Preface

The third edition of the *European Handbook of Dermatological Treatments* follows the successful second edition published in 2003, providing concise yet comprehensive, up-to-date overviews of treatment guidelines and pearls in a plethora of skin diseases.

Over the last years, dermatology has achieved major breakthroughs in molecular and clinical research that have enabled the discovery of new treatments; our therapeutic armamentarium has been enriched with biological agents for psoriasis, also used as off-label promising treatments in other skin diseases, targeted agents for malignant melanoma and basal cell carcinoma, and new treatment modalities for rosacea, acne, atopic dermatitis, and urticaria, to name a few.

The three main sections of the third edition of the handbook are (i) diseases, (ii) drugs, and (iii) methods, encompassing different skin diseases, drugs available for dermatological treatments, and various methods applied in dermatology, including fillers, botulinum toxin, laser, dermoscopy, cryosurgery, and electrosurgery. Each chapter is focused on treatments, also providing a brief synopsis of the etiology and clinical presentation of the skin disease. Each chapter is structured with an abstract and a list of key points, while a comprehensive presentation of dermatological treatments, recent updated guidelines and recommendations, indications, contraindications, modes of action, and dosages are analyzed by our colleagues, experts in the field.

The third edition is enriched with clinical photos aiming to make the reading of the handbook a pleasurable as well as a learning experience. The skin is the most visible organ, and skin diseases can be challenging to effectively treat. The handbook focuses on dermatological treatments; indeed, treating patients is the essence of medicine, following the words of Hippocrates of Kos: "*Primum non nocere*."

Diseases

Acne

1

Clio Dessinioti and Brigitte Dreno

Key Points

- Acne vulgaris (acne) is a chronic inflammatory dermatosis that requires long-term treatment.
- Topical treatments (retinoids, benzoyl peroxide [BPO], azelaic acid, or antibiotics) are recommended for mild comedonal or inflammatory acne and in combination with systemic treatment for moderate and severe acne.
- The use of systemic treatments is indicated for moderate to severe inflammatory acne vulgaris, for acne that is resistant to topical treatments, and for acne of the trunk.
- Combination treatments are recommended to enhance effectiveness and tolerability and to improve the patient's compliance to the proposed treatment regimen.
- Treatment should aim to reduce the risk of bacterial resistance. Antibiotics (oral or topical) should not be used for more than 3 months and always be combined with topical agents such as retinoids or BPO.
- The treatment choice should be individualized and should take into account the age and the medical history of the patient, the type and severity of acne, the impact of acne on the patient's quality of life, the risk of scarring, and the presence of prognostic factors such as a family history of acne, adult acne, hyperseborrhea, hyperandrogenemia, truncal acne, or a history of infantile acne.
- Topical treatment is recommended as maintenance therapy, usually with a topical retinoid, BPO, or azelaic acid.
- Conglobate acne is a rare but severe form of nodular acne mostly affecting adult males. It presents with numerous comedones, papules, pustules, nodules, abscesses, and draining sinus tracts on the chest, back, and buttocks. Oral isotretinoin is strongly recommended as a monotherapy for conglobate acne.
- Acne fulminans is a rare acne variant affecting adolescent boys. It is characterized by the sudden onset of painful, ulcerative crusting acne in association with systemic signs and symptoms including fever, weight loss, arthralgias, and myalgias.

Definition and Epidemiology

Acne vulgaris (acne) is the most common skin disorder, affecting more than 80 % of adolescents, although it may present at any age. It has been defined as a chronic inflammatory dermatosis characterized by comedones and inflammatory lesions, including papules, pustules, and nodules, on sebum-rich body areas such as the face and trunk. It may be associated with a severe psychological and social impairment, as it may result in dysmorphia and permanent scarring, with a risk of low self-esteem and depression.

Conglobate acne is a rare but severe form of nodular acne mostly affecting adult males. It presents with numerous comedones, papules, pustules, nodules, abscesses, and draining sinus tracts involving mainly the chest, back, and buttocks. It frequently results in extensive and disfiguring scarring.

Acne fulminans (also known as acute febrile ulcerative acne or acne maligna) is a rare acne variant affecting adolescent boys. It is characterized by the sudden onset of painful, ulcerative crusting acne in association with systemic signs and symptoms including fever, weight loss, arthralgias, and myalgias. Aseptic, osteolytic bone lesions, visible on radiographs, have also been reported. Acne fulminans can be the dermatologic manifestation of the synovitis-acne-pustulosis-hyperostosis-osteitis (SAPHO) syndrome.

Basic Concepts of Pathogenesis

The four major pathophysiologic factors that influence acne pathogenesis include sebaceous gland hyperplasia with hyperseborrhea, follicular hyperkeratinization, hypercolonization of the pilosebaceous unit with *Propionibacterium acnes (P. acnes)*, inflammation, and immune reaction. Although each of these factors may represent a potential therapeutic target, the sequence of events has not been elucidated yet.

Androgens are central players in acne, as they increase the size of sebaceous glands and the sebum production, and they stimulate keratinocyte proliferation in the ductus seboglandularis and the acroinfundibulum, thus contributing to comedone formation. Sebaceous gland lipids exhibit direct pro-inflammatory properties playing a key role in acne pathogenesis. Although the relative amounts of *P. acnes* may not differ between acne patients and normal individuals, it has been proposed that specific *P. acnes* predominate in acne patients and possess specific genes that may increase virulence, promote stronger adherence to the human host, or induce a pathogenic host immune response.

Clinical Presentation

The clinical lesions in acne vulgaris are either non-inflamed lesions including open or closed comedones or inflamed lesions including papules, pustules, or nodules.

Acne may be classified based on the age of onset, into childhood, adolescent, or adult acne. This classification is important as there are age-related differences in the clinical presentation and the treatment approach.

Acne may present in childhood, and it is classified depending on the age of presentation, in neonatal, infantile, mid-childhood, and prepubertal acne.

In adolescents, acne presents around 12–14 years of age and usually resolves around 18–20 years of age.

Adult acne affects individuals older than 20–25 years. Adult acne is termed late-onset acne or acne tarda, when it first presents in adulthood, while persistent acne refers to acne continuing from adolescence to the adult years of life. Persistent acne is the most common form of adult acne, accounting for 80 % of cases. There are two clinical forms of adult acne: the inflammatory form consisting of papulopustules and deep inflammatory nodules and the comedonal form characterized by macrocomedones.

Also, acne may be classified according to severity as mild, moderate, or severe and according to the lesions that predominate in a given patient as comedonal, papulopustular, or nodular (Figs. 1.1, 1.2, and 1.3). When there are a similar

Fig. 1.1 Mild facial acne with few papules and pustules. Several acne scars are present

Fig. 1.2 Moderate facial acne with some papules and pustules. Acne scars are present

number of comedones and papules, it is referred as comedopapular acne, while in case of a similar number of papules and pustules, it is termed papulopustular acne. Severe cystic acne is characterized by the presence of cysts and numerous comedones, papules, and pustules.

Fig. 1.3 Severe papulopustular acne

Differential Diagnosis

The diagnosis of acne is clinical. Acne is not an allergy or an infection, so laboratory evaluations are not necessary to confirm diagnosis, except if other conditions should be ruled out. The comedone is the sine qua non clinical lesion in acne. It is always present in acne and this is the key characteristic that establishes diagnosis.

Childhood acne should be differentiated from:

- Neonatal cephalic pustulosis: *Malassezia furfur* is found in microscopy, presents with pustules and no comedones, and responds to topical ketoconazole.
- Acne venenata infantum: is due to the application of topical oils and ointments.
- Milia: small cysts with keratin plugs. Spontaneous resolution.
- Acneiform eruption: due to maternal use of corticosteroids during pregnancy, no comedones, monomorphous lesions.
- Perioral dermatitis: may be due to the use of topical or inhaled corticosteroids. No comedones.

Adolescent acne should be differentiated from:

- Folliculitis: it presents with follicular pustules. Comedones are absent.

Adult acne should be differentiated from:

- Rosacea: it affects individuals after the age of 30 years. Comedones are absent.
- Perioral dermatitis: it affects individuals mainly after the age of 30 years. It is located around the mouth, nose, and eyes. Comedones are absent.

- Drug-induced acneiform eruptions due to glucocorticosteroids, antiepileptics, antidepressants, growth hormone, cyclosporine, vitamin B12, epidermal growth factor receptor (EGFR) inhibitors, and BRAF inhibitors: recent or current history of drug intake; comedones are absent.

General Principles of Treatment

Acne is a chronic disease, and patient education is critical to improve adherence to proposed treatment and optimize clinical results. It should be explained that acne treatment will continue over long periods of time and clinical improvement is not evident early but usually takes some (5–6) weeks to show. Topical treatments are fundamental for the management of acne, so the importance of applying topical agents should be communicated to patients. Topicals should be applied on the entire face and not just on the clinically visible lesions in order to effectively target the microcomedone, the primary acne lesion, that is not visible to the naked eye.

A mild cleanser may be used for washing the face twice daily. The use of noncomedogenic cosmetics and makeup products if camouflage is desired is encouraged. A suitable oil-free sunscreen during the summer and during oral isotretinoin treatment is advisable. Skin care products are often necessary to either complement the use of acne drugs or to counteract the drying effect of some acne medications, such as moisturizing creams during oral isotretinoin treatment and in combination with topical retinoids, in order to avoid topical irritation.

A common question often posed by acne patients is whether a specific food influences their acne. The intake of chocolate has been traditionally held as culprit for acne flare-ups. However, this has remained a myth and not a proven fact, and there are no evidence-based data to either support or refute an association of diet with acne. We suggest our acne patients to follow a balanced diet as part of a healthier mode of life in general.

Topical Treatments

Topical Antibiotics

Topical antibiotics include erythromycin, clindamycin, tetracycline, and nadifloxacin. They exert anti-inflammatory properties as well as antibacterial action against *P. acnes*.

Topical antibiotics are indicated for mild to moderate action. They should never be used as monotherapy but should be used in combination with another topical treatment such as retinoids, benzoyl peroxide, or azelaic acid, either in the context of alternate day regimens or as fixed-dose combinations. They are applied once or twice daily for a maximum period of 6 weeks.

Benzoyl Peroxide (BPO)

BPO has antibacterial, anti-inflammatory, and mild comedolytic actions. Topical BPO is indicated for mild papulopustular acne and for moderate to severe acne in combination with another topical treatment, such as retinoids, antibiotics, or azelaic acid. Also, it may be combined with systemic antibiotic therapy or, in women, with hormonal therapy. BPO is applied once or twice daily for a period that is determined by the treating dermatologist. It may be proposed as maintenance therapy.

Topical Retinoids

Topical retinoids include adapalene, isotretinoin, tazarotene, and tretinoin. They have comedolytic effects, and, in addition, adapalene exhibits mild anti-inflammatory action. Topical retinoids are indicated for comedonal and mild papulopustular acne. Also, they are indicated for moderate to severe acne in combination with another topical treatment, such as BPO, antibiotics, azelaic acid, and/or a systemic antibiotic or hormonal therapy. They are applied once or twice daily for a period that is determined by the treating dermatologist. They may be proposed as maintenance therapy.

Azelaic Acid (AZA)

Azelaic acid presents mild comedolytic, antimicrobial, and anti-inflammatory actions. AZA is indicated for comedonal and mild papulopustular acne. Also, it is recommended for moderate and severe acne in combination with another topical treatment such as BPO, retinoids, or antibiotic or in combination with a systemic antibiotic or hormonal therapy. It is applied twice daily, and treatment for at least 12 weeks is usually required for acne improvement.

Fixed-Dose Combination Topical Formulations

Fixed-dose combination topical agents combine two different agents used for acne treatment, such as combinations of antibiotic/retinoid or antibiotic/benzoyl peroxide or benzoyl peroxide/retinoid. Topical combination treatments target multiple pathogenetic factors at the same time, thus resulting in enhanced effectiveness and improved tolerability. Also, they present the advantage of a simpler application regimen, with a once- or twice-daily application of a single formulation, thus resulting in better adherence by the patient to the proposed treatment.

Topical retinoids in combination with topical antimicrobials have been shown to reduce inflammatory and noninflammatory acne lesions faster and to a greater degree than antimicrobial therapy alone. This may be explained by the fact that combination treatments target several areas of acne pathophysiology simultaneously. In addition, topical retinoids may affect skin permeability and facilitate the penetration of the topical antibiotic.

Clindamycin/zinc gel contains zinc acetate dehydrate applied once or twice daily in a formulation that reduces the extent of absorption of clindamycin through the skin while showing equivalent efficacy and safety to clindamycin lotion. Combinations of zinc with erythromycin may result in reduction of the risk of bacterial resistance.

Once-daily applied topical clindamycin/benzoyl peroxide and twice-daily applied erythromycin/zinc acetate are both effective treatments for acne, but clindamycin/benzoyl peroxide has an earlier onset of action. Also, a fixed clindamycin phosphate/tretinoin gel formulation applied once daily was more effective and faster acting in reducing acne lesions than clindamycin lotion formulation applied twice daily.

5 % Dapsone Gel

Dapsone is a sulfone with both anti-inflammatory and antimicrobial properties. Advances in cutaneous pharmacology have produced a new topical formulation of 5 % dapsone gel, which was shown to be an effective and safe treatment, when applied twice daily for 12 weeks. Glucose-6-phosphate dehydrogenase-deficient patients presented no laboratory abnormalities. It has been proposed that its action may be due to a direct inhibition of leukocyte trafficking and the generation of chemical mediators of inflammation by leukocytes. Alternatively, topical dapsone might act indirectly in acne, by altering the levels and/or activity of propionibacteria.

Topical Treatments at a Glance

- Topical treatments (retinoids, BPO, AZA, antibiotics) are recommended for mild comedonal or inflammatory acne and in combination with an oral treatment for moderate and severe acne.
- Topical antibiotics should not be used alone but in combination with another agent (e.g., retinoid or BPO) to avoid the risk of bacterial resistance.
- Topical treatments are recommended to be used in combination, either as separate agents or as fixed-dose combination agents.
- Fixed-dose combination agents aim to enhance effectiveness and tolerability and to improve patients' compliance to the propose treatment regimen.
- Topical treatment is recommended as maintenance therapy, usually with a retinoid, BPO, or AZA.

Systemic Treatments

The use of systemic treatments is indicated for moderate to severe inflammatory acne, for acne that is resistant to topical treatments, and for acne of the trunk. Established systemic acne treatments include oral antibiotics, isotretinoin, and hormonal therapies.

Antibiotics

Systemic antibiotics for acne treatment include tetracyclines (oxytetracycline, tetracycline chloride, doxycycline, and minocycline) and macrolides (erythromycin, azithromycin).

Antibiotics such as tetracyclines (oxytetracycline, tetracycline chloride, doxycycline, and minocycline), trimethoprim, and macrolide antibiotics (erythromycin) have been a mainstay of treatment for moderate and severe acne and treatment-resistant forms of inflammatory acne, for more than 30 years. The efficacy of tetracycline derivatives in acne vulgaris is believed to be related, besides to their antibiotic effects, also to their anti-inflammatory effects. Anti-inflammatory action may be exerted via reduction in neutrophil chemotaxis, as well as via inhibition of proinflammatory cytokines and matrix metalloproteinase-9 (MMP-9). Nevertheless, data concerning antibiotic use in acne has been based on anecdotal reports, clinical experience, and small clinical trials.

Recommended dosage regimens are 500–1,000 mg/day for tetracycline and erythromycin, 300 mg/day for lymecycline, and 50–200 mg/day for doxycycline and minocycline. Treatment should not exceed 3 months.

Acne treatment with systemic antibiotics may be associated with vaginal candidiasis and gastrointestinal disturbances. Moreover, doxycycline has been associated with photosensitivity, while minocycline has been associated with pigment deposition in the skin, mucous membranes, and teeth, particularly among patients receiving long-term therapy and/or higher doses of minocycline. Rare adverse effects reported with minocycline use include autoimmune hepatitis, a systemic lupus erythematosus-like syndrome, and serum sickness-like reactions (Table 1.1). Tetracyclines are indicated for individuals older than 8 years, after permanent dentition has been completed, and they are contraindicated during pregnancy and lactation.

Bacterial resistance to antibiotics is an increasing health problem worldwide. Resistance of *P. acnes* is more common with erythromycin; less common with tetracycline, doxycycline, and trimethoprim; and rare with minocycline. Although acne itself is not infectious, antibiotic-resistant propionibacteria should be considered transmissible between susceptible individuals. The use of antibiotics may result not only in an increase of resistance of *P. acnes* but also in an increase in other resistant organisms, such as *Staphylococcus aureus.* In order to avoid this, it is recommended to avoid antibiotic monotherapy, to restrict antibiotic use to a minimum (up to 3 months), and to use combination treatments for acne.

Released in 2006, anti-inflammatory dose doxycycline (40 mg capsule containing 30 mg immediate-release and 10 mg delayed-release beads) administered once daily was approved by the US Food and Drug Administration (FDA) for the treatment of papulopustular rosacea. This formulation presents anti-inflammatory activity devoid of antibiotic effects, so that there is no evidence of antimicrobial selection pressure associated with its use. In patients with moderate acne, doxycycline at a subantimicrobial dose

Table 1.1 Adverse events associated with oral antibiotic use in acne vulgaris

Antibiotic	Adverse events
Tetracycline	Gastrointestinal upset
	Vaginal candidiasis
	Reduced absorption with food and dairy products
Doxycycline	Gastrointestinal upset
	Photosensitivity
Minocycline	Dizziness
	Rarely, intracranial hypertension
	Hyperpigmentation of skin, oral mucosa, teeth
	Autoimmune hepatitis
	Lupus-like syndrome
	Serum sickness-like reactions
Erythromycin	Gastrointestinal upset
	Vaginal candidiasis
	Resistance of *P. acnes*

(20 mg twice daily) has been shown to reduce both inflammatory and noninflammatory lesions, while no resistant strains of *P. acnes* were evident.

Moreover, an extended-release (ER) minocycline tablet, administered at a dosage of 1 mg/kg daily for 12 weeks, was FDA approved for moderate to severe inflammatory acne vulgaris in patients over 12 years old. This formulation produces a slower release of active drug, which is believed to reduce the risk of side effects such as acute vestibular adverse reactions, and overall drug exposure with time.

Azithromycin is a methyl derivative of erythromycin that effectively inhibits significant intracellular pathogens, as well as Gram-positive and Gram-negative aerobic and anaerobic bacteria, including *P. acnes*. It has been found to be effective in treating noninflammatory and inflammatory acne lesions. Whether its efficacy is mediated primarily through antimicrobial or anti-inflammatory action remains unclear. There is no data on azithromycin resistance developing in *P. acnes*; however, due to high bacterial resistance to azithromycin in the population (20–27.4 %), its use as a first-line antibiotic therapy for acne is not advised. However, it may be considered as an alternative to conventional anti-acne treatment.

Isotretinoin

Systemic isotretinoin (13-*cis* retinoic acid), a vitamin A derivative, is the only therapeutic agent that targets all four major factors involved in acne pathogenesis. The European Agency for the Evaluation of Medicinal Products (EMEA) recommends that its use should be limited to severe forms of acne (such as nodular or conglobate acne or acne at risk of permanent scarring) that has proved resistant to adequate courses of standard therapy with systemic antibacterials and topical therapy. However, it has been proposed that oral isotretinoin may be considered as a first-line treatment, in the case of existing prognostic factors that have been proven to influence acne, such as family history, early onset of acne, trunk involvement, persistent and late-onset acne, hyperseborrhea, scarring potential, and severe psychological impact. Limitations can apply that may necessitate the use of a treatment with a lower strength of recommendation as a first-line therapy (e.g., financial resources/reimbursement limitations, legal restrictions, availability, drug licensing).

Isotretinoin is recommended at a dose of 0.3–0.5 mg/kg/day, given in two divided doses, for at least 6 months and until there is sufficient response. A lower clinical response with oral isotretinoin 0.5 mg/kg/day for 6 months, for mild to moderate adult female acne, has been associated with a high-glycemic-load diet, smoking, and early acne onset. Relapse after treatment with oral isotretinoin has been reported in 15–45 % of patients, and it has been associated with early acne, young age at the moment of isotretinoin initiation, family history of acne, prepubertal acne, localization on the trunk, important seborrhea, and a high number of inflammatory lesions at the end of treatment.

Systemic isotretinoin has been associated with a plethora of adverse events, most of which are dose dependent and self-limited. Mucocutaneous xerosis is the most common adverse event, resulting in dermatitis, cheilitis, epistaxis, and conjunctivitis. Laboratory evaluations during therapy should include triglycerides, cholesterol, transaminase levels, creatine phosphokinase, and complete blood counts. Hypertriglyceridemia and hypercholesterolemia have been reported in 25 % of patients but are reversible when isotretinoin is stopped. Elevated liver function tests have also been reported, which return to normal within 2–4 weeks despite continued treatment, and only rarely is treatment discontinuation needed. The most important adverse events are teratogenicity and psychiatric disorders. Isotretinoin is a known teratogen for women, so pregnancy should be avoided during treatment and for 1 month after cessation of treatment. Before treatment initiation, women of childbearing potential should be informed about teratogenicity of isotretinoin and the absolute need of effective contraceptive measures throughout treatment and for 1 month after treatment completion. Some studies and case reports have reported mood disorders, depression, suicidal ideation, and suicides in patients taking isotretinoin, while other studies have failed to

show such an association. There is not enough evidence to establish a causal link between isotretinoin use and suicide or major depression. On the contrary, isotretinoin therapy has been shown to improve anxiety and depressive symptoms in acne patients. Oral isotretinoin should not be combined with oral tetracyclines as there is increased risk of benign intracranial hypertension.

New developments and future trends are low-dose long-term isotretinoin regimens and new isotretinoin formulations (micronized isotretinoin). Intermittent moderate-dose isotretinoin has been proposed for adult patients with mild acne unresponsive or rapidly relapsing after treatment with oral antibiotics. In a study of 80 patients, isotretinoin was used at a dose of 0.5 mg/kg per day for 1 week every 4 weeks for a total period of 6 months. The acne resolved in 88 % of the patients, but 12 months after treatment 39 % of the patients had relapsed. Another intermittent isotretinoin regimen which was found to be a safe and effective option for the treatment of mild to moderate acne consisted of isotretinoin 0.5–0.75 mg/kg/day for 1 week, every 4 weeks, for a total period of 6 months (cumulative dose 35 mg/kg). The importance of continuing effective contraception should be underlined for women taking intermittent isotretinoin regimens.

Hormonal Therapies

Hormonal agents for acne treatment are indicated for female patients only, and they include antiandrogens and combined oral contraceptives (OC). Hormonal therapies exert their beneficial effects in acne by reducing circulating and local androgens and by opposing the actions of androgens in the pilosebaceous unit.

Appropriate patient selection is important when considering initiating hormonal therapy. Contraindications should be ruled out and treatment should be individualized. Hormonal therapy in acne is indicated for women, when oral contraception is desirable, when repeated courses of isotretinoin are needed to control acne, and when there are clinical signs of hyperandrogenism, such as androgenic alopecia, and seborrhea/acne/hirsutism/alopecia (SAHA) syndrome. Also, hormonal therapy can be proposed for late-onset acne (acne tarda) and for cases of proven ovarian or adrenal hyperandrogenism. Hormonal therapy can be very effective in females with acne whether their serum androgens are abnormal or not. Most women with acne have normal serum androgen levels, yet will respond if treated with hormonal therapy.

Polycystic ovary syndrome (PCOS) may present with acne as a marker of hyperandrogenism. Oral contraceptive pill therapy is the first-line therapy for women with PCOS, hirsutism, and acne. The choice of OC is important as some progestins are more androgenic (norgestrel, levonorgestrel) and should be avoided, while others are less androgenic. The combination of ethinyl estradiol with drospirenone has the advantage of the antiandrogenic effects of drospirenone. Antiandrogens such as cyproterone acetate in the form of combined oral contraceptive are effective in the treatment of recalcitrant acne in PCOS.

Systemic Treatments at a Glance

- Among oral antibiotics, doxycycline is recommended as first-choice agent for the treatment of moderate to severe inflammatory acne.
- Oral antibiotic therapy should be discontinued when response is achieved and after a maximum period of 3 months.
- Oral antibiotics should always be combined with a topical agent such as a retinoid, BPO, AZA, or their combinations, to decrease the risk of bacterial resistance.
- Oral antibiotic should not be combined with a topical antibiotic alone.
- Oral isotretinoin is recommended at a dose of 0.3–0.5 mg/kg/day in the recent European Guidelines.
- Hormonal therapy should be individualized for female acne patients.

Other Treatment Options for Acne

Other therapeutic options that have been used for acne treatment include the extraction of closed and open comedones, laser, and light sources, while chemical peels and lasers may be used for acne scarring.

Laser and light therapies, including blue or red light, intense pulsed light (IPL), and pulsed-dye laser (PDL), have been used for acne. It is known that *P. acnes* produces porphyrins, particularly coproporphyrin III. Visible light is able to activate these porphyrins to produce a photodynamic reaction that has the potential to destroy bacteria. Topical photodynamic therapy (PDT) uses light-activated agents (photosensitizers) that are selectively absorbed into the pilosebaceous unit to amplify the response to light/laser therapy. Topical photosensitizers used for PDT in acne include 5-aminolaevulinic acid (ALA) and methyl aminolevulinate (MAL), although controlled randomized investigator-blinded trials are lacking. The recently published European Guidelines propose an "open recommendation" (neither for nor against) for the use of light, IPL, laser, PDT for the treatment of mild or severe papulopustular/moderate nodular acne, and moderate nodular/conglobate acne, as optimal treatment regimens, frequencies, and device settings remain to be clarified.

There is only a low strength of recommendation for blue light monotherapy for the treatment of mild to moderate papulopustular acne.

Zinc

Zinc sulfate and zinc gluconate have been used for the treatment of inflammatory acne vulgaris with conflicting results. Oral zinc salts have been used at a dose of 30–150 mg of elemental zinc daily for 3 months. Adverse events during zinc treatment involve the gastrointestinal tract.

The mechanism of action of zinc salts is only partially known. Zinc acts via inhibition of polymorphonuclear cell chemotaxis and inhibition of growth of *P. acnes*. Also, its anti-inflammatory activity could be related to a decrease in TNF-α production and the modulation of the expression of integrins and the inhibition of Toll-like receptor 2 (TLR2) surface expression by keratinocytes.

Zinc gluconate has been proposed as an alternative therapy for inflammatory acne; it may be a useful treatment for pregnant women due to its favorable safety profile, and it may be proposed during summer as it causes no photosensitivity. In addition, zinc gluconate does not induce bacterial resistance, and when combined in a topical formulation with erythromycin, it has been shown to prevent the growth of erythromycin-resistant *P. acnes* strains and to be more effective in inflammatory acne than erythromycin alone.

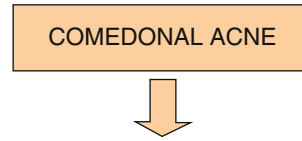
European Evidence-Based Guidelines for the Treatment of Acne

Treatment choice should be individualized and should take into account the age and the medical history of the patient, the type and severity of acne, the impact of acne on the patient's quality of life, the risk of scarring, and the presence of prognostic factors such as a family history of acne, adult acne, hyperseborrhea, hyperandrogenemia, truncal acne, or a history of infantile acne.

The recently published European Evidence-based (S3) Guidelines for the treatment of acne have systemically reviewed well-designed clinical trials of acne treatments and included a structured consensus process. Guidelines were based on the clinical form of acne.

For comedonal acne, topical retinoids are recommended as first-line therapy (Fig. 1.4). Available topical retinoids were found to have similar efficacy, but adapalene is superior due to its better tolerability profile.

For papulopustular acne, fixed-dose combination agents were more efficacious compared to their ingredients used alone. For mild to moderate papulopustular acne, there is high strength of recommendation for the use of fixed-dose combination BPO/adapalene or BPO/clindamycin. AZA, topical retinoids, or BPO is recommended with a medium strength of recommendation. For more widespread mild to moderate papulopustular



Strength of recommendation	Treatment
High	-
Medium	Topical retinodis
Low	BPO AZA
Negative recommendation	Topical antibiotics Hormonal therapy Systemic antibiotics Oral isotretinoin Artificial UVR
Open recommendation (neither for nor against)	Visible light Laser (visible, infrared wavelength) PDT, IPL

Fig. 1.4 Recommendations for comedonal acne based on the European evidence-based (S3) guidelines

acne, oral antibiotic combined with adapalene is recommended with a medium strength of recommendation. Blue light monotherapy has a low strength of recommendation (Fig. 1.5).

For severe papulopustular/moderate nodular acne, oral isotretinoin has been recommended, while there is medium strength recommendation for systemic antibiotics combined with adapalene, BPO/adapalene, or AZA (Fig. 1.6).

There are very few studies evaluating nodular or conglobate acne. The recommendations for nodular/conglobate acne are presented in Fig. 1.7.

It is recommended that oral antibiotic therapy should always be combined with topical therapy (other than antibiotics). Among oral antibiotics, doxycycline should be preferred as first-line antibiotic, compared to minocycline or tetracycline, as minocycline has been associated with more serious side effects and tetracycline has a more complicated dosage regimen. Topical antibiotic monotherapy is to be avoided due to increased risk of bacterial resistance.

Maintenance therapy (e.g., with a retinoid or BPO or AZA) is of cardinal importance in order to maintain acne remission.

Treatment Approach for Acne in Different Age Groups

The abovementioned guidelines apply for acne vulgaris during adolescence. Additional special considerations apply for childhood acne, adult acne, and acne during pregnancy and lactation. The proposed treatment approach for acne in different age groups is summarized in Fig. 1.8.

Special considerations of adult female acne include the resistance of acne to standard treatments, the fact that adult skin is more sensitive to possibly irritant topicals and there may be slower response, and the possibility of needing to treating acne during pregnancy or lactation. Patient education is important to increase therapeutic adherence.

MILD-TO-MODERATE PAPULOPUSTULAR ACNE

Strength of recommendation	Treatment
High	BPO/clindamycin BPO/adapalene
Medium	AZA BPO Topical retinoids Systemic antibiotics + adapalene, for widespread acne
Low	Blue light as monotherapy Erythromycin/tretinoin Erythromycin/isotretinoin Oral zinc Systemic antibiotics + BPO or +BPO/adapalene, for widespread acne
Negative recommendation	Topical antibiotics as monotherapy Systemic treatment with anti-androgens, antibiotics and/or isotretinoin Artificial UVR
Open recommendation	Red light, laser, PDT, IPL

Fig. 1.5 Recommendations for mild to moderate papulopustular acne based on the European evidence-based (S3) guidelines

Topical monotherapy usually is not sufficient to treat adult acne, as it fails to target the multiple factors implicated in acne pathogenesis. It is proposed to use combination topical treatments or combine oral and topical agents for optimizing results.

For adult women, topical retinoids are indicated for the treatment of mild comedonal and mild to moderate papulopustular acne. Adapalene is better tolerated. Given the oral teratogenicity of retinoids, it is recommended that women avoid pregnancy while using topical retinoids.

Azelaic acid (cream 20 %, gel 15 %) is proposed as first-line monotherapy for inflammatory and noninflammatory adult female acne, as it presents similar efficacy with other topicals, while it is characterized by a favorable tolerability profile. AZA has anti-tyrosinase action and is suitable to treat postinflammatory hyperpigmentation associated with acne. No harmful effects on fetuses have been reported during two decades of clinical experience with topical AZA.

In accordance with the European Guidelines, topical antibiotics are not proposed as monotherapy for adult female acne. They may be used as part of combination therapy.

BPO may cause photosensitivity and irritation to the adult female skin with erythema and dryness.

Topical combination treatments are indicated for inflammatory adult female acne. The application of a fixed-dose combination agent is easier to use compared to the combined use of different agents, and it may improve the patients' adherence to proposed treatment.

SEVERE PAPULOPUSTULAR ACNE (SPP) / MODERATE NODULAR ACNE (MNA)

Strength of recommendation	Treatment
High	Oral isotretinoin for SPP
Medium	Systemic antibiotics + adapalene, or + BPO/adapalene, or + AZA, for SPP
Low	Systemic antibiotics + BPO, for SPP, MNA Systemic antibiotics + oral anti-androgens for SPP, MNA (for females) Oral anti-androgens + topical treatment for SPP (for females)
Negative recommendation	Topical monotherapy Oral antibiotics as monotherapy Oral anti-androgens as monotherapy Visible light as monotherapy Artificial UVR
Open recommendation	PDT, IPL, laser

Fig. 1.6 Recommendations for severe papulopustular/moderate nodular acne based on the European evidence-based (S3) guidelines

NODULAR/CONGLOBATE ACNE (CA)

Strength of recommendation	Treatment
High	Oral isotretinoin for CA
Medium	Systemic antibiotics + AZA, for CA
Low	Systemic antibiotics + BPO, or + adapalene, or +BPO/adapalene, for nodular/conglobate acne Systemic antibiotics + oral anti-androgens, for CA (for females)
Negative recommendation	Topical monotherapy for CA Oral antibiotics as monotherapy for CA Oral anti-androgens as monotherapy for CA Visible light as monotherapy for CA Artificial UVR for CA
Open recommendation	IPL, laser for CA Although PDT is effective, it cannot yet be recommended for moderate nodular/conglobate acne due to a lack of stand treatment regiments that ensure a favourable profile of acute adverse reaction

Fig. 1.7 Recommendations for nodular/conglobate acne based on the European evidence-based (S3) guidelines

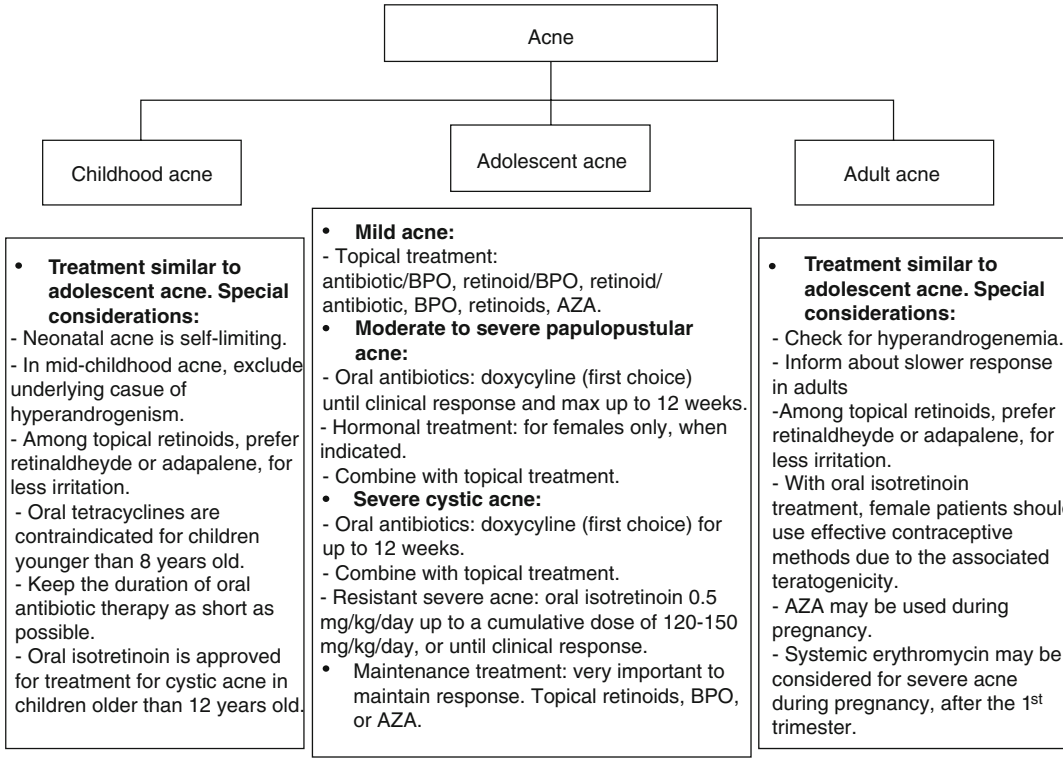


Fig. 1.8 Acne treatment in different age groups

For adult female acne, systemic treatment is indicated for moderate to severe acne, acne with risk of scarring, and acne resistant to therapies.

In accordance with the European S3 Guidelines for the treatment of acne, oral antibiotics are not recommended as monotherapy, but they should be combined with topical therapies, such as BPO, to decrease the risk of bacterial resistance, or azelaic (15 % or 20 %) as an alternative choice for adult women with intolerability to BPO. According to published guidelines, when indicated, oral erythromycin may be taken during pregnancy after the first trimester, whereas oral tetracyclines are contraindicated during pregnancy as they may inhibit the formation of the skeleton of the embryo.

Hormonal therapies (antiandrogens and/or oral contraceptives) are very effective for adult female acne, even when there are no underlying hormonal disorders. Hormonal therapy permits long-term therapy without any risk of emergence of bacterial resistance as is the risk with long-term antibiotic therapy. Also, hormonal therapy is an alternative choice for females that have relapsed after multiple oral isotretinoin treatments. Hormonal therapy should be combined with topical acne therapies such as antibiotics or BPO. Antiandrogens are contraindicated during pregnancy and lactation.

Topical maintenance treatment is necessary for adult female acne in order to decrease the risk of acne relapse after treatment discontinuation. For adult female acne, adapalene 0.1 % is proposed as first-line maintenance therapy and AZA 15 % or 20 % as an alternative. Topical antibiotics should not be used as maintenance therapy.

Future Perspectives

Future perspectives in acne treatment include insulin-sensitizing agents; selective inhibitors of key enzymes involved in cutaneous androgen metabolism, such as 5-α reductase type 1, as well

as Toll-like receptor antagonists; and agents targeting proinflammatory molecules that participate in acne pathogenesis.

Insulin-Sensitizing Agents

Hyperinsulinemia is an important factor in many cases of polycystic ovary syndrome (PCOS). It results from resistance to the effects of insulin on glucose metabolism, which has been found to occur independently of obesity and to be related to hyperandrogenism. Insulin may directly stimulate androgen-responsive pilosebaceous units. Antidiabetic agents that improve insulin sensitivity lower insulin levels and consequently improve ovarian function and plasma androgens. Recent studies, in women with PCOS, provide data for the efficacy and safety of metformin for acne treatment, while it has been suggested that patients who might benefit from metformin treatment are those with PCOS, diabetes, or impaired glucose tolerance.

Metformin, a biguanide, is the most commonly used insulin sensitizer for the treatment of PCOS. It inhibits hepatic glucose production and increases peripheral insulin sensitivity but does not cause hypoglycemia.

Halborne et al. reported in 52 women with PCOS similar self-assessed improvement in mild acne with metformin 1,500 mg daily for 14 months compared to oral contraceptive 35 μg ethinyl estradiol plus 2 mg cyproterone acetate, with no changes in sebum excretion rates. Kolodziejczyk et al. showed that in 39 women with PCOS and fasting hyperinsulinemia, treatment with metformin 1,500 mg daily for 12 weeks resulted in a decline of insulin and free testosterone and an improvement of acne.

Another study by Bergstrom et al. in 188 women with PCOS showed that metformin (500–1,000 mg twice daily) for a 6-month period resulted in improvement in acne severity, testosterone level, insulin resistance, and menstrual irregularities. Ibanez et al. in a randomized open-label trial in 34 adolescent girls with hyperinsulinemic androgen excess evaluated ethinyl estradiol-cyproterone acetate (EE-CA) compared to a low-dose combination (PioFluMet) of pioglitazone (7.5 mg/day), flutamide (62.5 mg/day), and metformin (850 mg/day) for 6 months. EE-CA and PioFluMet were equally effective in improving acne (reduction of 0.8–1.1 in Leeds acne score after 6 months, $p \leq 0.001$).

Steroidogenic Enzyme Inhibitors

The skin is a steroidogenic organ that possesses all major enzyme systems for synthesizing androgens de novo from cholesterol and for locally converting circulating weaker androgens to more potent ones. The enzymes involved in cutaneous androgen metabolism, such as 5α-reductase type 1, steroid sulfatase, and 3-β hydroxysteroid dehydrogenase, may represent attractive targets for pharmacologic inhibition in acne treatment.

Blocking the Activation of Toll-Like Receptors (TLRs)

P. acnes has been shown to induce an increased expression of TLR-2, TLR-4, and matrix metalloproteinase-9 (MMP-9) by human keratinocytes and to stimulate keratinocyte proliferation. Blocking the activation of TLRs could therefore represent an attractive therapeutic target.

Targeting Peroxisome Proliferator-Activated Receptors (PPARs)

PPARs (α, δ, and γ subsets) are ligand-activated nuclear receptors that form heterodimers with retinoid X receptors and regulate the expression of target genes involved in many cellular functions including cell proliferation, differentiation, and immune/inflammation response. PPARs may be important in the regulation of human sebum production and the development of acne. Activation of PPARα and PPARγ by their ligands resulted in stimulation of lipid droplet accumulation in cultured immature sebocytes and sebum production was increased in patients. On the other hand, PPAR activators have shown

antiapoptotic, sebostatic, and anti-inflammatory effects in human skin. As increased sebum production is an important element in the pathogenesis of acne vulgaris, targeting PPAR isoforms to interfere selectively with sebum formation may have implications for the treatment of acne.

Future Perspectives at a Glance

- Insulin-sensitizing agents
- Selective inhibitors of key enzymes involved in cutaneous androgen metabolism
- Toll-like receptor antagonists
- Targeting PPARs

Acne Fulminans

Oral corticosteroids are the treatment regimen proposed in reported cases of acne fulminans. Patients may require prednisolone up to 1 mg/kg daily for the effective control of cutaneous, constitutional, and musculoskeletal symptoms. Oral corticosteroids should be gradually tapered after the disease has been controlled. Systemic isotretinoin has been used successfully in acne fulminans but, paradoxically, may precipitate acne fulminans. So, the addition of oral isotretinoin has been proposed after the acute inflammatory phase of the disease has been controlled with oral corticosteroids, with a gradual increase in isotretinoin dose. After 1 year of treatment, the risk of relapse is low and acne fulminans in general does not recur.

Definition and Epidemiology

Actinic keratoses (AK) are common skin lesions in relation to disordered keratinocyte proliferation that are the result of cumulative ultraviolet radiation (UVR) from sun exposure. This chronic, long-term sun exposure results in mutagenic changes in epidermal keratinocytes and the development of various skin lesions ranging from actinic keratosis to invasive squamous-cell carcinomas. In consequence, currently we consider KA as "in situ" squamous-cell carcinoma (SCC) or a real "malignant neoplasm" from the very beginning. It should be considered a superficial squamous-cell carcinoma in the same form as there are superficial basal-cell carcinomas (Camacho 2014).

AK lesions may appear as rough, scaly spots or papules always on sun-exposed skin. The presence of certain clinical features such as large size, erythema, inflammation, induration, hyperkeratosis, ulceration or bleeding suggests risk of disease progression to invasive SCC. AK can be observed as a unique element or several elements over a field cancerization. In consequence, AK as an isolated element or as various elements, including the field of cancerization, will need different types of therapies.

AK appears on the skin of persons with phototype I to III who have received too much actinic radiations in a short time (acute AK) or during their lifetime (chronic AK) due to professional activity (e.g. sailors, farmers and drivers). Although it is almost certain that, sooner or later,

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_2, © Springer-Verlag Berlin Heidelberg 2015

100 % of these persons will present with AK, of the remaining people who had been exposed to the sun, it is unpredictable what percentage will develop AK.

AK is most frequent in sunny countries, e.g. Australia, part of the USA (such as California), southern Europe (e.g. Italy, France, Spain) and so on. Prevalence studies show clear differences depending on the country, being higher when closer to the equator. The prevalence in Australia is almost 60 % of population over the age of 40, in Italy of 1.4 % in persons with more of 45 years, in United Kingdom of 15.4 % in men of more than 40 years whereas in women of the same age was only of 5.9 % but this proportion increased till 34.1 % and 18.2 % respectively in patients with 70 years old (Guidelines ILDS 2015). In sum, despite its high prevalence large-scale records to estimate the exact incidence and prevalence in our environment have not been carried out.

Basic Concept of Pathogenesis

The natural history of actinic keratosis depends partly on environmental factors such as exposure to ultraviolet radiation, carcinogens and ionising radiation and partly on constitutional factors such as skin phototype, age, immune status or competence for DNA repair.

These neoplasms are extremely common on the sun-exposed skin of middle-aged and elderly fair-skinned individuals who live in sunny climates. It can be a consequence of chronic solar radiation, but occasionally they may also be due to exposure to x-radiation and to ultraviolet light from artificial sources. The last cause is very important because many persons, habitually young women, receive excessive amounts of this kind of radiation, from tanning beds.

But we go back to the concept of field cancerization since it would help us to understand the UVR aetiology of AK. Since the first explanation of Slaughter's concept of field cancerization in 1953, the knowledge of the mechanisms implicated in cancer after UVR exposure has progressively increased. Genetic alterations found in keratinocytes, mainly mutations in the TP53 gene, give rise to clonal units with a loss of cellular control. Additionally, molecular disturbance localised in the dermis may contribute to the development of skin cancer within field cancerization. These discoveries have allowed us to understand better how it is possible for a second skin tumour to appear, close to the primary one previously removed and localised in the same anatomical area.

The p53 chromosomal mutation, found in over 90 % of human cutaneous squamous-cell carcinomas, is also found in 50 % of AK, including renal transplant recipients – this may occur as an early step in transplant-associated skin carcinogenesis. Chronic UVB can produce molecular and genetic changes not only in the altered skin but also in all the photoexposed skin; in consequence, AK is currently considered as a "disease of field", not as an isolated lesion. UVB should modify the genetic material of keratinoblasts and fibroblasts, modifying the dermoepidermal interrelations and producing a clone of abnormal cells that, for some time, stay in the epidermis but, sooner or later and in unpredictable percentages, will go to the dermis as invaders. Excessive UV exposition also induces the expression of other tumor suppressor genes as $p14^{ARF}$, $p15^{ARF}$ and $p16^{ARF}$ in AK, SCC and peripheral tissues.

The UVB radiation is directly related to the presence of AK on skin phototypes I to III. The ozone layer in the stratosphere is a natural filter for UVB radiation, but as its thickness decreases, it allows more UVB to reach the earth's surface. Depletion of the ozone layer is another aetiological factor contributing to the incidence of AK.

There are other cocarcinogen factors that must be taken into account. For example, prior therapy with methotrexate might put patients treated with psoralen and UVA (PUVA) at risk of developing skin cancer.

Contact with environmental carcinogens has also been related to a higher risk to developing nonmelanoma skin cancer. Hydrocarbons act by direct contact, whereas arsenic is acquired by ingestion of contaminated water or alternative therapies. Ingestion of arsenic is associated with a high incidence of premalignant lesions, and its

effect can be potentiated by other factors such as sun exposure, smoking and pesticides.

Clinical Presentation

A dry and hyperpigmented photo-ageing skin that exhibits *dermatoheliosis* – previously named "chronic actinic degeneration" or "solar degeneration" – begins to develop multiple 1–2 mm rough lesions. They are circumscribed lesions that have irregular edges and are slightly elevated but frequently easier to visualise. They may be flesh coloured or rosy, erythematous with telangiectasias or deeply pigmented. Generally, the hyperkeratotic surface is formed by yellow or brown adherent scales, but when they are pulled up, they reveal some slight horny downward proliferation inside the follicular pores. The pull-up manoeuvre of the hyperkeratotic scales produces, in the majority of cases, small painful erosions and minimal haemorrhage.

Several years ago, we considered three types of AK in accordance with its quantity of hyperkeratosis: grade 1, easily seen and slightly palpable; grade 2, well developed and easily palpable; and grade 3, hyperkeratotic lesions. These different AK types were also nominated as KIN (keratinocytic intraepithelial neoplasia) by its similitude with the gynaecological CIN or SIN (squamous intraepithelial neoplasia) by its relation with SCC. This classification of three grades was not successful because the evolution of AK is not similar to CIN, not being obligated to pass.

Common locations for the lesion are the skin surfaces exposed to the sun such as the face, mainly the forehead, cheeks, nose and ears; back of the hands; forearms; and, occasionally, shoulders and scalp in men with premature baldness. The scalp is also the typical location of field cancerization. AKs on the face and the neck are thin, whereas those on the scalp, back of the hands or on the forearms are often thicker.

The normal course of development for AK is for hard horny proliferations known as "verrucous keratosis" to grow. In these circumstances, it is easier to display the progression to deep invasion. Although there are authors who have communicated that AK commonly undergoes spontaneous regression, there is no proof of this. Recently a review of natural history of AK has been published (Werner et al. 2013). According with this review, the actual risk of progression of single AK lesion to invasive SCC remains unclear (ranged from 0.0 % to 0.53 % per AK lesion per year). Although the rate of regression of single AK lesions was generally seen to be 20 % to 30 % with up to 63 % in one study, spontaneous regression of complete fields of AK were only seen in 0.0 % to 7.2 % of patients. One study assessed the rate of recurrences in AK fields after a complete regression and showed recurrences in 57 % of the observed fields (Guidelines ILDS 2015).

Diagnosis

Usually, the diagnosis of AK is possible on the basis of the clinical appearance. Sometimes biopsy may be performed. The cells of the stratum malpighii present a chaotic arrangement. Some of these cells present pleomorphism and anaplasia of their nuclei, and others present individual dyskeratosis with formation of corps ronds and grains. As the cytologic features of the neoplastic cells of AK are indistinguishable from those of thicker squamous-cell carcinomas, this justifies the theory of Ackerman that these two conditions, despite their different names, are really one and the same.

Microscopic study includes a wide spectrum of histological patterns, and even several patterns can coexist in the same lesion. These patterns range from hypertrophic form (warty) to other atrophic forms. The WHO describes six histological types of AK: hypertrophic, atrophic, bowenoid, acantholytic, pigmented and lichenoid. Additionally the pagetoid pattern has been described:

1. Hypertrophic, characterised by pronounced hyperkeratosis intermingled with areas of parakeratosis. The epidermis is thickened in some areas which shows irregular downward proliferation limited to the uppermost dermis. Atypia is minimal and exclusive of basal keratinocytes.

2. Atrophic, with slight hyperkeratosis and the epidermis on the whole is atrophic. The basal-cell layer shows atypical cells with large hyperchromatic nuclei that lie close together, and these cells may proliferate into the dermis as buds and duct-like structures.
3. Bowenoid, indistinguishable from that of Bowen's disease or carcinoma "in situ". Differential diagnosis might be made with "lumican" stain since it is positive in 91.8 % of Bowen's disease and negative in all AK.
4. Acantholytic or "Darier type", with intercellular clefts or lacunae as resulting from anaplastic changes in the lowermost epidermis that produce dyskeratotic cells without intercellular bridges. Within suprabasal clefts or lacunae, a few acantholytic cells may be observed. This form of AK was considered by Ackerman as a miniature type of pseudoglandular squamous-cell carcinoma and provided evidence to support his theory that AK and squamous-cell carcinoma were synonymous (Ackerman 1997). There is an acantholytic variety known as "epidermolytic AK" in which the acantholyses appear between normal and atypical keratinocytes.
5. Pigmented, with accumulation of the melanin within atypical basal keratinocytes and melanophages.
6. Lichenoid, with a dense band-like dermal infiltrate in the dermoepidermal interphase which damages the basal-cell layer producing degenerated basal cells known as "hyaline or colloid bodies".

Recently, new noninvasive evaluation techniques of skin cancer have evolved in the last years. In addition to dermatoscopy, new modalities of imaging include cross-polarised light and UV light photography, confocal reflectance microscopy and optical coherence tomography. With these tools precise diagnosis and monitoring of response to treatments in field cancerization and actinic keratosis are possible with no need of invasive biopsies. With dermatoscopy, a red pseudonetwork ("strawberry") pattern was significantly associated with AK (Zalaudek et al. 2012). Innovative high-definition optical coherence tomography (HD-OCT) demonstrates the following features in AK: disruption of the stratum corneum, architectural disarray, cellular/nuclear polymorphism in the stratum granulosum/stratum spinosum and bright irregular bundles in the superficial dermis. Reflectance confocal microscopy reveals characteristic features with good histological correlation: in the stratum corneum, corneocyte disruption is revealed as the presence of bright, highly refractile cells with polygonal morphology, whereas parakeratosis appears as round dark structures in the middle of the corneocytes; atypical keratinocytes are observed in the stratum granulosum and spinosum with dark nuclei and irregular shapes and sizes; the superficial dermis reveals varying degrees of solar elastosis, identified by its moderate–high brightness and a highly irregular reticulate pattern; and round blood vessels are observed crossing the dermal papillae.

Differential Diagnosis

It is possible that the following dermatoses have difficulties of diagnosis with AK: solar lentigo, basal-cell carcinoma, seborrheic keratosis and Bowen's disease. Really, the most problematic differential diagnosis is with solar lentigo since in many occasions both can coincide (Fig. 2.1a, b).

Solar Lentigo

Darkly and unevenly pigmented, inflamed, uniformly dark brown, macular, irregular outline, sharp margination, scalloped borders, occasionally with hypopigmented areas and light brown areas. Size from 0.5 to 2.0 cm; locations on the head and neck. Dermatoscopy shows linearly striated pigmented network that has been likened to a "fingerprint" pattern. Confocal features: variable presence of refractile particles/globules in the stratum corneum and inside the superficial epidermis; honeycomb and/or cobblestone epidermal pattern that are preserved; large, polymorphic and numerous dermal papillae; hyperrefractile papillary rings formed by round, uniform cells; and occasional large, bright cells

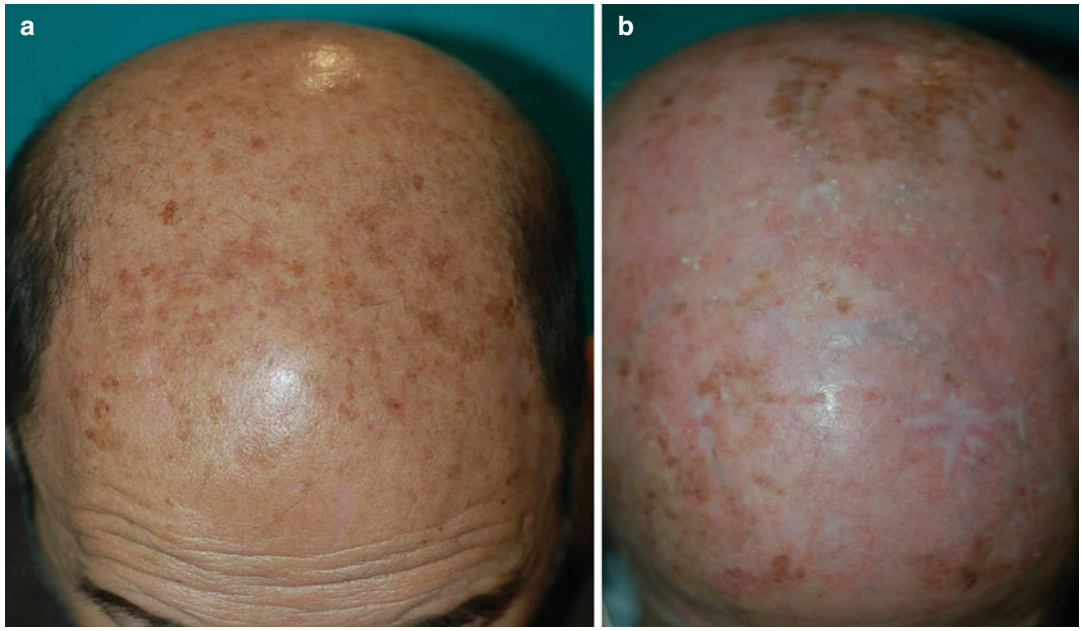

Fig. 2.1 (**a**) Solar lentigo. (**b**) Actinic keratoses. In this patient a scar can be observed. It is a consequence of squamous-cell carcinoma excised previously

in the dermis (melanophages) (Hirokawa and Lee 2011; Alsner et al. 2012).

Basal-Cell Carcinoma

Small telangiectatic vessels on its surface, pearly rolled border. Pigment and ulceration can be present. Dermatoscopy in nonpigmented forms: fine telangiectasias with subtle translucency, white streaks/white areas ("chrysalis" structures), translucency, milky-pink to red background, small ulceration and arborising vessels. In pigmented forms: island of pigment (blue-grey globules, blue-grey ovoid nests) and pigmented distribution pattern in maple-leaflike or spoke-wheel-like. Confocal features: elongated, monomorphic nuclei; nuclear polarisation along a single axis; and refractile stroma with frayed collagen bundles (gossamer), prominent inflammatory infiltrate, increased vascularisation and variable epidermal detachment (nucleated corneocytes, loss of the honeycombed pattern and nuclear pleomorphism of the keratinocytes) (Hirokawa and Lee 2011; Alsner et al. 2012).

Seborrheic Keratosis

Verrucous surface, soft and friable consistency and located on the trunk and occasionally in the face and scalp. Dermatoscopy: milia-like cysts, comedo-like openings and hairpin vessels. Confocal features: cerebriform-looking epidermal architecture, bright cysts often surrounded by a dark halo, bright cobblestone pattern in the stratum spinosum and poorly defined, bright polygonal cells in the upper dermis (melanophages) (Hirokawa and Lee 2011; Alsner et al. 2012).

Bowen's Disease (Intraepidermal Carcinoma)

Sharply demarcated, scaly, often hyperkeratotic, sometimes fissured macule, papule or plaque devoid of hairs; plaque may be composed of confluent reddish lenticular papules and nodules of variable size; tend to extend gradually with age in an annular or polycyclic pattern. Dermatoscopy features: dotted/glomerular vessels, diffuse

yellow opaque scales and microerosions are prevalent among intraepidermal carcinoma. Confocal features: disruption of the stratum corneum with evident parakeratosis; alteration of the epidermal pattern with severe keratinocyte detachment; and round, nucleated dyskeratotic cells present in the epidermis but never infiltrating the dermis (Zalaudek et al. 2012; Alsner et al. 2012).

General Principles of Treatment

AKs have the potential to spontaneously regress, remain stable or progress to nonmelanoma skin cancer. Given the high rates of regression and low rates of malignant transformation, some dermatologists think that not all AKs need to be treated. Others believe that AKs should be treated as a superficial squamous-cell carcinoma and in consequence must be removed using one of the several different methods of therapy selected by the dermatologists (Table 2.1).

Surgical Treatments

Radiosurgery

The original techniques in electrosurgery (electrodessication, electrocoagulation) after curettage have been replaced by machines that use radiofrequency waves. This enables AK to be removed easily under anaesthetics. It is the recommended technique for single or isolated AK (it allows to remove easily the AK after anesthesia, for which we used the Klein method) (Table 2.2).

Cryosurgery

Currently liquid nitrogen freezing is the most commonly used method to destroy AK. Up to 98.8 % cure rate has been reported, but more recent data indicate smaller cure rates (Schmitt and Bordeaux 2013). It is an easy method that permits removal of AK without the need for anaesthesia. It is possible to use cryoprobes of different sizes. When the AK has developed fully, it is preferable to first perform curettage and then to use a cryoprobe. When the patient presents with multiple AKs, it is better to use cryospray in a centrifugal or paintbrush pattern. Consequently, the spray technique is the most adequate (gold standard) for field cancerization. Cryosurgery is undoubtedly the most used method based on ease; excellent cosmetic outcome results; grace, despite being painful; and efficiency, but does not allow histological study (Table 2.2).

Dermabrasion

Dermabrasion is a method that is useful to treating multiple AKs or field cancerization. Diamond fraises or wire brushes with a range between 800 and 33,000 rpm are used. It has the inconvenient in that the patient must stay in hospital at least 1 week. It is well known that only this technique treats AK successfully and provides long-term prophylaxis. As laser has become the most frequently used method of resurfacing, some believe that dermabrasion will soon be absent from the dermatologic tool box. Nevertheless dermabrasion remains an effective, economical and, some might argue, superior, resurfacing modality addressing many indications, one of them the treatment of actinic damage and AK (Hanke et al. 2013) (Table 2.2).

Laser

Carbon dioxide (CO_2) laser skin resurfacing is being used with increasing frequency in

dermatologic practice. The ultrapulse CO_2 laser, introduced in 1990, is an excellent method to remove keratoses; it is relatively easy to perform. The results are better, and the operative time for full-face resurfacing is markedly reduced when using computer pattern generator (CPG), a computer scanning device, in conjunction with the ultrapulse laser (Camacho 2005a). Full-face laser resurfacing is one of the treatment modalities that can treat whole surface areas, offering an effective and efficient treatment option that successfully reduces the number of actinic keratoses on diffusely damaged skin and may show a prophylactic benefit for preventing nonmelanoma skin cancers. Investigations with fractional technologies have demonstrated that treatment with ablative lasers is superior when compared with non-ablative fractional photothermolysis. However ablation of the epidermis is complicated by prolonged recovery time and higher risk of secondary effects. Recent studies with fractionated 1927 nm non-ablative thulium laser show a promising new therapeutic option for the treatment of actinic keratosis based on the clinical and histological findings as well as on the reported patient satisfaction and safety (Weiss et al. 2013).

