis of medicinal plants are effective in advancing the development of traditional herbal remedies allowing to obtain a formulation that has an accurate and standard quantity of constituents with a real therapeutic value. One of the most important prerequisites for the production of a quality preparation is a well-defined and constant composition of the drug.

The processes of standardisation include a physical, chemical and biological evaluation to ensure herbal quality. Moreover preclinical and clinical studies confirmed, explained and clarified many pharmacological properties often acquired in a non-scientific way or, on the other hand, to show an incorrect use, highlighting the risks and adverse effects of herbal products.

One of the most representative examples is the study conducted on St. John's wort (*Hypericum perforatum*), the only herbal alternative to classic synthetic antidepressants in the therapy of mild to moderate depression, which has been considered a placebo for a long time. Similarly, a meta-analysis conducted on extracts of peppermint oil (*Oleum menthae piperitae*), garlic (*Allium sativum*) and *Serenoa repens* (saw palmetto) confirmed the pharmacological properties of these herbal products.

Thanks to a more rigorous scientific approach in the use of herbal plants, phytotherapy has become a medical discipline that evaluates the biological properties of vegetable drugs. But always bear in mind that although it is generally believed that most herbal preparations are safe, some herbs like most biologically active substances could be toxic with undesirable side effects.

Some herbal remedies are used in combination with synthetic drugs for the treatment of diseases like menopausal syndrome, sleep disorders, benign prostatic hyperplasia and many others. In any case the prescribing doctor will recommend the right therapeutic regimen according to the patient's pathology and its clinical history.

Phytotherapy in Dermatology

Natural remedies and herbal preparations are found to be useful in the treatment of dermatologic disorders; these products can be administered orally, externally or by inhalation and can be used alone or in combination with classical dermatological preparations. Obviously, the most serious skin conditions cannot be treated with herbal preparations while others may find a benefit from a correct phytotherapeutic approach. Learning all the information regarding the safety of each herb is very important for physicians because this will enable them to decide which herbal therapies they may want to use in practice. In this brief report, we would like to introduce some herbal medications that show clinical efficacy and that are used for the treatment of the most common dermatologic disorders.

Tea Tree Oil

The tea tree oil (TTO) is a volatile essential oil, extracted from the leaves and branches of *Melaleuca alternifolia*, a small tree indigenous to Australia. The primary uses of tea tree oil have historically capitalised on the antiseptic and anti-inflammatory actions of the oil. This oil contains about 100 chemical compounds, mainly terpene hydrocarbons, monoterpenes, sesquiterpenes and their corresponding alcohols. The use of tea tree oil is mainly topical and is indicated for the treatment of different dermatological problems.

Tinea Pedis

In a double-blind, placebo-controlled trial (Satchell et al. 2002a, b), 158 patients with tinea pedis were randomised to receive either placebo (20 % ethanol, 80 % polyethylene glycol) or 25 % or 50 % tea

tree oil mixed in ethanol and polyethylene glycol solution and were instructed to apply the solution to the affected areas twice daily for 4 weeks.

The results obtained showed that the two tea tree oil solutions (both 25 and 50 %) were found to be significantly more effective than placebo at eradicating the infection and that 25 % tea tree oil is associated with fewer complications than 50 % tea tree oil solution.

Few people developed dermatitis in response to the tea tree oil and had to drop out of the study, but most people did not experience any significant side effects.

Another double-blind, placebo-controlled trial (Tong et al. 1992) followed 104 people with athlete's foot who were given either a 10 % tea tree oil cream, the standard drug tolnaftate or placebo. The results showed that tea tree oil reduced the symptoms of athlete's foot more effectively than placebo but less effectively than tolnaftate. Neither treatment cured the infection in 100 % of the cases, but each treatment cured many cases. Other recent studies have demonstrated significant advances in the treatment of tinea pedis with TTO.

Dandruff

One placebo-controlled study has examined 126 people with mild to moderate dandruff. Patients were treated daily for 4 weeks with placebo or with a shampoo containing 5 % tea tree oil. The use of the shampoo has significantly reduced the symptoms of dandruff.

The dandruff was scored on a quadrant-area-severity scale and by patient self-assessment scores of scaliness, itchiness and greasiness. The 5 % tea tree oil shampoo group showed a 41 % improvement in the quadrant-area-severity score compared with 11 % in the placebo group ($P<0.001$). Unfortunately, this study (Satchell et al. 2002b) was not double blind, and for this reason, the results cannot be taken as completely reliable.

Head Lice

Head lice represent a very common problem, affecting millions of people each year, especially preschool and elementary school-aged children. Usually therapy is initiated with products that contain permethrin (1 %) or pyrethrins plus piperonyl butoxide when resistance to these products is not suspected. Plant-based compounds have been taken into account for their activity against both insects and their eggs and could represent an interesting approach to limit the emergence and the spread of the parasitic infestation.

The TTO activity against these insects has been evaluated in a randomised, assessor-blind, comparative, parallel study of 123 children with live head lice.

Children were divided into three groups: the first used a product containing tea tree oil and lavender oil 1 % (TTO/LO), the second a product that caused lice asphyxiation and the last one a product containing pyrethrins and piperonyl butoxide (P/PB); these products were applied two or three times at weekly intervals according to manufacturer instructions. The results showed that TTO/LO product and head lice "suffocation" products were both >97 % effective and were almost four times as effective as the P/PB product.

Acne

One of the first clinical trials of TTO evaluated the efficacy and skin tolerance of 5 % tea tree oil gel in the treatment of mild to moderate acne when compared with 5 % benzoyl peroxide lotion. Both treatments had reduced the number of comedones, although the onset of action in the case of tea tree oil was slower, but encouragingly, fewer side effects were experienced by patients treated with tea tree oil.

A randomised double-blind study (Enshaieh et al. 2007) has examined 60 patients with mild to moderate symptoms of acne. In this study, the participants were divided into two groups and treated with placebo or with 5 % tea tree oil gel. During the period of the study (45 days), the researchers assessed the seriousness of acne in two ways: by counting the total number of acne lesions and by looking at the acne severity on a standardised index (ASI). The results showed that the tea tree oil gel was significantly more

effective than placebo in reducing both, the number of acne lesions and even their gravity. This effect was possibly due to the anti-inflammatory and antibacterial effects of the tea tree oil.

Moreover the low and minimal side effects of this treatment render it as a suitable treatment option for mild to moderate acne vulgaris.

Other Pharmacological Properties

Tea tree oil has antimicrobial and anti-inflammatory properties, but there is still a lack of clinical evidence demonstrating efficacy against bacterial, fungal or viral infections. Some studies have demonstrated that tea tree preparations were effective, safe and well tolerated and could be considered in regimens for eradication of MRSA (methicillin-resistant *Staphylococcus aureus*) carriage (Flaxman and Griffiths 2005).

Borage Seed Oil

Borage oil is a light yellow liquid extracted from the seeds of *Borago officinalis*. Purified borage oil is rich in polyunsaturated fatty acids (PUFAs) like a minimum of 23 % γ-linolenic acid (GLA), known to be essential for normal skin function. Borage seed oil is used both as skin treatment and a dietary supplement, especially to fortify infant foodstuffs with essential fatty acid.

Chronic Dermatitis and Atopic Eczema

The GLA is necessary for proper growth and development of the epidermis. It is also required for synthesis of the important long-chain ceramides necessary to protect against dry skin and has anti-inflammatory effects. This oil finds many applications in dermatology, especially when there is alteration of the epidermal barrier and reduced water content in the epidermis like atopic dermatitis, seborrheic dermatitis, contact dermatitis, psoriasis, hives, etc.

Some clinical studies have shown that γ-linolenic acid contained in borage oil is effective against seborrheic and atopic dermatitis, in children.

Aloe Vera Gel

Aloe vera gel is the colourless mucilaginous gel obtained from the parenchymatous cells in the fresh leaves of *Aloe vera* (L) Burm. The main chemical components of aloe gel are water and polysaccharides (pectin, hemicellulose, glucomannan, acemannan and mannose derivatives). It also contains amino acids, lipids, sterols, tannins and enzymes.

Aloe vera gel is widely used for the external treatment of minor wounds and inflammatory skin disorders. Aloe gel is also indicated as a topical herbal remedy in dermatology. It is used for treatments of small wounds, irritations, first and second degree burns and abrasions.

Fresh aloe gel has been used for the treatment of radiation ulcers. Burns treated with the aloe vera gel healed faster (11.8 days) than the burns treated with petroleum jelly gauze (18.2 days).

Prodrugs

146

Andy Goren, John McCoy, and Torello M. Lotti

Key Points

- Prodrugs are a class of inactive drugs that require a physical or chemical transformation in order to provide a therapeutic benefit.
- Prodrugs may render certain compounds safer or more effective.
- Endogenously activated prodrugs present novel opportunities for the development of predictive response testing.
- Exogenously activated prodrugs in dermatology can be activated by a wide spectrum of natural or artificial agents.
- Prodrugs should always be considered as a first-line therapy in complex and chronic dermatological diseases requiring systemic therapy.
- Side effects from the prodrug or the activator need to be considered carefully prior to starting a prodrug regimen.
- Prodrug development is one of the most promising fields in medical research due to the targeted delivery and lower systemic adverse events associated with prodrug regimens.

General Principles

Prodrug Definition

Prodrugs are a unique class of inactive or weakly active drugs that require a physical or chemical transformation in order to exert a therapeutic benefit.

History

The earliest documented use of a prodrug dates to the nineteenth century. A white crystallized powder, hexamine, demonstrated antibacterial activity against urinary tract infections. While initially believed to have direct antibacterial effect, careful examination determined that hexamine exerted its antibacterial activity after hydrolysis to formaldehyde in the acidic environment of urine. Similarly, the mechanisms of action of many drugs were shown to require activation by chemical or enzymatic processes. The twenty-first century experienced the largest expansion

in the development of prodrugs, as directed drug design encountered the challenges of drug absorption, distribution, metabolism, and excretion toxicity (ADMET). In fact, it is estimated that approximately 10 % of all medicines can be classified as prodrugs and over 30 % of approved small molecule drugs are prodrugs.

Prodrug Design

Overcoming the challenges of ADMET is perhaps the most difficult problem encountered in drug design. Many candidate drug compounds exhibit promising safety and effectiveness in in vitro and in animal models but fail human studies largely due to pharmacokinetics, limited bioavailability at the site of therapy, and toxicity. Thus, during the early stages of drug development, prodrugs that can be activated on demand at a focal site of therapy by an endogenous or exogenous agent should always be considered as the preferred choice. Dermatological drugs present unique challenges and opportunities: while the skin allows for focal delivery, there remain the obstacles of barrier penetration, systemic side effects, and rapid metabolism. For this reason, dermatological prodrug design should take advantage of exogenous activation and skin permeability as well as the unique environment presented by the sebaceous glands and hair follicles.

Classification and Mechanisms of Action

There are several methods to classify prodrugs. Traditionally, prodrugs have been classified based on the location of their activation (e.g., intracellular vs. extracellular). Here, we suggest an alternative classification (Goren-McCoy-Lotti prodrug classification) for dermatological prodrugs. Due to the fact that cutaneous application provides for easy focal delivery, the classification of dermatological prodrugs is more appropriately based on whether the prodrug is activated by an endogenous (Class I) or exogenous (Class II) agent.

Class I. Endogenous Prodrug Activation

Endogenously activated prodrugs are converted to their active form by enzymatic catalysis or chemical degradation. The human hair follicle serves as a good model to illustrate prodrug activation in dermatology. Minoxidil, an oral drug originally developed to treat hypertension, was found to elicit hair growth as a side effect. The Upjohn Corporation exploited this property and subsequently developed a topical prodrug for the treatment of androgenetic alopecia (AGA). The mechanism of action by which minoxidil promotes hair growth is not known, but it was discovered that sulfation of minoxidil to its bioactive form, minoxidil sulfate, is required to exert its therapeutic effect. Minoxidil sulfate cannot be readily administered, as it is unstable. An interesting corollary to the use of endogenously activated prodrugs is that pretreatment testing of the endogenous activator can serve as a treatment response predictor. In the case of minoxidil, the follicular activity of the sulfotransferase enzyme (SULT1A1) that is required to convert minoxidil to its bioactive form, minoxidil sulfate, serves as a biomarker for treatment response.

Predicting minoxidil treatment response for androgenetic alopecia is an important clinical tool due to the long treatment duration (a minimum of 6 months) and low therapeutic efficacy (approximately 30–40 % of patients regrow hair) of the drug. To demonstrate the clinical utility and validity of such a prodrug response biomarker, a colorimetric enzymatic assay for SULT1A1 in plucked hair follicles was developed (Frame et al. 2000). The assay couples minoxidil sulfation and the conversion of p-nitrophenyl sulfate to p-nitrophenol (Fig. 146.1). Each molecule of minoxidil that is sulfated results in the production of p-nitrophenol, which is optically visible at 405 nm (i.e., appears yellow). In a clinical study that was subsequently conducted, the assay demonstrated 95 % sensitivity and 73 % specificity in predicting minoxidil treatment response for AGA (Goren et al. 2014a, b). Thus, when considering the use of an endogenously activated prodrug, it is important to evaluate the bioavailability of the

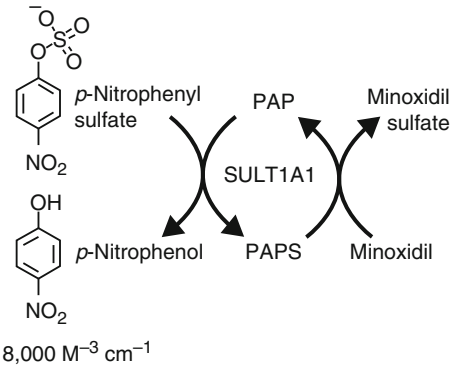

Fig. 146.1 Assay for predicting minoxidil response based on SULT1A1 enzymatic activity

activator and (if possible) administer a predicative response test.

Class II. Exogenous Prodrug Activation

The skin, being an external organ, presents a unique opportunity to combine topical or systemic prodrugs with a broad array of exogenous agents to deliver targeted therapy with minimal side effects. A further subclassification into artificial and naturally occurring prodrug activators is useful for determining applicability in dermatology practice. Artificial prodrug activators, such as artificial ultraviolet light therapy, require numerous visits to a light therapy clinic. The applicability of such a therapy may be limited by lack of equipment at the dermatological practice or poor patient compliance due to the demanding regimen (2–3 times a week for an average of 12 weeks). Naturally occurring prodrug activators, such as sunlight or resident bacterial flora, may provide an alternative to artificial activators when their use is feasible and results in improved patients' compliance.

Class II. a. Artificial Exogenous Activation

Artificial light and chemical agents are routinely used with prodrugs in dermatological practices. Some regimens require multiple sessions, such as psoralen plus ultraviolet A (PUVA), while others, such as photodynamic therapy (PDT), require a single session. PDT, a common treatment for actinic keratosis, basal cell carcinoma, Bowen's disease, and mycosis fungoides, is a prodrug-mediated therapy activated by artificial light. PDT is administered in two steps: (1) a photosensitive porphyrin-based prodrug is applied topically, orally, or interlesionally; (2) after sufficient absorption, the lesion is exposed to a suitable light source (typically blue light). The porphyrin, once excited with a specific wavelength of light, interacts with endogenous molecular oxygen to produce reactive singlet oxygen, which is cytotoxic to the targeted tissue and results in tissue destruction.

Class II. b. Natural Exogenous Activation

Natural exogenous activation of prodrugs holds the promise of higher patients' compliance in chronic disease management. Sunlight provides one such example as it is abundant. The sun at sea level provides minimal ultraviolet phototherapy benefit due to the development of erythema prior to achieving therapeutic dosage. The sun produces a wide spectrum of UVB and UVA radiation. Natural UVB radiation below 300 nm is harmful radiation leading to erythema with no therapeutic benefit. An optimal psoriasis action spectrum was determined to be radiation between 300 and 320 nm in the ultraviolet B (UVB) spectrum. A novel prodrug, Photocil (US FDA), recently introduced by Applied Biology, Inc., acts as selective filter for natural sunlight (McCoy et al. 2014). When applied to psoriasis lesions, Photocil attenuates a large percent of the sun's radiation below 300 nm and above 320 nm while allowing therapeutically beneficial radiation to reach the lesion. Several clinical studies have demonstrated that Photocil and other natural means (such as locals below sea level) of attenuating sunlight radiation below 300 nm clear psoriatic skin lesions on par with artificial light sources (Goren et al. 2014a, b; Harari et al. 2007). Since compliance is a major obstacle in artificial UVB

light therapy due to the numerous visits required to a specialized photo clinic, the sun as a natural exogenous activator of the prodrug Photocil can significantly improve patients' compliance.

Perhaps the most promising area of research in prodrug development is the use of microorganisms for exogenous prodrug activation. The recent breakthroughs unraveling the vast human microbiome and virome open the door to potential therapeutic applications utilizing these organisms. Among many projects utilizing symbiotic microorganism for prodrug activation, Goren and McCoy (subject of multiple US PTO patents) are currently exploring the use of microbial species residing in the hair follicle to sulfate minoxidil in patients deficient in SULT1A1. The future will undoubtedly bring many novel approaches to exploiting our symbiotic residents.

Indications and Other Uses

Prodrugs should always be considered as a first-line therapy in complex and chronic dermatological diseases requiring systemic therapy. The delivery, toxicity, and pharmacokinetics of traditional systemic drugs pose safety and efficacy concerns in long-term therapy often leading to lower compliance, lower response, and lower patient satisfaction.

While a prodrug regimen may address the delivery, toxicity, and pharmacokinetics issues associated with traditional drugs, the majority of prodrugs in dermatology require a more complicated treatment regimen. Typically, two steps are required: application of the prodrug followed by the activator agent. As such, it is important to assess the possibility of reduced compliance and hence ineffectiveness of the prodrug therapy. Each patient's lifestyle must be weighed carefully prior to selecting a treatment regimen. Keep in mind that in some cases of Class II. b. activators, such as natural light therapy with the novel prodrug Photocil, the more complicated prodrug regimen may yield higher compliance due to the convenience of at-home therapy.

Side Effects

Side effects of prodrugs regimens require careful evaluation of the patient to exclude contraindications related to (1) the inactive prodrug, (2) the activator, and (3) the activated prodrug. An activator, such as Class II. a. or Class II. b light therapy, may elicit an adverse event in patients prone to polymorphic light eruptions or those who have previously experienced an HSV outbreak. Keep in mind that the activated prodrug may elicit an adverse event as well. One example is the case when an endogenous enzyme that is deficient is required for the degradation of the activated prodrug.

Prodrug Regulation

When prescribing prodrugs, it is important to note that prodrugs are legally treated as drugs. Hence, the same limitations of off-label prescription and reimbursement should be taken into consideration. In addition, the activation mechanism of externally activated prodrugs may also be regulated as a drug or medical device in case of Class II. a. activators.

Retinoids

147

Jean-Hilaire Saurat and Olivier Sorg

Key Points

Retinoids are analogues of vitamin A:

- They exert multiple effects on cellular differentiation and proliferation, the skin, the immune system, embryonic development, and several other organs.
- They regulate gene transcription via nuclear receptors – retinoic acid receptors (RARs) and retinoid X receptors (RXRs).
- Topical retinoids are used to treat photoaging, moderate acne, and a number of other conditions; the limiting factor is skin irritation, but teratogenicity risk is very low to nonexistent.
- Systemic retinoids are used only orally:
  - Oral isotretinoin is still the single most effective drug for severe acne; other retinoids do not have such effects.
  - Other retinoids are used orally in many disorders of cornification (isotretinoin, acitretin) and in psoriasis, especially pustular forms (acitretin), pityriasis rubra pilaris (acitretin), cutaneous T-cell lymphoma (acitretin, bexarotene), and chronic hand eczema (alitretinoin).
  - Teratogenicity is the most important systemic toxicity.

J.-H. Saurat (✉) • O. Sorg
Department of Fundamental Medicine, Geneva University of Medical Center, Geneva, Switzerland
e-mail: jean.saurat@unige.ch

General Principles

Vitamin A (retinol) and related compounds with either structural (retinol derivative) or functional (vitamin A activity) analogy are known as retinoids (Sorg et al. 2006).

Natural Retinoids (Fig. 147.1)

They include retin*o*l, retinaldehyde (retin*a*l), and all the metabolites resulting from normal metabolism in humans. All-*trans*-retinoic acid (tretinoin, a*t*-RA) is the natural ligand of the nuclear receptors RARs. 13-*cis*-retinoic acid, a *cis*/*trans* isomer (isotretinoin, 13-*cis*-RA), is a naturally occurring metabolite retinoic acid. 9-*cis*-retinoic acid is another isomer of retinoic acid (alitretinoin, 9-*cis*-RA) and a ligand of RXR, thus also a natural metabolite of a*t*-RA.

Synthetic Retinoids (Fig. 147.1)

Looking for retinoids with better therapeutic focused activity, synthetic molecules with "vitamin A activity" were developed: etretinate, acitretin, adapalene, tazarotene, and bexarotene already reached the market. Historically, therapeutic retinoids were classified as first (tretinoin, isotretinoin), second (alitretinoin, acitretin, etretinate), and third generation (adapalene, tazarotene, bexarotene) (Orfanos et al. 1997).

DOI 10.1007/978-3-662-45139-7_147, © Springer-Verlag Berlin Heidelberg 2015

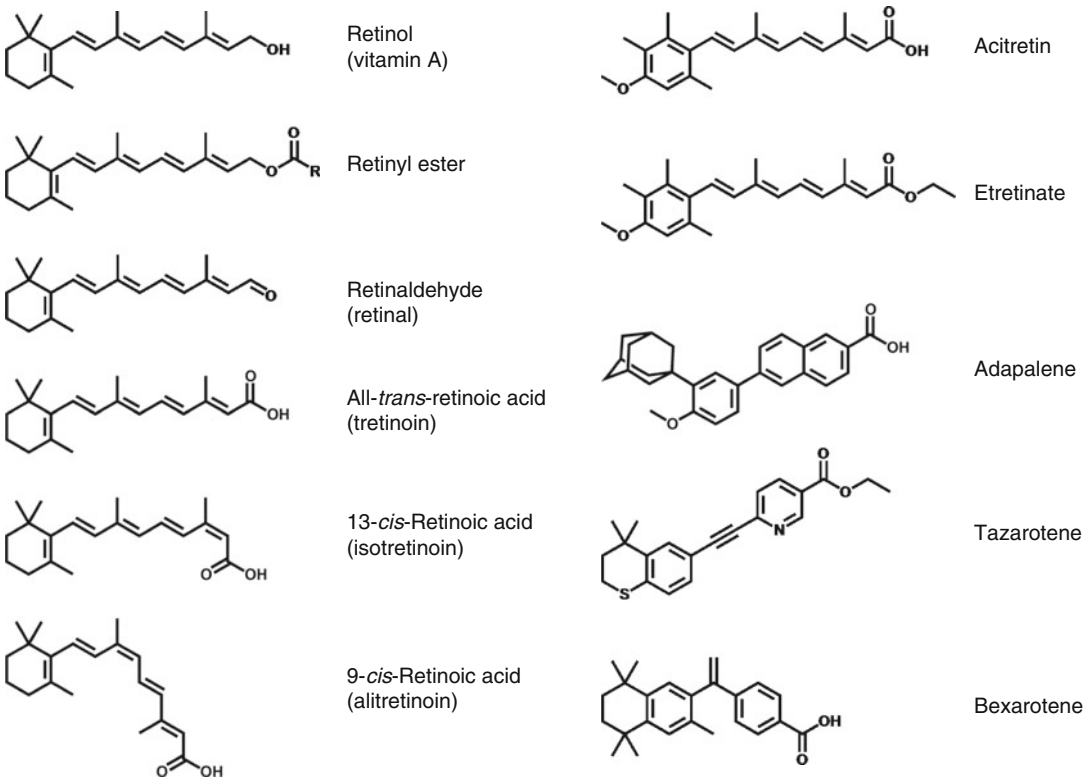

Fig. 147.1 Molecular structure of retinoids

Mechanisms of Action

Retinoids are involved in the regulation of diverse biologic functions. They affect cellular growth, differentiation, and morphogenesis; inhibit tumor promotion and malignant cell growth; exert immunomodulatory actions; and alter cellular cohesiveness.

Vitamin A Metabolism

Vitamin A is ingested as retinyl esters and as provitamin A carotenoids such as beta-carotene. Within the intestinal lumen, retinyl esters are hydrolyzed to retinol, which is then absorbed and stored in the liver in the ester form (especially retinol palmitate; Fig. 147.2). In the blood retinol is bound to a complex of retinol-binding protein (RBP) and transthyretin and delivered to organs including the skin (Blomhoff and Blomhoff 2006) (Table 147.1 and Fig. 147.3).

The biologically active ligands are thought to be generated within the target cell, a process designated as an "intracrine" system. In a reversible process, retinol (vitamin A alcohol) is oxidized to retinaldehyde (vitamin A aldehyde), which is then irreversibly converted to retinoic acid (vitamin A acid); subsequently, isomerization to 13-*cis* and 9-*cis* may occur. It is likely that, when given for therapeutic purpose, precursors such as retinol and retinaldehyde, which do not bind to receptors, exert part of their effects because they are transformed into retinoic acid within the target cell (Saurat et al. 1994).

Retinoid Receptors

Retinoids modulate DNA transcription through the binding to two distinct families of nuclear receptors: RAR (retinoic acid receptors) and RXR (retinoid X receptors). RAR and RXR belong to a superfamily of nuclear receptors that

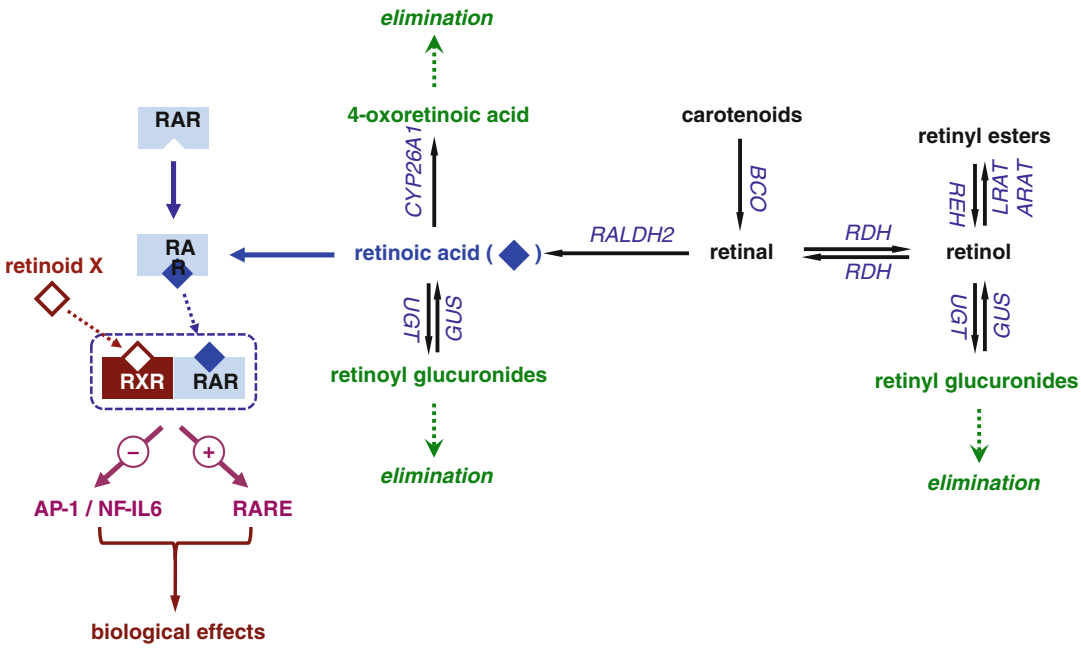

Fig. 147.2 Biology and metabolism of retinoids. Carotenoids, retinol, and retinyl esters come from the diet. In mucosal cells of the small intestine, retinyl esters are hydrolyzed to retinol, and some carotenoids may be converted to retinal. There is a reversible conversion between retinyl esters, retinol, and retinal, whereas retinal is oxidized irreversibly to retinoic acid, which binds to the nuclear receptors RAR. An unidentified retinoid X then binds to the RXR receptors, and the RAR/RXR heterocomplex binds to retinoic acid-response elements (RARE) in the promoter region of various genes, which induces their expression. On the other hand, the RAR/RXR complex inhibits the transcription factors AP-1 and NF-IL6

Table 147.1 Endogenous retinoid concentrations in the blood and the skin

	Retinoic acid	Retinaldehyde	Retinol	Retinyl esters
Blood	10	<5	2,500	400
Dermis	<5	<5	700	600
Epidermis	<5	<5	200	1,200

Values in (pmol/g ww)

act as ligand-activated transcription factors. The RAR receptor family contains three receptor isotypes (α, β, and γ) encoded by different genes. a*t*-RA binds only to RAR, whereas 9-*cis*-RA binds both to RAR and RXR. RAR functions as a heterodimer with RXR, whereas RXR may act as a homodimer or participate in the formation of heterodimers with a variety of other nuclear receptors, including vitamin D3, thyroid hormone, and peroxisome proliferator-activated receptors. Such heterodimers can provide a mechanism for cross talk between nuclear hormone signaling pathways.

Retinoid action is mediated via multiple pathways and results in the complex activation or inhibition of a large set of coordinately regulated genes. Retinoids can induce both direct and indirect effects on gene transcription as well as nongenomic effects (Dawson and Zhang 2002).

Classification

Natural Versus Synthetic

Natural retinoids are those that, besides their therapeutic or cosmeceutic use, are also constituents of the diet (e.g., retinol, retinaldehyde, and retinyl esters) and are transformed in the body into active molecules such as retinoic acid and its *cis*/*trans*

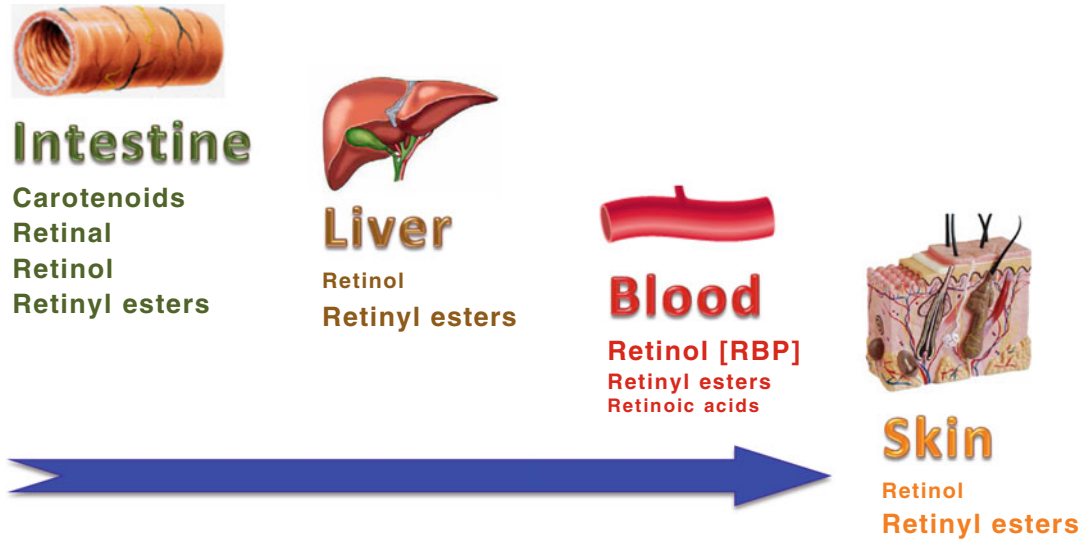

Fig. 147.3 Transport of retinoids in the body. Vitamin A precursors from the diet are converted to retinol and retinal in the small intestine and transported to the liver where there are stores mostly as retinyl esters. Endogenous retinoids circulate in the blood mostly as retinol bound to retinol-binding protein (RBP). In the skin, a part of retinol is esterified to fatty acids

isomers. These retinoids are thus inactive precursors of biologically active RAR/RXR agonists.