Surgical Extirpation

This procedure should be only considered when the AK is a firm horny papule with the possibility

of invading deeper. The chosen technique must be governed by the location of the AK, but commonly it is sufficient to remove the neoplasm and then perform a direct suture (Table 2.2). When the AK is large, it may be useful to use a local flap to close the defect. Exceptionally, a graft will be necessary.

Medical Treatments

Should the clinician and patient agree to move forward with treatment, many options are available for the treatment of AK. AK therapies recently were classified having assigned a strength of recommendation taxonomy (SORT). A ratings include 5-fluorouracil, imiquimod, diclofenac, photodynamic therapy and cryotherapy (Carlson and Bordeaux 2011). Nevertheless it should be noted that further options exist for the treatment of AK, including oral retinoids, lasers, curettage and chemical peels, although the evidence behind these therapies is lacking or inconsistent. Recently, ingenol mebutate gel has been incorporated as a new topical treatment of AK.

5-Fluorouracil (5-FU)

This is the oldest medical treatment for the removal of AK, especially when the patient has multiple AKs. Topical 5-FU was approved for use in AK in any location. 5-FU is an antineoplastic antimetabolite, which interferes with the synthesis of DNA and RNA, provoking unbalanced cell growth and death. The usual regimen is twice daily application of a 5 % cream for 2–4 weeks; however, longer treatment (5–6 weeks) is preferred for a higher cure rate. Nevertheless since too many patients have discomforts with this technique, it is not used so often now (Fig. 2.2a–c). AK of the scalp and face might be used at 0.5 %, applying twice a day for 2–4 weeks, reaching an 82 % of complete clinical health rate. There are no differences between 5-FU at 1 % or 5 %. When 5-FU is associated to keratolytics as 10 % salicylic acid its efficacy and tolerance increase reaching cure rate of 90 % in 8 weeks of treatment that is maintained 1 year later (Schmitt and Bordeaux 2013). Askew et al. (2009) review 13 randomised controlled trials (RTCs) with 5-FU: one study compared different dosing regimens of 5 % 5-FU (twice daily for 3 weeks vs twice daily for 1 day per week for 12 weeks). Three studies compared 0.5 % 5-FU with placebo and one more compared 0.5 % 5-FU with 5-aminolevulinic acid (ALA) PDT, activated through either blue light or pulsed laser light. And the other 8 studies compared 5 % 5-FU with other treatments as imiquimod, cryotherapy,

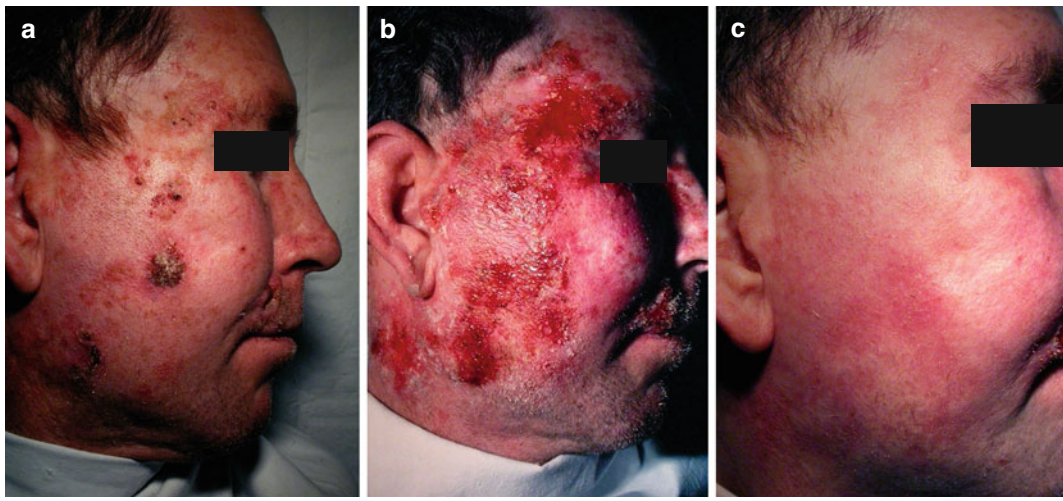

Fig. 2.2 AK treated with twice daily 5-FU 5 % cream. (**a**) Before treatment. (**b**) After 4 weeks of treatment. (**c**) One month after finishing the treatment

diclofenac sodium 3 % gel (DFS), full-face laser resurfacing, photodynamic therapy (PDT), 5 % 5-FU augmented with tretinoin 0.05 %, 30 % trichloroacetic acid peel, some of these combined, and lastly, the eighth compared with 0.5 % 5-FU once daily for 4 weeks (or until patient unable to tolerate). This systematic review provided valuable evidence to indicate that about one-half of patients using 5-FU for the treatment of AK lesions could expect complete clearance; that, overall, an 80 % reduction in lesion count could be expected; and that a 90 % reduction in total lesion count was likely. In sum, 5-FU that has been used in two different strengths is an extremely effective therapy for AK, typically only affects dysplastic areas of the skin, appears to be relatively well tolerated in practice, typically produces an excellent cosmetic reaction when used on the face, may be associated with a photosensitive reaction and needs to be continued for 4 weeks to obtain the full effect. A 8 weeks regimen with 0.5 % 5-FU associated to keratolytics as 10 % salicylic acid its efficacy and tolerance increase reaching cure rate of 90 %. As at 12 months 85.5 % of lesions did not recur, 0.5 % 5-FU demonstrated high sustained clinical efficacy, with high patient satisfaction (Stockfleth et al. 2011, 2012; Guidelines ILDS 2015).

Imiquimod (IMIQ)

Topical imiquimod, a modulator of the immune response which was originally approved for the treatment of anogenital warts, also was approved by the FDA in 2004 as therapy of actinic keratoses, including the field cancerization, and also may address subclinical disease. The usual regimen is once-daily treatment with 5 % IMIQ cream for 2–3 days per week for four (short treatment) to 16 weeks (long treatment), being effective in both schedules reaching complete clearance rate in 57.1 % and partial clearance rate in 72.1 %. Recurrence rates are 10 % during the first following year and 20 % during the two following years (Stockfleth et al. 2004).

A meta-analysis of four RCTs found that the odds of complete clearance of AK for patients using IMIQ are 20.76 times greater than for patients using placebo, and the recurrence rates at 12 months were 39 % in the IMIQ group and 59 % in the placebo group. When compared IMIQ with 5-FU have been found a higher average complete clearance rate with IMIQ treatment (70 % for IMIQ versus 52 % for 5-FU) suggesting that IMIQ is the topical election treatment of AK on the face and scalp. Another comparative study of 5 % 5-FU vs 5 % IMIQ vs cryotherapy demonstrated that at the 12-month follow-up, 81 % of patients treated with IMIQ have an excellent cosmetic outcome compared with just 4 and 5 % of those treated with 5-FU and cryotherapy, respectively (Krawtchenko et al. 2007).

A larger lesion diameter, specifically greater than 1 cm, and the presence of pain predict conventional treatment resistance. In these cases which have failed the standard therapy for AKs, combination treatment using topical IMIQ and 5-FU may be an effective alternative therapeutic strategy.

IMIQ may also be used at 2.5 and 3.75 % cream. Once-daily treatment with 3.75 % IMIQ cream for a 2-week period and once-daily treatment with 5 % IMIQ cream for 2–3 days per week for up to 16 weeks are both indicated for the treatment of multiple non-hyperkeratotic, non-hypertrophic AKs on the face and scalp and have a SORT rating of A (Swanson et al. 2010; Guidelines ILDS 2015).

Recently, a phase II dose-ranging study of topical resiquimod to treat AK was reported. Resiquimod, an agonist of type TOLL receptors, has greater immunologic effects than IMIQ with greater efficacy, but it may also have greater systemic and topical side effects (Szeimies et al. 2008). More studies with large follow-up are necessary.

Diclofenac

Diclofenac is a nonsteroidal anti-inflammatory drug administered as 3.0 % diclofenac sodium and 2.5 % hyaluronic acid gel for the topical treatment of AK. A meta-analysis of three RCTs showed that diclofenac produced a complete resolution of all target lesions in 39.6 % of patients at 30 days posttreatment. Another meta-analysis of RCTs reported total and cumulative lesion number scores of 0 in 50 % of patients treated for 90 days and 33 % of those treated for 60 days. Dirschka et al. (2010) investigated the effect of

diclofenac in 65 patients with AK. Biopsy specimens were taken and stained with H&E and immunological markers. They demonstrated complete clinical resolution in 11 patients (16.9 %). A significant ($P=0.001$) downgrading of AK grade was observed. Complete histological resolution was achieved in 15 patients (23.1 %). The number of mitoses per high-power field was reduced significantly ($P=0.001$). The expression of anti-p53 antibody decreased significantly ($P=0.009$) as did the expression of anti-MiB-1 antibody ($P=0.021$). Their conclusion was that 3.0 % diclofenac in 2.5 % hyaluronic acid gel causes regression of signs of cancerous transformation after 3 months' therapy, erythema, pruritus, dry skin, dermatitis and scaling being its most common adverse effects. Nevertheless, 0.5 % 5-FU has superior sustained clinical efficacy with similar tolerability.

Ingenol Mebutate Gel (IMG)

Ingenol mebutate is a diterpene ester extracted and purified from an active fraction of the sap of the plant *Euphorbia peplus*, which has shown efficacy in the treatment of actinic keratoses and nonmelanoma skin cancer, and exerts its action by a dual mechanism, which includes specific cell necrosis and mitochondrial oedema secondary to a more specific response mediated by protein kinase C that allows the recruitment of immune effector cells in the lesion. It is effective against both AK and cancerization field. Treatment of AK with 0.015 % IMG on the face and/or scalp for 3 days and 0.05 % IMG on the trunk or extremities for 2 days achieved high clearance rates (Martin and Swanson 2013; Lebwohl et al. 2012). The local inflammatory responses are typically mild to moderate and tend to resolve by the second week of the end of treatment. The main advantage of ingenol mebutate gel is that it provides a short treatment of only 2 or 3 days. The short-term treatment regimen and tolerability profile make this topical treatment a useful addition to therapies for AK. The safety and efficacy of IMG for the treatment of AK were evaluated in four multicenter randomised, vehicle-controlled, double-blind studies. In the two studies of AK of the face or scalp, 547 patients were randomised to 0.015 % IMG ($n=277$) or vehicle gel ($n=270$) that was self-applied once daily for three consecutive days to the 25 cm^2 treatment field. In the two studies of AK on the trunk or extremities, 458 patients were randomised, 226 to 0.050 % IMG and 232 to vehicle, in both cases applied daily for 2 days (Gupta and Paquet 2013). Efficacy results were pooled for the four studies. The proportion of patients who achieved complete and partial clearance on the face or scalp was significantly higher with IMG than with vehicle (42.2–63.9 vs 3.7–7.4, respectively; $P=0.001$). Efficacy analysis by anatomic location demonstrated higher rates of complete and partial clearances on the face than on the scalp. In the studies on the trunk or extremities, results for complete and partial clearances also demonstrated significantly higher with IMG than with vehicle (34.1–49.1 vs 4.7–6.9, respectively; $P=0.001$) (Table 2.2). Adverse effects in all groups were pain, pruritus and irritation, always in relation to the drug concentration (Martin and Swanson 2013). IMG has been approved by the European Medicines Agency (EMA) for the treatment of non-hyperkeratotic, non-hypertrophic actinic keratosis in adults. It should be applied once daily to the affected area for three consecutive days (Guidelines ILDS 2015).

Medium-Depth Chemical Peel

It is an excellent treatment for multiple AK. The medium-depth chemical peel may be achieved both with Jessner's solution and 35 % trichloroacetic acid. The patient treated with medium-deep chemical peel should be checked annually or every 1.5 years for reappearance of AK and retreatment as appropriated. Seventy per cent trichloroacetic acid instead of radiosurgery for individual AK can be used, and then anaesthesia is not necessary. Today, with the topical treatments previously explained, this technique is less used (Camacho 2005b).

Oral Retinoids

Topical tretinoin alone is only partially effective in the treatment of AK even after 1 year of daily applications. Oral retinoids as isotretinoin (13-cis-retinoic acid) and acitretin have an

antitumor effect being useful both as prophylaxis and in therapy. A combination of low-dose oral isotretinoin and topical 5-FU was found effective in drastically reducing the number of AK and preventing the appearance of new ones. Nevertheless, this treatment is reserved to cases of recent field cancerization (Sander et al. 1997).

Photodynamic Therapy (PDT)

Photodynamic therapy (PDT) using topical 5-aminolevulinic acid (ALA) or its methyl ester (MAL) as photosensitiser has been demonstrated useful in the treatment of various superficial cutaneous malignant neoplasms such as superficial basal-cell carcinomas, Bowen's disease and AK. The mechanism of action of the ALA, when it is applied topically on the skin, is dependent upon the accumulation of the endogenous photosensitiser protoporphyrin IX (PpIX) in epidermal cells of the lesion. Then, the PpIX is activated by the application of light, resulting in a tissue-specific phototoxic effect. There are several topical preparations of ALA, solution, nanoemulsion and adhesive patch, and also MAL cream. Different light sources, including light-emitting diodes (LED), intense pulsed light and lasers, have proven to be effective, red light ($\lambda = 630 \pm 10$ nm) being the most used. Clinical trials have shown a complete response rate of 86–89 % for mild and moderate AKs at the 3-month follow-up, decreasing to 68 % at the 12-month. PDT is suggested for AK especially if they are multiple and/or in the context of field cancerization, at sites of poor healing or where the cosmetic result is important. Size larger than 10 mm, histological severity, acral location and occurrence in organ transplant recipients are markers of poor response to PDT. Pain during illumination is the most important adverse effect, the size of the lesion and the facial location being the most reliable predictors and cold and nerve blocks the most effective measures to control it. The use of less powerful light sources, such as daylight or ambulatory devices (Ambulight®), has shown similar efficacy to conventional PDT with less pain. Compared to other treatments, PDT is the second most effective treatment after 5-FU in AKs, but better tolerated and more satisfactory for patients. Several methods to promote penetration of the photosensitiser, such as microneedling or fractional laser, or the combination of PDT with other treatments, such as imiquimod or diclofenac, apparently improve its efficacy. PDT currently has enough resources to effectively treat AK, specially in the context of field cancerization (Table 2.2).

Photoprotection

Photoprotection must always be recommended because ultraviolet radiation (UVR) exposure leads to harmful acute and chronic effects on the human skin. Acute effects of UVR include erythema, pigment darkening, delayed tanning, epidermal hyperplasia, free radial formation and vitamin D synthesis. Chronic effects of UVR include photo-ageing, immunosuppression, photocarcinogenesis and exacerbation of photodermatoses. In relation to photocarcinogenesis, UVR induces DNA mutations and malignant transformations, and the immunosuppressive properties of UVR concurrently impair host immune system recognition of damaged malignant cells. The relationship between UVR exposure and the development of skin cancer, including basal cell carcinoma, superficial and invasive squamous cell, lentigo maligna melanoma, and actinic keratosis are related to cumulative sun exposure.

In the past, the Federal Drug Administration recommended that sunscreens had a sun protection factor (SPF) of 15 to block the erythema response in persons with phototypes I to III. Years after, several studies have demonstrated that an SPF of no less than 30 is necessary to prevent immunosuppression and therefore sun avoidance is highly recommended. Broad-spectrum sunscreens (SPF 30) should be applied to all exposed skin before sun exposure. The application of an adequate quantity of sunscreen (2 mg/cm^2), clothes, and hats must be recommended (Lecha 2014). Three points must be considered to prevent sunburn and its consequences: habits, avoiding sun from 11 a.m. to 4 p.m.; sun protection with clothes, hats and glasses; and

sunscreen well distributed on the skin, especially on the face and scalp. While there are controversies involving sunscreen ingredients, formulations, and side effects, based on current data, the risk-benefit ratio indicates that it is appropriate to include the use of sunscreen as an important component of Photoprotection strategy (Table 2.2).

To all the patients with dermatoheliosis, whether with AK or not, 30 mg of β-carotene in the morning is recommended. Other systemic photoprotective agents such as *polypodium leucotomos*, afamelanotide, other carotinoids as lycopene, lutein, and zeaxanthin, polyphenols, nonsteroideal antinflammatory drugs, and antioxidants as vitamin C and E can be suggested (Wener et al. 2015). These vitamins, topically and orally, work synergistically to reduce oxidative stress. Simultaneous topical application of both AOs better protects against UV-induced erythema, sunburn cell formation and thymine dimer formation than when vitamin C alone is applied.

Adamantiades-Behçet Disease

3

Christos C. Zouboulis

Key Points

- Rare disease with a worldwide distribution but strongly varying prevalence; certain ethnic groups are mainly affected.
- A genetically determined disorder with a probable environmental triggering factor.
- Multisystem occurrence, with oral aphthous ulcers, genital ulcers, papulopustules, erythema nodosum-like lesions, uveitis, and arthropathy as most common signs.
- Inflammatory disease representing a neutrophilic vascular reaction or vasculitis.
- Diagnosis is defined by new clinical criteria.
- Chronic relapsing progressive course and potentially poor prognosis (especially in males with systemic presenting signs; mortality, 0–6 %).

Definition and Epidemiology

Adamantiades-Behçet disease is a multisystem inflammatory disease of unknown etiology, classified as systemic vasculitis involving all types and sizes of blood vessels and characterized clinically by recurrent oral aphthous and genital ulcers, skin lesions, and iridocyclitis/posterior uveitis, occasionally accompanied by arthritis and vascular, gastrointestinal, neurologic, or other manifestations (McCarty et al. 2003; Suzuki Kurokawa and Suzuki 2004).

Historical Aspects

The disease is named after Benediktos Adamantiades, a Greek ophthalmologist, and Hulûsi Behçet, a Turkish dermatologist, who, in 1931 and 1937, respectively, described patients with the characteristic clinical complex insisting for a single clinical entity (Zouboulis and Keitel 2002).

Epidemiology

Adamantiades-Behçet disease presents a worldwide occurrence with varying prevalence, being endemic in the eastern and central Asian and the eastern Mediterranean countries (along the so-called Silk Road) and rare in northern European countries, central and southern Africa, the American continent, and Australia (Zouboulis

DOI 10.1007/978-3-662-45139-7_3, © Springer-Verlag Berlin Heidelberg 2015

et al. 2003c). A prevalence of 80–420 patients per 100,000 inhabitants has been reported in Turkey (Azizlerli et al. 2003), whereas only 1.5 to 7.5:100,000 in southern Europe and 0.12 to 1.18:100,000) in Northern Europe and the United States (Zouboulis et al. 2003c). Its annual incidence is low; 0.75–1.0 new cases per 100,000 inhabitants were assessed in Japan (1990) and Germany (2005) (Altenburg et al. 2006).

Adamantiades-Behçet disease most often affects patients in their 20s and 30s; however, early and late onsets (first year of life to 72 years) have been reported. Both genders are equally affected; a male predominance is still observed in Arab populations, whereas female predominance is evident in Korea, China, some northern European countries, and the United States.

Etiology and Pathogenesis

The etiology of the disease remains unknown, although genetic factors, infectious agents, environmental pollution, immunologic mechanisms, and endothelial and clotting factors have been implicated and studied intensively (Zouboulis and May 2003; Hirohata and Kikutchi 2003). The endemic occurrence along the historical Silk Road, the major involvement of certain ethnic groups (mostly of Turkmen and Mongol descent), and associated immunogenetic data support the hypothesis that the disease followed the migration of these old nomadic tribes. On the other hand, the wide variation of the disease prevalence in the same ethnic group in association with different geographic areas of residence indicates an additional environmental triggering factor. Therefore, transfer of genetic material and/or of an unknown exogenous agent may have been responsible for the expansion of the disease.

There is no specific mode of Mendelian transmission in Adamantiades-Behçet disease (Zouboulis and May 2003; Hirohata and Kikutchi 2003). Familial occurrence with regional differences has been reported. A significant association exists between the disease and human leukocyte antigen (HLA)-B_{51} in Japan, the Middle East, and the Mediterranean countries (de Menthon et al. 2009). The allele also seems to be associated with a more severe prognosis (Zouboulis et al. 2003a). Its exact role in the disease mechanism is still unknown; however, it may be involved in the disease development through specific antigen presentation, molecular mimicry with microbial antigens, or participation in linkage disequilibrium with a presently unknown susceptibility gene (Fietta 2005; Durrani and Papaliodis 2008). Among the 24 currently described alleles, HLA-B5101 and B_{5108} have most frequently been associated with Adamantiades-Behçet disease (Zierhut et al. 2003). Shared amino acid residues (defining the Bw4 epitope) are crucial for antigen binding and natural killer cell interactions (Remmers et al. 2010), and Bw_4 was also reported to contribute to the severity of the disease (Papoutsis et al. 2010). Genes possibly associated with the disease have been localized on chromosome six in the region between the tumor necrosis factor gene and HLA-B or HLA-C genes, including the major histocompatibility complex class I chain A gene (A6 allele) and genes for heat shock proteins (Hirohata and Kikutchi 2003; Fietta 2005; Zierhut et al. 2003; Escudier et al. 2006).

Adamantiades-Behçet disease is not considered contagious, as no horizontal transmission has ever been reported. However, viral and bacterial infections have been implicated in initiating immunopathologic pathways, leading to the onset of the disease (Zouboulis and May 2003; Hirohata and Kikutchi 2003).

Immunologic mechanisms are considered to play a major role in the pathogenesis of Adamantiades-Behçet disease (Zouboulis and May 2003; Hirohata and Kikutchi 2003; Zierhut et al. 2003; Escudier et al. 2006). The disease has currently been classified among the autoinflammatory disorders (Gül 2005), which are caused by primary dysfunction of the innate immune system.

Clinical Presentation

Adamantiades-Behçet disease is a chronic, recurrent, multisystem, and, occasionally, life-threatening disorder (McCarty et al. 2003;

Altenburg et al. 2006). Recurrent oral aphthous ulcers, recurrent genital ulcers, skin manifestations, ocular lesions, and arthritis/arthropathy are the most frequent clinical manifestations. Vascular, gastrointestinal, neurologic, psychiatric, pulmonary, renal, and cardiac manifestations, epididymitis, and other findings can also occur. The clinical picture usually develops within a few months after the presenting sign; both an acute multisystem presentation and long-term development of the disease over years are possible.

Approach to the Patient

Diagnosis of Adamantiades-Behçet disease is based on clinical signs, as pathognomonic laboratory test or histologic characteristics are absent. There are several sets of diagnostic criteria, the most popular of them being the criteria of the International Study Group (International Study Group for Behçet's Disease 1990) and those of the Behçet Disease Research Committee of Japan (Kaneko et al. 1999). However, there have been several problems with these criteria, including their performance in selectivity and specificity, so that both of them have currently been revised (International Team for the Revision of the International Criteria for Behçet's Disease (ITR-ICBD) et al. 2013) (Table 3.1).

Table 3.1 Revised international criteria for Behçet's disease (International Team for the Revision of the International Criteria for Behçet's Disease (ITR-ICBD) et al. 2013)

Symptom	Points
Ocular lesions (recurrent)	2
Oral aphthosis (recurrent)	2
Genital aphthosis (recurrent)	2
Skin lesions (recurrent)	1
Central nervous system	1
Vascular manifestations	1
Positive pathergy test[a]	1

Scoring: score ≥4 indicates Adamantiades-Behçet disease

[a]Though the main scoring system does not include pathergy test, where pathergy testing is conducted, a positive result may be included for one extra point

Mucocutaneous Lesions

Recurrent oral aphthous and genital ulcers are the most frequently observed mucosal manifestations. Oral aphthous ulcers are the presenting sign in more than 80 % of the cases (McCarty et al. 2003; Altenburg et al. 2006). Although recurrent aphthous stomatitis is a common disorder, only a few patients progress to Adamantiades-Behçet disease, and it is not possible to determine in whom or when the transition may occur (Oh et al. 2009). Typically, lesions are multiple, painful, 1–3 cm in diameter, and sharply margined with a fibrin-coated base and surrounding erythema (Fig. 3.1). Oral aphthous ulcers usually heal without scarring (92 %). Genital ulcers may not recur as often and usually heal with a characteristic scar (64–88 %; Fig. 3.2). Spontaneous healing of aphthae occurs within 4 days to 1 month; genital ulcers may persist longer. Large oral ulcerations can also be associated with problems such as pharyngeal involvement, dysphagia, and dyspnea or fistulae involving the pharynx, larynx, trachea, or esophagus. Genital ulcers can occur on the penis, scrotum, vagina, labia, and urethra, and also in the anal, perineal, and inguinal regions.

Skin lesions that should be accepted as diagnostically relevant in Adamantiades-Behçet disease should be confined to pustular vasculitic lesions (including pathergy lesions), erythema nodosum-like lesions, Sweet-like lesions, pyoderma gangrenosum-like lesions, and palpable purpuric lesions of necrotizing venulitis (Fig. 3.3). All of these lesions are characterized in their early stages by a neutrophilic vascular reaction (Jorizzo et al. 1995). Acneiform lesions or follicle-based pustules should not be considered relevant.

Systemic Lesions

Ocular involvement is the major cause of morbidity in patients with Adamantiades-Behçet disease. The most diagnostically relevant lesion is posterior uveitis (also called *retinal vasculitis*), which can lead to blindness (Fig. 3.4). Other

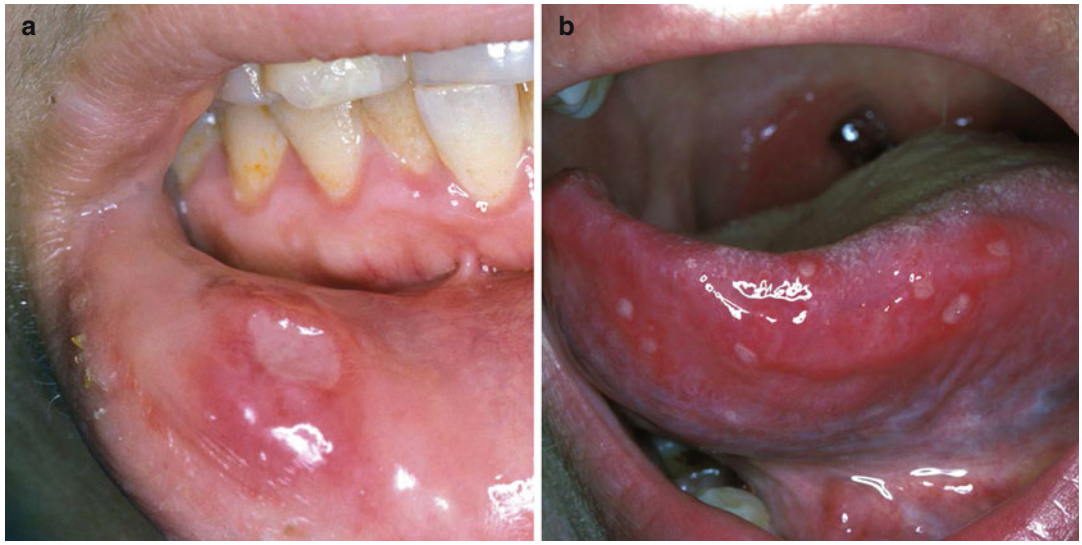

Fig. 3.1 Single (**a**) and multiple (**b**) oral aphthous ulcers (**a** From Altenburg et al. (2006), with permission)

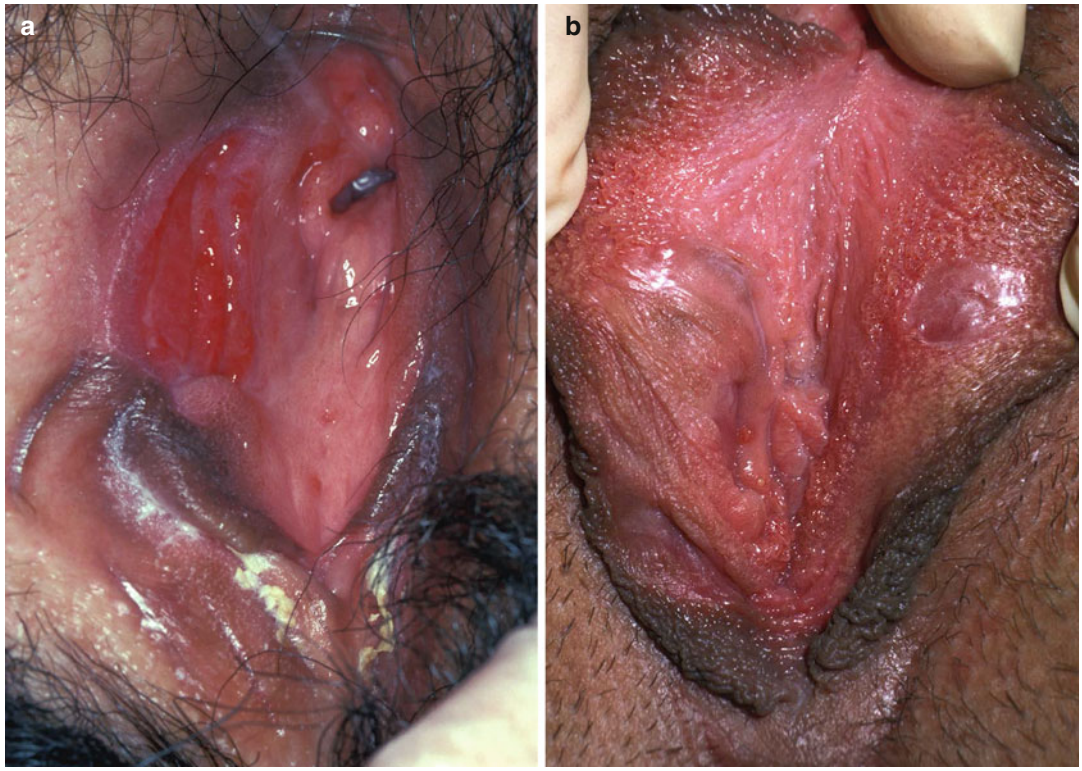

Fig. 3.2 Genital ulcer (**a**) healing with a demarcated flat scar (**b**)

ocular lesions include anterior uveitis, hypopyon (pus in the anterior chamber of the eye, which is now—due to early treatment—uncommon), and secondary complications such as cataract, glaucoma, and neovascular lesions (Krause 2005). Retinal inflammation can lead to vascular occlusion

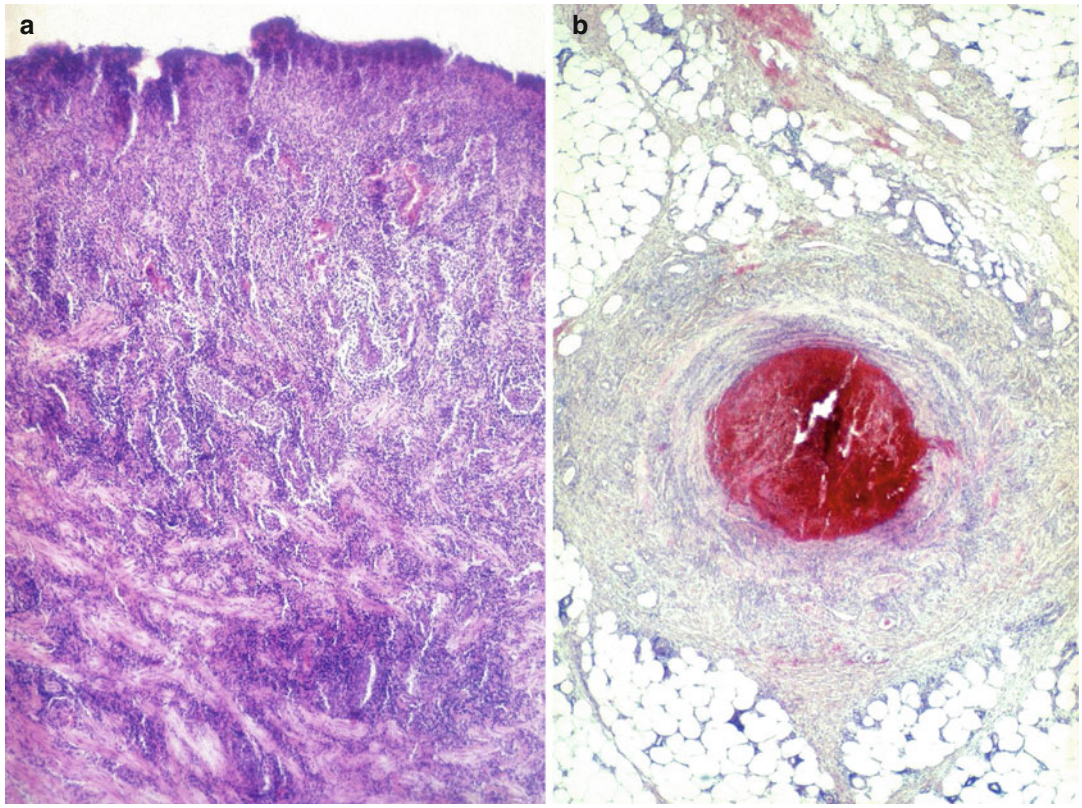

Fig. 3.3 (**a**) Abundant mixed inflammatory infiltrate dominated by neutrophils in an oral ulcer of Adamantiades-Behçet disease. (**b**) Vessel thrombosis in an erythema nodosum-like lesion

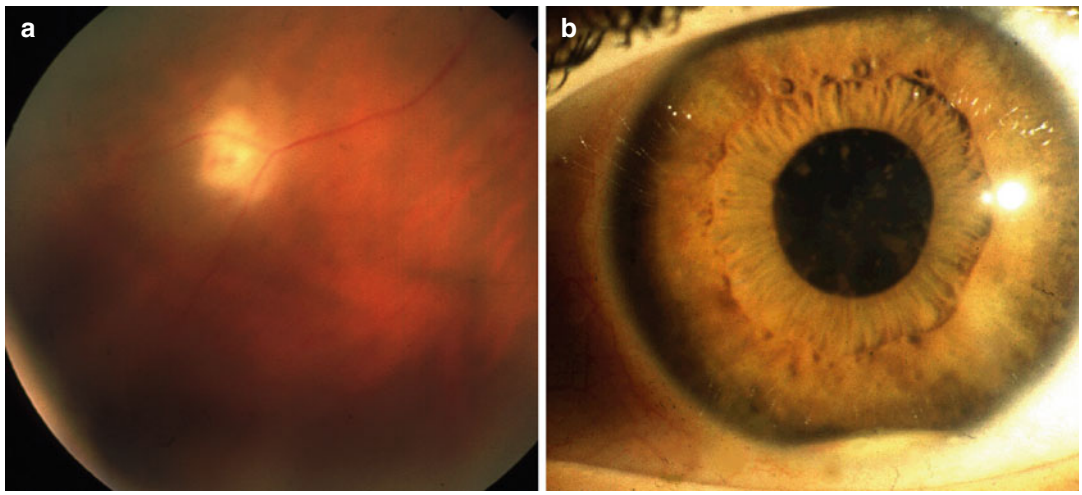

Fig. 3.4 (**a**) Posterior uveitis. (**b**) Hypopyon iritis (From Altenburg et al. (2006), with permission)

and, ultimately, tractional retinal detachment. Severe vitreous involvement, chronic cystoid macular edema, and possible—presumably also vasculitic—involvement of the optic nerve can result in vision loss. Recurrent vasculitic changes can ultimately lead to ischemic optic nerve atrophy.

The characteristic arthritis is a nonerosive, asymmetric, sterile, seronegative oligoarthritis; however, symmetric polyarticular involvement is common. Joint manifestations frequently occur first in one knee or ankle and then the other as migratory monoarthritis, then in both joints simultaneously, and finally affecting nearly all joints. An HLA-B27-positive, erosive sacroiliitis has to be excluded.

Systemic vascular involvement can be significant and includes venous occlusions and varices, arterial occlusions, and aneurysms, often being migratory. Cases of large-vein thrombosis (inferior vena cava, cranial venous sinuses) or large-artery aneurysms are potentially fatal (McCarty et al. 2003; Altenburg et al. 2006). Arterial involvement is rather rare and usually presents in the form of thromboses and, less often, of aneurysms, resulting from multicentric arteritis. Pulmonary artery aneurysms are the principal feature of pulmonary involvement in Adamantiades-Behçet disease, occasionally resulting in coughing and hemoptysis. Cardiac involvement can include myocarditis, coronary arteritis, endocarditis, and valvular disease. A wide spectrum of renal manifestations can occur, varying from minimal change disease to proliferative glomerulonephritis and rapidly progressive crescentic glomerulonephritis. Immune complex deposition is thought to be responsible for the underlying pathogenesis in some cases of glomerulonephritis. Gastrointestinal complaints can be a symptom for aphthae throughout the gastrointestinal tract and can rarely result in perforation and peritonitis (0.5 %). Inflammatory bowel disease has to be excluded. Sterile prostatitis and epididymitis can be present in male patients without genital ulcers.

Significant neurologic manifestations occur in approximately 10 % of patients and may be delayed in onset. Meningoencephalitis, cerebral venous sinus thrombosis, benign intracranial hypertension, cranial nerve palsies, brainstem lesions, and pyramidal or extrapyramidal lesions have been described. Poor prognosis is associated with a progressive course, relapses after treatment, repeated attacks, and cerebellar symptoms or parenchymal disease. Neurologic manifestations usually present with severe headache. Further symptoms include gait disturbance, dysarthria, vertigo, and diplopia as well as hyperreflexia, epileptic seizures, hemiplegia, ataxia, or a positive Babinski reflex. Psychiatric symptoms, such as depression, insomnia, or memory impairment, are also signs of neurologic involvement.

Histopathology

Characteristic histopathologic features of Adamantiades-Behçet disease are vasculitis and thrombosis (Fig. 3.3). Biopsies from early mucocutaneous lesions show a neutrophilic vascular reaction with endothelial swelling, extravasation of erythrocytes, and leukocytoclasia or a fully developed leukocytoclastic vasculitis with fibrinoid necrosis of blood vessel walls (McCarty et al. 2003; Altenburg et al. 2006). Although there are reports of lesions that consist primarily of a lymphocytic perivasculitis, most of these lesions are likely older. The neutrophilic vascular reaction should be considered the predominant histopathologic finding (Jorizzo et al. 1995). Aneurysms can also develop in large arteries as a result of vasculitis of the vasa vasorum with penetration of the lamina elastica.

Special Tests

Pathergy Test

A positive pathergy test (hyperreactivity reaction) manifests within 48 h as an erythematous papule (>2 mm) or pustule at the site of a skin needle prick or after intracutaneous injection of 0.1-ml isotonic salt solution using a 20-gauge needle without prior disinfection of the injection site. The skin prick is generally placed at an angle of 45° 3–5 mm intracutaneously on the volar forearm. Erythema without infiltration is considered a negative finding. Provoked oral aphthae and genital ulcers after injection or injury (such as chorioretinitis in the corneal region of the eye after photocoagulation of the ocular fundus region) can also be considered as positive pathergy

phenomenon. Broader pathergy phenomena also include the occurrence of aneurysms around vascular anastomoses as well as local recurrence of ulcers after resection of affected bowel segments. Although a positive pathergy reaction is a sign of Adamantiades-Behçet disease, it is not pathognomonic, as it can also occur in patients with pyoderma gangrenosum, rheumatoid arthritis, Crohn disease, and genital herpes infection.

Radiologic Findings

Scintigraphic evidence of arthritis is found in 50 % of the patients (Altenburg et al. 2006). Cranial magnetic resonance imaging allows documentation of hypodense or atrophic changes in the brain. Electroencephalographic detection of diffuse α waves is considered a positive finding. Vascular lesions can be detected by angiography

Differential Diagnosis (Table 3.2)

Table 3.2 Differential diagnosis of Adamantiades-Behçet disease

Oculocutaneous/mucocutaneous syndromes
Erythema multiforme exudativum and variants, including Stevens-Johnson syndrome
Vogt-Koyanagi-Harada syndrome
Reiter disease
Bullous autoimmune diseases: pemphigus vulgaris, cicatricial mucous membrane pemphigoid, epidermolysis bullosa acquisita
Viral infections (herpes, coxsackie, echo)
Syphilis
Articulomucocutaneous syndromes
Systemic lupus erythematosus
MAGIC syndrome (*m*outh *a*nd *g*enital ulcers with *i*nflamed *c*artilage)
Yersiniosis
Arthropathic psoriasis
Gastrointestinal/mucocutaneous syndromes
Ulcerative colitis, Crohn disease
Tuberculosis
Bowel-associated dermatitis-arthritis syndrome
Aphthae
Recurrent aphthous stomatitis (RAS)
Cyclic neutropenia
Herpes simplex infection
Genital ulcers
Ulcus vulvae acutum (Lipschütz ulcer)
Herpes simplex infection
Sexually transmitted infections
Uveitis
Other forms of uveitis
Arthritis
Ankylosing spondylitis
Juvenile rheumatoid arthritis
Central nervous system manifestation
Multiple sclerosis
Neuro-Sweet disease
Lung manifestation
Sarcoidosis

Adapted from Altenburg et al. (2006)

Clinical Course and Prognosis

The clinical course of Adamantiades-Behçet disease is variable. There can be a delay of up to several years before the diagnosis is made, and this may influence the prognosis. Mucocutaneous and joint manifestations usually occur first. Recurrent erythema nodosum and $HLAB_{51}$ positivity are risk factors for the development of superficial thrombophlebitis and vision loss (Zouboulis et al. 2003a, b; Sakamoto et al. 1995), and superficial thrombophlebitis, ocular lesions, and male gender are risk factors for the development of systemic vessel involvement (Zouboulis et al. 2003a, b; Coskun et al. 2005). A severe course, including blindness, meningoencephalitis, hemoptysis, intestinal perforation, and severe arthritis, occurs in approximately 10 % of patients. Blindness can often be prevented with early aggressive therapy of posterior uveitis. Lethal outcome has been seen in 0–6 % of affected patients in different ethnic groups. Central nervous system and pulmonary and large vessel involvement, as well as bowel perforation, are the major life-threatening complications; death may also result as a complication of immunosuppressive therapy. Markers of severe prognosis include HLA-B_{51} positivity, male gender, and early development of systemic signs (Zouboulis et al. 2003a). Onset in childhood

does not necessarily predict a poor prognosis. Spontaneous remissions of certain or all manifestations of the disease have been observed. Ophthalmic and neurologic sequelae are leading causes of morbidity, followed by severe vascular and gastrointestinal manifestations, and their effects on morbidity may be cumulative.

General Principles of Treatment

The choice of treatment for patients with Adamantiades-Behçet disease depends on the site and severity of the clinical manifestations of the disease. Recurrent aphthae are most often treated with palliative agents, such as mild diet, avoidance of irritating agents, and potent topical glucocorticoids and local anesthetics (Zouboulis 2003a; Alpsoy 2005); lately topical hyaluronic acid 0.2 % gel 2×/day over 30 days was found effective (Table 3.3) (Altenburg et al. 2007). For the topical treatment of genital ulcers and skin lesions, corticosteroid and antiseptic creams can be applied for up to 7 days. Painful genital ulcerations can be managed by topical anesthetics in cream. Corticosteroid injections (triamcinolone acetonide, 0.1–0.5 ml/lesion) can be helpful in recalcitrant ulcerations. They can also be beneficial on panuveitis and cystoid macular edema as a single intravitreal injection (triamcinolone acetonide 4 mg) (Atmaca et al. 2007; Tuncer et al. 2007).

Patients with mucocutaneous lesions resistant to topical treatment, those with systemic involvement, and patients with markers of poor prognosis are candidates for systemic treatment (Zouboulis 2003a; Pipitone et al. 2006; Hatemi et al. 2009). Several compounds have been found effective in randomized, double-blind, placebo-controlled trials (Mat et al. 2006; Matsuda et al. 2003; Davatchi et al. 2009; Yurdakul et al. 2001; Aktulga et al. 1980; Sharquie et al. 2002; Yazici et al. 1990; Alpsoy et al. 2002; Davies et al. 1998) (Table 3.4). Additional treatments have been successful in studies with a lower grade of evidence (Suzuki Kurokawa and Suzuki 2004; Zouboulis 2003a; Kiliç et al. 2009; Hamuryudan et al. 1998; Masuda et al. 1989; Ozyazgan et al. 1992; BenEzra et al. 1988; Melikoglu et al. 2005; Davies et al. 1988; Moral et al. 1995; Sfikakis et al. 2007; Nanke et al. 2008; Zouboulis and Orfanos 1998; Krause and Altenburg 2008; Guillaume-Czitrom et al. 2007; Zouboulis 2003b) (Table 3.5). Oral and intravenous prednisolone can be combined with other immunosuppressants, colchicine, dapsone, sulfasalazine, or interferon-α. A synergistic effect with cyclosporin A has been described in patients with ocular involvement. Prednisolone is one of the few medications that can be used

Table 3.3 Topical treatment of oral aphthous ulcers

Mild diet
Avoidance of hard, spicy, or salty nutrients and irritating chemicals, such as toasted bread, nuts, oranges, lemons, tomatoes, spices (pepper, paprika, curry), alcohol- or CO_2-holding drinks, mouthwashes, toothpastes containing sodium lauryl sulfate[a]
Topical treatment of the aphthous oral ulcers includes:
Caustic solutions (silver nitrate, 1–2 %; tinctura myrrha, 5–10 % weight/volume; H_2O_2, 0.5 %; methyl violet, 0.5 %) 1–2×/day
Antiseptic and anti-inflammatory preparations (amlexanox, 5 % in oral paste[a]; triclosan, 0.1 % mouthwash solution and in toothpastes[a]; amyloglucosidase- and glucose oxidase-containing toothpastes[a]; hexetidine, 1 %, chlorhexidine, 1–2 % mouthwash solutions; benzydamine; chamomile extracts) 3 % diclofenac in 2.5 % hyaluronic acid[a]; hyaluronic acid 0.2 % gel; tetracycline mouthwash (as glycerine solution 250 mg/5 mL glycerine) 2 min 4–6×/day[a] (caveat: pregnancy); doxymycine in isobutyl cyanoacrylate[a]
Corticosteroids (triamcinolone mucosal ointment, dexamethasone mucosal paste, betamethasone pastilles) 4×/day or during the night (ointment/paste) or intrafocal infiltrations with triamcinolone suspension 0.1–0.5 mL per lesion
Anesthetics (lidocaine, 2–5 %; mepivacaine, 1.5 %; tetracaine, 0.5 %–1 % gels or mucosal ointments) 2–3×/day (caveat: allergy)
5-Aminosalicylic acid (5 % cream) 3×/day (reduces the duration of lesions and the pain intensity)
Cyclosporin A, 500-mg solution for mouthwash 3×/day (effective as topical immunosuppressive drug)
Sucralfate suspension, 5 mL × 4/day[a] (for oral aphthous and genital ulcers)
A close association of smoking with a decrease of recurrences of oral aphthous ulcers has been described

[a]Small, randomized, double-blind, placebo-controlled trial against placebo

Table 3.4 Systemic treatment of Adamantiades-Behçet disease

Drug	Dose	Indication
Methylprednisolone	40 mg/every 3 weeks IM	Erythema nodosum (but not orogenital ulcers)
Rebamipide	300 mg/day PO (caveat: pregnancy, lactation)	Oral ulcers
Colchicine	1–2 mg/day PO (caveat: pregnancy, lactation—induces oligozoospermia)	Oral aphthous ulcers, genital ulcers, folliculitis, erythema nodosum
	1.5 mg/day	Erythema nodosum, arthritis, genital ulcers (oral ulcers in females)
		Ineffective
Dapsone	100 mg/day PO (caveat: pregnancy, lactation—methemoglobin increase: ascorbic acid, 500 mg/day)	Oral ulcers, genital ulcers, skin lesions, pathergy test
Azathioprine	2.5 mg/kg/day (caveat: pregnancy, lactation, severe liver disease, bone marrow depression, severe infection, children)	Recent onset ocular disease
Interferon-α 2a	6×10^6 IU/3×/week SC (caveat: pregnancy, lactation—induces psychotic signs, psoriasis, myopathy)	Oral ulcers, genital ulcers, papulopustular lesions
Interferon-α	1,000 and 2,000 IU/day PO	Ineffective
Thalidomide	100 mg/day or 300 mg/day (caveat: pregnancy, lactation—induces polyneuropathy: minimized at 25 mg/day)	Oral ulcers, genital ulcers, papulopustular lesions
Cyclosporin A	10 mg/kg/day PO (against colchicine, 1 mg/day PO) (caveat: lactation, renal insufficiency—induces pathologic central nervous system findings)	Ocular manifestations, oral ulcers, skin lesions, genital ulcers
	5 mg/kg/day PO (against cyclophosphamide pulses)	Visual acuity
	5 mg/d PO (against conventional treatment)	Ocular attacks
Etanercept	25 mg/2×/week PO (caveat: pregnancy, lactation)	Oral ulcers, nodular lesions, papulopustular lesions (not pathergy test)
Acyclovir	5 × 800 mg for 1 week +2 × 400 mg/day for 11 week	Ineffective
Azapropazone	900 mg/day over 3 weeks PO	Arthritis

Evidence grade A—randomized, double-blind, placebo-controlled trial (RCT) against placebo except otherwise mentioned

Table 3.5 Systemic treatment of Adamantiades-Behçet's disease

Drug	Dose	Indication
Corticosteroids	5–60 mg/day prednisolone equivalent PO	Active disease
	100–1,000 mg/day IV over 1–3 days (alone or in combinations) (can induce diabetes or psychosis)	Acute exacerbation (partic. uveitis, neurological manifestations)
Indomethacin	100 mg/day PO	Mucocutaneous lesions, arthritis
Pentoxifylline	300 mg × 1–3/day PO	Oral ulcers (partic. in children)
Oxpentifylline	400 mg × 3/day PO	
Irsogladine	2–4 mg/day PO	Recurrent aphthous ulcers
Cyclosporin A	3–6 mg/kg/day PO (serum levels: 100–150 ng/ml) (caveat: lactation, renal insufficiency – induces pathologic CNS findings)	Uveitis, mucocutaneous signs, thrombophlebitis, acute hearing loss
Tacrolimus	0.05–0.2 mg/kg/day PO (serum levels: 15–25 ng/ml)	Refractory uveitis
Interferon-α	9×10^6 IU × 3/week/3–9×10^6 IU × 5/week SC (3 10^6 IU × 3/week maintenance dose) (caveat: pregnancy, lactation – induces psychotic signs, psoriasis, myopathy)	Ocular lesions, long-term visual prognosis, arthritis, vascular lesions
	1.5–3 × 10^6 IU × 3/week according to body weight	Corticodependent uveitis in children

(continued)

Table 3.5 (continued)

Drug	Dose	Indication
Cyclophosphamide	1 g/month IV bolus (caveat: hemorrhagic cystitis: mesna 200 mg)	Uveitis, neurologic manifestations
Chlorambucil	0.1 mg/day PO (2 mg/day maintenance dose) (caveat: cumulative toxicity)	Neurologic manifestations, uveitis, thrombosis, mucocutaneous lesions
Methotrexate	7.5–20 mg/1× week PO (caveat: pregnancy, lactation, severe bone marrow depression, liver dysfunction, acute infections, gastrointestinal ulcers, kidney insufficiency)	Severe mucocutaneous lesions, arthritis, progressive psychosis, or dementia
Infliximab	5 mg/kg IV days 1, 7, 14, and 28 or days 1, 14/1, 30/1, and 45 (caveat: pregnancy, lactation)	Acute uveitis, refractory posterior uveitis, neurologic manifestations, intestinal involvement
Adalimumab		Refractory ocular lesions
Sulfasalazine	1.5–3 g/day PO	gastrointestinal ulcers
Thalidomide	2 mg/kg/day PO; increased to 3 mg/kg/day if necessary or decreased to 1–0.5 mg/kg/day according to the response (caveat: neurotoxicity)	Intestinal involvement (in children)

Evidence grade B—well-conducted open clinical trial

during pregnancy. Colchicine can be combined with immunosuppressants and interferon-α. A rapid relapse often occurs after discontinuing cyclosporin A, interferon-α, dapsone, or infliximab (Hamuryudan et al. 1998; BenEzra et al. 1988; Davies et al. 1988).

Prevention

- Patients with severe or progressive recurrent aphthous stomatitis should be followed up for years as potential candidates for Adamantiades-Behçet disease, particularly those patients with familial occurrence of the disease.
- Patients with suspected Adamantiades-Behçet disease should be referred early for specialist advice.
- Male patients with systemic involvement as a presenting sign and/or an early age of onset should be treated systemically because of the poor prognosis.

Alopecia Areata

4

Markus Böhm

Key Points

- Alopecia areata is a chronic and often relapsing non-fibrosing inflammatory skin disorder of the hair follicles.
- High-potency topical corticosteroids, e.g. clobetasol propionate, remain the mainstay of all therapeutic options for treatment of alopecia areata on the scalp.
- Topical immunotherapy with 2,3-diphenylcyclopropenone or squaric acid dibutylester is recommended for patients with alopecia areata of the scalp not resolving spontaneously within 1 year or for those not responding to topical corticosteroids.
- Intralesional injection of corticosteroids, e.g. triamcinolone acetonide, should be reserved for therapy-resistant patchy hair loss of the scalp and cosmetically sensitive sites such as the eyebrows.
- Other treatment options with limited level of evidence include topical dithranol, minoxidil, aroma oils and laser therapy.
- Systemic treatment with corticosteroids may be considered for those patients suffering from severe psychological distress and from acute bursts of the disease on the scalp.
- There is only limited evidence for the efficacy of other immunosuppressants (methotrexate, ciclosporin, sulfasalazine).
- Treatment should be individualized and depends on the extent of disease, age and individual level of psychological distress and social impairment.
- Supportive measures (counselling, wigs and other hairpieces, psychotherapy and patient support groups) are important cornerstones in the treatment of patients with alopecia areata.

Definition and Epidemiology

Alopecia areata is a chronic inflammatory skin disorder of the hair follicles with a lifetime incidence of 1–2 %. It affects both women and men equally. The disease most often starts in young adults with children frequently affected. The disease has a sudden onset of patchy areas of hair loss that can occur on the scalp or elsewhere on the body. The individual extent of psychological distress in patients with the disease is often underestimated and frequently leads to severe psychological distress and social impairment.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_4, © Springer-Verlag Berlin Heidelberg 2015

Basic Concepts of Pathogenesis

Alopecia areata is considered a CD8+T-cell-mediated, organ-specific autoimmune disease with several genetic factors contributing to the disease origin (about 20 % of affected patients have a positive family history for the disease). Several loci/regions with genome-wide significance have been reported to confer susceptibility to the disease. They include the histocompatibility leukocyte antigen and the cytokine genes of interleukin (IL)-13, IL-2/21 and IL-2 receptor alpha as well as genes implicated in the regulation of immune responses, i.e. cytotoxic T-lymphocyte-associated antigen 4, cytomegalovirus UL16-binding protein and C-type lectin domain family 16, member A. Several of these susceptibility genes have been associated with other autoimmune diseases. Accordingly, alopecia areata may also be a dermatological sign of an underlying autoimmune polyglandular disease. The pathogenetic concept of alopecia areata in which hair follicles lose their immune privilege is mirrored by histopathology in which a bee swarm-like lymphocytic infiltrate of variable extent is seen around the growing hair bulbs (bee swarm). This inflammation leads to increased numbers of catagen hairs and finally to dystrophic, miniaturized hairs. Notably, hair follicles are not destroyed during the course of the disease and retain their capacity for regrowth even in long-standing alopecia areata.

Clinical Presentation

The disease typically starts with a sudden onset of a single round or oval patch or multiple patches of hair loss that may coalesce into larger areas of alopecia. During the course of the disease, alopecia areata may progress to complete loss of all terminal hair follicles. The scalp is often the initial and only site of involvement, but any other areas of the body including the beard, eyebrows and eyelashes may be affected. Traditionally, alopecia areata is distinguished into limited disease, i.e. *unifocal* or *multifocal* alopecia areata and extensive disease, i.e. complete loss of the scalp hair (*alopecia totalis*) or complete loss of hairs of the total body (*alopecia universalis*). *Ophiasis* describes a band-like pattern of hair loss on the occipital scalp (Figs. 4.1, 4.2, 4.3 and 4.4). *Diffuse alopecia areata* describes a rare form of alopecia areata in which no patchy areas of hair loss are present. This form commonly progresses to alopecia totalis. The extent of hair loss on the scalp can be more precisely assessed by the so-called SALT (severity of alopecia areata tool). This quantification tool has been shown to be useful for monitoring the efficacy of the chosen therapy against alopecia areata. In addition to the changes of the hairy areas of the body, about 10–20 % of the patients with alopecia areata have structural nail abnormalities including pits and other forms of nail dystrophy (e.g. "sand paper nails") (Fig. 4.5).

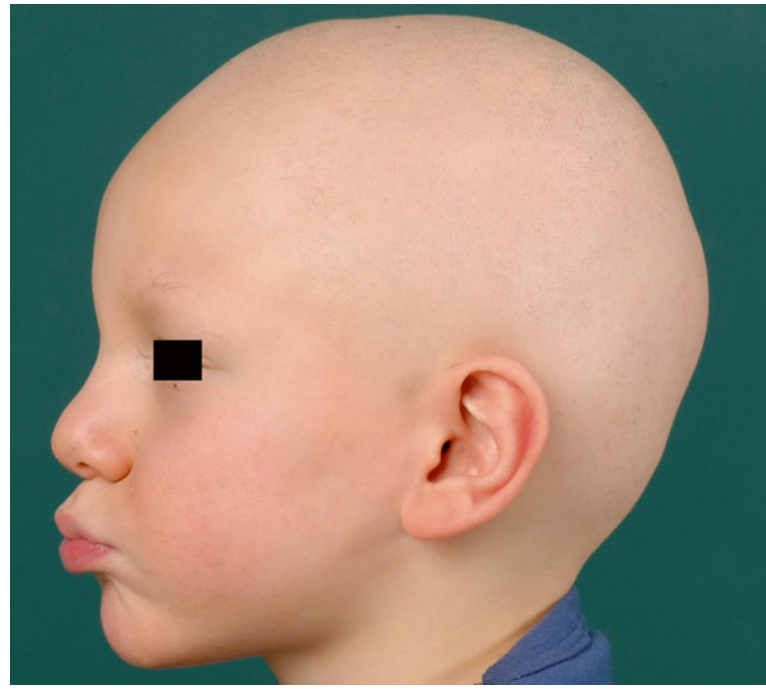

Fig. 4.4 Alopecia areata totalis. Note also almost full absence of eyebrows and eyelashes

Fig. 4.5 Typical changes of alopecia areata on the nail plate

Differential Diagnosis

Alopecia areata is a clinical diagnosis that rarely requires the need for an excisional skin biopsy. The typical patchy configuration of the hair loss together with the presence of exclamation mark hairs and the lack of fibrosis are indicative for the diagnosis. Patchy forms of hair loss, however, can also be found in the following:

- *Tinea capitis*. Inflammation is present on the scalp (erythema, scales, yellow crusts, scutula). Depending on the type of fungus, Wood light gives also a greenish fluorescence (*Microsporon*). KOH examination followed by fungal microscopy and cultures is positive. Children are most often affected.
- *Trichotillomania.* Here, the hair loss in the affected areas is often incomplete with multiple broken hairs of varying length. The epilation test ("pull test") at the margins of the lesions is negative. Children are most commonly affected and indicate an underlying psychological problem.
- *Fibrosing (cicatricial) alopecia*, e.g. chronic discoid lupus erythematosus (CDLE) and lichen planopilaris show fibrosis and signs of inflammation depending on the stage of the disease. CDLE of the scalp presents with irregular footstep-like patches of erythema and hyperkeratosis. Lichen planopilaris shows perifollicular erythema, hyperkeratosis and the paintbrush sign (bundles of residual hairs surrounded by fibrotic skin). To definitely exclude such forms of fibrosing alopecia, an excisional skin biopsy of the scalp may be necessary.

Diffuse alopecia areata must be differentiated from other forms of diffuse alopecia which include the following:

- *Syphilis* can rarely affect the scalp hair either as a patchy form of alopecia or as diffuse alopecia. Serologic testing easily excludes this differential diagnosis.
- *Loose anagen hair syndrome* occurs in children between the age of 2 and 5 years often with blond hair. Patients have typically short and dull hairs. Parents notice the sudden onset of a diffuse effluvium in which hairs can be easily pulled out without pain. The trichogram reveals almost exclusively anagen hairs.
- *Telogen and anagen effluvium* may mimic diffuse alopecia areata. In both conditions, the pathognomonic exclamation mark hairs of alopecia are not present. Careful exploration of the patient's history will usually identify a causative drug responsible for anagen effluvium.

General Principles of Treatment

Alopecia should never be considered a cosmetic problem but a disease that can severely affect the quality of life of an affected individual. Quality of life can be easily assessed, e.g. by a visual analogue scale. It does not only provide a simple proxy for the psychological distress of the patient but also an outcome measurement for the success of any therapy. Importantly, the individual extent of psychological distress and the resulting social impairment in patients with the disease is often underestimated by physicians. Professional counselling and supportive measures (e.g. wigs) of patients with alopecia areata including the offer of psychological intervention or contact to patient support groups are essential cornerstones in the state-of-the-art management of individuals with alopecia areata.

All patients should be encouraged that spontaneous resolution may occur even in long-standing and extensive alopecia areata due to the fact that hair follicles are not destroyed. As spontaneous resolution occurs in up to 80 % of patients with limited patchy hair loss and <1 year duration of the disease, *no treatment* remains a therapeutic option especially in young children. Notably, most patients with alopecia areata will not be satisfied with *therapia nulla* and request medical treatment. It should be further pointed out that the general course of the disease is unpredictable. Notably, its sustained remission is rare in patients with extensive alopecia areata. Prognostic factors indicating a prolonged course of the disease are early age of onset, coexisting atopic dermatitis and extensive disease, e.g. alopecia totalis or universalis.

The various forms of topical and systemic therapies should be briefly explained to all patients with alopecia areata. As only few randomized controlled trials have been published, the efficacy of all existing therapies must be interpreted in the light of the high rate of spontaneous resolution of the disease and the risk-benefit ratio of each treatment modality. It should be noted, moreover, that only very limited information exists on the long-term outcome of all presently available therapies for alopecia areata.

Topical Therapy

A variety of topical treatments exist for alopecia areata. Among them, topical high-potency corticosteroid formulations have the highest level of therapeutic evidence based on a randomized controlled trial. In addition, several controlled trials (often retrospective with a self-controlled design) highlight the relative efficacy of topical immunotherapy. All other topical treatments did either not fulfil the review criteria for inclusion into the most recent Cochrane's review or have yielded conflicting results with regard to efficacy.

Topical Corticosteroids

High-potency corticosteroids are frequently used in patients with alopecia areata and can be considered the mainstay therapy of this disease. They act by reducing the inflammatory infiltrate in the hair bulb and possibly promote spontaneous resolution. They are most useful for all limited forms of the disease (unifocal and multifocal alopecia areata) involving the scalp. The strongest evidence comes from a randomized controlled trial in patients with moderate to severe alopecia areata in which 0.05 % clobetasol propionate foam was given twice daily against the vehicle for 12 weeks and found to significantly promote hair regrowth. Other formulations of 0.05 % clobetasol propionate (cream, solution) may be administered accordingly with possibly similar effects. In patients suffering from alopecia areata totalis or universalis, 0.05 % clobetasol propionate under an occlusive dressing may further promote hair growth of the scalp. It can be applied overnight on six out of seven nights for 6 months and may promote long-term hair growth. No evidence for systemic absorption was noted under this treatment in adult patients. A well-known side effect of topical high-potency corticosteroids on the scalp is folliculitis. Upon extended treatment, skin atrophy will also occur. There are no data on the safety and efficacy of high-potency corticosteroids in children with alopecia areata.

Topical Immunotherapy

Topical immunotherapy (also known as contact immunotherapy) has an established role in the treatment of corticosteroid-refractory, prolonged and extensive disease (alopecia areata totalis and universalis) for many years. The precise mode of action of this therapy is still unclear, but the general therapeutic principle resides in the induction of a type IV allergic reaction to an epicutaneously administered allergen. During subsequent challenges with the antigen, a low-grade allergic contact dermatitis is elicited which alters the extent and nature of the perifollicular infiltrate. There are no randomized controlled trials of this treatment, but extensive experience over the last 30 years and a number of large observational studies with a self-controlled design (half-head method) support the efficacy of this therapy for alopecia areata. It is important to note that topical immunotherapy is tricky and time-consuming, both for the patient and for the treating dermatologist.

The commonly used allergens 2,3-dephenylcyclopropenone (DCP) and squaric acid dibutylester (SADBE) have probably the same therapeutic efficacy, but DCP is more suitable since it is more stable in solution. Therapy starts with sensitization of one half of the scalp with 2 % DCP in acetone. After 2 days, this solution is removed by washing. Two weeks after sensitization, the previously sensitized scalp area is challenged weekly with increasing DCP concentrations (0.0001, 0.0005, 0.001, 0.005, 0.01, 0.05, 0.1, 0.2, 0.3, 0.4, 0.5, 0.75, 1 and 2 %) until

Fig. 4.6 Regrowth of hairs under DCP immunotherapy on the right side of the scalp

an eczematous reaction consisting of erythema and pruritus for 2 days has been reached. Most patients develop the first eczematous reaction after applying a median concentration of 0.2 %. When the appropriate DCP concentration has been found, this dose is applied in weekly intervals to the aforementioned area until regrowth is detected (Fig. 4.6). Then, the solution is applied to the whole scalp to promote hair growth on both sides of the head. If no hair growth is observed after unilateral application of the allergen for total length of 1 year, topical immunotherapy is considered ineffective and should be discontinued. Once complete or cosmetically acceptable regrowth of scalp hair has been achieved, DCP should be best tapered off by prolonging the application intervals of DCP to 2 weeks, to 3 weeks and then to 4 weeks. In case of recurrence of hair loss, topical immunotherapy can be restarted in weekly intervals. Around 5 % of all patients treated with DCP are anergic and thus will not respond to this treatment. Here, DCP must be discontinued and SADBE can be tried as an alternative allergen. Prognostic factors for an unfavourable prognosis for DCP are extensive scalp involvement and long disease duration. Patients and treating physicians should also be aware that relapses frequently occur after cessation of the treatment.

The most commonly encountered adverse effect of topical immunotherapy is high-grade allergic contact eczema (blisters and bullae) which is not intended but can easily be controlled with topical class-II corticosteroids and a pause of allergen exposure for 1 week upon which it is reapplied in a lesser concentration. Careful titration of the allergen dose is thus essential to avoid this complication. Moreover, special care should be taken to not contaminate other regions of the body (face, hands) with the allergen. Accordingly, all patients should be requested to wear a wig or protective hat for 2 days after the allergen-containing solution has been applied to avoid contact eczema and elicitation of photoallergy in skin areas other than the scalp. Many patients further develop occipital and/or cervical lymphadenopathy during the treatment period. Additional side effects include urticaria, angioedema of the eyelids (upon high-grade allergic dermatitis) and pigmentary changes (both hypopigmentation and hyperpigmentation). Induction or exacerbation of vitiligo has been noted in several case reports. However, long-term side effects have not been reported albeit topical immunotherapy has been used for more than 30 years.

Importantly, it is should be noted that topical immunotherapy is an unlicensed treatment as it uses non-pharmacological-grade allergens. All patients need to be informed about the nature of the treatment, possible side effects and alternative treatments. All should give signed consent to the therapy. Furthermore, DCP- and SADBE-containing solutions must be stored in the dark and should be handled only with gloves during application onto the patients' scalp to avoid sensitization. Upon pregnancy, topical immunotherapy should be discontinued as no data on safety are available. Notably, topical immunotherapy may also be administered to children with alopecia areata.

Intralesional Corticosteroids

Injection of depot corticosteroids into patches of alopecia areata has long been performed by practitioners and may result in prolonged hair growth. Triamcinolone acetonide (5–10 mg/ml) and hydrocortisone acetate (25 mg/ml) are commonly used. The corticosteroids (0.05–0.1 ml) are injected with a needle into the upper subcutis or by a needleless device. Multiple injections, e.g. every 1–2 weeks, can be performed. Regrowth of hairs can be expected in >60 % of the treated patients. Since injection of corticosteroids is painful, this treatment is most suitable for single hairless patches or for a limited number of lesions, especially those located on cosmetically sensitive sites like the eyebrows. Skin atrophy is a common adverse effect, and physicians must be aware that injections of depot corticosteroids have also the risk for anaphylactic reactions, increased intraocular pressure and cataract. For children, intralesional injection of corticosteroids is not a suitable treatment option.

Other Topical Treatments

Minoxidil

Topical minoxidil solution (5 % for men and 2 % for women) is an effective and approved treatment for androgenetic alopecia. Its mode of action remains unclear, but induction of distinct growth factors is believed to play a role. Conflicting data have been reported regarding the efficacy of minoxidil in alopecia areata. While it is ineffective in alopecia areata totalis and universalis, it may be useful in limited disease (unifocal or multifocal alopecia areata) as a second-line treatment. It may also be used to prevent relapses. It should be applied twice daily (2 % for women; 5 % for men) and may also be used for regions not suitable for topical corticosteroids (e.g. beard and eyebrows).

Dithranol

Irritants such as dithranol may modulate the extent and composition of the inflammatory infiltrate around the hair follicles and thus may promote hair growth in alopecia areata. There is evidence from several case reports and uncontrolled trials that topical anthralin once sufficiently applied to induce irritant dermatitis may be beneficial to some patients. Dithranol is

applied daily in increasing concentrations (0.1–1.0 %) in short-term applications (not more than 20 min) and then washed off. It can be considered as a second-line treatment of alopecia areata and is suitable also for children.

Aromatherapy

Daily massage of essential aroma oils from lavender, thyme, rosemary and cedarwood for 2 min into the scalp skin has been reported to induce hair growth on alopecia areata. This form of therapy may also be combined with other treatment options, e.g. topical minoxidil or aromatherapy, and can also be used in children.

Laser Therapy

Preliminary data suggests that lasers may induce some hair growth in patches of alopecia areata. In one study, an infrared diode laser was used; in the other, a 308 nm excimer laser. In the latter study, laser treatment was performed twice weekly for 12 weeks.

Systemic Treatments

Corticosteroids

Since alopecia areata is an immune-mediated inflammatory disease, systemic corticosteroids appear to be a reasonable therapeutic approach to halt disease progression. However, there are no randomized controlled trials, and evidence for efficacy in alopecia areata is confined mostly to case reports and smaller case series. Perhaps systemic corticosteroids are best justified in patients suffering from extensive psychological distress together with an acute burst of the disease (positive pull test in all regions of the scalp) and resistance to previously applied topical corticosteroids. Prolonged therapy with systemic corticosteroids will lead to significant side effects, and upon cessation of the therapy, patients frequently experience relapses limiting the usefulness of this treatment in alopecia areata.

Oral prednisolone can be given at a starting dose of 40 mg per os followed by a tapering period over 6 weeks. Alternatively, dexamethasone (5 mg) twice weekly or prednisolone (200–300 mg) once monthly can be given. More invasive treatment protocols consist of intravenous pulse therapy with 250 mg methylprednisolone for 3 days or intravenous 2 g prednisolone. We have good experience with monthly intravenous pulses of dexamethasone (100 mg per day) for 3 consecutive days (100 mg per day). Six cycles of this therapy can be done to halt disease progress and promote hair regrowth. Side effects under this regimen are often minimal. Importantly, patients should be monitored under intravenous pulse therapy with corticosteroids.

Other Systemic Therapies

Based on the immune-mediated nature of alopecia areata, several other immunosuppressive or immunomodulating agents have been tried and reported in the past, all of which do not fulfil the criteria for a higher level of therapeutic evidence. While topical tacrolimus is ineffective in alopecia areata, oral ciclosporin was shown to induce hair regrowth in some patients with alopecia areata. Data from uncontrolled trials also suggested some therapeutic effect of sulfasalazine. A more recent study revealed some partial and complete responses in patients with alopecia treated with 15–25 mg methotrexate per week with our without prednisolone (10–20 mg per day). Notably, none of these agents is approved for alopecia areata but can lead to a number of adverse effects. Thus, these agents cannot be generally recommended for the routine therapeutic management of alopecia areata patients.

Phototherapy

In the past, all types of psoralen plus ultraviolet A (PUVA) treatment (oral and topical) have been assessed in patients with alopecia areata. None of these studies however were controlled. Due to uncertainty of the efficacy of PUVA in alopecia areata, its potential adverse effects (especially in systemic PUVA) and the long-term safety concerns PUVA of therapy cannot be currently recommended.

Supportive Measures

As pointed out above, life quality of patients with alopecia areata is often severely affected. Psychological profiling has shown that patients with alopecia areata experience more depressive, hysterical and anxiety feelings and may be more in conflict with their social environment. In light of this disease-associated psychological distress and social impairment, counselling and, if desired, psychological intervention including hypnotherapy are considered important supportive measures to optimally treat patients with alopecia areata. Many patients will further profit from the use of wigs, integrated systems, hairpieces, headscarves, hats and false eyelashes or permanent to better cope with the burden of the disease. Information on patient support groups should be offered to all patients suffering from a chronic course of the disease.

Guidelines for Treatment

Guidelines for the management of alopecia areata have been published by the British Association of Dermatologists in 2012. Accordingly, topical corticosteroids (level evidence 2+) and topical immunotherapy (level of evidence 2++) have the highest level of evidence followed by topical minoxidil (level of evidence 2–). All other therapies of alopecia areata as outlined above were classified as level 3 of evidence.

Androgenetic Alopecia

5

Ralph M. Trüeb

Abbreviations

AGA	Androgenetic alopecia
DHEA	Dehydroepiandrosterone
DTH	Dihydrotestosterone
EBM	Evidence-based medicine
PHL	Pattern hair loss

Key Points

- Androgenetic alopecia is the most common hair loss disorder.
- The hair loss is genetically determined, androgen induced, age dependent, and with sex-dependent differences in incidence, pattern, and severity.
- Due to the frequency and often significant impairment of life quality perceived by affected individuals, competent diagnosis and treatment are important.
- The diagnosis is established by history taking and clinical inspection, including dermoscopy, where a patterned, non-scarring, progressive alopecia with diversity of hair shaft diameters is observed.
- A systematic literature review revealed excellent evidence levels for the therapeutic use of topical minoxidil and oral finasteride. The limited success rate of evidence-based treatments points to a more important complexity of the problem. One must remain open-minded for the possibility of a multitude of cause relationships underlying hair loss, including seasonality of hair growth and shedding, hormonal factors, nutrition, inflammatory phenomena and scarring, and ageing.
- Finally, the influence of the prescribing physician should be kept in mind, since inspiring confidence versus scepticism and fear clearly impacts the outcome of treatment.

Definition and Epidemiology

Androgenetic alopecia (AGA), also referred to as male-pattern hair loss or common baldness in men and as female-pattern hair loss in women, is the most common hair loss disorder, affecting both men and women.

The hair loss is genetically determined, androgen induced, age dependent, and with sex-dependent differences in incidence, pattern, and severity.

It is assumed that the genetically predisposed hair follicles are the target for androgen-stimulated hair follicle miniaturisation, leading to gradual replacement of large, pigmented hairs (terminal hairs) by barely visible, depigmented hairs (vellus hairs) in affected areas. The result is a progressive decline in visible scalp hair density.

First signs often occur in adolescence, but may be observed as early as in childhood. The condition affects at least 50 % of men by the age of 50 years and up to 70 % of all males in later life. Estimates of its prevalence in women have varied widely, though recent studies claim that six per cent of women aged under 50 years are affected, increasing to a proportion of 30–40 % of women aged 70 years and over (Norwood 2001).

While male-pattern hair loss is characterised by its typical bitemporal recession of hair and balding vertex, female-pattern hair loss is set apart by its rather diffuse thinning of the crown and a usually intact frontal hairline.

Due to the frequency and the often significant impairment of life quality perceived by affected individuals, hair loss cures have been experimented on for centuries. What is remarkable about their history is that despite the more recent genuine advances in effective medical treatments, hair cosmetics, surgical procedures, and phony hair loss solutions continue to be marketed today with an amazing success. Therefore, competent diagnosis and treatment are particularly important in dealing with AGA.

Basic Concepts of Pathogenesis

Do not believe everything you hear on hair. Exactly as the fixation on treating hair loss is not a new phenomenon, age-old myths regarding hair growth and shedding continue to exist up to this day. In dealing with the fear or complaint of hair loss, it is important to weed out these myths from the facts: wearing hats causes hair loss, frequent washing and blow drying can lead to hair loss, hairstyling products and dyes cause hair loss, brushing your hair can make it stronger and more resistant to hair loss, or cutting your hair will make it grow back thicker.

While the popular or layman's myths are usually easy to dismiss, the physician's myths root deeper in the conception of primary care physicians. Adding to the patient's concern about hair loss may be prior frustrating experiences with physicians, who tend to trivialise complaints of hair loss or even to dismiss them completely. This attitude on the part of physicians may result from lack of knowledge or from misconceptions regarding hair loss in women. Among the most prevalent among physician's myths standing in the way to successful management of hair loss are the following:

The majority of women complaining of hair loss are suffering of imaginary hair loss. Fact is that with the appropriate methods for early diagnosis, a diagnosis of AGA can usually be made, and the appropriate therapy can be initiated. Only a minority of women complaining of hair loss suffer of imaginary hair loss. In these cases, we are dealing with hypochondrial disease and body dysmorphic disorder. More frequently we are dealing with adjustment disorders to a true hair loss disorder, and the best way to alleviate the emotional distress caused by a hair disorder is to eliminate the hair disease that is causing the problem.

Losing 100 strands of hair per day is normal. Fact is that the number of hair loss per day is dependent on the amount of hairs on the scalp and on a number of internal and external factors. The hair follicle is subject to constant turnover in the course of perpetual cycles through phases of proliferation, involution, and resting, with regeneration in the successive hair cycle. Cyclic hair growth activity occurs in a random mosaic pattern, so that on average, the amount of new scalp hair formation matches the amount that is shed, thereby maintaining a consistent covering. Each follicle possesses its own individual control mechanism over the evolution and triggering of the successive phases of the hair growing cycle, though systemic factors, such as the hormonal system, cytokines, and growth factors, as well as external factors linked to the environment, toxins, deficiencies of nutrients, vitamins, and energy, have influence. In AGA, hair loss results from a progressive shortening of the proliferation phase of the hair cycle without synchronisation, so that significant hair loss can result with a

relatively small number of hairs shed per day, while seasonal effects may result in partial synchronisation phenomena with temporary increase of hair shedding.

The most frequent disorder associated with hair loss in women is iron deficiency. Fact is that several studies have evaluated the relationship between decreased serum ferritin levels and hair loss and have resulted in opposing conclusions. A critical appraisal of available data points to the fact that iron deficiency is probably overestimated as a single cause of hair loss in women.

The first-line therapy for female AGA is anti-androgens. Since AGA is recognised as an androgen-induced loss of hair, at least in men, anti-androgens have been the first-line of treatment for AGA in women. Fact is that the observation that female AGA may develop in the absence of circulating androgens and that female AGA does not respond to anti-androgen treatment, unless there is a hyperandrogenic state, points to the fact that other, androgen-independent pathomechanisms underlie the condition in women and that therefore anti-androgen treatment has so far been overestimated.

Hair loss in men cannot be stopped or helped. In the past, this was true, and the history of treatments for hair loss is one of charlatanry and quackery. In a survey of 508 men, when topical minoxidil and oral finasteride were available for the treatment of androgenetic alopecia, we found that 27 % of balding men denied the use of hair growth-promoting agents because they did not believe in their efficacy (Trüeb et al. 2001). Fact is that today, with the advances in science and technology, and our understanding of hair growth and disorders, effective treatments have become available for the prevention of hair loss and recovery of hair. Hair loss medications and hair transplantation are effective means to help hair loss sufferers restore hair or improve the appearance of hair.

Evidence-Based Medicine

Evidence-based medicine (EBM) aims for the ideal that healthcare professionals should make conscientious, explicit, and judicious use of the best available evidence gained from the scientific method to clinical decision-making.

It seeks to assess the strength of the evidence of risks and benefits of diagnostic tests and treatments, using techniques from science, engineering, and statistics, such as the systematic review of medical literature, meta-analysis, risk-benefit analysis, and randomised controlled trials.

As *EBM guidelines* on hair disorders are rare, a European consensus group was recently constituted to develop guidelines for both diagnostic evaluation and treatment of AGA. The conclusions resulted in guidelines for diagnostic evaluation in androgenetic alopecia in men, women, and adolescents and in guidelines for the treatment of androgenetic alopecia in women and in men, both recently published in the European dermatologic literature (Blume-Peytavi et al. 2011; Blumeyer et al. 2011).

Clinical Presentation

AGA is diagnosed by history taking and a clinical hair and scalp inspection, including dermoscopy, where a patterned, non-scarring, progressive alopecia with diversity of hair shaft diameters is observed.

History taking is of paramount importance in assessing hair loss. By careful and systematic questioning, it is possible to assess the factors pertinent to differential diagnosis and particular lines of further investigation. It is advisable never to accept anything for true, neither from the patient nor from the referring physician, which is not clearly recognisable as such, that is to say, carefully to avoid precipitancy and prejudice and to comprise nothing more in one's judgement than what is presented to the mind so clearly and distinctly as to exclude all grounds of doubt.

A detailed *family history* relating to hair loss is pertinent to the diagnosis of genetic disorders.

The *personal history* encompasses on date of onset of the hair loss problem; periodicity of hair loss; rate of progression; previous investigations and treatments; present and past health status; medications, including hormonal treatments (oral

contraceptive, replacement therapy); dietary behaviour; associated symptoms relating to the condition of the scalp; and hair care habits.

The *medical history* should focus on most frequent causes of hair loss, especially in women: iron deficiency, thyroid disorder, and lupus erythematosus. Risk factors for iron deficiency are heavy menstrual bleeding (>80 ml per month), use of an IUD, history of iron deficiency anaemia, and insufficient dietary iron intake. Finally, a history should be taken of stressful life events, UV exposure, cigarette smoking, alcohol abuse and malnutrition, drug abuse, and sexual risk behaviour (syphilis, HIV infection).

The skin and hair are gratifying for diagnosis. One has but to look, and recognise, since everything to be named is in full view. Looking would seem to be the simplest of diagnostic skills, and yet its simplicity lures one into neglect. To reach the level of artistry, looking must be a skilful active undertaking. The skill comes in making sense out of what is seen, and it comes in the quest for the underlying cause, once the disorder has been named. The first look is best made without prejudices of former diagnoses and without bias of laboratory data. In many instances, a specific diagnosis is made in a fraction of a second if it is a simple matter of recognition. The informed look is the one most practised by dermatologists; it comes from knowledge, experience, and visual memory. Where the diagnosis does not come from a glance, the diagnostic tests come in, i.e. the dermatological techniques of examination and the laboratory evaluation.

By definition, alopecia is the acquired condition of recognisable hair loss. When examining the scalp, the distribution of hair loss (pattern recognition), the presence and characteristics of associated skin and nail lesions, and the presence of inflammation and scarring should be noted. Part widths should be measured and all abnormalities noted.

The *pull test* is an easy test to perform and to repeat, with the aim to roughly judge active hair shedding. Approximately 50 hairs are grasped by the thumb, index, and middle fingers. While the hairs are tugged away, the test is positive when >10 % of the grasped hair can be pulled out. Naturally, the test is influenced by the condition of hair with respect to shampooing, so that this must be taken into consideration. The test is performed in different scalp areas. In patients with active AGA, the pull test is positive only in the affected area, while a diffusely positive pull test requires further diagnostic evaluation to exclude telogen effluvium or diffuse alopecia areata.

Dermoscopy of the scalp or trichoscopy is a noninvasive diagnostic tool that permits recognition of morphologic structures not visible to the naked eye. Dermatologists involved in the management of hair and scalp disorders have discovered dermoscopy to be useful in their daily clinical practice. Ultimately, examination of the scalp by dermoscopy can reassure patients that they have received a thorough scalp examination, since patients with hair loss are very distressed and often feel that they are not properly examined. Using trichoscopy, signature patterns are seen in a range of scalp and hair conditions.

Trichoscopic features of AGA are diversity of hair shaft diameter, peripilar sign, and empty follicles. Originally Tosti et al. (2007) suggested that diversity of hair shaft diameter >20 % is diagnostic of female AGA. We found that trichoscopy is a valuable and superior method to the trichogram for diagnosis of female AGA, especially in early cases, with the highest yield irrespective of the suggested cut-off of 20 % diversity of hair shaft (Galliker et al. 2012). More recently, Rakowska et al. (2009) proposed more sophisticated diagnostic criteria for diagnosis of pattern hair loss (PHL) in women based on trichoscopic imaging. Major criteria are (1) ratio of more than four empty follicles in four images (at 70-fold magnification) in the frontal area, (2) lower average thickness in the frontal area compared to the occiput, and (3) more than 10 % of thin hairs (<0.03 mm in diameter) in the frontal area. Minor criteria were (1) increased frontal to occipital ratio of single-hair pilosebaceous units, (2) vellus hairs, and (3) peripilar signs. Fulfilment of two major criteria or of one major and two minor criteria allows diagnosis of PHL in women with a 98 % specificity.

The *trichogram* is a semi-invasive technique for hair analysis on the basis of the hair growth

cycle. It involves the forceful plucking of 50–100 hairs with a forceps from specific sites of the scalp. A major objective of trichogram measurements is to evaluate and count the status of individual hair roots and to establish the ratio of anagen to telogen roots. It is particularly useful to exclude diffuse telogen effluvium or in individual cases where loose anagen hair or dystrophic anagen effluvium is suspected.

In requesting *laboratory tests*, clinical suspicion is the determinant, and knowledge of clinical dermatology is prerequisite for combining medical sense with economic sense. The greater the number of different tests done, the greater the risk of getting false-positive or irrelevant leads. Therefore, laboratory testing must be kept sharply focused.

General Principles of Treatment

The aim of treatment is to increase hair coverage of the scalp and to retard progression of hair thinning. With respect to the treatment of male and female AGA, the European consensus group (Blumeyer et al. 2011) conducted a systematic literature review in Medline, Embase, and Cochrane databases until August 2008. One thousand three hundred seventy publications were found, 51 added by hand search. Eighty-five publications fulfilled the following inclusion criteria for the guideline: prospective study with a number of patients ≥20 (no minimal patient number required in twin studies), age ≥12 years, and with confirmed diagnosis of AGA (diagnosis either clinically or by further diagnostic evaluations, e.g. trichogram, TrichoScan, biopsy). The objective outcome measure of efficacy described for drug therapy was mean change from baseline hair count in target area or measurement of hair growth/loss in target area by global photography.

The guideline revealed excellent evidence levels for the therapeutic use of topical minoxidil (2 and 5 %) in men and in women and for 1 mg oral finasteride in men (Figs. 5.1a, b and 5.2a, b), low evidence levels for hormonal treatments, and insufficient or lacking evidence to the broad panel of miscellaneous treatments available claiming to be efficient too.

Minoxidil promotes hair growth through increasing the duration of anagen. It causes hair follicles at rest to grow and enlarges suboptimal follicles. While minoxidil was developed for the treatment of hypertension, and this feature of the drug's action is best understood, its mechanism of action on hair growth is poorly understood. Minoxidil is a potassium-channel opener and vasodilatator and has been reported to stimulate the production of VEGF in cultured dermal papilla cells. There is evidence that this effect is mediated by adenosine and sulfonylurea receptors, which are well-known target receptors for adenosine-triphosphate-sensitive potassium-channel openers. Topical solutions of 2 and 5 % minoxidil are available for the treatment of AGA in men and women.

Finasteride is a competitive inhibitor of type 2 5α-reductase and inhibits the conversion of testosterone to dihydrotestosterone (DHT). The rationale for the use of finasteride to treat AGA in men is based on the absence of AGA in men with congenital deficiency of type 2 5α-reductase and the presence of increased 5α-reductase activity and DHT levels in balding scalp.

While oral finasteride has unanimously been shown to be effective in the treatment of hair loss in men, its efficacy in women remains controversial. Due to teratogenicity for the male fetus, oral finasteride is contraindicated for use in premenopausal women. Differences in response of women to oral finasteride have led to the suggestion that not all types of female AGA have the same pathophysiology, i.e. a distinction should be made between alopecia with early (premenopausal) or late (postmenopausal) onset and with or without hyperandrogenemia. Up to date no predictive factor for response to finasteride treatment has been identified in women with female AGA.

Oestrogens and anti-androgens are traditionally used in women with AGA, although no controlled studies have been done with systemic oestrogens, and topical 17α-estradiol (alfatradiol) and anti-androgens have proven to be ineffective. Nevertheless, when a combination of oestrogen and a progestin is prescribed for oral contraception or hormonal replacement therapy in women with AGA, care should be taken to select a

Fig. 5.1 Successful treatment of male androgenetic alopecia in a 45-year-old male with 1 mg oral finasteride and 5 % topical minoxidil lotion twice daily, (**a**) before and (**b**) after 18 months of treatment

progestin with no androgenic activity, e.g. norethisterone, levonorgestrel, and tibolone. Women with this condition should also avoid androgens and their precursors as well, such as dehydroepiandrosterone (DHEA), since these may exacerbate hair loss.

As a general rule, topical minoxidil 2 % solution twice daily or topical minoxidil 5 % solution 1 ml once daily represents the first-line treatment for female AGA, irrespective of age. Increase of hair growth is evident within 8 weeks of treatment and generally peaks by 12–16 weeks. Response to treatment should be assessed at 6 months. If successful, treatment needs to be continued to maintain efficacy. In case of treatment failure, topical minoxidil 5 % solution twice daily may be tried, and in postmenopausal women without a family or personal history of breast cancer, 5 mg oral finasteride once daily may be considered.

One milligram oral finasteride once daily is the first-line treatment for male AGA in men between 18 and 40 years of age with mild to moderate AGA while topical 2 % or 5 % minoxidil solution twice daily (in children under 12 years once daily) is recommended for the treatment of premature alopecia and the treatment of AGA in men over 40 years who have retained some hair. The younger subjects experience better efficacy of topical minoxidil than the older subjects, although clear treatment effects are noted also in the older age group. Males show an inverse relationship between the effect of topical minoxidil and duration of balding: males with duration of balding <5 years show a significantly better effect than those with duration of balding >21 years. The diameter of vertex balding in men shows an inverse relationship with efficacy of topical minoxidil: males with <5 cm diameter vertex balding area show a better effect of

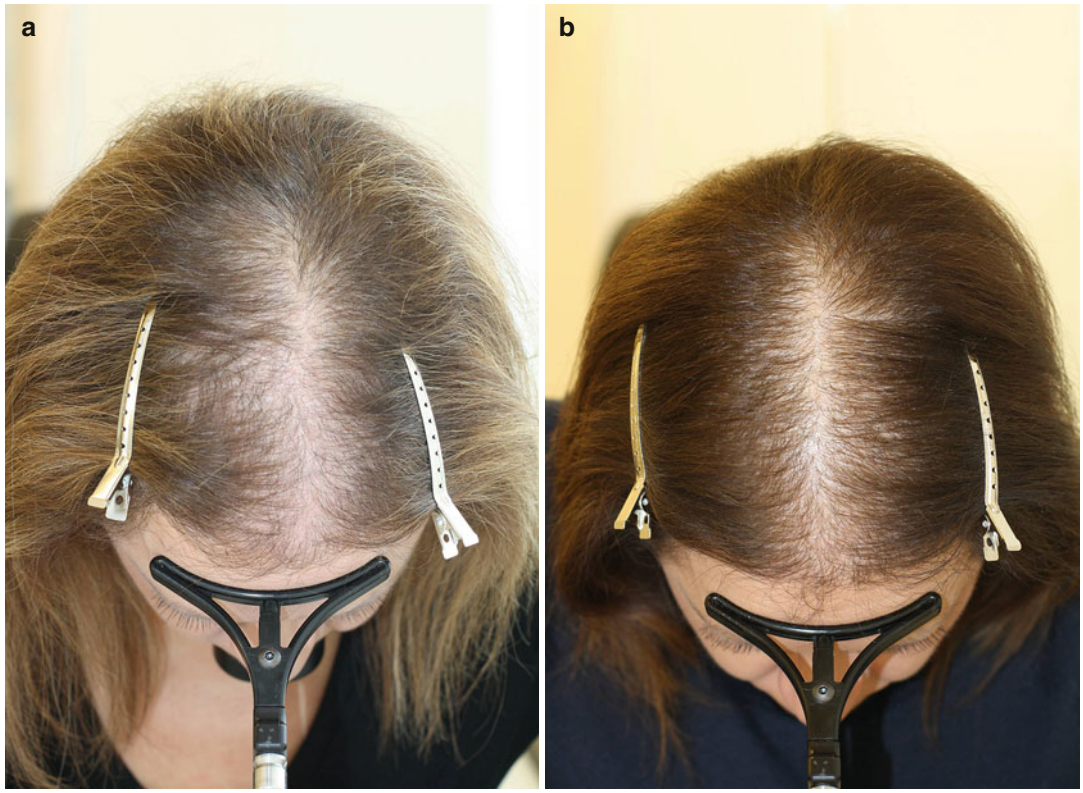

Fig. 5.2 Successful treatment of female androgenetic alopecia in a 51-year-old female with 5 % topical minoxidil lotion twice daily and oral supplementation therapy with L-cystine, medicinal yeast, and pantothenic acid, (**a**) before and (**b**) after 6 months of treatment

treatment than subjects with diameters >15 cm. Finally, duration of hair loss less than 1 year compared with more than 10 years at onset of treatment results in a significantly more effective treatment with topical minoxidil with respect to stabilisation of alopecia and new hair growth. Oral finasteride retains its efficacy in men over 40 years of age, though to a lesser degree and with a higher frequency of sexual adverse effects compared to men between 18 and 40 years. Again, response to treatment for both topical minoxidil and oral finasteride should be assessed at 6 months, although in some men response to finasteride may not become evident until 12 months. If successful, treatment needs to be continued to maintain efficacy, though finasteride may be tapered in the ageing male, due to decrease of efficacy and increase of sexual adverse events. For greater efficacy, the combination of topical 5 % minoxidil solution 1 ml twice daily and oral finasteride 1 mg daily may be considered.

Ultimately, surgery, specifically follicular unit transplantation (FUT), can be considered in male and female patients with unsatisfactory results of 1 year pharmacological treatment and sufficient occipital donor hair. In males, the combination of FUT with 1 mg oral finasteride daily is recommended to achieve more sustained results.

Beyond Evidence-Based Medicine

Although EBM is becoming regarded as the gold standard for clinical practice, there are a number of limitations of its use. EBM guidelines do not remove the problem of extrapolation to different populations or longer timeframes. Even if several top-quality studies are available, questions

always remain about how far, and to which populations, their results may be generalised. Certain groups have been historically under-researched, such as racial minorities and people with many comorbid diseases, and thus the literature is sparse in areas that do not allow for generalising. EBM applies to groups of people, but this does not preclude clinicians from using their personal experience in deciding how to treat each patient. Ex cathedra statements by the medical expert are considered to be the least valid form of evidence. Nevertheless, knowledge gained from clinical research does not directly answer the primary clinical question of what is best for the patient at hand and suggests that EBM should not discount the value of clinical experience. Good medical practice means integrating individual clinical expertise with the best available external clinical evidence from EBM.

Finally, one must remain open-minded for the possibility of a multitude of cause relationships underlying hair loss, including seasonality of hair growth and shedding, hormonal factors, nutrition, and medications; especially in the elderly the problems of comorbidities and multimorbidity must be taken into account.

Ultimately, combination treatments with topical minoxidil, oral finasteride, nutritional supplements, scalp surgery, and appropriate hair care may act synergistic to enhance hair growth (Fig. 5.3a, b). The scientific rationale for such an approach is given, but there is a need for clinical studies to establish increase in efficacy of combination regimes and adjuvant treatments.

At length, the influence of the prescribing physician should be kept in mind, since inspiring confidence versus scepticism and fear clearly impacts the outcome of treatment. Treatment

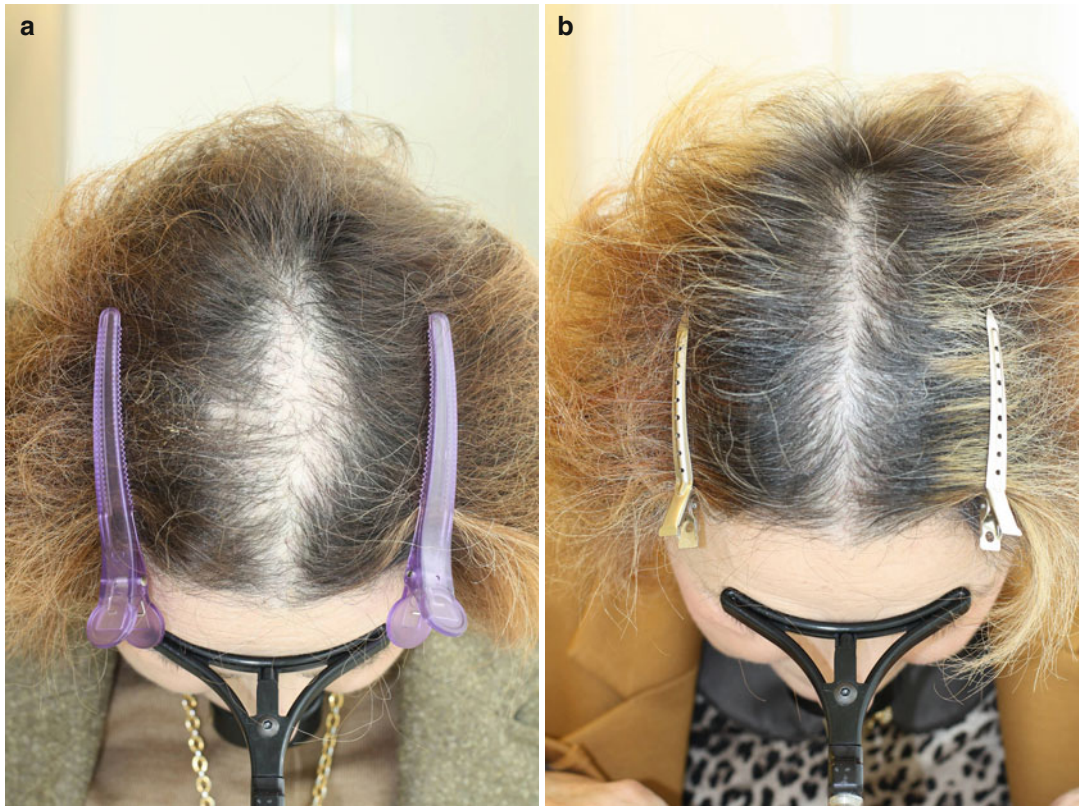

Fig. 5.3 Successful treatment of cicatricial-pattern hair loss in a 64-year-old female with 0.5 mg oral dutasteride, topical 5 % minoxidil, and 0.2 % triamcinolone acetonide, (**a**) before and (**b**) 3 months after autologous hair transplantation

success relies on patient compliance that, on its part, relies on comprehension of treatment benefit, confidence, and motivation. The overall goal is to gain short-term compliance as a prerequisite to long-term adherence to treatment.

A positive physician-patient relationship and regular follow-up visits are the most important factors in determining the degree of patient compliance. Only treatments that are effective in circumstances they are required should be recommended. Dosage regimen should be simplified by selecting different treatment or using a preparation that needs fewer doses during the day, e.g. 5 % topical minoxidil once daily instead of 2 % topical minoxidil twice daily for the treatment of female AGA. Treatments with lower levels of side effects or fewer concerns for long-term risks should be selected; possible side effects should be discussed with the patient, together with advice on minimising or coping with side effects. Ultimately, regular follow-up for reassurance on drug safety and treatment benefits is important, typically at 3, 6, and 12 months and yearly thereafter.

Global photographic assessment was successfully established as a standard method for objectively monitoring hair growth in the course of the minoxidil and finasteride trials. Since its introduction the technique has proven to be essential for follow-up of hair loss patients undergoing long-term treatment in daily clinical practice as well. For clinical study purposes the method is used in tandem with the phototrichogram technique. The former reflects the overall clinical changes in the patient over time in a standardised manner, while the latter yields a quantitative measure of the hair number (*n*), hair density (*n*/cm^2), ratio of anagen to telogen phase hairs (%), hair thickness (μm), and linear hair growth rate (mm/day) within a defined area of the scalp. For daily clinical practice, a combination of global photography with trichoscopic examination and photography is recommended.

Patients should be aware of seasonal fluctuations in hair growth and shedding, at times complicating the assessment of pharmacological effects. Awareness of these fluctuations is prerequisite to providing the correct cause and prognosis to the patient, ensuring patient adherence.

In the recent past some issues have arisen concerning the long-term safety of oral finasteride for the treatment of male AGA, e.g. sexual dysfunction, fertility problems, prostate cancer, and depression. For the time being, probably the best way in dealing with them, apart from a detailed patient information and follow-up visits, is to refrain from prescribing finasteride to patients with a personal history of depression, sexual dysfunction, or fertility problems. When fertility is an issue, one may consider performing a sperm count before and during treatment. Finally, PSA levels should be performed in all men 45 years and above, before and after initiating therapy and thereafter on twice yearly basis. The level should drop by ca. 50 % upon initiation of therapy, and in case of an increase >0.4 ng/ml per year, the prostate should be evaluated.

Cicatricial-Pattern Hair Loss

The limited success rate of the treatment of AGA with the available hair growth-promoting agents means that further pathogenic pathways may be taken into account. On histologic examination of scalp biopsies, the miniaturisation of terminal hairs is frequently associated with perifollicular lymphocytic infiltration and eventually fibrosis. The significance of these findings has remained controversial. However, morphometric studies in patients with AGA treated with minoxidil showed that a lesser percentage of those with microinflammation had regrowth in response to treatment, in comparison to those patients without inflammation and fibrosis. Moreover, inflammatory scarring alopecias with a pattern distribution have recently been described, underlining the fact that a subset of patients seemingly suffering of AGA show true signs of follicular inflammation and fibrosis. Finally, in 2005 Olsen acknowledged the existence of clinically significant inflammatory phenomena and fibrosis in AGA and proposed the term “cicatricial-pattern hair loss”. More recently, Kossard (2010) suggested that this unusual alopecia may hold the key to understanding the complex relationship of

pattern alopecia, sex-related differences, and triggers for autoimmune follicular destruction.

Senescent Alopecia

Ageing of the hair is characterised by a reduction in the duration of hair growth and diameter of hair shafts and a prolongation of the interval separating the loss of a hair in telogen and the emergence of a replacement hair in anagen. These phenomena resemble those observed in the course of AGA, though microarray analyses have demonstrated different gene expression profiles in senescent and AGA, suggesting that they represent different entities. In AGA, genes required for anagen onset, hair shaft differentiation, and anagen maintenance are downregulated, while genes for catagen and telogen induction and maintenance are upregulated. In senescent alopecia, genes involved in mitochondrial function are downregulated, while oxidative stress and inflammatory response genes are upregulated. Nevertheless, dermal papilla cells derived from AGA grow slower in vitro than normal dermal papilla cells, and this loss of proliferative capacity is associated with expression of markers of oxidative stress and DNA damage suggesting that dermal papilla cells in AGA are particularly sensitive to environmental stress. In contrast to AGA expression of 5α-reductase and response to treatment with 5α-reductase, inhibitors are decreased in senescent alopecia. Both commonalities and differences between AGA and senescent alopecia have implication for therapy.

Aphthous Stomatitis

6

George Laskaris

Definition and Epidemiology

Recurrent aphthous stomatitis (RAS) or recurrent aphthous ulcers (RAU) are painful oral ulcerations that characteristically recur at intervals ranging from days to months or even years. They represent the most common lesion of the oral mucosa with an overall prevalence, ranging from 15 to 30 %. Females are more commonly affected than males, and although they may begin at any age, they usually start during the second and third decades of life. Familial occurrence is common, and about 30–40 % of the patients with RAS have another affected family member.

Basic Concepts of Pathogenesis

Although RAS is one of the oldest oral diseases known from the time of Hippocrates (460–370 B.C.), its aetiology still remains unclear. Many predisposing factors have been incriminated such as genetics, trauma, food hypersensitivities, stress, infections [*Streptococcus sanguis and S. mitis*, *Helicobacter pylori*, *Herpes simplex virus-1* (*HSV-1*), *Varicella-zoster virus* (*VZV*), *Cytomegalovirus*], systemic diseases (Adamantiadis-Behçet's disease), gastrointestinal disorders (Crohn's disease, ulcerative colitis, coeliac disease), nutritional deficiencies, cyclic neutropenia, blood deficiencies, Sweet's syndrome, human immunodeficiency virus infection (HIV), hormonal changes, immunological disorders and others. Although these predisposing factors may play a role in the developments of RAS, the disease is idiopathic and its aetiology remains unknown. Accumulated data supports the concept that the pathophysiology is immunologically mediated and that the cell-mediated immune response is dysregulated. In addition, several reports show a negative association between RAS and smoking.

Clinical Presentation

The main clinical features of RAS are the recurrence of painful oral ulcerations at intervals ranging from days to weeks or even months. The prodromal stage is variable and is usually characterized by discomfort and occasionally erythema of 1–3 days duration. This stage is soon followed by a painful oral ulcer.

The lesions are usually confined to movable non-keratinized or poorly keratinized oral mucosa, e.g. the buccal mucosa, the labial mucosa, tongue, floor of the mouth, soft palate and uvula. Occasionally the attached gingiva and the hard palate may also be involved. The lesions

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_6, © Springer-Verlag Berlin Heidelberg 2015

usually begin in childhood or adolescence and have a slight predilection for females. Clinicians should keep in mind that RAS may be associated with the following systemic disorders:

- Adamantiadis-Behçet's disease
- Sweet's syndrome
- PFAPA syndrome
- MAGIC syndrome
- Crohn's disease
- Ulcerative colitis
- Coeliac disease
- HIV infection
- Malabsorption syndromes
- Haematinic deficiencies (vitamins B1, B2, B6, B12, folic acid, iron, zinc)
- Neutropenias

Based on clinical criteria, recurrent aphthae are classified into three forms: *minor*, *major* and *herpetiform ulcers*.

Minor RAS

This is the most common form of the disease. It is clinically characterized by a shallow oval and painful ulcer 2–6 mm in diameter (Fig. 6.1). The ulcer is covered by a yellow-white necrotic membrane and is surrounded by an erythematous halo. Ulcers may be single or multiple (Ball et al. 1997; Chavan et al. 2012; Haeyrinen-Immonen et al. 1994; Laskaris 1999, 2012); they persist for 6–10 days, heal with no evidence of scarring and recur usually at 1–5-month intervals.

Fig. 6.1 Minor aphthous ulcer

Fig. 6.2 Major aphthous ulcers

Fig. 6.3 Herpetiform ulcers

Major RAS

This is much less commonly encountered and represents the severe form of RAS. The ulcers are deep, extremely painful and 1–2 cm in diameter, and their number varies from one to three (Fig. 6.2). They last approximately 3–6 weeks and occasionally leave a scar on healing and often recur at 1–3-month intervals.

Herpetiform Ulcers

These belong to the least common variety of RAS. The lesions present as multiple (10–100 or more), shallow ulcers, 1–3 mm in diameter, and characteristically tend to occur in clusters (Fig. 6.3). The ulcers persist for 1–2 weeks, often recur over a period of 1–3 years and are more commonly seen in females. The onset is at an older age than the other forms of RAS.

Table 6.1 The differential diagnosis of aphthous stomatitis

Traumatic ulcer	History, clinical features, histopathological examination
Primary and secondary herpetic stomatitis	History, clinical features, serum viral antibody tests, viral cultures
Hand, foot and mouth disease	Clinical evaluation, viral cultures
Herpangina	Clinical evaluation, viral cultures
Erythema multiforme	Clinical features, histopathological examination
Pemphigus	Clinical features, histopathological examination, direct and indirect immunofluorescence
Mucous membrane pemphigoid	Clinical features, histopathological examination, direct and indirect immunofluorescence tests
Primary and secondary syphilis	Clinical evaluation, microbiology, serological tests
Adamantiadis-Behçet's disease	Clinical features, histopathological examination, HLA antigens
Crohn's disease	Clinical evaluation, histopathological examination
Ulcerative colitis	Clinical evaluation, histopathological examination
Coeliac disease	Clinical evaluation, histopathological and immunological examination
Cyclic neutropenia	Clinical evaluation, repeated determination of neutrophils in the peripheral blood

Diagnosis

The diagnosis of all three forms of aphthous stomatitis is based exclusively on clinical criteria, as there is no specific diagnostic test, unless there is an underlying systemic disease.

Differential Diagnosis

See Table 6.1.

General Principles of Treatment

- It is important in managing RAS to rule out aphthous-like ulcers associated with systemic diseases. The great majority of patients with RAS are healthy individuals without a history or signs of a systemic disease.
- Successful therapy for RAS requires a correct diagnosis and control of the contributing aetiological factors.
- The treatment of RAS depends on the frequency, the number and the size of the ulcers.
- A wide spectrum of therapeutic regimes or agents have been suggested, but the management of RAS is unsatisfactory, as there is no cure and all attempts are palliative.
- The goal of treatment should be (a) elimination of pain and discomfort, (b) shortening of the course, (c) extension of the time between recurrence and (d) avoidance of recurrence (see table 6.2).

Recommended Therapies

Control of Possible Contributing Aetiological Factors

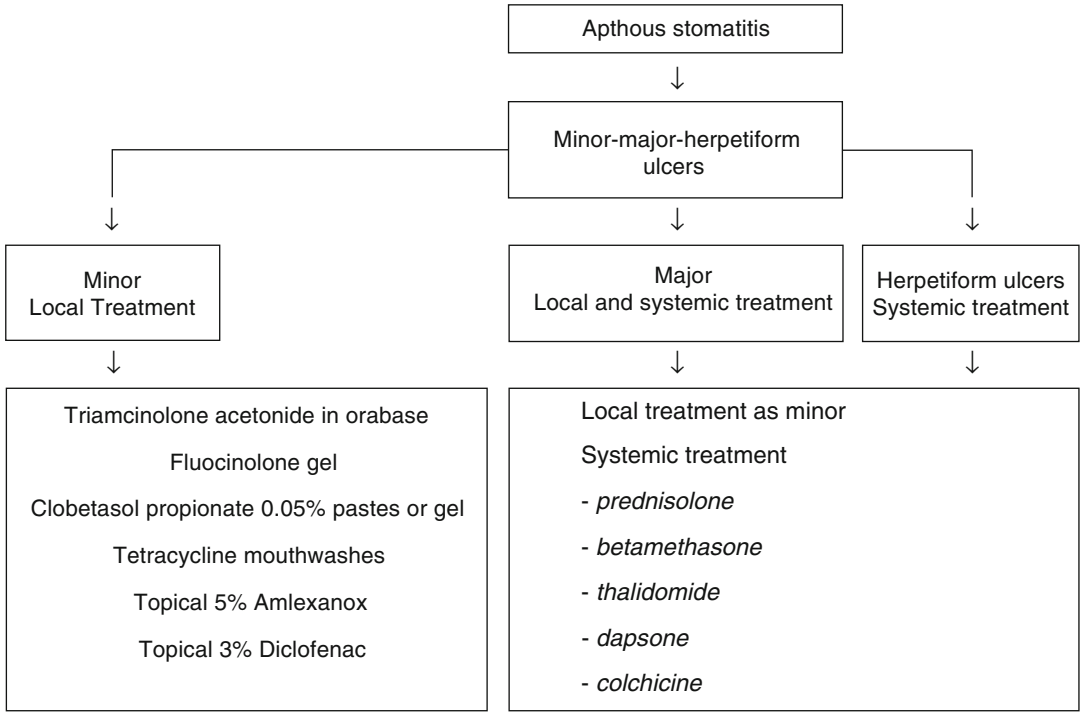
Patients should be encouraged to keep a food diary in an attempt to identify a potential precipitating link with the onset of aphthous ulcers. Patients should avoid minor trauma of the oral mucosa. Stress and female sex hormonal changes should also be controlled. A gluten-free diet may be useful in controlling lesions even in the absence of coeliac disease.

Topical Measures

Topical medications may reduce pain and shorten the course, but they do not prevent recurrence.

Topical anaesthetics such as 2 % viscous lidocaine, benzocaine and benzydamine hydrochloride may reduce pain only for a short time. Recently, 5 % amlexanox oral paste and 3 % diclofenac in 2.5 % hyaluronan have also been used to reduce pain. Topical tetracyclines have been used with partial success. A 250-mg capsule is dissolved in 30 mL of water. Then 5 mL of the solution is used to rinse the lesion four to six times a day. This is repeated for 3–5 days. Many other anti-inflammatory and antimicrobial agents (e.g. chlorhexidine) have also been used with unsatisfactory results. The best of the topical treatments is 0.1 % triamcinolone acetonide in an

Table 6.2 Proposal treatment of aphthous stomatitis



oral adhesive base (Orabase) or fluocinonide gel (Lidex gel) or clobetasol propionate gel 0.05 % (Temovate) applied to the ulcer three to four times a day for 4–6 days. Intralesional injection of triamcinolone acetonide retard or betamethasone dipropionate and sodium phosphate retard may be successfully used only in major aphthous ulcers.

Systemic Measures

Systemic corticosteroids (prednisolone, betamethasone) in an average dose of 20–30 mg or 2–3 mg, respectively, for 4–8 days is very helpful for major ulcers or herpetiform ulcers. In cases of repeated episodes and when new ulcers occur before the previous ones have healed, systemic medications may prove useful in preventing new lesions.

In my experience 20 mg prednisolone or 2 mg betamethasone for 10–15 days and then an injection of betamethasone dipropionate and sodium phosphate retard every 2 weeks for a period of 2 months may significantly increase the time intervals between recurrence. Long-term systemic corticosteroid is contraindicated because of its side effects.

In severe cases with a high recurrence rate and in HIV-infected patients, thalidomide 100–300 mg/day for 2–3 months may result in complete remission of the ulcers for a long time. However, teratogenesis and polyneuropathy preclude the routine use of thalidomide.

Clinicians should know that safe prophylaxis of RAS recurrence for a long time is not available. Conclusively, until RAS aetiology is discovered, treatment will remain partially effective.

Alternative and Experimental Treatments

In severe cases, many other systemic medications have been used with ambiguous results. These include the following:

- Dapsone 25–50 mg/day for several weeks
- Levamisole hydrochloride
- Azathioprine
- Colchicine
- Interferon-α
- Cyclosporine
- Pentoxifylline
- Clofazimine
- Acyclovir
- Etretinate

Atopic Dermatitis

7

Angelo Massimiliano D'Erme and Jan D. Bos

Abbreviations

AD	Atopic dermatitis
ASIT	Allergen-specific immunotherapy
BB-UVB	Broadband ultraviolet B
CsA	Cyclosporine A
EASI	Eczema area and severity index
EH	Eczema herpeticum
EM	Eczema molluscatum
FTU	Fingertip unit
MMF	Mycophenolate mofetil
MTX	Methotrexate
nbUVB	Narrowband UVB
SCORAD	Scoring of atopic dermatitis
TCI	Topical calcineurin inhibitors
TCS	Topical corticosteroids
UV	Ultraviolet irradiation

Key Points

- Atopic dermatitis (AD) is an inflammatory, pruritic, chronic, or chronic relapsing skin disease.
- The hallmarks of atopic dermatitis are a chronic, itching, and relapsing skin inflammation, a disturbance of epidermal-barrier function that culminates in dry skin, and IgE-mediated sensitization to food and environmental allergens.
- Because the skin-barrier dysfunction, dry skin, and chronic inflammation are features of AD, short-term and long-term management plans have to be carried out.
- The long-term management should emphasize prevention, intensified skin care, the control of chronic inflammation, and reduction of bacterial colonization.
- The basic therapy is represented by basic rules the patient has to follow in order to counteract every day the disturbed barrier function.
- The patient has to be carefully educated to:
  - Cleansing and bathing
  - Application of emollients
  - Avoidance of irritants and identification and addressing of specific trigger factors
  - Antimicrobial treatment

- The new *proactive* approaches (low weekly dose/application of topical corticosteroids/topical calcineurin inhibitors (TCS/TCI) for a long period) aim to control the residuals of the disease and to prevent new flares. These approaches have been shown to be safe and effective, to reduce the use of the pharmacological treatment, and to improve the quality of life of patients.
- Many patients achieve very good results from artificial UV (ultraviolet) radiation, mainly UVA1 and narrowband UVB as well as *heliotherapy and balneophototherapy*.
- *Cyclosporine A* is an immunosuppressant drug licensed in many European countries for treatment of AD. Despite its well-proved efficacy, its side effects limit its use, especially in long-term treatment.
- *Systemic steroids* are commonly used, but they present a largely unfavorable risk/benefit ratio for the treatment of this disease.
- Pruritus in AD has a multifactorial and complex etiopathogenesis. Despite that antihistamines have been used for decades, in attempt to relieve pruritus, surprisingly there are no conclusive data concerning the real efficacy of oral antihistamines in the treatment of pruritus in AD.

Definition and Epidemiology

Atopic dermatitis (AD), also called atopic eczema, neurodermitis (in German-speaking countries), or endogenous eczema, is an inflammatory, pruritic, chronic, or chronic relapsing skin disease. It is one of the most common skin diseases affecting up to 30 % of children and 1–3 % of adults in Europe. The prevalence of AD has doubled or tripled in industrialized countries during the past decennia, and its incidence is still increasing.

This disorder can represent the first step in the development of other atopic diseases including allergic oculo-rhinitis, asthma, and other allergic diseases.

The lower prevalence of AD in rural as compared with urban areas suggests a link to the "hygiene hypothesis," which supposes that the absence of exposure to infectious agents at early age increases the susceptibility to allergic diseases.

The hallmarks of atopic dermatitis are a chronic, itching, and relapsing skin inflammation, a disturbance of epidermal-barrier function that culminates in dry skin, and IgE-mediated sensitization to environmental and food allergens.

It is clinically characterized by a heterogeneous spectrum of clinical manifestations, varying with age. Clinical and laboratory criteria have been introduced for the definition. The most commonly used are the Hanifin and Rajka criteria.

Basic Concepts of Pathogenesis

Atopic dermatitis is a very complex genetic disease that is the result of gene–gene and gene–environment interactions. Research in the last decades has led to change the view in genomic and immunologic mechanisms that drive cutaneous inflammation. They have highlighted the critical role of the epidermal-barrier function and the immune system.

The genetic influence is important as shown by the higher concordance rate for AD among monozygotic twins (about 80 %) than dizygotic twins (about 20 %).

Characteristic features of pathophysiology have to be considered in a personalized or stratified approach to a patient suffering from AD. They are the following:

- Th2 immune response in the initiation phase with consequent increased IgE production. It precedes a chronic phase in which Th0 cells (cells that share some activities of both Th1 and Th2 cells) and Th1 cells are predominant.
- Abnormal skin-barrier function that causes "dry" skin. It is the result of epidermal-barrier components (filaggrin mutation, protease inhibitor deficiency, etc.) and/or abnormal lipid metabolism.

- Microbial colonization with pathogenic organisms, such as *Staphylococcus aureus* and *Malassezia furfur*.
- Strong psychosomatic factors that influence the autonomic nervous system and an increased production of inflammatory mediators.
- Pruritus that induces scratching that, as a vicious circle, increases pruritus.

A new picture of the pathogenesis of AD has emerged recently, and it is possible to highlight three phases (Fig. 7.1).

The first phase, the *nonatopic form* of AD (when sensitization is not occurred yet) is the result of genetically determined epidermal-barrier dysfunction and the effect of environmental factors.

Subsequently, many patients (60–80 %) become sensitized as a consequence of the interaction between the genetic predisposition for IgE-mediated sensitization, the allergen exposition, and *Staphylococcus aureus* enterotoxin products (*atopic form of AD*).

In a last phase, which can occur also in early life, the release of structural proteins due to tissue damage by scratching and molecular mimicry with *Staphylococcus aureus* proteins triggers an IgE response to self-proteins (*autoreactivity*). The presence of auto-IgE has been shown to be associated to a worse prognosis (higher severity and higher risk of becoming chronic).

Clinical Presentation

Atopic dermatitis is an itching and inflammatory disorder that, starting often in early age, can present a chronic or chronic relapsing course.

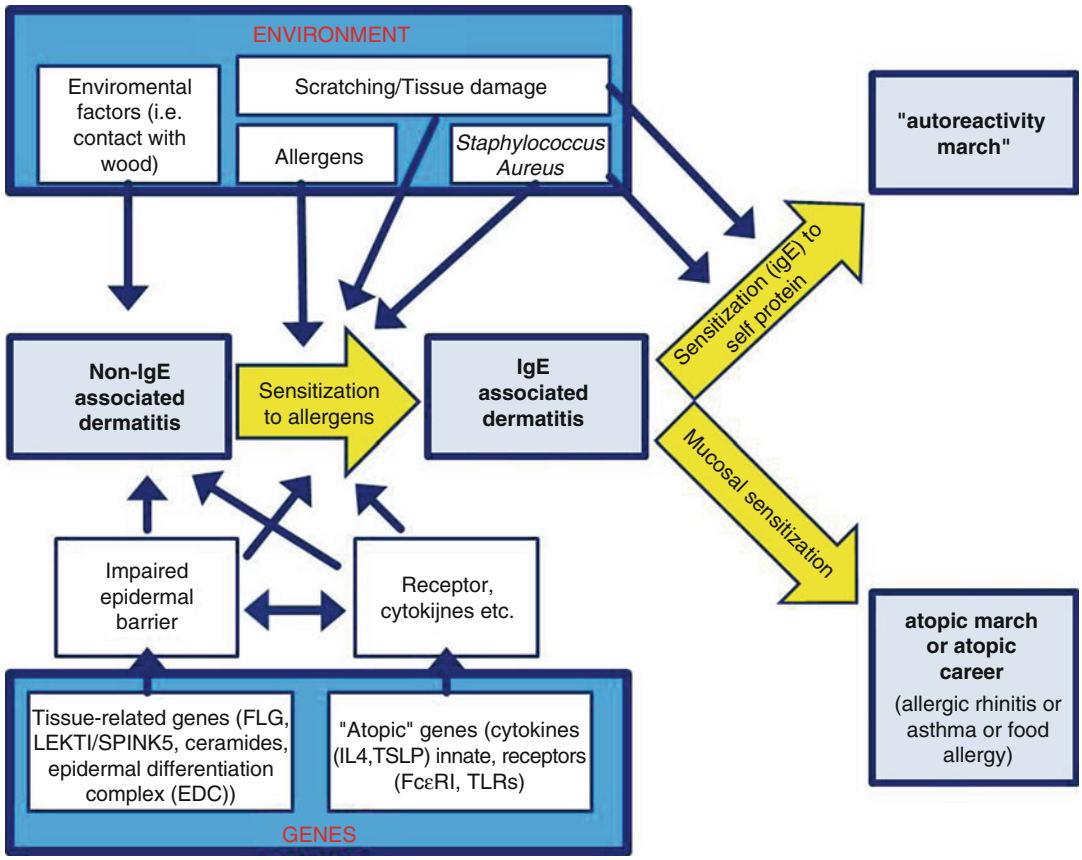

Fig. 7.1 Pathogenesis course of AD (From Bieber (2008, 2011))

Fig. 7.2 Atopic dermatitis involving antecubital flexures

AD may be divided in four phases: infantile, childhood, adolescent/adult, and senile phases.