Synthetic *nonnatural* retinoids are analogues that have been synthetized for specific therapeutic purpose, with the aim of minimizing unwanted effects and optimalizing efficacy. This growing group includes etretinate, acitretin, adapalene, tazarotene, and bexarotene (Fig. 147.1).

Topical Versus Systemic

Retinoids can be given orally for the treatment of skin diseases that cover large surface areas and/or are not responsive to topical retinoid treatment. Four are currently available for oral use: isotretinoin, alitretinoin, acitretin, and bexarotene.

Eight are currently available for topical use: retinyl esters, retinol, retinaldehyde, tretinoin, isotretinoin, adapalene, tazarotene, and bexarotene.

Retinoids Currently Used in Humans as Drugs or Cosmeceutics

Natural retinoids and some retinoate esters are currently used in humans as drugs or cosmeceutics (Sorg et al. 2006).

Retinyl Esters

Retinyl esters are the main storage form of vitamin A in the body. The liver and the skin may esterify retinol to fatty acids and may release retinol from its esters. Retinyl esters also have the best tolerance profile among topical retinoids. For these reasons, many cosmetic products claim containing retinyl esters. The concentration is not always indicated. The claimed specificity of a given RE, based on the type constitutive fatty acid, is seldom based on sound scientific evidence.

Retinol

Topical retinol is more easily converted to retinoic acid and shows better antiaging activity than retinyl esters. It is usually available in Europe at the concentration of 0.1 % or more for the cosmeceutic treatment of skin aging. So far no controlled studies have compared its activity, which appears as inferior, to that of retinoic acid (Kang et al. 1995). It is likely that much higher concentrations should have a better activity profile; however, concentrations as high as 1 % may lead to side effects such as skin irritation without providing better antiaging activity. The best compromise between a good activity and minimal side effects seems to be 0.1 % (Bellemère et al. 2009).

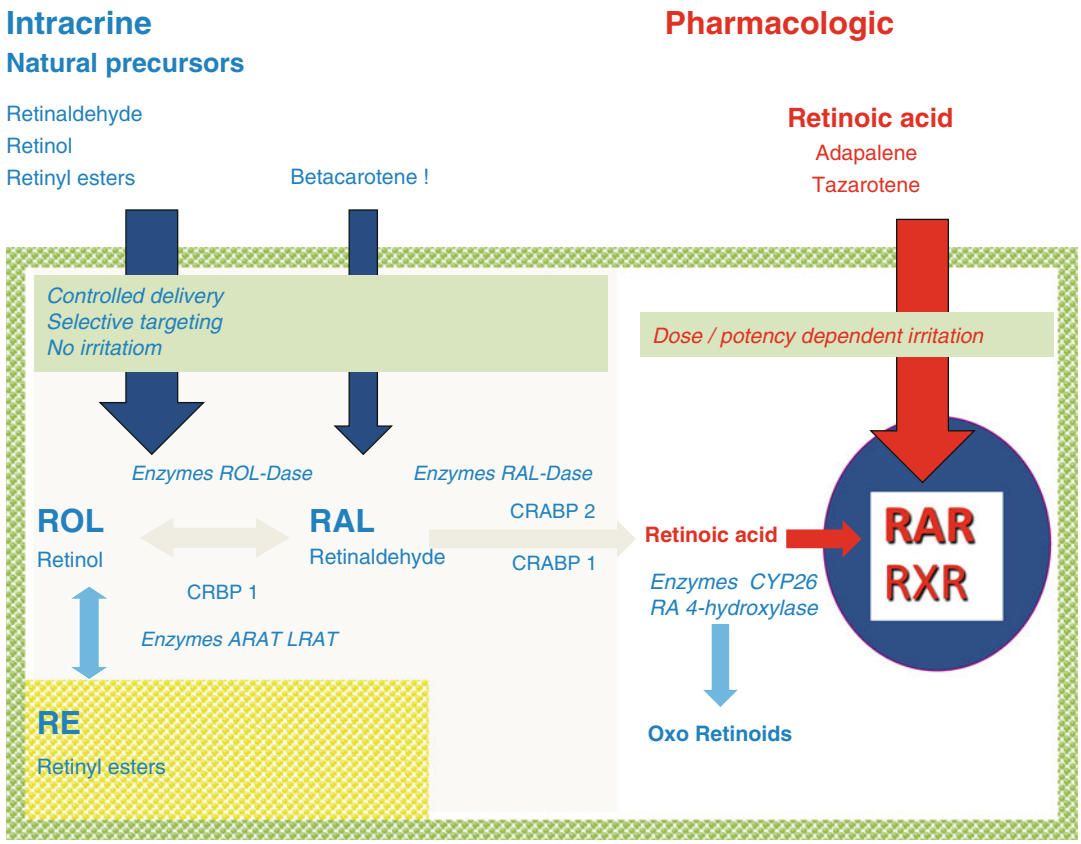

Fig. 147.4 Intracrine mechanism of endogenous retinoids. Retinoic acid precursors such as retinyl esters, retinol, and retinal are converted in the keratinocytes to retinoic acid, which exert its biological action via its binding to nuclear receptors, which are expressed in keratinocytes too

Retinaldehyde

Retinaldehyde, with retinol and retinyl esters, belongs to the natural retinoic acid precursors (Sorg and Saurat 2014). In the skin topical retinoids exert their biological activity via an intracrine mechanism: they are converted to the biologically active retinoic acids in keratinocytes, the cells that respond to retinoic acid activity by expressing RAR and RXR receptors (Fig. 147.4). Retinaldehyde requires only one step to be converted to retinoic acid, compared to retinol and retinyl esters, which required two and three steps, respectively (Fig. 147.2). In vivo animal and ex vivo human studies show that retinaldehyde is the natural retinoid with the best penetration profile through the skin (Antille et al. 2004; Tran et al. 2001), a property that makes topical retinaldehyde a good candidate to reverse UV-induced cutaneous vitamin A deficiency (Tran et al. 2001; Sorg et al. 2001, 2005). Its aldehyde functional group gives it a unique reactivity among retinoids; for instance, retinaldehyde exerts antibacterial activity against *P. acnes*, a property not shared with other retinoids (Péchère et al. 1999, 2002), which explains its use as adjuvant therapy of mild acne in association with glycolic acid (Kasraee et al. 2005; Tran et al. 2005). All these properties make retinaldehyde a good topical retinoid. Indeed, retinaldehyde was shown to exert retinoid biological activity in human skin in vivo (Saurat et al. 1994). It is available in concentrations between 0.015 and 0.1 %.

Retinaldehyde was demonstrated to be as effective as tretinoin in treating photodamage in less extensive trials but has a better tolerance profile (Creidi et al. 1998). It has been hypothesized that the reduction in side effects seen with retinaldehyde (compared with retinoic acid) may be

due to a more controlled delivery of retinoic acid to target cells via the "intracrine pathway" (Fig. 147.4), thus limiting an "overload" of retinoic acid in the skin, which may be responsible, in part, for producing the cutaneous irritation.

Based on CYP26 enzymatic activity, the biological activity of topical retinoids is as follows: Retinoic acid > retinaldehyde > retinol >> > retinyl esters. Their tolerance profile, however, is almost the reverse ranking order: retinyl esters > retinol = retinaldehyde > > retinoic acid.

Another use of topical retinaldehyde, based on its specific activity, is its high potential in inducing hyaluronate production by keratinocytes: this explains its use in association with defined hyaluronate fragments of intermediate size (HAFi) in dermatoporosis (i.e., chronic skin insufficiency; Kaya and Saurat 2007) and the prevention of topical steroid-induced skin atrophy (Kaya et al. 2006a, b)

Retinoic Acid

Topical retinoic acid has a long history of clinical and cosmeceutical use due to its high biological activity (Craven and Griffiths 1996; Kligman et al. 1986). It is available in the concentration of 0.025, 0.05, and 0.1 % for the treatment acne and photoaging (0.05 %). Other uses include a large number of skin conditions.

Acute promyelocytic leukemia, characterized by a chromosomal translocation involving the retinoic acid receptor alpha gene, is treated by oral retinoic acid in combination with an anthracycline chemotherapeutic agent (daunorubicin or idarubicin) or arsenic trioxide (Douer 2000).

Isotretinoin (13-*cis*-Retinoic Acid)

Isotretinoin is a naturally occurring physiologic compound resulting from the metabolism of vitamin A. 13-*cis*-RA and a*t*-RA are two interconvertible isomers that differ in their elimination half-lives: approximately 20 h for isotretinoin and 1 h for retinoic acid. Isotretinoin undergoes first-pass metabolism in the liver and subsequent enterohepatic recycling. In plasma, isotretinoin is greater than 99 % bound to plasma proteins, mainly albumin. There is neither liver storage nor adipose tissue storage, in sharp contrast to vitamin A. The major metabolite of isotretinoin (4-oxo-isotretinoin) is produced by oxidation. Isotretinoin and its major metabolites are excreted in the urine and feces.

After discontinuation of isotretinoin, natural concentrations of 13-*cis*-RA and its major metabolites are reached within 2 weeks, ranging from 2 days for a*t*-RA to 10 days for 4-oxo-isotretinoin. Therefore, 1 month of post-therapy contraception provides an adequate safety margin.

Among natural and synthetic retinoids, only oral isotretinoin significantly suppresses sebum production and considerably improves acne. Since no clear affinity with isotretinoin has been identified for any retinoid receptor, other mechanisms of action must be considered (Torma 2001). It may even be that isotretinoin is a prodrug that targets the sebaceous gland with sebosuppressive metabolites. Isotretinoin has a specific antiproliferative effect on human sebocytes due to cell cycle arrest and sebocyte apoptosis, which was not recapitulated by alitretinoin or tretinoin. Isotretinoin-induced apoptosis was shown to be an RAR-independent mechanism. Transcriptional profiling of patient skin and cultured human sebaceous gland cells indicated that lipocalin 2 was among the genes most highly upregulated by 13-*cis*-RA (Nelson et al. 2008).

Alitretinoin (9-*cis*-Retinoic Acid)

Alitretinoin is an endogenous pan-agonist retinoid that binds to both RAR and RXR retinoid receptors (Molin and Ruzicka 2008); likewise, it is considered as the natural endogenous ligand for RXRs. Topical alitretinoin gel (0.1 %) is indicated for cutaneous Kaposi's sarcoma, whereas systemic alitretinoin is a newly launched therapy for refractory chronic hand eczema (CHE) in adult patients. The absorption of alitretinoin from the gastrointestinal tract is variable and dose proportional over the therapeutic range from 10 to 30 mg. The absolute bioavailability of alitretinoin has not been determined. Alitretinoin is metabolized by oxidation by CYP3A4 isoenzymes of the liver into 4-oxo-alitretinoin. Both compounds undergo isomerization into all-t*rans*-retinoic acid and 4-oxo-all-*trans*-retinoic acid. The major metabolite 4-oxo-alitretinoin is further glucuronidated and eliminated in the urine.

Alitretinoin concentrations return to normal range within 1–3 days after treatment cessation and elimination is mainly in the urine. Elimination half-life of unchanged alitretinoin ranges between 2 and 10 h. The mechanism of action of alitretinoin in chronic hand eczema is unknown. Alitretinoin has demonstrated immunomodulatory and anti-inflammatory effects that are relevant to skin inflammation. Alitretinoin suppresses the expansion of cytokine-activated leukocyte subsets and antigen-presenting cells.

Acitretin

Acitretin is the major metabolite and the pharmacologically active compound of etretinate. Although acitretin and etretinate are equally effective, acitretin has a profound pharmacokinetic advantage because of its more rapid elimination compared with etretinate. The major serious adverse effect of synthetic retinoids is teratogenicity, and, therefore, the length of time that these drugs are present in the body is of great importance. Acitretin has an elimination half-life of 2 days. Paradoxically, acitretin activates all three RAR subtypes but binds poorly to them.

Re-esterification of acitretin to etretinate may occur when acitretin is taken simultaneously with alcohol. This finding prompted the manufacturer to extend the time of contraception in patients taking acitretin to 2 years after discontinuation, as it is for etretinate. The FDA advises a contraceptive period of at least 3 years for acitretin, based on the pharmacokinetics of acitretin and etretinate observed in clinical trials and on previous safety experience with etretinate. The pharmacokinetic advantage of acitretin over etretinate still holds true for all women who strictly avoid alcohol during treatment and for 2 months thereafter (Wiegand and Chou 1998).

The mechanism of action is still not clearly understood. Evidence supports a normalization of differentiation and proliferation as well as a modification of inflammatory responses and neutrophil function.

Adapalene

Adapalene is a light-stable, rigid, synthetic retinoid with higher affinity for RAR-β/RAR-γ than for RAR-α. Since RAR-β is not expressed in keratinocytes, RAR-γ is the primary retinoid target receptor for adapalene in the epidermis, provided the effects are receptor mediated.

Tazarotene

Tazarotene is a prodrug that is rapidly converted by skin esterases to its free carboxylic acid (tazarotenic acid), which is the active metabolite. It has a higher affinity for RAR-β/RAR-γ than for RAR-α and no affinity for RXR. Because of its rapid metabolism, systemic exposure is low. Tazarotenic acid upregulates tazarotene-inducible genes (TIG-1,2,3) and has antiproliferative properties.

Bexarotene

Bexarotene, a specific RXR-selective retinoid (rexinoid), was approved in 1999 in the USA for treatment of cutaneous T-cell lymphoma (CTCL) refractory to at least one systemic therapy. This compound is about 100-fold more potent at binding to RXR than to RAR. Bexarotene probably has a clearance profile similar to that of isotretinoin, with a terminal half-life between 7 and 9 h (Ethan-Quan and Wolverton 2001). The exact mechanism of action of bexarotene in CTCL is still unknown, but bexarotene probably acts through regulation of cellular differentiation and proliferation and induction of apoptosis. Clinical and biochemical central hypothyroidism frequently occur with bexarotene and is probably mediated through suppression of thyrotropin β-subunit (TSH-β) secretion by the thyrotrope cells of the anterior pituitary, which express RXR-γ.

Indications and Other Uses

Topical Retinoids

The most important element in topical therapy with retinoids is education of the patient. Local skin irritation can be expected with some but not all compositions, and noticeable beneficial effects may take weeks or months to appear. Administration of topical retinoids should be titrated depending on cutaneous irritant reactions, which may mean decreasing the concentration

or the frequency of application. It is generally wise to begin with the lowest strength formulation and then increase the concentration as tolerance builds. Another tactic is to start by applying a given concentration every other day. Daytime moisturizers with sunscreen are important components of any topical retinoid regimen. Of interest is the fact that irritation was initially considered, as a sine-qua-non condition for efficacy. Recent molecular and kinetic data indicate that retinoic acid-induced irritation is rather the mere indication of a toxic overload, whereas optimal gene regulation and therefore adequate response may be reached with either lower concentrations or ligands with controlled delivery to the receptors through the intracrine pathway (see Figs. 147.2 and 147.4).

Acne

Topical retinoids, of which tretinoin (a*t*-RA) is the prototype, are mainstays in the treatment of comedonal acne, even if their effect is slow and almost never reaches complete clearance. The primary mode of action is believed to be normalization of abnormal differentiation and proliferation of the follicular epithelium, which leads to the loosening and unseating of microcomedones. In addition, topical retinoids may have anti-inflammatory activity. The mechanism of action of topical isotretinoin is similar to that of topical tretinoin because of intraepithelial isomerization of isotretinoin to tretinoin. In contrast to oral isotretinoin, topical isotretinoin (as well as all topical retinoids) fails to suppress sebum production to the same extent. Isotretinoin is less irritating, but it is probably somewhat less effective than tretinoin. Because of the birth defects induced by the oral formulation, topical isotretinoin has not received FDA approval in the USA.

The newer synthetic derivatives, adapalene and tazarotene, are intended to improve tolerability while maintaining similar efficacy when compared to topical tretinoin. In company-sponsored studies of patients with acne, adapalene 0.1 % gel was as effective as tretinoin 0.025 % gel against open and closed comedones and more effective against inflammatory lesions and with less irritation (Cunliffe et al. 1997a). Tazarotene 0.05 and 0.1 % topical gels significantly decreased acne lesions compared with control patients, with tolerability clinically comparable to tretinoin.

Topical retinoids should be applied to the entire face, once a day (if tolerated) and in the evening to minimize inactivation by UV. The medication should be applied on dry skin to minimize dermal absorption correlating with skin irritation. Patients should be advised that the therapeutic response is slow, and beneficial effects do not become evident for weeks to months. An apparent exacerbation may occur during the first month of therapy, representing the externalization of deeper-seated acne lesions as the follicular epithelium is loosening. Topical retinoids, except in very mild acne, should be used concomitantly with antibiotics (oral or topical) or benzoyl peroxide, which have different modes of action and which target primarily inflammatory lesions

Psoriasis

Topical application of tretinoin or isotretinoin has limited efficacy in psoriasis. Tazarotene has been the first topical retinoid proven effective in treating mild to moderate plaque-type psoriasis not exceeding 10–20 % of the body surface area. When compared with twice-daily fluocinonide cream, tazarotene 0.05 and 0.1 % gels applied once daily were shown to produce similar reductions in plaque elevation. Nevertheless, tazarotene 0.1 % gel carries a significantly lower risk of relapse than does fluocinonide cream after 12 weeks off therapy (Lebwohl et al. 1998). A combination of tazarotene and a mid-potency corticosteroid improved efficacy and reduced the incidence of local adverse effects; this combination may also reduce the risk of corticosteroid-induced atrophy.

Photoaging

Photoaging is the consequence of UV-induced damage to the skin characterized by decreased expression of RXR-α and RAR-γ in the acute setting, by upregulation of AP1-driven matrix

metalloproteinases, as well as severe depletion of the vitamin A content of the epidermis (since retinoids are destroyed by the UV) (Wang et al. 1999). Topical retinoids promote cellular dedifferentiation and extracellular matrix synthesis, including an increase in hyaluronic acid via a CD44-mediated mechanism (Calikoglu et al. 2006). Histologic findings after repeated topical application of tretinoin include: compaction of the stratum corneum, epidermal hyperplasia (acanthosis), correction of atypia (e.g., actinic keratoses), dispersion of melanin granules, increased dermal collagen synthesis, and angiogenesis. These findings explain the reported smoother skin, rosy glow, decrease in blotchy pigmentation, and diminished fine lines and wrinkles.

Several controlled studies have clearly demonstrated that topical retinoids, particularly tretinoin and more recently tazarotene cream, improve fine wrinkling and lighten uneven pigmentation. It generally takes 3–6 months of daily applications to see significant clinical improvement. Cutaneous irritation is usually the limiting factor. It is not clear if the observed effects on parameters of skin aging with these retinoids are associated with a beneficial long-term effect. It has been reported that long-term use of retinoic acid for the prevention of actinic keratosis in fact resulted in a trend to increased incidence of actinic keratosis and squamous cell carcinoma. One hypothesis was that retinoic acid does not reverse the UV-induced vitamin A epidermal depletion due to the irreversible bioconversion of retinaldehyde to retinoic acid. This suggests that cosmeceutical retinoids such as retinaldehyde, which do restore epidermal vitamin A pool, warrant consideration (see section "Retinaldehyde").

Other Indications

Other approved indications include topical treatment of cutaneous Kaposi's sarcoma by alitretinoin (9-*cis*-RA) 0.1 % gel and topical treatment of CTCL by bexarotene (Breneman et al. 2002). Non-approved indications of topical retinoids are numerous.

Retinoids in Cosmeceutic Ranking and Issues

As mentioned in section "Retinaldehyde", the tolerance profile and the clinical efficacy are inversely correlated:

- Tolerance profile: retinyl esters > retinol = retinaldehyde > > retinoic acid
- Clinical efficacy: retinoic acid > retinaldehyde > retinol >> > retinyl esters

There is a need to determine the best dose of each retinoid, specifically natural retinoids such in consideration of the above.

Topical Retinoids and the Sun

Retinoids strongly absorb light in the UVA-UVB range (260–380 nm), which means that cutaneous retinoids are photosensitive. Indeed, in vitro and animal and human in vivo studies demonstrated a dose-dependent decrease of epidermal retinoids, leading to epidermal vitamin A deficiency (Sorg and Saurat 2014). Given that cutaneous vitamin A deficiency is a risk factor for skin cancer development (Fields et al. 2007), those topical retinoids that replenish endogenous levels of epidermal vitamin A might exert a preventive effect against sun-induced skin cancers (Carr et al. 2011).

The use of topical retinoids, which are photosensitive, raises the question of the possible phototoxic reactions. Although no photoallergic or phototoxic reactions have been proven for topical retinoids, many patients note a decreased tolerance to UV radiation shortly after sun exposure (Sachs and Voorhees 2011). This reaction is often accentuated by a sensation of heat, raising the question of involvement of infrared irradiation. For this reason, it is recommended to avoid sun exposure after the application of topical retinoids.

Systemic Retinoids

Psoriasis/Acitretin

Pustular Psoriasis

The efficacy of acitretin in plaque-type (Arechalde and Saurat 2000a) and pustular psoriasis has been established on several randomized

multicenter trials. The best results have been obtained in acral or generalized (von Zumbusch) pustular psoriasis, in which acitretin is considered to be first-line therapies. The lesions of both localized and generalized pustular psoriasis, as well as those of erythrodermic psoriasis, cleared more rapidly with etretinate or acitretin monotherapy than with most other therapies (White et al. 1985). Rebound does not usually occur after stopping treatment, and reintroduction produces a beneficial response.

Plaque-Type Psoriasis

Plaque-type psoriasis responds variably to acitretin. The decrease in the Psoriasis Area and Severity Index (PASI) score is approximately 60–70 %, depending on the dosage and duration of treatment. Many of the plaques may remain, but they are thinner with less scale and erythema. Approximately 20 % of patients may be considered treatment failures (Lowe 1991).

An initial worsening of the disease with an increase in erythema and/or extent of the involvement may occur within a few days of starting therapy at a dosage of 0.5–1 mg/kg/day (i.e., 30–70 mg/day in adults). A therapeutic dosage scheme utilizing a low-dosage (10 mg/day) acitretin initially, followed by progressively increasing the dosage, seems preferable. Different dosages (10–75 mg/day) were compared with placebo in a double-blind fashion. At the end of an 8-week treatment period in two studies, acitretin at doses of 25 and 50 mg/day (Lassus et al. 1987) or 50 and 75 mg/day (Goldfarb et al. 1988) was superior to placebo.

Total clearance of psoriatic lesions usually requires a combination of therapies, such as topical corticosteroids, topical vitamin D derivatives, anthralin (dithranol) or photochemotherapy (PUVA), bath PUVA, and NB-UVB phototherapy (Lebwohl 1999; Saurat et al. 1988).

Isotretinoin is less effective on psoriasis than acitretin although some efficacy has been shown in combination with PUVA (Saurat 1998). Nevertheless, isotretinoin is still used in women of childbearing age with psoriasis who need systemic retinoids to avoid the long post-acitretin contraception period.

Acne/Isotretinoin

Isotretinoin is still the only compound that has been shown to induce long-term remissions and even "cure" acne, because it is the only one that affects, albeit not to the same degree or permanently, all the etiologic factors implicated in acne: sebum production, comedogenesis, and colonization with *Propionibacterium acnes*.

Only oral isotretinoin, among all natural and synthetic retinoids tried in humans, was found to suppress sebum excretion and to significantly improve acne. The "sebo-specificity" of oral isotretinoin still remains unexplained in 2014.

In the early 1980s, isotretinoin use was restricted to patients suffering from severe nodulocystic acne. Its use has been extended to (i) patients with less severe disease who have responded unsatisfactorily to conventional therapies such as long-term antibiotics, (ii) patients with moderate acne that may induce scars, and (iii) patients with significant psychosocial consequences of acne in interpersonal and work-related difficulties. Studies with quality-of-life instruments have shown that isotretinoin treatment significantly improves sociability and self-esteem.

It was initially considered that optimal benefit would be achieved with a high daily dose of approximately 1 mg/kg/day (Layton et al. 1993). However, this high dose can induce undesirable effects, and similar short-term therapeutic results were obtained with doses below 0.5 mg/kg/day. In order to avoid the higher incidence of relapses associated with low-dose isotretinoin, the latter approach required that the treatment be maintained over a longer period of time in order to reach a critical cumulative dose threshold. The concept of cumulative dose (mg/kg body weight), introduced by Harms in 1989 (Harms et al. 1989), is the total amount of oral isotretinoin taken by the patient over the entire duration, divided by the body weight. A patient weighing 50 kg and receiving 25 mg/day of isotretinoin for 100 days would have received a cumulative dose of 50 mg/kg (25 mg × 100 = 2,500 mg, divided by 50 kg = 50 mg/kg). Data from several centers indicated that post-therapy relapse was minimized by a treatment course amounting to a total of at least 120 mg/kg (Lehucher-Ceyrac and

Weber-Buisset 1993), with no further therapeutic gain beyond about 150 mg/kg (Cunliffe et al. 1997b). Low dose (20 mg/daily) was also found to be effective in the treatment of moderate acne with a low incidence of severe side effects and at a lower cost than higher doses (Amichai et al. 2006).

A lag period of 1–3 months may exist before the onset of the therapeutic effect. Continued healing after the discontinuation of therapy is regularly observed. Approximately one-third of patients with acne require a second course of therapy, either for persistent disease or for relapse. The only predictive factor of resistance to isotretinoin treatment is closed comedonal acne and microcystic acne (Lehucher-Ceyrac et al. 1999).

A flare of disease during the first few weeks of treatment, and subsequent evolution of acne cysts into lesions resembling pyogenic granulomas, may be observed with isotretinoin treatment. The incidence of this side effect may be reduced by using lower doses of isotretinoin during the first 3–4 weeks of therapy.

Women of childbearing potential must have a (in the USA, two) negative pregnancy test(s) and practice effective contraception for 1 month prior to therapy, during therapy, and for 1 month after completing therapy. To afford a sufficient safety margin, a 1-month post-therapy contraceptive period is mandatory because plasma concentrations of isotretinoin return to physiologic levels within 10 days of completing therapy.

Isotretinoin has a more limited effect on hidradenitis suppurativa and dissecting cellulitis of the scalp. These disorders may occur together as part of the follicular occlusion tetrad. Some investigators recommend oral isotretinoin during the weeks or months preceding surgery for hidradenitis suppurativa and sometimes also during the postoperative period.

Cutaneous T-Cell Lymphoma/ Bexarotene

The FDA approved bexarotene as oral therapy for the treatment of CTCL that is refractory to at least one systemic therapy and as a gel formulation for cutaneous manifestations of early-stage refractory or persistent CTCL (Duvic et al. 2001a). Toxicity including hypothyroidism was a significant problem at the high oral doses. Response rates are approximately 50 % for the patients with advanced CTCL (Duvic et al. 2001b). Bexarotene combination therapies with PUVA/NB-UVB, IFN-α, denileukin diftitox, and methotrexate have also been evaluated by various clinical trials and case reports (Gniadecki et al. 2007).

Isotretinoin and acitretin are somewhat effective and are considered to be of equal potency in the treatment of mycosis fungoides (MF). They can be used in combination with PUVA, interferon, or systemic chemotherapy. Despite initial improvement of the various stages of MF, it is often impossible to maintain remissions with these retinoids as monotherapy.

Chronic Hand Eczema/Alitretinoin

A multicenter study of 6-month duration in adults with severe chronic hand eczema has shown responses to oral alitretinoin of this complex and difficult-to-define condition. Responses defined as “clear or almost clear hands” were seen in up to 47 % of patients treated with 30 mg, 27.5 % with 10 mg, and 16.6 % with placebo. Treatment was well tolerated, with dose-dependent adverse events including headache, mucocutaneous events, hyperlipidemia, and decreased free thyroxine and thyroid-stimulating hormone. The median time to relapse, defined as recurrence of 75 % of initial signs and symptoms, was 5.5–6.2 months in the absence of anti-eczema medication (Ruzicka et al. 2008).

Alitretinoin is indicated in adults who have severe chronic hand eczema that is unresponsive to potent topical corticosteroids (Ruzicka et al. 2008; Bollag and Ott 1999). Treatment should be initiated at 30 mg daily and duration should not exceed 12–24 weeks. Low dosage of 10 mg is indicated in patients experiencing adverse events at high dosage. High dosage induces a more rapid improvement and has a higher response rate. Clinical signs of improvement appear after only 4 weeks of treatment. Patients with a marked hyperkeratosis are best responders to treatment. Therapy should be interrupted in case of a nonresponse after 12 weeks. Eighty percent of the

patients who previously achieved "clear" or "almost clear" hands following treatment with alitretinoin 30 mg per day also respond to a second course of treatment, making intermittent therapy suitable for the long-term management of CHE.

A head-to-head comparison of alitretinoin (high-cost therapy) with acitretin (lower-cost therapy) would be interesting, since it is not unlikely that revisiting acitretin in this indication with an adequate RCT may help some patients.

Other "Off-Label" Clinical Uses

The pleomorphic effects of retinoids explain the broad potential benefit they could provide to patients with skin disease. Many other skin disorders respond to retinoids, but the benefit has been established in controlled studies for only a few of them (Arechalde and Saurat 2000b).

Ichthyosis/Acitretin

The best results can be obtained by using acitretin for non-bullous congenital ichthyosiform erythroderma and lamellar ichthyosis. Good results have also been observed in patients with recessive X-linked ichthyosis and ichthyosis vulgaris; however, the more limited severity of these diseases does not usually require systemic retinoid therapy. Given the lifelong duration of these disorders, intermittent courses are sometimes prescribed.

Darier's Disease/Acitretin

Severe forms of Darier's disease are often treated with systemic retinoids, but therapy should be initiated with a very low dose (e.g., acitretin 10 mg/day) in order to prevent an initial exacerbation of the disease; usually 20 mg/day is sufficient for significant improvement.

Pityriasis Rubra Pilaris/Acitretin

Early treatment with retinoids appears to offer the best chance for clearing pityriasis rubra pilaris (PRP). In extensive cases, concomitant use of methotrexate may be advantageous. Etretinate (now acitretin) has been considered to be superior to isotretinoin for the treatment of adult-onset PRP (Clayton et al. 1997).

Rosacea/Isotretinoin

In severe forms or treatment-resistant rosacea, isotretinoin often has a greater effect on inflammatory lesions than on vascular lesions (Erdogan et al. 1998). A low daily dose (10 mg) is often sufficient, although acne vulgaris regimens are sometimes used in severe disease.

Premalignant and Malignant Skin Lesions/Acitretin

Acitretin were both shown to be effective in the treatment of premalignant skin lesions, including HPV-induced tumors and actinic keratoses. In the nevoid basal cell carcinoma syndrome and in xeroderma pigmentosum, these drugs are able to dramatically reduce the incidence of malignant evolution of cutaneous lesions. A double-blind study demonstrated that acitretin (30 mg/day for 6 months) prevented the development of premalignant and malignant cutaneous neoplasms in renal transplant recipients (Bavinck et al. 1995).

Graft-Versus-Host Disease

In an open study, 3 months of etretinate therapy produced encouraging responses among patients with refractory sclerodermatous chronic GVHD resulting from allogeneic bone marrow transplantation (Marcellus et al. 1999).

Lichen Sclerosus

The use of acitretin is an effective treatment for patients with severe vulvar (and, occasionally, nongenital) lichen sclerosus. It may be used intermittently in patients who are intolerant of or resistant to topical therapies.

Lupus Erythematosus

Both isotretinoin and acitretin have been used successfully in patients with various forms of lupus erythematosus (LE). Recurrence of the lesions after completion of the treatment is a limiting factor. Comparable therapeutic efficacy has been observed for acitretin and hydroxychloroquine in chronic cutaneous LE and in subacute cutaneous LE (Ruzicka et al. 1992).

Side Effects

Topical Retinoids

By far the most common side effect of topical retinoids is skin irritation. This "retinoid dermatitis" occurs within the first month of treatment and tends to recede thereafter. It responds to a temporary reduction in the frequency or amount of retinoid application and to application of moisturizers. Desquamation and peeling correspond to the hyperproliferative response of the epidermis to tretinoin mediated by RARs, but the erythema does not seem to be receptor mediated (Kang et al. 1995). The perioral area of the face is most sensitive to peeling and use in this area can be limited or avoided.

Although no photoallergic or phototoxic reactions have been proven for topical retinoids (Sachs and Voorhees 2011), many patients note a decreased tolerance to UV radiation shortly after sun exposure. This reaction is often accentuated by a sensation of heat, raising the question of involvement of infrared irradiation.

Potential teratogenicity from long-term use of topical retinoids is very low: systemic absorption of topically applied retinoids is inconsequential in both animal and human studies (Jick 1998), and there is no evidence that application of tretinoin causes congenital disorders. Temporary worsening of acne may occur within the first weeks of therapy. Uncommon side effects include transitory hypo- or hyperpigmentation, koebnerization of psoriasis (especially tazarotene), allergic contact dermatitis, and ectropion.

Systemic Retinoids

Teratogenicity is the most troublesome adverse effect of oral retinoids. The side-effect profile of systemic retinoids qualitatively resembles the toxic effects of vitamin A or hypervitaminosis A syndrome.

Teratogenicity

Systemic retinoids are potent teratogens, and this is the major concern in treating fertile women with oral retinoids. With regard to teratogenicity, no safe minimal dose during pregnancy has been established. The range of defects seen in retinoid embryopathy includes multiple abnormalities (Lammer et al. 1985). The abnormalities may lead to premature birth, spontaneous abortion, or fetal death. The putative mechanism involves toxic effects on neural crest cells, particularly in the case of exposure during the fourth week of gestation.

No typical retinoid embryopathy malformations have been reported in pregnancies where the male partner had been the one taking acitretin or isotretinoin at the time of conception. However, it is usually recommended that men who are actively trying to father children avoid systemic retinoid therapy.

Skin and Mucous Membrane Adverse Effects

Dose-dependent mucocutaneous toxicity is the most commonly observed side effect with oral retinoids, and it mainly reflects a decreased production of sebum, reduced stratum corneum thickness, and altered skin barrier function. Dry lips or cheilitis is the earliest and the most frequent sign that appears after starting therapy. Dryness of the mouth accompanied by thirst and dryness and fragility of the nasal mucosa leading to epistaxis are also frequently observed.

Systemic retinoids do have different mucocutaneous side-effect profiles. Isotretinoin causes more mucosal dryness, and acitretin has been associated with higher incidences of alopecia and palmoplantar peeling, whereas bexarotene induces milder mucocutaneous and ocular side effects than do other classes of retinoids.

Dyslipidemia

Hypertriglyceridemia is the most frequently observed systemic effect of retinoid therapy. Isotretinoin and etretinate/acitretin elevate triglycerides in 50 % and cholesterol in 30 % of

treated patients (Koo et al. 1997; Pilkington and Brogden 1992; Tangrea et al. 1993), whereas bexarotene induces elevated triglycerides and cholesterol in approximately 79 and 48 % of patients, respectively (Duvic et al. 2001a).

Baseline serum lipids should be obtained before initiating bexarotene therapy, as well as every 1–2 weeks during therapy until levels become stable (generally in 4–8 weeks). For other oral retinoids, monitoring levels monthly for the first 2 months and then at 2- to 3-month intervals (if there are no increases in dosage) is adequate in cases of normal baseline lipid levels and an absence of risk factors (obesity, high alcohol intake, diabetes). Discontinuation of therapy is suggested if fasting triglycerides reach 800 mg/dl (8 g/l). Less severe increases may be treated by dose reduction, withdrawing therapy until normalization of serum lipids occurs, and dietary or physical management. In some instances, lipid-lowering agents may be indicated (Vahlquist et al. 1995). Coadministration of statins, including atorvastatin, in case of hypercholesterolemia, or fenofibrate for hypertriglyceridemia (or both) with bexarotene, is recommended to treat the retinoid-induced hyperlipidemia and to lower the risk of pancreatitis (Wiegand and Chou 1998; Talpur et al. 2002). Some authors even recommend to start in all patients a fibrate (ex fenofibrate) on day 7 before bexarotene treatment initiation (Gniadecki et al. 2007).

The effect of retinoid-induced hyperlipidemia, and its management during long-term therapy, on the development of atherosclerotic cardiovascular disease is unknown. Retinoids probably cause hyperlipidemia by interfering with lipid clearance. Bexarotene increases the expression of apolipoprotein C-III, which prevents the uptake of lipids from very-low-density lipoproteins (VLDL) into cells (Vu-Dac et al. 1998).

Liver Toxicity

Transitory abnormal elevations in serum transaminases have been reported in approximately 20 % of patients treated with either etretinate or acitretin, occurring much less frequently with isotretinoin or bexarotene therapy. Circulating levels of alkaline phosphatase, lactic dehydrogenase, and bilirubin may also become elevated during retinoid therapy. Liver function abnormalities, mostly mild, usually occur between 2 and 8 weeks of starting therapy, and they return to normal within another 2–4 weeks, despite continued therapy. Severe or persistent hepatotoxic reactions have been seen in less than 1 % of patients. Acitretin therapy elicited no biopsy-proven hepatotoxicity in a 2-year prospective study, thus suggesting that periodic liver biopsy is not necessary (Roenigk et al. 1999). No specific studies have evaluated the use of retinoids in patients with hepatic insufficiency. However, since retinoids are metabolized by hepatic cytochrome P450 isoenzymes (CYP3A4) and undergo partial biliary elimination, significant hepatic insufficiency may be expected to interfere with drug elimination. Transaminase elevations to greater than three times the upper limit of normal should lead to discontinuation of retinoid therapy. With two- to threefold transaminase elevations, therapy should be withdrawn until normalization of tests of liver function occurs (Wiegand and Chou 1998). Other causes should simultaneously be excluded.

Ophthalmologic Side Effects

The most common ocular retinoid effects are dryness and irritation. Alterations in visual function, mainly nyctalopia, excessive glare sensitivity, and changes in color perception, have also been reported (Safran et al. 1991). Competitive inhibition of ocular retinol dehydrogenase by retinoids, resulting in decreased rhodopsin formation, may be the cause of hemeralopia.

Central Nervous System and Psychiatric Effects

CNS side effects are rare. Although individual signs of increased intracranial pressure, such as headache, nausea, and vomiting, are occasionally observed, the complete syndrome with papilledema (pseudotumor cerebri) and blurred vision is considered very rare (Bonnetblanc et al. 1983). Concomitant use of other drugs associated with intracranial hypertension (e.g., cyclines) is considered a major risk factor for developing pseudotumor cerebri and should therefore be avoided

(Lee 1995). Examination for papilledema should be performed immediately when a patient receiving retinoid therapy complains of persistent headache, especially if it is accompanied by visual changes, nausea, or vomiting, or when pseudotumor cerebri is otherwise suspected.

There have been anecdotal reports suggesting a causal association between isotretinoin therapy in acne patients and severe depression, psychosis, and suicide attempts. That isotretinoin increases the risk of depression has actually not been proven (Bigby 2008). Patients with depressive symptoms or suicidal ideation should be carefully monitored and advised before treatment initiation (Bigby 2008).

Hypothyroidism

Clinical and biochemical central hypothyroidism occurred in 40 % of patients in the CTCL trials with bexarotene, and it was rapidly and completely reversible with cessation of therapy without any clinical sequelae (Duvic et al. 2001a; Sherman et al. 1999). This effect is probably mediated through suppression of thyrotropin β-subunit (TSH-β) secretion by the thyrotrope cells of the anterior pituitary, which express RXR-γ. Free T4 levels should therefore be monitored before and during bexarotene therapy and normalized with thyroid hormone replacement as necessary. Some authors recommend an initial dose of levothyroxine 0.05 mg daily, increased to 0.1–0.125 mg daily, depending on the bexarotene dose and the free T4 level which should be normal (Gniadecki et al. 2007).

Gastrointestinal Side Effects

Uncommon nonspecific gastrointestinal complaints have been reported in association with retinoid therapy. Synthetic retinoids have been temporally linked with other toxicities, such as inflammatory bowel disease; however, no cause-and-effect relationship has been established.

Bone Toxicity

Several reports have implicated synthetic retinoids, including acitretin and isotretinoin, after long term use, in the formation of diffuse hyperostosis of the spine (diffuse idiopathic skeletal hyperostosis [DISH]), as well as calcification of tendons and ligaments, particularly in the ankles (Carey et al. 1988). Prospective studies have shown that the effect of retinoids on bone, if present at all, is likely to involve worsening of preexisting skeletal overgrowth rather than induction of de novo changes. Even long-term use of isotretinoin in acne patients rarely causes clinically significant radiologic abnormalities, as most hyperostoses are asymptomatic and clinically insignificant (Ling et al. 2001).

Osteoporosis has been observed with hypervitaminosis A and after long-term therapy with etretinate but not with isotretinoin (DiGiovanna et al. 1995).

Muscle Effects

Muscular pain and cramps can be observed in patients taking acitretin; however, these symptoms are associated primarily with isotretinoin, especially in individuals involved in vigorous physical activity. Occasionally, elevated creatine kinase levels may be observed. Increased muscle tone and axial muscle rigidity and myopathy were reported to be related to etretinate and acitretin therapy, respectively (Lister et al. 1996).

Hematologic Toxicities

A high incidence (28 %) of dose-related leukopenia was reported in the studies of bexarotene in CTCL, occurring as early as 2–4 weeks, with a decrease in neutrophils rather than lymphocytes (Duvic et al. 2001a). Hematologic abnormalities are much less common with other retinoids, but careful hematologic monitoring in HIV-infected patients is warranted.

Contraindications

Topical Retinoids

Topical retinoids should be avoided during pregnancy and nursing, due primarily to medicolegal issues raised by the teratogenicity of oral isotretinoin. Concomitant use of irritating topical products should be avoided.

Systemic Retinoids

The absolute contraindications are pregnancy or women contemplating becoming pregnant, noncompliance with contraception, breastfeeding, and hypersensitivity to preservatives present in acitretin's capsule (parabens). Relative contraindications are leukopenia, moderate to severe hypercholesterolemia or hypertriglyceridemia, significant hepatic (especially bexarotene) or renal dysfunction, hypothyroidism (especially bexarotene), young children, and suicidal ideation (isotretinoin).

Drug Interactions

The following should be avoided or used with caution:

- *Cyclines* such as tetracycline, doxycycline, and minocycline may increase intracranial pressure. This side effect was in fact related to the very high doses of isotretinoin used in the early development of the drug (up to 2 mg/kg). Currently, the doses used are much lower, and patients given isotretinoin 0.25 mg/kg for severe rosacea may benefit of short periods of association with a cyclin.
- *Alcohol* may increase conversion of acitretin to etretinate (special problem in women; see above) and hepatotoxicity.
- *Methotrexate* may have synergistic liver toxicity with retinoids; however, combination used with caution in patients with PRP or severe psoriasis.
- *Vitamin A supplement* carries the risk of hypervitaminosis A.
- *Azoles and macrolides* are CYP3A4 inhibitors that may increase retinoid drug levels and resultant potential toxicity.
- In contrast, *antituberculosis drugs* (rifampin) *and anticonvulsants* (phenytoin and carbamazepine) may decrease the drug levels of retinoids via CYP 3A4 induction.
- Retinoids may also increase the drug levels of cyclosporine via competition for CYP3A4 metabolism (Wiegand and Chou 1998).

Use in Infant Children and Elderly

There are no significant age-related problems with prescribing retinoids, provided contraindications and drug interactions cited above are considered.

Pregnancy and Breastfeeding

Systemic Retinoids

All systemic retinoids are teratogenic and are absolutely contraindicated during pregnancy and lactation (FDA category X), which should be excluded by a pregnancy test before considering retinoid therapy and then at regular intervals (e.g., monthly in the case of isotretinoin) during its administration. Two pregnancy tests are recommended before instituting isotretinoin therapy. Pregnancy is not only an absolute contraindication to starting therapy; it must also be avoided throughout therapy and for an appropriate interval after completion of therapy. Adequate contraception for at least 1 month before therapy is required for all systemic retinoid therapy. Acitretin requires contraception for 3 years (USA) or 2 years (Europe) after cessation of therapy, whereas isotretinoin, bexarotene, and alitretinoin require contraception for just 1 month after cessation of therapy.

Topical Retinoids

Although no evidence exists for teratogenicity of topical retinoids in humans (Nohynek et al. 2006; Sorg et al. 2007), they are nevertheless not recommended for use during pregnancy. Since no dermatologic condition that is known to be responsive to topical retinoids, and which may be observed during pregnancy, is life threatening to the mother or fetus, it is wiser to postpone treatment until after delivery (primarily due to medicolegal rather than scientific data in the opinion of these authors). The same recommendations are also valid for lactating women, as it is not known whether topical retinoids pass into the breast

milk. Consequently, topical retinoid use is not recommended during breastfeeding; it may cause unwanted effects in the nursing baby.

Scabicides and Pediculicides

148

Anna Górkiewicz-Petkow

Key Points

- Scabies and pediculosis are still very common and often underestimated ectoparasite infections.
- In new epidemiologic situations – prolonged life, various immunodeficiency syndromes and development of resistant strains – new challenging problems in the therapy are raised; therefore, new considerations should be made about the schedules for treating individuals and endemics in school, nursing homes, hospitals and underdeveloped communities. The use of medications is often influenced by economical circumstances.
- The treatment of scabies and pediculosis is mainly external, but it is possible to use orally administered drugs in difficult cases (ivermectin).
- Effectiveness of the various treatments depends not on the drug itself but on proper use and epidemiological approach to the treatment.

A. Górkiewicz-Petkow
Department of Dermatology,
Warsaw Medical University,
Warsaw, Poland
e-mail: anna.gorkiewicz@wp.pl

General Principles

Scabies and pediculosis are still very common and often underestimated ectoparasite infections. Chronic, not recognized infestations complicated by local secondary bacterial infections can lead to superinfection with MRSA or nephritogenic strains of *Streptococcus* spp. in the population.

Infestations may result not only from human mites or insects but also from domestic animals, grain and dust mites. In the presence of unexplained, often puzzling, pruritic, papular eruption, the possibility of an ectoparasite infestation should always be considered. In new epidemiological situations – prolonged life, acquired immunodeficiency syndrome (AIDS) and other immunodeficiency syndromes and development of resistant strains – new challenging problems in therapy are raised. Laboratory studies indicate that acaricide resistance in scabies is likely mediated by P-glycoprotein (for ivermectin) and sodium channel blocker mutations (for permethrin). Addition of enzyme synergists can reverse resistance in vitro to permethrin, suggesting a possible improvement of local therapy. Therefore, new considerations should be made about the schedules for treating individuals and endemics in schools, nursing homes, hospitals and underdeveloped communities. It is important that treatment schedules with different medications should correlate with life cycle of the scabies mite or lice acting on living organisms and/or eggs. The frequency of use of different insecticides varies in

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_148, © Springer-Verlag Berlin Heidelberg 2015

different countries. Among well-known drugs, there are often locally produced herbal preparations recommended for the treatment. The use of different medications is also influenced by economic circumstances. Effectiveness depends not only on the drug itself but also on their proper use according to the instructions and epidemiological approach to the treatment. In ectoparasite infections it is necessary to treat not only the patient but also the contacts and often the environment to prevent the reinfection and spread of the disease.

An accurate and informative education programme is also very useful. The treatment of scabies and pediculosis is mainly external, but there are reports on possible use of orally administered drugs (co-trimoxazole, ivermectin, thiabendazole). The most effective insecticides originate from plants (pyrethrins) or from pesticides used in agriculture and for household purposes (lindane, malathion, carbaryl); therefore, the therapy has some potential toxicity.

Table 148.1 Efficacy of different scabicides

Drug	Treatment regimen	Day 28 (cure rate %)
Permethrin	5 % topical single dose	100
Benzyl benzoate	12.5 % topical single dose	70.5
	12.5 % topical two doses 1 day apart	95.8
Sulphur	8–10 % single dose	42.4
	8–10 % three consecutive nights	90.6
Ivermectin	200 mg/kg single dose	90.0
	200 mg/kg two doses 14 days apart	89.7
Ivermectin	1 % topical single dose only to affected sites	100.0
Lindane	1 % topical two applications 1 week apart (*withdrawn from treatment in many countries*)	69.1

Modification from Mounsey and McCarthy (2013)

Topical Treatments (Tables 148.1 and 148.2)

Pyrethrins and Pyrethroids

The insecticide properties of flowers in the genus *Chrysanthemum* have been known for centuries and originate from ancient Persia. Pyrethrum is the name of dried flowers; pyrethrins are the active component of pyrethrum. The first commercialized production started in Dalmatia in 1840; then by the year 1860 the Dalmatian powder was widely used as household insecticide. In 1948 the first synthetic pyrethroid (permethrin) was developed. Based on oral LD values in rats, permethrin is about 3 times less toxic than malathion, 15 times less than carbaryl and about 40 times less than lindane and DDT. In 1986, permethrin was introduced for the treatment of head lice and soon after for scabies. Percutaneous absorption in human studies is less than 2 %; permethrin is rapidly detoxified by esterase hydrolysis in the blood and most body tissues including the skin. Plasma levels of permethrin following topical application of 5 % cream formulation in human clinical trials were below detectable levels. In adverse reactions some irritation of the skin may occur at the time of treatment. Some concern has been expressed about possible allergic reactions, since some individuals are allergic to pyrethrum, but a sensitizing factor was removed from the final product. For topical treatment single dose or two doses 1 week apart is recommended. Permethrins have also been used for impregnation of beds, curtains and military clothes to prevent mosquito, ticks and tsetse fly bites.

Commercial Preparations

- Lyclear dermal cream (5 % permethrin), scabicide
- Lyclear cream rinse (1 % permethrin), pediculicide
- Nix (1 % permethrin), pediculicide

Acetylcholinesterase Inhibitors

Malathion, Carbaryl

From 1954, acetylcholinesterase inhibitors have been used as pesticides in agriculture and for household purposes. In 1971 malathion and in 1977 carbaryl were introduced as pediculicides and scabicides following evidence of the

Table 148.2 Pharmacologic treatment of pediculosis (head lice, pubic lice)

Treatment	Ovicidal	Directions
Permethrin 1 % lotion (Nix)	No	Apply to damp hair and leave on for 10 min; then rinse and repeat in 7 days
Pyrethrins 0.3 %/piperonyl butoxide 4 % shampoo or mousse	No	Apply to dry hair and leave on for 10 min, and then rinse
Malathion 0.5 % lotion	Partial	Apply to dry hair enough to sufficiently wet the hair and scalp; allow to dry naturally Shampoo 8–12 h later, rinse and use lice comb Repeat after 7–9 days if live lice still are present
Spinosad 0.9 % topical suspension (Natroba)	Yes	Apply to dry hair and leave on for 10 min; then rinse and repeat in 7 days only if live lice are seen
Ivermectin (Stromectol not approved for treatment of pediculosis)	Partial	200–400 mcg/kg, given on day 1 and day 8 (total of two doses) in refractory cases
Infection of eyelashes: physostigmine eye ointment, malathion and carbaryl aqueous sol. With caution. Petrolatum, mercuric oxide eye ointment, mechanical removal of lice		

Modification from Gunning et al. (2012)

emergence of the resistance of head lice to other drugs, mainly organochlorine insecticides. Malathion is rapidly broken down by hepatic enzymes in humans and warm-blooded animals, thus diminishing its cholinesterase inhibitory properties. In insects it is converted to the oxy-analogue, which is an active metabolite. Human studies with inhalation of malathion aerosols, the use of powder or dust on the skin, indicated no inhibition of cholinesterase activity. Possible poisoning manifestations include visual disturbances, respiratory difficulty and gastrointestinal hyperactivity. Malathion and carbaryl are also ovicides for head lice, although the ovicidal activity is not complete. Malathion is absorbed into keratin within 6 h and confers residual, protective effect against reinfection for about 6 weeks. The effectiveness of carbaryl is determined by the components of the bases used in preparations. Both insecticides are degraded by heat. Generally, the medications are well tolerated, safe and effective.

Commercial Preparations

- Carylderm lotion (carbaryl 0.5 % alcohol-based lotion), Carylderm shampoo (pediculicide)
- Derbac-C (carbaryl 1 % aqueous solution), Derbac-C shampoo (pediculicide)
- Derbac-M (malathion 0.5 % aqueous solution) (pediculicide/scabicide)
- Prioderm (malathion 0.5 % alcohol lotion), Prioderm shampoo (pediculicide)
- Malathion powder – disinfection of clothes

Chlorinated Insecticides

Gamma-Hexachlorocyclohexane (Lindane)

This drug has been known since 1940 to be both a potent pesticide and an effective topical scabicide/pediculicide. Until recently the use of lindane was limited only by the potential side effects which appear to have occurred almost entirely in children when it was not used properly or was accidentally ingested. Adverse effects are associated with central nervous system (CNS) effects (vertigo, seizures, convulsions) and the gastrointestinal tract (nausea, vomiting). Lindane binds to plasma proteins, epidermis, dermis and subcutaneous tissue and is readily dissolved in fat tissue. In animal studies (guinea pig), plasma and brain levels of lindane were significantly higher than permethrin. Lindane absorption through the skin was ten times greater as compared with permethrin. Within the past decade, there have been reports on drug resistance concerning both scabies and pediculosis treatment. The following recommendations have been proposed to minimize the potential risk of lindane, mainly in the treatment

of scabies: the drug should not be applied after a hot bath (enhancement of absorption); avoid or use with extreme caution in the treatment of children under 4 years of age and pregnant women (FDA pregnancy category C); time of skin exposure should be no longer than 8–12 h; use with caution in patients with epidermal barrier dysfunction and excoriations; use the lowest effective concentration; treatment should be reapplied only in proven reinfestation and no more than twice a month. Following all the instructions, lindane remains as a second-line treatment for scabies and head lice infestation. Recently, lindane has been withdrawn from many countries worldwide due to concern regarding neurotoxicity and evidence that it is less effective than other treatments.

Commercial Preparations

- Quellada lotion – 1 % lindane (scabicide)
- Quellada shampoo – 1 % lindane (pediculicide)
- Scabicide (cream), Aphtiria (cream, powder) and Jacutin (emulsion, gel, cream) – 1 % lindane (scabicide, pediculicide)

Other Medications Used for the Treatment of Scabies and Pediculosis

Benzyl Benzoate

Benzyl benzoate is known for over 60 years for the treatment of scabies. In the past it was used as a compound of Balsam of Peru and from 1937 manufactured synthetically. General toxicity occurs only if ingested orally in large amounts (convulsions). Locally, benzyl benzoate may be an irritant to the skin or give allergic reactions. Because of low toxicity, it is recommended in lower concentrations for children (exclusion of neonates [gasping syndrome] and up to 4 months of age) and pregnant women.

Commercial Preparations

- Ascabiol 10 % solution benzyl benzoate for children. Twenty-five percent benzyl benzoate solution for adults (mainly scabicide may be used as pediculicide). It is still very effective.

Sulphur

Sulphur remained in use from other old remedies for scabies (like hydrargyrum, creosote, resorcine, formalinum, chrysarobinum, lactic acid). Sulphur is a compound of ointments and lotions used for the treatment of scabies known as ung (Wilkinson ung). It was used in different concentrations from 6 % to 50 %. It acts through keratolytic properties. Sulphur still remains as a recommended treatment of scabies in children and pregnant women, but it is not pleasant and very messy to use. There are no toxicology or percutaneous absorption studies.

Commercial Preparations

- Six percent or ten percent ointments in petrolatum or 25 % ung. Wilkinson in zinc paste in equal dose

Crotamiton (*N*-Ethyl-*O*-Crotonotoluidide)

Very little is known about the toxicology of crotamiton. There are no studies on percutaneous absorption. The drug has a lower efficacy in the treatment of scabies but has been useful in the follow-up treatment of postscabietic pruritus or pruritus of other origin.

Commercial Preparations

- Eurax – lotion or ointment (10 % crotamiton)
- Euraxil – 5 % crotamiton gel (scabicide)

Spinosad

The 0.9 % solution available from 2011 (new compound) derived from fermented *Saccharopolyspora spinosa* is acting causing hyperexcitation, paralysis and death of lice. Spinosad is more effective than 1 % permethrin for treatment of head lice.

Commercial Preparations
- 0.9 % topical suspension, pediculicide

Monosulfiram

Introduced in 1940 for the treatment of scabies, monosulfiram is chemically similar to disulfiram (Antabuse). A disulfiram-like reaction occurs with flushing, sweating and tachycardia if alcohol is ingested during or soon after treatment. Monosulfiram is not an efficient scabicide, often needs several applications and may cause prolonged inhibition of aldehyde dehydrogenase enzyme which is needed for enzymatic breakdown of alcohol, thus making possible an accumulation of acetaldehyde. Such a reaction is potentially serious in children. A single report was published on TEN induced by monosulfiram, and local irritation of the skin is reported. Consequently, the drug is not recommended for use as a scabicide, since other more efficient drugs are available.

Commercial Preparations
- Tetmosol 25 % solution, Tetmosol soap (scabicide)

Copper II Oleate-Tetrahydronaphthalene

This mixture diluted in acetone and mineral oil is a pediculicide for head lice. It is very effective but readily combustible and an irritant, so it should not be applied to patients with eczema.

Commercial Preparation
- Cuprex (head lice)

Oral Treatment of Scabies and Pediculosis

Ivermectin

Ivermectin is an antiparasitic agent with a structure similar to the macrolide antibiotics but without antibacterial activity. It is a synthetic derivative of abamectin. The drug has an endectocidal effect causing paralysis by suppressing the conduction of the nervous impulses in the interneuronic synapses of parasites. Ivermectin is widely used for the treatment of onchocerciasis. During 15 years of this treatment, there have been few side effects described: macular eruption, headache, tachycardia and hypotension. Ivermectin is also used worldwide to control infestation with sarcoptic mites in domestic animals. Since 1992 there have been reports of the general administration of this drug for uncomplicated scabies infestations in humans (worldwide), scabies in HIV positive patients, crusted scabies and endemics in the nursing homes. There have been single reports on possible death in elderly patients treated with ivermectin for scabies.

Commercial Preparation
- Ivermectin (Stromectol) – not registered for the treatment of scabies and pediculosis in humans in all countries. The recommended dose is 200 μg/kg twice in week intervals (7 days apart) in scabies and head lice in children >15 kg. Use with caution only in cases of resistance to other treatments of scabies, and do not administer in pregnant or lactating women. There are reports on topical use of ivermectin 1 % lotion for scabies with effects comparable to 5 % permethrin cream.

Trimethoprim (Sulfamethoxazole TMP/SMX)

The efficacy of oral co-trimoxazole in the eradication of head lice was discovered incidentally in 1978 while treating a child for an upper respiratory tract infection. This effect is probably related to ingestion of the antibiotic by feeding lice and its subsequent effect on their symbiotic bacteria present in a midgut organelle. These bacteria are essential for the synthesis of B vitamins without which the lice cannot survive. Suggested duration of treatment is 4–7 days with adult or children dose of the antibiotic. Due to possible drug reaction (Stevens-Johnson syndrome, erythema

multiforme), TMP/SMX should be considered only in head lice infestation refractory to other treatment.

Possible New Therapeutics for Scabies and Pediculosis

To avoid resistance and improve topical efficacy, new combined formulations of pyrethroids with synergists (e.g. pyrethrins with piperonyl butoxide) or new synthetic pyrethroids or use of insect growth regulators in topical treatment is proposed. As for oral treatment, moxidectin is a new macrocyclic lactone closely related to ivermectin but with longer half-life activity.

Alternative Therapies

Several essential oils and herbal remedies show acaricidal activity in vitro, e.g. eugenol and derivatives, clove oil, neem oil, tea tree oil and aloe vera. Very few of these natural products have been assessed in clinical trials.

Sunscreens

149

John L.M. Hawk

Key Points

- Sunscreens have effect through absorbing ultraviolet radiation into appropriately shaped molecules of organic chemical substances and re-emitting it as harmless quantities of heat (chemical sunscreens) or by reflecting (remitting) it through scattering by tiny particles of titanium dioxide or zinc oxide (physical sunscreens) or a combination of both.
- Sunscreens are effective if used properly against skin sunburning, skin photo-ageing, nonmelanoma and probably melanoma skin cancer and many photodermatoses, particularly polymorphic light eruption.
- Sunscreens are usually not used properly, so it should be used last in the hierarchy of sun-protective measures, namely, first, avoidance of exposure when sun high in sky; second, use of shade and third, use of clothing cover.
- Proper use of sunscreens means using high protection factor products (preferably 50 or more) offering good UVA protection (preferably at least a third of the sun protection factor), applying it liberally to all exposed areas, including the ears in males, about 15–30 min before exposure and again 15–30 min after and also again after perspiration or exercise and for greatest reliability, every 2–3 h as long as exposure continues.
- Adverse effects include not infrequent mild irritation at the time of exposure and rarely contact or photocontact dermatitis.
- Concerns have also been intermittently raised about the carcinogenic effects of sunscreens, either directly on DNA or through encouraging long sun exposure with poorly applied sunscreen, anti-inflammatory effects of sunscreens masking inefficacy and oestrogenic effects of sunscreen through skin absorption and impaired vitamin D production through sunscreen use, but except perhaps for encouraging excessive exposure, these possibilities have not come to pass in any important way.

General Principles

Sunscreens, also variously known as sun creams, sunblocks, suntan lotions or similar, are creams, lotions, sprays, gels or salves applied to the skin to attenuate the effects of ultraviolet radiation

J.L.M. Hawk

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_149, © Springer-Verlag Berlin Heidelberg 2015

(UVR) emitted by the sun or other sources, thereby theoretically reducing the likelihood of its damaging effects.

The originator of sunscreens appears to have been Swiss chemistry student, Franz Greiter, who developed one with a sun protection factor (SPF) of two, as later measured, after suffering sunburn while climbing the mountain Piz Buin in the Swiss Alps. PIZ BUIN sunscreens, as he named them, still exist today. Shortly after, in 1944, Florida pharmacist Benjamin Green produced red veterinary petrolatum, a messy substance again with only moderate UVR-protective effect, for use on chronically sun-exposed soldiers' skin during World War II. It was then marketed in the USA under the Coppertone label in the 1950s, following which in 1962, Greiter introduced the concept of the SPF, now a worldwide standard of sunscreen efficacy. Sunscreen development has since proceeded steadily and modern sunscreens when used carefully are generally extremely effective against UVR-induced skin effects. They are also very cosmetically acceptable for the most part, and in spite of various intermittent claims to the contrary, largely free of adverse effects, as well as being able to withstand water and sweat wash-off and the effects of heat.