The infant phase usually starts during the third month, and it is characterized by red scaling areas on the cheek and chin, sparing the perioral and paranasal regions. Moreover, the eczema lesions can affect the arms, legs, and trunk. Scratching, which frequently starts a few weeks later, causes crusted erosions. The nappy area is usually spared.

Exudative lesions typical of the infant phase are not common in the childhood phase.

In the latter, lesions involve flexures, the nape, and the dorsal aspects of the limbs, and they are characterized by lichenification and depigmentation (Fig. 7.2).

AD, in adolescence and adulthood, is characterized by lichenified eczematous plaques affecting flexures, hand and/or foot, face (typical around the eyes), and neck (Fig. 7.3).

Lastly, an AD may occur in the elderly. Manifestations similar to adult AD, such as eczematous dermatitis involving the face and neck, trunk, and extensor and flexure sites of extremities, and atypical ones, as diffuse eczema, xerosis, and nummular eczema, have been described.

In each stage, the presence of pruritus all day long causes sleep loss and substantially impairs the patient's quality of life.

Despite that part of children have a spontaneous remission before adolescence, in a lot of cases, the dermatitis becomes a lifelong chronic disease and persists up to adulthood and elderly, often with intermittent periods of remission.

Fig. 7.3 Atopic dermatitis in adulthood involving popliteal flexures

According to the classification of Wuthrich, it is possible to distinguish five subgroups based on the age of onset: previous to 2 years (the so-called early-onset AD) (60 % of cases), between 2 and 6 years, between 6 and 14 years, between 14 and 20 years, and later than 20 years (the so-called late onset).

The early onset is characterized by an increased risk of development of high levels of total and specific IgE (also known as *atopic march* or *atopic career*). The presence of high level of IgE is connected to the risk for AD of becoming chronic.

On the basis of the presence of IgE, one classification distinguishes an IgE-associated form of AD (called "extrinsic" AD) from a non-IgE-associated form (called "nonatopic" or "intrinsic" or "atopiform" AD). This division might imply that extrinsic and intrinsic forms are two different diseases. As seen previously, the absence of IgE-mediated sensitization may be only a transient factor, and there is a need to reconcile these divergent hypotheses and to better describe the two "forms" and the different courses. In fact, a few patients with "intrinsic" AD will never produce high level of IgE, and they will not develop the atopic march. In these patients, allergen avoidance does not make sense. On the other hand, it is important to recognize which patients become sensitized (extrinsic AD) because they will benefit from allergen avoidance.

Moreover, as reported in a recent paper by Garmhausen et al. (2013), the dermatitis is often chronic, and it is possible to individualize five most common groups according to the onset and course of AD. These five groups, which cover the 85 % of the clinical course of AD, differentiate each other for the onset (one group for each of the five Wuthrich's groups) and for some clinical characteristics (i.e., the development of IgE is higher in those with early onset). It is worthy to know that in these five groups, the disease persists up to the adulthood with a chronic course.

Several criteria have been established in the diagnoses of AD. Since there are no laboratory tests available to confirm the diagnosis, this is made clinically. For the heterogeneous clinical presentations and courses, it becomes very important to individualize some candidate biomarkers, characterized by the potential use for screening patients, to prevent and to recognize the disease, to perform the prognosis, and to better manage the disease.

The Hanifin and Rajka criteria published in 1980 represent an important tool in performing the diagnosis (Table 7.1). To fulfill the criteria, the patient must have three or more of the major and three or more of the minor criteria.

Rarely a biopsy can be necessary. The histologic features of acute eczematous patches are spongiosis pattern and a prominent perivascular infiltrate of lymphocytes, monocyte macrophages, and some eosinophils in the dermis. In subacute and chronic lichenified plaques, the spongiosis is milder, the epidermis is thickened, and its upper layer is hypertrophied.

The presence of atopy can be confirmed by serum testing (i.e., radioallergosorbent test or RAST) or by intracutaneous challenge, looking for allergen-specific IgE antibodies to:

- House dust mite
- Pollen (tree, grass, weed)
- Animal dander (cat, dog)
- Molds
- Food (apple, peanuts, etc.)

Table 7.1 Hanifin and Rajka criteria

Major criteria
Pruritus
Flexural lichenification
Chronically relapsing course
A personal or family history of atopy
Minor criteria
Xerosis
Ichthyosis
Immediate skin test reactivity
Elevated serum IgE
Early age of onset
Tendency for developing cutaneous infections
Tendency for developing nonspecific hand or foot dermatitis
Dennie–Morgan infraorbital fold
Keratoconus
Anterior subcapsular cataracts
Orbital darkening
Facial pallor/erythema
Pityriasis alba
Itch when sweating
Intolerance to wool and lipid solvents
Perifollicular accentuation
Food intolerance
The influence of emotional factors
White dermographism/delayed blanch

Presently, the level of total IgE can allow us to help distinguish "intrinsic" AD from "extrinsic."

After establishing the diagnosis of AE, the severity of the disease has to be determined. The classical method is the "scoring of atopic dermatitis" (SCORAD) developed by the European Task Force on Atopic Dermatitis. The patient-oriented SCORAD (PO-SCORAD) is a new patient-assessment scale in atopic dermatitis validated in Europe that has demonstrated a good correlation with SCORAD.

AD with an objective SCORAD higher than 40 is generally regarded as "severe," whereas below 20 can be regarded as "mild."

Differential Diagnosis

Due to the heterogeneous manifestations, a lot of diseases have to be distinguished from AD at different ages. The main differential diagnoses are reported in Table 7.2.

General Principles of Treatment

As a result of the skin-barrier dysfunction, dry skin and chronic inflammation are features of AD, and short- and long-term management has to be carried out. The long-term management should emphasize prevention, intensified skin care, the control of chronic inflammation, and reduction of bacterial colonization.

Correct skin care programs and allergen avoidance strategies should be beneficial in infants and children before and after the diagnosis of IgE-mediated sensitization.

Early and proactive pharmacological intervention can control the skin inflammation, prevent new flares, and reduce the *S. aureus* colonization.

According to the European guidelines published recently (Ring et al. 2012a, b), some therapeutical proposals are summarized in Fig. 7.4.

It is possible to classify the therapeutical proposal in three main groups: basic therapy, topical therapy, and phototherapy/systemic therapy.

Basic Therapy

The basic therapy is represented by basic rules the patient has to follow in order to contrast every day the disturbed barrier function. The skin must be cleaned gently and carefully in order to get rid of crusts and mechanically eliminate bacterial contaminants.

The duration of the bath is suggested short (5 min) and daily. The use of bath oils has to be preferred in order to avoid epidermal dehydration.

Topical emollients for restoring the stratum corneum are preferentially applied directly after a bath or a shower when the skin is still slightly humid. Their long-term use is highly suggested, except on inflamed acute patches because it is poorly tolerated. It is better to treat the inflamed skin with pharmacological medication first.

The amount required is usually high, and the cost may restrict their use (only in a few countries they are reimbursed). The high-quality emollients (i.e., sterile and low in contact allergens) are suggested, but sometimes their higher cost may reduce the patient's compliance. A better knowledge of the AD pathogenesis may help to develop new specific topical agents versus barrier defects (i.e., mutation or filaggrin).

Glycerol, urea plus sodium chloride, and white petrolatum with liquid paraffin in equal parts are very effective. Glycerol seems to be better tolerated than urea plus sodium chloride.

Preventive use of emollients containing allergens such as peanuts may increase the risk of skin sensitization and allergy.

As reported in the European guidelines, there is consistent evidence of short- and long-term steroid-sparing effect by a regular use of emollients. Furthermore, their use has an important role in the persistence of remission obtained with topical corticosteroids/topical calcineurin inhibitors.

Elimination of Trigger Factors

Numerous environmental factors can irritate the skin of patients with AD that is usually more sensitive than healthy controls. Sometimes these factors can trigger eczema flares.

Table 7.2 AD differential diagnoses

Type of disease	Diagnosis	Differentiating features	Age	Notes
Inflammatory	Seborrhoeic eczema	Seborrhoeic areas	Infantile AD	Sometimes the diagnosis is challenging
		No excoriated lesions on the extremities		
	Allergic contact dermatitis	No improvement with appropriate treatment	Childhood, adolescence/ adulthood, elderly	
		Patch test positive		
	Irritant contact dermatitis	No improvement with appropriate treatment		
		Carefully anamnesis		
	Photocontact and photoallergic dermatitis	Photodistribution	Childhood, adolescence/ adulthood, elderly	
		Photopatch test positive		
	Lichen simplex chronicus (LSC)	Clinical presentation Circumscribed, limited to single area	Childhood, adolescence/ adulthood, elderly	LSC can be a consequence of an AD patch
	Psoriasis	Sharply demarcated, scaly, biopsy, carefully anamnesis	All the ages	The differential diagnosis between psoriasis and AD severe at the hands can be very challenging
	Xerotic eczema	No history of AD, clinical presentation (diffuse xerosis)	Elderly	
	Erythroderma	Carefully anamnesis. Clinical presentation		AD can be a cause of erythroderma
	Nodular prurigo (NP)	Carefully anamnesis. Clinical presentation (nodular lesions mainly at the arms and legs)	Adulthood, elderly	Atopy history can be present in patient with NP
Infectious	Dermatomycosis	Carefully anamnesis	Children, adulthood, elderly	
		KOH examination		
	Scabies	Interdigital or genital burrow	All the ages	Lesions involving the face can be present in the infants
Immunological or infiltrative	Cutaneous T-cell lymphoma (CTCL)	Clinical presentation, histology	Adulthood, elderly	
	Wiskott–Aldrich syndrome (WAS)	Thrombocytopenia	Infant, childhood	The clinical findings of WAS are almost indistinguishable from AD
	Hyper-IgE syndrome	γ-Globulin, boys	Infant, childhood	
	Severe combined immunodeficiency (SCID)	Clinical presentation: pyoderma and candidiasis	Infant	

(continued)

Table 7.2 (continued)

Type of disease	Diagnosis	Differentiating features	Age	Notes
Genetic	Netherton's syndrome	Bamboo hairs	Infant	SPINK5 (serine protease inhibitor Kazal-type 5)/LEKTI (lymphoepithelial Kazal-type-related inhibitor) is involved also in AD
	Acrodermatitis enteropathica	Clinical examination (periorificial area distal extremities)	Infant	
	Ataxia, telangiectasia (AT)	Ataxia, telangiectasia, pigmentation abnormalities	Infant	AD was noted in two patients with AT
	Ectodermal dysplasia	Anhidrosis, dental or hair abnormalities	Infant	
	Phenylketonuria	Pyogenic infections, laboratory phenylalanine	Infant	

Modified from Beltrani et al.

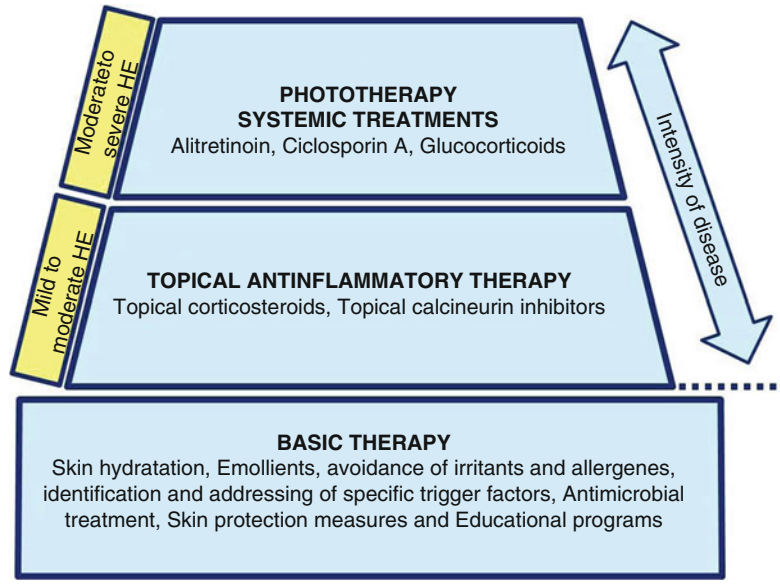

Fig. 7.4 Stepwise management of patients with AD

They can be physical (i.e., wool, irritating synthetic fibers, occlusive clothing, prolonged hot showers, high or low temperature, low humidity, indoor and outdoor environments, and smoking exposure), chemical (acids, bleaches, use of nickel-releasing jewelers, solvents, soaps, perfumes, makeup, and water), or biological (microbes). It is important to educate the patients to identify and avoid the individual trigger factors. Thus, adequate skin care and hygiene procedures at home and at job place have to be discussed with the patient.

Allergen Avoidance

Regarding the aeroallergens, the most important in atopy are the following:

- House dust
- House dust mite
- Pollen (tree/grass/weed)
- Animal dander (cat/dog)
- Mold

It is generally believed that they should be avoided because they have been shown to elicit eczematous skin lesions. Especially patients who will develop sensitization will benefit from avoidance strategies.

Particularly, house dust mite avoidance strategies have been proved to have positive effects on the course of the disease. House dust mites live in a complex ecosystem consisting of air humidity, temperature, and organic materials. Contacts with these allergens can be prevented with the use of dust mite-proof (Gore-tex) covers for mattresses and pillows, wet-mopping floors, and avoiding rugs (especially in bedrooms).

In spring- and summertime, pollen exposure as well as dusty ambient may exacerbate AE; thus, pollen avoidance measures have to be recommended.

Lastly, in selected highly sensitized patients, an allergen-specific immunotherapy (ASIT) may have positive therapeutic implications in AD and its associated allergic respiratory diseases. The best evidence so far is available for ASIT with house dust mite allergens.

Among food allergens, several studies have emphasized the etiological role of food allergens in AD exacerbation in infancy. Common implicated food allergens are cow's milk, hen's egg, wheat, soy, tree nuts, peanuts, fish, and apple.

It is accepted that the importance of food allergens rapidly decreases with increasing age.

The role of diet and food allergy/intolerance in AD management is still controversial. Patients with moderate to severe AD can benefit from a diet eliminating those foods that have elicitated clinical early or late reactions upon controlled oral provocation tests.

Antimicrobial Treatment

The high rate of cutaneous *Staphylococcus aureus* colonization (up to 90 % in moderate to severe eczema) characterizes the AD lesions.

In general, improving eczema with anti-inflammatory regimens (i.e., topical corticosteroids (TCS), topical calcineurin inhibitors (TCI), and ultraviolet irradiation (UV)) decreases staphylococcus colonization. Anyway, patients can benefit from combination of corticosteroids and antimicrobial treatment, i.e., antiseptics such as triclosan or chlorhexidine, or from the addition of antiseptic to the bathing waters (i.e., natriumhypochlorit).

The use of silver-coated and silk textiles has been introduced recently in the management of AD. They can reduce *S. aureus* colonization and eczema severity.

It is worth to remember that the European Guidelines do not suggest the use of topical antibiotics for long periods due to the risk of sensitizations and increasing resistances. It is important to check in daily practice the possible superinfections of the lesions by bacteria (*S. aureus*), virus (molluscum, herpes), and fungi and to treat them immediately.

Educational Programs

Stress, anxiety, and depression can represent trigger factors because they may reduce the threshold for pruritus. Similarly, pruritus dramatically affects the patients' quality of life and represents a significant trigger for anxiety and depression. To reduce the scratch behavior, the help of psychologist and/or educational programs can be useful.

Psychosomatic counseling in AD can include psychotherapeutic approaches and behavioral therapy techniques.

Educational programs, also known as training programs, or "eczema schools" have been successfully developed in many countries as an adjunct to conventional therapy in children and adults.

Educational programs aim to improve the adherence in eczema management, the itch/scratching cognition, and the clinical and psychological condition.

The nurse-led programs want to achieve a more effective use of topical pharmacological and non-pharmacological therapies, sparing doctor's time.

The evaluation of all these factors is a prerequisite for long-term management of the disease in order to achieve longer phases of remission or total clearance of symptoms.

Basic Therapy at a Glance

The basic therapy is represented by basic rules the patient has to follow in order to contrast every day the disturbed barrier function.

The patient has to be carefully educated properly to:

- Cleansing and bathing (daily, short, and with the use of bath oils)
- Application of emollients (at least once a day, directly after a bath or a shower when the skin is still slightly humid)
- Avoidance of irritants (chemical, physical, and biological) and aero- and food allergens
- Identification and addressing of specific trigger factors
- Antimicrobial treatment
- Attend educational programs

The evaluation of all these factors is a prerequisite for long-term management of the disease in order to achieve longer phases of remission or total clearance of symptoms.

Topical Anti-inflammatory Therapy

Before corticosteroids were introduced in the late 1950s, coal tar ointment was the most frequently used therapy.

Nowadays, topical corticosteroids (TCS) and, recently, topical calcineurin inhibitors (TCI) have replaced the previous medication.

In a correct management program, proper strength, dosage, and application have to be taken into consideration.

Previously anti-inflammatory topical therapy was suggested to be used only to lesional skin. Their use had been stopped or tapered down when the visible lesions were cleared. In the last years, this *reactive* approach (Fig. 7.5a) has been combined with the *proactive* approach (Fig. 7.5b), which is

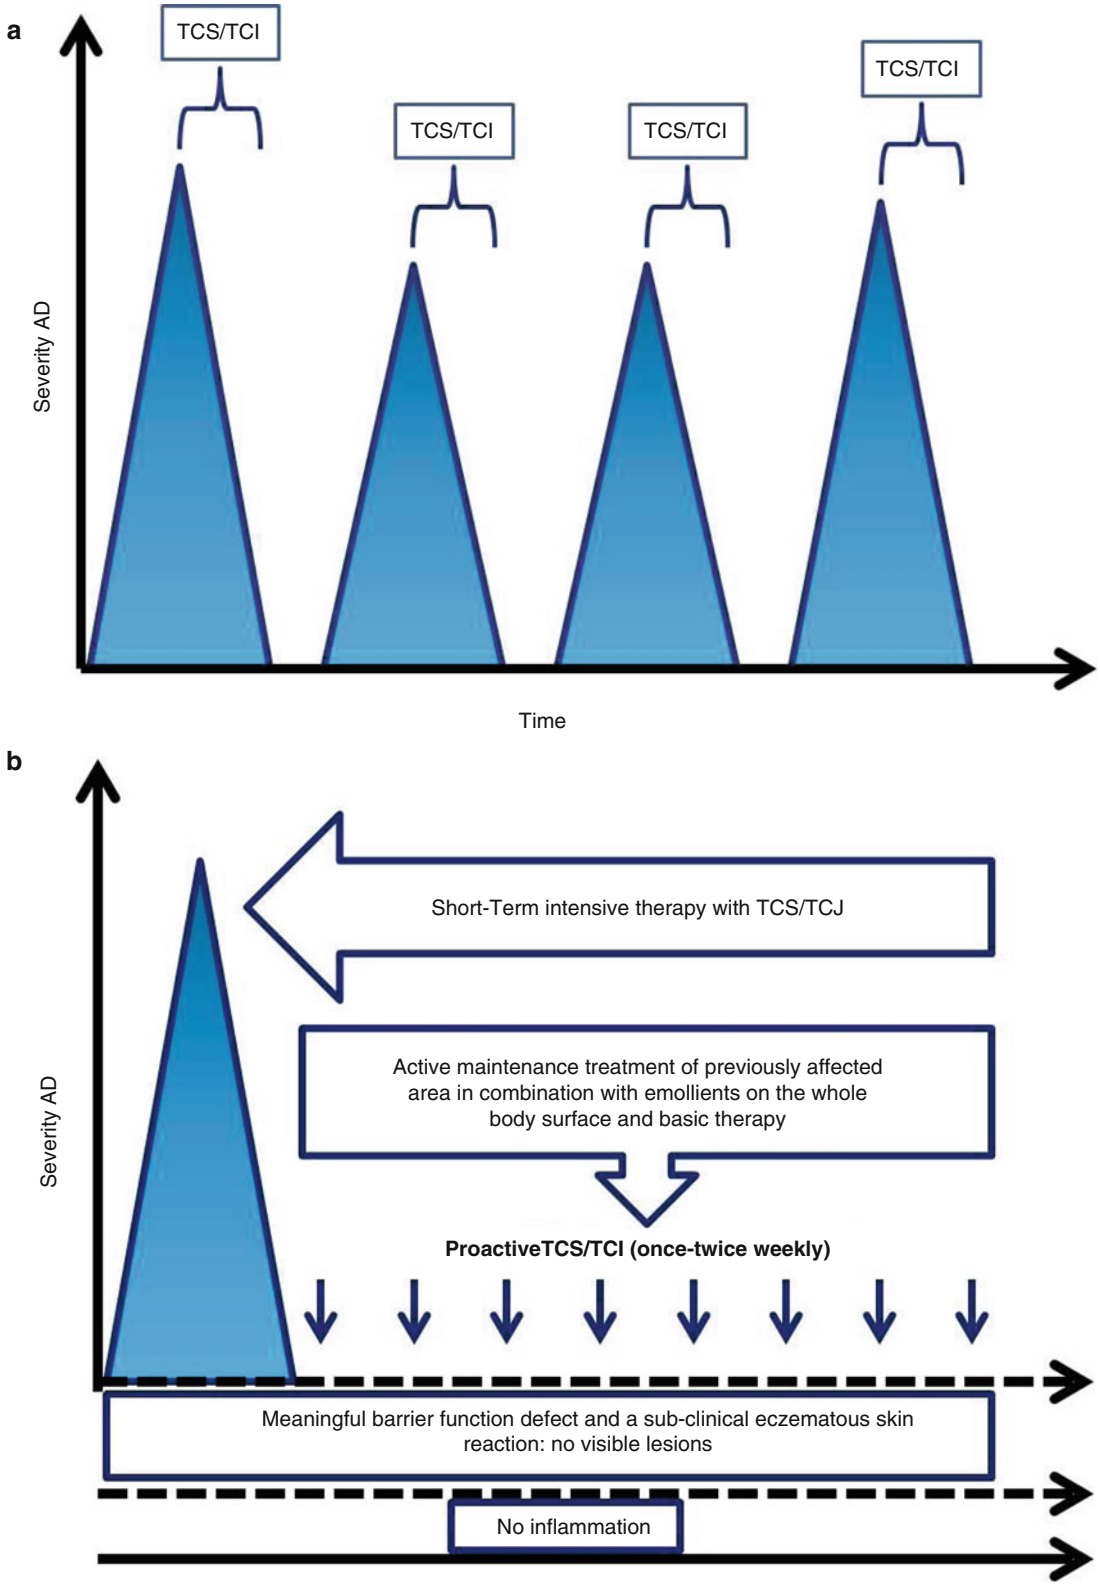

Fig. 7.5 (**a**) Reactive approach. (**b**) Proactive approach

defined as a predefined, long-term, low-dose treatment with anti-inflammatory drugs that have to be applied to the previously affected areas.

The use of emollients on the entire body and basic therapy remain the basis with whom the reactive and proactive anti-inflammatory treatments are going to be combined. The emollient should be applied first, about 15 min before the topical anti-inflammatory treatments. Patients with acute and erosive lesions sometimes do not tolerate standard topical application. In these cases, wet wraps should be used. They are also protective to persistent scratching, and they decrease the itch by cooling the skin.

Topical Corticosteroids

Topical corticosteroids (TCS) are a first-line anti-inflammatory treatment in AD.

They can be applied on inflammatory skin according to the needs (pruritus, sleeplessness, new flares). A large variety of topical steroids are available. The potency of these corticosteroids ranges from mild to very potent. In addition, the vehicle may differ, which is of limited influence on therapeutic efficacy. Most steroid preparations are available as lotion, cream, fatty cream, and ointment. It is worthy to remember that the corticosteroid concentration and its efficacy may be different when the preparation changes. For example, fluticasone propionate 0.005 % ointment is considered a potent corticosteroid, while fluticasone propionate 0.05 % cream is a moderately potent corticosteroid. Another analogous example can be made with mometasone: in this case, the concentration of the active principle is the same.

An overview is given in Table 7.3.

To prevent tachyphylaxis, side effects, and rebound phenomena, it is suggested to use a potent steroid in a short term, followed by a less potent preparation. Tachyphylaxis is the phenomenon that a given therapy loses efficacy during continuous treatment.

In the first weeks, TCS can be used once or twice daily in combination with basic therapy. Then, they should be used once/twice a week as maintenance (*proactive therapy*) for a long period, and during the other days the patients continue with only emollients.

The patient should be instructed to not stop the treatment too early and to be educated in the correct use of TCS for a long period. In fact, with subclinical to mild disease activity, a small amount of topical corticosteroids from once to thrice weekly (considering a monthly amount in the mean range of 15 g in infants, 30 g in children, and up to 60–90 g in adolescents/adults), together with a correct use of emollients, generally allows a good and long-term maintenance therapy.

The application amount of topical anti-inflammatory therapy should follow the fingertip unit (FTU) rule. An FTU corresponds to the amount of topical corticosteroid measured from the distal skin crease to the tip of the index finger (approximately 0.5 g); this amount should cover two adult palm areas.

Topical Calcineurin Inhibitor (TCI)

Tacrolimus ointment and pimecrolimus cream are macrolide-type inflammatory cytokine inhibitors licensed for topical eczema treatment. They have a mechanism of action similar to cyclosporine A (CsA). Differently from the latter, they are effective in the topical treatment of AD due to their relative small size.

They are available in two different formulations of tacrolimus ointment: 0.03 and 0.1 %. In Europe, the first is licensed for children over the age of 2 years, and the latter over 16. There is only one formulation of pimecrolimus: 1 % cream, licensed for older than 2.

The anti-inflammatory efficacy of 0.1 % tacrolimus ointment is similar to a corticosteroid with intermediate activity, which is more active than 1.0 % pimecrolimus cream.

TCI are highly effective against pruritus. In contrast to TCS, they have a more favorable side-effect profile that allows their use in daily practice.

They are usually used as second-line therapy in patients who do not respond adequately to TCS or in whom their use is contraindicated.

Some typical effects of long-term use of corticosteroids, such as atrophy, telangiectasia, and

Table 7.3 Overview of the topical corticosteroids commonly used in AD

Power of corticosteroids	Active principle	Formulation
Very potent	Betamethasone dipropionate	Ointment (0.05 %), cream (0.05 %)
	Clobetasol propionate	Ointment (0.05 %), cream (0.05 %)
Potent	Amcinonide	Ointment (0.1 %), lotion (0.1)
	Betamethasone valerate	Ointment (0.01 %)
	Budesonide	Cream (0.025 %)
	Desoxymethasone	Ointment (0.25 %), cream (0.25 %), gel (0.05 %)
	Fluocinonide	Ointment (0.05 %), cream (0.05 %), gel (0.05 %)
	Fluticasone propionate	Ointment (0.05 %)
	Methylprednisolone aceponate	Ointment (0.1 %), cream (0.1 %), emulsion (0.1 %)
	Mometasone furoate	Ointment (0.1 %)
	Triamcinolone acetonide	Ointment (0.5 %), cream (0.5 %)
Moderately potent	Clobetasone butyrate	Cream (0.05 %)
	Betamethasone valerate	Cream (0.01 %), lotion (0.01 %)
	Fluocinolone acetonide	Ointment (0.025 %), cream (0.025 %)
	Fluticasone propionate	Cream (0.05 %)
	Hydrocortisone butyrate	Cream (0.1 %)
	Mometasone furoate	Cream (0.1 %)
	Triamcinolone acetonide	Ointment (0.1 %), lotion (0.1 %)
Mild potency	Hydrocortisone acetate	Cream (0.5 %)
	Betamethasone valerate	Lotion (0.05 %)
	Triamcinolone acetonide	Cream (0.1 %)

From Luger (2011), modified

striae, are not reported with the use of TCI. TCI are especially indicated in delicate body areas, such as the face (eyelids, perioral skin), intertriginous sites, and the anogenital area.

Burning of the skin or a feeling of warmth is a side effect of these new compounds. It starts about 5 min after each application and may last up to 1 h. These side effects usually disappear after a few days of treatment. Only a transient increase of viral infections such as eczema herpeticum (EH) or eczema molluscatum (EM) has been observed during TCI treatment. These drugs are contraindicated for use in infected skin, and they have to be stopped in case of superinfections. Clinical and preclinical data do not indicate an increased incidence of the induction of lymphoma or photocarcinogenicity for TCI. However, UV avoidance and/or protection has been advised due to the known risk of these side effects from the oral administration of the tacrolimus or cyclosporine.

"New" Proactive Approaches

The chronic and relapsing nature of AD stimulated the insiders to develop long-term management strategies. Research has shown that normal-looking, nonlesional AD skin is not normal at all, but it is characterized by a clinically meaningful barrier function defect and a subclinical eczematous skin reaction.

In the last years, the *reactive* approach (Fig. 7.5a) has been combined with the *proactive* approach (Fig. 7.5b), which is defined as a predefined, long-term, low-dose treatment with anti-inflammatory drugs that have to be applied to the previously affected areas.

These new *proactive* approaches aim to control this subclinical disease with minimal use of anti-inflammatory drugs (Fig. 7.5b). These approaches have been shown to be safe and effective, to reduce relapses and the use of the

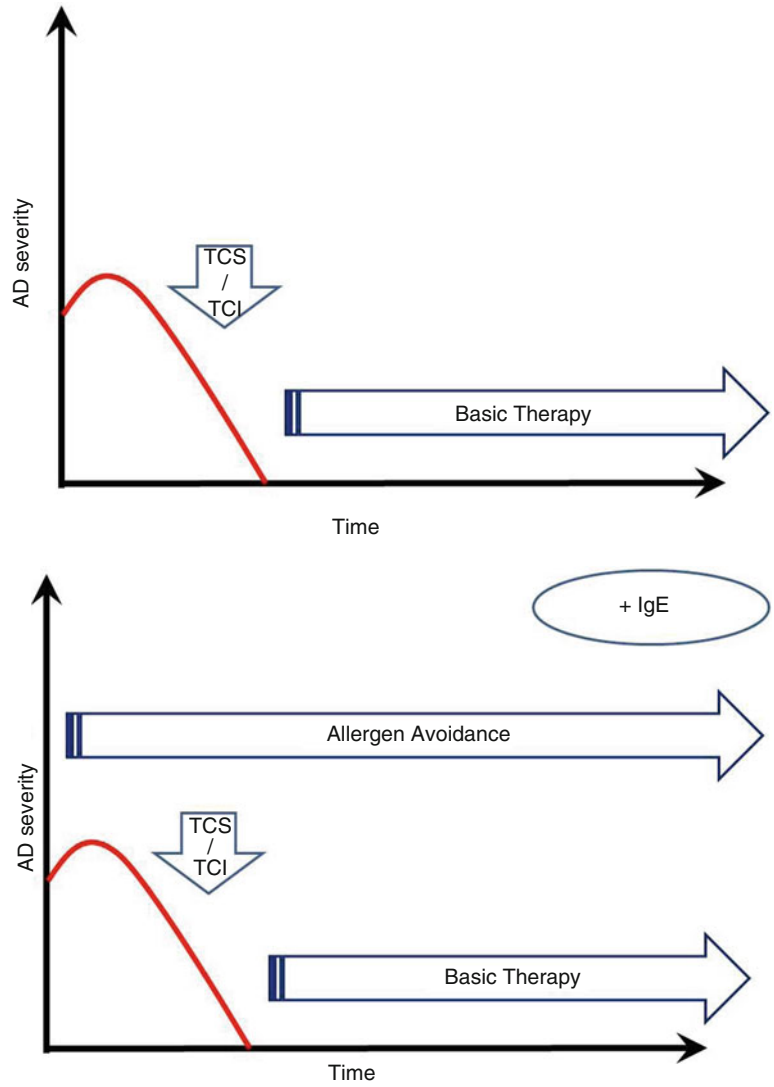

Fig. 7.6 Therapeutic approaches in AD

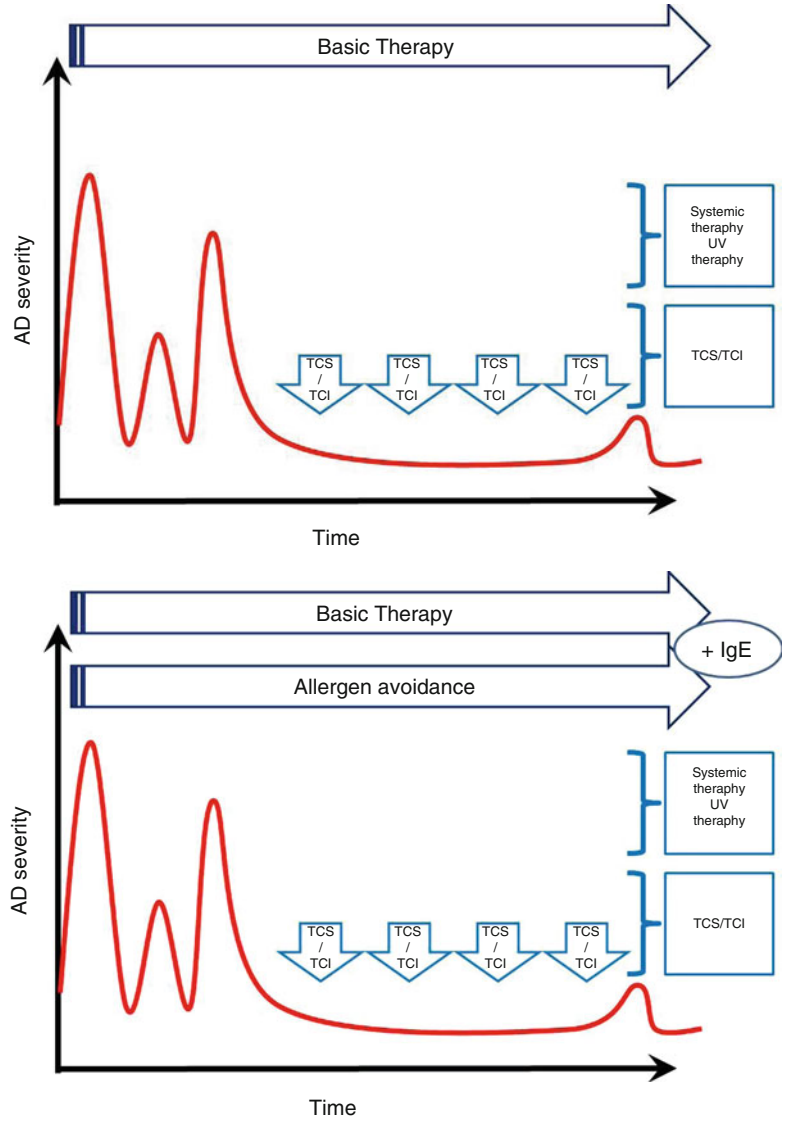
pharmacological treatment, and to improve the quality of life of patients. The choice of proactive strategies is supported by immunological, clinical efficacy, quality of life, and pharmacoeconomic data.

Proactive therapy should be carried out in children and in adults. Long-term studies (up to 4 years) have been performed either with tacrolimus (0.03 % and 0.1 %) or with corticosteroids (i.e., fluticasone propionate cream and ointment and methylprednisolone cream).

In adults, long-term treatment with 0.1 % tacrolimus ointment appears to be as effective as a corticosteroid regimen for the trunk and extremities and more effective in the face and neck area. Moreover, the instauration of these strategies at a very early stage of the disease might even have a beneficial effect also on respiratory symptoms and serum IgE (*atopic march*), but this tempting hypothesis needs to be addressed in future studies.

In daily practice, these new approaches should be explained to each patient (and with parents, family, doctors, and pediatricians) in order to achieve the highest rate of compliance.

Fig. 7.6 (continued)



Topical Therapy at a Glance

Topical corticosteroids (TCS) and, recently, topical calcineurin inhibitors (TCI) represent first-line therapies for AD.

In the correct management, proper strength, dosage, and application have to be taken into consideration.

TCS can be applied on inflammatory skin according to the needs (pruritus, sleeplessness, new flares). It is suggested to use a potent steroid in a short term, followed by a less potent preparation in long-term maintenance treatment.

Tacrolimus ointment (0.% and 0.03 %) and pimecrolimus cream are macrolide-type inflammatory cytokine inhibitors licensed for topical eczema treatment. TCI are especially indicated in delicate body areas, such as the face (eyelids, perioral skin), intertriginous sites, and the anogenital area.

The new *proactive* approaches (low weekly dose/application of TCS/TCI for a long period) aim to control the residuals of the disease and to prevent new flares (Fig. 7.5b). The choice of a proactive strategy is favored by

immunological, clinical efficacy, quality of life, and pharmaco-economic data. These approaches have been shown to be safe and effective, to reduce the use of the pharmacological treatment, and to improve the quality of life of patients.

Phototherapy

Many patients achieve very good results from artificial UV radiation as well as from heliotherapy and balneophototherapy. Thus, development of different ultraviolet (UV) schedules for the management of this disease has been carried out.

Currently, different UV source equipments are available.

- UVA1 (340–400 nm)
- Narrowband UVB (nbUVB = peak: 311–313 nm)
- Broadband ultraviolet B (BB-UVB = approx. 280–320 nm)
- PUVA therapy
- 308 nm excimer laser

UV sources have an immunomodulatory and antimicrobial effect (reducing the colonization of *S. aureus*), and they increase the vitamin D balance.

Phototherapy is usually a part of a wider treatment plan in adults and much less in children. Phototherapy should be avoided in children under the age of 12 years and in those patients who reported a worsening of their dermatitis during sun exposure.

Chronic, pruritic, lichenified forms (which are the most common manifestations of AD in adults) can benefit from phototherapy. In case of acute eczema exacerbation, UVA1 should be the suggested UV source.

Since this treatment cannot be applied at home, one of the major disadvantages is that the patient has to go to the hospital three to five times a week for the treatment.

Narrowband UVB is to be preferred to broadband UVB. Studies have shown that medium-dose UVA1 has similar efficacy as narrowband UVB. The choice of a UV treatment also depends on the availability of the equipment. At the beginning of UV treatment, topical steroids and emollients can be used in combination, whereas TCI should be avoided.

PUVA (photochemotherapy) (UVA in combination with psoralens) has demonstrated the same efficacy as UVA and nbUVB, but due to several side effects (from nausea to headache, irregular skin pigmentation, and proven carcinogenicity), it is not the first choice.

New devices, such as the 308 nm excimer laser, increase therapeutic options, but they are reserved for patients with localized and therapy-resistant AD.

Systemic Therapy

Patients with severe, generalized inflammation who do not respond to treatment including the use of topical treatment and phototherapy may benefit from systemic treatments and sometimes are candidates for hospitalization.

Cyclosporine A (CsA) is an immunosuppressant drug licensed in many European countries for treatment of AD. It is one of the first-line drugs in chronic, severe cases of AD in adults. In children, it may be used "off-label." Despite its well-proved efficacy, its well-known side effects limit its use, especially in long-term treatment.

An initial daily dose between 3 and 5 mg⁄kg⁄day, divided upon two single doses, is recommended. When a satisfactory clinical response is achieved, a dose reduction of 0.25–0.5 mg⁄kg⁄day every 2 weeks is recommended. A detailed patient monitoring, especially of the renal status and blood pressure, is advisable.

The combination with UV therapy should be avoided; the patient should be educated to a proper photo protection in summertime due to the increased risk of cutaneous malignancies (nonmelanoma skin cancers).

Systemic corticosteroids are commonly used in cases of moderate to severe AD. Despite their widespread use, they present a largely unfavorable risk/benefit ratio for the treatment of this disease. For this reason, the European guidelines have recommended to restrict their use to adults with acute and severe flares (resistant cases) for a short period (up to 1 week). Long-term use is not recommended,

especially not in children. The recommended daily dose should be adjusted to body weight.

Azathioprine is used since many years in Great Britain and the United States in adults. It can be used, off-label, as second-line therapy in patients who do not have responded adequately to CsA or in whom the use of CsA is contraindicated. Patients have to be screened for TPMT (thiopurine S-methyltransferase) activity before starting therapy (for the bone marrow toxicity). The suggested dose range is 1–3 mg⁄kg⁄day.

The use of *mycophenolate mofetil* (MMF) and *methotrexate* (MTX) may be an alternative (off-label) in adults with severe AD resistant to other topical and systemic treatments.

The use of the last three drugs in children and adolescents is not supported by published studies.

When AD is severe, unresponsive to topical steroid, and localized at the hands, *alitretinoin* may be used. The use of this drug is allowed only in adults. Small studies have reported an improvement of extrapalmar AD lesions during the treatment.

Dupilumab, a fully human monoclonal antibody that is directed against the shared alpha subunit of the interleukin-4 receptors and that blocks signaling from both interleukin-4 and interleukin-13, have been proved to be efficacy in patients with moderate to severe AD (phase I and phase II study), after a phase II study on asthma (Beck et al., 2014; Wenzel et al., 2013).

The introduction of this new drug, that has the potential to become the first biological systemic therapy for AD approved by US FDA and by EMEA, will significant increase the therapeutic armamentarium of physicians in the management of moderate to severe AD.

Phototherapy and Systemic Therapy at a Glance

A lot of patients achieve very good results from artificial UV radiation as well as *heliotherapy and balneophototherapy*.

Studies have shown that medium-dose UVA1 has similar efficacy as narrowband UVB, and these two UV sources are those to be preferred.

UV has an immunomodulatory and antimicrobial effect (reducing the colonization of *S. aureus*), and they increase the vitamin D balance.

Their disadvantage is that they, with exceptions, cannot be used at home.

Cyclosporine A is an immunosuppressant drug licensed in many European countries for treatment of AD. Despite its well-proved efficacy, its well-known side effects limit its use, especially in long-term treatment.

Systemic corticosteroids are commonly used, but they present a largely unfavorable risk/benefit ratio for the treatment of this disease. Their use should be restricted to adults with acute and severe flares (resistant cases) for a short period (up to 1 week).

Azathioprine, *methotrexate*, *mycophenolate mofetil*, and *alitretinoin* can represent a good alternative choice (off-label) in adults with severe AD resistant to other topical and systemic treatments.

Antipruritic Therapy

Pruritus represents one of the four major features in the diagnosis of atopic dermatitis.

Although it is a very common sign, few studies have investigated the efficacy of treatment on this sign alone. In fact the majority of studies have analyzed it within the global clinical scores,

Table 7.4 Antipruritic therapies in AE

General principles
Cleansing, bathing use of emollients/basic therapy. They reduce dry skin
Elimination of provocative factors: avoidance strategies (i.e., too long and hot bathing, contact with irritant substances or allergens, etc.)
Anti-inflammatory therapy
TCS and TCI
CsA
Phototherapy
Adjuvant specific antipruritic therapies
Creams/lotions containing urea, camphor, menthol, topical polidocanol or N-palmitoylethanolamine, topical capsaicin
Opioid receptor antagonists (e.g., naltrexone)
Sedation by the use of (mainly first generation) anti-H1 antihistamines

From Ring et al. (2012a, b) modified

measured with eczema area and severity index (EASI) and/or SCORAD.

As reported in the European guidelines, pruritus in AD has a multifactorial and complex etiopathogenesis. Thus, it can benefit from several and different treatments with different mechanisms as reported in Table 7.4.

Antihistamines

Although antihistamines have been used for decades, in attempts to relieve pruritus, surprisingly there are no conclusive data concerning their real efficacy in the treatment of pruritus in AD. There are only a few controlled studies evaluating the efficacy of antihistamines in treating the pruritus in AD with controversial results.

Children and adults may benefit from the treatment with the first generation of sedative antihistamines because they may allow a better sleep pattern in acute AD phases. Studies on the second-generation, nonsedating antihistamines, i.e., loratadine, cetirizine, or fexofenadine, demonstrated no or only a weak relief of pruritus. But second-generation antihistamines have the advantage to be very efficacious in the relief of the symptoms of common mucosal comorbidities such as allergic asthma and rhino-conjunctivitis. They are safe to use, also for a long period.

Antipruritic Therapy at a Glance

Although pruritus is a very common and important sign, few studies have investigated the efficacy of treatment on this sign alone.

Pruritus in AD has a multifactorial and complex etiopathogenesis. Thus, it can benefit from several and different treatments with different mechanisms as reported in Table 7.4.

Although antihistamines have been used for decades, in attempt to relieve pruritus, surprisingly there are no conclusive data in the literature concerning the real efficacy of oral antihistamines in the treatment of pruritus in AD.

Conclusion

Barrier dysfunction of the skin and chronic inflammation are peculiar features of AD: the prevention with new individually adapted skin care products, eventually shortly after birth, the inflammation control by the regular use of topical corticosteroids or topical calcineurin inhibitors for long-term periods, the management of pruritus, and the reduction of bacterial colonization have to be considered in the long-term strategies.

Biomarkers will allow to carry out future approaches in the context of stratified or personalized medicine.

Now we can highlight therapeutic approaches in five courses of the dermatitis after its onset:

1. Remission of AD (Fig. 7.6a).
2. Remission of AD and development of high levels of IgE and mucosal sensitization (Fig. 7.6b).
3. AD becomes a chronic disease, without the development of high level of IgE (Fig. 7.6c).
4. AD becomes a chronic disease, with the development of high levels of IgE and mucosal sensitization (atopic march) (Fig. 7.6d).
5. AD becomes a chronic disease, with the development of high levels of IgE, with/without mucosal sensitization, and with the development of high levels of auto-IgE (autoreactivity march). In this case, the therapeutic approach will be the same as case 4.

The therapeutic approaches are shown in Fig. 7.6a–d. Up to now, there are not enough standardized biomarkers that allow us to prognosticate the course of the AD.

Balanitis

8

Derek Freedman

Key Points

- Balanitis is usually a simple intertrigo with no specific aetiological agent.
- In most cases, the course will be episodic with recurrences, unless specific care is taken to reverse the predisposing factors.
- The vast majority of cases respond to *simple measures*:
  (a) Retraction of the foreskin
  (b) Saline baths
  (c) Simple drying powder
- Topical antifungal creams give temporary relief only: powders are more effective.
- Persisting lesions should be biopsied.

Definition and Epidemiology

Balanitis: Inflammation of the glans penis.

Balanoposthitis: Inflammation of the foreskin and surface of the underlying glans penis. Frequently occurs with a tight or not easily retracted foreskin, or phimosis. Usually a more acute and extensive local inflammation than simple balanitis.

Posthitis: inflammation of the preputial mucosa.

The term 'balanitis' is frequently used to include all of the above.

The condition is common in infancy when the prepuce is adherent, non-retractable and subject to moisture and contamination from urine and faeces.

It is very common in adulthood. It is not related to poor hygiene, but to intertrigo and accumulation of sub-prepuce secretions. It is equally frequent with overzealous, and even obsessive washing, causing irritation. Candida balanitis is a much less common cause of balanitis and is associated with diabetes mellitus. Sexual transmission is not described in the literature, but most physicians have clinical experience of balanitis occurring postcoitus with a woman who has either candida or bacterial vaginosis. It may be an indicator of sexual risk taking and as such warrants a full STD screen, unless risk is specifically denied.

Essentially, diagnosis is anatomical, but there are multiple causes.

Basic Concepts of Pathogenesis

The blind sub-prepuce sac gives a warm moist environment, with an accumulation of desquamated cells – smegma, an ideal culture medium. The epithelium of the glans penis is protected and covered, so that it remains moist,

D. Freedman
GUIDE Clinic, St. James' Hospital,
88 Ranelagh Village, Dublin 6, Ireland
e-mail: df@freedman.ie

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_8, © Springer-Verlag Berlin Heidelberg 2015

non-keratinised, thin and sensitive. In many respects, the male preputial sac is the equivalent of the vagina, a closed space, with a polymicrobial ecology and a similar susceptibility to overgrowth of microorganisms normally present to produce symptomatic conditions, and a similar predisposition to recurrence of these conditions.

Most commonly, balanitis is a simple intertrigo with no specific aetiological agent. The majority of cases are mild and may have mechanical or irritant associations. It may present after a recent regretted sexual encounter, where anxiety and increased awareness of genital sensations lead to closer scrutiny of the area. A full STD screening is mandatory in these circumstances.

With infective causes, a more acute inflammatory reaction may be seen, such as with infection/overgrowth of candida or anaerobes. Many dermatological conditions also affect the genital epithelium, where their clinical features may be atypical due to the different morphology of the epithelium.

Sexual transmission has been described with both candidal and anaerobic infections, but it is thought to be infrequent. Partner treatment does not markedly influence the risk of recurrence.

Clinical Presentation

Clinical presentation is variable and is frequently inversely related to guilt and anxiety. The anxious or guilty patient may present with symptoms of non-specific irritation, itching or burning of the glans/prepuce and little or no findings at all. Often there is just a minimal red spotty rash or some macules on the glans. Other patients may present with an obvious red inflamed glans and prepuce, erosive ulcers and an offensive subprepuce discharge: an amine odour indicating anaerobic overgrowth. Inguinal adenopathy is rarely present with simple balanitis and its presence should indicate consideration of a wider differential diagnosis, including the need to exclude sexually transmitted infections and carcinoma.

In most cases, the course will be episodic with recurrences, unless specific care is taken to reverse the predisposing factors.

Diagnosis

In simple balanitis, diagnosis is clinical and tested by response to simple measures.

Microscopy of the sub-prepuce secretions may reveal candida or anaerobes, which may point to the same condition in the sexual partner(s). Potassium hydroxide preparation is useful in the identification of candida; Gram stain will be more specific for anaerobes. Culture will identify bacterial causes, although one must be careful not to attribute the causation to commensals.

The presence of ulceration, adenopathy or a positive sexual risk history should prompt a full screen for sexually transmitted infections. Samples from ulcerated lesions should be examined by dark ground microscopy and/or PCR detection to eliminate syphilis, as well as serology. An HSV DNA detection for herpes virus should be taken – HSV culture being less sensitive. Consideration should be given to chancroid, lymphogranuloma venereum and granuloma inguinale. A high degree of suspicion should be maintained for squamous cell carcinoma of the penis and any persisting or suspicious lesions biopsied.

The skin of the glans penis and prepuce may be affected by a wide variety of dermatological conditions, the more important of which are considered in the differential diagnosis which follows. The presentation and appearance of these conditions is modified in the soft non-keratinised skin. In case of persisting lesions, or if in any doubt, do a biopsy.

Differential Diagnosis

As an area of skin, the prepuce and glans penis is subject to abrasion, trauma, infection and the entire gamut of dermatological conditions, including cancer and precancerous lesions (Table 8.1) (Fig. 8.1).

Table 8.1 Balanitis: differential diagnosis of common or important conditions

Condition	Clinical features	Diagnosis
Sexually transmitted		
Herpes genitalis	Vesicles – sores – crusts	HSV DNA detection
	Painful	Viral culture – less sensitive
Syphilis	Ulcer(s) – painless	TP DNA detection
Primary	Condylomata lata	Dark ground microscopy
Secondary	Multiple circinate lesions	Serology (>3/12)
Chancroid	Painful ulcer(s)	Culture
	Adenopathy	P.C.R.
Lymphogranuloma venereum	Painful shallow ulcer(s)	NAATS
	Adenopathy	
Granuloma inguinale	Beefy lesions	Microscopy
	Painless	Biopsy
Gonorrhoea	Acute ulcers and pustules	Microscopy
	Acute infection of glands and ducts, i.e. tysonitis, Cowper's duct	DNA detection test Culture
Trichomonas	Acute erosive adenopathy	TV DNA detection
		Microscopy (wet – 50 % sensitivity)
Human papilloma virus	Asymptomatic	Aceto – white lesions
	Patchy variable macula	(5 % acetic acid stupes)
	Hypoaesthesia – pruritus Chronic/recurrent	Confirm by biopsy
	Warts	HPV typing
Infections: sexual possibility of transmission		
Candida infection	Short incubation	Microscopy
	Burning, itching – acute pain	KOH preparation
	Variable erythema – dry glazed small papules and pustules coalesce to form erosive patches	'Adhesive tape' sample
	Prepuce edge fissures	
Candida hypersensitivity	Transient post-coital erythema and burning	History
		Check partner
Gardnerella	Mild symptoms	Clinical
	Macular erythema	Culture
	'Fishy' odour	
Anaerobic erosive balanitis (Bacteroides spp.)	Tender ulcers	Microscopy
	Odour	Mixed spirochetes
		Bacteria ++
Group B	Erythema – purulent discharge	Culture
Haemolytic streptococci	Cellulitis	
Infections: sexual transmission unlikely		
Group A	Prepubertal	Culture
Haemolytic streptococci	Erythematous, moist	
Staphylococcus aureus	Prepubertal boys (toxic shock syndrome)	Culture
Pityriasis versicolor	Discrete fine scaling	Fluoresce with 'woods' light
	Hypopigmented areas	
Herpes zoster	Pain ++	Clinical
	Grouped blisters	Dermatome distribution
		Serology
		HVZ – DNA

(continued)

Table 8.1 (continued)

Condition	Clinical features	Diagnosis
Specific balanitides		
Lichen sclerosis et atrophicus	Atrophic white papules or plaques. Phimosis, burning, pruritus, hypoaesthesia, sexual dysfunction	Sclerotic white ring at tip of prepuce
	Lesions progress to sclerotic/atrophic white/ivory/blue flat-topped papules	Biopsy
	Progressive chronic course	
	Fibrosis – obliteration of anatomical features	
Plasma cell balanitis	Solitary glazed-smooth red-orange plaque *cayenne pepper*	Biopsy
Localised balinitides		
Fixed drug eruption	Well-demarcated erythematous areas	History
	Bullous – occasionally ulcerated	Recur at same site on re-exposure to drug
Allergic and contact dermatitis	Intense pruritus/burning	History
	Marked oedema	Patch testing
	Rapid onset	
Trauma	Direct accidental: burn/scald/frostbite suction/vacuum erection devices	History
	Zipper entrapment	
	Sexually induced: pubic hair friction, dental induction, instrumentation, masturbation	
Implantation	Studs, rings, balls, etc.	Clinical
Manifestation of systemic/ generalised disease		
Psoriasis	Well-demarcated erythematous plaques without scale (inverse pattern) in uncircumcised	Other stigmata of psoriasis
		Family history
		Biopsy
Behçet's syndrome	Ulcers	Extragenital lesions
		Biopsy
		Pathergy test
Aphthous ulcers	Painful, solitary halo of erythema	Outrule other causes of genital ulcers – especially Behçet's syndrome
Circinate balanitis	Moist plaque with irregular ragged border – geographic (circumcised – dry scaling)	Other clinical features of Reiter's syndrome HLA B27^{+ve} (80 %)
Seborrhoeic dermatitis	Mild erythema and scaling	Clinical
Lichen planus	Polygonal violaceous flat-topped papules	Clinical
	Lacy erosive ulcers	
Erythema multiforme	Erythematous papules	Clinical
	Vesicles – ulcers	
Pemphigus	Vegetating plaques	Biopsy
Neoplasia		
Erythroplasia of Queyrat	Plaques: glazed – velvety	Biopsy
	Slightly raised	
	Sharp margins	
Penile carcinoma	Pruritus/burning	Biopsy
	Papillary/flat	
	Ulcer with rolled edge	
Verrucous carcinoma	Exophytic lesions	Biopsy (large deep)

Table 8.1 (continued)

Condition	Clinical features	Diagnosis
(Buschke-Lowenstein)	Infiltrative	
Extra mammary	Plaques	Biopsy
Paget's disease	Red-brown	
	Raised, scaly	

Fig. 8.1 Retracted prepuce. Retraction of the prepuce dries out the epithelium, enhances keratinisation and resolves most cases of balanitis

General Principles of Treatment

The principle is to change the micro-ecosystem of the sub-prepuce sac to one which will not readily become superinfected by candida, anaerobes or other bacteria. Exposure and drying of the skin encourages keratinisation and further enhancement of resistance to infection, abrasion and trauma.

Recommended Therapies

The vast majority of cases respond to *simple measures*:

(a) Retraction of the foreskin
(b) Saline baths
(c) Simple drying powder

Retraction of the Foreskin

Advising patients to change their habits of a lifetime and maintain retraction of the foreskin requires considerable persuasion. Most find it uncomfortable and oversensitive initially, and it takes about 3–4 weeks for the hypersensitivity to settle down as keratinisation occurs. Once this has been achieved, few wish to revert to their previous mode of wearing the foreskin down.

Some men cannot achieve retraction because of a tight prepuce: application of an emollient cream and stretching over a period of time may allow the desired effect to be achieved. Retraction may not be maintained by others because of a natural tendency of the prepuce to slip down. Use of a thin narrow surgical tape (Micropore® 12.5 mm, 3M®) along the shaft of the penis may retain the prepuce back for a sufficient time for keratinisation to occur.

Patients must be warned to guard against paraphimosis on retraction of the foreskin. This may occur at night, with erotic dreams, when patients may awake with an acute paraphimosis.

Some men have a non-retractile prepuce or phimosis. Use of an ultra-potent topical steroid, combined with gentle stretching over a period of several months, may facilitate retraction to take place. The above warning regarding paraphimosis is particularly pertinent.

On occasions, circumcision is warranted for persisting irritation.

Saline Baths

These appear to help dry out the skin and encourage keratinisation and may have a mild fungistatic/bacteriostatic effect. Essentially, a tablespoon (20 ml) of ordinary domestic table salt in a warm bath of water or more convenient for frequent daily use, use a pinch of salt in a

tumbler glass or small jar. The penis and sub-prepuce area should be dried gently, by patting, rather than any rough or abrasive action. Care should be taken not to use too much salt, or the skin will become *pickled* or irritated, which would be quite counterproductive.

If retraction is not possible initially, one can wash out the sub-prepuce space with warm saline by the use of a small syringe to irrigate the area.

Simple Drying Powder

Application of a simple drying powder to the sub-prepuce space can assist in maintaining dryness. A simple talc may be used or one with a mild antiseptic as commonly used for infants (calcium undecylenate 10 % powder, Caldesene®). Care should be taken to ensure that there is no hypersensitivity to the talc or other constituents.

Some soaps, shower gels and shampoos can be an irritant, as well as contain potential allergens. Again, use of simple non-astringent agents is recommended, with advice against overwashing and abrading with drying. This is particularly important where there is broken skin.

Topical treatments at a glance	
Simple measures	Retraction of prepuce
	Saline baths
	Drying powder
Antifungal powders	Miconazole
Antifungal creams	Not recommended
Topical steroids	Not recommended

Alternative Treatments

Antifungals and Steroids

Antifungal creams (clotrimazole, miconazole, nystatin) are very commonly prescribed, and many patients will present having tried antifungal creams, often obtained OTC. The experience is of relapse with these agents, and they can be only useful in providing short-term symptomatic relief. Recurrence occurs shortly after discontinuation of usage. There is danger of hypersensitivity to these agents and their vehicles, especially clotrimazole. Systemic fluconazole has also been recommended, but as only a small proportion of cases are due to Candida infection (Van der Meijden 2014), and these usually respond to simple measures; its utility is questionable.

Antifungal/antibacterial powders produce better results as they dry out the area. They are particularly useful in acute erosive balanitis, with secondary bacterial infection. Miconazole powder, used three to four times a day, is one such agent.

Local corticosteroid applications should only be used sparingly, and where there is a specific need, as they weaken the skin and may mask an infection. Particularly, steroids may reduce the local immune response and facilitate the expression of a latent HPV infection as genital warts.

Simple measures should be tried initially and given sufficient time for patient compliance to be established and for them to show effect. With persisting balanitis, much stronger consideration must be given to the differential diagnosis, taking special care to exclude a sexually transmitted disease, dermatosis or a precancer/cancer. At this stage biopsy becomes mandatory.

Screening for Sexually Transmitted Diseases

This is mandatory in all cases where a history of potential acquisition has been obtained and is a useful reassurance in the majority of other cases. Many patients who present with balanitis have an underlying anxiety regarding STDs, and this must be definitively addressed.

Circumcision

Recognition of the protective benefit of circumcision on male acquisition of HIV has raised a much greater awareness of the procedure. Current estimates show it to confer a 70 %+ protection

after 5 years. It has also been shown to be of some benefit in relation to HPV and HSV acquisition in males (Edwards et al. 2008).