The damaging effects on the skin of sunlight which sunscreens are designed to avoid, much more likely in fair skins, are principally skin sunburning, ageing and cancer, although a significant minority of subjects also develop UVR-induced skin rashes, also known as photodermatoses. UVR (100–400 nanometres, nm) comprises only 5–10 % of terrestrial sunlight, of which the much more damaging UVB (280–315 nm) forms only about 5 % and UVA (315–400 nm) the remaining 95 %. Both UVB and UVA cause similar deleterious skin effects but much more so the more active UVB, even though reaching the earth only in relatively small amounts and when the sun is high in the sky. UVA though much less active is constantly present, so for optimal efficacy, sunscreens should offer high both UVB and UVA protection, and virtually all do nowadays.

The theoretical protection offered by sunscreens against UVR-induced skin damage has also been confirmed in practice by a series of studies, the efficacy against sunburning being definite in that the SPF is defined by its efficacy at reducing sunburn, as described below. In addition, they have been shown to be very effective against the development of actinic keratoses and squamous cell carcinoma, while studies on photo-ageing, basal cell carcinoma and melanoma prevention show less definitive efficacy, though good if not total protection is strongly suggested and would be expected if the sunscreens are used very carefully throughout life. Sunscreens may also be very effective in patients with photodermatoses such as polymorphic light eruption (PLE), actinic prurigo (AP), hydroa vacciniforme (HV) and chronic actinic dermatitis (CAD) and light-exacerbated dermatoses, particularly seborrhoeic eczema and xeroderma pigmentosum, though not usually in solar urticaria (SU) or the porphyrias. PLE is the commonest of these and sunscreens are usually effective for this and the other disorders mentioned except in more severe forms.

Classification and Structure

Sunscreens may be classified as:

1. Chemical sunscreens (organic chemical absorbers)
2. Physical sunscreens (metal oxide inorganic absorbers)
3. Combination sunscreens (combining both chemical and physical agents)

Chemical sunscreen agents are organic molecules capable because of their structure of absorbing UVR, then re-emitting it as harmless low energy longer wavelengths, mostly in the infrared region. Physical sunscreens scatter and reflect UVR, though modern nanoparticulate metal oxide products also absorb it.

Chemicals cannot absorb both UVB and UVA efficiently at concentrations suitable and permissible in commercial preparations, and thus sunscreens generally contain multiple ingredients so as to offer a broad spectrum of protection. Chemical absorbers in general are compounds with an aromatic ring structure conjugated with a

carbonyl group, with an electron-releasing amine or methoxyl group substituted in the *ortho* or *para* position of the ring. Derivatives of *para-aminobenzoic* acid (PABA), cinnamates, salicylates, camphor, anthranilates, benzophenones and dibenzoylmethanes are the seven major groups of these agents currently used in sunscreen formulations. Such agents with a high optical density or molar extinction coefficient at the wavelength of maximum UVR absorption, the so-called absorption maximum (λ_{max}), are likely to give maximum protection at the lowest concentrations.

The SPF is the most widely accepted way of measuring this protection and is the ratio calculated by dividing the UVR dose (as produced by artificially produced solar simulated sunlight) required to evoke minimal erythema on skin covered by 2 mg/cm^2 or 2 μl/cm^2 of sunscreen by that required on unprotected skin. Substantivity (water resistance) is a sunscreen's ability to remain on the skin when subjected to environmental conditions likely to remove it, such as swimming or sweating, as measured by determination of the SPF after one or more 20 min immersions of the sunscreen-applied test site in moving water.

More recently, effective methods of assessing UVA protection have also been sought, since UVA as stated above is also damaging to skin. It produces similar though in sunlight more slowly induced effects to UVB but particularly tends to induce photo-ageing and photodermatoses, as well as contributing somewhat to sunburning and cancer. Several assessment techniques have been considered.

Of the techniques used, the persistent pigment darkening (PPD) method is most widespread, being similar to the SPF method of measuring protection against erythema during SPF testing with a solar simulator. However, the PPD technique instead assesses persistent tanning (as distinct from the transient immediate pigment darkening) of the skin with and without sunscreen following just UVA irradiation, such tanning known to be reliably inducible by UVA. Following this, Colipa, the European Cosmetics Association, has also developed an in vitro technique claimed to provide the same result. Given the deleterious effects on the skin now known to be induced by UVA, the European Union now requires a minimum one-third level of UVA protection in relation to the SPF.

In the UK and Ireland, the Boots Company in Nottingham has developed a so-called star rating system, recently modified slightly following development of the Colipa UVA PF test mentioned above. This is a proprietary in vitro method of assessing the ratio of sunscreen UVA to UVB protection based on prior work by Diffey et al. The test logo and methodology are also licensed to any other sunscreen brand sold in Boots' shops, while those not offered by Boots are excluded. Five-star (5*) products are best, and three-star products least effective. The method uses a spectrophotometer to measure the sunscreen absorption of UVA and UVB after samples are pre-irradiated to ensure photostability of the product.

Finally, Asian brands, particularly Japanese, often use the Protection Grade of UVA (PA) system, again based on the PPD reaction, PA+ on sunscreen labels indicating a UVA PF of two to four, PA++ four to eight and PA+++ more than eight.

Chemical Sunscreens

The names of chemical sunscreen ingredients tend to be a confusing array of differing nomenclatures. The nature and UVR absorptivity of a selection of these are outlined below with a more detailed listing provided in Table 149.1.

PABA has a reactive carboxylic and an amino group substituted in a *para* orientation on the benzene nucleus. It has a λ_{max} at 296 nm and a molar extinction coefficient of 13,600 and is therefore a good UVB absorber. However it is easily oxidised and stains clothing, may crystallise and has a moderate contact sensitising potential. On the other hand, PABA derivatives such as the ethyl, butyl, amyl and octyl esters of *N,N-dimethyl-PABA* were designed to minimise the disadvantages of the parent molecule while retaining its UVB screening ability. Thus N,N-dimethyl-PABA octyl ether, also

Table 149.1 The following are US Food and Drug Administration (FDA)-allowable active sunscreen ingredients

UVR filter	Other names	Maximum concentration	Permitted countries	Safety testing results
p-Aminobenzoic acid	PABA	15 % (European Union-banned from sale to consumers from 8 October 2009)	USA, AUS	Protects against skin tumours in mice. Shown able to increase DNA defects and now less commonly used
Padimate O	OD-PABA, octyldimethyl-PABA, σ-PABA	8 % (EU, USA, AUS), 10 % (JP)	EU, USA, AUS, JP	Not tested
		Not currently supported in EU and may be delisted		
Phenylbenzimidazole sulphonic acid	Ensulizole, Eusolex 232, PBSA, PARSOL HS	4 % (US, AUS), 8 % (EU), 3 % (JP)	EU, USA, AUS, JP	Genotoxic in bacteria
Cinoxate	2-Ethoxyethyl-p-methoxycinnamate	3 % (US), 6 % (AUS)	USA, AUS	Not tested
Dioxybenzone	Benzophenone-8	3 %	USA, AUS	Not tested
Oxybenzone	Benzophenone-3, Eusolex 4360, Escalol 567	6 % (US), 10 % (AUS, EU), 5 % (JP)	EU, USA, AUS, JP	Not tested
Homosalate	Homomenthyl salicylate, HMS	10 % (EU, JP), 15 % (US, AUS)	EC, USA, AUS, JP	Not tested
Menthyl anthranilate	Meradimate	5 %	USA, AUS	Not tested
Octocrylene	Eusolex OCR, 2-cyano-3,3-diphenyl acrylic acid, 2-ethylhexylester	10 %	EU, USA, AUS, JP	Increases ROS
Octyl methoxycinnamate	Octinoxate, EMC, OMC, ethylhexyl methoxycinnamate, Escalol 557, 2-ethylhexyl-paramethoxycinnamate, PARSOL MCX	7.5 % (US), 10 % (EU, AUS), 20 % (JP)	EU, USA, AUS, JP	
Octyl salicylate	Octisalate, 2-ethylhexyl salicylate, Escalol 587	5 % (EU, USA, AUS), 10 % (JP)	EU, USA, AUS, JP	Not tested
Sulisobenzone	2-Hydroxy-4-methoxybenzophenone-5-sulphonic acid, 3-benzoyl-4-hydroxy-6-methoxybenzenesulphonic acid, Benzophenone-4, Escalol 577	5 % (EU), 10 % (US, AUS, JP)	EU, USA, AUS, JP	Not tested
Trolamine salicylate	Triethanolamine salicylate	12 %	USA, AUS	Not tested
Avobenzone	1-(4-Methoxyphenyl)-3-(4-tert-butyl phenyl) propane-1,3-dione, butyl methoxy dibenzoylmethane, BMDBM, PARSOL 1789, Eusolex 9020	3 % (US), 5 % (EU, AUS), 10 % (JP)	EU, USA, AUS, JP	No longer available

UVR filter	Other names	Maximum concentration	Permitted countries	Safety testing results
Ecamsule	Mexoryl SX, terephthalylidene dicamphor sulphonic acid	10 %	EU, AUS (US: approved in certain formulations up to 3 % via New Drug Application (NDA) route)	Protects against skin tumours in mice
Titanium dioxide	CI77891	25 % (no limit in JP)	EU, USA, AUS, JP	Not tested
Zinc oxide		25 % (US), 20 % (AUS) (EU, 25 % provided particle size >100 nm) (JP, no limit)	EU, USA, AUS, JP	Protects against skin tumours in mice

Other ingredients approved within the EU and other parts of the world, not included in FDA Monograph			
UVR filter	Other names	Maximum concentration	Permitted in
4-Methyl-benzylidene camphor	Enzacamene, PARSOL 5000, Eusolex 6300, MBC	4 %	EU, AUS
Tinosorb M	Bisoctrizole, methylene bis-benzotriazolyl tetramethylbutylphenol, MBBT	10 %	EU, AUS, JP
Tinosorb S	Bis-ethylhexyloxyphenol methoxyphenyl triazine, Bemotrizinol, BEMT, anisotriazine	10 % (EU, AUS), 3 % (JP)	EU, AUS, JP
Neo Heliopan AP	Bisdisulizole disodium, disodium phenyl dibenzimidazole tetrasulphonate, bisimidazylate, DPDT	10 %	EU, AUS
Mexoryl XL	Drometrizole trisiloxane	15 %	EU, AUS
Benzophenone-9	Uvinul DS 49, CAS 3121-60-6, sodium dihydroxy dimethoxy disulphobenzophenone	10 %	JP
Uvinul T 150	Octyl triazone, ethylhexyl triazone, EHT	5 % (EC, AUS), 3 % (JP)	EU, AUS
Uvinul A Plus	Diethylamino hydroxybenzoyl hexyl benzoate	10 % (EC, JP)	EU, JP
Uvasorb HEB	Iscotrizinol, diethylhexyl butamido triazone, DBT	10 % (EC), 5 % (JP)	EU, JP
PARSOL SLX	Dimethico-diethylbenzalmalonate, Polysilicone-15	10 %	EU, AUS, JP
Isopentenyl-4-methoxycinnamate	Isoamyl p-methoxycinnamate, IMC, Neo Heliopan E 1000, amiloxate	10 %	EU, AUS

Table 149.2 Indications for sunscreen use (after the hierarchy of all other possible UVR avoidance measures has been used first, as outlined in the text)

1. To avoid sunburning
2. To avoid photo-ageing, actinic keratoses cell carcinoma, squamous cell carcinoma, basal cell carcinoma and malignant melanoma (though the evidence remains only moderate for photo-ageing, basal cell carcinoma and malignant melanoma)
3. To avoid photodermatoses, particularly polymorphic light eruption, mild actinic prurigo, mild hydroa vacciniforme (to a degree), mild chronic actinic dermatitis, light-exacerbated dermatoses and xeroderma pigmentosum (if used constantly and very carefully) but not usually solar urticaria to any extent or the porphyrias

known as padimate O, has overcome most of the undesirable effects of PABA, being a liquid with almost double the molar extinction coefficient of PABA and an efficient and popular UVB sunscreen (Tables 149.1 and 149.2).

Salicylates are *ortho*-disubstituted aromatic compounds with peak absorption around 300 nm and hence UVB absorbers. They are non-water-soluble, stable compounds easily incorporated into cosmetic formulations and excellent solubilisers of other nonsoluble ingredients such as benzophenones. They also have an excellent safety profile but are relatively weak UVR absorbers. The most widely used of the group is octyl salicylate, also known as 2-ethylhexyl salicylate.

Cinnamates are UVB absorbers with a λ_{max} around 310 nm. 2-Ethylhexyl p-methoxycinnamate or octyl *p-methoxycinnamate* is the most popular member of the group, while octocrylene is a more recent introduction.

Anthranilates, as with the salicylate group, are stable and safe compounds. Menthyl anthranilate is an *ortho*-disubstituted aminobenzoate with a λ_{max} at 336 nm.

Benzophenones are aromatic ketone derivatives of dibenzoylmethane capable of some absorption in the UVA range of the spectrum, some exhibiting a shift in λ_{max} in different solvents; for example, dioxybenzone has been shown to have a λ_{max} of 326 and 352 nm in polar and nonpolar solvents, respectively. These compounds however are relatively difficult to solubilise in cosmetic formulations and have a sensitising potential.

Dibenzoylmethanes are substituted diketones capable of undergoing keto-enol tautomerism. Compounds such as isopropyl dibenzoylmethane (Eusolex 8020) and butyl-dibenzoylmethanes (avobenzone, PARSOL 1789) absorb UVA relatively well but are not very photostable. Avobenzone has a λ_{max} of 355 nm and a very high extinction coefficient of greater than 30,000.

Camphor derivatives (bicyclic compounds), such as 3-benzylidene camphor and benzylidene camphor sulphonic acid, are UVB absorbers. This group of agents is currently not approved by the Federal Drug Administration for use in the USA. In particular, however, terephthalylidene dicamphor sulphonic acid (Mexoryl SX) is a newer derivative with a λ_{max} of 345 nm, with excellent photostability and UVA absorptivity.

Recently, concerns have been raised that many chemical sunscreen ingredients have an anti-inflammatory effect on the skin, thereby reducing the erythema of sunburn and also artificially raising the SPF as measured in vivo, as is usual, compared with that in vitro. As a result, it might be possible that sunburn is prevented while DNA damage continues unabated to long-term disadvantage. However, although such an anti-inflammatory effect does seem to occur, some of the in vitro SPFs were higher than the in vivo measurements, indicating some experimental uncertainty, while also many studies over the years have confirmed sunscreen efficacy in reducing DNA damage, as well as actinic keratosis and skin cancer incidence, as described earlier. Thus if there is any artificial anomalous raising of the SPF, the residual sunscreen efficacy is clearly still sufficient to maintain its substantial effect.

Physical Sunscreens

Titanium dioxide and zinc oxide are chemically inert particulate metal oxides which have a num-

ber of advantages in that they are photostable, not a cause of photoallergy or phototoxicity and protective against UVB, UVA and to some extent visible radiation. In the past such preparations have tended to be thick, opaque and cosmetically unacceptable to many people, but more recently, micronised or nanoparticulate formulations containing particles of less or much less than 100 nm diameter have ensured improved translucency and cosmetic acceptability. They are also often combined with organic chemical absorbers in order to achieve higher SPFs than when used alone.

Recently, concerns have been raised concerning nanotitanium dioxide-containing sunscreens, because they demonstrate unusual solar radiation responses as compared with the earlier thicker forms of the same material, in that their electrons are contained within each minute particle in a way which produces quantum molecular behaviour. As a result, ultraviolet radiation (UVR) attenuation is much higher than in continuous forms of the same material, but free radical formation may occur within them during UVR exposure and even sometimes without. This would be of concern if they were adjacent to or within living cells, but many in vitro studies, as well as many in vivo studies in animals and man, have shown their at most minimal penetration beneath the inert stratum corneum and also their lack of significant penetration into or persistence within hair follicles, where they are in any case still outside the stratum corneum. They are therefore unable to cause damage to living tissue, as further supported by their lack of adverse effects in the majority of the in vitro and in vivo studies undertaken and by clinical experience over the years, which has revealed no deleterious outcomes.

Another concern with respect to either chemical or physical sunscreen use has been that systemic vitamin D production, initiated in the skin by the UVB radiation in sunlight, might be prevented or seriously reduced as a result, with potentially serious consequences for normal bone metabolism and a host of other vitamin D-ASSOCIATED metabolic functions. However, careful studies have shown that even careful use of high-SPF sunscreens in areas of high UVR intensity at most mildly reduces systemic vitamin D levels, suggesting the substance is slowly created in the skin with even minimal exposure, a contention supported by the fact that average population summer and winter levels at all latitudes are the same.

Indications for Sunscreen Use

UVR exposure whether to UVB or UVA leads to acute inflammatory changes in the skin with vasodilatation, erythema, inflammatory cellular infiltration and release of pro-inflammatory mediators such as prostaglandins (PGD_2, PGE_2) and interleukins (IL_1, IL_6), along with keratinocyte apoptosis. Such effects are most pronounced in the sunburn reaction. UVR-mediated damage to DNA can be detected as early as 30 min after exposure, probably then leading causally to the subsequent inflammatory changes. Both epidermis and dermis are affected, principally by UVB, but UVA is known also to produce significant dermal damage, probably playing an important role in skin photo-ageing, the gradual deterioration of cutaneous structure and function from the cumulative imperfectly repaired damage of long-term recurrent UVR exposure. Manifestations of this include wrinkling, freckling, lentigines, telangiectasia, comedones, mottled pigmentation, coarseness and a yellowish discoloration of the skin. UVR has also been shown to be the most important cutaneous carcinogen, its role in the development of nonmelanoma skin cancers such as squamous and basal cell carcinomas having been clearly demonstrated. There is strong evidence also for the aetiological involvement of UVR in melanoma, although this has not yet been indisputably proven. An individual's inherent burning and tanning capacity along with associated behavioural and environmental factors greatly influences these events, those with fairer skins being more prone to damage. As mentioned previously, sunscreens are therefore strongly indicated as protective agents against the occurrence of skin sunburn, photo-ageing and cancers. Nevertheless some studies have shown a slightly increased incidence of melanoma in subjects who

claim to have used sunscreens, but this is thought likely to be due not to the sunscreen agents themselves but to other factors, particularly inadequate product use along with a possible tendency to stay outdoors for longer periods in the belief that protection is now adequate.

As also mentioned previously, sunscreens are routinely advised and can be very effective in patients with photodermatoses such as PLE, AP, HV, chronic actinic dermatitis (CAD), XP and the light-exacerbated dermatoses such as seborrhoeic eczema, but not usually SU. PLE is the commonest of these and usually affects young adults with an itchy erythematous papular eruption over some or all exposed areas within a few hours of sun exposure, thereafter subsiding within a few days; it may be induced by UVB, UVA or both, and broad-spectrum sunscreen use is advised, usually with very good effect except in very severe cases. AP is a more chronic condition of generally young girls characterised by an excoriated papular or nodular eruption of the exposed sites with a tendency to involve covered areas as well; as in PLE it may be induced by UVA or UVB. Sunscreen use is helpful only in milder instances. HV is a rare blistering and scarring photodermatosis otherwise closely resembling PLE; it responds moderately to sunscreen use, UVB and short wavelength UVA probably being causal. SU is an uncommon wealing condition induced by sunlight and only responding to sunscreen use in the rare mild cases induced by UVB. CAD is a relatively persistent eczematous condition of elderly males, the face, neck, upper chest and hands usually being involved with sparing of the eyelids, submental, retroauricular and other photo-protected areas. Most patients with CAD react abnormally to both UVA and UVB, so broad-spectrum sunscreens are advised, although again with only moderate effect.

Porphyrias are disorders of haem biosynthesis resulting in the excess production of porphyrin and its precursors; these compounds absorb radiation of wavelengths around 400 nm and then re-emit the energy leading to the production of free radicals destructive to cellular components. Patients with these disorders require protection particularly in the short visible light range of the spectrum, but this is not well provided by topical sunscreens, although inorganic chemical preparations such as titanium dioxide may help to a very small extent. Oral agents such as β-carotene 120–180 mg/day have long been tried in erythropoietic protoporphyria (EPP), but their benefit has never been proven. A newer agent is alpha-melanocyte–stimulating hormone given by injection, thereby stimulating a tan, but not theoretically enough to work: however, some patients are convinced of its efficacy.

Eczemas such as atopic and seborrhoeic dermatitis, not light-induced by themselves, can sometimes be worsened by sun exposure in some patients and sunscreens may be helpful in these, as mentioned above, as well as in other much rarer light-exacerbated dermatoses such as systemic lupus erythematosus.

Adverse Effects and Cross-Reactions

Sunscreen users may note an immediate burning or stinging sensation at sites of sunscreen application, more frequently with the benzophenones and PABA esters. Preparations containing physical agents may also cause on occasion miliaria due to occlusion. As with other topically applied agents, sunscreen preparations too may at times induce allergic contact dermatitis from preservatives, fragrances and other non-active constituents of the preparation, although the sunscreen chemicals themselves are also being increasingly reported as allergenic; sensitisation is higher in those with photodermatoses, especially CAD or PLE. In the early years of sunscreen use, PABA was the most frequent cause of this, but reactions over the last decade have been fewer because of its decreasing use. Glyceryl PABA was also reported as a potent sensitiser in several patients until the reaction was later shown to be due to impurities present in the preparation, the contaminant being either benzocaine (ethylaminobenzoic acid) or other unidentified agents. Procaine, benzocaine, *p*-phenylenediamine and sulphonamides can cross-react with PABA such that patients sensitised to any of these compounds

may also demonstrate an allergic reaction to sunscreens containing PABA or its esters. In recent years however the benzophenone (oxybenzone, mexenone) group has replaced PABA as the most frequent cause of sunscreen allergy, especially as these compounds are also widely used in non-sunscreen cosmetics and toiletries. Several allergic reactions have also been reported to isopropyl dibenzoylmethane, leading to its removal from several products; it can cross-react with the structurally related butyl methoxydibenzoylmethane. 3-4′-Methyl-benzylidene camphor was previously used in combination with isopropyl dibenzoylmethane and those sensitive to one agent often demonstrated a concomitant sensitisation to the other. Amongst the cinnamates, 2-ethoxyethyl-*p*-cinnamate (cinoxate) is the most frequent sensitiser; these compounds also cross-react with balsam of Peru, balsam of tolu, cinnamic aldehyde, cinnamic acid and cinnamon oil, all ingredients used in cosmetics, fragrances, toothpastes and flavourings.

Photoallergic reactions too have been reported to a variety of sunscreen chemicals, the photoallergen being apparently formed in some instances when a parent molecule undergoes chemical alteration following the absorption of radiation, usually UVA, thus resulting in the formation of an altered compound or hapten; this then presumably binds to carrier protein to form allergen. Alternatively, the photochemical alteration of an already formed protein-hapten complex by radiation absorption could probably make it allergenic. Photoallergy has been reported to 2-hydroxy-4-methoxy methylbenzophenone (Eusolex 4360, oxybenzone), benzophenone-4, isopropyl dibenzoylmethane (Eusolex 8020), butyl methoxydibenzoylmethane (PARSOL 1789) and isoamyl *p*-methoxycinnamate.

Potential absorption of sunscreen ingredients to cause carcinogenic or oestrogenic effects has also been of intermittent concern, but absorption is minimal and has not been shown to be of importance during everyday sunscreen usage.

However, despite this list of possible adverse effects from multiple ingredients, sunscreens generally are very effective without causing major problems.

Sunscreen Usage

The recommended thickness of application of a sunscreen for achievement of the quoted SPF and optimum benefit is 2 mg/cm^2 or 2 μl/cm^2, being a relatively liberal amount. However studies have shown that users generally apply much less than this recommended quantity in practical settings. Thus most have found the applied film thickness to range from 0.5 to 1 mg/cm^2, while a European study on 148 students found the median quantity to be 0.39 mg/cm^2. This leads to SPF values of around a third of the quoted value because of the reduced ingredient thickness through which the UVR passes to be attenuated. It has therefore been proposed that the methodology of testing and labelling of sunscreens might be altered to suit a more realistic consumer usage pattern; this approach has so far not been adopted however because of concerns that major consumer confusion might ensue. Further, SPF assessments for the same thickness of application may vary considerably in actual practice, and it has been suggested that the term SPF be abandoned in favour of a system referring to sunscreen protectivity as low, moderate, medium, high and very high or similar, but this has not been adopted either, given the consumer familiarity now with the SPF. In addition to inadequate application when sunscreen is applied, it is frequently not applied to all exposed areas or before sun exposure begins or reapplied after sweating or swimming, so the chances of effective use are hugely diminished. Further, sunscreen reapplication has been advised every 2–3 h, partially because of possible product photodegradation and partially the likelihood of removal in environmentally unsuitable conditions, and this still is the case for some products, but most modern sunscreens do not photodegrade and do persist for long periods on the skin, so though 2–3 hourly reapplication is still safest, more recent work by Diffey now suggests in addition that sunscreens are best first applied 15–30 min before exposure and then again 15–30 min after exposure has begun for maximal effect, in addition to the further applications thereafter mentioned above.

Clearly sunscreens are very effective if used carefully by users, but significant effort on their part is required to ensure that this is the case.

Targeted Therapies for Melanoma 150

Claus Garbe, Friedegund Meier,
and Thomas K. Eigentler

Key Points

- Before the treatment of disseminated melanoma metastases, a mutational testing for BRAF and NRAS and in subgroups for c-Kit has to be performed.
- For patients with BRAF mutation, treatment with BRAF inhibitors and their combination with MEK inhibitors results in a high percentage of tumor remissions.
- New immunotherapies with blockade of the inhibiting receptors CTLA-4 and PD-1 on T lymphocytes lead to durable remissions in 15–50 % of patients with disseminated metastases of melanoma.
- In part of the patients, particularly with BRAF and probably with NRAS mutation, both therapeutic approaches can be applied.
- The best combined therapies and sequential schedules with all these new therapeutic approaches have to be investigated in the future.

General Principles

A new era of melanoma therapies began few years ago. In the past, chemotherapies and unspecific immunotherapy mainly with interferon alpha were available for metastatic melanoma and for adjuvant treatment. This situation changed, and new substances are now applied for systemic treatment of metastatic melanoma (Garbe et al. 2011). Targeted therapy with kinase inhibitors is particularly used for metastatic melanoma carrying the BRAF V600 mutation (Eigentler et al. 2013). Two specific BRAF inhibitors are currently on the market in the USA and in Europe: vemurafenib and dabrafenib. Additionally, a MEK inhibitor has been approved in the USA and will come onto the market in the near future in Europe: trametinib. Combination of specific BRAF and MEK inhibitors seems to improve the treatment outcome and seems even to decrease adverse events. Furthermore, MEK inhibitor are presently tested in patients with metastatic melanoma carrying an NRAS mutation. Several other MEK inhibitors are presently under clinical development: selumetinib, cobimetinib, binimetinib, etc. (Table 150.1).

Another important development is the targeting of lymphocytes for immunotherapy of metastatic melanoma. During the last decade, a number of activating co-stimulatory lymphocyte receptors and of inhibiting receptors have been detected and better understood in their function.

Table 150.1 Specific inhibitors of the MAP kinase signaling pathway, approved or in clinical trials for metastatic melanoma

Generic name	Brand name	Company	Specific inhibition	Indication	Dosage (mg/day)
Vemurafenib	Zelboraf	Roche Pharma	Mutated BRAF	Met. melanoma BRAF mutated	2×960
Dabrafenib	Tafinlar	GlaxoSmithKline	Mutated BRAF	Met. melanoma BRAF mutated	2×150
Encorafenib	–	Novartis	Mutated BRAF	Met. melanoma BRAF mutated	300–450
Trametinib	Mekinist	GlaxoSmithKline	MEK	Met. melanoma BRAF mutated; NRAS mutated?	2
Cobimetinib	–	Roche Pharma	MEK	Met. melanoma BRAF mutated; NRAS mutated?	60
Binimetinib	–	Novartis	MEK	Met. melanoma BRAF mutated; NRAS mutated?	2×45
Selumetinib (AZD6244)	–	AstraZeneca	MEK	Met. melanoma BRAF mutated; NRAS mutated?	2×75
Imatinib	Glivec	Novartis	c-Kit	Met. melanoma c-Kit mutated	1–2×400

Table 150.2 Monoclonal antibodies for immune checkpoint blockade of T lymphocytes for immunotherapy of metastatic melanoma

Generic name	Brand name	Company	Specific inhibition	Indication	Dosage, (infusions)
Ipilimumab	Yervoy	Bristol-Myers Squibb	CTLA-4	Met. melanoma	3 mg/kg, 4× every 3 weeks
Tremelimumab	–	Pfizer	CTLA-4	Met. melanoma	15 mg/kg, once every 90 days
Nivolumab (BMS-936558)	–	Bristol-Myers Squibb	PD-1	Met. melanoma	1 mg/kg, 4× every 3 weeks
Pembrolizumab	–	Merck	PD-1	Met. melanoma	10 mg/kg, every 3 weeks
BMS-936559	–	Bristol-Myers Squibb	PD-L1	Met. melanoma	10 mg/kg, every 2 weeks

Blocking the inhibiting receptors was found to be an effective and survival-prolonging strategy in melanoma treatment. An unexpected high percentage of melanoma patients seem to have developed functional immune responses to the tumor antigens which are blocked by inhibiting signals to the T lymphocytes. A blockade of the inhibiting receptors by monoclonal antibodies was suitable for releasing the functional immune responses of T cells to the tumor. This led to partial and complete responses which seemed to be durable. This strategy is not dependent on the mutational status of the melanoma patients. Currently, the most important targets are the CTLA-4 receptor and PD-1 receptor on T cells. The CTLA-4 blocking antibody ipilimumab is already on the market in Europe and in the USA, and several antibodies against PD-1 are presently tested in clinical trials (Table 150.2).

Both therapeutic approaches, blockade of the MAP kinase signaling pathway with selective kinase inhibitors and activating immunotherapies

with CTLA-4 and PD-1 blockade, will also be tested in the adjuvant setting. A large adjuvant trial with ipilimumab has already been completed in its recruitment, and trials with vemurafenib and a combination of dabrafenib and trametinib are presently ongoing.

With the introduction of kinase inhibitors into the treatment of metastatic melanoma, a substantial progress in comparison to former chemotherapeutic treatments has been achieved. However, the development of immunotherapy in metastatic melanoma is another simultaneous event which opens new treatment approaches by the use of immune checkpoint blockade (Ott et al. 2013). The combined treatment with the CTLA-4 blocking antibody ipilimumab and the PD-1 blocking antibody nivolumab resulted in more than 50 % objective responses, which seem to be durable. Therefore, immune checkpoint blockade may develop to first-line treatment in metastatic melanoma in the future, and kinase inhibitors may find its place in second- and x-line treatments.

Mutational Testing

There are several activating mutations in the mitogen-activated protein kinase (MAPK) pathway, which drive melanoma proliferation and inhibit programmed cell death.

The most commonly mutated oncogene identified to date in melanoma is BRAF (~50 %), an upstream mediator of the MAPK pathway (Davies et al. 2002; Flaherty 2006). In over 80 % of the patients, this activating mutation results from the substitution of valine by glutamic acid at amino acid 600 (V600E mutation) with most of the remainder consisting of an alternate substitution (lysine for valine) at the V600 locus (V–K) (Satyamoorthy et al. 2003). Increased activation of the MAPK pathway is implicated in melanoma tumor genesis and is enhanced in advanced-stage melanoma. Generally, BRAF-mutated melanomas occur in younger-aged patients, on skin without signs of solar damage, and affect less frequently the head and neck area. Therefore BRAF-mutated melanomas seem to arise early in life at low cumulative UV doses, whereas melanomas without

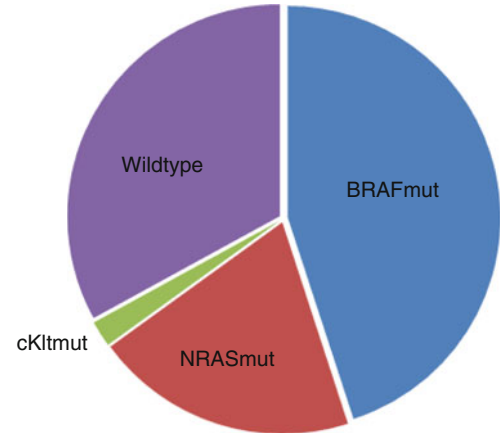

Fig. 150.1 Frequency of mutations in metastatic melanoma

BRAF mutations seem to require accumulation of high UV doses over time (Bauer et al. 2011).

Another 15–20 % of all melanomas harbor activating NRAS mutations. The most common oncogenic change with >80 % of all NRAS mutations is a point mutation leading to the substitution of glutamine by leucine at position 61. Mutations at positions 12 and 13 occur less frequently. NRAS mutations at position 61 are associated with impaired GTPase activity and the locking of the NRAS protein in its activated conformation (Bos 1989). Generally, BRAF and NRAS mutations are mutually exclusive.

Activating c-Kit (CD117) mutations are found in not more than 1–2 % of melanoma patients, mainly in acral and mucosal melanoma subtypes, with a frequency of 5–10 % in these subtypes. c-Kit is a receptor tyrosine kinase on the cell surface, which is naturally activated by binding of stem cell factor and then activates the MAPK and other pathways. Inhibiting molecules for c-Kit are available (Fig. 150.1).

BRAF Kinase Inhibitors

Vemurafenib

Vemurafenib is an inhibitor of the oncogenic V600E mutant BRAF kinase, which has been approved for unresectable advanced melanoma in

the USA and Europe. In a phase II trial (BRIM-2) evaluating 132 patients with metastatic melanoma carrying a BRAF V600 mutation, the confirmed overall response rate was 53 % (Sosman et al. 2012). Median duration of response was 6.7 months, the median progression-free survival was 6.8 months, and the median overall survival was 15.9 months. Results from the phase III registration trial (BRIM-3) were published in 2011 (Chapman et al. 2011). Six hundred seventy-five patients were randomly assigned to vemurafenib (960 mg p.o. bid) or dacarbazine (1,000/m^2 i.v. every 3 weeks). At 6 months, overall survival was superior in the vemurafenib group in contrast to the dacarbazine group (84 % vs. 64 %). The hazard ratio (HR) for death in the vemurafenib group was 0.37 ($p<0.001$). Response rates were 48 % for the vemurafenib and 5 % for the dacarbazine treatment arm. In an updated analysis, median overall survival rates for vemurafenib- and DTIC-treated patients were 13.2 and 9.6 months, respectively. In the BRIM-3 trial, a crossover from DTIC to vemurafenib was allowed after progression, and, therefore, the OS >9 months in the chemotherapy arm is rather high.

Vemurafenib has multiple adverse reactions. To the common adverse reactions, occurring in about 30 % of patients, belong skin rashes, photosensitivity reactions, joint pain, fatigue, nausea, alopecia, and pruritus. In addition, about one-fourth of patients develop cutaneous squamous cell carcinoma (SCC) mainly from the keratoacanthoma subtype, which can be successfully removed surgically. So far, no development of metastasis from this SCC has been described. Additionally, the development of second primary melanomas was observed in some patients. The toxicity is well manageable and less severe as compared to most chemotherapeutic treatments.

Dabrafenib

The BRAF inhibitor dabrafenib was likewise tested in clinical trials. For dabrafenib a clinical objective response rate of 66 % has been reported in V600-mutant melanoma patients treated with >150 mg two times daily (bid) (Ascierto et al. 2013a). Data from a registration phase III trial comparing dabrafenib and dacarbazine have led to its approval in the USA and in Europe (Hauschild et al. 2012). In this trial, 250 BRAF (V600E) patients were randomly assigned to receive either dabrafenib 150 mg twice daily p.o. (187 patients) or dacarbazine 1,000/m^2 i.v. every 3 weeks (63 patients). Median progression-free survival was 5.1 months for dabrafenib and 2.7 months for dacarbazine (HR, 0.30; $p<0.0001$).

In another multicenter, open-label, phase II trial for patients with V600E or V600K BRAF-mutant melanoma metastatic to the brain, 172 patients with at least one asymptomatic brain metastasis ($\geq$5 and $\leq$40 mm in diameter) were enrolled to receive 150 mg oral dabrafenib bid until disease progression, death, or unacceptable adverse events (Long et al. 2012). The primary end point was the proportion of patients with Val600Glu BRAF-mutant melanoma who achieved an overall intracranial response, which was defined as a complete response or partial response. An objective intracranial response was achieved in 29 (39.2 %) of 74 patients with V600E BRAF-mutant melanoma previously untreated, as was observed in 20 (30.8 %) of 65 of the pretreated patients. This opens a new perspective for the treatment of brain metastasis in advanced melanoma, where nearly no treatment options exist.

The spectrum of adverse reactions of dabrafenib is similar to that of vemurafenib. Common side effects include pyrexia, skin rashes, joint pain, fatigue, nausea, alopecia, and pruritus. Likewise, about 10 % of patients develop cutaneous squamous cell carcinoma (SCC) mainly from the keratoacanthoma subtype. A possible difference is a lower phototoxicity rate, which was ~3 % with dabrafenib versus ~30 % with vemurafenib according to the phase III trials.

Encorafenib

No clinical data have been published on encorafenib so far except initial results from a phase I, open-label, dose-escalation study reported at ASCO 2013. It is a potent and selective RAF

kinase inhibitor with little activity against wild-type BRAF (Huang et al. 2013). encorafenib did not suppress the growth of >400 cell lines expressing wild-type BRAF. Encorafenib treatment at oral doses as low as 6 mg/kg in human melanoma xenograft models resulted in strong MAPK pathway blockade.

MEK Kinase Inhibitors

Trametinib

The MEK inhibitor trametinib was approved in May 2013 for treatment of unresectable advanced melanoma in the USA, and approval in Europe is expected soon. First clinical results have been reported for trametinib in 20 patients with BRAF-mutant melanoma showing six partial responses and two complete responses (40 % OR) and were presented at the ASCO meeting 2010. Interestingly, two partial responses have likewise been observed in 22 BRAF wild-type melanoma patients (Infante et al. 2012). In 2012, data of the phase III registration study (METRIC) have been published (Flaherty et al. 2012a). In this trial 322 patients with a V600K/E BRAF mutation were randomly assigned to receive either trametinib (2 mg p.o. daily) or chemotherapy (dacarbazine 1,000/m^2 i.v. every 3 weeks or paclitaxel 175 mg/m^2 i.v. every 3 weeks) in a 2:1 ratio. A crossover to the trametinib arm was permitted for patients who were progressive in the chemotherapy arm. Median progression-free survival was 4.8 months in the trametinib arm versus 1.5 months for the chemotherapy arm (HR for disease progression or death, 0.45; $p<0.001$). The 6-month overall survival was 81 % in the trametinib group compared to 67 % in the chemotherapy group despite crossover (HR for death, 0.54; $p=0.01$). These data show the clear superiority of trametinib versus monochemotherapy; however, the efficacy of MEK inhibition seems to be below BRAF inhibition.

Trametinib has a broad spectrum of adverse reactions. Most commonly found (greater than or equal to 10 % of any grade) in patients receiving trametinib were rash, diarrhea, lymphedema (swelling of the face, arms, or legs), acne-like rash, stomatitis (mouth sores), hypertension (new or worsening high blood pressure), abdominal pain, hemorrhage (bleeding), dry skin, pruritis (itching), and paronychia (nail infection). A decreased ejection fraction or ventricular dysfunction was observed in 7 % of patients. Ocular events (mostly grade 1 or 2) occurred in 9 % of patients. No cutaneous squamous cell carcinomas were diagnosed under trametinib.

Selumetinib

Selumetinib (AZD6244, ARRY-142886) is a potent inhibitor of MEK1/2 kinase (Davies et al. 2007). First results of selumetinib antitumor activity were presented at the ASCO 2008 annual meeting, indicating partial responses in mainly BRAF-mutated patients (Kirkwood et al. 2012). Recently, data of a double-blind, randomized, placebo-controlled phase II study investigating selumetinib plus dacarbazine versus placebo plus dacarbazine as first-line treatment was published (Robert et al. 2013). Patients were randomly assigned 1:1 to take either oral selumetinib (75 mg bid in a 21-day cycle) or placebo; all patients received dacarbazine (1,000 mg/m^2 on day 1 of a 21-day cycle) intravenously. The primary end point was overall survival analyzed by intention to treat. Ninety-one patients were randomly assigned to receive dacarbazine in combination with selumetinib ($n=45$) or placebo ($n=46$). Overall survival did not differ significantly between groups (median, 13.9 months in the selumetinib plus dacarbazine group and 10.5 months in the placebo plus dacarbazine group; HR, 0.93). However, progression-free survival was significantly improved in the selumetinib plus dacarbazine group versus the placebo plus dacarbazine group (HR, 0.63, one sided; $p=0.021$), with a median of 5.6 months versus 3.0 months, respectively (Robert et al. 2013).

The spectrum of adverse reactions shows some differences in comparison to trametinib. Most frequently nausea was observed in 64 % of patients, followed by acneiform dermatitis in

52 %, diarrhea in 48 %, vomiting in 48 %, and peripheral edema in 43 %. The most common grade 3–4 adverse event was neutropenia in 14 % of patients. Dysgeusia, mucositis, and flatulence have likewise been observed less frequently.

Binimetinib

Data of a phase II clinical trial of binimetinib, a small-molecule MEK1/2 inhibitor, in patients with NRAS-mutated or V600 BRAF-mutated advanced melanoma were published in 2013 (Ascierto et al. 2013b). Three different arms were evaluated: binimetinib 45 mg bid for NRAS-mutated and BRAF-mutated melanoma and binimetinib 60 mg bid for BRAF-mutated melanoma. The primary end point was the proportion of patients who achieved an objective response (CR or PR). Unfortunately only data of the 45 mg groups were reported. Seventy-one patients who received at least one dose of binimetinib 45 mg were evaluated. Median follow-up was 3.3 months. Six of 30 patients with NRAS-mutated melanoma (20 %) achieved a partial response as did 8 (20 %) of 41 patients with BRAF-mutated melanoma. No complete response was detected.

In the trial reported above, at 45 mg bid, binimetinib showed a good safety profile with manageable toxicity. Acneiform dermatitis and diarrhea were the most frequent adverse events as grade 1–2. Ocular toxicity impacted in 18 %, as grade 1–2, and it was reversible without interruption of treatment in the majority of patients. No cardiac adverse event was observed in this study.

Combination of BRAF Kinase Inhibitors and MEK Kinase Inhibitors

Flaherty et al. reported about results from their phase I and phase II trials of a combined treatment with dabrafenib (BRAF kinase inhibitor) and trametinib (MEK kinase inhibitor) (Flaherty et al. 2012b). Two hundred forty-seven patients suffering from BRAF V600-mutant metastatic melanoma were included. Eighty-five patients received dabrafenib (75 or 150 mg bid) and trametinib (1, 1.5, or 2 mg daily). One hundred sixty-two patients were then randomly assigned to receive combination therapy with dabrafenib (150 mg) plus trametinib (1 or 2 mg) or dabrafenib monotherapy. Median progression-free survival for patients treated with the combination of 150 mg dabrafenib and 2 mg trametinib was 9.4 months, as compared with 5.8 months in patients treated with dabrafenib alone (HR, 0.39; $p<0.001$). The rate of complete or partial responses in the cohort treated with 150 mg dabrafenib and 2 mg trametinib was 76 %, as compared with 54 % in patients with dabrafenib alone ($p=0.03$).

Most frequent adverse reactions in the subgroup treated with highest dosages were pyrexia in 71 % and chills in 58 %. Other adverse reactions more common in the combination group than in the monotherapy group included fatigue in 53 % of patients, nausea in 44 %, vomiting in 40 %, and diarrhea in 36 %, in the broad majority of grade 1 or 2. Most frequently occurring grade 3 or 4 adverse reactions were neutropenia in 11 % of patients. The incidence of cutaneous squamous cell carcinoma (including keratoacanthomas) was clearly reduced in the combination arms with 2–7 % as compared to the monotherapy arm with 19 %. Also the rates of rash in the combination 150/1 and 150/2 groups were lower than the rate in the monotherapy group (20 % and 27 %, respectively, vs. 36 %).

Adjuvant Treatment with BRAF Kinase Inhibitors and MEK Kinase Inhibitors

It is an interesting question whether potential future uses of kinase inhibitors in an earlier phase of melanoma progression such as in the adjuvant setting will be more effective than therapy in unresectable advanced melanoma. There are presently no data in regard to this question, but there are already phase III clinical trials on the way. The BRIM-8 adjuvant vemurafenib study is ongoing, and patients with stage III disease and complete tumor resection are eligible. A phase III

adjuvant trial with the combination of dabrafenib and trametinib (COMBI-AD) has also recently started. Currently it remains a speculation as to whether the use of kinase inhibitors will improve overall survival for earlier-stage patients or only extend progression-free survival.

Mechanisms of Resistance to BRAF and MEK Inhibition

A major challenge for the clinician is the development of resistance to BRAF kinase and MEK kinase inhibitors. Numerous mechanisms have already been described. One major mechanism is the reactivation of the MAPK pathway through amplification of mutant BRAF or truncations in the BRAF protein through alternate splicing resulting in an increased dimerization and kinase activity (Poulikakos et al. 2011; Shi et al. 2012). Additionally, secondary mutations in NRAS and MEK have been described in patients with BRAF inhibitor treatment (Nazarian et al. 2010). Another reported mechanism is the overexpression of Cancer Osaka thyroid (COT) kinase, which activates ERK through MEK-dependent mechanisms not depending on RAF signaling. Even if BRAF kinase inhibitors sufficiently block the MAPK pathway, expression or activation of PDGFR-β or IGF1R can induce oncogenic signaling through the PI3K-AKT-mTOR pathway (Shi et al. 2012). One treatment strategy focuses on the combination of BRAF kinase inhibitors and MEK kinase inhibitors significantly prolonging the time period to the development of resistance and tumor progression (Flaherty et al. 2012b).

KIT Inhibitors

Imatinib

A minority of melanomas arising from acral, mucosal, and chronically sun-damaged locations harbor activating mutations and amplification of the type III transmembrane receptor tyrosine kinase KIT. The KIT inhibitor imatinib mesylate is approved and well established in other cancers such as gastrointestinal stromal tumors (GIST) and dermatofibrosarcoma protuberans. In a phase II trial by Carvajal and colleagues, 295 patients with melanoma were screened for the presence of KIT mutations and amplification (Carvajal et al. 2011). A total of 51 patients were identified, and 28 of these were treated with imatinib mesylate 400 mg orally bid. Two complete responses and two durable and two transient partial responses among 25 evaluable patients were observed. Overall durable response rate was 16 %, median time to progression 12 weeks, and median overall survival 46.3 weeks. Response rate was superior in cases with mutations affecting recurrent hot spots or with a mutant to wild-type allelic ratio of more than 1, indicating positive selection for the mutated allele. A recent study of Hodi et al. led to a clarification of the presence of mutations or amplifications only: objective responses were statistically significantly different by mutation status (7 of 13 or 54 % KIT mutated, 0 of 11 KIT amplified only) (Hodi et al. 2013).

In another phase II trial, 43 patients with metastatic melanoma harboring c-Kit mutations and amplification were enrolled (Guo et al. 2011). Patients received imatinib mesylate 400 mg daily unless intolerable toxicities or disease progression occurred. Fifteen patients who experienced progression of disease were allowed to escalate the dosage to 800 mg daily. Median progression-free survival was 3.5 months; the 6-month PFS rate was 36.6 %. Ten patients (23.3 %) and 13 patients (30.2 %) achieved partial response and stable disease, respectively. Nine of the ten patients with partial responses had mutations in exons 11 or 13. One-year overall survival rate was 51 %.

Most frequently, hematologic toxicities have been observed, anemia in 61 % of patients and leukopenia in 31 % (Carvajal et al. 2011). In ~50 % of patients, fatigue, nausea, periorbital edema, and cutaneous rashes have been reported. In more than 20 % of patients, edema of the lower extremities, diarrhea, vomiting, and pruritus occurred. As known from long-term treatments in chronic myeloid leukemia, the toxicity is on an average rather mild, and the drug is well tolerated also for years.

Antibody Blockade of Cytotoxic T-Lymphocyte Antigen-4 (CTLA-4)

Full T-cell activation requires stimulation through the T-cell receptor as well as a co-stimulatory signal provided by the binding of B7 on the antigen-presenting cell (e.g., dendritic cell) to CD28 on the T cell. Cytotoxic T-lymphocyte-associated antigen-4 is a homologue of CD28 and is an inhibitory T-cell receptor that is upregulated following T-cell activation (Ascierto et al. 2011). The normal function of CTLA-4 is to compete with CD28 to bind B7 in order to downregulate T-cell activation, acting as a natural "brake" by removing the co-stimulatory signal. The CTLA-4-B7 interaction can be blocked with an anti-CTLA-4 monoclonal antibody (mAb), which has a higher affinity for CTLA-4 than B7. Thus, the inhibitory signal is prevented and the "brake" on T-cell activation released. Phase III trials have been completed with two fully human anti-CTLA-4 mAbs: ipilimumab (MDX-010, Bristol-Myers Squibb) and tremelimumab (CP-675,206, Pfizer).

Ipilimumab

Two phase III trials have been conducted with ipilimumab which led to the approval of this drug for unresectable metastatic melanoma in the USA and in Europe. In a first trial, ipilimumab was compared to a cancer vaccine based on HLA-A*0201-restricted peptides deriving from the melanosomal protein glycoprotein 100 (gp100). Altogether, 676 HLA-A*0201-positive patients with unresectable stage III or IV melanoma received ipilimumab plus gp100 (403 patients), ipilimumab alone (137), or gp100 alone (136) (3:1:1 ratio randomization) (Hodi et al. 2010). Ipilimumab was administered at a dose of 3 mg/kg of body weight with or without gp100 every 3 weeks for up to four treatments (induction phase). Some patients could receive a re-induction therapy. The median overall survival was 10.0 months for patients receiving ipilimumab plus gp100 and 10.1 months for patients receiving ipilimumab alone versus 6.4 months for patients receiving gp100 alone (hazard ratio for death, 0.68 and 0.66, respectively; $p < 0.003$). The overall response rate was 11 % in the ipilimumab alone arm and 1.5 % in the gp100 alone arm. Survival rates at 24 months were 23 % in the ipilimumab alone group and 13.7 % in the gp100 alone group. Grade 3 or 4 immune-related adverse events occurred in 10–15 % of patients treated with ipilimumab and in 3 % treated with gp100 alone.

A second phase III trial compared ipilimumab plus dacarbazine with dacarbazine alone. A total of 502 patients with unresectable metastatic melanoma were randomized in a 1:1 ratio, to ipilimumab (10 mg/kg) plus dacarbazine (850 mg/m^2 of body surface area) or dacarbazine (850 mg/m^2) plus placebo (Robert et al. 2011). This was administered at weeks 1, 4, 7, and 10, followed by dacarbazine alone every 3 weeks until week 22. Patients with stable disease or an objective response and no dose-limiting toxic effects received ipilimumab or placebo every 12 weeks thereafter as maintenance therapy. Overall survival was 11 months in the group receiving ipilimumab plus dacarbazine and 9.1 months in the group receiving dacarbazine plus placebo (hazard ratio for death, 0.72; $p < 0.001$). Survival rates were higher in the ipilimumab-dacarbazine group at 1 year with 47.3 % versus 36.3 %, at 2 years with 28.5 % versus 17.9 %, and at 3 years with 20.8 % versus 12.2 %. Best overall response rate was 5.2 % in the ipilimumab plus dacarbazine arm and 10.3 % in the dacarbazine plus placebo arm. Grade 3 or 4 adverse events occurred in 56.3 % of patients treated with ipilimumab plus dacarbazine, as compared with 27.5 % treated with dacarbazine and placebo ($p < 0.001$). Taken together, both studies demonstrated an about 10 % survival advantage for patients treated with ipilimumab which was durable over several years (McDermott et al. 2013).

Drug-related adverse events were frequent and occurred in 80 % of patients treated with ipilimumab alone. Most frequent were fatigue, diarrhea, and nausea followed by vomiting, constipation, abdominal pain, pyrexia, headache, cough, dyspnea, and anemia. Pruritus and skin rashes occurred in more than 20 % of patients.

Diarrhea as immune-related event was observed in 27 % of patients and colitis in 8 % of patients. Furthermore, endocrine toxicity was observed in 8 % of patients comprising hypothyroidism, hypopituitarism, hypophysitis, and adrenal insufficiency.

Tremelimumab

Two phase II studies with tremelimumab have been conducted in unresectable metastatic melanoma (Camacho et al. 2009; Kirkwood et al. 2010). Based on these phase II studies, a treatment regimen with 15 mg/kg every 90 days was chosen for further evaluation. In a phase III trial, patients with treatment-naive unresectable stage III or IV melanoma were randomly assigned to treatment with tremelimumab (15 mg/kg once every 90 days) or physician's choice of standard-of-care chemotherapy (temozolomide or dacarbazine) (Ribas et al. 2013). A total of 655 patients were enrolled in this study. The trial was prematurely stopped because the prespecified futility boundary was crossed at second interim analysis after 340 deaths. At final analysis the median OS was 12.6 months for tremelimumab and 10.7 months for chemotherapy (hazard ratio, 0.88; $p=0.127$). Objective response rates were similar in both arms: 10.7 % in the tremelimumab arm and 9.8 % in the chemotherapy arm. However, the response duration was significantly longer after tremelimumab (35.8 vs. 13.7 months; $p=0.0011$). Diarrhea, pruritus, rash, and endocrine toxicities were the most common treatment-related adverse events in the tremelimumab arm. This phase III study failed to demonstrate a significant survival advantage for the treatment with tremelimumab in comparison to standard-of-care chemotherapy. A possible explanation may be the treatment schedule with administration of the drug only every 90 days. The elimination half-lives of tremelimumab and ipilimumab are 25.6 and 14.7 days, respectively (Wilson and Kotb 2013). Ipilimumab had been administered every 21 days.

Toxicities of tremelimumab are similar to those of ipilimumab. Most frequently observed were diarrhea and colitis (51 %), nausea (34 %), fatigue (33 %), cutaneous rash (33 %), pruritus (31 %), vomiting (23 %), and decreased appetite. Endocrine disorders have likewise been observed.

Antibody Blockade of Programmed Death-1 (PD-1)

The programmed death-1 receptor (PD-1) is similar to CTLA-4, an inhibitory T-cell receptor. It is activated by two known ligands, PD-L1 (also known as B7-H1 or CD274) and PD-L2 (also known as B7-DC or CD273). Both ligands are predominately expressed on the tumor and the tumor microenvironment. As for PD-1 the immune suppressive signals are predominately delivered by the cancer; it is likely that PD-1 blockade will have greater antitumor activity and fewer side effects than CTLA-4 inhibition (Ribas 2012).

Nivolumab

Presently several phase III trials in unresectable malignant melanoma are conducted in order to evaluate the efficacy and safety of nivolumab. So far, results have been published from a phase II trial in advanced melanoma, non-small cell lung cancer, castration-resistant prostate cancer, renal cell cancer, and colorectal cancer. In this study, the anti-PD-1 antibody nivolumab (BMS-936558) was administered at the dose of 0.1–10.0 mg/kg of body weight every 2 weeks. Patients received up to 12 cycles until disease progression or a complete response occurred. A total of 296 patients were enrolled and response evaluation was possible for a total of 236 patients. The objective response rate in melanoma patients was 28 % (26 of 94 patients). Similar response rates have been observed in renal cell cancer and non-small cell lung cancer. Interestingly, in 17 patients with PD-L1 negative tumors, no objective responses were assessed, whereas 9 of 25 patients with PD-L1 positive tumors (36 %) showed an objective response.

Grade 3 or 4 drug-related adverse events were observed in 14 % of patients, and three deaths from pulmonary toxicity have been observed.

Toxicity under the highest dosage of 10.0 mg/kg was observed in 38 % of patients. Diarrhea was the most frequent adverse event (9 %) followed by rash (8 %) and pruritus (7 %). Four percent of patients developed a pneumonitis. Endocrine disorders were observed in 2 % of patients.

Pembrolizumab

Presently, several phase III trials with pembrolizumab are conducted in unresectable metastatic melanoma. So far, a phase II trial was reported with pembrolizumab. In this trial pembrolizumab was administered intravenously at a dose of 10 mg/kg of body weight over 2 or 3 weeks or 2 mg/kg every 3 weeks (Hamid et al. 2013). A part of these patients had received a prior treatment with ipilimumab; another part had not. A total of 135 patients with advanced melanoma were enrolled in the trial. The confirmed response rate was 38 %, with the highest confirmed response rate in the cohort that received 10 mg/kg every 2 weeks (ORR 52 %). There were no significant differences between patients who had received prior ipilimumab and those who had not. The median follow-up time was 11 months, and at this time point 81 % of patients who had a response were still stable and continued receiving treatment. These results show that the objective response rate is clearly higher as compared to ipilimumab and that most of these responses seem to be durable.

Common adverse events were fatigue (30 %), rash and pruritus (21 %), diarrhea (20 %), myalgia (12 %), headache (10 %), asthenia (10 %), hypothyroidism (8 %), pyrexia (7 %), and dyspnea and pneumonitis (4 %).

BMS-936559

BMS-936559 is an anti-PD-L1 antibody; this means it is directed to the ligand of PD-1. Only a phase I trial has been published so far in advanced metastatic melanoma with BMS-936559. In this multicenter phase I trial, anti-PD-L1 antibody was administered at escalating doses ranging from 0.3 to 10 mg/kg of body weight every 14 days in 6-week cycles for up to 16 cycles (Brahmer et al. 2012). A total of 207 patients have been enrolled in this trial with multiple solid cancers. Among them were 55 patients with metastatic melanoma. An objective response was observed in 9 of 52 patients with melanoma (18 %). The responses were durable.

Toxicity was mild and in infusion-related reactions was most frequently observed (10 %), followed by diarrhea (9 %), cutaneous rashes (7 %), pruritus (6 %), and hypothyroidism (3 %).

Combination of CTLA-4 Antibodies and PD-1 Antibodies

One phase I trial of nivolumab combined with ipilimumab in patients with advanced melanoma has been published to date. Intravenous doses of nivolumab and ipilimumab were administered in patients every 3 weeks for four doses, followed by nivolumab alone every 3 weeks for four doses (concurrent regimen). The combined treatment was subsequently administered every 12 weeks for up to eight doses. A total of 53 patients received concurrent therapy with nivolumab and ipilimumab. The objective response rate for all patients in the concurrent-regimen group was 40 %. Evidence of clinical activity (OR + SD) was observed in 65 % of patients. At the maximum doses (nivolumab at a dose of 1 mg/kg and ipilimumab at a dose of 3 mg/kg), 53 % of patients had an objective response, all with tumor reduction of 80 % or more.

Grade 3 or 4 adverse events related to therapy occurred in 53 % of patients in the concurrent-regimen group but were qualitatively similar to previous experience with monotherapy and were generally reversible.

Prospects

Both the introduction of selective kinase inhibitors and the blockade of immune checkpoints on T cells in melanoma patients are major progresses in melanoma treatment. With the introduction of BRAF kinase inhibitors and MEK kinase inhibitors during the last years, treatment for advanced melanoma changed dramatically. For patients

with a BRAF mutation, the objective response rate increased to 50 % and more, and the progression-free survival and overall survival are significantly prolonged. A major problem is the development of resistance to the kinase inhibitors through multiple different mechanisms.

Dramatic progress developed in the immunotherapy of melanoma with the immune checkpoint blockade in T lymphocytes involving CTLA-4 and PD-1 receptor antibodies. Likewise response rates around 50 % were achieved with these new immunotherapies, which was quite unexpected for the immune approach. The blockade of inhibitory receptors on T cells showed that many patients have functional T-cell responses against tumor antigens but that these were inhibited by different mechanisms. Seemingly the tumor responses induced by immunotherapy are rather durable and are lasting with ipilimumab in some patients already 5 years and longer. Probably we will see cures in metastatic melanoma in an unknown percentage of patients in the future.

Combined therapies and sequential schedules are currently under evaluation. Several authors feel that beginning with immunotherapy would be the best option for melanoma patients (Ascierto et al. 2012). Antibodies for checkpoint blockade can be administered without consideration of the mutational status of the tumor and may also make kinase inhibitor therapies dispensable. The combined use of both or the administration of kinase inhibitors directly after the immune therapy may be associated with unexpected high toxicity (Harding et al. 2012). Combinations and sequences will be evaluated in many different clinical trials in the future.

In conclusion, selective kinase inhibitors and immune checkpoint blockade have completely changed the therapy of unresectable metastatic melanoma, and cures of patients with metastatic melanoma will come into reach in the near future.

Topical Anaesthetics

151

Flora B. de Waard-van der Spek
and Arnold P. Oranje

Key Points

- Topical anaesthetics are used to decrease the pain associated with superficial dermatological, aesthetic, and laser procedures.
- Topical anaesthetics act on sodium channels in the nerve membranes.
- EMLA is the only topical anaesthetic registered for use in children from the age of 3 months.
- It is important to take into account the maximum recommended dose, application area, and application time by age and weight, when using topical anaesthetics.
- Factors that should be considered to reduce the risk of adverse effects associated with the use of topical anaesthetics include the amount of product used, body location, size of the surface area, and duration of product application.

History

The Incas derived a substance from the plant *Erythroxylum coca*, 'coca', and discovered anaesthetic and stimulatory properties. In 1860, Niemann isolated cocaine, the plant's active ingredient. In 1884, Karl Koller demonstrated that general anaesthesia could be avoided for ophthalmic procedures by the application of cocaine to the conjunctiva. In the early twentieth century, ester anaesthetics, such as procaine and tetracaine, were created. These were noted to result in high rates of allergic contact dermatitis. In 1943, Löfgren synthesised the first amide anaesthetic, lidocaine. Subsequently, a large number of topical formulations of esters, amides, and adrenalines have been developed and used for dermatological procedures.

General Principles: Classification and Structure

A local anaesthetic cream consists of hydrophilic groups, usually a tertiary amine, and hydrophobic groups, generally an aromatic residue. These groups are separated by an alkyl chain. They may be separated into two groups: those containing an ester linkage (e.g. procaine, tetracaine, cocaine) and those containing an amide linkage (e.g. lidocaine and prilocaine). The linkage is responsible for the pathway by which the molecule is metabolised and excreted. Ester and amide anaesthetics

differ in their chemical stability and metabolism. Esters are hydrolyzed by plasma cholinesterases and form para-aminobenzoic acid, a common allergen. Amides tend to be more stable and less allergenic and are metabolised in the liver by microsomal enzymes. Mucosal surfaces are penetrated more easily than a keratinised (skin) surface because of the absence of a stratum corneum.

Topical anaesthetics exist in many different preparations and vehicles for delivery. Only after traversing the superficial layers of the skin and affecting the nerve endings within the dermis the topical anaesthetics will be effective. For optimising the percutaneous absorption of topically applied drugs, different strategies are utilised in formulations. The first strategy is using a vehicle or device which maximises drug delivery into the skin without affecting the physiochemical properties of stratum corneum, and the second is using penetration enhancers. Occlusion is a physical method utilised to enhance the permeation of the anaesthetic through the skin.

Eutectic mixtures permit higher concentrations of anaesthetic to be used safely and facilitate application to the skin. Liposomal encapsulation is another vehicle that facilitates percutaneous drug delivery. Liposomes are microscopic, spherical, phospholipid-based carriers. These carriers deliver a greater concentration of local anaesthetic to sensory nerves than other conventional formulations with lower lipophilicity.