Circumcision is of specific use in lichen sclerosis, after failed topical therapy 3,4, and similarly in lichen planus 5, Zoon's balanitis(Kulkarni et al. 2009). Circumcision is curative in non-specific balanitis.

Whilst circumcision is usually curative in the above conditions, careful consideration should be given to assiduously try the simple measures outlined previously, as they can usually achieve the same effect without the expense and discomfort of surgery. The challenges are lack of awareness by the physician and difficulty in compliance by the patient.

In relation to prevention, the American Academy of Pediatrics (AAP) task force on circumcision of the male infant (2012) Poter et al. (2001) concluded that 'the health benefits of newborn male circumcision outweigh the risks; furthermore, the benefits of newborn male circumcision justify access to this procedure for families who choose it. Specific benefits from male circumcision were identified for the prevention of urinary tract infections, acquisition of HIV, transmission of some sexually transmitted infections, and penile cancer. Male circumcision does not appear to adversely affect penile sexual function/sensitivity or sexual satisfaction'. More widespread adoption of newborn male circumcision will result in reduction of balanitis in the population. However, there are several vociferous anti-circumcision groups and some very strong-held opinions in relation to this topic. The optimal time for circumcision is the newborn period (Kumar et al. 1995).

Basal Cell Carcinoma

9

Dimitrios Papakostas and Eggert Stockfleth

Key Points

- Basal cell carcinoma (BCC) accounts for 80 % of all nonmelanoma skin cancers (NMSCs) and is the most common human malignancy with higher morbidity than mortality since metastases are extremely rare.
- Sun exposure, genetic predisposition, and immunosuppression are the main risk factors; activation of the sonic hedgehog pathway plays a key role in BCC formation.
- Prognosis, treatment strategies, and follow-up depend on BCC classification as high or low risk after thorough clinicopathological correlation.
- Surgical excision remains the treatment of choice for high-risk BCCs, radiotherapy retaining a complementary role as alternative treatment to surgery or postoperatively in selected cases.
- Nonsurgical destructive methods such as cryotherapy, photodynamic therapy, electrodessication after curettage, and topical treatment with imiquimod should be reserved for the treatment of superficial BCCs and selected low-risk nodular BCCs or in case of inoperability due to patient's medical background or refusal of a more aggressive therapeutic approach.
- Tumor eradication and limited recurrence rates without a disproportionate risk for the patient and an acceptable cosmetic outcome are the key points in the selection of the optimal treatment.
- Novel inhibitors of the hedgehog pathway could revolutionize treatment of inoperable or metastasized BCCs and make an individualized therapeutic approach possible in the years to come.
- Follow-up after treatment is essential, since many BCCs could recur even 5–10 years later. Approximately 45 % of the patients treated will develop a new BCC within the first 3 years after initial diagnosis and treatment.

Definition and Epidemiology

Basal cell carcinoma (BCC), also known as basalioma or basal cell epithelioma, is the most common cancer in Europe, Australia, and the USA, accounting for more than a million case per year in the USA. The annual incidence is globally increasing with a peak of 726/100,000 in Australia. In Germany around 100 out of 100,000 inhabitants are diagnosed each year with an average age of presentation of 60 years, though an age shift is the current trend, proposing a further increase of the incidence of BCC in the next decades.

BCCs account for 80 % of all nonmelanoma skin cancers (NMSCs); they present as slowly growing tumors, with local invasive and destructive potential, infiltrating adjacent tissues with fingerlike outgrowths remaining contiguous with the main tumor mass. Metastasis is extremely rare (1:1,000 to 1:35,000) and probably limited to giant BCCs (80 % of metastatic BCCs) and atypical histological variants such as the metatypical BCCs. Thus morbidity rather mortality is the main issue regarding the medical, financial, and social impacts of this common malignancy.

Basic Concepts of Pathogenesis

Eighty percent of all BCCs appear on sun-exposed areas of the face and the neck, preferably of fairly skinned individuals, indicating ultraviolet exposure, genetic predisposition, and skin type as the main predisposing factors, followed by immunosuppression, exposure to arsenic salts, ionizing radiation, and trauma.

Ultraviolet light has a known mutagenic potential and signature mutations such as C→T are found in sun-exposed skin. Patients with xeroderma pigmentosum, a rare genetic disease with impaired DNA correction, report an increased incidence of BCCs among other forms of NMSC. Still, in the majority of BCC patients, this is not the case; the study of the autosomal dominant inherited basal cell nevus syndrome (BCNS) or Gorlin syndrome improved our understanding of the molecular basis of this malignancy. These patients typically develop numerous BCCs at younger ages, they present with skeletal anomalies and other deformations regarding the embryogenesis, and they are prone to the development of other tumors such as the medulloblastoma. Not only in patients with BCNS but also in the majority of sporadic BCCs as well the sonic hedgehog pathway is activated. The hedgehog pathway plays a key role in developmental processes during embryogenesis. In most normal adult tissues, the pathway is silenced though and the reactivation can lead to cancer. Central component of the hedgehog pathway is the transmembrane protein SMO, which is being inactivated by another transmembrane protein called Patched (from the PTCH-1 gene, which is mutated in patients with Gorlin syndrome, resulting in inactivation of the Patched protein and activation of SMO). After binding of the hedgehog ligand to its receptor on Patched, the suppression on SMO is relieved and a downstream phosphorylation cascade is activated, leading to activation of the GLI transcription factors, their accumulation in the nucleus, and the active transcription controlling of hedgehog target genes. Eighty to ninety percent of sporadic BCCs have a PTCH-1 mutation and about 10 % an SMO mutation. In either cases activation of the SMO signaling results in uncontrolled BCC formation.

Clinical Presentation

The typical nodular BCC on sun-exposed areas of the face and the neck presents as a red-yellowish papule, slowly growing in size, with possible ulceration, remaining well circumscribed with a pearly border. Superficial BCCs (Fig. 9.1) on the trunk impose on the other hand as slowly growing flat red plaques, being easily confused with inflammatory diseases of the skin or Bowen disease. Aggressive variants of the BCC are the morpheic BCCs presenting like a scar with unclear borders, making R0 resection rather challenging, and the local destructive variants known as ulcus rodens and ulcus terebrans. Pigmented (Fig. 9.2), cystic, keratotic, and baso-

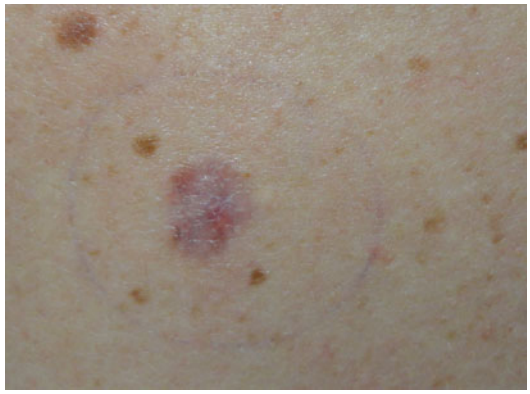

Fig. 9.1 Superficial basal cell carcinoma on the trunk

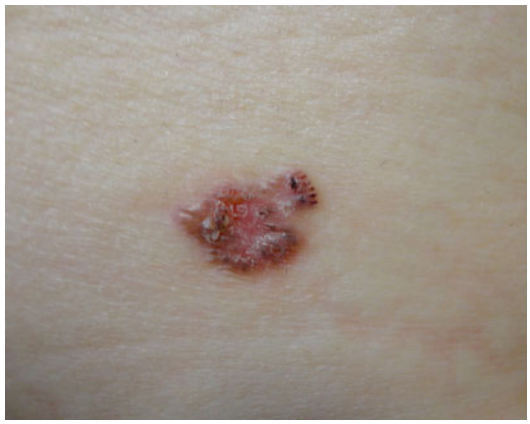

Fig. 9.2 Pigmented basal cell carcinoma

squamous variants emphasize the clinical diversity of BCCs and challenge the physician in making the right diagnosis.

This clinical diversity may be the result of the tumor cells' origin, probably from a stem or progenitor cell of the basal cell layer of the epidermis or the outer root sheath of the hair follicle. This explains the histological diversity as well; histological subtypes include superficial, nodular and micronodular, adenocystic, pigmented, sclerosing, keratotic, basosquamous/metatypical, and infiltrating BCCs and the fibroepithelioma of Pinkus. The primary cellular components of the BCC resemble undifferentiated basal cells of the epidermis and the hair follicle; these cells form palisades at the tumor periphery and are distinctively separated from the adjacent fibroblastic stroma, characteristic for BCC.

The clinical and histological diversity explains the broad spectrum of the clinical course of these skin malignancies, stretching from slowly growing superficial tumors to recurrent and giant ulcerative, infiltrating, and locally destructive tumors with perineural and perivascular involvement. Metastasis, though extremely rare, remains a possibility in the case of giant tumors or basosquamous/metatypical variants.

Diagnosis

Clinical diagnosis should be no problem for the experienced dermatologist in most cases; good lighting, magnification, and dermoscopy could prove really helpful in improving the accuracy of the clinical diagnosis. Still, the variety of histological types with diverse clinical courses and the need for a tumor-adapted optimal treatment emphasize the need for biopsy prior to treatment of high-risk tumors. In an ideal scenario, all BCCs would be biopsied prior to treatment selection; in many cases though, due to various patient-related circumstances such as age, comorbidities, medication, and logistical obstacles, the dermatologist could be justified to skip this diagnostic step. At the time of definite treatment though, e.g., after excision, a pathological specimen should be always submitted for pathological confirmation of the diagnosis. Modern apparative diagnostic methods such as the confocal laser scan microscopy (CLSM) try to bridge the gap between clinical and histological diagnosis and to make possible an individualized diagnostic approach in the cases mentioned above.

In cases of multiple superficial tumors, biopsy (incisional or excisional) of a characteristic tumor should be performed prior to potential selection of non-excisional destructive methods.

Further imaging such as lymph node sonography or CT/MRI should be considered to exclude metastasis in advanced tumors and in the diagnostic approach of locally invasive and destructive tumors.

General Principles of Treatment

A variety of treatment modalities has been successfully involved in the approach of BCC patients in past years, as a result of the diverse clinical appearance and course of the most common cancer, accounting for 5 % of all Medicare cancer costs in the USA. In order to guide physicians through this labyrinth and with the goal of evidence-based treatment selection, a number of national and international guidelines have been developed recently. An algorithm for the therapeutic approach of BCC is depicted on Fig. 9.3.

Though BCCs can be staged following the UICC classification like other skin malignancies (squamous cell carcinoma, malignant melanoma), the lack of lymph node involvement and metastases in most cases make this classification impractical for the choice of treatment.

BCCs are currently assigned as low or high risk of recurrence according to a number of prognostic factors with the goal of a tumor-adapted choice of treatment. Tumor eradication and limited recurrence rates without a disproportionate risk considering the medical background and an acceptable cosmetic outcome for the patient are the key points in the selection of the optimal treatment.

Clinical and pathological correlation prior to treatment selection, meaning a detailed history and clinical examination, including observation and palpation to determine exact location, size, and possible infiltration of adjacent tissues and the consideration of the histological findings actively influence the physician's decision. Diverse criteria such as tumor size, tumor thickness, tumor site, definition of clinical margins, histological subtype, histological features of aggression, recurrence, and immunosuppression make stratification in high and low risk possible (Table 9.1).

The wide range of therapeutic modalities can be divided in surgical, destructive, topical, and systemic treatments and radiotherapy.

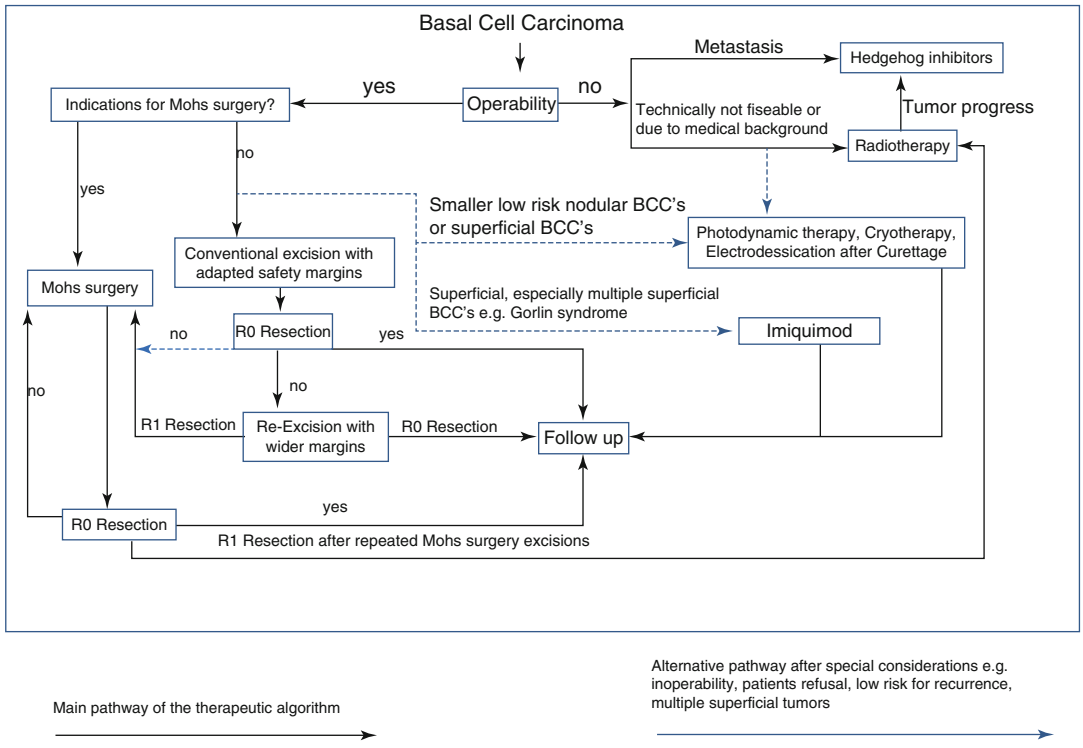

Fig. 9.3 Algorithm for the therapeutic approach of basal cell carcinoma

Table 9.1 High-risk basal cell carcinomas

Tumor size depending on location:
>20 mm in low-risk areas of the trunk and extremities, even smaller tumors in high-risk areas of the head and neck, genitalia, and hands, especially in problematic locations (central face, ears, around the eyes, fingers, and genitalia)
Histological type:
Sclerosing, metatypical, micronodular, infiltrating
Histological findings:
Perineural or vascular involvement, infiltration of adjacent tissues
Poorly defined margins (e.g., *after radiotherapy*)
Recurrence
Immunosuppression

Surgical excision with histological control remains the standard treatment. A conventional excision with respective safety margins should be effective in most primary BCCs. On the other hand, in more demanding clinical cases, Mohs micrographic surgery has superior results in regard to histological verification, recurrence rates, and sparing of healthy tissue. A shave excision with conventional histology plays a role in the therapeutic approach of superficial BCCs, especially on the trunk and extremities. Radiotherapy retains its role in the treatment of selected tumors, as a fair alternative to surgical treatment or in case of inoperability, incomplete excision, or patient's refusal of surgical intervention. Nonsurgical destructive methods without histological control such as cryotherapy, curettage with electrodesiccation, photodynamic treatment (PDT), and topical treatments (immunological therapy with imiquimod 5 %) should be preferably limited to superficial BCCs or in the treatment of BCNS (Gorlin syndrome) patients with multiple tumors. Still, the final choice of treatment should be individualized, taking into consideration comorbidities, age, medication, and disproportionate risk of aggressive surgery or refusal of surgical intervention. The nonsurgical methods mentioned above, alone or in combination, could be reasonable alternatives in selected cases, after individualized risk-benefit evaluation.

Surgical Treatments

Mohs Micrographic Surgery

This demanding technique is generally reserved for high-risk tumors on problematic locations of the face, the hands, and the genitalia, recurrent tumors, or BCCs of aggressive histological subtypes or with aggressive histological findings (Table 9.2). Long-term recurrence rates for primary tumors of less than 1–2 % and for recurrent tumors of less than 6–7 % have been reported. First described by Frederic Mohs (Mohs micrographic surgery, MMS) and further refined in following years, micrographic surgery aims to the total eradication of the tumor mass, leaving no traces of tumor cells behind and thus limiting recurrence rates. Keeping in mind the three-dimensional expansion of subclinical tumor outgrowths, especially in the case of more aggressive subtypes such as the sclerosing BCC, a more subtle histological approach is asked in order to avoid wide excision margins in problematic locations where sparing of healthy tissue can prove of crucial importance for an acceptable cosmetic and functional outcome.

Depending on the facilities of the surgery unit, re-excision and plastic reconstruction of the gap can take place within hours; histology is performed using frozen tissue sections. In centers where the histology takes a number of days for evaluation, the gap is filled with use of alloplastic materials and the excisional material is being embedded in paraffin. Paraffin sections are considered to be of greater accuracy though, compared to frozen tissue section.

Table 9.2 Mohs surgery indications

High-risk tumors in problematic locations of the face, hands, and genitalia where sparing of healthy tissue is essential for a good cosmetic and functional outcome
Aggressive histological variants:
Sclerosing, infiltrating, metatypical, micronodular
Aggressive histological findings:
Perineural or vascular involvement, infiltration of adjacent tissues
Recurrence (e.g., after conventional excision or radiotherapy)
Clinically poorly defined margins

Conventional Excision

A standard surgical excision of primary BCCs is a reliable therapeutic approach with rather limited recurrence rates when performed with tumor-adapted safety margins. Compared to MMS which allows a comprehensive margin examination in a three-dimensional manner, after convention excision only the peripheral and deep surgical margins are examined in paraffin-embedded sections, thus making tumor-adapted safety margins necessary to limit the likelihood of residual tumor and subsequent recurrence. The cosmetic and functional outcome is in most cases good. Small tumors at any site as well as bigger tumors (>20 mm) on trunk and extremities are good candidates for conventional surgical excision. The safety margins vary and depend on tumor size and histological subtypes, tumors bigger than 20 mm or of high-risk histological subtypes (e.g., sclerosing, infiltrating, metatypical) requiring wider safety margins of clinically healthy tissue excised in order to achieve an acceptable 5 % probability of residual tumor compared to 4–5 mm safety margins for tumors smaller than 20 mm or of nonaggressive histological subtypes such as nodular or superficial BCCs. Interestingly enough there is a 15 % chance of R1 resection after conventional excision with 3 mm safety margins of even low-risk tumors. Not all microscopically proven residual tumors would recur though; a safety margin of 3–5 mm is thus currently recommended for low-risk tumors. After conventional excision of aggressive histological variants with 5 mm safety margins, the probability of residual tumor is considerable (18 %) though, requiring wider safety margins (13–15 mm, 5 % likelihood of residual tumor) and highlighting the superiority of MMS in cases where sparing of healthy tissue is essential for a good cosmetic or functional outcome.

In case of R1 resection with histologically proven residual tumor without any clinically seen tumor rests, there is indeed, as mentioned above, enough evidence that a clinical recurrence of the tumor is not obligatory. In such cases wait and see in the context of an individualized follow-up could be a reasonable approach. Still, when dealing with high-risk tumors or with tumors with residual involvement of the deep safety margin, re-treatment should be always performed, either as re-excision with wider safety margins, MMS, or even postoperative radiotherapy.

Shave Excision with Conventional Histology

Tangential (shave) excision with conventional histology may prove of value in cases of multiple superficial BCCs on trunk or extremities, when the burden of multiple conventional surgical interventions can cause more problems than the lesion itself, thus making a more conservative surgical approach coupled with higher recurrence rates reasonable.

The Role of Radiotherapy

Radiotherapy retains its role in the nonsurgical treatment of BCC. Effective in the treatment of primary BCCs, it can be considered a fair alternative to conventional excision, especially in the case of small tumors or patients unwilling or not able to undergo surgery. Postoperatively (R1 or R2 resection) radiotherapy could be used as an adjuvant treatment. Scaring and radiodystrophy, altered pigmentation, and telangiectasia are the most common side effects. Lack of margin control and increased risk for future cancers should also be taken into consideration. In genetic disorders with predisposition to skin cancer, such as Gorlin syndrome or xeroderma pigmentosum, radiotherapy is contraindicated.

In order to improve tolerability and cosmetic outcome, fractioned treatment regiments have been developed, limited though to major medical centers. The total dose of 50–70 Gy depending on site and tumor size is being fractioned in 2–5 Gy single doses. When used as an adjuvant treatment postoperatively, more limited total doses of 40 Gy (R1) and 60 Gy (R2) are used.

Single-fraction strategies could be still considered in the case of elderly patients ready to accept a poorer cosmetic outcome in order to avoid repeated hospital visits and a prolonged course of therapy.

Destructive Treatments

Cryosurgery

Cryotherapy with liquid nitrogen (−196 °C) using either a spray or the contact method aims to deep destruction of tumor and surrounding tissue without histological control. Cryotherapy could be generally recommended for small superficial BCCs, especially of the eyelid, or in selected clinical situations such as elderly patients where better established methods with a higher evidence level are not feasible or are being refused from the patient. Indeed in expert hands cryotherapy could also have a role in the treatment of more advanced lesions, such as nodular BCCs, either alone or in combination with other methods, e.g., after curettage or in combination with modified imiquimod protocols.

Generally double-freeze/thaw cycles are recommended, to the adverse reactions count pain, edema and blister formation, and hyper- or hypopigmentation.

Photodynamic Treatment (PDT)

Photodynamic treatment with methyl aminolevulinate (MAL) is another efficient treatment of superficial BCCs or of patients with BCNS, the indications for its use overlapping with those for cryotherapy. After application the photosensitizing active component is localized in cancer tissue or other diseased cells in case of inflammatory diseases, and the use of energy-rich narrow-length light source results in accumulation of protoporphyrin IX, causing an iatrogenic porphyria, production of free radicals, and selective tumor destruction. When treating BCCs with increased tumor thickness, there is higher rate of residual tumor after PDT treatment, resulting to higher recurrence rates. Considering the general medical background of selected patient groups though, PDT after non-painful superficial curette or even CO_2 laser, aiming to tumor debulking prior to PDT application, could be a reasonable alternative to more aggressive surgery in the treatment of some low-risk nodular BCCs as well.

PDT results generally to good cosmetic outcomes, probably better compared to other non-surgical destructive techniques such as cryotherapy. Some pain and erythema is experienced from the majority of patients though, in some cases even inflammation with crust formation. Supportive measures such as use of a fan or local anesthesia could alleviate pain and improve patients' compliance during treatment.

Curettage and Cautery

Another cost-effective and, in some countries, widely used technique for the treatment of low-risk BCCs is curettage alone or with use of electrodessication. Smaller nodular or superficial BCCs on non-critical locations could be easily treated, the rather high rate of residual tumor cells not directly correlating to recurrence rates, unidentified wound-healing procedures suggested of being possibly responsible for that. On the other hand, when dealing with high-risk tumors, the technique is contraindicated due to very high risk of tumor recurrence. Scarring, hyperpigmentation, and hypopigmentation are the most common side effects.

CO_2 Laser

Some authors report encouraging results with acceptable cosmetic outcomes when treating multiple superficial BCCs with CO_2 laser. New, more elaborate CO_2 laser devices in past years with new functions as the ultrapulse modus have resulted to better cosmetic results than in previous years, postoperative pain and complications

being probably more limited when compared to more established thermal destructive techniques for the treatment of low-risk tumors. Due to lack of sufficient number of respective clinical trials, the recommendation strength and the evidence level remain low so far though.

Topical Treatments

Imiquimod

Imiquimod, an innovative topical immune response modifier, widely used nowadays in the treatment of actinic keratoses (in situ squamous cell carcinoma), has revolutionized the treatment of field cancerization. A 6-week treatment strategy, five times a week, is the current recommendation in Europe for the treatment of superficial BCCs, especially multiple BCCs. Imiquimod binds to Toll-like receptor 7 on inflammatory cells such as the Langerhans cells of the epidermis, dendritic cells, and monocytes and induces cytokine secretion (IFN-α and TNF-α), resulting to a local immune response and eradication of the cancer cells. Sustained clearance rates of 80 % after treatment are reported with the protocol mentioned above. There is evidence that BCCs with a tumor thickness >0.40 mm are more likely to recur, thus limiting its use to the treatment of superficial BCCs. Some authors report acceptable results in the treatment of smaller nodular tumors as well, especially after curettage or when combining with cryotherapy. These treatment strategies could be eventually discussed in selected case, if surgery is refused or contraindicated due to patient-related limitations. Imiquimod, along with cryotherapy, topical FU, and PDT, is also a reliable alternative to surgery in the treatment of patients with BCNS, dealing with multiple eruptive tumors constantly.

Excessive topical inflammation during treatment or systemic flu-like symptoms could affect patient's compliance and result to disruption of treatment. In spite of the frequent inflammation of treated lesions, they usually heal well, leaving no scars but a good cosmetic result instead.

Systemic Treatments

Chemotherapy

For the therapeutic approach of uncontrolled or metastatic disease, many chemotherapeutic protocols have been proposed so far, those based on cisplatin appearing to be the most efficient with relatively high remission rates; unfortunately enough remission in most cases does not last longer than some months.

Hedgehog Inhibitors

Understanding of the molecular biology of BCC and of the role of the sonic hedgehog pathway activation has been a major breakthrough, making possible in recent years the development of elaborate targeted treatments inhibiting the pathway activation. Vismodegib is the first synthetic SMO inhibitor to complete early clinical evaluation successfully (Phase I); a dose of 150 mg/day was recommended as Phase II dose, and based on these data, FDA approved in January 2012 its use for the treatment of advanced basal cell carcinoma, clinically uncontrolled or metastasized, in the context of an early access program. Since about 80–90 % of BCCs harbor PCTH mutations leading to SMO activation and another 10 % demonstrate SMO mutations, the selected use of an SMO inhibitor like vismodegib appears reasonable in either case. Thus treatment can be initiated without any genetic screening required, compared to malignant melanoma where B-Raf mutations are seen only in about 60 % of melanoma patients. Elevated levels of Gli1, a downstream marker of the hedgehog pathway, have confirmed the role of the pathway activation in the pathogenesis of BCCs. The most common adverse reactions include alopecia and dysgeusia, both probably directly related to inhibition of the pathway, since in related tissues the hedgehog pathway seems to retain some role after the embryogenesis. Muscle spasms, weight loss, nausea, and diarrhea are further clinical signs of vismodegib-related toxicity which could lead to treatment discontinuation. A median progression-free survival of 9, 6 months after treatment discontinuation, has been reported.

The drug-related adverse effects make the feasibility of a wider prophylactic use of vismodegib in BCNS patients for the prevention of new BCCs questionable. Another great challenge could constitute the occurrence of drug resistance, already reported in patients with medulloblastoma where the sonic hedgehog pathway also plays a role.

Currently new hedgehog inhibitors are tested. Limiting toxicity and thus optimizing patient compliance may play a key role in the wider use of hedgehog inhibitors. Novel therapeutic agents targeting not only SMO but other points downwards in the pathway cascade as well may be developed, opening new horizons not only in the treatment of advanced BCC but also offering new systemic therapeutic approaches in the treatment of multiple BCCs and of patients with the Gorlin syndrome in the years to come.

Follow-Up

Follow-up for a period of at least 3 years is generally recommended after diagnosis and treatment of any new BCC, not only due to the considerable recurrence rates (recurrent disease can present even after 5–10 years) but considering the possibility of new BCCs as well. Indeed there is a tenfold increase compared to the general population. Patients with high-risk BCCs should be clinically assessed twice yearly; imaging techniques such as ultrasound or CT/MRI could be used if required to exclude metastasis. For patients with low-risk BCCs, a yearly clinical examination should be enough. In any case follow-up strategies should be individualized; in selected patient groups such as the immune compromised or patients with genetic predisposition to BCC formation, a lifetime follow-up should be advised.

Bowen's Disease

10

Mirna Situm

Abbreviations

5-FU	5-Fluorouracil
ALA	5-Aminolevulinic acid
BD	Bowen's disease
HPV	Human papillomavirus
MAL	Methyl aminolevulinate
PDT	Photodynamic therapy
SCC	Squamous cell carcinoma

Key Points

- Bowen's disease (BD) is an intraepidermal squamous cell carcinoma (SCC) with a tendency for progressive growth and low invasive risk, characterized by slowly growing, erythematous plaque with an irregular border, surface scaling and crusting.
- The aetiology of BD is multifactorial including irradiation, carcinogens (e.g. arsenic), immunosuppression and viral infection.
- The age and sun-exposed body distribution of BD suggest the importance of chronic sun damage as a factor in the carcinogenesis of BD.
- The goal of therapy for Bowen's disease is to reduce morbidity and to prevent complications.
- The choice of treatment should be guided by its efficacy, location and size of BD, number of lesions, availability of the therapy, the clinician's expertise, patient's age, immune status, concomitant medication, comorbidities and patient compliance and, not less important, cosmetic outcome of the treatment.
- There is also an increasing choice of home-applied treatments today, with less treatment-related morbidities.
- Sun avoidance is strongly recommended for all patients with skin tumours.

Definition and Epidemiology

Bowen's disease (BD) is an intraepidermal squamous cell carcinoma (SCC) with a tendency for progressive growth and low invasive

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_10, © Springer-Verlag Berlin Heidelberg 2015

risk, characterized by slowly growing, erythematous plaque with an irregular border, surface scaling and crusting. The risk of progression to invasive SCC is 3–5 % for extragenital lesions and 10 % for genital lesions. BD is very common in the Caucasian population with an incidence of 14 per 100,000 in some populations. The peak age group for BD is the seventh decade. The ratio of Bowen's disease is approximately equal between males and females. BD is more commonly found on the head and neck of men and on the lower limbs and cheeks of women. BD is usually a solitary lesion, but in 10–20 % of patients, it occurs at multiple sites.

Fig. 10.1 Bowen's disease on the anterior neck

Basic Concepts of Pathogenesis

The aetiology of BD is multifactorial including irradiation, carcinogens (e.g. arsenic), immunosuppression and viral infection. The age and sun-exposed body distribution of BD suggest the importance of chronic sun damage as a factor in the carcinogenesis of BD. Photochemotherapy and radiotherapy are also important irradiation aetiologic factors. Arsenic exposure occurs after a time lag of 10 years. The main sources of arsenic exposure in the past included Fowler solution, a medication formerly used to treat psoriasis, and Gay solution, formerly used to treat asthma, contaminated well water and certain pesticides. Agricultural workers may be exposed to arsenic salts used as fungicide, weedkiller or pesticide. Human papillomavirus (HPV) type 16 is the most common subtype isolated from lesions of Bowen's disease, although other subtypes have also been found (e.g. type 18, 31, 33, 51). Aetiological involvement of HPV has strong therapeutic implications, as HPV-induced BD is responsive to agents that have combined antiviral and antitumour effect. Immunosuppressed patients (e.g. renal transplant patients, AIDS) with BD are more likely to have multiple tumours and more aggressive tumours. Therefore, educating immunosuppressed patients about sun exposure is very important. Other possible causes include genetic factors, trauma, chronic injury or dermatoses.

Fig. 10.2 Pigmented Bowen's disease on the right groin

Clinical Presentation

Patients often present with an asymptomatic, slowly growing, erythematous, well-demarcated scaly patch or plaque most frequently occurring on the lower legs but can occur anywhere on the skin or mucosal surfaces (Fig. 10.1). The head, neck and extremities are the most commonly affected anatomic locations in men, while the lower limbs and cheeks are most commonly affected in women. The initial lesion is a small, red, scaly, slightly raised area that gradually enlarges in irregular fashion. The scales can easily be removed from the surface, without bleeding. The surface is usually flat but may become hyperkeratotic or crusted. Ulceration is a sign of invasive carcinoma, usually arising many years after the initial

lesion. Lesions vary in size from a few millimetres to several centimetres in diameter. Lesions are rarely pigmented (Fig. 10.2), especially in the genital region and the nails. Bowen's disease may also occur on mucous membranes. When it arises on the glans penis, it is known as erythroplasia of Queyrat and is characterized by moist, velvety or smooth plaques. BD presents as a single lesion in two-thirds of cases. Multiple lesions are more common in immunosuppressed patients.

Diagnosis

The diagnosis of BD is confirmed by skin biopsy. It is important to sample many areas of larger lesions to exclude evidence of invasion. The normal epidermis is replaced by abnormal keratinocytes, which show disordered differentiation and loss of epithelial polarity. There is a disturbance of epidermal organization, and cells keratinize prematurely losing their intercellular connections. There are a variable acanthosis and thickened interpapillary ridges but intact dermal-epidermal junction. The atypical cells have large, hyperchromatic nuclei. Vacuolization, individually keratinizing cells and multinucleated cells are present in the epidermis. Large pale keratinocytes with abundant ground-glass cytoplasm, so-called pagetoid cells, are often distributed haphazardly throughout the epidermis. Multiple mitotic figures are usually visible. The surface scale is formed by thickened, loose, parakeratotic cells. There is a dense inflammatory infiltrate in the papillary dermis. Although the basal cell layer is intact, extension of keratinocyte atypia down the follicular epithelium is seen (Fig. 10.3a, b).

Bowen's disease must be distinguished from papulosquamous dermatoses like lichen simplex and psoriasis. The lack of improvement to topical steroids is suggestive of Bowen's disease. Malignant tumours like superficial basal cell carcinoma or premalignant lesions like actinic keratosis may also mimic BD. The diagnosis of BD is confirmed by pathological examination of lesional skin biopsy. Complete skin examination must be performed in patients with BD, especially of sun-exposed skin, because of higher incidence of nonmelanoma skin cancer in these patients. Dermoscopy has become an integrative part of the clinical examination of skin tumours and premalignant lesions like actinic keratosis and Bowen's disease.

Differential Diagnosis

Differential diagnosis of well-demarcated pink-red plaque(s) of BD includes nummular eczema, contact eczema, psoriasis, lichen planus, seborrheic keratosis, tinea corporis, actinic keratosis, verruca vulgaris, condyloma acuminatum, superficial basal cell carcinoma, squamous cell carcinoma, melanoma, Merkel cell carcinoma and Paget's disease.

General Principles of Treatment

The history of Bowen's disease and other intraepithelial neoplasia is not yet completely understood; therefore it is difficult to determine how aggressive treatment should be. The age group, number and size of lesions and affected site(s) may all influence therapeutic choice. In the elderly patients with slow progressive thin lesions on the lower leg where healing is poor, there is an argument for observation rather than intervention. Therapeutic aim should be to avoid mutilating surgery. Most treatments have a recurrence risk; therefore follow-up at 6–12 months is recommended. The shorter follow-up is recommended with history of past recurrence, presence of multiple lesions and immunosuppression.

5-Fluorouracil

Topical chemotherapy with 5-fluorouracil (5-FU) is used for the treatment of single or few small lesions at good healing sites like the face. It should be avoided for lesions at poor healing sites and for perianal lesions, due to a higher recurrence

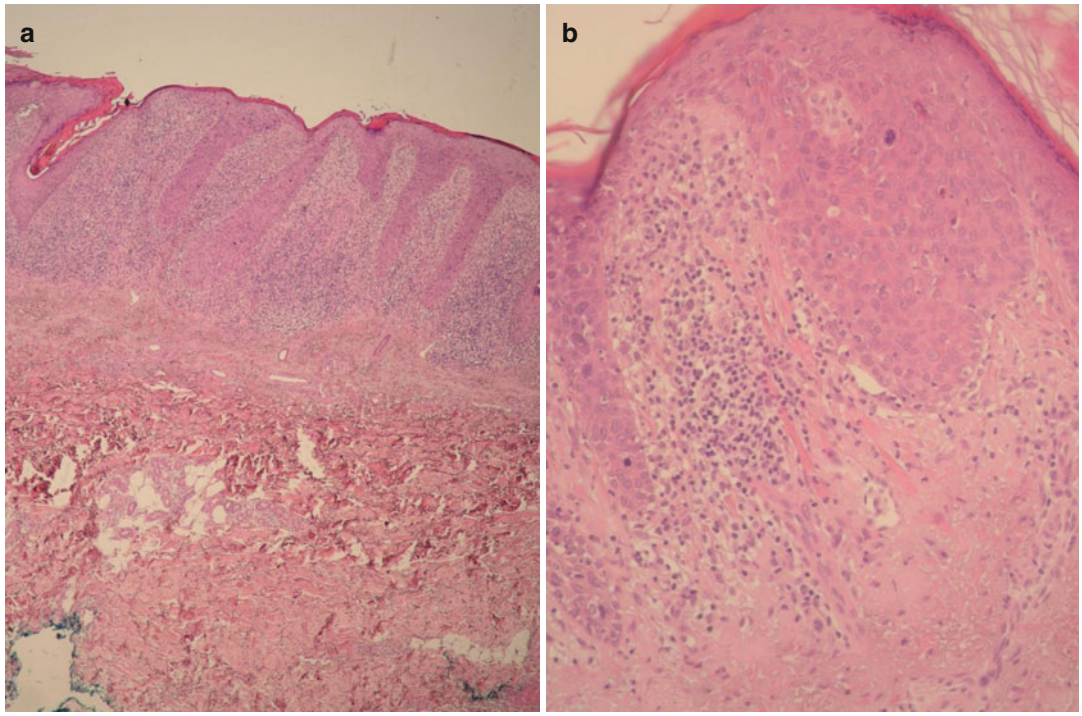

Fig. 10.3 (**a**) Bowen's disease on the left wrist (40×). (**b**) Bowen's disease on the left wrist (200×)

rate of perianal BD treated with 5-FU cream. Five percent 5-FU cream is applied once or twice daily for a period between 1 week and 2 months, and the treatment is repeated if required. Efficacy is increased by occlusion or iontophoresis. In erythroplasia of Queyrat, application of 5 % 5-FU cream twice daily for 4–5 weeks is recommended, but irritation and inflammation usually limit the treatment.

Imiquimod

Topical 5 % imiquimod cream should be used for the treatment of small and large, single lesions on poor healing sites, as well as on good healing sites and for penile lesions. It is not licensed for BD treatment in many countries. It has both anti-HPV and antitumour effects and is therefore useful for HPV- and non-HPV-associated BD. The recommended duration of treatment is 16 weeks and the dose varies from once weekly to five times per week. Five percent imiquimod cream is also beneficial in the treatment of BD in immunosuppressed patients. It can be used in combination with topical 5 % 5-FU. There is evidence that cytokines induced by imiquimod improve the therapeutic efficacy of 5 % 5-FU in Bowen's disease (Smith et al. 2001a, 2001b).

Diclofenac

Diclofenac 3 % gel has been successfully used in the treatment of actinic keratosis. There are promising data of BD successfully treated with 3 % diclofenac gel once or twice daily for 8 weeks (Dawe et al. 2005). The treatment was well tolerated with mild inflammation after 6 weeks and mild side effects like itching and dryness. Complete clinical and histological clearance was proven by biopsies taken 4 weeks after end of treatment (Patel and Stockfleth 2007). Given its mechanism of action, diclofenac 3 % gel may have potential to halt the progression

of actinic keratoses (AKs) in the setting of field cancerization and BD. These promising data have to be proven in randomized controlled trials, and recurrence rates in long-term follow-up have to be investigated.

Cryotherapy

The results of BD treatment with cryotherapy depend on the used techniques and regimens. Liquid nitrogen cryotherapy is used in single freeze-thaw cycle (FTC) of 30 s or two FTCs of 20 s with a thaw period. These regimens cause discomfort and may cause ulceration on the lower leg. Cryotherapy is recommended for the treatment of multiple BD on good healing sites, facial BD as well as digital, penile and small, single lesions on poor healing sites. Cryotherapy has good success rate with adequate technique. It is less effective than curettage and PDT but also less expensive and less time consuming.

Curettage with Cautery/ Electrocautery

Curettage is the treatment of choice for small, single or few lesions on good or poor healing sites and facial lesions. It should be avoided for the treatment of perianal BD and large lesions on good or poor healing sites. Cure rates ranged from 81 % for curettage up to 98 % for curettage and cautery with a follow-up of 2.5–4 years. Curettage and cautery are a safe and effective therapy of BD with a very good cost-benefit analysis.

Excision

Surgical excision of BD is the treatment of choice for small and single lesions, as well as digital and perianal BD. The main advantage is the securing of histological free excision margins. Mohs micrographic surgery is the recommended treatment for digital and genital BD, the sites of the body where tissue-sparing surgery is necessary (e.g. fingers and nail unit, penis). Mohs micrographic surgery uses the removal of skin cancers with very small margins of normal tissue followed by frozen section examination of nearly 100 % of the tissue margin. It is also an excellent method for larger lesions, poorly demarcated lesions and recurrent lesions on the head and neck.

Photodynamic Therapy (PDT)

Photodynamic therapy involves the introduction of a photosensitizing agent into the body, which is retained preferentially by the tumour cells. PDT is based on the combination of light and light-sensitive agents (e.g. porphyrins) in the presence of oxygen. The energy of photons is absorbed by porphyrins and then transferred to surrounding oxygen molecules resulting in formation of singlet oxygen and free radicals responsible for cell death. Most commonly used topical photosensitizers are 5-aminolevulinic acid (ALA) and methyl aminolevulinate (MAL). For the production and accumulation of these photoactive porphyrins, a sufficient period of time is necessary before the light activation, for MAL 3 h, for ALA 4–18 h. PDT is well suited for single or multiple large lesions and poor healing sites. The adverse effects include local side effects, such as burning and stinging, and, rarely, erosions, ulceration and hyperpigmentation or hypopigmentation. PDT has been particularly useful in immunosuppressed subjects (e.g. transplant recipients) because of the possibility for repeated treatment of large lesional areas.

Radiotherapy

Different radiotherapy techniques like external beam radiotherapy, grenz rays and radioactive skin patches have been used in the treatment of BD with reported cure rates between 94 and 100 %. Radiation therapy should be considered for poor surgical candidates or patients with multiple lesions. It should be avoided for lower extremity lesions due to impaired healing.

Laser

Lasers have been used to treat lesions at difficult sites, such as the fingers and genitalia. Case reports and series have shown a benefit of using argon, carbon dioxide and Nd:YAG lasers in the treatment of some BD lesions. There are also reported laser treatment failures or progression to invasive SCC of lower leg lesions after 100 % healing at 2 months and complete response at 6 months. Therefore, CO_2 laser can be used for penile or digital BD, but there is limited data of recurrence rates (Table 10.1).

Other Treatments

Acitretin

Retinoids have been used alone or in combination with 5-FU in anecdotal cases, but the relative merits of each are unclear in the combination approach. The other patient did not tolerate the acitretin and no improvement was seen in BD lesions.

General Therapy Guidelines

The goal of therapy for Bowen's disease is to reduce morbidity and to prevent complications. The choice of treatment should be guided by its efficacy, location and size of BD, number of lesions, availability of the therapy, the clinician's expertise, patient's age, immune status, concomitant medication, comorbidities and patient compliance and not less important, cosmetic outcome of the treatment. There is also an increasing choice of home-applied treatments today, with less treatment-related morbidities. Sun avoidance is strongly recommended for all patients with skin tumours, and due to a 10 % recurrence rate with most treatment options, patients with a history of Bowen's disease or other skin cancers should be evaluated with a total body skin examination every 6–12 months.

Table 10.1 Summary of treatment options for Bowen's disease

	Application	Treatment duration	Advantages	Disadvantages	Lesion characteristics
5-Fluorouracil 5 % cream	Once or twice daily	1–8 weeks	High cure rates	Irritant	Small, single/few on poor healing site
Topical imiquimod 5 % cream	Once daily	Up to 16 weeks	High cure rates	Expensive	Large, single/poor healing site
Cryotherapy	Single freeze-thaw cycle	30 s	Low recurrences	Slow healing, painful	Facial, multiple, good healing site
Curettage		Single treatment	Cheap, high cure rates	Morbidity	Small, single, few on good and poor healing site
Excision		Single treatment	Cheap, high cure rates	Morbidity on lower leg wounds	Perianal, digital, small, single/few on poor healing site
PDT	Topical PDT using topical 5-ALA	One or two treatments	High cure rates	Expensive, painful	Large or small, single, poor healing site
Radiotherapy	External beam X-radiation	Single/repeated	High cure rates	Acute radiation reactions	Perianal, penile
Laser	CO_2 laser	Single/repeated	Penile lesions	Depth of treatment, progression to SCC	Penile, digital

Bullous Pemphigoid

11

Panagiotis G. Stavropoulos and Eleni Remoudaki

Key Points

- Bullous pemphigoid is considered the most common autoimmune blistering disease.
- The target antigens are the BP antigens with molecular weights of 230 and 180 kDa, BPAG1 and BPAG2, respectively.
- Treatment can be divided into three phases: initial control, consolidation, and withdrawal.
- Severity, age of patient, and presence of underlying disease must be considered in determining therapeutic agents and doses.

Definition and Epidemiology

Bullous pemphigoid (BP) is an acquired, non-scarring, subepidermal blistering disease, usually occurring in the elderly, but may rarely affect children and younger adults. BP is considered the most common autoimmune blistering disease. Women and men are equally affected and no racial or geographical predilection is recognized. There is no known specific HLA correlation. BP has been reported in association with a variety of autoimmune diseases, including systemic lupus erythematosus, diabetes mellitus, lichen planus, rheumatoid arthritis, Hashimoto thyroiditis, pemphigus vulgaris, psoriasis, and neurological disorders, particularly dementia and Parkinson's disease. There have been many reports of BP associated with malignancy, although there is much controversy over this association.

A. Syggros Hospital, Athens, Greece

Basic Concepts of Pathogenesis

BP is an autoimmune skin disease and the cause of the autoantibody production remains obscure. The target antigens are the BP antigens with molecular weights of 230 and 180 kDa, BPAG1 and BPAG2, respectively. BP180 is a type II transmembrane protein that spans the lamina lucida and projects into the lamina densa of the epidermal basement membrane. Furthermore the 230-kDa protein called BP230, which was originally identified as the major antigen of BP, is a cytoplasmic component of hemidesmosomes that belongs to the plakin family; it promotes the linkage of keratin intermediate filaments to hemidesmosomes. Antibody binding to BP antigen is postulated to be the initial step in blister formation. Fixation of immunoglobulin G to the basement membrane zone activates the complement cascade (mainly C3, C5a), which causes

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_11, © Springer-Verlag Berlin Heidelberg 2015

chemotaxis of leucocytes and degranulation of mast cells. Eosinophils and neutrophils are recruited by mast cell-produced factors to the basement membrane zone, where they release tissue-destructive enzymes (proteases) resulting in dermal-epidermal separation. Several drugs have been associated with the onset of BP including furosemide, spironolactone, neuroleptics, sulfasalazine, penicillamine, and captopril. Local irritation and damage to the skin have been all implicated in the induction of disease. Ultraviolet (UV) light or psoralen and UVA (photochemotherapy) and other physical agents including thermal burns, wounds skin grafts, and radiotherapy have been reported to induce BP in normal skin.

Clinical Presentation

Urticarial and figured erythemas are common prodromal eruptions in BP, by weeks or months. In some cases, bullae may not become clinically apparent. Subsequently, large tense blisters arise with a base of normal or erythematous skin (Fig. 11.1). Grouping may be present and lower abdomen, inner thighs, groin, axillae, and flexural aspects of the forearms and the legs are sites of predilection for the lesions. However, localized forms of BP are not uncommon. Pemphigoid nodularis, vegetans, and dyshidrosiform represent some clinical variants of "classical" BP. Nikolsky's sign is negative and mucosal lesions are usually clinically insignificant, consisting of small tense bullae in the oropharynx. The natural history of BP is that of persistent disease with eventual remission occurring within 5 years in the majority of patients. Prognosis is considered fair, but BP is a potentially fatal disease particularly in the elderly, where health may already be fragile.

Diagnosis and Differential Diagnosis

A subepidermal split and a mixed dermal infiltrate of numerous eosinophils, some neutrophils, and lymphocytes are found in biopsy specimens. IgG and/or C3 is deposited along the basement membrane zone in virtually all active cases of BP (direct immunofluorescence), and about 70–80 % of patients are found to have circulation IgG to the

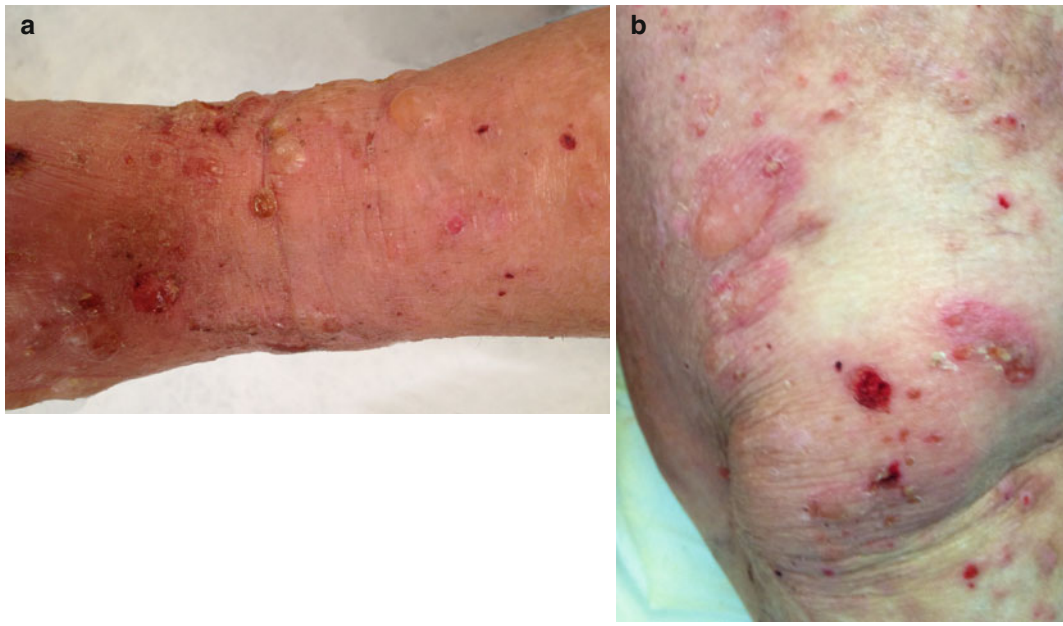

Fig. 11.1 Typical clinical pictures of BP, with tense blisters, erosions, and crusts

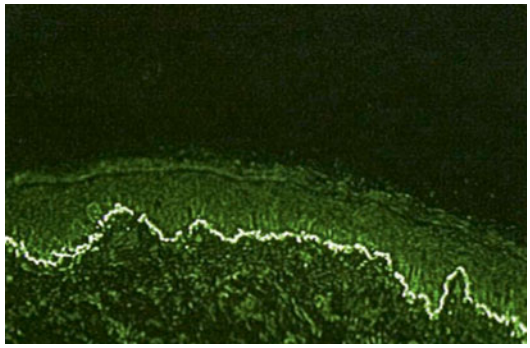

Fig. 11.2 Direct immunofluorescence findings in bullous pemphigoid. Linear deposition of mainly IgG and C3 along the epidermal junction

basement membrane zone of normal stratified squamous epithelia (indirect immunofluorescence) (Fig. 11.2). When 1 mol/L sodium chloride split skin is used as the substrate, circulating autoantibodies from the patient's serum deposit on the roof side of the artificial blister at the dermoepidermal junction (DEJ). In occasional cases, these diagnostic techniques will require supplementation with immunoelectron microscopy, immunoblotting, and immunoprecipitation (Table 11.1).

Table 11.1 Differential diagnosis of bullous pemphigoid

Pemphigoid gestationis	Rare disease of pregnancy and postpartum period
Cicatricial pemphigoid	Scarring autoimmune bullous disease primarily affecting mucosal surfaces
Epidermolysis bullosa acquisita	Trauma-induced blisters healing with scars, different target antigen
Dermatitis herpetiformis	Young adults, pruritic papules and vesicles symmetrically distributed over extensor surfaces. Enteropathy (80 % of cases). HLA-B8-DR3
Linear IgA dermatosis	Younger age group, linear IgA deposition at basement membrane zone (direct immunofluorescence)
Erythema multiforme (bullous)	Typical distribution of lesions, different immunofluorescence findings
Bullous systemic lupus erythematosus	Lesions distributed on sun-exposed areas, subepidermal blisters with neutrophils, different immunofluorescence findings
Other disorders	Porphyria cutanea tarda, drug reactions, insect bite reaction, bullous lichen planus, etc.

General Principles of Treatment

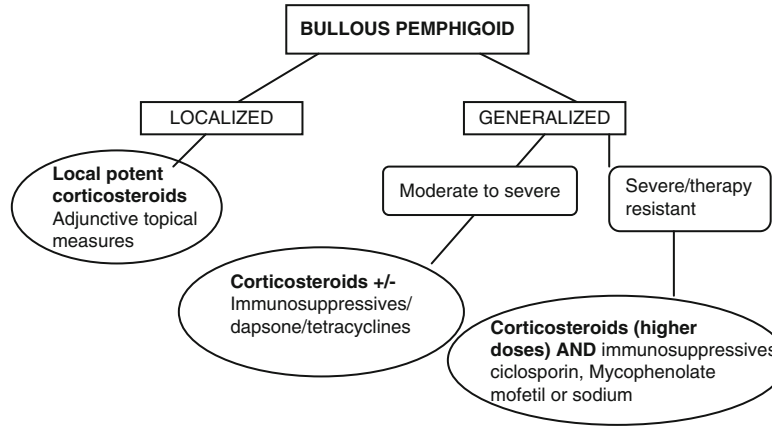
- Treatment can be divided into three phases: initial control, consolidation, and withdrawal. The first objective is stopping or significantly reducing new blister formation. Therapy is introduced and adjusted upward as required and slowly reduced to the lowest possible level while maintaining a low level of disease activity. Complete withdrawal of therapy is carried out if possible.
- The severity of disease, age of patient, and presence of underlying disease (diabetes mellitus, hypertension, peptic ulceration, osteoporosis, malignancy) must be considered in determining therapeutic agents and doses.
- Localized disease may initially be managed with local very potent steroids and adjunctive measures.
- Moderate (20–60 lesions) to severe (more than 60 lesions) disease will usually require systemic steroids in moderate doses alone or in combination with immunosuppressives, dapsone, or tetracyclines.
- Severe therapy-resistant disease requires systemic steroids in higher doses and immunosuppressives, cyclosporin, plasmapheresis, or γ-globulin therapy as adjunctive agents.
- Immunosuppressive agents, due to their delayed onset of action (4–8 weeks), can be started at the same time as systemic steroids. Thus, steroids are used to achieve initial control then tapered at the time when the immunosuppressives are taking effect.

Recommended Therapies (Table 11.2)

Supportive care and adjuvant therapy

Supportive care is essential in cases in which widespread skin denudation and immobility render the patient susceptible to fluid loss, electrolyte imbalance, infection, and thromboembolic events. A bed that spreads pressure is useful in severe disease. The blisters caused by widespread cutaneous and mucosal erosive disease may

Table 11.2 Algorithm of recommended therapies



require frequent oral analgesics, and sedating antihistamines are frequently given in the initial stages of BP to reduce pruritus. Diluted saline or potassium permanganate compresses and baths assist in keeping the lesions clean. Gastric protection, usually with a proton pump inhibitor, should be considered in patients receiving systemic steroids. Calcium supplementations, vitamin D, and bisphosphonate are recommended and have been shown to be effective in preserving bone density in patients receiving systemic corticosteroids, especially in postmenopausal women and men over 50 years.

Topical Therapy

Topical steroids should be considered first-line treatment in localized or moderate BP, and they are also extremely useful adjuvants to systemic therapy when disease is more severe. Very potent topical steroids (clobetasol propionate 0.05 % twice daily) are usually required initially, with tapering to lower potency agents. However, their use in extensive disease may be associated with systemic absorption and adverse events. Triamcinolone acetonide 3.10 mg/mL may be injected weekly to resistant lesions. In the event of secondary infection, topical antibacterial agents may be safely applied. Oral hygiene should be maintained with antiseptic mouthwashes between meals. A soft diet including pureed food and liquid protein supplements is best during active disease. Severe pain may be treated with topical anesthesia (lidocaine (lignocaine) 2 % viscous solution) particularly before meals. Tetracycline mouthwashes (250 mg dissolved in 50 mL of water) may be used to treat oral mucosa infections.

Systemic Corticosteroids

These are most useful drugs in the treatment of BP, rapidly inducing remission in the majority of patients. Our experience and most large series show that the majority of patients respond to 40-80 mg daily of prednisone or prednisolone and it is only rarely necessary to exceed 100 mg daily. In general, doses of prednisolone 0.75–1.0 mg/kg daily in widespread BP are effective within 1–4 weeks in about 60–90 % of the patients. However, depending on the severity of the disease, the doses can be adjusted. For patients with severe involvement, doses of 0.75–1 mg/kg are recommended and lower doses of 0.5 mg/kg for moderate disease and 0.3 mg/kg for mild or localized disease, respectively. Healing of existing lesions and cessation of new blister formation reflect a positive response to therapy. Once the disease is under control, the steroid dose should be tapered slowly and eventually changed to an alternate-day regimen to minimize the steroid side effects. The duration of systemic steroid treatment is likely to be many months and sometimes indefinite. Corticosteroid pulse therapy, in which patients are given 1 g of methylprednisolone intravenously for three consecutive days, may be given for resistant disease. Oral steroids must then be given as maintenance therapy.

However, caution must be recommended in utilizing this type of therapy, particularly concerning the effects of prolonged systemic steroid therapy which are numerous: diabetes mellitus, hypertension, gastrointestinal bleeding, osteoporosis, cataracts, and increased susceptibility to bacterial, fungal, and viral infections. Immunosuppressive and metabolic adverse events are considered dose dependent. Appropriate monitoring includes urinalysis for glucose, fluid imbalance, blood pressure, and body weight. Routine biochemistry may be done at weekly or twice weekly intervals in the first instance, dropping to monthly thereafter. Osteoporosis profile tests and ophthalmological examination for cataracts should be performed as a baseline and thereafter every 6 months, particularly in postmenopausal women.

Immunosuppressive Agents

Azathioprine

This drug is most commonly employed in combination with steroids and sometimes for maintenance following steroid withdrawal. The usual dose is 50–100 mg daily. Azathioprine dose can be optimized with regard to myelosuppression risk by prior assay of thiopurine methyltransferase (TPMT). However a normal TMPT lever does not totally preclude myelotoxicity. The usual dose of azathioprine use, the steroid maintenance dose, may be significantly reduced and in some instances discontinued. Side effects of azathioprine include dose-dependent bone marrow depression, idiopathic hepatitis, increased susceptibility to infection, teratogenicity, and increased risk of internal and cutaneous liver function tests and urinalysis. The full blood count and renal and liver function tests are repeated weekly for 8 weeks and then monthly.

Cyclophosphamide

Cyclophosphamide is more toxic than other immunosuppressive drugs used for BP. It may be considered only for exceptionally refractory disease. The drug may be given initially in doses of 100–200 mg daily and 3 weeks later in maintenance doses of 100 mg daily. A pulsed steroid cyclophosphamide regimen is effective in severe cases of BP, permitting low cumulative steroid doses. Dexamethasone 100 mg i.v. given on three consecutive days, with the addition on day 1 of cyclophosphamide 500 mg, is given per day between pulses. The pulses are initially repeated every 2 weeks, reducing to every 10 weeks in combination with ongoing oral cyclophosphamide over a period of 6 months. Side effects include nausea and vomiting, bone marrow depression, hemorrhagic cystitis, and increased risk of malignancy. Monitoring is as for azathioprine, with the addition of urinalysis weekly for the first 8–12 weeks and every 2 weeks thereafter. Cardiac monitoring is required during pulse therapy.

Chlorambucil

Chlorambucil has been used as a steroid-sparing agent in the treatment of BP with excellent results. However, its use is not recommended except in special cases because of concern about the induction of hematological malignancy (acute myeloid leukemia). The drug is initially given at 0.1 mg/kg per day in combination with prednisolone 40–60 mg/day. The chlorambucil dose is reduced over 6 weeks to a maintenance dose of 2 mg daily. Prednisolone is gradually withdrawn over a 4-month period, chlorambucil being discontinued some weeks later. There is a 50 % reduction in the cumulative dose of prednisolone. Side effects include bone marrow suppression, which can be severe, often resulting in transient dose-related thrombocytopenia. Appropriate monitoring is with baseline and weekly blood counts. Hematological malignancies may be related to a cumulative dose of 1 g or more of the drug.

Cyclosporin

Cyclosporin cannot be recommended in the routine treatment of BP. However it has been used in the treatment of BP at doses of 5–8 mg/kg per day as a single agent or of 5 mg/kg per day in combination with steroids. According to our experience, combined therapy has a significant steroid-sparing effect and induces remission of BP in all patients, with monotherapy being less successful. The side effects include hypertension, renal dysfunction, raised lipids, hypertrichosis, gum hyperplasia, susceptibility to infection, and

increased risk of malignancy. Baseline blood pressure should be recorded, and the laboratory investigations required include complete blood picture, urea, serum creatinine, creatinine clearance, liver function tests, fasting lipids, and urinalysis. Serum creatinine should be repeated every 2 weeks for the first month with all the other previously mentioned laboratory parameters.