Mechanism of Action

Local anaesthetics act on sodium channels in the nerve membranes. The conduction is decreased via interaction with specific binding sites, and total inhibition of conduction is achieved with increasing concentration of the local anaesthetic.

Drugs

Local anaesthetics play a useful role in simple or superficial interventions.

Lesions can be frozen by refrigerants such as ethyl chloride spray. The same effect may be achieved with liquid nitrogen, but its lower temperature may cause greater post-operative discomfort. Local anaesthetics are generally ineffective when applied to intact human skin because they are poorly absorbed.

Lidocaine has a rapid onset and intermediate duration of action. Prilocaine has a slower onset of action but a longer duration of action than lidocaine.

EMLA is a topical anaesthetic cream developed by Broberg and Evers for use on intact skin. The acronym EMLA stands for Eutectic Mixture of Local Anaesthetics. EMLA is a mixture of lidocaine 25 mg/g and prilocaine 25 mg/g. EMLA is composed of the following ingredients: lidocaine 25 mg, prilocaine 25 mg, Arlatone 289 (emulgent), Carbopol 934 (thickener), and distilled water in 1 ml cream.

The lidocaine/tetracaine patch (lidocaine 70 mg/tetracaine 70 mg, Synera™, known in Europe as Rapydan™) is a novel drug delivery system designed to warm the skin and enhance the delivery of local anaesthetics through the skin. The patch contains a small amount of topical anaesthetic under a patented heating element that raises the temperature to 40 °C for longer than 14 h and enhances delivery of the anaesthetic. The heating system portion of the patch is activated through an exothermic reaction when oxygen interacts with the internal components of iron powder, activated carbon, wood flour, sodium chloride, and water. When the patch is applied to the skin, it increases the skin temperature by approximately 5 °C, but the maximum skin temperature produced by the patch at the site of application does not exceed 40 °C. The product manufacturer states that the patch should be placed on intact skin 30 min before superficial dermatological procedures such as a shave biopsy. The safety and effectiveness of this patch have been established in patients 3 years or older. In a double-blind study in 82 healthy adult volunteers, the lidocaine/tetracaine patch provided effective anaesthesia before a vascular access procedure, with an application time as short as 10 min, and was better than lidocaine/prilocaine cream at all application times shorter than 60 min, demonstrating a substantial improvement in time to onset of anaesthesia. In a prospective, randomised, single-blinded, and monocentre study in 200 children aged 3–13 years, the Synera/Rapydan

patch led to superior analgesia during venous puncture than the EMLA patch after a contact time of 35 min.

Local Anaesthetics That Are Used

- Amethocaine patch
- EMLA (Eutectic Mixture of Local Anaesthetics), a mixture of lidocaine 25 mg/g and prilocaine 25 mg/g
- Ethyl chloride spray
- Lidocaine gel
- Lidocaine gel 10 % glycyrrhetinic acid monohemiphthalate disodium (absorption promoter)
- Lidocaine adrenaline tetracaine (LAT) gel
- Lidocaine 15 % and prilocaine 5 % ointment
- Lidocaine 23 % and tetracaine 7 % ointment
- Lidocaine 7 % and tetracaine7 % patch (heated) (Synera™)
- Liquid nitrogen
- Tetracaine adrenaline cocaine (TAC) gel
  Tetracaine cream

Adverse Effects

By using topical anaesthetics, a risk of systemic toxicity should be a concern. Some reasons for inducing systemic toxicity are use of excessive amounts of topical anaesthetics, covering of a large surface area with anaesthetic, occlusion, treated area (mucosal surfaces?), long duration of application, inadequate skin barrier function, and impaired hepatic or renal function. Lidocaine has dose-dependent central nervous system toxicity. An overdose of prilocaine can cause methaemoglobinaemia.

Dermatological Indications of Eutectic Mixture of Local Anaesthetics (EMLA), a Mixture of Lidocaine 25 mg/g and Prilocaine 25 mg/g

EMLA will produce effective analgesia in the skin prior to a variety of superficial skin interventions. Ethyl chloride spray (ECS) has caused more local irritation in a study in which the analgesic and local tolerance of EMLA and ECS before intravenous cannulation in premedicated children were compared.

Several more local anaesthetics are available and have been evaluated. For example, 10 % lidocaine gel containing glycyrrhetinic acid monohemiphthalate disodium as an absorption promoter has reduced the pain upon venous cannulation in adults and in children, although further improvement seemed necessary in order to achieve ideal conditions.

Tetracaine adrenaline cocaine (TAC) gel has been effective in laceration repair, but serious adverse reactions have been reported. Lidocaine adrenaline tetracaine (LAT) gel has worked as well as TAC gel for topical anaesthesia in facial and scalp lacerations in a randomised double-blind study in 95 children aged 5–17 years, but additional studies on its safety have to be done.

Amethocaine in the form of a self-adhesive patch has been evaluated in an open study in children before venous cannulation. A satisfactory anaesthesia was achieved in 80 % of the patients, but 20 % of the patients felt moderate to severe pain.

EMLA cream has been compared with a 4 % tetracaine-containing cream for preventing venipuncture-induced pain in children. It was reported that EMLA reduced the pain more effectively.

EMLA used with glyceryl trinitrate (GTN) ointment which promotes venous dilatation has been found to make intravenous cannulation in adults technically easier. However, adverse effects of GTN include headaches and hypotension. Further studies will be necessary, especially in children, for establishing the efficacy and the safety of this combination.

EMLA is the only topical anaesthetic registered for use in children from the age of 3 months. Studies in neonates indicated that EMLA has also been safely used in neonates. EMLA is approved for anaesthesia of healthy skin in children of 0–3 months, an age range in which it used to be contraindicated. Several studies proved that the use of EMLA cream in neonates is safe when used once a day. Based on available clinical data on the use of EMLA in neonates, infants, and children, maximum dosage recommendations were made (Table 151.2).

EMLA

At present, we prefer to use EMLA for inducing local anaesthesia for superficial interventions in children. Indications for EMLA cream are discussed in the following section.

We have evaluated the efficacy and minimal effective application time for EMLA cream for the removal of mollusca contagiosa in children. Eighty-three children aged 4–12 years, scheduled for curettage of at least five molluscum contagiosum lesions, participated in a double-blind, time (15, 30, and 60 min) response study. The pain was assessed by the children and the physician as none, slight, moderate, or severe. In addition, the children rated the pain on a Visual Analogue Scale (VAS). EMLA effectively prevented the pain for all three application times ($P<0.01$). The proportion of children reporting no pain on the verbal scale increased from 36 % in the 15 min group to 61 % in the 60 min group.

EMLA and Skin Biopsy

It is important to achieve analgesia up to a sufficient skin depth for taking skin biopsies. The maximum depth of analgesia provided by EMLA is about 5 mm. There are controversial reports on the efficacy of EMLA for taking biopsy. We have conducted a double-blind, placebo-controlled study to investigate the analgesic effect of the EMLA patch as a premedication for skin biopsy in 63 children. There were two parallel groups. One group received an EMLA patch and the other placebo on the skin at the site of the biopsy for 60 min. After removal of the patch, the physician infiltrated the skin as usual with 1 ml lidocaine and took the biopsy with a 4 mm biopsy punch. EMLA was significantly more effective in decreasing the pain at the injection site of the lidocaine infiltration. There was no difference in the pain scores for the biopsy.

Other Indications for EMLA

Only the most relevant ones are mentioned here. The efficacy of EMLA analgesia during the treatment of condylomata acuminata by cauterisation or laser treatment has been investigated in a number of clinical studies. Most effective analgesia has been achieved after applying EMLA for 5–15 min on the genital mucosa. Longer application times have resulted in less effective analgesia.

EMLA applied for 60 min has provided analgesia for the treatment of port-wine stains with pulsed-dye laser. EMLA did not affect the efficacy of the removal of the port-wine stain. However, our own experience has been that the analgesic efficacy of EMLA is not adequate.

Effective analgesia has been achieved with EMLA for surgical debridement of leg ulcers of venous or arterial origin.

Other indications are painful inflamed acne lesions, light electrocautery and fulguration of whiteheads, and hair removal by thermolysis in hirsutism.

EMLA has not been effective for removing common warts by curettage. We have observed the EMLA analgesia is not sufficient for the removal of common warts by cryotherapy.

Studies have also been undertaken to investigate the effectiveness of EMLA for (intramuscular) vaccinations. EMLA has been found to significantly reduce the pain of diphtheria, pertussis, and tetanus (DTP) vaccination in children.

We have conducted a double-blind, placebo-controlled study to investigate the analgesic effect of EMLA for the subcutaneous administration of mumps, measles, and rubella (MMR) vaccination in 96 children aged about 9 years. There was no significant difference between the pain scores in the EMLA group and the placebo group, although the difference almost reached significance ($P=0.052$).

There was a trend that in the EMLA group less pain was felt. However, this trend was not significant. Probably the pain of MMR vaccination was not due to skin penetration but due to the injection of the liquid into the subcutaneous space.

The most important dermatological indications for the use of EMLA cream are for the removal of molluscum contagiosum and as premedication for taking skin biopsy in childhood. The biopsy procedure is much easier to perform. Moreover, it may also provide material of improved quality for histological investigation. Other local anaesthetics need to be investigated further.

Adverse Effects

No major adverse effects of EMLA have been reported. A brief period of local redness or pallor of the skin may occur. Despite the frequent and widespread use of EMLA, we have encountered only very few cases in the literature of contact allergy caused by EMLA. In the patients, patch tests were positive for EMLA and prilocaine. For 10 years, we have treated 3,500–4,000 children with EMLA, mainly as an anaesthetic for the removal of molluscum contagiosum. We have observed purpura in five patients, which disappeared within several days. In these patients, patch tests were performed. All tests were negative. We concluded that the purpuric reaction was not of an allergic nature and possibly caused by a toxic effect on the capillary endothelium.

Regimen

The indications and recommended application times for EMLA are shown in Table 151.1. EMLA acts more rapidly in children with atopic dermatitis. Several studies have been undertaken to determine the plasma levels of lidocaine and prilocaine after application of EMLA. In these studies, plasma levels were far below the toxic levels. There is a relative risk for methaemoglobinaemia in children younger than 3 months. Prilocaine can induce methaemoglobinaemia via its *O*-toluidine metabolite. The activity of erythrocyte methaemoglobin reductase does not reach adult levels until after the age of 3 months.

We recommend that the use of EMLA per day is limited to a maximum of 1 g in children aged 0–3 months, 2 g in children to a maximum aged 3–12 months, and 10 g in older children.

Table 151.2 shows the recommendations by the US Food and Drug Administration (FDA) on dose, application area, and application time by age and weight of EMLA, for infants and children based on application to intact skin (source: www.accessdata.fda.gov).

Topical Anaesthetics in Laser Treatment and Intense Pulsed Light (IPL) Treatment

Topical anaesthetics may reduce the pain associated with laser or IPL procedures. The Food and Drug Administration (FDA) has approved mixtures

Table 151.1 Indications and the recommended application times for EMLA

Indication	Application time (min)
Molluscum contagiosum	15–30
Skin biopsy (pretreatment)	60
Condylomata acuminata	5–15
Port-wine stains (pulsed-dye laser)	60
Debridement of leg ulcers	30
Vaccination	60

Table 151.2 EMLA cream maximum recommended dose, application area, and application time by age and weight[a], for infants and children based on application to intact skin

Age and body weight requirements	Maximum total dose of EMLA cream (g)	Maximum application area[b] (cm^2)	Maximum application time (h)
0 up to 3 months or <5 kg	1	10	1
3 up to 12 months and >5 kg	2	20	4
1–6 years and >10 kg	10	100	4
7–12 years and >20 kg	20	200	4

Source: www.accessdata.fda.gov

Please note: If a patient greater than 3 months old does not meet the minimum weight requirement, the maximum total dose of EMLA cream should be restricted to that which corresponds to the patient's weight

[a]These are broad guidelines for avoiding systemic toxicity in applying EMLA cream to patients with normal intact skin and with normal renal and hepatic function

[b]For more individualised calculation of how much lidocaine and prilocaine may be absorbed, physicians can use the following estimates of lidocaine and prilocaine absorption for children and adults: the estimated mean (±SD) absorption of lidocaine is 0.045 (±0.016) mg/cm^2/h. The estimated mean (±SD) absorption of prilocaine is 0.077 (±0.036) mg/cm^2/h

such as 4 % lidocaine cream or 2.5 % lidocaine/2.5 % prilocaine eutectic mixture (EMLA), but these do not always provide adequate topical anaesthesia. The onset action of EMLA is 1–2 h, and occlusion is recommended, which does not permit the brief IPL procedural time that patients desire. Compounded formulations with a higher concentration of the mixture or other topical anaesthetics in an occlusive base are used to increase the onset of action and duration and reduce the pain.

Of the many products used, 23 % lidocaine/7 % tetracaine in an ointment base has become a common formulation for preprocedure anaesthesia in laser therapy. Serum lidocaine levels and cutaneous adverse effects after application of 23 % lidocaine/7 % tetracaine ointment to the face were studied in 52 adult volunteers. The 23 % lidocaine/7 % tetracaine ointment was applied to their faces for 2 h. Eleven of 52 volunteers (21 %) reported a symptom that has been associated with high blood concentrations of lidocaine: dizziness; drowsiness; light-headedness; numbness or tingling other than on the face, lips, or tongue; and back pain. At the time of reported symptoms, only 2 of 11 volunteers had serum lidocaine levels greater than 2 μg/mL. Cutaneous adverse effects of the topical anaesthetic were frequent, a.o. flaking, scaling, peeling, itching, or burning.

Another compound is lidocaine 15 %/prilocaine 5 % ointment. In a single-centre safety study in 20 adults, lidocaine 15 %/prilocaine 5 % topical anaesthetic ointment was applied to the face or face, neck, and chest for 60 ± 15 min before IPL. Toxic levels of lidocaine and prilocaine were not reached.

Adverse Effects

Adverse effects are usually caused by high plasma concentrations of topical anaesthetics, resulting from excessive exposure and/or application to abraded or torn skin. Possible adverse effects include:

- Burning or stinging local to the administration site.
- High plasma concentration initially produces central nervous system (CNS) stimulation (including seizures), followed by CNS depression (including respiratory arrest). The CNS stimulatory effect may be absent in some patients, particularly when amides (e.g. tetracaine) are administered. Solutions that contain epinephrine may add to the CNS stimulatory effect.
- High plasma levels depress the heart and may result in bradycardia, arrhythmias, hypotension, cardiovascular collapse, and cardiac arrest. Local anaesthetics that contain epinephrine may cause hypertension, tachycardia, and angina.
- Methaemoglobinaemia (with Prilocaine)

The US Food and Drug Administration (FDA) has issued an advisory regarding the risk of serious adverse effects with the use of topical anaesthetics for cosmetic procedures. Topical anaesthetics are sometimes used in ways not approved and at doses that may pose a risk for serious harm. The FDA reported fatal cases: two women applied topical anaesthetics to their legs to lessen the pain of laser hair removal. These women then wrapped their legs in plastic wrap, as they were instructed, to increase the creams' numbing effect. Both women had seizures, fell into comas, and died from the toxic effects of the anaesthetic drugs. The skin numbing creams used in these two cases contained high amounts of the anaesthetic drugs lidocaine and tetracaine.

Conclusion

Topical anaesthetics are able to decrease pain during different cutaneous procedures. Awareness of the indications, pharmacologic mechanisms, appropriate methods of application, and safety profiles of the available topical anaesthetics is very important.

Careful attention must be paid to the location (skin, mucosa, face, body, a.o.), the total surface area covered, and the duration of anaesthetic skin contact. Adverse outcomes are associated with the use of compounded products, often non-FDA-approved, that have inappropriately high anaesthetic concentrations and with the use of topical anaesthetics on excessively large skin surface areas, for example, during laser treatments.

Serum levels are clearly related to the surface area to which the anaesthetic is applied. Physicians using topical anaesthetics are cautioned to limit the surface area to which they are applied. However, safe use of topical anaesthetics can decrease or eliminate pain during many cutaneous procedures and, also important to keep in mind, will decrease anxiety in patients who fear pain from procedures.

Many studies in children show the effect of EMLA cream as topical anaesthetic in superficial and dermatological procedures. EMLA cream at recommended dosage is a safe and effective topical anaesthetic agent in children.

For optimising the percutaneous absorption of topically applied drugs, different strategies are utilised in formulations. A patch containing a eutectic mixture of lidocaine 70 mg and tetracaine 70 mg (Synera™) consists of a thin, uniform layer of a local anaesthetic formulation with an integrated, oxygen-activated heating component that is intended to enhance the delivery of the local anaesthetic. The safety and effectiveness of Synera™ have been established in paediatric patients aged 3 years and older in well-controlled studies.

Topical Preparations and Vehicles 152

Marcello Monti and Stefania Motta

Key Points

- As a general consideration, the chemical agents that may be applied to the skin for their local effects belong to two categories: drugs and non-drugs.
- The agents of the first category have a selective action in terms of chemical and pharmacological activity on the skin. Antibiotics, antimycotics, corticosteroids and antineoplastics are some examples.
- The second category is composed of a heterogeneous group of agents showing mostly a non-selective action, has limited chemical and pharmacological activity and, sometimes, has just a physical action.
- Therefore, excluding drugs, topical treatment may be subdivided into non-specific treatment with bases and specific treatment with active agents.
- Dermatological bases or vehicles serve not only as vectors for incorporating active ingredients but also possess some therapeutic effects because of their own physicochemical properties.
- Specific topical treatments are prescribed by dermatologists in so-called magistral formulations. In this case, the topical treatment consists of the local use of some active substances in a suitable vehicle. These locally acting agents include most absorbents, astringents, demulcents, rubefacients, keratolytics and miscellaneous other ingredients.

e-mail: marcello.monti@humanitas.it; stefania.motta@humanitas.it

General Principles and Classification

Dermatological therapy can be a combination of systemic and topical treatments although topical treatment is often the only therapy prescribed. As a consequence, dermatologists have to be familiar with the use of topical preparations, whether a drug or an active agent needs to be added or not. Tailor-made preparations have undoubtedly a great positive impact on patients, but their use is limited by two main factors: the poor confidence of practising dermatologists to prescribe magistral preparations and the difficulty in finding pharmacists able and willing to provide them. In a recent analysis of compound prescriptions, some mixtures prescribed by dermatologists were questionable either because of the number of active ingredients or the selected

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_152, © Springer-Verlag Berlin Heidelberg 2015

concentrations. As a general consideration, the chemical agents that may be applied to the skin for their local effects belong to two categories:

- Drugs
- Non-drugs

The agents of the first category have a selective action in terms of chemical and pharmacological activity on the skin. Antibiotics, antimycotics, corticosteroids and antineoplastics are some examples. They are prepared by pharmaceutical companies according to strict international rules on suitable vehicles and are ready to use. Their use in combination with other ingredients is neither recommendable nor economically worthwhile.

The second category is composed of a heterogeneous group of agents which, by exclusion, do not belong to the first. They have mostly a non-selective action, have limited chemical and pharmacological activity and, sometimes, have just a physical action. These locally acting agents include most absorbents, astringents, demulcents, rubefacients, keratolytics and miscellaneous other ingredients used in dermatology. The local treatment of skin disorders also includes the exclusive use of vehicles. Therefore, excluding drugs, topical treatment may be subdivided into:

- Non-specific treatment with bases
- Specific treatment with active agents

Non-specific Treatment with Bases

Dermatological bases or vehicles serve not only as vectors for incorporating active ingredients but also possess some therapeutic effects because of their own physicochemical properties. In this case, the bases themselves are the active ingredients. The ideal base should have the following properties:

- Easy to apply and remove
- Non-toxic, irritant or allergenic
- Chemically stable
- Pharmacologically inert
- Cosmetically acceptable

The bases may be liquid, semi-solid or solid. Some bases are utilized in non-specific dermatological treatment, while others are just vehicles.

Table 152.1 Classification of topical preparations

Bases utilized in non-specific treatments	Bases utilized as vehicles
Fatty ointments	Aqueous solutions
Fatty pastes	Tinctures
Powders	Varnishes
Hydrogels	Sprays
Hydroalcoholic lotions	Hydrosoluble ointments
Creams W/O	Creams O/W
Liquid emulsions	
Oils	

Another classification of vehicles is based on their physical phase:

- Monophasic: powders and greases
- Biphasic: paste, status lotions or emulsions
- Triphasic: cooling paste

The main effects, clinical indications and contraindications of bases are discussed according to the categories listed in Table 152.1.

Fatty Ointments

Fatty ointments are anhydrous, lipophilic and hydrophobic bases consisting of mineral, synthetic or plant and animal fats. Paraffin, petrolatum, lanolin, castor oil and olive oil are examples of fats used in ointments. The ointments cover the stratum corneum promoting the inhibition of this layer by softening the skin and promoting drug penetration. They are useful for the treatment of dry skin, hyperkeratotic and scaling dermatoses. The obstruction of the release of heat and water may produce maceration, increase inflammation or produce dyshidrotic eruptions.

Fatty Pastes

Pastes are mixtures of powder and ointment or cream. The powders are at least a 10 % strength, and depending on their concentration, the pastes are subdivided into:

- Pastes: powder/ointment ratio 1:1
- Soft pastes: powder/ointment ratio 1:2
- Hard pastes: powder/ointment ratio 2:1

Zinc oxide, talc and wheat starch are the most utilized powders. The pastes have a cooling, anti-inflammatory and skin-protective action.

They are useful for the treatment of chronic dermatoses, especially when lichenification is present. Some of them have particular secretion absorbing or drying effects. The hard pastes have the same contraindications as ointments.

Powders

Powders are composed of micronized and dispersed granular particles. They can be homogeneously distributed on large body areas directly from a dusting can. Talc, zinc oxide, starch and magnesium carbonate are examples of the most commonly used powders. They have protective antifrictional activity together with cooling and drying effects. They are used in erythematous exanthems and in some pruritic conditions. They dry the skin absorbing water and lipids from the surface, and they crust the skin in oozing and erosive dermatoses.

Hydrogels

Hydrogels are composed of cellulose compounds and derivatives, alginic acid and others that swell with water to produce a gelatinous base. Hydrogels have cooling and slight anti-inflammatory action so they are used in erythematous and pruritic exanthems as well as for the treatment of acute exogenous dermatitis. They may be applied to hairy parts but have a drying effect on prolonged application.

Hydroalcoholic Lotions

Hydroalcoholic lotions are a mixture of ethanol 40–70 % or isopropanol 20–40 % and water. They are mostly used as vehicles for active substances but may be used as is for their defatting and drying effects. They are indicated in seborrhoeic conditions and contraindicated in xerotic and scaling dermatitis.

Creams W/O

Creams (W/O type) are a two-phase system of fatty substances (up to 70 %), water (30 %) and emulsifying agents. They are mainly used as vehicles for active substances, and due to the high concentration of fats, they have a smoothing and softening effect, together with slight cooling and anti-inflammatory action. For these properties, they are employed to counteract xerotic, dry skin and to soften scales and crusts in chronic dermatoses. They are less tolerated with respect to O/W creams on seborrhoeic types of skin.

Liquid Creams

Liquid creams are emulsions with low fatty component (less than 30 %). They appear milky in colour and consistency and usually are employed in cosmetics as cleansing and body lotions. Liquid creams possess a slight anti-inflammatory, antipruritic effect and may be used even in exudative and vesicular dermatoses. However, they dry the skin due to rapid evaporation of water. They are not suitable for chronic scaly dermatosis treatment.

Oils

Oils, as medical preparations, are used for dissolving fat-soluble active ingredients but may be used alone or for suspending powders. Oils have lubricating action and may be used to soften crusts and scales and to remove ointments and pastes. They are indicated in acute superficial dermatoses especially in children and are less indicated in adults especially with seborrhoea or seborrhoeic dermatoses.

In Table 152.2, the bases for dermatological non-specific treatment are listed. Some of these vehicles are rarely used mainly because of their poor cosmetic acceptability; only emulsions are largely used as vehicles for non-specific topical treatment. The most widely used cream in European countries is a base cream called cetomacrogol cream present in many pharmacopoeia. Cetomacrogol cream consists of 30 % soft greases including white soft paraffin and petrolatum. Cetomacrogol 1,000, the emulsifying agent, is a condensation of cetostearyl alcohol with ethylene oxide. Cetomacrogol cream is

Table 152.2 Effects, indications and contraindications of vehicles

Vehicles	Effects	Indications	Contraindications
Fatty ointments	Softening, warming	Hyperkeratotic fissured dermatoses Xerosis Dry skin	Acute inflamed skin Vesicular dermatoses
Pastes	Cooling, anti-inflammatory, secretion absorbing, protective	Chronic dermatoses Lichenified dermatoses	Acute dermatoses Erosive dermatoses
Powders	Cooling, protective, antifrictional, drying	Erythematous exanthems	Dry skin, crusting, oozing, erosive dermatoses
Hydrogels	Cooling, superficial anti-inflammatory, antipruritic	Erythematous or urticarial exanthems Dermatitis solaris	Dry skin
Hydroalcoholic lotions	Drying, cooling	Dermatoses of hairy parts, seborrhoea	Dry skin
Creams O/W	Cooling, anti-inflammatory, emollient	Acute dermatoses, seborrhoeic skin	Dry skin
Creams W/O	Softening, slightly cooling, anti-inflammatory	Chronic inflammation, soft scales and crusts Xerotic dermatoses	Acute inflamed skin Dyshidrosis
Liquid creams	Cooling, anti-inflammatory, emollient	Acute, exudative dermatoses	Scaly or crusty dermatoses
Oils	Lubricating, softening scales and crusts	Superficial inflammation large-area dermatoses. Removal of ointments and pastes	Seborrhoeic dermatoses

non-allergenic, non-greasy, washable, low cost and easy to prepare. Usually, it is prescribed as a vehicle for active ingredients, but it is useful in many non-specific treatments and even as a placebo. Cetomacrogol cream is also produced by pharmaceutical companies.

Specific Treatment with Active Agents

Specific topical treatments are prescribed by dermatologists in so-called magistral formulations. In this case, the topical treatment consists of the local use of some active substances in a suitable vehicle. The vehicles are the same as proposed in the previous section, and the local acting agents may be differentiated by their specific activity on the skin. There is no international agreement about the terminology for describing activity of these compounds on the skin. Moreover, there is no clear distinction between drugs and non-drugs, so that the limit of a magistral prescription is not well defined.

Theoretically, all topical dermatological treatments can be carried out with extemporaneous preparations. However, some of them are technically difficult to prepare and economically not worthwhile. Others are purchased from pharmaceutical companies and have a high safety profile. The main actions of topical active ingredients are listed in Table 152.3. The actions of active ingredients and the ingredients themselves are discussed in the following sections.

Protectives and Absorbents

Protectives and absorbents are intended to absorb moisture, decrease friction, discourage bacterial growth and absorb fats contributing to a decrease in body odours. These actions are achieved using dusting powders and some mechanical and chemical protectives. Dusting powders considered for this activity are bentonite, calcium carbonate, calcium precipitate, talc, titanium dioxide, zinc oxide and zinc stearate. Other

Table 152.3 Action of topical active ingredients

Recommended for magistral prescription	Difficult to prepare or not economically worthwhile	Use of registered drugs is recommended
Protective and absorbent	Pigmenting	Antibacterial
Lenitive	Depigmenting	Antifungal
Emollient	Sun protecting	Virostatic
Astringent and antiperspirant antipruritic	Depilatories	Anti-inflammatory
Rubefacient	Insect repellent	Cytostatic
Caustic	Antiparasitic	Anaesthetizing
Keratolytic		
Keratoplastic		
Cleansing		
Opacifying, sebum absorbing		

substances such as propylene glycol and glycerol may be added to increase the protective action. An example is zinc paste:

Zinc oxide	10
Propylene glycol	15
Glycerol	40
Purified water	35

Collodion varnish may be used to protect non-affected areas of the skin from topically applied irritants or caustics:

Pyroxylin	4
Ether	71
Ethanol	25

Vaseline and silicones are examples of other chemical protectives. Hydrophilic and lipophilic emulsions containing a variety of constituents, such as allantoin, linoleic acid, pantothenol, urea and vitamins, have been considered by other authors to be protective. However, their activity has not been demonstrated yet.

Lenitives

Lenitives are employed to alleviate skin irritation in many superficial skin dermatoses. They also prevent drying of affected areas. Lenitives are mainly in the form of lotions, wet dressings or simply powders. Alginates, mucilages, gums, dextrins, starches, certain sugars, glycerol and many oils are commonly considered as lenitives. Zinc oxide, talc and calamine are sometimes added for their astringent anti-inflammatory effect. Typical formulations are:

Calamine	15
Zinc oxide	5
Glycerol	5
Water	Up to 100

Zinc oxide	3
Magnesium silicate	3
Cetomacrogol cream	Up to 100

Emollients

Emollients are used to render the skin softer and more pliable and also possess some anti-irritative properties. Oils of mineral, vegetable and animal origin as well as waxes are considered emollients. In particular some vegetable fats, such as karite butter or jojoba liquid wax, possess both a good emollient and cosmetic acceptance. Both creams and ointments are suitable for this purpose. All ointments are considered emollients, and virtually all emulsions, due to the presence of fat components that penetrate easily into stratum corneum layers, are also emollients. For this reason, emulsions instead of ointments are now prescribed as

emollients. Cetomacrogol cream is an example of an emulsion utilized as an emollient:

Karite butter	4
Jojoba liquid wax	4
Avocado oil	4
Cetomacrogol cream	Up to 100

Astringents and Antiperspirants

Astringents are active substances. When applied locally, they are protein precipitants, having low cell penetrability so that their action is limited to the surface. Astringents in dermatology are used to reduce erythema and pruritus; they also have an antiperspirant effect by causing protein precipitation in the sweat ducts. Astringents/antiperspirants also have deodorant properties due to an interaction with odorous fatty acids liberated by bacteria and by suppressing bacterial growth by virtue of low pH. The main astringents are:

- Salt of the cations aluminium, bismuth, iron, manganese and zinc
- Other salts containing these metals such as permanganates
- Tannins or related polyphenolic compounds

Dusting powders, lotions and gels are used for this purpose. An example of a powder is astringent powder:

Tannic acid	10
Zinc oxide	10
Talc	Up to 100

Aluminium chloride hexahydrate aqueous or hydroalcoholic solution 5–10 % may be used as an astringent in many chronic oozing dermatitis cases as well as an antiperspirant at concentrations of 10–20 %.

Antipruritics

Pruritus is a common symptom of different dermatoses of eczema, atopia, urticaria, exanthema type and neurodermitic type, etc. It can also be linked to internal diseases or skin senescence. Most astringents, keratoplastics or rubefacients possess antipruritic activity. Menthol, phenol, salicylic acid, polidocanol and coal tar are used as topical antipruritics in different dermatoses. Some examples of antipruritic formulae are:

Menthol	1
Ethanol 70 %	Up to 100

Aluminium chloride hexahydrate	5
Hydroxyethylcellulose	4
Propylene glycol	5
Ethanol	20
Water	Up to 100

Coal tar is an effective antipruritic agent and can be used in emulsion: coal tar 2 % in cetomacrogol cream.