Dapsone and Sulfonamides

BP may respond well to dapsone or the sulfonamides (sulfapyridine and sulfamethoxypyridazine) either alone or in combination with other agents. Dapsone is started at 50 mg daily and increased to 100 mg daily after 5–7 days if no response is apparent. Response is rapid, within 2 weeks. Dapsone may be used in combination with topical steroids or may be added (150–300 mg daily) to prednisolone or azathioprine therapy, achieving adequate control of disease activity and permitting a reduction in the steroid dose. Although these are not drugs of first choice for BP, they may be useful in the management of patients in whom corticosteroids are contraindicated or not tolerated. Side effects include dose-related hemolysis and methemoglobinemia, cutaneous hypersensitivity reactions, peripheral neuropathy, hepatic damage, and renal failure. Monitoring should be with baseline tests and electrolytes. Glucose-6-phosphate dehydrogenase deficiency must be excluded prior to commencing therapy. Estimation of methemoglobinemia is obtained as clinically indicated.

Alternative and Treatment Suggestions

Topical Tacrolimus

The use of topical tacrolimus is limited due to local irritation and high price compared to topical steroids. It may be used as an alternative in localized disease as it is not implicated in skin atrophy.

Mycophenolate Mofetil (MMF) or Sodium (MMS)

MMF is an inhibitor of purine synthesis in activated T and B cells and is considered a generally well-tolerated immunosuppressive agent. They are both used for prevention of allograft rejection in transplantation medicine. MMF is a well-tolerated and effective corticosteroid-sparing agent in autoimmune bullous disease, and several suggest that complete remission is achieved more frequently with the use of MMF over azathioprine, with less hepatotoxicity. They have been reported as effective in controlling BP in doses of 0.5–1 gr twice daily, both as adjunct to systemic prednisolone and as monotherapy following disease relapse.

Anti-inflammatory Antibiotics/ Niacinamide

Tetracyclines and niacinamide (nicotinamide) may be considered as treatment in adults, perhaps in combination with topical corticosteroids. Niacinamide is used between 500 and 2,500 mg daily, usually started at 500 mg and then gradually increased. Tetracycline has been used at doses of 500–2000 mg daily, doxycycline at 200–300 mg daily, and minocycline at 100–200 mg daily. Minocycline has a worse side-effect profile and therefore is not the first choice. Erythromycin should be considered for treatment, particularly in children and perhaps in combination with topical corticosteroids. Side effects include gastrointestinal symptoms, photosensitivity, headache, benign intracranial hypertension, hyperpigmentation (minocycline), and candidosis. The combination of tetracycline 500 mg four times daily or minocycline 100 mg twice daily and niacinamide 500 mg twice daily is efficacious in some BP patients.

Plasmapheresis

Plasmapheresis is used as an adjuvant to corticosteroids in the treatment of BP, showing a steroid-sparing effect. Prednisolone is administered in combination with eight large-volume plasma exchanges over 4 weeks. In our experience a higher mean daily steroid dose is required to control disease activity when steroid is given alone (1 mg/kg) than with the dual therapy (0.6 mg/kg). The mild side effects of fever, chills, and hypertension are relatively common. However, the potential difficulties include maintaining venous access, a bleeding tendency, electrolyte imbalances, allergic reactions, pulmonary edema, and septicemia.

Deaths may also occur. Frequent observation of vital signs and cardiac monitoring are required during the procedure. It is suggested that weekly full blood examination, electrolytes, coagulation studies, and liver function tests are carried out.

Gammaglobulins

Gammaglobulins given alone in a dose of 100–400 mg/kg for five consecutive days do not appear to be more than temporarily effective in the treatment of BP. The possible steroid-sparing effect awaits further investigation.

Methotrexate

Methotrexate (5–15 mg weekly) can be effective at controlling BP in elderly patients, either as monotherapy or in combination with topical or systemic steroids**.**

Biologic Agents

Only a few reported cases have been treated with tumor necrosis factor-α (anti-TNF-α) and the anti-CD20 agent, rituximab. Regarding anti-TNF-α agents, there is conflicting evidence as to whether these agents treat or induce BP. Until further supportive evidence is available, their role in BP remains limited.

Childhood Bullous Pemphigoid

Due to its rarity and benign nature, preference should be given to low-toxicity treatments (e.g., erythromycin) and topical steroids.

Candidiasis

12

Dimitris Rigopoulos

Key Points

- Candidiasis refers to infections caused by *Candida* species.
- The most common encountered infections include oral candidiasis, superficial cutaneous candidiasis, candida balanitis, vaginal candidiasis, candida paronychia, candida onychomycosis and chronic mucocutaneous candidiasis.
- Therapy should always include removal of underlying predisposing factors with encouragement for dental and mouth hygiene, keeping dry skin folds, avoidance of detergents that flare up chronic paronychia and reduction of the *Candida* reservoir in the mouth and gut.
- Topical agents used in the treatment of candidiasis include amphotericin B, nystatin, natamycin, miconazole, ketoconazole, econazole, omoconazole, tioconazole and clotrimazole.
- Systemic agents used include itraconazole and fluconazole.

D. Rigopoulos
University of Athens Medical School, 2nd Department of Dermatology, Attikon Hospital, 1 Rimini street, 12641, Athens Greece
e-mail: drigop@hol.gr

Definition and Epidemiology

The term candidiasis refers to infections caused mainly by the classic opportunistic pathogen *Candida albicans* or occasionally by other species of *Candida*, such as *C. tropicalis*, *C. guilliermondii*, *C. parapsilosis*, *C. krusei*, *C. stellatoidea*, *C. pseudotropicalis* and *C. glabrata*. These various yeast species differ in their potential to invade and colonize epithelial and epidermal sites, *C. albicans* being the species with the greatest such potential. Infections of the skin, nails and mucous membranes are the most often encountered candida infections.

Basic Concepts of Pathogenesis

C. albicans, which is part of the normal human flora, is a dimorphic organism, developing in different morphological forms, such as yeasts, hyphae and pseudohyphae. This development is dependent on local conditions. *Different predisposing factors exist, which lead to different types of candidiasis*. Immunosuppression or leukopenia usually leads to systemic candidiasis, which is rare; endocrinopathies (hypoparathyroidism, hypothyroidism, diabetes mellitus), iron or zinc deficiencies and inherited defects of immunity lead to chronic mucocutaneous candidiasis, which is also rare; and diabetes, pregnancy,

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_12, © Springer-Verlag Berlin Heidelberg 2015

antibiotic therapy, high humidity, immersion in water and oral contraceptive drugs lead to *localized cutaneous candidiasis*, which *is the commonest type of disease*. These predisposing factors are extremely important in the management of candidiasis patients, since the reversal of these factors is of great significance and part of the treatment protocol.

Clinical Presentation

Oral Candidiasis

This disease is most commonly seen in infants and the elderly (associated with denture plates). The lesions may be situated on the mucosal surfaces of the tongue or at the corner of the mouth. *One or more whitish*, *sharply defined*, *adherent plaques are the characteristic signs of the condition*. If these plaques are wiped off, an underlying erythematous base is seen. Erosions or ulcerations are occasional complications.

In some cases, patients present with erythema, soreness, marked pain, atrophic mucous membranes and lack of whitish plaques (acute atrophic oral candidiasis).

Hyperplastic plaques on the cheek or the tongue that are not easily removed and develop especially in men who are smokers and over the age of 30 constitute a condition known as candida leukoplakia (chronic hyperplastic candidiasis).

Median rhomboid glossitis is another condition associated with candidiasis and presents with erythema of the tongue surface in the absence of papillae, pain and tenderness.

Chronic atrophic candidiasis (denture stomatitis) affects nearly 25 % of all denture wearers and sometimes children with orthodontic appliances. The condition is characterized by bright red of dusky erythema of the palate and gums, with atrophy of the epithelium and sometimes oedema.

Angular cheilitis (perleche) occurs at the corner of the mouth and it is not always associated with *Candida*. The area is moist, red and fissured, and the symptoms include pain.

Superficial Cutaneous Candidiasis (Candidal Intertrigo)

Any occluded skinfold, especially in hot and humid weather, may become moist and macerated, favouring the development of candidiasis. *Erythema and moist exudation deep in the fold are the characteristic symptoms at the beginning*. Erythema with well-defined borders though not razor sharp as in tinea cruris, subcorneal pustule, satellite pustular or papular lesions, itching and soreness make up the typical clinical pictures as the condition progresses.

Candida Balanitis

Although *candida balanitis* (which *is seen mostly in uncircumcised men*) is usually acquired form a sexual partner with vulvovaginitis, the possible oral and anal origins of the disease should not be forgotten. In mild cases, erythema and tiny papules predominate and are seen after intercourse; in more severe cases, the entire glans can be involved, and soreness may prevent sexual intercourse as it becomes painful.

Vaginal Candidiasis

It has been estimated that 75 % of all adult women will suffer from vaginal candidiasis at some time during their lives. There are two types of the disease, the occasional and the recurrent. In the case of occasional vaginal candidiasis, *C. albicans* is the commonest causative yeast, accounting for over 80 % of isolates. The predisposing factors are antibiotics (which alter the normal vaginal flora), peak production of oestrogen before menstruation or use of high-oestrogen contraceptives (increase of glycogen, a nutrient source of *C. albicans*), pregnancy (increased levels of circulating oestrogen and progesterone raise the glycogen content of vaginal epithelial cells), immunosuppressive drugs of disease, increased sugar levels of the urine

and vaginal secretions and synthetic or tight-fitting clothes (they create a warm and moist environment). The condition presents with itching, soreness, erythema and a thick, creamy-white discharge. *Vaginal candidiasis is recurrent in 10–20 % of patients*, and the male partner may play a part in reinfection (50 % of male partners carry the same strain of *Candida* on the penis or in the mouth). Symptoms are the same as in occasional vulvovaginitis, and only in chronic cases does the vaginal mucosa become glazed and atrophic.

Candida Paronychia

This is a chronic condition found *mainly in those who frequently immerse their hands in water* (housewives, chefs, etc.) The nail fold is red and swollen, thick white pus may be discharged and the patient complains of pain. Nail dystrophy, with onycholysis and nail plate discoloration, is also found.

Candida Onychomycosis

C. albicans infection of the nail may be seen *secondary to chronic paronychia or onycholysis*. The nail plate is opaque, brownish-green in colour and altered in shape. There may be nail plate changes secondary to the inflammation of the nail fold.

Chronic Mucocutaneous Candidiasis

This is an immunodeficiency disease, which is characterized by persistent candidiasis of mucous membranes, skin and nails. The infection may vary from mild, localized, persistent lesions to a severe, generalized condition. The disease usually starts in infancy and is often associated with endocrinopathy (mainly Addison's disease and hypoparathyroidism). A few late-onset cases are associated with thymic tumours; candida granulomas may appear on the scalp and face.

Diagnosis

Diagnosis is based on the clinical examination and the history and is usually confirmed by laboratory examination (direct microscopy and culture).

Direct Microscopy

Skin scrapings are examined microscopically for yeasts, pseudohyphae or hyphae, after the addition of 10 % KOH solution to the slide preparation.

Culture

Swabs from suspected areas are cultured on Sabouraud's agar. *C. albicans* is a fast grower; colonies mature in 1–3 days (with the exception of nail-clipping cultures, which must be kept for at least 7 days). Other candida species may require longer time to mature.

Differential Diagnosis

Leukoplakia	Does not clear with prolonged anti-*Candida* therapy
Flexural psoriasis	Histology, microbiology
Bacterial intertrigo	Microbiology
Tinea	Microbiology, sharp edges
Seborrhoeic dermatitis	Microbiology
Hailey-Hailey disease	Histology
Flexural Darier's disease	Histology
Trichomonas vaginitis	Watery brown discharge, microbiology
Contact dermatitis of vagina	Microbiology, history
Herpes simplex of the penis	Anti-HSV antibodies positive (1gM), history
Psoriasis of the penis	Chronic psoriasis plaques in other body areas
Erythroplasia	Chronic, persistent more dusky colour
Napkin dermatitis	The skin deep in the fold is free of symptoms
Bacterial paronychia	Microbiology, acute onset

General Principles of Treatment

- Removal of underlying predisposing factors.
- Denture hygiene and frequent mouth toilet plus abstention form smoking will help those suffering from oral candidiasis.
- Infected skinfolds should be kept dry and if possible separated.
- Patients with chronic paronychia should keep their hands warm and dry.
- In most cases of candida infection, topical treatment alone is sufficient.
- Consideration should always be given to reduction of the *Candida* reservoir in the mouth and gut.

Recommended Therapies

(a) Topical therapeutic agents
(b) Systemic therapeutic agents
(c) Treatment of clinical forms

Antifungal drugs belonging to the polyene and azole families are the ones used in the treatment of *Candida* infections. A morpholine antifungal agent, amorolfine, is also active.

Topical Therapeutic Agents

These drugs are used in the forms of creams, solutions, suspensions, vaginal suppositories, lacquers, shampoos and powders.

The members of the polyene family used are topical amphotericin B, nystatin and natamycin, while the azole family provides the imidazole derivatives miconazole, ketoconazole, econazole, omoconazole, tioconazole and clotrimazole for use in these conditions.

Amorolfine is also used in the form of cream of nail lacquer.

The use of topical preparations is effective in the majority of *Candida* infections, but their use is restricted by the extent of the area involved. Factors that should be considered when choosing topical agents include the lack of side effects of these drugs, when administered topically; the minimal development of resistance, except in the case of nystatin; and their lack of interaction with other classes of drugs.

The topical formulations (except amorolfine nail lacquer) should be used one to three times daily, and their application should continue at least for 1 week after clinical resolution of the disease, to allow reconstitution of the stratum corneum.

The type of formulation selected for treatment depends on the site and the symptoms of the disease (for dry lesions, lotions of creams are preferable, for wet lesions powders, for oral lesions suspensions, for vaginal lesions pessaries and for nail lesions lacquers).

Topical Treatment at a Glance

- The use of topical preparations is effective in the majority of Candida infections, but their use is restricted by the extent of the area involved.
- Use lotions or creams for dry lesions, powders for wet lesions, suspensions for oral lesions, pessaries for vaginal lesions and lacquers for nail lesions.
- The main treatment agents for oral candidiasis are topical nystatin suspension and miconazole oral gel.
- Amorolfine and ciclopirox nail lacquers for 12 months are the main treatment for mild nail candidiasis.

Systemic Antifungal Agents

For systemic candidiasis or extensive skin disease, in immunosuppressed patients and when there are frequent relapses after topical treatment of high patient compliance is needed, the triazoles i*traconazole* and *fluconazole and* the imidazole *ketoconazole are used for systemic treatment*. The major disadvantages of these drugs are the potential toxicity (ketoconazole) and the development of both clinical and microbiologically proved resistance (fluconazole). Another serious disadvantage of these antifungals is their interaction with other drugs.

The chief side effects of ketoconazole are nausea, pruritus, transient elevations in liver enzymes and significant liver toxicity, which can lead to death.

The incidence of adverse events is higher during long-term itraconazole therapy (16.2 %) than during short-term administration (7.0 %). The side effects observed with itraconazole are not severe and mainly take the form of gastrointestinal disturbances (nausea, epigastralgia and diarrhoea).

The most frequent side effects of fluconazole are gastrointestinal symptoms and rash.

Use of the azoles is not recommended in pregnancy. Azole resistance is substantial problem. It is found in AIDS patients, in intensive care units and in leukaemia patients. It is manifested in two ways. The first is replacement of susceptible *Candida* isolates with resistant *Candida* spp., such as *C. glabrata* and *C. krusei*. The second is in situ development of resistance in a certain isolate. The problem of the resistance is focused chiefly on fluconazole, although cross-resistance to the other azoles in common.

Some of the drugs with which ketoconazole interacts are agents decreasing gastric acidity: rifampicin, acyclovir, coumarins, cyclosporin, phenytoin, terfenadine and astemizole. Fluconazole is reported to interact with amphotericin B, coumarins, cyclosporin, phenytoin, oestradiol, cimetidine, astemizole, terfenadine, sulfonyl ureas, thiazides, etc.

Itraconazole interacts mainly with cyclosporin, food, digoxin, phenytoin, rifampicin, H2 antagonists, terfenadine and astemizole.

Systemic Treatment at a Glance

- Itraconazole or fluconazole should be used for systemic candidiasis or extensive skin disease.
- Fluconazole 50–100 mg daily for 1 week, or itraconazole 100 mg daily for 1–3 weeks are effective in persistent oral candidiasis.
- Recurrent vulvovaginitis is treated with a single dose of 150 mg fluconazole, given on day 21 of each menstrual cycle or clotrimazole as a 500 mg vaginal pessary once a week for 6–12 months.

Treatment of Clinical Forms

Oral Candidiasis and Perleche

The main treatment agents are topical nystatin suspension and miconazole oral gel. For more persistent disease, oral antifungals are used: ketoconazole 200 mg daily for 1–2 weeks, fluconazole 50–100 mg daily for 1 week or itraconazole 100 mg daily for 1–3 weeks. Fluconazole is reported to be effective with a single 150 mg dose. Perleche is treated with topical antifungal creams.

Cutaneous Candidiasis

Topical antifungal preparations are used, with excellent results. For widespread disease, oral antifungal drugs are used: itraconazole 200 mg daily for 1 week or fluconazole 50–100 mg for 1–3 weeks. A dose of 150 mg fluconazole once a week for 2 weeks has also proven to be very effective in the treatment of cutaneous candidiasis.

Candida Balanitis

Topical treatment has proven sufficient in treating this condition. Fluconazole in a single 150 mg dose is effective in more resistant cases

Vaginal Candidiasis

Topical treatment generally results in a good mycotic and clinical cure rate. Owing to common relapses and complaints from patients that intravaginal products are messy and often leak, oral treatment is prescribed. Cases of occasional vulvovaginitis are treated with fluconazole orally in a single dose of 150 mg, ketoconazole 200 mg daily for 5 days or itraconazole 400 mg in a single dose. Recurrent vulvovaginitis is treated with a single dose of 150 mg fluconazole, given on day 21 of each menstrual cycle for 6–12 months. Clotrimazole as a 500 mg vaginal pessary once a week has proven efficient in suppressing relapses of recurrent vaginitis.

Candida Paronychia

This condition requires prolonged topical treatment. The hands should be kept warm and dry.

Candida Onychomycosis

Topical treatment with the ordinary polyene or azole antifungal drugs *is not effective*, as these drugs are not absorbed from the nail plate. For mild candida onychomycosis of the hands involving not more than 60 % of the entire nail plate, amorolfine nail lacquer is used once a week

for 6 months. For more severe onychomycosis of the hands, itraconazole is used in a pulsed regimen of 400 mg daily for 1 week. This scheme is repeated for 3 months.

For mild onychomycosis of the feet, amorolfine nail lacquer is used once weekly for 12 months and for more severe cases itraconazole pulse therapy with 400 mg daily for 1 week. This scheme is repeated for 4 months.

Fluconazole is used in a dose of 150 mg weekly for 6 months for hand onychomycosis and for up to 9 months for foot onychomycosis.

Chronic Mucocutaneous Candidiasis

A combination of antifungal drugs and immunological reconstruction is needed in the treatment strategy for this condition. A restoration of T-cell function is attempted by using transfer factor of thymosin or by grafting compatible lymphocytes from blood or marrow or foetal thymic tissue.

The antifungal drugs most commonly used are ketoconazole, fluconazole and itraconazole, which are used for some years. The main problems encountered with the use of these drugs are the growing problems of infection with *Candida* that has become resistant and hepatotoxicity with long-term use of ketoconazole.

Cheilitis and Oral Disease

13

Eleni Gagari

Key Points

- Cheilitis presents with a variety of pathogenetic mechanisms and etiologies. Proper diagnosis is essential for effective treatment.
- Combination of different types of cheilitis may be present in the same patient making this disease entity a therapeutic problem.
- Biopsy is necessary in actinic cheilitis, cheilitis glandularis, and cheilitis granulomatosa.
- Association of cheilitis with oral and systemic disease entails a different therapeutic approach than local disease and needs to be evaluated carefully.
- Moisturizing agents are necessary for optimal effect of topical treatment modalities.
- Choice of topical vs. systemic treatment depends on the type of cheilitis and the severity of the lesions.

Definition and Epidemiology

Cheilitis is etymologically a term of Greek origin and indicates a nonspecific inflammation of the lips. It is therefore essential to qualify this term with specific descriptors in order to provide diagnostic definitions, namely:

- *Angular cheilitis:* Bilateral inflammation of the commissures of the lips of multifactorial etiology, presenting with redness, scaling, and erosions limited to the corner of the lips.
- *Allergic contact cheilitis:* Redness, crusting, and superficial ulceration of the vermillion of the lips often associated with perioral dermatitis, caused by contact hypersensitivity to a variety of topical agents.
- *Exfoliative cheilitis:* Increased production of keratin of the vermillion of the lips and persistent subsequent desquamation resulting in scaling and flaking appearance. Most frequently caused by habitual lip licking and self-caused injury (factitial cheilitis).
- *Actinic cheilitis:* Mottled discoloration, scaling, and focal ulceration of the lower lip vermillion border, representing premalignant or malignant change (in later stages) caused by sun damage.
- *Cheilitis glandularis:* Inflammation of the minor salivary glands of the lower lip causing suppuration and ulceration of the lower lip. A significant percentage (18–35 %) is associated with development of squamous cell carcinoma of the lower lip.
- *Cheilitis granulomatosa:* Pronounced swelling of the lips caused by submucosal or subcutaneous

DOI 10.1007/978-3-662-45139-7_13, © Springer-Verlag Berlin Heidelberg 2015

granulomata. The condition may arise in the context of orofacial granulomatosis or as a clinical manifestation of granulomatous diseases (more frequently Crohn's disease or sarcoidosis).

Basic Concepts of Pathogenesis

The vermillion border of the lips represents a very finely constructed meeting point of skin and oral mucosa. The major pathogenetic mechanisms involved can be separated into the following broad categories:

- Reaction to mechanical or environmental stimuli or compromised anatomy (reduced vertical dimension due to lack of teeth and aging of the skin).
- Allergy to local antigenic challenge (contact hypersensitivity) or part of a generalized allergic reaction that affects the orofacial structures.
- Candidal and/or bacterial infection.
- Systemic disease such as Crohn's disease, sarcoidosis, tuberculosis, chronic granulomatous disease and leprosy. Indirectly, anemia, iron deficiency, and diabetes may predispose to a candidal infection of the lips.
- Idiopathic when there are granulomata present in the lips, but there is absence of any systemic disease that can account for them. Orofacial granulomatosis is a "blanket" term currently used to encompass entities such as cheilitis granulomatosa of Miescher and Melkersson-Rosenthal syndrome.

Often, cheilitis may present with a composite of pathogenetic mechanisms. For example, angular cheilitis or exfoliative cheilitis may develop in the presence of cheilitis granulomatosa due to the altered anatomy of the swollen lips.

Clinical presentation

Angular Cheilitis

The location of the lesions at the corners of the lips is characteristic. The lesions are red, occasionally speckled with white detachable plaques of candidal infection and may also have mildly erosive areas (Fig. 13.1). Several factors contribute to this clinical appearance and should be methodically evaluated. The loss of vertical dimension due to edentulous alveolar ridges or ill-fitting dentures, as well as slacking/wrinkling of the skin due to aging, creates a compromised anatomy of the area that allows pooling of saliva. This favors the development of a yeast infection that is combined with a bacterial infection. Microbiologic studies have indicated that 20 % of these lesions represent *C. albicans*, 20 % bacterial infection with *S. aureus*, and 60 % of these lesions represent a mixed infection of the two. It is important to examine the oral cavity for presence of oral candidiasis and to rule out anemia, diabetes, immunosuppression, and B12 or iron deficiency as predisposing factors. Presence or absence of mucosal erythema, atrophic glossitis, or pseudomembranous/atrophic oral candidiasis should be carefully evaluated. Due to a feeling of irritation the patient may engage in lip licking causing a secondary presentation of exfoliative cheilitis.

Fig. 13.1 Angular cheilitis

Allergic Contact Cheilitis

Both lips appear red, crusted, fissured, and bleeding on occasion (Fig. 13.2). There is often perioral erythema and dermatitis. The sudden appearance and association with a cosmetic or topical agent being applied is important for the diagnosis. Occasionally the local allergen is mild and may be more difficult to discover. A careful and thorough history of habits involving the area

needs to be obtained. Usually there is no presence of oral disease, with the exception of oral food allergen syndrome where the lip manifestations are part of anaphylactic stomatitis (redness and discomfort) in those parts of oral mucosa that come into contact with food the most during mastication (buccal mucosa, lips, tip of the tongue).

Exfoliative Cheilitis

Scaling, cracking, and peeling of the vermillion borders of the lips is noted. Thick, yellowish hyperkeratotic crusts that may leave extensive fissuring or a hemorrhagic surface behind may also develop as the condition worsens (Fig. 13.3a, b). Perioral skin may become involved and exhibit the same features. It is prevalent in people younger than 30 years of age with a predilection for females. The exact cause is unknown, but it is thought chronic irritation of the area, such as lip licking and mouth breathing, is involved. There appears to exist a relationship with psychiatric disorders, atopy, and photosensitivity, although it has not been well substantiated. A chronic form of candidiasis such as is encountered in immunosuppressed patients may also contribute to the clinical appearance. Exfoliative cheilitis is a common side effect of chronic isotretinoin use and appears to be linked to excessive dryness of the lips caused by the medication.

Actinic Cheilitis

Most common on the lower vermillion of the lip, actinic cheilitis represents a premalignant condition caused by chronic sun damage. The lack of homogeneity of color and the appearance of uneven scaly patches or focal ulceration are characteristic (Fig. 13.4). A biopsy is often indicated to rule out development of squamous cell carcinoma.

Fig. 13.2 Allergic contact cheilitis to propolis

Fig. 13.4 Actinic cheilitis

Fig. 13.3 (**a**) Exfoliative cheilitis. (**b**) Exfoliative cheilitis after topical tacrolimus 0.1 % treatment

Cheilitis Glandularis

The orifices of minor salivary gland ducts of the lower lip give rise to suppurating fistulae that can be probed using a dental probe (Fig. 13.5). The etiology of this inflammatory condition is unknown, but it is most common in middle aged or older men. A biopsy may be indicated due to the association with squamous cell carcinoma.

Cheilitis Granulomatosa

Swelling, fissuring, and deformation of the upper lip is most common (Fig. 13.6), although swelling may also be present in the lower lip. Biopsy is needed to establish the presence of granulomata. This form of cheilitis may be part of a disease entity called "orofacial granulomatosis" in which granulomatous inflammation of the lips and other parts of the oral mucosa, such as buccal mucosa, palate, gingival, and mucobuccal fold, *exist in the absence of systemic disease*. There is a "cobblestone" appearance of the oral mucosa accompanied by erosions or focal ulcerations. The lips may be the only part affected, and this represents Miescher's cheilitis. Concomitant presence of facial nerve paralysis and fissured tongue constitutes Melkersson-Rosenthal syndrome.

Cheilitis granulomatosa may represent a clinical manifestation of Crohn's disease especially in young male adults and should be ruled out by colonoscopy. Other granulomatous diseases such as sarcoidosis and tuberculosis should also be ruled out with appropriate testing.

Fig. 13.5 Cheilitis glandularis

Fig. 13.6 Cheilitis granulomatosa

Differential Diagnosis

Appropriate diagnostic workup and accurate diagnosis of the type of cheilitis present are essential in implementing the correct treatment.

Step 1: Careful evaluation of clinical appearance of the lip lesions. Some clinical features are "hallmarks" of specific types of cheilitis:

- Lesions confined to the commissures of the lips: *angular cheilitis*
- Presence of extensive swelling on one or both of the lips: *cheilitis granulomatosa or allergic contact cheilitis*
- Peeling, fissuring, and thick crusting of the lips: *exfoliative cheilitis*
- Suppuration of lower lip: *cheilitis glandularis*
- Discoloration and loss of distinct color margins of the vermillion of the lower lip: *actinic cheilitis*

Step 2: Evaluation of oral mucosa and perioral skin:

- Erythematous oral mucosa, presence of red and white detachable lesions, atrophic glossitis, and point to oral candidiasis more often associated with angular cheilitis.
- Erythematous patches of oral mucosa, "cobblestone mucosa," and presence of erosions suggest orofacial granulomatosis

and mandate diagnostic exclusion of Crohn's disease.
- Perioral redness and scaling: associated most often with exfoliative cheilitis and point to excessive lip licking.

Step 3: Evaluation of medical history for medication and allergies:
- Report of contact challenge with local factors such as lipstick, balms, or ointments and history of oral food allergy syndrome: allergic contact cheilitis
- Medical history of food allergies, atopy: cheilitis granulomatosa
- Use of isotretinoin for acne: exfoliative cheilitis

Step 4: Exclusion of underlying systemic disease:
- If the clinical diagnosis is angular cheilitis, blood test evaluation for anemia, diabetes, and immunocompromised status may be required, especially if the condition recurs often.
- If the clinical diagnosis is cheilitis granulomatosa, biopsy, colonoscopy, chest X-ray, SACE levels, and Mantoux are indicated along with detailed blood tests, in order to rule out Crohn's disease, sarcoidosis, and tuberculosis
- If the clinical impression is swelling of the lips, angioedema must be ruled out with biopsy of the lip lesions.

General Principles of Treatment

Cheilitis is a challenging treatment problem. Accurate diagnosis is the most important determining factor in obtaining optimal treatment outcome. The guidelines for successful treatment revolve around maintaining optimal anatomy and hydration of the vermillion border of the lips, reducing inflammation, treating local opportunistic infections, and managing underlying systemic disease.

Depending on the etiology and pathogenesis of cheilitis, a wide variety of therapeutic agents have been used:
- Moisturizing agents that create a "barrier" on the vermillion of the lips in order to avoid the detrimental effect of saliva
- Topical corticosteroids
- Intralesional corticosteroids
- Systemic corticosteroids
- Antibiotics
- Calcineurin inhibitors
- Immunomodulatory agents
- Monoclonal antibodies

It is essential to note that in those cases where cheilitis is a clinical manifestation of systemic disease, successful treatment of the underlying disease is required in order to achieve complete resolution of the lip lesions.

Topical Treatments

Topical Corticosteroids

Topical corticosteroids have been used widely for the treatment of cheilitis. The most popular formulations are cream and ointment formulations of hydrocortisone, fluticasone propionate, betamethasone, and clobetasol propionate in varying concentrations (0.05–0.1 %) twice daily. They should be used along with moisturizing agents especially where cream formulations are concerned as there is a drying effect on the lips that may worsen scaling and peeling. The use of topical steroids entails the risk of exacerbating a candidal or bacterial infection if used alone, especially in angular cheilitis. These formulations are not effective alone, but when used along with another immunomodulatory agent, they may improve allergic contact cheilitis, exfoliative cheilitis, and very mild cases of cheilitis granulomatosa. Complete resolution of cheilitis on the basis of single-agent topical steroid use can only be observed in very mild cases of cheilitis.

Topical Antibiotics

Topical antimicrobial agents and antibiotics, when used as a single-agent treatment, are not successful in cheilitis treatment. Neomycin and mupirocin ointments have been used, but they often worsen the condition because they cause dryness and they create an imbalance in microbial flora

that predisposes to candidiasis. The bacterial component plays only a limited role in the etiology of cheilitis, and therefore topical antibiotic treatment is only relevant in cases of angular cheilitis.

Combination Topical Treatment

The combination of topical antifungal, corticosteroid, and antimicrobial treatment is effective in cases of angular cheilitis. Triamcinolone acetonide 1 mg/g nystatin 100,000 units/g, neomycin 2.5 mg/g, and gramicidin 0.25 mg/g may be used twice daily for 7–10 days with good results. Triamcinolone counteracts the drying effects of neomycin and gramicidin, while nystatin controls the yeast infection that could worsen from the combined use of corticosteroid and antibacterial agents. Bacterial resistance is a potential caveat. Combination topical treatment is not useful in other forms of cheilitis.

Calcineurin Inhibitors

Tacrolimus ointment (0.03 % and 0.1 %) and pimecrolimus ointment 1 % have been used with considerable success in the treatment of exfoliative cheilitis at a regimen of twice daily for 7–10 days and with partial success as an adjunct to the treatment of cheilitis granulomatosa. Calcineurin inhibitor action is unknown but thought to inhibit T-lymphocyte activation. Due to the "black box" warning of skin cancer or lymphoma, long-term use is not recommended. However, exfoliative cheilitis responds well with a short course, and the medication is well tolerated (Fig. 13.3b). The more serious side effects of HSV or HVZ infection are not encountered. Occasional burning sensation is the most common side effect observed in the above treatment regimen.

Intralesional Injections of Corticosteroids

Triamcinolone acetonide 40 mg/ml has been used for intralesional injections in cases of cheilitis granulomatosa. The regimen is usually two to three injections every 14–21 days depending on the severity of the lesions and the response after the first cycle. In a number of cases, intralesional injections require additional systemic immunomodulatory medication use to maintain a long remission. The regimen provides a systemic steroid-sparing effect to young patients. The most common side effect is local scarring or atrophy which is not often encountered. They are not used in any other form of cheilitis.

Systemic Treatments

Antibiotics

Systemic antibiotic treatment has been used in the treatment of cheilitis granulomatosa. Minocycline 100 mg/day, roxithromycin (an erythromycin derivative) (150–300 mg/day), and metronidazole 750–1,000 mg/day have all been used in conjunction with systemic or intralesional corticosteroid treatment of cheilitis granulomatosa. The benefit from the use of these antibiotics lies in their antiinflammatory not in their antibacterial properties. A significant drawback is that the protracted use of these agents (needed to achieve remission) may cause antibiotic resistance. Broad-spectrum antibiotics may also be prescribed if suppuration is present in cheilitis glandularis or if there is resistance to topical antibacterial agents in angular cheilitis.

Corticosteroids

Systemic administration of prednisolone is often used in cheilitis treatment to reduce inflammation or the immune response (granulomata). In the literature, the dosage reported varies from 20 to 50 mg/day, although in the vast majority of cases, dosages no higher than 30 mg/day are enough to achieve satisfactory treatment outcome. Prednisolone is often administered together with an antibiotic for the treatment of cheilitis granulomatosa, or with an antifungal, systemic, or topical for angular cheilitis. Usually

the duration of administration is not long enough to cause significant side effects, although caution should be exercised in young and in immunocompromised patients. Careful monitoring of development and endocrinological evaluation should be performed in patients <18 years of age.

Antifungals

Systemic administration of antifungal agents is indicated when there is evidence of candidal infection of the oral mucosa or the perioral skin in association with angular cheilitis. Fluconazole is a cytochrome p450 inhibitor and is the drug of choice for oral candidiasis. An indicative regimen for oral candidiasis is initiated at 200 mg/day the first day and 100 mg/day for the next 9 days for a total of 10 days. Fluconazole presents with a variety of drug interactions so careful monitoring of patient medication is required to avoid serious side effects. It is otherwise well tolerated.

Immunomodulators and Monoclonal Antibodies

Systemic administration of immunomodulating agents has only been used in cases of cheilitis granulomatosa that are refractory to treatment. It is not always clear in the literature that these instances do not represent cheilitis as a manifestation of Crohn's disease. Clofazimine, a medication derived from the phenazine dye that has bacteriostatic and immunomodulatory activity, has been used with promise. Infliximab, a chimeric anti-TNF-a monoclonal antibody, has also been proposed at infusion dosages ranging from 3 to 5 mg/kg. Thalidomide at 100 mg/day every other day has been used and methotrexate at 5–10 mg administered orally on a weekly basis has also been reported. Given the safety profile of these medications and the benign nature and course of most types of cheilitis, the risk to benefit ratio is currently not favorable enough to recommend these agents in the treatment of cheilitis.

Cheilitis: Treatment at a Glance

Angular Cheilitis

- Establish the presence/absence of intraoral candidiasis, anemia, or diabetes.
- Correct vertical dimension.
- If there is intraoral candidiasis present, treatment with systemic antifungal agents precedes any topical treatment.
- Topical treatment with a combination steroid/antifungal/antibacterial ointment twice a day for 7–10 days.
- If lesions persist, obtain microbial culture from commissures and administer targeted systemic antibiotic treatment in combination with topical treatment.

Allergic Contact Cheilitis

- Discovering the allergen responsible is of paramount importance.
- Patch testing may be necessary.
- Moisturizing agents.
- Topical corticosteroid treatment in mild cases.
- Systemic corticosteroid treatment with per os prednisolone at dosages of 20–30 mg/day for short duration in order to achieve speedy remission.

Exfoliative Cheilitis

- Careful evaluation of patient habits, psychological profile, and history of isotretinoin use
- Moisturizing agents for lips and perioral area
- Tacrolimus ointment 0.1 % twice daily for 7–10 days

Actinic Cheilitis

- Sun protection.
- Biopsy to rule out squamous cell carcinoma.
- Cryotherapy or surgical treatment is treatment of choice.
- Imiquimod has been used.

Glandular Cheilitis

- Systemic broad-spectrum antibiotic treatment for cases of suppuration, preferably after microbial culture is performed for sensitivity.

- Biopsy to rule out SCC when ulceration is present.
- Surgical treatment may be indicated if there are frequent recurrences.

Cheilitis Granulomatosa

- Biopsy to establish diagnosis.
- Evaluation of oral mucosa for other sites of involvement.
- Colonoscopy, chest X-ray, Mantoux, and blood tests (serum angiotensin-converting enzyme and calcium levels) need to be performed to rule out Crohn's disease, sarcoidosis, and tuberculosis.
- If systemic disease has been ruled out, systemic corticosteroids (30 mg prednisolone/day) and minocycline (100 mg/day) is initiated with a 3-week taper.
- Intralesional triamcinolone injections (40 mg/ml) with or without minocycline may alternatively be used in cycles of 14–21 days.
- If systemic disease is present, effective treatment of the systemic disease will either resolve the cheilitis completely or put it in long-term remission.
- If the patient is <18 years of age, careful monitoring of endocrinological status and development is needed during systemic corticosteroid administration.

Chronic Actinic Dermatitis

14

Sally Jane O'Shea, Christian Gulmann, and Gillian M. Murphy

Key Points

- Drug-induced photosensitivity must be carefully excluded.
- Strict photoprotection and allergen avoidance are essential.
- Treatment options include topical steroids, topical tacrolimus and systemic immunosuppressant medications such as azathioprine, cyclosporine and mycophenolate mofetil.

Definition and Epidemiology

Chronic actinic dermatitis is a persistent photodermatitis that has a predilection for older men but has also been known to occur in individuals with atopic dermatitis and in the presence of human immunodeficiency virus (HIV) infection (Ive et al. 1969 and Hawk et al. 2010). It tends to affect sun-exposed skin; however, covered skin may also be affected to a lesser degree. It is postulated that a delayed-type hypersensitivity reaction to photoinduced allergens underpins the diagnosis. UVA, UVB and even visible light are capable of evoking changes Hawk (2010). Therefore, the clinical findings are usually more pronounced during summer months.

Basic Concepts of Pathogenesis

A chromophore is the part of a molecule which is responsible for its colour, arising as a result of the absorption of certain wavelengths of visible light and the reflectance of others. DNA damage can be induced when UV light comes into contact with chromophores in human skin that do not possess the ability to rapidly convert the energy into harmless heat energy. Exposure to UV irradiation at doses considerably lower than the minimal erythema dose (MED) can induce clinical signs in patients with chronic actinic dermatitis. Patients with this disorder are usually very photosensitive. The action spectrum in chronic actinic dermatitis is similar to that of sunburn and the action spectrum for the formation of thymine dimers, implicating DNA as the chromophore (Menagé et al. 1995).

Clinical Presentation

The condition manifests as a photo-distributed, pruritic, eczematous rash. A sharp cut-off is often seen between the affected, sun-exposed

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_14, © Springer-Verlag Berlin Heidelberg 2015

skin and covered, normal skin. Skin sparing may be noted in the post-auricular areas and in shaded areas, such as between the fingers, under a watch strap, in the submental area and under the hair. Lichenification is a feature, and a pseudolymphomatous appearance (Fig. 14.1) or even erythroderma (Fig. 14.2) can develop in severe cases, making the diagnosis more elusive. It is estimated that resolution of the condition occurs in approximately 10 % of those affected after 5 years (Dawe et al. 2000).

Diagnosis

A detailed history is essential to rule out a drug-induced photosensitivity. Laboratory investigations to exclude other causes should also be done, including anti-nuclear antibodies, extractable nuclear antigens and a porphyrin screen. As patients with chronic actinic dermatitis may also have contact allergy to airborne allergens, including plant antigens and fragrances, patch and photopatch testing is done to identify precipitating allergens and to differentiate chronic actinic dermatitis from other conditions. Testing is done at lower doses than the MED, but identification of photoallergens may still be possible with a UVA dose of 1 J/cm^2.

Fig. 14.1 Infiltrated, pseudolymphomatous patches and plaques on the back of a patient with severe chronic actinic dermatitis

Fig. 14.2 Severe chronic actinic dermatitis and presented with erythroderma

Histology

Epidermal acanthosis, spongiosis, and a deep, dense, mixed, dermal, perivascular infiltrate are usually seen. Pseudolymphomatoid features, such as lymphocyte exocytosis, may also be seen in severe cases which may lead to suspicion of cutaneous T-cell lymphoma (Fig. 14.3). Further characterisation of the T-cell infiltrate, however, demonstrates predominantly CD8+ T cells, and T-cell receptor gene rearrangement studies are negative in chronic actinic dermatitis (Hawk et al. 2010).

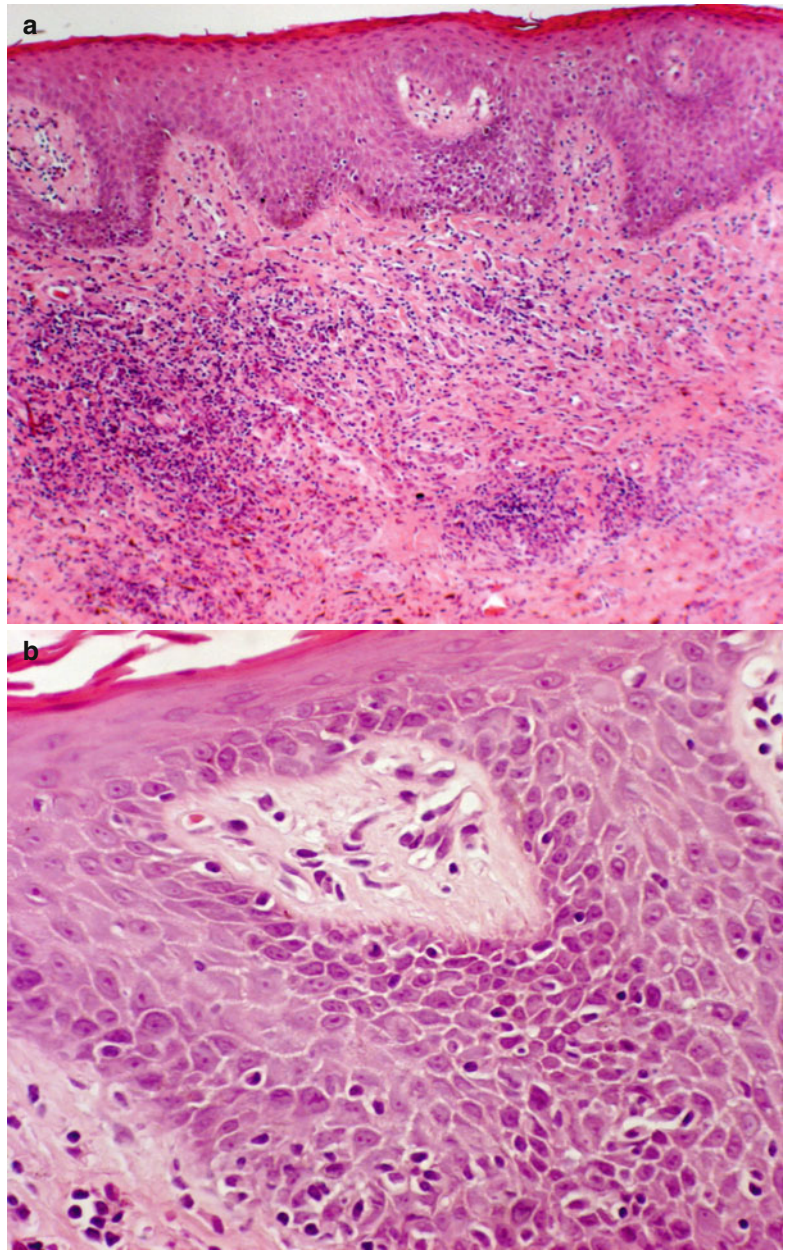

Fig. 14.3 (**a**) Low-power view shows intense dermal inflammation and fibrosis, epidermal acanthosis and parakeratosis. Haematoxylin and eosin, ×10 objective lens. (**b**) High-power view of epidermis highlights spongiosus as well as lymphocytic exocytosis. Haematoxylin and eosin, ×40 objective lens. (**c**) Mixed dermal inflammatory infiltrate composed of lymphocytes, histiocytes and many eosinophils. Plasma cells are also present. Haematoxylin and eosin, ×40 objective lens

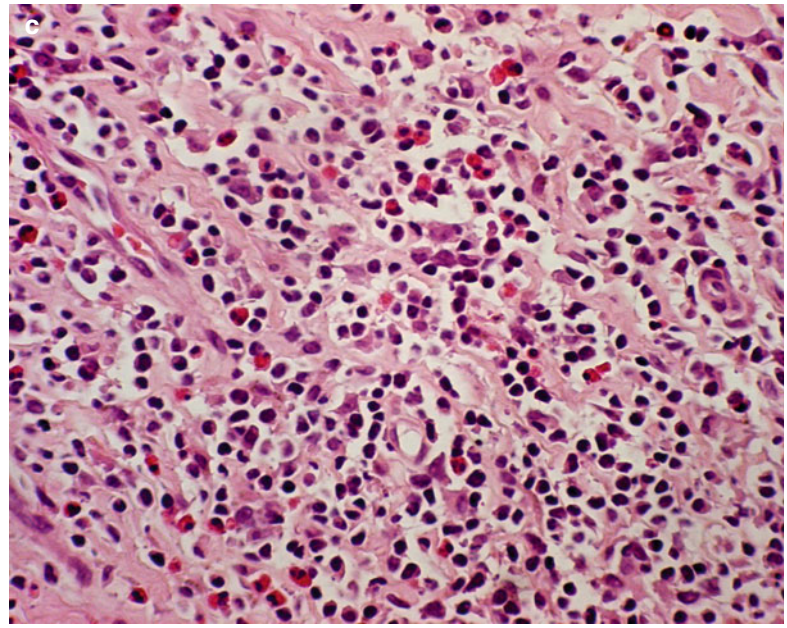
Fig. 14.3 (continued)



General Principles of Treatment

All patients with chronic actinic dermatitis are counselled about strict photoprotection and allergen avoidance. (Please see reference 9 for a patient information leaflet). Sun block with complete UV spectrum protection is advised; these include those containing titanium dioxide and zinc oxide. Yellow blinds, which exclude UV and blue visible light energy, are also required. Museum film can be applied to windows, to minimise penetration by ultraviolet light. Bonwyke Dermagard is an example, although many brands exist.

Desensitisation with PUVA or TLO1 phototherapy can be considered. Other established treatment options include topical steroids, topical tacrolimus, azathioprine (Murphy et al. 1989), cyclosporine (Granlund et al. 1998) and mycophenolate mofetil (Thomson et al. 2005).

Systemic Treatments

Azathioprine, an imidazole derivative of 6-mercaptopurine, generates an immunosuppressive effect. It is generally prescribed at a dose of 1.0–2.5mg/kg/day. The exact mechanism of action remains to be elucidated, but it is thought to act by competitive binding of thionucleotide metabolites in a series of biochemical pathways. Its efficacy in chronic actinic dermatitis was first highlighted in a double-blind controlled trial, comparing azathioprine 50mg tds with placebo. After 6 months of treatment, five out of eight patients in the azathioprine cohort, compared with zero out of ten in the placebo group, achieved remission (Murphy et al. 1989).

Cyclosporine 3.5–5mg/kg/day results in rapid control of symptoms, but relapse upon weaning can pose a management problem.

Mycophenolate mofetil 25–40mg/kg/day is another alternative off-label treatment (Hawk et al. 2010). It exerts its effects, predominantly on lymphocytes, by inhibition of the enzyme inosine monophosphate dehydrogenase. This leads to depletion of guanosine nucleotides which results in impaired DNA, RNA and protein synthesis. Evidence supporting its use in the management of chronic actinic dermatitis relies mainly on case reports. Two male patients with recalcitrant disease noted symptomatic improvement within 16 weeks of treatment, with doses ranging from 500mg bid on a continuous regimen in one patient to 1g bid during spring and summer months only in the second patient (Thomson et al. 2005). The precise duration of treatment has not yet been determined.

Cicatricial Alopecia

15

Antonella Tosti, Eric L. Maranda,
and Bianca Maria Piraccini

Key Points

- Cicatricial alopecia is a permanent condition that cannot be reversed by treatment.
- Early diagnosis of primary cicatricial alopecia is imperative and it should be treated aggressively to reduce permanent scarring.
- Dermoscopy may assist in selecting the optimal site of biopsy for pathological diagnosis.
- Improper lipid metabolism in lichen planopilaris leads to a toxic build-up of lipids in the sebaceous gland that may be initiating the inflammatory response.
- Peroxisome proliferator-activated receptor-γ, a master transcription factor that regulates the expression of genes involved in lipid metabolism, is aberrant in lichen planopilaris.
- Pioglitazone, a peroxisome proliferator-activated receptor-γ agonist, may be a novel means to effectively treat lichen planopilaris.
- In discoid lupus erythematous, autoreactive Granzyme B-positive CD8+ T cells are recruited to the hair follicles resulting in epidermal, dermal, and follicular destruction.
- Antimalarial drugs are the treatment of choice for discoid lupus erythematous.
- Retinoids may be used as an alternative treatment for patients with discoid lupus erythematous that do not respond to topical glucocorticoids, sunscreens and tacrolimus.
- Studies using field emission scanning electron microscopy and confocal laser scanning microscopy suggest that bacterial biofilm organization may play a role in the pathogenesis of folliculitis decalvans.
- Keratosis follicularis spinulosa decalvans is a rare, inherited or sporadically acquired X-linked disorder with a

mutation in the MBTPS2 gene mapped to Xp21,13-p22.2.
- Global gene expression profiles in lichen planopilaris and pseudopelade of Brocq are distinct from one another and should be considered as separate conditions.
- Dysregulation of connective tissue metabolism in localized scleroderma leads to an excess deposition of collagen.
- Early stages of localized scleroderma are characterized by an elevation of Th1/Th17-associated cytokines and Th2-associated cytokines during the late stages of the disease.
- The downregulation of microRNAs, in particular miRNA let-7a, may perpetuate the fibrosis seen in localized scleroderma.
- Localized scleroderma usually resolves spontaneously in a few years.

Definition and Epidemiology

A large number of scalp disorders may destroy the hair follicles and result in cicatricial alopecia (Table 15.1). These include diseases that primarily affect the hair follicles as well as diseases that affect the dermis and secondarily cause follicular destruction. Once established, cicatricial alopecia is a permanent condition that cannot be reversed by treatment. The differential diagnosis between the diseases that cause cicatricial alopecia requires a pathological examination. The site of biopsy is crucial for pathological diagnosis and can be better selected using dermoscopy. Current treatment options of primary cicatricial alopecia are limited as the precise mechanisms that trigger the diseases are still unknown should be treated aggressively. Early diagnosis and treatment is necessary in order to avoid diffuse follicular destruction. When treating cicatricial alopecia, one must explain to the patient that hair that has been lost will not regrow. Surgical treatment of cicatricial alopecia includes excision of the scarring area after tissue expansion or hair transplantation. The latter technique is complicated by the poor recipient conditions due to the reduced blood perfusion present in scar tissue that may impair graft survival. There is also the possibility that grafting may precipitate relapses through a Koebner phenomenon. In many cases, the treatment selected is based on anecdotal and individual preferences, due to the limited number of double-blind, randomized studies completed and the small number of cases. This chapter discusses optimal management and treatment of some inflammatory scalp disorders that commonly cause primary cicatricial alopecia.

Table 15.1 Causes of cicatricial alopecias

Primary cicatricial alopecia
Lichen planopilaris
Frontal fibrosing alopecia
Fibrosing alopecia in a pattern distribution
Discoid lupus erythematosus
Keratosis follicularis spinulosa decalvans
Folliculitis decalvans
Central centrifugal scarring alopecia
Acne keloidalis nuchae
Secondary cicatricial alopecia
Traction alopecia
Bacterial or fungal infection
Localized scleroderma
Radiation
Pemphigoid
Chemical or physical injuries
Scalp metastases

Clinical Presentation and Treatment

Lichen Planopilaris

Lichen planopilaris (LPP) is the most common cause of cicatricial alopecia and is considered the follicular form of lichen planus. Microarray analysis has recently shown a reduction in the

Fig. 15.1 Frontal fibrosing alopecia: hairline recession and loss of eyebrows. Also note prominence of temporal veins and papular lesions

expression of genes necessary for lipid metabolism and peroxisome biogenesis in LPP. Improper lipid metabolism in the sebaceous gland results in a toxic build-up of lipids that may be initiating the inflammatory response in this condition. It was hypothesized that peroxisome proliferator-activated receptor-γ (PPAR-γ), a master transcription factor that regulates these processes, is aberrant in LPP. To confirm the role of PPAR-γ in the pathogenesis of LPP, PPAR-γ was deleted in the follicular stem cells of mice, producing a phenotype similar to cicatricial alopecia. This finding supports the role of PPAR-γ in the pathogenesis of cicatricial alopecia and modulation of this pathway may be a new option to treat LPP.

The clinical variants of lichen planopilaris include classic lichen planopilaris, frontal fibrosing alopecia (Fig. 15.1), fibrosing alopecia in a pattern distribution and Graham-Little syndrome.

Classic lichen planopilaris presents as follicular destruction with a multifocal or central distribution and rarely involves the entire scalp. Patients usually seek medical advice once they have noticed one or several patches of hair loss. A certain degree of itching and burning is frequently reported. The pull test from these areas typically reveals anagen hairs with hyperkeratotic sheaths.

Frontal fibrosing alopecia causes progressive recession of the frontal hairline and loss of the eyebrows. The new hairline is uneven and lacks vellus follicles, while the alopecic area shows less signs of photoaging, compared to the skin of the forehead. This clinical variant most commonly presents in postmenopausal women. The pathogenesis of FFA is still unknown but the role of environmental toxins is suggested by epidemiology.

Treatment

Treatment results in complete remission of disease in about one-third of patients. Partial remission is obtained in another third, while the disease progresses despite treatment in the remaining patients.

Systemic Treatment

1. Steroids represent our treatment of choice. We utilize intramuscular triamcinolone acetonide at the dosage 0.5–1 mg/kg/month. Steroids are gradually tapered when active lesions disappear. This may require 6–12 months.
2. Azathioprine 100 mg/day is useful in association with systemic steroids in severe cases.
3. Systemic cyclosporine 3 mg/kg/day in our experience is scarcely effective.
4. Oral hydroxychloroquine at 200 mg, twice daily for 6–12 months is a second-line treatment. Dosage should not exceed 6.5 mg/kg.
5. Pioglitazone, a peroxisome proliferator-activated receptor (PPAR)-γ agonist is effective at a dosage of 15 mg daily. Liver function tests should be performed before starting therapy. Increased risk of bladder cancer has been reported in women taking the medication for more than 1 year.
6. Finasteride 1 mg/day in men and 2.5–5 mg/day for women or dutasteride 0.5 mg daily is useful in fibrosing alopecia in a pattern distribution and in frontal fibrosing alopecia.
7. Low-dose excimer 308-nm laser, two to three times a week, is useful in reducing the inflammation both in LPP and FFA.
8. We do not recommend retinoids for the treatment of LPP or FFA.

Topical Treatment

1. Topical 2 % or 5 % minoxidil may prevent fibrosis and is useful in association with systemic steroids. It also induces thickening of the remaining hair and allows better coverage of the alopecic area.
2. High-potency topical steroids can be prescribed in association with systemic treatment. However, they may aggravate skin atrophy, particularly in FFA.
3. Topical tacrolimus 0.1 % is useful as it does not cause skin atrophy. In lichen pigmentosus, topical tacrolimus 0.03 % twice daily can improve the pigmentation of the lesions.

Discoid Lupus Erythematosus

Discoid lupus erythematous (DLE) is the most frequent form of chronic cutaneous lupus erythematosus that leads to primary cicatricial alopecia. While it was previously shown that type 1 IFN production drives the inflammatory processes in DLE, new studies show that autoreactive Granzyme B-positive CD8+ T cells are recruited to the hair follicles, resulting in epidermal, dermal, and follicular destruction. Additionally, scientists have found a variant of a gene that may exert a strong genetic influence on the risk of developing DLE, independently from systemic involvement. It was found that the coding variant rs1143679 of ITGAM was highly associated with DLE patients without systemic involvement and with SLE patients that exhibited discoid rashes.

Diagnosis of DLE is strongly suggested by the presence of photosensitivity and "discoid" erythematous papules with follicular hyperkeratosis. As the disease progresses, the plaques enlarge and spread centrifugally and eventual atrophy with telangiectasia become evident. DLE may also present with cysts and comedones. Patients most commonly complain of single or multiple patches of hair loss, burning and scalp tenderness. Direct immunofluorescence is useful for the diagnosis and is often necessary for differentiating DLE from other primary lymphocytic cicatricial alopecias. All patients with discoid lupus erythematosus should be examined for systemic lupus erythematosus. Complications include the development of squamous cell carcinoma.

Treatment

DLE usually responds to treatment.

Systemic Treatment

1. Antimalarial drugs are the treatment of choice. Hydroxychloroquine 200 mg twice a day or chloroquine (200 mg/day) can be prescribed alone or in association with systemic steroids. Treatment lasts for at least 3 months and is then tapered to the lowest effective dose.
2. Quinacrine may be used in combination with other antimalarials in patients that have resistance or only partially respond to chloroquine or hydroxychloroquine. It may also be used as a monotherapy in patients with preexisting eye problems that contraindicate the use of chloroquine or hydroxychloroquine. The dosage of quinacrine as monotherapy or in combination therapy is 100 mg/day, for approximately 9 months.
3. Systemic steroids: initial dosages should be 40–60 mg/day of oral prednisone or 0.5–1 mg/month of intramuscular triamcinolone acetonide. Steroids are gradually tapered when active lesions disappear. This may require 3–6 months.
4. Thalidomide (100–300 mg/day) is a possible alternative. Low-dose thalidomide is an effective treatment for refractory DLE, but its benefits need to be balanced against the potential adverse effects.
5. Retinoids may be used as an alternative treatment for DLE patients that do not respond to topical glucocorticoids, sunscreens and tacrolimus.

Intralesional Steroids

Triamcinolone acetonide (5 mg/ml sterile saline solution) can be useful in localized lesions.

Topical Treatment

1. High-potency topical steroids can be utilized when the disease is circumscribed to a small area of the scalp.

2. Tacrolimus (0.1 %) ointment can be applied twice daily.
3. Topical 2 % or 5 % minoxidil may prevent fibrosis and can be prescribed in association with systemic steroids.
4. Topical tocoretinate 0.25 % ointment applied twice daily has been shown to improve erythema after 1 month. Improvements in skin pigmentation and atrophy can be observed after 12 months of treatment. Alternatively, topical tazarotene 0.05 % gel applied once daily at bedtime may show improvements.

General Measures

Patients should wear a hat to avoid sun exposure.

Folliculitis Decalvans (FD)

This term is utilized to include a spectrum of scalp disorders characterized by painful acute inflammatory changes with or without pustules (Fig. 15.2). Eventually, relapsing inflammatory episodes result in irregularly shaped areas of cicatricial alopecia and tufted folliculitis. Although *Staphylococcus aureus* may frequently be isolated from the pustules, FD is not an infective condition. Some cite local immunological deficits as a predisposition to this condition, while others propose the cause to be an abnormal host response against staphylococcal antigens or toxins. Recent studies suggest that bacterial biofilm organization may play a role in the pathogenesis. Biofilm presence in the root sheaths and on the hair shafts within the lesions was confirmed using field emission scanning electron microscopy and confocal laser scanning microscopy.

Fig. 15.2 Folliculitis decalvans: scarring alopecia and tufted folliculitis

Treatment

Although the inflammatory scalp lesions usually subside with treatment, the condition has a chronic course with frequent relapses.

Systemic Treatment

1. Oral antibiotics are the treatment of choice. Possible alternatives include erythromycin 1 g/day, clarithromycin 500 mg/day, cephalosporins or tetracyclines (minocycline 100 mg/day or hydroxytetracycline 200 mg/day). All of these are usually effective in arresting the inflammatory process, but relapses are common as soon as the treatment is interrupted. Combination therapy with fusidic acid 1,500 mg/day for 3 weeks and zinc sulphate 400 mg/day resulted in permanent remission in three patients (Abeck et al. 1992). The association of rifampicin 300 mg and clindamycin 300 mg taken both orally twice daily for 10 weeks is probably the most effective treatment (Powell et al. 1999, Powell and Dawber 2001). This may be due to the fact that rifampicin is an effective antistaphylococcal agent in addition to its immunomodulatory properties. This regimen produces long-term remissions in most patients. This particular association is required to avoid development of rifampicin resistance that is common when using this antibiotic alone.
2. Isotretinoin 0.5–1 mg/kg/day is effective in some patients but actually worsens the scalp inflammation in most cases.
3. TNF-alpha blockers are an option in recalcitrant cases. Infliximab at a dose of 5 mg/kg of body weight can improve symptoms after three infusions.

A short course of systemic and topical steroids, associated with oral antibiotics, can be utilized to suppress inflammation.

Topical Treatment

1. Shampoos containing antibacterial agents or 2 % ketoconazole may be helpful in preventing relapses.
2. Photodynamic therapy with methyl aminolevulinate has been shown to be effective in some cases.
3. Shaving of the scalp may improve the disease.

Keratosis Follicularis Spinulosa Decalvans (KFSD)

KFSD is a rare, inherited or sporadically acquired X-linked disorder with a mutation in the MBTPS2 gene, mapped to Xp21,13-p22.2. A more severe form of KFSD that is inherited in an autosomal dominant fashion has recently been proposed (Bellet et al. 2008). MBTPS2 codes for an intramembrane zinc metalloprotease necessary for the cleavage of sterol regulatory element-binding proteins (SREBPs). This genetic condition usually becomes evident in infancy and worsens into adulthood. Clinical diagnosis is suggested by the presence of follicular keratotic papules and pustules involving the vertex followed by progressive alopecia. Its severity considerably varies from patient to patient and may involve follicular papules on the eyebrows and cheeks. Due to the clinical and genetic heterogeneity observed in patients with KFSD, clear diagnosis is frequently challenging.

Treatment

In most patients the disease does not respond to treatment.

Systemic Treatment

1. Acitretin (0.5–0.75 mg/kg/day) may be effective in some cases. Isotretinoin 1 mg/kg/day is usually not effective.
2. Dapsone 100 mg/day can be tried in patients who do not respond to retinoids.
3. Oral antibiotics (tetracyclines, macrolides or rifampicin) as treatment for folliculitis decalvans are rarely effective.

Topical Treatment

1. Topical steroids and keratolytics may partially improve the symptoms.
2. Intense pulsed light (IPL) and pulse dye laser (PDL) has improved the condition in some patients.

Pseudopelade of Brocq

Pseudopelade of Brocq was classically thought of as not a separate entity but a representation of the final outcome of advanced lichen planopilaris. Yu et al. (2010), using significance analysis of microarrays, showed that the global gene expression profiles in lichen planopilaris and pseudopelade of Brocq are distinct from one another. This data suggest different etiologies accounting for these two disorders, which should be considered as separate conditions. The scalp presents multiple atrophic, irregular areas involving the vertex with little to no signs of inflammation. Mild pruritus and involvement of the beard area have also been reported. Clinicopathological features of classic pseudopelade of Brocq show nonspecific findings. There have been case reports of alopecia areata clinically mimicking this disease (Kittridge et al. 2010). The pull test from these areas typically reveals anagen hairs during active disease.

Patients with this diagnosis may fall into two possible categories:

- Patients in whom the disease has already spontaneously remitted
- Patients in whom the biopsy has been wrongly taken from an atrophic area

Currently, no established protocols exist for treating this condition.

Treatment

No chemical medical treatment is available.

Surgical autologous hair transplantation may be considered in patients with stable disease. Initial test transplantation of approximately 50 grafts should be done to exclude the possibility of reactivating the disease during the larger grafts.

Localized Scleroderma

Localized scleroderma (LE) is a connective tissue disorder in which a dysregulation of connective tissue metabolism leads to an excess deposition of collagen. Early stages of the disease are characterized by an elevation of Th1/Th17-associated cytokines and Th2-associated cytokines during the late stages of disease, resulting in fibrosis. Furthermore, microRNAs (miRNAs) may perpetuate the fibrosis seen in LE. Studies have shown that the miRNA let-7a, in particular, is downregulated in LE lesions (Makino et al. 2013; Etoh et al. 2013). Interestingly, miRNA injection of let-7a into the mouse model of bleomycin-induced dermal sclerosis improved the skin fibrosis. Insight into the role of miRNA in the pathogenesis of localized scleroderma may aid in the development of novel therapeutics to treat this disease.

Localized scleroderma of the scalp presents as a slowly progressing irregular patch of hair loss. The skin often shows a certain degree of erythema or pigmentation in the absence of follicular keratosis or scaling. The patch is often not completely bald but presents some vellus or intermediate hairs. Severe atrophy with involvement of the hypodermis and muscles is a feature of frontoparietal linear scleroderma ("en coup de sabre").

Treatment

Localized scleroderma usually resolves spontaneously in a few years.

Systemic Treatment

1. Systemic calcitriol at the dosage of 0.50–0.75 mg/day is effective in localized scleroderma of the scalp including frontoparietal linear scleroderma.
2. Oral methotrexate at 15 mg/m^2 (maximum 20 mg/week) for 6 months may be combined for the first 3 months with oral prednisone (1 mg/kg/day, maximum 50 mg/day) as a single morning dose.
3. Ultraviolet (UV) A1 phototherapy is a possible option.

Topical Treatment

1. Topical 2 % or 5 % minoxidil.
2. Calcipotriol lotion may be effective.
3. Tacrolimus 0.1 % ointment twice a day is a possible option.

Patients with frontal linear scleroderma ("en coup de sabre") can gain functional and aesthetic results from surgical volumetric restoration with fat grafting.

Key Points

- Contact dermatitis (CD) is used to describe a polymorphic pattern of skin inflammation in response to the contact with exogenous substances.
- It is one of the most common dermatoses that includes allergic contact dermatitis (ACD), irritant contact dermatitis (ICD), photocontact dermatitis (FCD), systemic contact dermatitis (SCD), and contact urticaria (CU).
- Occupational contact dermatitis (OCD) refers to a dermatitis developed at workplace, and it represents a wide social and economical burden.
- The clinical history of a patient with CD has to be collected accurately.
- Patch test is an essential investigation in order to perform the proper diagnosis. Patients with persistent eczema and suspected ACD or not responding to conventional treatment should be patch tested with an extended standard series of allergens, including the risk-related series.
- The treatment should be effective and prompt in order to avoid the dermatitis of becoming chronic. The prognosis of contact dermatitis, especially occupational contact dermatitis, is poor if the trigger persists.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_16, © Springer-Verlag Berlin Heidelberg 2015

- The essential principle in the therapeutic management consists in:
  - Basic therapy, including explanation and comprehension of the diseases; recognition, avoidance, and protection from irritant or allergic substances; and proper use of cleansers and emollients.
  - Topical anti-inflammatory drugs (topical corticosteroids) and antipruritic drugs as a first line of therapy.
  - Systemic treatments (in particular oral corticosteroids) are reserved for chronic and severe cases.

Definition

The terms "dermatitis" and "eczema" are often used synonymously in order to describe a polymorphic pattern of inflammation. The clinical presentation of dermatitis ranges from acute phase with erythema and vesiculation to chronic phase with scales. Eczema rather reflects a later stage of inflammation with thickening and lichenification. Pruritus is almost always present.

Dermatitis is characterized by a spongiotic pattern, with epidermal spongiosis and perivascular lymphohistiocytic infiltrate in superficial dermis.

"Contact" dermatitis is commonly used to describe a skin inflammation in response to the contact with exogenous substances. It may be the result of external agents acting either as irritants or as allergens. In the last case, a T-cell-mediated immunity is involved, termed contact hypersensitivity (CHS).

Contact dermatitis (CD) can be divided in the following types:

- Irritant contact dermatitis (ICD)
- Allergic contact dermatitis (ACD)

Often ICD and ACD present simultaneously.

Moreover, both ICD and ACD can lead to a chronic eczema due to the repetitive exposure or the lack of treatment.

This chapter also includes the following:

- Phototoxic, photoallergic, and photoaggravated contact dermatitis
- Systemic contact dermatitis
- Protein contact dermatitis
- Immunological and non-immunological contact urticaria

Epidemiology

Few epidemiological studies address the prevalence of dermatitis in general population.

The prevalence of dermatitis, including also other types (e.g., atopic dermatitis), varies between 1 % and 20 %. An increase of its incidence has been registered in the last decades.

Contact dermatitis represents about 4–7 % of all dermatological consultations.

Irritant contact dermatitis (ICD) is more common than allergic contact dermatitis (ACD). The latter has a worse prognosis unless the allergen is identified and avoided. Among the most common allergens are nickel and chromate. Nickel contact dermatitis has become an epidemic disease in the industrialized world.

It has been estimated that in Europe about 65 million of people suffer from nickel allergy (54 million women and 11 million men). In Italy, the incidence in women is up to 20 %. Among teenagers, nickel is the most frequent cause of sensitization, and the incidence increases with age.

The high frequency of nickel ACD is related to its contact in both occupational and non-occupational settings. Due to its wide presence, nickel allergy is a lifelong condition and can be an important factor of chronic eczema.

European laws have led to a reduction of the nickel release from products over the years. The European Commission (EC) (Commission Directive 2004/96/EC of 27 September 2004) has established that the rate of nickel release from pierced parts of the human body must be less than 0.2 μg/cm^2/week.

National and European laws have led to a drastic reduction of prevalence of sensitized patients. In Europe, new cases have been linked to the

introduction of 1 and 2 euro coins made of nickel, brass, and copper. Yet, as the contact with coins is very short, coins are a very rare source of ACD.

Lastly, some concerns emerged from the nickel released from mobile phones and from some products made in China. So, the surveillance has to remain high.

Contact dermatitis represents a social and economical burden when it develops at the workplace (occupational contact dermatitis (OCD)). In Italy (Tuscany), about 10 % of all occupational diseases are skin diseases, with 97 % being contact dermatitis (85 % ACD and 12 ICD). ACD is usually more severe, and it is easier to identify ACD than OCD.

The professionals most frequently involved are construction and metalworkers, hairdressers, and health workers.

The main body sites involved are the hands, especially in OCD.

Basic Concept of Pathogenesis

The etiopathology of ACD is complex.

It is possible to distinguish two phases: induction phase (sensitization) and effector phase (elicitation).

The *sensitization* reflects the establishment of a T-cell-mediated memory response. The sensitization frequently occurs when skin damaged by ICD has contact with the allergen. It is complete when the individual is able of giving a positive ACD reaction.

The sensitization can be divided in the following steps:

- Binding of allergen to skin components
- Activation of allergen-presenting cells (APC), loaded with hapten
- Migration of hapten-loaded APC to the draining lymph node
- Recognition of allergen-modified dendritic cells (DC) by specific T cells
- Proliferation of specific interferon-producing T cells in draining lymph nodes
- Systemic propagation of the allergen-specific T-cell progenies

The *elicitation* is due to a renewed contact of healthy skin with the allergen. It results in clinical manifestation of ACD.

Irritant contact dermatitis (ICD) may be due to accidental exposure to strong irritants, as acids, or alcohols, causing severe wounding. However, it is much more common to face mild, repeated, and damaging insults to the skin that slowly cause visible damage by gradual denaturation of keratins, removal of horny layer lipids, and alteration of the water-holding capacity of the skin.

Individual susceptibility varies greatly: atopics and individuals with fair skin suffer more easily from irritant dermatitis.

The openly exposed areas of the skin are the most affected ones, e.g., the backs of the hands and the webs of the fingers. ICD can develop in numerous professions, especially in those that are performed in "humid" environment (the so-called wet workers), as:

- Catering
- Cleaning
- Construction work
- Medical (doctor, nursing, etc.)
- Engineering
- Gardening
- Hairdressing
- Housework
- Motor mechanics

Clinical Presentation

CD is characterized by a polymorphic pattern of skin inflammation, from acute to chronic.

ICD ranges from slight dryness, redness, to acute caustic burns, depending on the nature of irritant, the time of contact, and the area involved.

The first manifestation of ACD is often an acute eczema, although the severity ranges from mild to severe.

The polymorphic pattern of skin inflammation, characterized by erythema, edema, vesiculation, scaling to thickening, and lichenification, may be the result of combination of ICD and ACD, as well as the variable course of each type of dermatitis.

The prognosis of contact dermatitis is more problematic in atopic individuals and for people allergic to certain allergens, particularly nickel and chromate.

The clinical features of CD of the hand are reported elsewhere (→ see hand dermatitis chapter).

Other Types of Contact Dermatitis

Photodermatitis (PD)

Photodermatitis is an abnormal skin reaction to ultraviolet (UV) rays: from acute (sudden) to chronic (ongoing) skin reactions have been reported, with itchy erythematous rash, blisters, scaly patches, and hyperpigmentation. Several factors can increase the skin sensitivity to UV rays; individual factors mainly determine the sensitivity to UVB. The sensitivity to UVA is mainly determined by environmental factors, namely, topical or systemic drugs; exposition to certain plants, e.g., those belonging to the Apiaceae or Umbelliferae family; etc.

It is important to separate direct toxic mechanisms (phototoxic dermatitis) from allergic mechanisms (photocontact dermatitis (PCD)). As reported in an Italian multicenter study, the predominant groups of photoallergens were drugs, followed by organic UV filters and antimicrobial agents. Importantly, inappropriate UV irradiation can aggravate a preexisting contact dermatitis.

Systemic Contact Dermatitis (SCD)

Systemic contact dermatitis (SCD), or systemically reactivated allergic contact dermatitis, refers to a type of systemic contact hypersensitivity reaction (CHS) due to the ingestion of, or systemic exposure to, a contact allergen in an already sensitized person. Clinically significant SCD occurs only to certain allergens to which we are frequently exposed through a wide variety of routes.

Systemic nickel allergy syndrome (SNAS) is the most studied. It was highlighted some decades ago, and it still represents a common problem. Other potential allergens are balsam of Peru, neomycin, chromate, garlic, food colors, preservatives, and antioxidants.

A variety of clinical patterns have been reported in patients suffering from SCD: from focal flares of previous patch test sites to flares at sites of previous dermatitis, e.g., atopic eczema, diaper dermatitis, or drug rashes; to widespread eczema, sometimes associated with urticarial lesions; and to acral purpuric lesions, vasculitis, erythema multiforme-like lesions, "baboon syndrome," etc. Baboon syndrome refers to an acute SCD of the buttocks and upper inner thighs, with a pronounced erythema, reminding the red rump of a baboon.

A wide range of systemic symptoms can follow the dermatitis: from headache to asthenia, itching, intestinal, and respiratory symptoms.

Contact Urticaria (CU)

Contact urticaria (CU) is a rare condition characterized by itching wheals and flare response due to the relapse of histamine and other inflammatory mediators after the contact with proteins or with physical agents (cold) that either cause urticaria as an irritant reaction (frequently cold stress) or, rarely, as a type I allergic reaction (IgE mediated).

The skin manifestation ranges from wheals to anaphylactic shock.

CU can be distinguished in immune and nonimmune types. The first is IgE mediated and more common in atopics. The contact with latex proteins has to be always taken into consideration in case of surgical operation. In highly sensitized people or after extended exposure, the IgE response can lead to systemic response until anaphylactic shock.

Diagnosis

The clinical features frequently suggest the correct diagnosis. Yet, appropriate testing is mandatory for a definitive diagnosis. In some patients

with a clear history distinguishing ACD from ICD and atopic eczema, e.g., when the dermatitis is localized at the hands (→ see Hand Dermatitis), the diagnosis may be feasible without further tests. However, it is more frequent to face a more complex situation, where the role of an ICD, and ACD, and an atopic dermatitis can only be determined after testing.

Thus, following an accurate anamnesis, patch test represents an essential investigation to clarify the origin of an eczema that is unresponsive to topical treatment or immediately worsens after the end of the treatment. Testing is also needed if an ACD is suspected or cannot be ruled out. Patch test can or cannot confirm the nature and etiology of a contact dermatitis.

The most frequent sensitizers have been compiled to a "standard series" comprising 20–30 allergens in order to have a shared screening series.

The standard series should be revised on a regular basis.

Table 16.1 reports the European baseline series (Bruze et al. 2008) (28 allergens or better haptens).

The standard series usually varies from country to country. In fact, each national society board has approved its standard series according to the European recommendation. Table 16.2 reports the standard Italian series 2012, as suggested by SIDAPA (Italian Society of Allergological, Occupational and Environmental Dermatology) (25 haptens).

Importantly, dermatologists and dermatology centers adapt the spectrum of haptens/allergens to be tested by combining the European standard with allergens that may be of local importance.

The standard series of patch tests allow to detect approximately 80 % of the relevant sensitizations. Thus, it is worthy to emphasize the importance of using specific additional series, when the patient's history leads to a reasonable diagnostic hypothesis. This also includes testing products used by the patient; yet it is frequently difficult or impossible to standardize these procedures. Some Italian studies showed that not a small group (8.2 %) of patch-tested patients that is negative to standard series reacts positive to additional series.

Importantly, allergens may be commercially available in several additional series. Some examples are reported in Table 16.3.

Table 16.1 European Society of Contact Dermatitis (ESCD) and European Contact Dermatitis Research Group (EECDRG) standard series (2008)

The Procedure of Patch Testing

An important aspect is the preparation of the patients. The skin on the back has to be free from dermatitis, and an eczema elsewhere has to be controlled as far as possible by local treatment. Patients have also to be instructed to not take oral corticosteroids, or other immunosuppressive drugs, the days preceding the patch tests. It is also important not to apply potent topical steroids to the back or to undergo a UV therapy. These factors are linked to a significant risk of false-negative results.

A diagnosis of acute or chronic irritant contact dermatitis is made by an accurate anamnesis that reveals a significant exposure to an irritant, the clinical manifestation, the course of the eczema, and negative results at the patch testing.

The most important causes of irritant contact dermatitis are as follows:

- Water
- Skin cleansers
- Detergents and solvents
- Acids and alkalis
- Cutting oils
- Chemicals
- Physical and mechanical factors
- Biological agents

The first three factors are the most common ones, causing irritant during the normal life, while the following three can have an important role in the occupational environment.

Special Conditions of Testing

Open Patch Test

Open patch test is useful when sensitizers, which may also cause irritant dermatitis, are assessed. It is useful in the investigation of ACD, contact urticaria, and protein contact dermatitis. It is usually performed on the forearm, and the site of investigation should be controlled for the first 30–60 min, to detect urticaria. A further reading should be made after 3–4 days.

Photopatch Test

When photoallergic dermatitis is suspected, photopatch test may be carried out.

It involves the application of the photoallergen series and any suspected materials (also patients' products) in duplicate on either side of the upper back. One side is irradiated with a dose of 5 J cm^2 of UVA after 1 or 2 days; the other is uncovered after 2 days. A final reading is taken for both sides after another 3 days. Importantly, in case of photoallergy an erythema is evaluated as "positive."

Differential Diagnosis

Other exogenous (such as tinea) and endogenous eczemas should be excluded.

Among the endogenous eczemas, atopic dermatitis, dyshidrosis, nummular eczema, or prurigo may be differential diagnoses. Moreover, endogenous and exogenous substances may cause other reactions such as erythema multiforme-like to lichenoid, purpuric, pigmented, and nodular reactions or granulomatous contact dermatitis.

Psoriasis and mycoses, especially when the dermatitis involves the hands, lichen planus, erythema multiforme, and prurigo nodularis have to be ruled out.

When the dermatitis involves the face or the scalp, psoriasis, seborrheic dermatitis, and rosacea are the most common skin diseases.

Prognosis

Several studies have confirmed that the long-term prognosis for contact dermatitis is often very poor. A Swedish study, which investigated a sample of patients with OCD, showed that only 25 % had the skin completely healed over a 10-year period. One half reported periodic symptoms and one quarter permanent symptoms. The overall prognosis of the disease was not improved in 40 % of the patients who had changed their occupation.

General Principles of Treatment

The essential principles in the management of contact dermatitis are as follows:

- Comprehension and explanation of the disease.
- Recognition, avoidance, and protection from irritants and/or allergens.
- Application of emollient and topical anti-inflammatory treatment (corticosteroids).
- Sedation of the itch.
- Rarely, in severe cases, a systemic treatment is needed.

The therapeutic strategies have to be realized promptly to avoid the dermatitis from becoming chronic.

A wide variety of local treatment modalities are available as reported in Fig. 16.1.

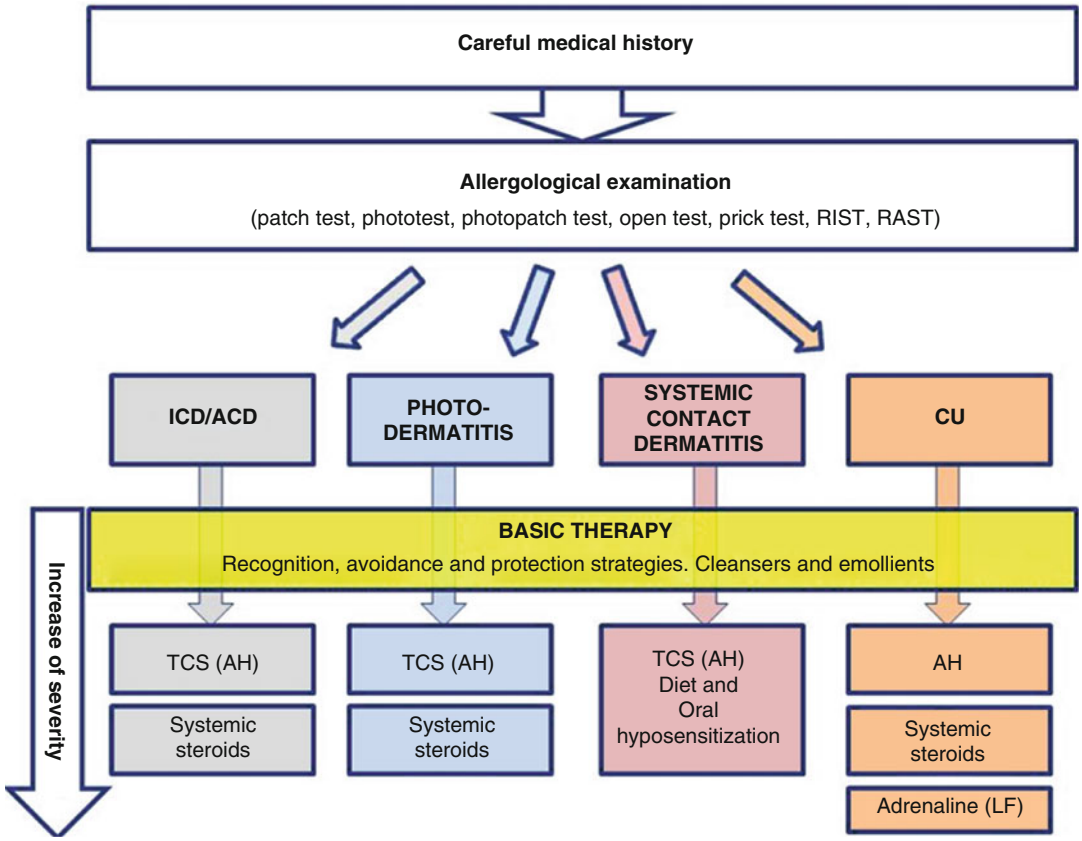

Fig. 16.1 Therapeutic algorithm in contact dermatitis. *ICD* irritant contact dermatitis, *ACD* allergic contact dermatitis, *CU* contact urticaria, *TCS* topical corticosteroids, *AH* (oral) antihistamines, *LF* life-threatening cases, *RIST* radio-immunosorbent test, *RAST* radioallergosorbent test

Basic Therapy

The first step in the management of irritant and allergic CD involves the explanation of the disease, followed by avoidance, protection, and substitution strategies. Educational programs are needed.

Avoidance

The recognition and avoidance of the exposure to all possible irritant and allergic factors from the domestic and professional environment has to be realized as consequently and as soon as possible. A careful investigation of the patients' habits together with a visit of the workplace may be necessary to identify all the potential skin irritants and allergens.

Protection

The protection is an essential step for the effective treatment. Its proper fulfillment depends on the nature of the irritant, the body area involved, and the environment where the contact is.

As many diseases involve the hands, gloves are the mainstay of protection. At home, rubber or polyvinyl chloride gloves, possibly over cotton gloves, should be sufficient. It is also important to educate the patient to properly use and remove gloves after their application. In fact, sweating and occlusion can trigger or aggravate the dermatitis. At the workplace, the choice of gloves to use depends on the work and the nature of the chemicals involved. Then, the choice of the gloves should be made carefully because many and different solvents and chemicals can

penetrate gloves with time, depending on the material. Table 16.4 reports the suggested types of gloves for different hazardous products.

The efficacy of barrier creams in the protection to irritants and allergens is questionable. They can be used, but their use should not be over-promoted. Their efficacy is not comparable to gloves, if used alone, and they may confer on workers a false sense of security. Emollients seem to provide some benefits in the treatment of irritant contact dermatitis.

Substitution

Some irritant agents, like soap, water, etc., can be substituted with nonirritating ones. Avoidance of an individual allergen is frequently difficult to realize.

Table 16.4 Gloves suggested for specific hazardous products

Hazard	Type of glove suggested
Microorganisms	NRL, thermoplastic elastomer
Disinfectants	NRL, PVC, PE, EMA
Pharmaceuticals	NRL (permeability time very short)
Composite materials	NRL (permeability time in minutes)
Solvents	PE, PVC, nitrile, NRL, neoprene, butyl rubber, Viton
Corrosives	NRL, PE, PVC, neoprene, butyl rubber, Viton
Detergents	NRL, EMA, PE, neoprene, PVC, nitrile
Machining oils	NRL, PVC, nitrile, neoprene

From Bourke et al. (2009) modified
NRL natural rubber latex, *PVC* polyvinyl chloride, *PE* polyethylene, *EMA* ethylene methyl methacrylate

Educational Programs

Educational programs have to be carried out to increase the knowledge of people and workers on this common disease.

Topical Treatment

The choice of the treatment depends on the severity and course of the dermatitis. A practical summary of recommendations is given in Fig. 16.1 and Table 16.5.

Cleaning and bathing are normally recommended if appropriately performed as in other diseases, e.g., atopic dermatitis. Yet, it is extremely important to investigate the patients' habits in cleaning and bathing to avoid misuse that can cause ICD and, in case of ICD, to modify them.

The vehicle of emollient or TCS is important and varies according to the clinical presentation. Cream is better for acute lesions, whereas ointment may be used in the case of lichenified and scaly thickened infiltrates.

Daily application of emollient is helpful in improving ICD and in preventing dryness. They should be used after wearing gloves at home or at the workplace and at the end of the work shift.

The soothing effects of paste bandage or wet dressing may help to improve the itch/scratch vicious circle.

Treatment should not be stopped until healing is complete. It is also important to explain to a patient that his/her skin will remain especially vulnerable for some weeks beyond the end of the

Table 16.5 Suggested treatment for different clinical manifestations

Therapeutic agents	Acute	Subacute	Chronic	Prophylactic
Wet dressing	++	+	–	–
Creams/lotion (emollients)	++	+	+	++
Pastes/ointments (emollients)	+	++	++	+
Topical corticosteroids (creams/lotion)	++	++	+	–
Topical corticosteroids (ointment)	+	++	++	–
Topical immunosuppressant	+	+	+	–
Polythene or bandage occlusion	+	+	+	–
Systemic steroids (and systemic treatment)	+	+	++	–

– Not recommended, +/– recommended in some clinical presentations, + sufficiently recommended, sometimes not as the first line, ++ recommended

treatment. Thus, an education in the daily skin care is mandatory to treat the skin and to prevent relapses.

Patients have to follow these basic recommendations for very long periods of time, often forever.

Topical Corticosteroids (TCS)

Topical corticosteroids (TCS) are widely accepted as the first-line treatment of established contact dermatitis. Studies regarding their use are present especially in allergic contact dermatitis. The choice of the potency of TCS depends on the severity of dermatitis, the area to be treated, and the age of the patient. Mild corticosteroids are usually preferred for sensitive areas (e.g., face and genital areas) and for children, whereas more potent molecules may be preferred on the other parts of the body and when the dermatitis is moderate to severe. Their use under polythene occlusion may be helpful: however, it has to be considered that the occlusion increases the TCS effects (both efficacy and side effects). TCS suppress the inflammation, but at the same time they make the epidermis thinner and can alter the barrier function. Thus, they have to be used properly.

It is worthy to remember that TCS can be an important cause of ACD even though rarely. ACD caused by TCS has to be suspected when the dermatitis persists and does not respond or worsens with the use of TCS.

TCS allergic contact dermatitis represents about 1 % of all ACD, and the patch test represents a mandatory step in the confirmation of the diagnosis. A late reading of the corticosteroids patch test reaction at day 7 is frequently necessary for the appropriate testing.

Corticosteroid molecules can be classified according to their allergological group, as reported in Table 16.6.

Cross-sensitivity among each group of corticosteroids is common and needs to be taken always into consideration. Patients, suffering from an ACD to a corticosteroid, can be treated with a corticosteroid of another group, but not with a corticosteroid of the same group. For example, a patient with contact sensitivity to a corticosteroid of class B (e.g., budesonide) can be treated with a corticosteroid of class D1 (e.g., fluticasone propionate).

Cross-reactivities between topical and systemic corticosteroids among each group have also been reported.

The sensitization to corticosteroids is linked to several factors. These are the following structures: the C(16)-methyl substitution and the C16-methyl corticosteroids (groups C and D1). The latter seems far less allergenic than the non-methylated molecules and may be preferred.

Topical Calcineurin Inhibitors (TCI)

Topical calcineurin inhibitors (TCI), especially pimecrolimus and tacrolimus, are frequently effective in the treatment of atopic dermatitis

Table 16.6 Classification of corticosteroids as allergens

A	B	C	D1	D2
Hydrocortisone 21-acetate	Budesonide	Desoximetasone	Mometasone furoate	Hydrocortisone 17-butyrate
Prednisone	Desonide	Dexamethasone	Betamethasone dipropionate	Methylprednisolone aceponate
Methylprednisolone acetate	Halcinonide	Betamethasone	Clobetasol 17-propionate	Prednicarbate
	Fluocinolone acetonide	Fluocortolone	Clobetasone 17-butyrate	
		Diflucortolone valerate	Alclometasone dipropionate	
			Fluticasone propionate	

(AD). Large-scale studies have been performed for AD, in children and adults, confirming their efficacy in a condition sharing many pathophysiological similarities with contact dermatitis (as eczema, itch, and the presence of inflammatory cell infiltrates in the skin). Studies have demonstrated the TCI to be effective in a model of allergic contact dermatitis to nickel. As compared to topical corticosteroids, TCI generally do not cause skin atrophy. However, their use in contact dermatitis is limited, and their recommendation is supported by few studies. They represent a second-line treatment of contact dermatitis: their use is suggested for sensitive areas (e.g., face, genital, etc.) and in cases who do not respond to TCS or in the case of sensitization to TCS.

Proactive strategies were not investigated in contact dermatitis.

Antimicrobial Treatments

Where secondary bacterial infection complicates an eczema, the combined use of topical corticosteroids together with topical antiseptic compounds may be useful, even if this approach is supported only by few studies.

In case of extended clinical skin infection, oral antibiotics have to be used that are effective against *Staphylococcus aureus*.

Systemic Therapy

Systemic Corticosteroids

Moderate to severe acute contact dermatitis may very rarely be required with a 14–21-day course of oral corticosteroids.

The initial dose of 25–50 mg of prednisone, daily, after breakfast should be decreased by 10 mg/day every 3–5 days according to the improvement of the dermatitis.

The oral therapy should be continued for at least 7–10 days after the clinical remission in order to avoid relapse. Importantly, all exogenous triggers, irritant or allergic, should be individualized and avoided; otherwise, the side effects of a steroid abuse become threatening.

Antihistamines and Antipruritic Measures

Pruritus has many causes, mediators, and treatment modalities (→ see Atopic Dermatitis).

Pruritus can be reduced by proper topical treatment, mainly TCS and basic treatment, and systemic treatment according to the severity.

Antihistamines are frequently used for their antipruritic effects in contact dermatitis. Yet, their efficacy is questionable. The efficacy of either first- or second-generation antihistamines has not been investigated deeply in contact dermatitis.

Patients suffering from pruritus that is severe or disturbs the daily life and sleep can benefit from first-generation antihistamines for their sedative effects.

Other Treatments

Phototherapy, with psoralen plus UVA (PUVA), UVA1, and broad- or narrowband UVB, is used either in moderate to severe AD or in chronic hand eczema.

Similarly, the use of cyclosporine A (CSA) and azathioprine (AZP) is supported by trials in these diseases. In contact dermatitis, these therapeutic strategies can be used with similar modalities.

Phototherapy, CSA, and AZP are second-line therapies for patients with moderate to severe contact dermatitis that does not respond to topical corticosteroids.

The use of one of these treatments depends on the severity of the dermatitis, the availability of the treatment, and the involved areas.

These treatments are discussed in detail elsewhere (→ see hand dermatitis, atopic dermatitis, psoriasis, phototherapy, immunosuppressive therapies).

The risk/benefit ratio of a treatment with CSA or with AZP should be considered before the start and during the treatment.

When the hands are involved, new therapeutic strategies are available in several European countries, such as alitretinoin (→see hand dermatitis chapter).

Summary of Recommendations at a Glance (Fig. 16.1, Table 16.6)

- The clinical history of a patient with CD has to be carried out accurately.
- Patients with persistent eczema, or not responding to conventional treatment, should be patch tested to at least an extended standard series of allergens.
- The treatment consists in basic therapy and use of TCS and antipruritic drugs as a first line of therapy. Systemic treatment is reserved for chronic and severe case.

(Nickel) Elimination Diet and Oral Hyposensitization

Nickel contact allergy is very common in Western countries, and the dermatitis may require prolonged treatment. The development of new strategies aims to improve the disease and the quality of life of affected individuals.

There are many evidences in supporting the benefit of low-nickel diet in some nickel-sensitive patients, in particular in those with wide and systemic manifestations.

In Table 16.6, the low-nickel diet is summarized.

High-nickel foods (forbidden)	Low-nickel foods (allowed)
Canned foods	Flour
Asparagus, mushrooms, onions, spinach, tomato, potatoes	Olive oil
Legumes, lentils, beans	Butter
Lettuce, carrots, broccoli	Eggs
Whole-wheat flour, oat, millet	Meat
Pear, plum, figs, apricot, kiwi, pineapple	Fish (with the exceptions signalized before)
Hazelnut, almond, peanuts	Milk and cheese
Dried fruit	Fruits and vegetables (with the exceptions signalized before)
Cocoa, chocolate	Wine
Margarine	Coffee
Herring, oyster, mackerel	Muesli
(Green) the	
Marzipan	
Licorice	
Vitamins and nutritional supplement	

Oral tolerance impedes or contrasts with the development of undesired immune responses toward dietary antigens. Oral hyposensitization with a daily dose of 50 μg (micrograms) of elemental nickel (given as $NiSO_4 \cdot 6H_2O$) has led in nickel-allergic individuals to a significant improvement of their cutaneous and systemic symptoms. This method is a promising approach for the management of cutaneous and systemic nickel allergy. Oral hyposensitization can be used also for the other systemic contact dermatitis.

Cutaneous Vasculitis

17

Serena Gianfaldoni, Angelo Massimiliano D'Erme, Jana Hercogová, and Torello M. Lotti

Key Points

- Cutaneous vasculitides (CV) are a group of clinical diseases characterized by angiocentric segmental inflammation, endothelial cell swelling, and fibrinoid necrosis of blood vessel walls.
- Usually they involve postcapillary venules. CV can be idiopathic, can be associated with an underlying chronic disease, or can be precipitated by infections or drugs.
- Although skin lesions of CV are various, palpable purpura is the most commonly described.
- Some patients may have also a systemic involvement of the small blood vessel.
- Evaluation of patient should include a thorough history, physical examination, laboratory tests, and histopathology studies. When it's possible, therapeutic approach to CV is to find out and to remove the causative agent.
- Otherwise, local and systemic treatments are necessary.

Definition and Epidemiology

Vasculitis is a broad, poorly defined category of diseases, characterized by inflammation of the blood vessel that leads to various clinical manifestations depending on which organ systems are involved.

The clinical condition of dermatological interest is mainly related to "cutaneous vasculitis" (CV), a not uncommon disorder characterized by an inflammation and tissue damage of the blood vessel and skin lesions.

CV are a group of clinical diseases characterized clinically by palpable purpura and histologically by angiocentric segmental inflammation, endothelial cell swelling, and fibrinoid necrosis of blood vessel walls. On the basis of histopathological pattern, two major forms of CV are recognized: a leukocytoclastic form and a lympho-monocytic one. More recently, an eosinophilic vasculitis has also been described.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_17, © Springer-Verlag Berlin Heidelberg 2015

Usually, they involve small and medium blood vessels, especially postcapillary venules.

The disorder occurs equally in both sexes and at all ages. About 10 % of patients are children and suffer from the Henoch-Schönlein purpura.

An associated disease determines the age of the affected individual. Geographic variations in CV may reflect an environmental influence, although the seasonal variation may suggest an infectious etiology.

Cutaneous vasculitis may occur idiopathically or in association with chronic diseases, malignant neoplasm, and precipitating agents (Table 17.1).

The pathogenesis of leukocytoclastic vasculitis depends mainly upon immune complex formation. Immune complexes may activate complement system and lead to the generation of C5a anaphylatoxin. This one attracts neutrophils and degranulas mast cells. Finally, neutrophils produce lysosomal enzymes and reactive oxygen products that damage tissue.

A possible role of lymphocytes has been suggested by their presence in many skin biopsies. Lymphocytes may be activated by IC, by cellular immune mechanisms, and by primary activation in autoimmune disease. In the first cases, lymphocytes perpetuate CNV; in the other, they start the pathological process.

Time course analyses are evaluating the role of mast cells in CNV, especially in patient with urticaria. Eosinophils seem to be of less importance, except in eosinophilic vasculitis and drug-induced CNV. They increase vascular permeability and cause the release of mediators from mast cells.

Finally, there is ANCA-associated cutaneous necrotizing vasculitis. ANCAs are antineutrophil cytoplasmic antibodies, which can start the inflammation and the endothelial cell injury.

Clinical Presentation

Subtypes of Cutaneous Vasculitis

CV can be idiopathic, can be associated with an underlying chronic disease, or can be precipitated by infections or drugs (Table 17.1)

Many factors, such as infection, drugs, chemicals, and food, should be considered as a possible cause of CV. Really, most of the etiologic factors have been incriminated by the association rather than by direct demonstration.

Approximately 22 % of all cases of CV are associated with an infectious etiology, and maybe this prevalence is underestimated. The most common infection agents are β-hemolytic streptococcus, *Staphylococcus aureus*, *Mycobacterium leprae*, and hepatitis B and C viruses. More rarely, CV has been documented in other bacterial (e.g., *Neisseria meningitidis*, *Neisseria gonorrhoeae*), viral, fungal, protozoan, or helminthic infections. Cold, stasis, previous injury, or constitutional defects may predispose patients to the development of vasculitis. Biopsy usually reveals a mixed small- and medium-sized vessel vasculitis. The cutaneous features include hemorrhagic petechiae, purpura, blister, bullae, macules, or nodules.

Cutaneous vasculitis may be also a product of the exposure to many drugs (e.g., penicillin, hydantoin, thiazides, oral contraceptives, serum) and is considered as immune complex reactions. Usually, the interval between the ingestion of the drug and onset of the vasculitis varies from hours to days, more rarely years. The cutaneous manifestations vary from maculopapular, vesicular, or purpuric rash. Lesions can be localized or diffuse and may be associated to other systemic symptoms, like fever, malaise, arthralgias, nausea, and vomiting. Usually, the skin lesions resolve in few days, without sequelae.

CNV has been reported in association with coexistent diseases, most frequently with hyperglobulinemic states or cryoglobulinemia.

Connective-tissue disease vasculitis is an uncommon complication, which is described most frequently in association with systemic lupus erythematosus, rheumatoid arthritis, and Sjögren's syndrome. Usually, skin biopsy reveals a vasculitis of small- and medium-sized vessel. The clinical appearances can be many, but typically we describe purpura, vesiculobullous lesions, urticaria, and splinter hemorrhages. Ulcers, subcutaneous nodules, gangrene, livedo

Table 17.1 Classification of cutaneous vasculitis

Idiopathic disorders	Henoch-Schönlein purpura Urticaria vasculitis Erythema elevatum diutinum Nodular vasculitis Livedoid vasculitis Atrophie blanche Acute hemorrhagic edema of infancy Cutaneous polyarteritis nodosa Genetic complement deficiencies Idiopathic	
CNV associated with coexistent diseases	Chronic diseases	Systemic lupus erythematous Sjögren's syndrome Rheumatoid arthritis Behçet's disease Hyperglobulinemic states Cryoglobulinemia Ulcerative colitis Cystic fibrosis Primary biliary cirrhosis HIV/AIDS
	Solid tumor	Lung cancer Colon carcinoma Renal Prostate Head and neck cancer Breast cancer
	Lymphoproliferative disorders	Hodgkin's disease Mycosis fungoides Lymphosarcoma Adult T-cell leukemia Multiple myeloma
Precipitating factors	Viral infections (HAV, HBV, HCV, HSV, HTLV) Bacterial infections (β-hemolytic streptococcus group A, *Staphylococcus aureus*, *Mycobacterium leprae*) Fungal infections (*Candida albicans*) Protozoan infections (*Plasmodium malariae*) Helminth infections (*Schistosoma haematobium*, *Schistosoma mansoni*, *Onchocerca volvulus*) Drugs (insulin, penicillin, hydantoins, streptomycin, aminosalicylic acid, sulfonamides, thiazides, phothiazines, vitamins, allopurinol, phenylbutazone, quinine, streptokinase, tamoxifen, anti-influenza vaccine, oral contraceptive, serum, contrast media, methotrexate, drug additives, infliximab, etanercept, adalimumab, rituximab) Chemicals (insecticides, petroleum products) Foodstuff allergens (milk protein, gluten)	

Modified from Hautmann et al. (1999)

racemosa, and pyoderma gangrenosum can also be seen and represent arterial involvement.

Lupus vasculitis has been described in 20–40 % of patients with systemic lupus erythematosus, especially in young men. More rarely, it can be seen also in patients with subacute cutaneous lupus erythematosus. The most common cutaneous presentation is macules or depressed

punctuate scars and expression of skin infarcts. Lesions are mainly localized on the palms and on fingers. Other cutaneous manifestations include purpura, urticaria, and livedo.

Rheumatoid vasculitis is an uncommon complication of rheumatoid arthritis, which is described mainly in an adult man. RV is associated with high rheumatoid factor titer, joint erosion, rheumatoid nodules, and extra-articular symptoms (e.g., mononeuritis). The typical skin lesion is palpable purpura, localized on the lower extremities. Other cutaneous manifestations include maculopapular erythema, hemorrhagic blisters, nodules, ulcers, livedo, and atrophie blanche.

Patients with Sjögren's syndrome usually develop a systemic vasculitis. The most common skin lesions are palpable purpura, urticaria, and ecchymoses.

More rarely, CV can be seen in dermatomyositis, scleroderma, and polychondritis.

Occasionally, CV is associated with other chronic disorders, like bowel bypass syndrome, ulcerative colitis, primary biliary cirrhosis, and HIV/AIDS. Cutaneous vasculitis can be also described in lymphoproliferative disorders, such as Hodgkin's lymphoma, lymphosarcoma, adult T-cell leukemia, and multiple myeloma. More rarely, CV has been described in association with adenocarcinoma of the lung, prostatic carcinoma, kidney carcinoma, bladder carcinoma, or colon carcinoma.

In many patients the cause of CV remains unknown.

The Henoch-Schönlein purpura is the widely recognized one. It is a rare disorder, which occurs predominantly in children that are 4–8 years old. More rarely, it has been described in adults. The disease usually follows an upper respiratory tract infection, with a latency of 1–3 weeks. Clinically, it is characterized by a typical symmetric palpable purpura localized on the lower extremities, which regress in 10–14 days. Direct immunofluorescence studies show IgA deposits affecting small vessels. Most of the patients suffer arthralgias and arthritis and gastrointestinal (e.g., colicky pain, vomiting, melena) or renal symptoms (e.g., proteinuria, hematuria, glomerulonephritis). Central nervous system involvement may occur as diplopia and headaches.

Urticaria vasculitis is a chronic recurrent disorder, usually affecting young adult women in their fourth or fifth decades of life. Skin manifestations are pruritic, erythematous wheals that may contain foci of purpura. Lesions usually persist for 2–3 days. Occasionally, there could be macular erythema, livedo reticularis, nodules, bullae, or angioedema. Systemic symptoms (e.g., fever, arthralgias, abdominal pain) are usually present. The Schnitzler syndrome is a particular form of recurrent urticaria vasculitis, described in patients with monoclonal IgMκ M component. It's a rare disorder characterized by a systemic involvement (e.g., lymphadenopathy, hepatosplenomegaly, renal failure, neurological compromission) and by the risk of development of hematologic malignant conditions.

Erythema elevatum diutinum is a chronic cutaneous vasculitis. It's a rare disease, more frequent in female patient. The etiology is largely unknown; maybe there is an association between EED and connective-tissue disease, infection, and hematologic abnormalities. Clinically, EED is characterized by symmetric and persistent red or brown papules, plaques, or nodules on the extensor surface and over the gluteal area.

Behçet's disease is a chronic inflammatory disease, rarely described in Europe or North America, while it's more common in Asia. Typically, Behçet's disease affects young men who develop oral and genital ulcers and ocular defects. Patients may show also arthralgias and gastrointestinal or neurological symptoms. Cutaneous manifestations include erythema nodosum or purpura. Rarely, there could be hemorrhagic bullae, pyoderma gangrenosum-like lesions, or erythema multiforme-like lesions.

Nodular vasculitis affects women from 30 to 60 years of age. In some cases, it's associated with *Mycobacterium tuberculosis* infection ("erythema induratum"). Clinically, nodular vasculitis is characterized by a prodromal phase consisting of fever, malaise, and arthritis. After that, patients show the typical nodular skin lesions, localized on the posterolateral face of the legs. Lesions evolve slowly. The nodules that don't ulcerate may heal in 2–6 weeks, with residual scarring and hyperpigmentation.

Livedo vasculitis is characterized by a flat network of intersecting blue-red lines. Lesions are localized on the legs, arms, or lower trunk. Typically, patients develop painful ulcers of the lower extremities that resolve in sclerotic pale areas surrounded by telangiectasias ("atrophie blanche"). Livedoid vasculopathy is more common in women. It could be an idiopathic disorder or may occur in patients with connective-tissue disorder, thrombophilia, or malignant conditions. Sneddon's syndrome is a particular form of livedo, associated with ischemic cerebrovascular lesions, hypotension, and arterial and venous thromboses.

Acute hemorrhagic edema of infancy is another rare CV. It's characterized by edema and palpable purpura in infants younger than 2 years old. The disease has a short course, followed by spontaneous complete recovery.

Cutaneous polyarteritis nodosa is a limited form of polyarteritis nodosa which presents with skin lesions, fever, arthralgias, myalgias, and peripheral neuropathy. There aren't other systemic symptoms. The disease is more common in women that are 20–40 years old. The typical skin lesions are subcutaneous nodules localized on the lower extremities and on the buttocks. Other skin lesions include livedo reticularis with ulcerations, atrophie blanche, petechiae, purpura, or necrosis.

Rarely, CV has been described in young patients with genetic C2 deficiency. Also the deficiencies of C4A and C4B have been recognized in some adult patients with the Henoch-Schönlein purpura.

Finally, there are patients with CV that don't meet the criteria for recognized syndrome and are classified as idiopathic.

Clinical Features

The skin lesions of CNV are polymorphous; however, palpable purpura is the most common (→see also purpura chapter). It's characterized by erythematous papules that don't blanch when the skin is pressed. Initially, lesions might be only purpuric; as the process continues, they become palpable, ranging in size from pinpoint to several centimeters. Occasionally, subcutaneous edema can be observed in the same area.

Table 17.2 Systemic involvement in CNV

Kidney	Hematuria, proteinuria, glomerulonephritis, interstitial nephritis, acute and chronic renal failure
Gastrointestinal tract	Colicky pain, nausea, vomiting, diarrhea, hemoptysis, melena
Respiratory tract	Laryngeal edema; dyspnea; tracheal stenosis; chronic obstructive, restrictive, or interstitial pulmonary disease; hemoptysis; pleural effusion
Heart	Arrhythmias, valvular defects, congestive heart failure, myocardial angiitis, pericarditis
Nervous system	Headache, diplopia, hypo- or paresthesia
Joints	Arthralgia, arthritis
Eyes	Conjunctivitis, episcleritis, iridocyclitis, uveitis, retinal vasculitis, vasculitis of the optic nerve
Miscellaneous	Pancreatitis, hepatitis, lymphadenopathy, hepatosplenomegaly

Erythematous macules, wheals, papules, blister, nodules, ecchymoses, pustules, hemorrhagic vesicles, ulcers, and livedo reticularis are less common manifestations.

Lesions can occur anywhere, but they are most commonly found on the lower legs, where they are often distributed symmetrically. The mucous membranes are rarely involved (petechiae, hemorrhagic blisters, ulcers).

Lesional symptoms include pruritus, burning, or pain.

Usually, lesions persist from 1 to 4 weeks and resolve with hyperpigmentation and/or residual scarring.

The disease may be self-timing but can recur or become chronic.

Often, it's confined to the skin. In some cases, the cutaneous manifestations may be attended by fever, malaise, or signs and symptoms of a defined underlying disease. Some patients may have also a systemic involvement of the small blood vessel (renal, gastrointestinal, pericardial, neurological, and rheumatological) (Table 17.2).

Diagnosis

Evaluation should include a thorough history and physical examination with attention to possible etiological agents or associated diseases.

A complete history usually reveals risk factors and symptoms of systemic involvement. Drug or infection history, chemical exposure, food allergens, and travel histories are all essential. At the same time, it's important to investigate the presence of connective-tissue disease or other chronic disorders.

The clinical examination should follow a logical pattern beginning with the assessment of the primary clinical lesions (e.g., palpable purpura, livedo, urticaria) and of the secondary ones (e.g., ulceration, infection). A complete cardiopulmonary, abdominal, and neurologic examination must be performed in all patients, especially in whom systemic vasculitis is suspected.

The laboratory screening is always required to confirm the diagnosis of vasculitis, to find an associated disorder, and to determinate the extent of systemic involvement (Table 17.3). The laboratory's evaluation depends on the clinical history and physical examination of the patients.

Table 17.3 Evaluation of the patient with CV

History	Infections?
	Drugs?
	Chemicals?
	Foodstuff allergens?
	Underlying systemic disease?
	Systemic symptoms?
Physical examination	Primary clinical lesions
	Secondary clinical lesions
	Systemic involvement
Laboratory studies	Complete blood count
	Hepatitis surface antigen
	Rheumatoid factor
	Circulating immune complexes
	Complement components
	Antinuclear antibodies
	Antiphospholipid antibodies
	Cryoglobulins
	Antineutrophil cytoplasmic antibodies
	Urinalysis
Histopathological evaluation	Skin biopsy
	Muscle biopsy
	Renal biopsy
	Lung biopsy

The most common laboratory finding is an increased erythrocyte sedimentation rate.

In some patients with leukocytoclastic vasculitis, we can also find leukocytosis, anemia, and thrombocytosis.

Decreased levels of complement components are often noted in CNV associated with rheumatoid arthritis (C1, C2, C4), systemic lupus erythematosus (C1q, C2, C3, C4, C9, factor B), cryoglobulinemia, and Sjögren's syndrome. More rarely, a hypocomplementemia may be described in patient with urticarial vasculitis or idiopathic CV.

Autoantibodies to vascular endothelial cells are described in patients with urticaria or concomitant connective-tissue disease. In the Henoch-Schönlein purpura, serum IgA levels are elevated, IgA ANCA can be present, and urinary endothelin-1 can be increased.

Circulating immune complexes, rheumatoid factor, antinuclear antibodies, antiphospholipid antibodies, antistreptolysin antibodies, and hepatitis surface antigens may be detected.

Also anticardiolipin antibodies occur in patients with various forms of CNV.

Cryoglobulins may be found in patients with idiopathic CNV and in patients with connective-tissue disease and lymphoproliferative disorders or infections.

In patients with systemic vasculitis, to test the antineutrophil cytoplasmic antibodies (p-ANCA, c-ANCA) can be diagnostically helpful. ANCAs have been demonstrated in Wegener's granulomatosis, the Churg-Strauss syndrome, microscopic polyarteritis nodosa, idiopathic glomerulonephritis, and many other leukocytoclastic CNV. The sensitivity of ANCAs to this group of disease is high when there is a renal involvement. However, the ANCA levels aren't correlated with the severity of vasculitis, an increase of their title may precede a relapse, and their disappearance is associated with the absence of disease activity.

Patients have only one of the two types of ANCA antibodies. c-ANCAs are specific for Wegener's granulomatosis and microscopic polyarteritis. p-ANCA occurs in idiopathic glomerulonephritis, the Churg-Strauss syndrome, polyarteritis nodosa with visceral involvement, and vasculitis overlap syndrome.

Urine analysis may reveal many abnormalities of sedimentation, such as proteinuria, hematuria, and cylindruria, caused by possible renal involvement.

Because significant morbility can result from systemic involvement of CV, careful evaluation of the patient should be done to define the type and severity of the involvement too. If the laboratory results are normal, further invasive studies (e.g., nerve, muscle, or lung biopsy) are warranted.

Skin biopsy is required for definitive diagnosis. The hallmark histopathologic pattern of CV is leukocytoclastic vasculitis. It's characterized by angiocentric segmental inflammation, endothelial cell swelling, and fibrinoid necrosis of blood vessel walls. A cellular infiltrate, largely composed by neutrophils, can be described around and within blood vessels. In the later phase lymphocytes and monocytes predominate in the infiltrate.

More rarely, we can describe a lymphocytic or an eosinophilic pattern.

Biopsy location, depth, and timing must be taken into consideration by the clinician to increase the diagnostic yield. Small vessels, for example, reside in the upper dermis, while medium-sized, muscular vessels are found in the deep dermis and subcutis.

Routine microscopy is best obtained from a newer primary lesion of 24–48 h duration if possible. Biopsies performed in that period can show a neutrophilic, eosinophilic, or lymphocytic infiltration, depending on the underlying process. After 48 h, lymphocytes replace the other inflammatory cells and the histological pattern becomes nondiagnostic.

In addition to routine microscopy, special stains for microorganisms, including the Gram stain, acid-fast stains, and methenamine silver stains, are recommended. In some cases, also the tissue cultures may be needed to rule out infection.

Direct immunofluorescence microscopy is usually helpful in selected cases of CV. DIF biopsies are best taken from a leading erythematous edge or perilesional in the recent lesions, better of less than 24 h duration. By direct immunofluorescence microscopy, fibrin deposition in venules is always identified, while the deposition of immunoglobulins and complement components varies widely. Immunoglobulin G, rather than IgM, is more likely to be present when there is an underlying collagen vascular disease. IgA are indicative of the Henoch-Schönlein purpura. C3 is the only complement protein which has been described with frequency in CNV.

General Principles of Treatment

Therapeutic approach to CNV is to find out and to remove the causative agent (e.g., infections, drugs, food allergens). This may be all that is required for the treatment because it's usually followed by the clearing of skin lesions. Interferon-α induces clearing of skin manifestations in patients with hepatitis C virus infection.

Otherwise, local and systemic treatments are necessary. In each case, the correction of local factors (e.g., trauma, cold stasis) may be important.

Local therapies (corticosteroids, antibiotics) are helpful only in some patients.

Better results are obtained with systemic therapy (Table 17.4).

Oral corticosteroids (prednisone 60–80 mg/day) are recommended in patients with a significant systemic involvement. Because of the risk of rebound effect, it's really important to reduce the dose slowly.

Patients with persistent or necrotic lesions may benefit from nonsteroidal anti-inflammatory drugs (e.g., acetylsalicylic acid, indomethacin). Chronic disease can also be treated with oral colchicines (0.6 mg twice or three times daily). This drug seems to be particularly useful in patients with erythema elevatum diutinum.

Table 17.4 Treatment of CV

Drug	Suggested dose	Suggested recommendation
Systemic glucocorticoids	60–80 mg/day	
Nonsteroidal anti-inflammatory agents		
Colchicines	0.6 mg twice or three times/day	Erythema elevatum diutinum
Dapsone	50–200 mg/day	Only skin involvement
H1 antihistamines		
Potassium iodine	0.3–1.5 g four times/day	Nodular vasculitis
Azathioprine	50–200 mg/day	
Methotrexate	10–25 mg/day	
Cyclosporine	3–5 mg/kg/day	
Cyclophosphamide	2 mg/kg/day	
Mycophenolate mofetil	0,6 mg twice/day	Severe and resistant CV
Intravenous gamma globulin		Severe and resistant CV
Plasmapheresis		Severe and resistant CV
Infliximab, rituximab		Severe and resistant CV

In patients with the only skin involvement, we can use dapsone (50–200 mg/day).

Potassium iodide (0.3–1.5 g four times daily) is useful in nodular vasculitis.

H1 antihistamines, eventually used in combination with H2 antihistamines, are helpful to alleviate pruritus and to reduce tissue deposition of circulating immune complexes. H1 antihistamines can be used also with nonsteroidal anti-inflammatory.

Fibrinolytic agents may be used in patients who have decreased fibrinolytic activity. Stanozolol (5 mg twice daily), heparin (5,000 U twice daily), mesoglycans (50–100 mg/day), and defibrotide (700 mg/day) have been used successfully in many hypofibrinolytic conditions.

On the other hand, aminocaproic acid (8–16 mg/day) is useful to treat patients with hyperfibrinolytic states.

Immunosuppressive agents, like cyclophosphamide (2 mg/kg per day or as a monthly intravenous pulse), methotrexate (10–25 mg/week), azathioprine (50–200 mg/day), and cyclosporine (3–5 mg/kg per day), are recommended in patients with CNV with a rapid course and systemic involvement, which aren't controlled with corticosteroids.

If there still is no therapeutic response, it is possible to treat the patient with plasmapheresis, intravenous immunoglobulin, mizoribine, infliximab, or rituximab.

Patients with urticarial vasculitis can be treated with the same therapeutic option. Intramuscular gold therapy, cyclophosphamide-dexamethasone pulse therapy, mycophenolate mofetil, thalidomide, PUVA therapy, anakinra, and cinnarizine have been reported to benefit some patients.

Patients with livedoid vasculitis can be treated with nonsteroidal anti-inflammatory agents, glucocorticoids, colchicines, dapsone, and low-dose heparin. Additional case reports exist on the treatment of patients with nifedipine, pentoxifylline, hyperbaric oxygen therapy, PUVA therapy, infusion of prostacyclin or prostaglandin E, intravenous immunoglobulin, or rituximab.

Darier's Disease

18

Federico Bardazzi, Giulia Odorici,
and Riccardo Balestri

Key Points

- Darier's disease (DD) is an autosomal dominant disease induced by haplo-insufficiency with variable expressivity but with complete penetrance in adults.
- Lesions are hyperkeratotic, greasy papules, which are skin colored, yellow, or brown, that may coalesce into large plaques. Pruritus occurs in 80 % of patients and may be intractable. Nails, mucous, and folds can be involved. The disease usually has a chronic relapsing course.
- Diagnosis must be confirmed by histology, showing focal acantholytic dyskeratosis.
- Therapy is challenging and sometimes frustrating. It is based on topical and systemic retinoids or surgical procedures.
- Sun and heat avoidance, use of sunscreens, and maintenance of personal hygiene can be helpful. Clothing should be cool cotton and not too tight.

Definition and Epidemiology

Darier's disease (DD) is an autosomal dominant genodermatosis belonging to the group of keratinization disorders that can affect the epidermis, the nails, and the mucous membranes. Darier and White first described the condition independently in 1889; although it is also known as "keratosis follicularis," this term should be avoided since it is inappropriate as the lesions are not follicular.

The prevalence ranges from 1 in 100,000 to 1 in 30,000, and it affects both males and females, of all ethnic groups. It has been reported that in women the disease shows a milder rash than in men. The disease is rarely observed before the age of 5, and it usually begins during the first two decades of life, although it may go unnoticed until aggravated by sweating, heat, or during summer.

Basic Concepts of Pathogenesis

DD is an autosomal dominant disease induced by haplo-insufficiency with variable expressivity but with complete penetrance in adults. Sporadic cases are not unusual.

It is caused by a mutation in the *ATP2A2* gene on chromosome 12q23-24.1. This gene encodes the sarco/endoplasmic reticulum Ca^{2+} ATPase type 2 isoform (SERCA/2) which transports Ca^{2+} from the cytosol back to the endoplasmic reticulum lumen.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_18, © Springer-Verlag Berlin Heidelberg 2015

The connection between molecular alterations and clinical expression is not completely understood. It has been hypothesized that abnormalities of SERCA2 in DD may alter cell signaling, and this induces the alteration of synthesis, folding, or trafficking of desmosomal components, causing interference with the adhesion and differentiation of keratinocytes.