Rubefacients

Rubefacients are able to induce hyperaemia and slight inflammation that produces a feeling of comfort, warmth, sometimes itching and hyperaesthesia. Most rubefacients in high concentrations are vesicants. Rubefacients are sometimes used for treating the sensory and visible effect of irritation, giving the patient the impression of receiving an effective medication. They are also used to treat pernioses and to promote hair growth especially in alopecia areata. Examples are:

- Alcohol camphor
- Anthralin
- Capsicum
- Benzoin menthol
- Resorcinol
- Methyl salicylate
- Nicotine acid and its esters

Caustics

Caustics are agents that cause the destruction of tissue; therefore, they are used in hyperkeratoses or hyperplastic tissues, but they can be used also for the destruction of tumours such as basaliomas and xanthelasmas. These agents usually precipitate proteins so that they may be considered as

astringents at low concentration. Caustics are also bactericidals. Examples are:

- Trichloroacetic acid
- Glacial acetic acid
- Phenol
- Silver nitrate
- Nitric acid
- Potassium hydroxide

Caustics are usually applied to the skin with a stick swab. Examples are:

- Trichloroacetic acid 50 % aqueous solution is used to remove xanthelasmas.
- Liquefied phenol 20 % in water to bleach hand freckles.

Keratolytics

Keratolytics loosen the keratins or intercellular cement facilitating desquamation of scales and softening horny material or crusts so they may be used in hyperkeratotic conditions. They also eliminate parasites or fungi. However, the real action of some keratolytics is not completely elucidated. Examples are:

- Salicylic acid
- Sulphur
- Urea
- Resorcinol
- Calcium chloride
- Some alkali-containing compounds such as sodium and potassium hydroxide.

Among these, salicylic acid is the most commonly used in a variety of formulations. Around 6–10 % of salicylic acid is needed for a keratolytic effect even if the possibility of toxicity due to absorption has to be considered. Therefore, high concentrations are employed in very small areas incorporated in collodion. Examples are:

- Salicylic acid for pityriasis capitis

Salicylic acid	3
Glycerol	10
Ethanol 50 %	Up to 100

Keratoplastics

Keratolytic agents at low concentrations stimulate the renewal of the horny layer through a slight reducing action and favouring desquamation. Salicylic acid, alpha-hydroxy acids, sulphur, urea and ichthyols are considered keratoplastics.

Examples of formulations with this property are:

- Sulphosalicylic shaking lotion

Salicylic acid	2
Sulphur	2
Ethanol 50 %	Up to 100

- Glycolic salicylic lotion

Salicylic acid	2
Glycolic acid	10
Ethanol 50 %	Up to 100

- Glycolic salicylic cream

Salicylic acid	2
Glycolic acid	10
Cetomacrogol cream	Up to 100

Other ingredients are able, via a toxic event, to reduce DNA synthesis and mitosis, especially in hyperproliferative disorders. Some of these substances, namely, tars, also possess antipruritic-anti-inflammatory action so that they may be used in a variety of skin disorders ranging from psoriasis to atopic dermatitis. This activity should be defined as a reducing activity, but many authors regard it as a keratoplastic activity. Examples of these compounds are coal tar, resorcinol, anthralin, ichthyol and phenols. Examples are:

- Coal tar solution

Coal tar	2
Polysorbate 80	0,5
Ethanol	Up to 100

- Ichthyol pale cetomacrogol cream

Ichthyol pale	10
Cetomacrogol cream	Up to 100

Coal tar can easily be incorporated into cetomacrogol cream up to 4 %. The result is a cosmetically acceptable and washable preparation, useful for outpatient treatment.

Cleansing

Cleansing may be carried out with detergents, solvents, abrasive substances singly or in combination. Soaps and shampoos are often used as vehicles for active agents such as antibacterial, antifungal, salicylic acid or tars. Some detergents are also antibacterial such as benzalkonium chloride. Substances in this group include:

- Ethanol sodium lauryl sulphate
- Isopropanol benzalkonium chloride

A simple example in which it is possible to suspend the active ingredients is:

- Anionic detergent

30 % Sodium lauryl ether sulphate	40
30 % Alkyl amido betaine	10
Distilled water	Up to 100

Liquid creams and creams O/W on cotton swabs are also suitable for cleansing affected skin or for removing topical medicaments or makeup.

Opacifying and Sebum Absorbing

Opacifying and sebum absorbing agents are used to diminish the brightness of oily or seborrhoeic skin. The micronized dusting powders by virtue of their absorbent properties have the action of physically absorbing secretion of both sweat and sebaceous glands. Examples are:

- Bentonite
- Zinc oxide
- Caolin
- Titanium dioxide

Each of these compounds may be incorporated in shake lotions or creams O/W. The amount depends on the degree of micronization of the powder employed. Iron oxide may be added in small quantities to match the skin colour.

Hydrosoluble Ointments

A frequently used vehicle that is not classifiable as a base with non-specific activity is polyethylene glycol ointment. This ointment is classified as a hydrosoluble ointment and is also called a greaseless ointment base. This is composed of water-soluble constituents, namely, polyethylene glycols (PEG). PEG ointment is particularly useful because it is an inert, anhydrous, viscous compound that is completely washable. It is possible to incorporate into a PEG ointment almost all active ingredients and distribute them to all body areas, hairy parts included. Washability of this ointment renders it very acceptable to patients. PEGs are hydrophilic compounds and, when applied to eroded or ulcerated skin, exert an absorbing action on exudates and are usually well tolerated. PEGs do not have cellular toxicity and do not interfere with cell growth and migration during the tissue repair process. Moreover, the use of PEG dressing enables anti-adherence and water vapour permeability properties. For these reasons, PEG ointment has to be considered the ideal dressing for dermatological surgery.

- PEG Ointment

Polyethylen glycol 4000 30 % and polyethylen glycol 400 70 %.

The ratio of the two components can be varied depending on the desired viscosity of the compound.

In the treatment of ulcers, allantoin, which induces healing by stimulating healthy granulations and removing necrotic material, is usually added to PEG ointments up to 5 %.

New medication based on PEG-allantoin–soaked gauze will be useful and practical in the dressing of surgical wounds as well as of ulcers.

Allantoin-PEG ointment is stable and nontoxic, and the treatment of ulcers is painless, simple and inexpensive.

Vitamins and Nutritional Supplements

153

Alexandru Tataru and Andreea Nicoleta Boca

Key Points

- Complementary and alternative medicine approaches are frequently chosen by patients with various skin conditions.
- An important number of botanical-based preparations and vitamins are used for skin care or dermatological diseases, even if rarely supported by evidence-based science.
- More studies, especially clinical ones, are needed to determine their efficacy and risks.
- Clinicians should be informed of the benefits, as well as specific side effects of natural products and vitamins used for various skin disorders.

General Principles

Complementary and alternative medicine (CAM) represents an array of health-care approaches with a history of use, or origins outside of conventional medicine, as explained by the US National Center for Complementary and Alternative Medicine (NCCAM). According to NCCAM, the most frequently used CAM approaches are natural products. There are numerous diet-based therapies, dietary supplements, and herbal extracts with proven or sometimes only supposed beneficial effects.

Patients with various skin conditions are reported to use CAM, especially herbal remedies, as first therapeutic approach, with higher frequency than general population. For Europe, it is estimated that 35–70 % of them use CAM at least once during their lifetime.

Herbal extracts are also used in conventional dermatology, accepted by historical experience or based on scientific studies: psoralens, podophyllin, and pyrethrins.

This chapter summarizes the use of important CAM approaches, more exactly herbal extracts, dietary supplements, and vitamins, in dermatology. It contains a general presentation of the herbal extracts, their chemical classification, and biological effects, in order to make it more comprehensible in this area of interest, which includes a large number of different substances. In fact,

natural extracts always contain mixtures of organic compounds, belonging to different classes, with different properties. The most used or useful herbal extracts are then presented, each one with their peculiar properties. The last part of this chapter is an overlook on vitamins and their benefits in various skin conditions.

Herbal Extracts

Classification and Biochemistry

Polyphenols are active constituents of many plants, some of them frequently used in CAM. They are a very large class of organic chemicals characterized by the presence of phenol structural units. Polyphenols are mostly natural, but can also be synthetic or semisynthetic, each with unique properties, according to the number and characteristic of their phenol structures.

The wide class of polyphenols includes phenolic acids, flavonoids, stilbenes, or lignans. Flavonoids are probably the most studied among them.

Flavonoids (lat. flavus = yellow) are a class of plant secondary metabolites, found in a large variety of natural sources and including a number of subclasses as shown in Table 153.1. From a chemical point of view, flavonoids can be glycosides (those connected with one or more sugar molecules) and aglycones (those without such connection). In nature, catechins and proanthocyanidins are aglycones, while all others are glycosides.

Starting from the natural compounds, a number of useful semisynthetic and synthetic derivatives have been developed, like diosmin, recommended in chronic venous insufficiency.

The bioavailability of flavonoids is relatively low due to limited absorption and rapid elimination. Isoflavones like those from soy are the most bioavailable ones, as opposed to flavanols like proanthocyanidins and tea catechins.

General Biological Properties of Flavonoids

Direct and Indirect Antioxidant Activity

Diets containing flavonoids are known to have important antioxidant effects. Flavonoids are potent direct scavengers of free radicals of oxygen in vitro. In vivo, most circulating flavonoids are actually flavonoids' metabolites, with lower antioxidant activity than the original molecules, and low plasma and intracellular concentrations. Therefore, the relevance of the flavonoids' direct antioxidant activity in vivo remains questionable. In topical applications, the poor transcutaneous penetration and rapid local metabolization are the main limitations for their beneficial effects.

An indirect antioxidant activity of flavonoids is due to their capacity of metal chelation, especially iron and copper (at least in vitro). Free iron

Table 153.1 Classification of flavonoids

Subclass	Examples	Common herbal sources
Flavones	Apigenin, luteolin	Parsley, thyme, celery, hot peppers
Flavonols	Quercetin, myricetin, isorhamnetin, kaempferol	Yellow onions, scallions, broccoli, apples, berries, teas
Flavanones	Hesperitin, naringenin, eriodictyol	Citrus fruits
Flavanols monomers (catechins)	Catechin, epicatechin, epicatechin gallate, epigallocatechin gallate	Green tea, some cocoas, and chocolate
Flavanols dimers	Theaflavins, thearubigins	Teas (especially oolong black)
Flavanols polymers	Proanthocyanidins	Red grapes, berries, apples, chocolate
Anthocyanidins	Cyanidin, dephinidin, malvidin, pelargonidin, peonidin, petunidin	Red and purple grapes, blue and purple berries
Isoflavones	Genistein, daidzein, glycitein	Soybeans

and copper ions are able to generate radicals of oxygen. In living organisms, most iron and copper ions are bound to specific proteins, limiting their oxidant capacity. Therefore, the importance of such reactions in reducing the oxidative stress in vivo has not been established so far.

Effects on Cell-Signaling Pathways

Data from cell culture experiments suggests that the main biological effect of flavonoids relies in their ability to modulate cell-signaling pathways, including growth, proliferation, angiogenesis, and apoptosis.

Intracellular concentrations of flavonoids required for cell-signaling pathways are lower than those required for antioxidant effects, plus flavonoids' metabolites are also able to interact with cell-signaling proteins.

Studies suggest that flavonoids selectively inhibit protein kinases that catalyze the phosphorylation of specific receptor proteins, like the growth factor receptor. This could help prevent tumor development by inhibiting cell proliferation, neoangiogenesis, tumor invasion, and inducing apoptosis. Flavonoids also promote the excretion of potentially toxic or carcinogenetic chemicals.

By modulation of cell-signaling pathways, flavonoids could prevent cardiovascular diseases by decreasing chronic inflammation associated to atherosclerosis, vascular cell adhesion molecules' expression, platelet aggregation, and increasing endothelial nitric oxide synthase activity.

By decreasing the chronic inflammation and fighting against oxidative stress, they could be helpful in neurodegenerative diseases and least but not last, in a large spectrum of skin conditions.

Adverse Effects of Flavonoids

Due to their low bioavailability, rapid metabolism, and elimination, no significant adverse effects have been associated with normal dietary intake of plant-based flavonoids.

Drug Interactions

Flavonoids quercetin and naringenin, and furanocoumarins, especially dihydroxybergamottin (in grapefruit juice), have a documented potential to inhibit the intestinal cytochrome P450 3A41, both in vitro and in vivo. This results in increased risk of toxicity for a large number of drugs, such as antiarrhythmics, benzodiazepines, carbamazepine, terfenadine, cyclosporine, sildenafil, and statins.

For quercetin, naringenin, and the green tea flavanol epigallocatechin gallate, in vitro inhibition of the P-glycoprotein has been reported. The impairment of P-glycoprotein's (efflux transporter) function can increase the potential toxicity of antihypertensive, antiarrhythmic, antifungal drugs, digoxin, HIV protease inhibitors, and H2 receptor antagonists.

High intakes of flavonoids from purple grape juice and dark chocolate can increase the risk for bleeding when taken with anticoagulant or antiplatelet drugs.

Because all flavonoids have metal chelating properties, the consumption of tea or cocoa decreases the absorption of non-heme iron found in plant foods and iron supplements.

Dietary Sources of Flavonoids

Anthocyanidins are found mainly in blueberry, bilberry, elderberry, black currant, and red grape, but content may vary considerably.

Flavanols are found in all types of teas. Green tea extracts have higher levels of flavanol monomers (catechins), black tea extracts are richer in flavanol polymers (theaflavins and thearubigins), while the oolong tea extracts are in between them. All kinds of teas also contain different concentrations of caffeine.

Flavanones are represented by hesperidin glycosides, naringenin, and eriodictyol, which are found mainly in citrus fruits.

Flavones are represented by tangeretin, nobiletin, and sinensetin and can be found in the citrus peels.

Flavonols, found in citrus and many other vegetables, are represented by quercetin and its glycoside rutin.

Isoflavones are a subclass of flavonoids, belonging to polyphenols. Isoflavones of nutritional and medical interest are derivatives of isoflavone (itself

has no interest) by replacement of two or three hydrogen atoms with hydroxyl groups. Isoflavones are produced almost exclusively by the family of Fabaceae (bean family), the most well known being the soybean. They are genistein, daidzein, naringenin, and naringenin chalcone. These isoflavones are potent antioxidants, because of their ability to trap singlet oxygen, and many act as phytoestrogens in mammals.

Catechins

Catechins belong to the class of flavanols. Their name comes from "catechu," a plant extract from which they were first isolated. The main natural source is the leaves of different types of tea (Camelia sinensis).

According to the processing procedures, teas are classified into white, green, oolong, black, post-fermented, and yellow. The highest quantity of catechins is found in green tea, up to 35 % more than in other type. Black tea contains more flavanols polymers, theaflavins, and thearubigins.

Experimental research on cell cultures and animal models revealed numerous biological effects of catechins; due to their ability to modulate different cell functions, they are involved in DNA transcription, protein expression, DNA repair, cell cycle control, and cell-to-cell communication, plus they possess a potent antioxidant effect.

Regarding skin cancers, data from animal models suggest that catechins from green tea could protect against tumorigenesis induced either by UV radiation or chemicals and could influence the tumors' growth. However, data on humans are insufficient for recommending the use of green tea in the prevention or treatment of skin cancers.

They are some studies reporting good efficacy of topically applied extracts of green tea for the treatment of genital warts, facial telangiectasia, and acne.

Quercetin

Quercetin is one of the most prominent dietary antioxidants. It is present in all vegetables, fruits (especially citrus and berries), tea, and wine. The biological effects are those of flavonoids in general: antioxidant, anti-inflammatory, and anticarcinogenic; via signaling modulation, quercetin is able to downregulate the expression of mutant p53 protein.

For oral administration, quercetin is found in capsules containing 400 mg quercetin and 100 mg bromelain (pineapple extract, increasing intestinal absorption) each. Recommended dose is 500–1,000 mg/day, in intermittent cycles of 8–12 weeks. More than 1,000 mg/day could cause renal toxicity.

Topical application of the quercetin aglycone has been shown experimentally to be effective in the prevention of UV-induced liposome peroxidation and in UVB-induced glutathione depletion.

Genistein

The most studied isoflavone, genistein is abundantly present in soybeans and can be found in smaller amounts in Gingko biloba, fava bean, kudzu, and red clover.

Genistein is known to have good effects on atherosclerosis, cancers, oxidative stress, and helminthic infestations. Several studies have confirmed its efficacy against *Echinococcus* spp. and *Fasciola* spp.

Recent studies on genistein reported skin beneficial effects, such as antiaging, antioxidative, and anti-inflammatory; it has been tested in antiaging cosmetic preparations with interesting results. In addition, results on animal models showed that genistein inhibited the initiation and promotion of chemically induced skin tumorigenesis; there were also promising results on wound healing.

Genistein can be used alone, or more frequently in combination with quercetin and other isoflavones extracted from soybean. The usual dose is 8 mg/day, for 3–12 months.

Terpenes and Terpenoids

Terpenes and terpenoids, also known as isoprenoids, are a large class of organic compounds which are derivatives of the basic molecule

isoprene. Their classification is based on the number of basic isoprene units linked together in linear chains or arranged to form rings:

- Hemiterpenes (a single isoprene unit): prenol and isovaleric acid.
- Monoterpenes (two units): geraniol, limonene, and terpineol.
- Sesquiterpenes (three units): humulene, farnesene, and farnesol.
- Diterpenes (four units): cafestol and taxadiene, important because they are precursors of retinol, retinal, and phytol.
- Sesterpenes (five units): geranylfarnesol.
- Triterpenes (six units): very important because the linear form is squalene, the structural precursor of all steroids. In vegetals, lipophilic triterpenes in combination with hydrophilic glycosides generate saponins, substances with marked antimicrobial and antifungal effects.
- Sesquarterpenes (seven units): less important.
- Tetraterpenes (eight units): the acyclic form is lycopene, and the cyclic forms are the important and studied subclass of carotene and carotenoids; the monocyclic tetraterpene is gamma-carotene, and the bicyclic tetraterpene generates alpha-carotene and beta-carotene.
- Polyterpenes have long chains of isoprene units and generate, for example, the natural rubber.

Terpenoids contribute to the resin of conifers, the scent of palms like *Eucalyptus*, the flavors of cinnamon and ginger, the yellow color in sunflower, and the red color in tomatoes.

Well-known terpenoids are the menthol and camphor, the cannabinoids found in *Cannabis indica*, ginkgolide and bilobalide in Gingko biloba, and the curcuminoids in turmeric and mustard seeds.

Curcumin

Curcumin, a low-molecular-weight terpene, is the active ingredient in the spice turmeric and, in smaller amounts, in mustard seeds. In naturopathic Ayurveda Indian medicine, it is applied on the skin to enhance wound healing and to facilitate the process of epithelialization after herpes zoster, sometimes even after autoimmune blistering diseases. Unfortunately, scientific evidence supporting these beneficial roles of curcumin is limited.

Phase II clinical trials used systemic curcumin in psoriasis with limited response. Other studies were focused on topical administration of curcumin in vitiligo, phototoxic dermatitis, and morphea, with some beneficial effects reported, based on its photoprotective effect.

Experimental studies reported antiproliferative and proapoptotic effects of curcumin, which can inhibit the epidermal growth factor receptors, the sonic hedgehog pathway, downstream signaling pathways like nuclear factor kappa-B, and signal transducers and activators of transcription. Future studies will reveal if oral administration of curcumin, alone or with other drugs, could be helpful to treat basal cell carcinoma, melanoma, and primary cutaneous T-cell lymphoma.

Due to its antioxidant and photoprotective properties, curcumin is included in a number of marketed cosmetic products.

For oral administration, curcumin is frequently combined with bromelain, insuring improved intestinal absorption. The dosage is 400–600 mg capsules with standardized powder, three times per day. For preventive purposes, a 900 mg/day life-long treatment is recommended.

Carotenoids

Carotenoids are a group of over 600 liposoluble pigments, divided in two classes, xanthophylls (contain oxygen) and carotenes (purely hydrocarbons). They are widespread, being responsible for the yellow, orange, red, and purple colors of many fruits, flowers, birds, insects, and marine animals.

Although hundreds of carotenoids are found in nature, only few possess the well-known beneficial effects. Actually only about ten of them are found in plasma and tissues, and only two in the retina (lutein and zeaxanthin). The most studied ones are beta-carotene and lycopene (belonging to the subgroup of carotenes), along with lutein, zeaxanthin, and beta-cryptoxanthin (subgroup of xanthophylls). Only few carotenoids,

such as alpha-carotene, beta-carotene, and beta-cryptoxanthin, display a provitamin A activity (can be converted to retinal).

Animals and humans cannot synthesize carotenoids, thus obtaining them from fruits and vegetables. Alpha-carotene is found in carrots; beta-carotene in carrots, squash, and dark-green leafy vegetables; lycopene in gac fruit, tomatoes, and watermelon; lutein in spinach and broccoli; and ß-cryptoxanthin in oranges and papaya. The richest source of carotenoids with provitamin A activity is crude palm oil.

Several epidemiological studies reported association of carotenoid-rich foods consumption and reduced risk to develop cancers, cardiovascular diseases, and aged-related eye macular degeneration. This could be related to their function as vitamin A precursors, for alpha-carotene, beta-carotene, and beta-cryptoxanthin, as well as to their antioxidant effects, modulators of immune response and inducers of gap junctional communications. Carotenoids are able to scavenge free radicals such as singlet molecular oxygen and peroxyl radicals, to protect cellular systems from oxidative damage.

Carotenoids play an important part in the skin's antioxidant defenses; thus, many studies focused on assessing their potential for skin tumor prevention. In vivo carotenoid concentration, evaluated by Raman spectroscopy in basal cell carcinomas, actinic keratosis, and their perilesional skin, was reported to be significantly lower compared to region-matched skin of healthy subjects. Even if there is a clear need for more scientific studies in this direction, dietary supplements claiming photoprotective effect are already marketed.

For beta-carotene, the recommended dose is 50 mg/day, for lutein 4–20 mg/day, and for zeaxanthin 0.2–1 mg/day, without a specific time limit.

Lycopene

The most potent antioxidant among various carotenoids is lycopene. Its health benefits include trapping singlet oxygen, reducing mutagenesis, anti-inflammatory, antimutagenic, and anticarcinogenic effects. In physiological concentrations, lycopene has been proven to inhibit human tumor cell growth, through mechanisms including inhibition of prostatic IGF-I and androgen signaling, as well as IL-6 expression. In addition, lycopene improves gap junctional communication and induces phase II drug metabolizing enzymes and oxidative defense genes. Interestingly, it has been shown that a combination of low concentrations of lycopene with 1.25-dihydroxyvitamin D3 exhibits a synergistic effect on cell proliferation and differentiation.

Regarding its benefits for the skin, some studies reported promising results for topically applied lycopene in protecting against UVB radiations. Mechanisms involved include suppressing ornithine decarboxylase and reversing the reduction of proliferating cell nuclear antigen (vital for DNA synthesis and cell repair) caused by UVB exposure.

Likely due to its immunostimulant and anti-inflammatory properties, lycopene has also been reported as efficient adjuvant therapy in HPV infections of the genital area.

Lycopene is available in capsules of 10 mg; doses of 10–30 mg should be taken three times per day, for 3–6 months. Alternatively, one cup of tomato juice provides an intake of approximately 23 mg lycopene. For lycopene from direct natural sources, there is no limit in quantity or intake period.

Resveratrol

Resveratrol is a stilbenoid, a resorcinol derivative produced naturally by several plants; being a phytoalexin, it protects them against insects and pathogenic microbes. Stilbenoids are hydroxylated derivatives from stilbene; they share most of the biosynthesis pathway with chalcones, all belonging to the large family of polyphenols.

It is present in high concentrations in red wines produced from grapes of *Vitis vinifera* (skin of red grapes), *Polygonum cuspidatum* (roots), and *Muscadinia rotundifolia* (skin and seeds).

Resveratrol is known and used especially for its antioxidant effect and beneficial cardiovascular protective potential. Some derma-cosmeceutical products use topical resveratrol to improve the aspect in women cellulitis, periocular cernes, and

striae. Still, there is limited scientific evidence with regard to its efficacy in these indications.

Resveratrol is available in capsules of 20, 30, or 100 mg. It is recommended in a single dose, of up to a maximum of 100 mg/day.

Silymarin

Silymarin is a mixture of flavonolignans, polyphenolic substances derived from phenylalanine via dimerization of cinnamic alcohols. Lignans are good antioxidants and act as a class of phytoestrogens, along with the isoflavones.

The main sources of silymarin are the seeds and fruits of milk thistle (*Silybum marianum*). Silymarin has a good efficacy on hepatotoxicity caused by agents like *Amanita phalloides*, ethanol, and paracetamol, as well as in chronic active hepatitis of various causes.

Regarding skin conditions, silymarin has been extensively studied for its photoprotective capacity. It has been proven to have chemopreventive effects against chemical and photocarcinogenesis in various animal tumor models. In vivo studies report antioxidant, anti-inflammatory, and immunomodulatory properties of silymarin. Available experimental data suggest that silymarin may supplement sunscreen protection, increasing anti-photocarcinogenic defenses, and be useful in conditions associated with UV radiation-induced inflammation, oxidative stress, and immunomodulatory impairment.

According to different clinical trials, silymarin dosage varies between 230 and 600 mg/day, for a standard period of 8 weeks.

Aloe vera

The active components of *Aloe vera* leaves are saponin, a triterpene with antimicrobial activity, anthraquinones (especially aloesin) with a moderate photoprotective effect, and polymannan, a polysaccharide derived from sugar mannose, with anti-inflammatory and immunostimulatory properties.

Aloe vera leaf extract is used topically for wound healing, including first-degree burns, and minor cutaneous infections like herpes simplex, rarely microbial or fungal ones. It was tried for plaque psoriasis, atopic dermatitis, seborrheic dermatitis, acne, diaper dermatitis, lichen planus, aphthous stomatitis, human papilloma virus, and frostbite, with various results. With respect to topical applications of *Aloe vera* for prevention of radiation-induced injuries or photoprotection, studies show conflicting results. Though there are some promising data regarding its use for some dermatologic conditions, clinical effectiveness of oral and topical aloe vera need more scientific confirmation.

Use of topical aloe vera gel may cause allergic reaction. It should be avoided in patients with known hypersensitivity to *Aloe vera* or plants of the Liliaceae family (e.g., garlic, onions, tulips). Taken orally, it may lower blood sugar levels; caution is advised in patients with diabetes, hypoglycemia, or glucose intolerance.

Marigold

Marigold (*Calendula officinalis*) is used topically as water solution from leaves, containing: triterpene saponins, with antimicrobial effect, and flavonoids and carotenoids, with moderate anti-inflammatory effects.

It can be useful in the treatment of wounds, burns, ulcers, mouth and throat inflammation, and seborrheic dermatitis, reducing residual erythematic and inflammation after herpes zoster and carbuncles. There is evidence that marigold can be efficient as prophylaxis for acute radiation dermatitis. Studies on animal models suggest that marigold has a good efficiency against UVB irradiation-induced skin damage, most likely associated to improvement in collagen synthesis in the subepidermal connective tissue.

There are reports of contact dermatitis, as well as aggravation of chronic leg eczema in venous insufficiency after the use of marigold extracts.

Arnica

Arnica (*Arnica montana*) is a plant belonging to the Compositae (Asteraceae) family. It is used in topical application only on intact skin, because of

its direct irritant effect. The active components are sesquiterpene lactones, with potent anti-inflammatory properties.

Arnica extracts are used topically for treatment of myalgia, arthralgia, bruises, insect bites, sometimes gingivitis, hemorrhoids, acne, and less frequent seborrheic dermatitis and psoriasis. The scientific evidence supporting its efficacy is still limited.

Arnica is available as standardized gel at a 50 % concentration.

If ingested, *Arnica* has a high toxic risk. There are reported cases of contact dermatitis following topical arnica applications.

Chamomile

Chamomile is the common name given to daisy-like plants of the Asteraceae family (*Matricaria recutita*, *Chamomilla recutita*). It is widely used all over the world, either orally, as tea, or in topical applications.

There are an important number of chemical compounds present within chamomile, each with different effects. The known antiseptic properties are due mainly to monocyclic sesquiterpene alcohols alpha-bisabolol, bisabolol oxides A and B, and secondary to other sesquiterpenes: chamazulene, farnesene, and matricin. The anti-inflammatory effects are due to a number of flavonoids: apigenin, quercetin, luteolin, and patuletin. These flavonoids have a proven moderate inhibitory effect on cyclooxygenase and lipoxygenase, on histamine release and also in promoting granulation tissue formation. For topical chamomile, studies reported an anti-inflammatory effect comparable to that of topical hydrocortisone 0.25 %. Apigenin has also been shown to have strong chemopreventive effects. Coumarin compounds such as herniarin and umbelliferone may have blood-thinning properties, and umbelliferone has also been reported to be fungistatic.

Chamomile extracts have been used for various inflammatory skin conditions like atopic dermatitis and psoriasis, mucous membrane inflammations, for rosacea, seborrheic dermatitis, and also for promoting wound healing, with variable results and scientific evidence.

Because chamomile can cause uterine contractions, leading to miscarriage, pregnant women are advised not to consume it. There is also risk of allergic reaction, contact dermatitis, or even anaphylaxis. It is still unclear whether individuals with reported allergies to chamomile were actually exposed to it, or to plants with similar appearance.

Horse Chestnut

The seed extract from horse chestnut (*Aesculus hippocastanum*) contains escin, a mixture of triterpene saponins with vasoconstrictor and vasoprotective effect, and also esculin, a coumarin glucoside which potentiates anticoagulation and has marked renal and liver toxicity. The esculin must be removed by adequate procession of the horse chestnut seed extract (HCSE).

The escin inhibits the release of elastase and hyaluronidase from leukocytes, thus preventing vascular leakage and degradation of proteoglycans from the vascular wall. Because of these favorable effects, oral HCSE escin is indicated in the treatment of chronic venous insufficiency, and topical HCSE escin can be used for varicose veins, phlebitis, and hemorrhoids.

Licorice

The extract from licorice root (*Glycyrrhiza glabra*, *G. uralensis*, and *G. inflata*) contains three xenoestrogens: liquiritin (a flavanone), glabrene and glabridin (isoflavonoids), and a peculiar compound, glycyrrhizic acid, with a sweet taste and marked antiviral properties.

Glycyrrhizic acid is used in Japan for the treatment of chronic viral hepatitis, and recent studies indicate that oral glycyrrhizic acid disrupts latent Kaposi's sarcoma.

Glycyrrhizic acid has also mineralocorticoid effects, so overdose could lead to the so-called syndrome of apparent mineralocorticoid excess

(hypertension, edema, congestive heart failure, and hypokalemia).

Topical use of licorice has also been investigated. Studies report good results for topical licorice extract 7 % in the treatment of melasma and other pigmentary abnormalities and glabridin inhibiting tyrosinase activity in melanocytes.

Licorice is available as tablets, tincture, or dried root for decoction. Recommended doses are 0.4–1.6 g three times per day for tablets, 2–4 ml three times per day the tincture, and 1–5 g three times per day as decoction, in repeated cycles of 3 months/year.

Olive Oil and Olive Leaves Extract

The extract of the fruit and leaves of the olive tree (*Olea europaea*) has been used since ancient times to moisturize and help rejuvenate damaged skin. Nowadays, the health benefits of olive oil are extensive, and new positive attributes keep being discovered.

Both olive oil and olive leaves extract contain oleic and palmitic acids and a spectrum of polyphenols: flavonoids, lignans, and especially a type of monoterpene called secoiridoid glucosides. These compounds have anti-inflammatory and antioxidant effects, benefiting a number of skin conditions. Olive oil and olive leaves extract are mostly used for hydration, but also for treating sunburns, atopic dermatitis, psoriasis, seborrheic dermatitis, acne, diaper dermatitis, calluses, stretch marks, and scars. Additional research is needed to confirm their benefits in these indications; still, cosmetic products containing olive oil and olive leaves extract have been extensively marketed for many years.

Capsaicin

Capsaicin, a mixture of vanillyl amides and isodecenoic acid, is found in hot peppers. Its most important biological effect is decreasing the intensity of different types of neurologically induced pain.

Topical capsaicin is used for a variety of neuralgias: post herpes zoster neuralgia, diabetic neuropathy, notalgia paresthetica, reflex sympathetic dystrophy, and also for hemodialysis-induced pruritus. Few reports mentioned some beneficial effects on plaque psoriasis and in the treatment of verrucae.

The use of topical capsaicin can be limited by the temporary erythema and burning sensation on the site of application.

Capsaicin is available as gels and creams with variable concentrations of 0.1–8 %. For the treatment of neuralgias, the 8 % concentration is recommended.

Vitamins and Their Use in Various Skin Conditions

Definition and Epidemiology

Vitamins are organic compounds required by our organism as a vital nutrient. Together with minerals, they are also called micronutrients, because in comparison with the major nutrients (water, proteins, fat, and carbohydrates) they are required in smaller amounts.

Role

They can serve as precursors to various cofactors, or directly as coenzymes. In addition, some vitamins have also other functions like antioxidants or hormones. Tiny as the amounts are, they are essential for the production of enzymes, hormones, and other substances essential for proper cell function, growth, and development; therefore, consequences of their absence can be severe.

Vitamins and Medical Conditions

Any disease caused by a vitamin deficiency is called hypovitaminosis.

A chronic vitamin deficiency is called avitaminosis.

Table 153.2 Reference daily intake chart for vitamins (Institute of Medicine, Washington, DC)

Vitamin	0–6 months	7–12 months	1–3 years	4–8 years	9–13 years	Male 14–18 years	Female 14–18 years	Male adult	Female adult
A (μg)	400	500	300	400	600	900	700	900	700
B1 (mg)	0.2	0.3	0.5	0.6	0.9	1.2	1	1.2	1.1
B2 (mg)	0.3	0.4	0.5	0.6	0.9	1.3	1	1.3	1.1
B3 (mg)	2	4	6	8	12	16	14	16	14
B5 (mg)	1.7	1.8	2	3	4	5	5	5	5
B6 (mg)	0.1	0.3	0.5	0.6	1	1.3	1.2	1.3	1.3
B7 (μg)	5	6	8	12	20	25	25	30	30
B9 (μg)	65	80	150	200	300	400	400	400	400
B12 (μg)	0.4	0.5	0.9	1.2	1.8	2.4	2.4	2.4	2.4
C (mg)	40	50	15	25	45	75	65	90	75
D (μg)	5	5	5	5	5	5	5	5	5
E (mg)	4	5	6	7	11	15	15	15	15
K (μg)	2	2.5	30	55	60	75	75	120	90

Hypervitaminosis is the condition that can result from chronic excessive intake of vitamins.

Reference Daily Intake (RDI) represents the average daily level of intake that is sufficient to meet the nutrient requirements of 97–98 % of healthy people (Table 153.2).

Classification

Vitamins are classified according to their biological and chemical activity, not their structure. Therefore, each vitamin includes a number of vitamer compounds, with biological activity associated with that particular vitamin. In the body, they are convertible to the active form of the vitamin, and sometimes interconvertible.

Until the mid-1930s, vitamins were available only through food intake, from various natural sources (the most important ones presented in Table 153.3). Then, vitamin B complex (from yeast extract) and semisynthetic vitamin C supplements became available, all others following. Currently, vitamins are commercially produced as semisynthetic and synthetic preparations, containing one vitamin, or a multivitamin complex.

According to their solubility, vitamins can be classified as:

- Fat soluble: vitamins A, D, E, and K
- Water soluble: vitamins B1, B2, B3, B5, B6, B7, B9, B12, and C

Vitamins in Dermatology

The use of vitamins as prophylactic and therapeutic agents in the management of multiple medical conditions increased over the years. As research on their implication in various diseases continued, it became clear that many vitamin deficiencies had cutaneous manifestations. Currently, all 13 vitamins are used also for skin disorders.

Vitamin A

Vitamers: retinol, retinal, retinoic acid, and several provitamin A carotenoids, among which beta-carotene is the most important.

Function: These fat-soluble retinoids are involved in immune function, vision, reproduction, cell growth and differentiation, bone remodeling, hematopoiesis, and antioxidant activity. They also exert a significant influence on the skin, due to their anti-inflammatory effect, seborrhea control, effects on keratinocyte differentiation and proliferation, and support of natural reparative processes in photodamaged skin.

Deficiency and Health Benefits: Vitamin A deficiency is quite rare in developed countries. However, it is still common in many developing countries due to limited access to animal-based foods containing preformed vitamin A, as well as

Table 153.3 Vitamins' natural sources

Vitamin	Natural sources
A	Cod liver oil, turkey liver, beef, pork, fish liver, carrot, sweet potato, butter, spinach, pumpkin, egg, apricot, papaya, mango
B1	Whole-wheat flour, oatmeal, flax, sunflower seeds, brown rice, whole grain rye, asparagus, cauliflower, potatoes, oranges, liver (beef, pork, and chicken), eggs
B2	Dairy products, eggs, nuts, meat, enriched flour, bananas, popcorn, broccoli, green beans, asparagus
B3	Yeast extract spread, bran (rice, wheat), fish, liver, paprika, peanuts, meat (mostly veal), tomatoes
B5	Small quantities are found in almost all foods, but higher amounts are found in whole grains, broccoli, avocado, eggs, meat, yogurt, and yeasts
B6	Chickpeas, beef liver and other organ meats, fish, chicken, cereals, potatoes, turkey, bananas
B7	Raw egg yolk, Swiss chard, liver, peanuts, seeds, soya
B9	Leafy vegetables (folic acid—from lat. folium = leaf), egg yolk, yeast, bread, cereal, sunflower seeds, liver
B12	Beef, other meats (especially liver), seafood, dairy products, eggs, fortified foods (e.g., fortified breakfast cereals, soy products, energy bars)
C	Acerola, sea buckthorn, rose hip, blackcurrant, red pepper, parsley, kiwifruit, broccoli, redcurrant, Brussels sprouts, strawberries, citrus fruits, cantaloupes, berries, spinach, tomatoes, potatoes
D	Cod liver oil, fish, milk, yogurt and other dairy products, egg yolks, beef liver
E	Oils (wheat germ, sunflower, nut), nuts, leafy vegetables: spinach, turnip, beet greens, avocado, asparagus, kiwifruit, broccoli, pumpkin, tomato
K	K1: green leafy vegetables, mustard, plant oils, soybeans, kiwifruit and grapes; K2: liver, soft cheese, egg yolk, butter, goose, chicken

to sources fresh vegetables and fruits containing beta-carotene.

Not only lack of exogenous supply can lead to lower vitamin A levels but also genetics and lifestyle factors such as smoking. A number of drugs (e.g., aspirin, phenobarbital, arsenicals) can also decrease vitamin A levels. Vitamin A plasma level drop only after the deficiency has been prolonged, so blood analyses are not very helpful for early diagnosis.

Excessive intake of vitamin A can also have severe consequences. Beta-carotene hypervitaminosis increases the risk for lung cancer in smokers and leads to skin discoloration. Chronic excess of retinoids can cause birth defects, liver toxicity, reduced bone mineral density, as well as hair loss, excessive skin dryness, and peeling. Vitamin A supplements should be avoided in people allergic to any of the products' ingredients. Same is valid for all other vitamin supplements.

The therapeutic use of vitamin A in dermatology began almost at the time of its discovery. Currently, synthetic retinoids, especially retinoic acid, are used for a number of dermatologic conditions including severe forms of psoriasis, many forms of acne, and various keratinization disorders and other dermatoses. Moreover, retinoids show antineoplastic activity.

Systemic and local administration of retinoids promotes epidermal cell growth and differentiation and sebaceous gland activity and exhibits immunomodulatory and anti-inflammatory properties, but their exact mechanisms of action are not fully understood. Intracellularly, they interact with cytosolic proteins and specific nuclear receptors, RARs and RXRs. These receptors are tissue specific, skin expressing mainly RAR gamma and RXR alpha. This could lead to development of receptor-selective retinoids, improving their therapeutic profile.

Their major adverse effect is teratogenicity, all others being dose dependent and controllable. Therefore, contraception is essential during treatment. Side effects of topical retinoids include local irritation, dry skin and mucous membranes, rashes, hair loss, skin atrophy, and easy bruising.

In psoriasis, retinoids have been established as effective systemic therapy since their introduction for clinical use. Preparations are available both for systemic and topical use. Available

preparations include acitretin, isotretinoin, and tazarotene. Despite their clear clinical efficacy, their mechanism of action has not been fully elucidated. They are known to induce keratinocyte differentiation and reduce epidermal hyperplasia, leading to the slowing of cell reproduction.

Topical retinoids are a mainstay of acne treatments, showing anti-inflammatory effects, reducing the size and secretion of the sebaceous glands and the bacterial population in ducts and skin surface, expelling mature comedones, and reducing microcomedone formation. Starting from the first-generation retinoid tretinoin, to isotretinoin, and the third-generation adapalene and tazarotene, all have a favorable safety profile compared to the systemic ones. Their broad anti-acne efficacy and good safety profile justifies their use as first-line treatment in most acne types.

Severe rosacea cases can benefit from isotretinoin as well. It is used also in pyoderma faciale after initial oral steroids, and good results have been reported in its use for granulomatous perioral dermatitis. Isotretinoin is also the regimen of choice in severe seborrhea, majorly reducing sebocyte lipid synthesis. Contraception is of course essential for all women of childbearing age.

Other dermatologic conditions such as keratosis pilaris, Darier's disease, familial benign chronic pemphigus, pityriasis rubra pilaris, ichthyosis, condylomata acuminata, granuloma annulare, lupus erythematosus, lichen planus, lichen sclerosus and atrophicus, and chronic hand eczema have been shown to respond to the immunomodulatory and anti-inflammatory activities of retinoids.

Retinoids were also proved to have antitumor activity. Bexarotene is used for the skin manifestations of advanced-stage cutaneous T-cell lymphoma. Retinoids like acitretin and isotretinoin are effective for chemoprevention of nonmelanoma skin cancer. Isotretinoin is preferred in xeroderma pigmentosum and nevoid basal cell carcinoma syndrome, whereas acitretin is used more in transplant recipients and severe sun damage.

Cosmetic skin issues such as wrinkles can also benefit from treatment with vitamin A. Tretinoin is probably the most potent for photoaging therapy. It works by increasing the production of new collagen, stimulating new blood vessels in the skin, in some cases even reducing actinic keratosis. Although retinoids show good results, irritant reactions limit their acceptance by patients.

Available options for topical use include adapalene (0.1 % gel, cream and solution; for acne), bexarotene (0.1 % gel; for cutaneous T-cell lymphoma), isotretinoin (0.05 % gel, 0.05 or 0.1 % cream; for acne), retinaldehyde (0.05, 0.1, or 0.2 % cream, gel, and lotion; cosmetic indications), retinol (0.01–4 %, serum and cream; cosmetic indications), retinol palmitate (0.5–5 % cream and lotion; cosmetic indications), tazarotene (0.05 or 0.1 % gel; for psoriasis, acne), and tretinoin (0.01–0.4 % cream, gel, solution, lotion, and ointment; for acne and photoaging).

For systemic use, medical options include acitretin (psoriasis, disorders of keratinization), bexarotene (cutaneous T-cell lymphoma resistant to other treatments), isotretinoin (severe acne and acne-related dermatoses), retinol (prevention and treatment of hypovitaminosis A), tretinoin (acute promyelocytic leukemia), and alitretinoin (chronic hand eczema).

The recent development of vitamin A derivates is likely to improve actual skin therapies. Highly receptor-selective molecules, receptor inducers, antagonists, and inverse agonists will probably be part of retinoid development in the near future. More effective and less toxic retinoids, alone or in combination and new delivery systems, may provide improved therapeutic solutions for various skin disorders.

Vitamin B1

Vitamer: thiamine and its phosphate derivatives.

Function: Thiamine phosphate derivatives are involved in a number of important cellular processes. Thiamine pyrophosphate is a coenzyme in the catabolism of carbohydrates and branched-chain amino acids. Thiamine is also important for the protein metabolism. Human body uses thiamine for the biosynthesis of acetylcholine and gamma-aminobutyric acid.

Deficiency and Health Benefits: Thiamine is the main transport form of the vitamin, while the

active forms are its phosphorylated derivatives. Thiamine derivatives are present in most cells of the body; therefore, a thiamine deficiency would be expected to have a high impact on most systems. However, only the nervous system is particularly sensitive to thiamine deficiency, due to its dependence on the oxidative metabolism.

Well-known syndromes caused by thiamine deficiency include beriberi, Wernicke-Korsakoff syndrome, and optic neuropathy. Since it is known to increase the capacity of cells to generate energy and help metabolize fats and proteins, it is also considered important for maintaining healthy skin and hair. It has been tried in cases of psoriasis, seborrheic dermatitis, acne, and hair loss, but to present no clear scientific evidence recommends thiamine supplementation for any cutaneous pathologies.

Vitamin B2

Vitamers: riboflavin, flavin mononucleotide, and flavin adenine dinucleotide.

Function: Vitamin B2 is mostly found as coenzymes flavin mononucleotide and flavin adenine dinucleotide, and only in a small percentage as riboflavin. It has a crucial role in oxidation-reduction and metabolic reactions. It is also involved in the metabolism of lipids, proteins, ketone bodies and carbohydrates, vitamin B6, and in red blood cell production. Riboflavin is critical for normal cell growth, development, and tissue repair.

Deficiency and Health Benefits: Riboflavin is mostly used in ariboflavinosis (B2 deficiency), cervical cancer, and migraine headaches.

Regarding skin, ariboflavinosis can result in dry cracked lips, inflammation of the mouth lining, glossitis, mouth ulcers, angular cheilitis, seborrhea around the nose, eyes, and ears, as well as scaling skin (affecting mostly the scrotum, labia majora, or nasolabial folds); it can also cause scrotal dermatitis, mucositis, and, in some cases, even epidermal necrolysis. Thus, riboflavin deficiency is classically associated with the oral-ocular-genital syndrome. All mentioned signs and symptoms disappear after administration of B2 supplements.

Riboflavin has been reported to help clear up cases of rosacea, acne, and seborrheic dermatitis and also accelerate the healing of various skin lesions like ulcers or burns. Recent studies focused on the therapeutic effects of systemic riboflavin in psoriasis, reporting various percentages of improvement.

Vitamin B3

Vitamers: niacin and nicotinamide.

Function: Niacin and nicotinamide are precursors of nicotinamide adenine dinucleotide (NAD) and nicotinamide adenine dinucleotide phosphate (NADP). NAD is essential in the catabolism of lipids, proteins, and carbohydrates and also in DNA repair and cell signaling, while NADP mostly in fatty acid and cholesterol synthesis.

Deficiency and Health Benefits: Nowadays, B3 deficiency occurs rarely, mostly in conditions of malnutrition. Severe deficiency of niacin causes pellagra, a disease classically characterized by diarrhea, dermatitis, dementia, and death. Other symptoms and signs include digestive disturbances, photosensitivity, ataxia, peripheral neuritis, insomnia, mental confusion, depression, and delirium.

Pellagra, the oldest known cutaneous manifestation among vitamin deficiencies, includes skin lesion like the "Casal's necklace" (hyperpigmentation and thickening of the lower neck's skin), or dermatitis on sun-exposed areas, characteristically bilateral and symmetrical on the dorsum of the hands, but also described on the elbows, knees, axillae, perianal, and genital region. These lesions are sharply demarcated; the skin is erythematous, rough, with scaling, and fissures, and sometimes angular cheilitis, stomatitis, glossitis, oral ulcers, or alopecia can be associated. In most cases, niacin requires association of thiamine and riboflavin to clear up the pellagra lesions.

Nicotinamide has been used for more than 40 years for various dermatological conditions. Currently, systemic but also topical nicotinamide preparations, due to their anti-inflammatory and sebum-reducing properties, have proved useful in various forms of acne, rosacea, seborrheic dermatitis, atopic dermatitis, autoimmune bullous

dermatoses, psoriasis, and granuloma annulare. It also improves skin barrier function, decreasing water loss through the epidermis, thus increasing skin hydration, and improves the pigmentation, blotchiness, and redness of aging skin; therefore, it is also included in a number of cosmeceutical products.

Recently, nicotinamide has shown benefits also in the treatment and prevention of photoaging and photoimmunosuppression; it reduces solar keratoses and possibly the risk of skin cancer.

Overdose of vitamin B3 should not be overlooked, since it can lead to skin rashes, xerosis, and various digestive disorders; it also has teratogenic risks.

Vitamin B5

Vitamers: pantothenic acid, panthenol, and pantethine.

Function: Pantothenic acid is required for the synthesis of coenzyme A (CoA), important in energy metabolism and also in the biosynthesis of acetylcholine. CoA also serves as a cofactor for a variety of reactions important in the metabolism of carbohydrates, fatty acids, proteins, sterols, steroid hormones, and porphyrins.

Deficiency and Health Benefits: Vitamin B5 deficiency is exceptional, due to its widespread distribution; thus, it has not been thoroughly studied.

Pantothenic acid is important for a normal epithelial function, so it is included in preparations used in various skin disorders. Dexpanthenol, stable alcoholic analog of pantothenic acid, is suitable for topical use due to its good skin penetration. It acts as moisturizer, activates fibroblast proliferation, and accelerates reepithelization, promoting wound healing both in vitro and in vivo. Dexpanthenol has also been shown to have an anti-inflammatory effect. Its efficacy has been shown in patients with skin grafts, burn injuries, scar treatment, and different dermatoses. As an adjuvant, dexpanthenol improved skin dryness, roughness, scaling, pruritus, erythema, and erosions, proving helpful also in itching, insect bites, poison ivy, diaper rash, and acne. Regarding its benefits on gray hair or dandruff, although cosmetic industry began adding pantothenic acid to various cosmetic products, including shampoos, there are no scientific data supporting it.

Vitamin B6

Vitamers: pyridoxine, pyridoxine 5′-phosphate, pyridoxal, pyridoxal 5′-phosphate, pyridoxamine, pyridoxamine 5′-phosphate, and 4-pyridoxic acid.

Function: Vitamin B6 through its active form, pyridoxal phosphate (PLP), acts as a coenzyme for many enzymes involved predominantly in macronutrient metabolism. PLP is also an essential for the biosynthesis neurotransmitters, conversion of tryptophan to niacin, hemoglobin synthesis and function, as well as gene expression.

Deficiency and Health Benefits: Vitamin B6 deficiency is rare, being usually associated with other B complex vitamin deficiencies. It is associated with microcytic anemia, electroencephalographic abnormalities, confusion, irritability, depression, and weakened immune function.

Cutaneous signs of vitamin B6 deficiency include seborrheic eruptions localized mostly on the face, neck, and shoulders, glossitis, oral ulcerations, cheilitis, intertrigo, and a pellagra-like dermatitis. For these conditions, and others like psoriasis, or acne, treatment with oral or parenteral pyridoxine has been tried, with variable and unconfirmed results.

Pyridoxine is also used topically, being included in a number of cosmetics, both hair and skin care products, but there is no scientific evidence of their efficacy.

Vitamin B7

Vitamers: biotin.

Function: Biotin is essential for cell growth; it plays a key role in critical metabolic pathways, including gluconeogenesis, fatty acid synthesis, and amino acid catabolism. It is also a cofactor for enzymes involved in carboxylation reactions. Biotin interacts with nuclear histone proteins and

thus seems to be important in DNA replication and transcription.

Deficiency and Health Benefits: The rare cases of biotin deficiencies can be seen in alcoholics, gastrectomy, inflammatory bowel disease, metabolic disorders, long-term antibiotic or antiepileptic use, and sometimes increased consumption of raw egg whites. Pregnant women are exposed to a higher risk of biotin deficiency.

Biotin deficiency can cause neurological symptoms, increased susceptibility to bacterial and fungal infections, hair loss, and a typical periorificial dermatitis, as seen also in zinc deficiency. The characteristic facial rash, with a particular facial fat distribution, has been named the "biotin-deficient face." Biotin deficiency generally improves with supplementation.

Additionally, biotin has been tried as adjunctive therapy in palmoplantar pustulosis, seborrheic dermatitis, acne rosacea, psoriasis, systemic lupus erythematosus, and atopic dermatitis, with little and conflicting reported result.

Biotin deficiency can cause hair loss, and deficient subjects reported nails to break easily. Thus, biotin is often recommended as a dietary supplement for strengthening hair and nails, and found in many cosmetics, though there is little scientific data supporting its efficacy in these conditions.

Vitamin B9

Vitamers: folic acid, folinic acid, and 5-methyltetrahydrofolate.

Function: Vitamin B9 is important for nucleotide biosynthesis, DNA synthesis, repair, and production of healthy erythrocytes. It also acts as a cofactor in a number of biological reactions, and it is crucial in periods of rapid cell division and growth, such as infancy and pregnancy.

Deficiency and Health Benefits: Folate deficiency is more common in chronic alcohol consumers, morbidly obese patients, patients with celiac disease and cobalamin deficiency, or due to drugs which interfere with its biosynthesis (e.g., methotrexate, trimethoprim, valproic acid).

Concerning skin conditions, folic acid has been reported useful in the treatment of aged and photoaged skin, topical formulations containing folic acid exerting sustained effects on collagen metabolism. Folate has also been used for oral ulcers from methotrexate and for gingival hyperplasia from phenytoin. It is also used in acne and hair loss, but there is no scientific evidence to support this.

Side effects of folate are rare and include gastrointestinal disorders and allergic reactions. There is concern that very high doses might increase the risk of lung and prostate cancer.

Vitamin B12

Vitamers: cyanocobalamin, hydroxocobalamin, methylcobalamin, and adenosylcobalamin.

Function: Vitamin B12 is crucial for the normal function of the nervous system and the synthesis of erythrocytes. It is involved in DNA synthesis and regulation, fatty acid synthesis, and energy production. Recently vitamin B12 has also been proven to have an immunomodulatory effect on T lymphocytes and cytokines.

Deficiency and Health Benefits: Deficiency is generally due to decreased intrinsic factor production (atrophic gastritis, gastrectomy), decreased acid secretion, microbial competition, or impaired absorption, and only in exceptional cases can be caused by insufficient intake.

Vitamin B12 deficiency is characterized principally by megaloblastic anemia. Neurological findings are also common and can occur before anemia, allowing early diagnosis.

Dermatological signs of vitamin B12 deficiency include cutaneous hyperpigmentation, commonly affecting the face, hands, flexural regions, and pressure points, angular cheilitis, Hunter glossitis, and hair depigmentation; all tend to remit after a proper vitamin B12 treatment.

Studies have also noted low levels of this vitamin in psoriatic plaques. Thus, the potential use of vitamin B12 in psoriasis therapy has recently started to be evaluated.

Vitamin B12 has also been tried as supplemental therapy for stomatitis, seborrheic dermatitis, erythema nodosum, herpes zoster, hyperpigmentation, trophic ulcers, burns, and hair loss, with various and conflicting results.

Vitamin C

Vitamers: ascorbic acid, dehydroascorbic acid, calcium ascorbate, sodium ascorbate, and other salts of ascorbic acid.

Function: Vitamin C acts as an essential cofactor in enzymatic reactions forming hydroxyproline, which is critical for collagen stability. It has many other functions, including antioxidant effects, decreasing UV-induced DNA damage and lipid peroxidation, and increasing the immune's system activity, iron absorption, and steroidogenesis. Essential also for the proper functioning of the skin barrier, vitamin C normalizes epidermal lipid formation, including glucosphingolipids and ceramides, crucial for the stratum corneum.

Deficiency and Health Benefits: The avitaminosis resulting from the lack of vitamin C is scurvy, and its manifestations are mostly due to the impaired synthesis of collagen. Generally, the first cutaneous signs characterizing scurvy are the bruise-like spots surrounding hair follicles, perifollicular hyperkeratotic papules, appearing generally on the shins. The central hairs are very fragile, twisted like corkscrews. Progressing, these papules form large purpuric areas. Gums may swell, become erythematous, fragile and bleed easily. Other possible signs include xerostomia, keratoconjunctivitis sicca, and salivary glands hyperplasia, mimicking Sjogren syndrome. Scurvy responds well to treatment with ascorbic acid.

A number of dermatologic diseases seem to benefit from systemic and topical vitamin C supplementation; conditions might be improved due to its anti-inflammatory action (e.g., postinflammatory hyperpigmentation, acne, rosacea, psoriasis), depigmenting effect (melasma, postinflammatory hyperpigmentation), as well as its effect on collagen synthesis (wound healing, especially pressure ulcers). Some cases of dyskeratoses, such as keratosis pilaris and Darier's disease, which failed to respond to vitamin A, were also reported to respond to vitamin C. Studies also focused on the protective role of vitamin C in nonmelanoma skin cancer, but their results are still contradictory.

Aging and excessive exposures to UV light have been reported to lower vitamin C skin levels; studies assessing the antiaging and photoprotective effects of vitamin C showed promising but not conclusive results.

Topical products such as creams, gels, serums, etc., containing various concentrations of vitamin C generally ranging from 5 to 20 % are widely marketed. Their claimed indications are multiple, few of these having scientific support.

Overdose of vitamin C can cause stomach disturbances, abdominal cramps, diarrhea, flushes, headache, and increased urination. For topical use, rare side effects include discoloration of the skin, hypopigmented hair, stinging, erythema, and dryness.

Vitamin D

Vitamers: ergocalciferol (D2) and cholecalciferol (D3).

Function: Vitamin D is mainly responsible for promoting intestinal absorption and maintaining adequate serum levels of calcium and phosphate. It is also important for cell growth, proper function of the neuromuscular and immune systems, and inhibition of the inflammatory response.

Both vitamin D and its analogs can bind to specific nuclear receptors, enhancing keratinocyte differentiation, inhibiting keratinocyte proliferation, promoting proapoptotic effects, and regulating the local immune response.

Deficiency and Health Benefits: Vitamin D deficiencies can result from insufficient dietary intake, impaired absorption or function, increased requirements, as well as limited exposure to sunlight and dark skin.

The classical forms of vitamin D deficiency are rickets and osteomalacia. Osteoporosis is generally associated with low calcium intake, but insufficient vitamin D also contributes to this condition.

Due to the multiple effects that vitamin D has on the skin, a number of analogs have been tried in various dermatological conditions. Such molecules were proved to be a therapeutic success in psoriasis, at present the main cutaneous

indication. Due to their immunomodulatory effect, oral calcitriol and calcipotriene have been reported useful in the treatment of morphea, and topical calcipotriene in a number of lichen sclerosus cases. Favorable effect of topical calcipotriol on actinic keratoses has also been described.

Vitamin D and its analogs have been investigated for chemoprevention in melanoma and metastasis of malignant tumors. The results of the various studies are conflicting, so more research on the topic is needed.

Recently, it has been shown that calcitriol, the active form of the vitamin D, is responsible for regulating antimicrobial peptides, a major component of the antimicrobial innate immune responses. Bacteria hardly develop resistance against them; based on this, a new class of antimicrobial agents is being developed.

Although the specific mechanism of action is not fully known, a number of studies stress the association of vitamin D and nonmelanoma skin cancers. Other researches focused on the benefit of the vitamin in cases of rosacea, seborrheic dermatitis, and atopic dermatitis. Unfortunately, clear scientific data supporting the benefit of vitamin D in these indications is still required.

Three vitamin D analogs, namely, calcipotriol, calcitriol, and tacalcitol, are currently marketed for topical use, main indication being psoriasis. Calcipotriol is available as ointment, cream (both at the concentration of 50 mcg/g), and scalp lotion (50 mcg/ml). Once or twice/day applications are recommended, with improvement usually within 2 weeks. This can often be maintained by continuing treatment. The maximum dose, by the manufacturer's recommendations, is 100 g/week for adults, 75 g for children over 12 years, and 50 g for children of 6–12 years. Under 6 years, the use is not recommended. Calcipotriol is also available in combination with betamethasone dipropionate, having greater efficacy than either constituent alone.

Calcitriol is available as ointment, containing 3 mcg/g of 1:25 dihydroxycholecalciferol. It is less irritant but also less effective than calcipotriol. It can be useful for the face and flexures, but it should not exceed 30 g/day and should not be applied on more than 35 % of the body surface. Tacalcitol is also less irritant than calcipotriol. It is available in 4 mcg/g concentration, suitable for the face and flexures. Amount applied should not exceed 10 g/day.

Vitamin E

Vitamers: tocopherols and tocotrienols (alpha, beta, gamma, delta).

Function: Vitamin E is mostly known for its antioxidant function, acting as a scavenger of free radicals. Being fat soluble, it is incorporated into cell membranes, protecting them from oxidative damage. Throughout the body, it is involved in many other processes, including gene expression, enzymatic activities, neurologic functions, inhibition of platelet aggregation, and cell signaling (the most important activity, according to recent studies).

Deficiency and Health Benefits: Vitamin E deficiency is very rare and almost never due to a poor intake. It can be caused by genetic abnormalities of tocopherol transfer protein, fat malabsorption conditions, or protein-calorie malnutrition.

Various dermatological conditions have been reported to benefit from vitamin E supplementation. Due to its anti-inflammatory action, vitamin E has been used in atopic dermatitis, psoriasis, discoid lupus erythematosus, granuloma annulare, and lichen sclerosus et atrophicus, with various results. It also seems to reduce sebum production in seborrheic skin, being efficient in seborrheic dermatitis and acne. In addition, it has been reported to decrease pruritus, improve wound healing, limit hypertrophic scar formation, and promote hair growth. There is a definite need for more scientific data to support the efficacy of vitamin E in these conditions.

Based on vitamin E's antioxidant effect, oral and topical preparations containing it have been evaluated for their potential in antiaging, photoaging, skin tumors, and photoprotection. Cosmeceutical products such as creams, serums, or gels, containing various concentrations of vitamin E, are already marketed claiming these indications, but more research is actually needed to confirm such benefits.

Skin conditions such as contact dermatitis with topical use of vitamin E and pruritus following oral supplementation have been reported.

Vitamin K

Vitamers: phytomenadione (K1), menaquinones (K2), and menadiones (K3-5, synthetic forms).

Function: Vitamin K is crucial for the synthesis of a number of coagulation factors, like factors II, VII, IX, and X, and protein C and S. It is also involved in the bone and other tissues' metabolic pathways.

Deficiency and Health Benefits: Primary vitamin K deficiency is very rare in healthy adults. This deficiency impairs the coagulation cascade, which results in hemorrhagic events, purpura, ecchymosis, hematomas, anemia, and bleeding.

A number of skin conditions seem to benefit from systemic and also from topical application of vitamin K, which has been reported to accelerate wound healing, reduce bruising and swelling and hyperpigmentation, improve venous circulation, and relieve itching accompanying biliary cirrhosis. Commercial vitamin K formulations are already marketed, claiming to remove spider veins, bruises, scars, and stretch marks, heal wounds, treat rosacea, or improve the elasticity of the skin, but more scientific evidence is needed to properly rate vitamin K for these uses.

Vitamins K1 and K2 have a good safety profile, but vitamin K3 (synthetic form) has known toxicity. In large doses, it can cause allergic reactions, hemolytic anemia, and cytotoxicity.

Future Perspectives

- Further research including clinical assessment of selected active compounds from natural sources will supply more scientific evidence, supporting their efficacy in various dermatological conditions.
- New delivery systems with increased topical absorption and improved stability might increase the efficacy of these natural remedies.
- The World Health Organization stresses on global awareness by upgrading and expanding the Vitamin and Mineral Nutrition Information System (VMNIS).
- Increasing the knowledge on their mechanisms of action and scientifically proven benefits will help include nutritional supplements and vitamins in the daily clinical practice.