Clinical Presentation

Considerable variation in severity as in clinical manifestation was found between families. In some patients with classic disease, no mutation was identified.

The distinctive lesions are firm, persistent, hyperkeratotic, greasy papules, which are skin colored, yellow, or brown (Fig. 18.1). The lesions may coalesce into large plaques or papillomatous masses, predominantly in the seborrheic areas of the trunk (Fig. 18.2a) and face (Fig. 18.2b), mostly the scalp margins (Fig. 18.2c), temples, ears (Fig. 18.2d), and scalp, symmetrically. In pigmented skin, flat and freckle-like lesions can be observed as pale macules.

The groin, axillae, and anogenital regions are also frequently affected and cause the major discomfort. These areas are prone to maceration; moreover, the lesions are often vegetating, infected, and malodorous due to secondary bacterial infections. Involvement of the hands is seen in the majority of patients. On palms and soles, small pits and/or punctuated keratoses, strongly suggestive of DD, can be observed. On the dorsa of the hands and feet, discrete papules are clinically identical to those of acrokeratosis verruciformis of Hopf (Fig. 18.3). Nail dystrophy is specific for the disease and it consists in nail fragility, red and white longitudinal ridging, V-shaped nick at the free margin of the nail, and subungual hyperkeratosis.

Although rarely, all mucous membranes can be involved. Oral lesions are asymptomatic and comprise multiple white papules in the buccal mucosa and the soft and hard palate, giving a cobblestone appearance. The non-affected skin is normal.

Clinical variants are papular-vesicular form, erosive-bullous form, vegetating form, acral form, and linear (localized) form.

The localized form is rare and it is characterized by keratotic papules unilaterally distributed in streaks or whorls following Blaschko's lines. It typically has a late onset and it is aggravated by sunlight. This form probably reflects genetic mosaicism.

Although DD is strictly confined to the skin, association with neuropsychiatric disorders (e.g., bipolar disorders, epilepsy, and learning difficulties) and other systemic involvement, including bone cysts, salivary glands obstruction, renal and testicular agenesis, cataract, and corneal opacity, have been reported. The high lifetime rate of affective disorders, mostly major depression, bipolar disorder, and psychosis with suicidal tendencies, in individuals with DD is probably due

Fig. 18.1 Clinical appearance of Darier's disease: brown skin-colored papules

Fig. 18.2 Clinical appearance of Darier's disease: hyperkeratotic, greasy papules. (**a**) Trunk, (**b**) centrofacial, (**c**) hairline, and (**d**) ear

Fig. 18.3 Darier's disease with acrodermatitis verruciformis-like lesions on the back of the hands

to a susceptibility locus for affective disorders which is located adjacent to SERCA2 gene.

Pruritus is common, occurring in 80 % of patients, and may be intractable; pain is unusual.

The disease usually has a chronic relapsing course and may worsen with age, and general health is normally maintained. Patients with DD seem to have an increased susceptibility to herpes and bacterial infections but the exact immunologic relationship is not clear.

Diagnosis

Clinical manifestations are highly suggestive for diagnosis but the histological confirmation showing focal acantholytic dyskeratosis is mandatory. Direct and indirect immunofluorescence studies are negative.

The histological changes of DD, characterized by focal acantholytic dyskeratosis, are distinctive but not entirely pathognomonic.

Histological features of DD are as follows:

- Suprabasal lacunae resulting from suprabasal acantholysis
- Villi (irregular upward proliferation of dermal papillae lined with a single layer of basal cells)
- Corps ronds (small groups of cells around the lacunae separated from their neighbors; enlarged and presenting a darkly staining nucleus surrounded by a clear cytoplasm and a glistening ring; they occur in the upper stratum malpighii, particularly on the granular and horny layers)
- Grains (dyskeratotic small cells with elongated and often grain-shaped nucleus surrounded by shrunken cytoplasm; they are seen in the horny layer and in the suprabasal lacunae)
- Hyperkeratosis, acanthosis, and papillomatosis
- Chronic inflammatory infiltrate in the dermis

Acantholysis occurs first, dyskeratosis later.

Electron microscopy shows loss of the desmosomal protein attachments that normally link keratinocytes and perinuclear aggregation of keratin filaments. Also immunocytochemical study shows that desmosomal proteins are spread in the cytoplasm.

Differential Diagnosis

It includes seborrheic dermatitis, seborrheic keratosis, and candida infection, for the classic form; Grover disease for the papular-vesicular form; Hailey-Hailey disease, pemphigus vulgaris, Langerhans cell histiocytosis, and impetigo, for the erosive-bullous form; pemphigus vegetans for the vegetating form; verruca plana for the acral form; and epidermal nevus with acantholytic dyskeratosis for the linear (localized) form.

General Principles of Treatment

Despite the progress in understanding the pathophysiology of DD, a standardized real effective treatment is still lacking. Only one third of patients noted improvement with age. A good doctor-patient relationship to satisfied patients' emotional needs as well as medical requirements is necessary.

Sun and heat avoidance, use of sunscreens, and maintenance of personal hygiene can be helpful. Clothing should be cool cotton and not too tight.

Recommended Therapies

Treatment of DD can be challenging. In cases with mild skin involvement, a topical therapy can control the disease; however, in extensive cases a systemic therapy is necessary.

Topical Therapy

If skin lesions are limited, emollients containing urea, lactic acid, or salicylic acid, at low concentration, can be used to reduce crusting.

Topical retinoid acid (*TRA*) can reduce hyperkeratosis in a few months, but irritancy is often limiting, especially in patients with inflammatory disease. Topical adapalene and tazarotene have been also reported as effective. In particular, tazarotene 0.1 % gel is suggested as "short contact" therapy in linear DD.

*Steroids of m*oderate potency may help in reducing irritation.

Topical calcineurin inhibitors, *tacrolimus and pimecrolimus,* may be alternative agents in the treatment of DD, although the mechanism by which these agents improve this condition is not fully understood. *Other topical treatments* include the successful application of topical vitamin D as well as 5-fluorouracil. Vitamin E ointment can alleviate the symptoms.

Systemic Therapy

Retinoids

Retinoids are the conventional therapy for generalized or severe DD, because of their action on the disorder of keratinization. The rationale for their use includes the promotion of exfoliation. Their clinical response is good in up to 90 % of patients. We can start with 25–30 mg per day for 14 days–1 month.

Long-term therapy with retinoids has to be avoided because of mucosal dryness; nosebleeds; skin fragility; elevation of triglycerides, cholesterol, and serum liver enzymes; teratogenicity in women; possible depression; and suicide attempts. A topical antibiotic therapy is sometimes recommended in order to control infections of exfoliative, wet, and exudative lesions induced by retinoids.

However discontinuation of retinoid therapy is usually marked by relapse.

Cyclosporine

Several cases nonresponding to traditional therapy have been treated with cyclosporine (2.5 mg/kg/day) with controversial effects.

Photodynamic Therapy (PDT)

PDT has been described in a small number of patients as being a tissue-selective treatment for DD, although the mechanism by which PDT improves DD is not fully understood. Studies investigating photodynamic therapy with aminolevulinic acid have had variable results; in one case it has been reported a worsening of disease not only in the treated but also in adjacent areas after PDT treatment. Side effects of this treatment include pain, hyper-/hypopigmentation, and an inflammatory reaction in treated areas.

PDT should be used as a potential adjuvant modality for Darier's disease and should not be considered as a substitute for retinoids in patients who require systemic treatment.

Surgical Treatments

Dermabrasion can produce good long-term effects. There are recent reports of surgical treatment of DD, using electro- and cryosurgery.

Laser therapy: Er: YAG and CO_2 laser ablation have shown clinical efficacy. The treatment of DD with ablative lasers may induce complete remission after one treatment session, although some recurrences were noted: ablating the papillary dermis is recommended for successful treatment, because a too superficial treatment can cause early relapse. Potential problems of ablative procedures are scarring and hyperpigmentation. Also fractional photothermolysis has been used and is based on the injury of the dermis created by thermal columns. The intact stratum corneum aids in rapid healing and is associated with a low complication rate.

A case of unresponsive DD treated with electron beam has been reported.

Treatment with flashlamp-pumped pulsed dye laser has been shown to improve DD.

Despite the availability of many therapeutic weapons, treatment of DD is frequently very frustrating and several attempts are often necessary before the most effective therapy for the patient can be found.

Dermatitis Herpetiformis

19

Ines Lakos Jukic and Branka Marinović

Key Points

- Dermatitis herpetiformis (DH) is a chronic, lifelong subepidermal autoimmune bullous disease associated with gluten sensitivity.
- It is most common in individuals of Northern Europe heritage.
- There is a strong association between DH and HLA-DQ2 and HLA-DQ8 antigens.
- Tissue transglutaminase (tTG) is a major autoantigen for celiac disease, while epidermal transglutaminase (eTg) is the dominant autoantigen in DH.
- There is an increased prevalence of other autoimmune diseases in DH, most commonly of thyroiditis.
- Enteropathy-associated T-cell lymphoma is a recognized risk in patients with DH.
- Classic clinical finding in DH are grouped "herpetiform"-arranged papules and papulovesicles on erythematous urticarial base, symmetrically located on extensor surfaces of the upper and lower extremities, elbows, knees, buttocks, nuchal area, and scalp.
- Lesions are intensely pruritic.
- Direct immunofluorescence (DIF) study of perilesional, normal-appearing skin with granular deposits of IgA within the tips of dermal papillae is pathognomonic.
- Demonstration of circulating antibodies against tTg and eTg is a useful serologic tool in confirming the diagnosis as well as in monitoring disease activity.
- Gluten-free diet is effective for both skin lesions and enteropathy.
- Pharmacological treatment of choice in DH is dapsone; it has no effect on small bowel damage.
- Regular screening for dapsone-induced side effects is mandatory.
- The prognosis of DH is usually favorable.

Definition and Epidemiology

Dermatitis herpetiformis (DH) is a chronic, subepidermal autoimmune bullous disease associated with gluten sensitivity, and thus it can be defined as a cutaneous manifestation of celiac disease (CD).

The prevalence of DH is different among ethnical populations; it is most common in individuals of Northern European heritage. Epidemiologic studies from Sweden and Finland reported prevalence rates of 39 and 66 per 100,000 people. Smith et al. have found prevalence of 11.2 per 100,000 in Utah, United States. In contrast to Caucasoid, DH is very rare among African Americans and Asians.

The onset of disease varies; it can start at any age. However, the second, third, and fourth decades are the most common. Although childhood DH overall is a rare disease, studies from Hungary and Italy have suggested DH is common among children in these countries. There is a slight male preponderance among patients with DH, which is opposite to higher female prevalence of celiac disease. In childhood, DH affects both genders equally.

These various prevalences and geographical distribution of DH may be dependent on genetic predisposition and environmental factors, such as diet. Genomic typing of patients with DH, as well as of patients with CD, has shown strong association with class II alleles DQA1*0501 and DQB1*02 in chromosome 6. These genes encode HLA-DQ2. Different studies have reported HLA-DQ2 in 86 %, 95 %, and 100 % of the patients with DH. Thus, HLA typing of class II region genes might be a diagnostic marker for CD and DH. The remaining patients with DH (5–12 %) presented with alleles DQA1*03 and DQB1*0302 encoding HA-DQ8. Ohata et al. in a study of 91 Japanese patients with DH have not observed association of these HLA antigens with DH.

Genetic factors, beside HLA genes, are important key in pathogenesis of DH. Association of genomic variants at interleukin-1 (IL-1) and interleukin-21 (IL-21) region in chromosome 4q27 and CD has been reported. There is a report of monozygotic twins, one with DH and the other with CD, suggesting the role of environmental factors in development of CD and DH. Hervonen et al. have reported that 18 % of patients with DH had a first-degree relative with DH or gluten intolerance. The practical use of these findings is to consider serologic screening for first-degree relatives of DH patient to identify silent or latent signs of gluten sensitivity.

Basic Concepts of Pathogenesis

As mentioned above, DH is multifactorial disease with genetic and autoimmune background, influenced by environmental factors. There has been a quite progress in understanding pathogenesis of DH since Marks et al. first described small bowel changes in 9 of 12 patients with DH in 1966. The next major advance was identification of antibodies to tissue transglutaminase (tTg) in sera of patients with DH. Subsequently, tTg was identified as a major autoantigen for CD. Three years later, Sardy et al. have demonstrated that epidermal transglutaminase (eTg) is the dominant autoantigen in DH patients. eTg is homologous but not identical to tTg. While tTg is ubiquitously expressed in many tissues, including the skin, eTg is found only in the epidermis, small intestine, brain, and testis. Transglutaminase plays a crucial role in pathogenesis of gluten intolerance. Gluten is a protein found in wheat, barley, and rye. Upon the digestion of gluten-containing food, gliadin, which is the alcohol-soluble fraction of gluten, elicits an immune response in predisposed individuals. After absorption of gliadin into the intestinal mucosa, deamidation of gliadin by tTg leads to formation of efficient antigen with high affinity for HLA-DQ2 on dendritic antigen-presenting cells. Gliadin antigen is then presented to sensitized helper T cells in lamina propria, resulting in T-cell proliferation, synthesis of proinflammatory cytokines, and matrix metalloproteinases resulting in inflammatory response, which is responsible for mucosal epithelial cell damage. T-helper cells can stimulate B cells to produce antibodies to tTg. These antibodies are predominantly of IgA class, directed against gliadin and gliadin cross-linked to tTg, tTg, or eTg. The production of antibodies directed against eTg is probably the result of intermolecular epitope spreading in patients who already have IgA anti-tTg antibodies. These IgA anti-eTg antibodies reach the dermis and form immune complexes with eTg in dermal papillae, resulting

in neutrophil chemotaxis. Degranulation of neutrophils releases proteases, which are responsible for proteolytic cleavage of the lamina lucida and formation of subepidermal blister.

Associated Diseases

Patients with DH have an increased prevalence of other autoimmune diseases. The most common associated disorder is thyroiditis, more likely with hypothyroidism then hyperthyroidism. Several studies have demonstrated that incidence of thyroid disorder ranged from 11 to 14 % in DH patients. An increased incidence of insulin-dependent diabetes mellitus (type I), in ranges from 2.3 to 5 %, has also been noticed in patients with DH. Association with pernicious anemia has been identified, with incidence ranging from 1.9 to 3 %. Other diseases, which have been reported in DH patients, with association weaker than that with thyroid disorders, are Addison disease, connective tissue disorders, Sy Sjögren, vitiligo, alopecia areata, and rheumatoid arthritis. Disorders associated with DH, due to malabsorption, are microcytic or macrocytic anemia, folate, B12 or zinc deficiency, and osteoporosis.

Lymphoproliferative disorders, not only enteropathy-associated T-cell lymphoma, but also B-cell lymphoma, are a recognized risk in patients with DH, with incidence less than 2 %. It is still unclear whether adherence to strict gluten-free diet is protective against lymphoma in this population.

Clinical Presentation

DH is a polymorphous, intensively pruritic, papulovesicular disorder. Classic manifestation of DH includes grouped "herpetiform" papules and papulovesicles on erythematous urticarial base, symmetrically located on extensor surfaces of the upper and lower extremities, elbows, knees, buttocks, nuchal area, and scalp. Secondary to scratching because of severe pruritus, patients usually present with erosions, crusted papules, and excoriations, and thus, DH only rarely manifests as a clear bullous disease. The lesions usually resolve with postinflammatory dyschromia, most commonly hyperpigmentation. Besides pruritus, patients often complain about burning and stinging; these symptoms can precede the onset of skin eruption. Uncommon presentations of DH are palmoplantar purpura, which is more common in children, isolated lesions on the face or in the scalp, or development of lesions mimicking prurigo pigmentosa. Although there are reports about mucosal involvement in DH, including vesicles, erythematous macules, or erosions on the oral mucosa or tongue, overall it is rarely seen. Since other DH-associated disease like CD or connective tissue disorders may cause oral lesions, direct immunofluorescence of the oral mucosa is "conditio sine qua non" for a diagnosis of mucosal involvement in DH. Patients with DH can present with tooth enamel abnormalities. The most common enamel defects reported in both childhood and adult DH, as well as in CD, are horizontal grooves, enamel pits, and discoloration.

Diagnosis

The diagnosis of DH is based on clinical findings, histopathology, immunofluorescence studies, and serology. Obtaining a good biopsy specimen is prerequisite to reach the correct diagnosis; an early papule, papulovesicle, or a small bulla with healthy appearing skin around it should be used for histopathologic study. The typical early finding in DH is characterized by superficial perivascular and interstitial lymphocyte and neutrophil infiltrates and edematous papillary dermis. With progression of the lesion, neutrophils are accumulated in some dermal papillae. Further accumulation of neutrophils leads to formation of abscesses in dermal papillae with subepidermal separation (Fig. 19.1). The fully developed lesion is characterized by subepidermal blister. Beside neutrophils, eosinophils can be also found in infiltrate as well as in papillary abscesses; their number increases with age of the lesion. Similar histologic findings can be found in other diseases, like in linear IgA disease, epidermolysis bullosa

Fig. 19.1 Accumulation of neutrophils within tips of dermal papillae with partial subepidermal separation (HE X50)

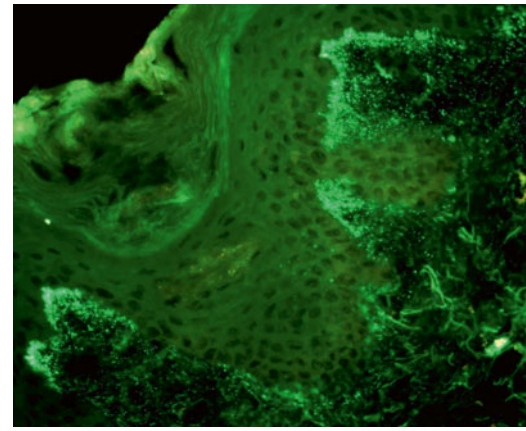

Fig. 19.2 Direct immunofluorescence of perilesional skin: granular deposits of IgA within the dermal papillae

acquisita, or in bullous form of lupus erythematosus, so histology is evocative, but it is not diagnostic. Therefore, direct immunofluorescence (DIF) study of perilesional, normal-appearing skin still remains the gold standard for diagnosis of DH. Typical, pathognomonic finding are granular deposits of IgA within the tips of dermal papillae (Fig. 19.2). Sometimes granular deposits along basement membrane zone can also be detected. In Japanese population of patients with DH, fibrillar pattern of DIF has been described; deposits of IgA present as linear streaks in the papillary dermis. This finding is usually associated with atypical clinical presentation of DH, like urticarial or psoriasiform lesions, absence of gluten-sensitive enteropathy, and without, for DH and CD, specific HLA antigens.

As mentioned above, patients with DH demonstrate circulating IgA antibodies against eTg and tTg, so serologic tests are useful tools in confirming the diagnosis as well as in monitoring disease activity. It is important to emphasize that patients with DH have no circulating antibodies against components of cutaneous basement membrane or to other adherent structures of the skin. Levels of IgA antibodies against tTg, detected by ELISA (enzyme-linked immunosorbent assay), correlate with bowel disease and adherence to gluten-free diet in patients with DH and CD. The sensitivity of this assay ranges between 47 and 95 % with specificity range up to 100 %. Antibodies directed against eTg are the most sensitive serologic marker in treated and untreated patients with DH, with specificity of commercially available ELISA up to 100 %. Endomysial antibodies (EMA) belong to the IgA1 subclass and are directed against endomysium – reticular connective tissue in smooth muscle. The endomysial antigen has been identified as tTg. These antibodies are detected by indirect immunofluorescence study on monkey esophagus as a substrate. EMA is a marker for small bowel damage, not for skin lesions, and it disappears with a gluten-free diet (47). Antigliadin and antireticulin antibodies are no longer considered as a sensitive and specific sign of DH. Today, the most reliable test to confirm gluten sensitivity in DH patients is detection of antibodies directed against deamidated gliadin-derived peptides.

Measurement of total IgA level is also included in serologic workup with patients with DH. Although selective IgA deficiency has an increased prevalence in patients with CD, no cases of IgA deficiency have been reported in DH patients. However, partial IgA deficiency has been documented in some patients with DH.

Because of the strong association between DH and thyroid dysfunctions, especially Hashimoto thyroiditis, thyroid-stimulating hormone and anti-thyroid peroxidase antibodies testing should be performed in patients with DH. Testing for serum level of glucose, antigastric parietal cells, and anti-nuclear antibodies should also be considered.

More than 90 % patients of DH have some degree of gluten-sensitive enteropathy. A milder degree of villous atrophy than that seen in celiac disease is typically seen in approximately two-thirds of DH patients with elevated intraepithelial lymphocyte counts in the remainder of DH patients' small bowel biopsy specimens. A biopsy of the small intestine is not necessary in patients with diagnosis of DH confirmed by DIF finding and positive serologic tests.

The differential diagnosis includes linear IgA dermatosis, bullous pemphigoid, scabies, atopic dermatitis, and arthropod bites.

General Principles of Treatment

Since DH is a cutaneous manifestation of gluten sensitivity, it is logical to expect that a cornerstone of therapy is lifelong gluten-free diet. A gluten-free diet is effective for both skin lesions and enteropathy, although intestinal symptoms tend to respond faster than skin. It is very important to motivate the patients to strict adherence to a gluten-free diet, which means complete avoidance of wheat, barley, rye, and their products. Besides gluten-containing food, exacerbation of DH may be induced by iodide, food additives in vitamin supplements, distilled white vinegar, malts, vegetable gum, and preservatives. Some patients may have long-term remission of disease, and gluten-free diet may be discontinued. It seems that gluten-free diet has protective effect against development of intestinal lymphoma. It usually takes from several months up to 2 years to control skin lesions with a gluten-free diet as a monotherapy.

Dapsone (4,4′-diamino-diphenyl sulfone) is pharmacological treatment of choice for DH. Dapsone has antimicrobial and anti-inflammatory effect. As an antibiotic, it inhibits the growth of microorganisms that are dependent of endogenous folic acid synthesis. Although the mechanism of action of dapsone in inflammatory diseases is not well understood, it seems that it may directly affect neutrophil function. Dapsone has a dramatic effect in DH patients; pruritus and skin lesions usually resolve within 48–72 h. In contrary, dapsone has no effect on small bowel damage, caused by gluten sensitivity. Most patients with DH may be maintained on 50–100 mg dapsone daily. However, some patients may need only 25 mg to control the disease, while others may have multiple skin lesions despite therapy with 300 mg. Overall, dapsone is well tolerated. It is associated with both pharmacological and idiosyncratic adverse reactions. Patients with pulmonary, cardiovascular, or hematologic disease as well as with glucose-6-phosphate dehydrogenase (G6PD) deficiency have an increased risk for the development of pharmacological side effects. Methemoglobinemia is the most common side effect of dapsone. Cyanosis, with brown pasty mucous membranes, is seen at 15 % of methemoglobin and it is often asymptomatic. The percentage above 45 is associated with acidosis, dyspnea, seizures, arrhythmias, and coma. Vitamin E, C, and cimetidine seem to have some protective effect against formation of methemoglobin. Hemolysis is also a common dose-related adverse event, and it occurs to some degree in all patients taking dapsone. Patients with deficiency of G6PD have been demonstrated to have a twofold increase in sensitivity towards dapsone-induced hemolytic anemia. The most serious, but very rare, idiosyncratic reaction to dapsone is agranulocytosis. Another rare, idiosyncratic adverse event of dapsone is hypersensitivity syndrome or "dapsone syndrome," clinically characterized by fever, cutaneous

eruption, and hepatitis. Patients usually have peripheral eosinophilia, too. Other side effects, as a single symptom or as a part of "dapsone syndrome," that have been reported to be associated with dapsone are peripheral neuropathy, hepatotoxicity, and renal toxicity. Considering adverse reaction associated with dapsone, patient should be regularly monitored. Baseline evaluation must include complete blood count (CBC), liver function panel, renal function test, and level of G6PD. Follow-up evaluation includes CBC weekly for the first month, then monthly for next 5 months, and later, semiannual while patient is taking dapsone. Liver and renal function tests should be checked every 3–4 months.

Once the diagnosis of DH has been achieved, the therapy with dapsone in combination with gluten-free diet is usually recommended.

In patients intolerant to dapsone, second-line pharmacological agents for treatment are sulfasalazine, in dose of 1–2 g/day, and sulphamethoxypyridazine with suggested dosage of 0.25–1.5 g/day. Both medications can cause hemolytic anemia, proteinuria, and crystalluria, as well as hypersensitivity reactions. Patients usually complain of nausea, vomiting, and anorexia.

Application of potent or very potent topical steroids and third-line antihistamines can be useful to decrease pruritus and itching. It is also important to recognize possible secondary bacterial infection.

Conclusion

Dermatitis herpetiformis, or, as Sarolta Karpati suggested, gluten-sensitive dermopathy, is a lifelong waxing and waning disease, most commonly clinically characterized by intensely pruritic papulovesicular eruption on extensor surfaces. The diagnosis is based on the correlation between clinical, histologic, immunological, and serologic findings. Granular deposits of IgA in dermal papillae on direct immunofluorescence assay are pathognomonic. Considering the fact that gluten is responsible for both enteropathy and skin lesions, it is most important for patients to understand that gluten-free diet is an essential part of the treatment. Dapsone is the only medicine approved by FDA (Food and Drug Administration) for therapy of DH. Regular screening for dapsone-induced side effects, as well as for associated diseases, is needed. The prognosis of DH is usually favorable. A multidisciplinary approach, involving dermatologist, nutritionist, and gastroenterologist, is required in the treatment and follow-up of patients with DH.

RCTs	Randomized controlled trials
SCLE	Subacute cutaneous lupus erythematosus
SLE	Systemic lupus erythematosus
TNF	Tumor necrosis factor
VCAM	Vascular cell adhesion molecule-1

Key Points

- Dermatomyositis (DM) belongs to chronic idiopathic inflammatory myopathies (IIM), heterogeneous group of autoimmune disorders that predominately target the skeletal musculature and/or skin.
- Typical clinical symptoms are symmetrical proximal muscle involvement and typical cutaneous inflammatory lesions.
- Clinical examination and the histopathology analysis of the muscle are fundamental for the diagnosis.
- Therapy must be oriented in relation to the symptomatology and the severity of the disease.
- Pharmacological treatment is based on immunosuppressive agents, as glucocorticoids, azathioprine, or methotrexate.

Definition and Epidemiology

Dermatomyositis (DM) belongs to chronic idiopathic inflammatory myopathies (IIM), heterogeneous group of autoimmune disorders that predominately target the skeletal musculature and/or skin. Typical clinical symptoms are symmetrical proximal muscle involvement and typical cutaneous inflammatory lesions. DM affects approximately 5/1,000,000 population, twice more often in females.

Some following forms are distinguished (from Sontheimer and Costner, modified):

DM
Adult onset
Classic DM
Classic DM alone
Classic DM with malignancy
Classic DM as part of an overlap connective tissue disorder
Clinically amyopathic DM
Amyopathic DM
Hypomyopathic DM
Juvenile onset
Classic DM
Clinically amyopathic DM
Amyopathic DM
Hypomyopathic DM
Polymyositis (*PM*)
PM alone
PM as part of an overlap connective tissue disorder
PM associated with internal malignancy
Inclusion body myositis
Other clinical pathologic subgroups of myositis
Focal myositis
Proliferative myositis
Eosinophilic myositis
Granulomatous myositis

In childhood DM is not rare, and it is defined as juvenile dermatomyositis (JDM). In about 10 % of the patients, cutaneous symptoms are not associated with muscular involvement (amyopathic DM). Moreover, in about 30 % of the cases, DM is correlated with cancer (paraneoplastic DM).

Basic Concepts of Pathogenesis

The etiology is not clear. The inflammatory processes of the muscle and skin manifestations, followed by the cellular and humoral autoimmune abnormalities, have led to the hypothesis that DM results from a genetically determined, aberrant autoimmune response to environmental agents.

A genetic predisposition has been demonstrated in DM. This disease is linked to the 8.1 ancestral haplotype (HLA-A1, C7, B8, C4AQ0, C4B1, DR3, DQ2), in particular with HLA-B8, DR3, and DRw52.

The cutaneous manifestations of DM are exacerbated by environmental factors, as ultraviolet radiation and infections that could induce the loss of self-tolerance and the production of autoantibodies, immune complexes, and/or autoreactive T cells.

Several autoantibodies have been indentified to be specific of DM. Among those, we can remember 155 kd, 140kd, Jo-1, and Mi2.

Predominately humoral autoimmune mechanisms targeting the microvasculature have been implicated in the pathogenesis of muscle injury in DM.

The vessel injury is linked with deposits in the intramuscular vasculature of autoantibodies that compose the membrane attack complex of complement (MAC), an increased expression of interleukin-1 (IL-1), intercellular adhesion molecule-1 (ICAM-1), and vascular cell adhesion molecule-1 (VCAM-1) in endothelial cells of capillaries. The involvement of cellular immune response is demonstrated by the presence of activated lymphocytes in the inflammatory infiltrates. The cell-mediated response seems to be responsible for the muscle and skin injury.

Clinical Presentation

The principal cutaneous signs are:

Pathognomonic distinctive signs (Figs. 20.1, 20.2, 20.3, 20.4, and 20.5)

Figs. 20.1, 20.2, 20.3, 20.4, and 20.5 *Pathognomonic distinctive signs of dermatomyositis*: Gottron's sign and Gottron's papules

- Gottron's sign: symmetrical erythema overlying the knuckles, elbows, knees, interphalangeal, and metacarpophalangeal joints
- Gottron's papules in the latter location

Characteristic signs

- Edema and heliotrope periorbital erythema
- Periungual telangiectasia and erythema with or without dystrophic cuticles and cuticular hemorrhage
- Symmetric confluent macular violaceous erythema overlying on the extensor aspects of the arms and hands, deltoids, posterior shoulders and neck (shawl sign), V area of anterior neck, and upper chest (V sign)
- Mechanic's hand lesion: (keratotic plaques on the palms and the ventral and lateral sides of the fingers, with erythematous changes on the dorsal aspects)

Compatible signs

- Poikiloderma atrophicans vasculare (poikilodermatomyositis) (especially in the chronic cases) light hypersensitivity
- Alopecia
- Lipoatrophy in chronic cases
- Panniculitis (rarely)
- Calcinosis cutis

Cancer disease is strictly related to DM progression. Atypical presentation, most severe skin signs, like necrotic ulcerations over the elbows, knees, and malleoli, may emerge before paraneoplastic signs at visceral level. The diagnosis of cancer can be done before, simultaneously, or within 2 years after the onset of DM. The most common associated cancers are ovary, breast, and lung cancer, melanoma, mycosis fungoides, and lymphoproliferative malignancies.

Muscle Disease

The muscular activity deficiency is characterized by the weakness and possible tenderness of the proximal muscles, leading to muscle wasting in chronic cases. An elevation in the serum level of CK is the most sensitive and specific laboratory indicator of muscle disease activity in DM.

The Course of DM

The course shows significant variations. High level of Mi2 antibody can be associated with a chronic disease with milder skin and muscle symptoms. In rare case associated with anti-tRNA synthetase antibodies, the pathology affects pulmonary functionality (interstitial lung disease—ILD), and the symptoms are clearly visible. In chronic cases after the regression of cutaneous and inflammatory muscle changes, subcutaneous lipoatrophy, atrophy of muscles, and calcinosis are identifiable.

The reported mortality rates vary from 25 % to 80 %. In the past two decades, the mortality rate has decreased considerably because of the more aggressive use of glucocorticoids and other immunosuppressives and better supportive medical care (Sontheimer and Costner 2008).

Diagnosis

Clinical examination and the histopathology analysis of the muscle are fundamental for the diagnosis.

Some cutaneous lesions, as Gottron's papules/sign, are specific and distinctive of the disease and clearly direct the diagnosis even if the skin biopsy is usually not contributory. Muscle activity is evaluated by manual testing, functional performance, electromyography (preferably quantitative EMG), and muscle enzyme levels (creatine phosphokinase, aldolase).

The muscle biopsy, together with skin and muscular clinical signs, can confirm the diagnosis. Characteristic features of muscular involvement in DM are muscle fibers necrosis and regeneration, microinfarcts, perifascicular atrophy, inflammatory infiltrates of T cells, predominantly of CD4 type, and inflammatory vascular changes or capillary depletion.

In the severe cases, characterized by pulmonary fibrosis, pronounced Raynaud's phenomenon, arthralgia, and not infrequently scleroderma-like cutaneous changes, there is the need of respiratory function evaluation.

A nail fold capillaroscopy is indicated in all cases (which shows characteristic "bushy," highly enlarged capillaries of the subpapillary plexus and extravasations).

In adults over 40–50 years old, cancer screening is recommended (in females mammography and pelvic ultrasonography, and serological examination for the ovarian tumor with marker CA-125, and in all patients, lung and digestive tract studies). The follow-up of the patients is based on sensitive and noninvasive new methods for assessment of the muscle: magnetic resonance imaging (MRI) and P-31 magnetic resonance spectroscopy.

Differential Diagnosis

The diagnosis is quite simple when the clinical features of DM are typical. Pronounced photosensitivity should be exploited to differentiate from systemic lupus erythematosus (SLE) associated with myositis (differs by visceral and cutaneous involvement and by serological markers). JDM cases can be confused with SLE, since that pronounced vasculitis and photosensitivity are commonly in both the pathology. In these cases clinicians should refer to the serological markers of SLE. Cases of amyopathic DM should be differentiated, besides systemic lupus erythematosus (SLE), subacute cutaneous lupus erythematosus (SCLE), and discoid lupus erythematosus (DLE), from polymorphous light eruption, lichen planus, seborrheic dermatitis (not infrequent scaling scalp lesions in DM), and erythema elevatum and diutinum.

General Principles of Treatment

Therapy must be oriented in relation to the symptomatology and the severity of the disease. Pharmacological treatment is based on immunosuppressive agents, as glucocorticoids, azathioprine, or methotrexate, even their benefit/risk ratio is not so clear. Randomized controlled trials (RCTs), confirming the value of immunosuppressants in inflammatory myositis, are not available. For this reason, it is important for physicians and patients to appreciate the precise benefit and risk of immunosuppressants in inflammatory myositis.

Additional considerations should be spent for the clinical assessment of juvenile DM. The evaluation of the involvement and severity of muscle inflammation has a significant importance in assessing disease activity and response to therapy in juvenile DM patients. Muscle strength is the primary clinical measure used to assess muscle disease. The manual muscle testing (MMT) and Childhood Myositis Assessment Scale (CMAS) are among the main tests exploitable. In JDM there is an imperfect correlation of serum muscle enzymes and myositis activity. Moreover health-related quality of life has been increasingly recognized as an important domain to be included in therapeutic trials and observational studies of patients with juvenile DM because it addresses aspects of disease that are not fully captured by other endpoints.

Therapeutic Ladder for Cutaneous Dermatomyositis

First Line
Photoprotection
Topical and systemic corticosteroids
Topical calcineurin inhibitors
Antipruritics
Antimalarials (single agent initially, consider combination if failed)

Second Line
Methotrexate
Mycophenolate mofetil
Human intravenous immunoglobulin IVIg

Third Line
Dapsone
Thalidomide
Azathioprine
Rituximab
Calcineurin inhibitors

Corticosteroids

Topical Corticosteroids

Topical corticosteroids are frequently used to manage the cutaneous inflammation and pruritus of DM. The application, in a vehicle most amenable to the patient and suitable for the area treated, should be once-twice daily. Appropriate breaks from use should be considered in order to prevent side effects as cutaneous atrophy, acneiform eruptions, striae, telangiectases, etc. For regions including the trunk, extremities, and scalp, a stronger (usually class 1 or 2) topical corticosteroid may be prescribed, whereas lower potency corticosteroids are suggested for the face. To increase potency and penetration, especially for hyperkeratotic refractory lesions, occlusion with a plastic wrap or steroid-impregnated tape is recommended.

In addition, there is a low risk of transient adrenal suppression and other effects from systemic absorption when large body surface areas are being treated. When prolonged use is anticipated, practice of cyclic therapy (e.g., 2 weeks of continuous therapy followed by 1–2 weeks treatment-free) is advised.

Systemic Corticosteroids

Systemic corticosteroids are the traditional first-line agent for management of DM. Normally the therapy consists of prednisone orally at 0.5–1 mg/kg per day. Some authors suggest giving methylprednisolone intravenously at 1 g daily for 3–5 days, followed by oral therapy, when muscle disease is severe. The well-documented adverse effects of corticosteroids as well as the known refractory nature of cutaneous DM lesions limit their use for the post-myopathic DM therapy. Some experts suggest short courses of prednisone 1 mg/kg/day tapered over 2–3 months for particularly symptomatic skin DM. Other experts prefer to avoid systemic steroids for skin-limited disease because the doses required to effectively treat cutaneous DM frequently result in steroid-related side effects. In JDM, both oral prednisone and intravenous methylprednisolone have been studied, particularly at the onset of disease, and efficacy has been demonstrated mainly for muscle disease as well as for prevention of calcinosis cutis.

Photoprotection

It is well known that sunlight can exacerbate or induce DM skin lesions. It is strongly recommended photoprotection year-round, based on the use of sun-protective clothing, wide-brimmed hats, and broad-spectrum sunscreen. A sun protection factor of at least 50 should be applied daily, with emphasis on reapplication every 3–4 h. Midday sun should also be avoided if possible, as well as tanning beds. Supplementation of vitamin D can be considered for patients with low levels of vitamin D.

Topical Calcineurin Inhibitors

They are T-cell-selective immunosuppressants, which mainly acts through inhibition of calcineurin and subsequent blockade of cytokine gene transcription (interleukin-2, interferon-gamma, and granulocyte-monocyte colony-stimulating factor). Particularly important is the blocking of interleukin-2, a cytokine essential in the T-cell activation pathway. Numerous case series and open-label studies have reported their efficacy in skin lesions.

Antipruritics

Topical Antipruritics

The management of pruritus associated to DM is an important therapeutic target for improving the quality of life of the patient. Clinicians can choose from the most simple bland moisturizers and emollients up to antipruritic formulations containing menthol, camphor, and/or pramoxine.

Systemic Antipruritics

Oral sedating antihistamines, such as hydroxyzine 10–50 mg given during the day and at bedtime, can be exploited for relief from the often-incapacitating pruritus and/or dysesthesia

caused by cutaneous lesions of DM. Doxepin and amitriptyline, long-acting tricyclic antidepressants with potent antihistaminic effects, given in doses of 10–50 mg at bedtime can be helpful for refractory pruritus. Other medications, such as gabapentin and pregabalin, may be considered.

Antimalarials

The antimalarials most commonly employed in dermatology are hydroxychloroquine, chloroquine (4-aminoquinolines derived from quinine), and quinacrine (yellow acridine dye compound). Their mechanisms of action are not clear, and their use is debated. They show immunomodulatory, anti-inflammatory, antiproliferative, and photoprotective properties. Normally they are considered for the treatment of cutaneous DM, and not for muscle disease. Monotherapy based on antimalarials appears to be less valuable in controlling cutaneous disease in DM than in cutaneous lupus, and additional medications are often needed.

Methotrexate (MTX)

This folic acid analog, competitively and irreversibly, inhibits dihydrofolate reductase, an enzyme that produces a necessary cofactor for the synthesis of purine and pyrimidine nucleotides. This blocking disrupts DNA and RNA synthesis and leads to inhibition of cell proliferation. The proposed mechanism of action in inflammatory cutaneous disorders appears to be related to its effect on adenosine, through inhibition of 5-aminoimidazole-4-carboxamide ribonucleotide (AICAR) transformylase. The biological effect consists of an increase adenosine levels, a purine nucleotide with potent anti-inflammatory effects. MTX can be the first-line systemic therapeutic agent considered for cutaneous DM in a patient who fails to improve with diligent photoprotection, topical medications, and antimalarials. With MTX, the most commonly observed side effects include nausea, malaise, and fatigue, particularly following the weekly dose. Other more disabling adverse events include hepatotoxicity, hematologic disturbances including pancytopenia, ulcerative mucositis, and rarely pneumonitis or pulmonary fibrosis. Specific screenings, evaluating comorbidities that would prevent the use of this medication, alcohol consumption, and childbearing preferences that would impact the safe use of the drug, should be done prior to administrate MTX. The typical starting dose is 10 mg orally or subcutaneously per week with folic acid supplementation 1 mg daily. Follow-up laboratory studies are done at 2 weeks, and if normal, the dose is increased to 20–25 mg weekly. Like the antimalarials, it typically takes a minimum of 6–8 weeks of continuous therapy before a noticeable improvement can be appreciated.

Mycophenolate Mofetil (MMF)

MMF is a prodrug of mycophenolic acid, a lymphocyte selective immunosuppressive agent that inhibits inosine monophosphate dehydrogenase, reducing the novo synthesis of purine nucleotides. It reduces lymphocytic proliferations, suppress antibody production, and decrease lymphocyte migration and recruitment. The dose is typically titrated to 1 g twice daily after 2 weeks of therapy. The therapeutic effect is usually noted after an initial delay of 6–8 weeks. In patients transitioning from MTX to MMF, MTX may be continued at a lower dose (10–15 mg weekly) while starting MMF to prevent disease flares. Overall, MMF is a relatively well-tolerated medication. The most common adverse effect is dose-related gastrointestinal distress, especially significant when given at doses of greater than 2 g daily, which is often alleviated by taking the medication with meals.

Human Intravenous Immunoglobulin (IVIg)

Immunoglobulin (Ig) preparations are derived from pooled plasma collected from thousands of donors and are highly purified to contain mostly

Ig. The most common route of administration is intravenous Ig (IVIg), although subcutaneous and intramuscular products are also available. When used in autoimmune and inflammatory disorders, IVIg is considered an immunomodulatory agent and is usually administered at higher doses than when being utilized for replacement Ig therapy. In general, IVIg is reserved for patients who have failed, are intolerant of, or have contraindications to antimalarials and MTX. Generally, IVIg is well tolerated and appears beneficial for the skin disease of DM, including in patients who have failed other systemic medications such as MTX and MMF. It is generally given as monthly infusions of 1 g/kg on two consecutive days for an initial 6-month period and tapered thereafter according to skin response.

Dapsone

Dapsone, or 4,4′-diaminodiphenylsulfone, is a sulfone antibiotic and anti-inflammatory agent used to treat a variety of disorders, including Hansen's disease (leprosy), autoimmune bullous disorders, and neutrophilic dermatoses. It shows antibiotic properties through the inhibition of dihydropteroate synthetase, an important enzyme for the folic acid production. The mechanism of action of dapsone in cutaneous disorders is less well understood. The efficacy of dapsone in cutaneous DM is limited to a case report and two small case series. Known associated adverse events include hemolytic anemia (which correlates with the level of G6PD, which should be measured prior to initiating dapsone), agranulocytosis, peripheral neuropathy, hypersensitivity syndrome, and gastrointestinal disturbances. Treatment is usually initiated at 25–100 mg daily and may be increased to 200–300 mg daily as tolerated and according to response.

Thalidomide

The use of thalidomide was reportedly effective in controlling up to 60 % of the cutaneous disease activity in a case of drug-induced DM to gemfibrozil. It was also found to be beneficial in a case of JDM with extensive calcinosis accompanied by systemic inflammatory symptoms refractory to multiple therapies. In this child, thalidomide administered at 75 mg daily resulted in a reduction in pain and a decrease in inflammatory markers and symptoms; however, the existing calcium deposits remained.

Azathioprine (AZA)

AZA is a prodrug of 6-mercaptopurine, a purine analog. It is used in many autoimmune and inflammatory dermatologic diseases in doses ranging from 1 to 3 mg per kg daily. Its therapeutic success in skin disease is not clearly demonstrated, and the use in muscle inflammation shows mixed results. For this reason, the use of AZA in DM should be carefully evaluated. Known side effects associated with AZA include bone marrow suppression, hepatotoxicity, hypersensitivity reactions, and increased risk of nonmelanoma skin cancers. AZA is rarely used as a steroid-sparing agent in DM, and preference is usually given to MTX, MMF, or IVIg unless contraindications or comorbidities prohibiting their use.

Biological Drugs

DM shows elevated concentrations of proinflammatory interleukins (TNF, IL-1, IL-6) and increased expression of molecules related to costimulation of T lymphocytes. In this view the use of biologics in those conditions seems reasonable. Open-label studies are scarce, comprising mainly case reports and series. The most considered biologics are anti-TNF-α, anti-IL-6, and anti-CD-20. The latter has the most promising results.

Tumor Necrosis Factor (TNF)-α Inhibitors

TNF-α inhibitors have received attention in recent years for the treatment of refractory inflammatory myopathies with mixed results.

Increasing data on anti-TNF-induced cutaneous eruptions lend support to the consideration that cases of anti- TNF-induced DM do exist. With these potential adverse reactions and mixed results in the literature regarding the efficacy of anti-TNF agents in DM, it is difficult to formulate any formal treatment recommendations. Anti-TNF agents are usually reserved for refractory cases of DM that have failed treatment with multiple agents. Ideally, the results of upcoming controlled studies will provide more concrete data for therapeutic decision-making.

Tocilizumab

Tocilizumab is a humanized monoclonal anti-IL-6 antibody. Some reports have been published recently. It has been accepted in Castleman's disease.

Rituximab

Rituximab is a chimeric, murine-human, monoclonal antibody directed against the CD20 B-cell specific lymphocyte antigen expressed by pre-B and mature B cells. Data regarding the use of rituximab in the treatment of DM have yielded conflicting results. Case series and open uncontrolled studies have demonstrated efficacy in the treatment of both the myopathy and the cutaneous manifestations of DM. The skin changes that seemed to demonstrate the most improvement included the heliotrope eruption and the poikilodermatous photodistributed erythema. The doses used most frequently are 1,000 mg given as two intravenous infusions 2 weeks apart (which is the typical rituximab dosing regimen for rheumatoid arthritis) and 375 mg/m^2 given as four weekly intravenous infusions (the classic dosing regimen used in non-Hodgkin's lymphoma). Adverse events with rituximab infusions are generally rare; however, mild infusion-related reactions can occur, typically accompanied by fever, chills, nausea, and/or rash.

Sirolimus

Although similar to the systemic calcineurin inhibitors (CNIs) discussed previously, sirolimus (or rapamycin) inhibits the mammalian target rapamycin instead of calcineurin. It promotes the deactivation of T lymphocyte as well as the reduction of keratinocyte proliferation and vascular growth factors level. A recent case report documents its success in treating the skin and muscle disease in a refractory case of DM.

Tacrolimus

Tacrolimus, a macrolide immunosuppressant also acting via inhibition of calcineurin, has been used in the treatment DM. Its mechanism of action is similar to that of CsA, predominantly through interference with T cell activation, but it is 10 to 100 times more potent. A few case series have documented efficacy with this drug, particularly in cases of refractory muscle disease in JDM. In addition, a seemingly impressive resolution of skin lesions has been reported in several cases of JDM, including cutaneous calcinosis and vasculitis.

Plasma Exchange

Plasma exchange, the replacement of one volume of plasma with 5 % albumin in saline, could be considered for polymyositis or dermatomyositis that is resistant to corticosteroids. Significant clinical trials demonstrating its efficacy are not available.

Alkylating Agents

Cyclophosphamide (CP), administered orally or intravenously, has been mainly reported in patients with severe DM/PM associated with interstitial lung disease and in cases with rapidly progressive respiratory disease. Although chlorambucil, a nitrogen mustard-type alkylating agent, was reported to be well tolerated and successful in treating myositis in a series of patients with refractory DM, this medication did not seem to have much effect on skin manifestations.

Conclusions

The diagnostic tests, such as highly specific Mi2 antibody, the antisynthetase antibodies, and other myositis-specific antibodies should be done promptly for an early diagnosis and a correct choice of therapeutic regimen. Generally the outcome is positive if more aggressive is introduced at early stage of illness.

Dermatophyte Infections

21

Antonella Tosti, Kautilya Shaurya,
and Bianca Maria Piraccini

Abbreviations

DLSO	Distal and lateral subungual onychomycosis
FDA	Food and Drug Administration
M.	*Microsporum*
OSI	Onychomycosis severity index
PDT	Photodynamic therapy
PSO	Proximal subungual onychomycosis
RCT	Randomized controlled trial
SO	Superficial onychomycosis
T.	*Trichophyton*
TDO	Totally dystrophic onychomycosis

Key Points

- Topical treatment with imidazoles is adequate for localized tinea corporis and tinea cruris.
- Widespread or follicular lesions of tinea corporis and tinea pedis require systemic treatment.
- Topical treatment with allylamines is indicated to treat most cases of tinea pedis.
- Systemic treatment with itraconazole, terbinafine, or fluconazole is necessary in cases of chronic tinea pedis, when topical therapy fails, or in "moccasin"-type tinea pedis.
- Controlling humidity and maceration is important in the prevention of recurrence of tinea pedis.
- Dermoscopy is a valuable tool in the diagnosis of tinea capitis.
- Tinea capitis usually requires systemic treatment.
- Tinea capitis caused by *Microsporum canis* is treated with griseofulvin, while terbinafine is used to treat tinea capitis caused by *Trichophyton* infections.
- The treatment of onychomycosis depends on the clinical type of infection.
- Superficial onychomycosis with patch infiltration and distal subungual onychomycosis with less than 50 % nail

involvement can be effectively treated topically with nail lacquers.
- Distal subungual onychomycosis with greater than 50 % nail involvement, proximal subungual onychomycosis, and deeply infiltrating white superficial onychomycosis require systemic therapy, usually with terbinafine or itraconazole.
- Lateral nail plate involvement, dermatophytomas, and total dystrophic onychomycosis may require nail plate avulsion combined with topical or systemic treatment.

Tinea Corporis

Definition and Basic Concepts of Pathogenesis

Tinea corporis is an infective skin disease resulting from invasion and proliferation by the causal fungi in the stratum corneum. The fungi most commonly involved are *Microsporum* (*M.*) *canis*, *Trichophyton rubrum*, and *Trichophyton mentagrophytes*. It most commonly involves exposed parts of the body, but can affect any site. Typical lesions are annular in shape, with a raised scaling erythematous edge. The presence of perifollicular granulomatous papules (Majocchi's granuloma) is a definite indication for systemic treatment.

General Principles of Treatment

Topical Treatment

In localized lesions of tinea corporis, topical treatment with imidazole derivatives, allylamines, phenylpropylmorpholine derivatives, tolnaftate, or cyclopiroxolamine is adequate. Treatment period varies between 2 and 4 weeks, except for allylamines that are effective after 1–2 weeks of therapy. Efficacy among the different classes is similar; however, butenafine may achieve faster mycological cure. Sertaconazole, a newer imidazole derivative, may be more effective at controlling symptoms of pruritus.

Systemic Treatment

Systemic treatment is required in widespread tinea corporis or when follicular lesions (Majocchi's granuloma) are present. Itraconazole (200 mg daily for 1 week), terbinafine (250 mg daily for 2 weeks), and fluconazole (150 mg weekly for up to 4–6 weeks) are currently preferred because time to treatment is usually shorter and they are better tolerated than griseofulvin.

Tinea Cruris

Definition and Basic Concepts of Pathogenesis

This infection mainly occurs in adult men and is usually caused *by Trichophyton rubrum* and *Epidermophyton floccosum*. Tinea cruris presents with an itchy scaling of the groin and insides of the thighs. The margin of the affected area typically presents with a raised erythematous border.

General Principles of Treatment

Topical Treatment

In localized lesions topical treatment, as for tinea corporis, may be sufficient.

Systemic Treatment

This is mandatory in long-standing lesions or when follicular granulomas are present. Itraconazole (200 mg daily for 1 week), terbinafine (250 mg daily for 2 weeks), and fluconazole (150 mg weekly for up to 4–6 weeks) are very effective.

Tinea Pedis

Definition and Basic Concepts of Pathogenesis

Tinea pedis is the most common dermatophyte infection and in most cases is caused by

Trichophyton (*T.*) *rubrum*, followed by *Trichophyton interdigitale*. *Trichophyton rubrum* usually produces noninflammatory lesions with different degrees of severity ranging from mild scaling to diffuse "moccasin-type" scaly rash. *Trichophyton interdigitale* usually causes interdigital or plantar inflammatory lesions that are often vesicular and pruritic.

General Principles of Treatment

Topical Treatment

Topical antifungals are usually used to treat tinea pedis. They are also commonly utilized to prevent reinfections. Generally, allylamines have been shown to be more efficacious than azoles. Usually, topical therapy lasts 1–4 weeks. Naftifine and terbinafine are the commonly used allylamine in tinea pedis. A new drug that has completed phase III testing, terbinafine film-forming solution, has shown to be safe and efficacious in preventing tinea pedis with only one application (Chauvin et al. 2008). Among the azole treatment options are ketoconazole, econazole, oxiconazole, miconazole, and clotrimazole. A newer treatment option is sertaconazole. Compared to miconazole, sertaconazole has a statistically higher complete clinical cure rate. Sertaconazole also provided patients with greater relief from erythema and desquamation. Sertaconazole has the added benefit of being effective with once daily application. Luliconazole is a new drug currently undergoing phase 2 testing (Jarratt et al. 2013). Flutrimazole and bifonazole are available as powders that can be applied twice daily for 2–4 weeks and may be effective in curing tinea pedis.

Alternative treatment options, including *Ageratina pichinchensis* extract (active ingredient encecalin), Brazilian green propolis extracts, green tea polyphenols, and tea tree oil, have shown some effectivity. *Ageratina pichinchensis* demonstrated similar cure rates to ketoconazole. Use of Brazilian green propolis extracts showed improvement of clinical features over petroleum jelly. Green tea polyphenols have been shown in one randomized controlled trial (RCT) to improve tinea pedis; however, the study design only had one physician making assessments and thus lacked interobserver validity (Ikeda et al. 2013). Tea tree oil shows significant promise as an alternative treatment for tinea pedis. In an RCT, tea tree oil demonstrated statistically significant improvement in mycological as well as clinical cure rates compared to placebo after 4 weeks of twice daily application (Satchell et al. 2002).

Systemic Treatment

Systemic treatment is indicated, if topical therapy fails, in chronic conditions, or in cases of moccasin-type tinea pedis. Itraconazole, terbinafine, and fluconazole are effective in the treatment of tinea pedis. Common treatment regimens include itraconazole at 100 mg/day for 2–4 weeks, terbinafine at 250 mg/day for 2 weeks, or fluconazole at 150 mg weekly for up to 6 weeks. However, clinically, there is some variance in the regimens. Terbinafine may be the preferred agent as it may be more efficacious, has lower recurrence rates, and requires a shorter treatment duration.

Prevention of Recurrences

1. Reduction of maceration and humidity can be obtained by regular use of talcum powders.
2. The demonstration that dermatophytes occur in shoes (up to 17 % in one study), flooring, and carpets (Muslim community) indicates that any treatment directed solely at the feet is inadequate to control the disease. Effective control measures must also include simultaneous eradication of the organisms (such as disinfection of shoes with 1 % 8-hydroxycholine sulfate, formaldehyde) and/or the environment to prevent reinfection. However, there is limited data which shows a correlation of such measures and the prevention of athletes' foot. In such circumstances, evaluating the preventative efficacy of these measures against athletes' foot remains guesswork.

Tinea Capitis

Definition and Basic Concepts of Pathogenesis

In Europe, tinea capitis is predominantly caused by *Microsporum canis* and increasingly by *Trichophyton tonsurans*, with *Microsporum canis* being the most common agent of tinea capitis in Italy. Other dermatophytes responsible for tinea capitis include *T. soudanense*, *T. violaceum*, *M. gypseum*, *T. mentagrophytes*, and *T. schoenleinii*. The most common causative agents vary significantly by geographic region. The clinical manifestations of tinea capitis range from mild scalp scaling to severe inflammatory reactions. Cervical lymph nodes are often enlarged.

Dermoscopy is an important and underutilized tool in the diagnosis of tinea capitis. It can be especially useful in African-American patients where erythema may be subtle and difficult to appreciate. Characteristic signs such as comma hairs and corkscrew hairs may help in making the diagnosis. In tinea capitis favosa, there is no significant hair structure abnormality, but large amorphous yellow areas and wax-colored perifollicular areas can be observed. Black dots and broken dystrophic hairs are also seen in tinea capitis but are not specific to the disease.

General Principles of Treatment

Topical Treatment

Although tinea capitis always requires systemic treatment, the use of adjunctive topical therapy is important. Periodic hair shaving prevents diffusion of the infection. Antifungal shampoos such as ketoconazole 2 %, selenium sulfide shampoo 1 %, and ciclopirox shampoo 1 % should be given to the patient and family members in order to reduce transmission of infection. Family members and primary contacts should be screened for asymptomatic disease. Family pets of patients with *Microsporum canis* infection should be treated. Fomites, including toys, phones, clothing, furniture, and hair care items, may contribute to spread of the infection and can be sterilized using high temperature or microwaves.

Systemic Treatment

Microorganism identification may be useful in the treatment of tinea capitis as the different species show varying susceptibilities. In tinea capitis due to *Microsporum canis*, griseofulvin is commonly prescribed. The drug should be administered at 10–25 mg/kg per day for 2–3 months. The azole antifungals fluconazole and itraconazole are effective in the treatment of *Microsporum canis* infection of the hair, with fluconazole being the only one available in a pleasant-tasting liquid formulation. The suggested regimen for fluconazole is 4–6 mg/kg per day for 8–12 weeks and may be administered on a weekly basis as well. Itraconazole can be administered at 5 mg/kg per day or as pulse therapy and is available in both capsule and oral solution. The length of treatment varies by organism, with *M. canis* requiring treatment for 6 weeks. Terbinafine is less effective in tinea capitis due to *M. canis* but may be more efficacious compared to griseofulvin in treating infection by the *Trichophyton* species. Dosages used in this setting are 3.125–6.25 mg/kg per day for terbinafine, 3–5 mg/kg per day for itraconazole, and 4–6 mg/kg once a week for fluconazole. Duration of treatment ranges from 2 to 6 weeks. Oral or topical steroids can be given in association with systemic antifungals to reduce pain, swelling, and inflammation.

Onychomycosis

Definition and Basic Concepts of Pathogenesis

Dermatophytes account for more than 90 % of onychomycosis, with T. rubrum being the most common pathogen. They may produce several different clinical types of onychomycosis, depending on the modality of nail invasion by the fungus.

Distal and Lateral Subungual Onychomycosis (DLSO)

DLSO (Fig. 21.1) is the most common of the clinical entities and involves invasion from the lateral or distal part of the nail plate. The affected

Fig. 21.1 Distal subungual onychomycosis due to *T. interdigitale* involving the distal 1/3 of the nail

nails usually show subungual hyperkeratosis, onycholysis, and white or yellow discoloration. Infrequently, brown, black, or orange discoloration may also be seen. In certain cases, longitudinal streaking of the nail, called dermatophytoma, can be seen. These infections are difficult to treat and may require excision of the area and systemic treatment rather than topical therapy. Since the skin of the palms and soles is the primary site of infection, DLSO is usually associated with tinea manuum or tinea pedis. This form of infection is seen with a variety of causative agents including dermatophytes.

Superficial Onychomycosis (SO)

SO can present with superficial patches or transverse striae and may arise from the superficial nail plate or emerge from the proximal nail fold. These bear clinical implications on treatment. In the classic form, previously known as white superficial onychomycosis, dermatophytes colonize the most superficial layers of the nail plate without penetrating it. The affected nail presents multiple friable white opaque spots in a patchy distribution that can be easily scraped away. This form is amenable to topical treatment. In contrast, in the striate form when the infection emerges from the proximal nail fold and with deep penetration of the nail plate, oral therapy is indicated.

Endonyx Onychomycosis

Endonyx onychomycosis is characterized by massive nail plate parasitization in the absence of nail bed inflammatory changes. Clinically, the affected nail may show lamellar splitting and a milky white discoloration. The nail plate is firmly attached to the nail bed and there is no nail bed hyperkeratosis or onycholysis. This type of infection is commonly seen with *T. soudanense* but can also be seen with *T. violaceum*.

Proximal Subungual Onychomycosis (PSO)

PSO is characterized by a primitive invasion of the nail matrix keratogenous zone through the proximal nail fold horny layer. Fungal elements are typically located in the ventral nail plate with minimal inflammatory reaction. The affected nail shows proximal leukonychia that progresses distally with nail growth. PSO can be divided into either patchy, striate, or secondary to paronychia. Among the dermatophytes, these infections are usually caused by T rubrum. PSO is difficult to treat and requires oral therapy.

Mixed Pattern Onychomycosis

Oftentimes, different patterns of infection may be seen in the same patient. DLSO may occur with superimposed SO or PSO and SO may occur with superimposed DLSO or PSO. The most common of these are PSO with SO or DLSO with SO. Mixed pattern onychomycosis often requires oral treatment.

Totally Dystrophic Onychomycosis (TDO)

TDO is the end stage of onychomycosis and can result from DLSO as well as PSO. The nail plate, in these cases, crumbles and the underlying nail bed is thickened.

Secondary Onychomycosis

In some cases of nail pathologies such as psoriasis or traumatic nail dystrophy, a secondary fungal infection can occur.

General Principles of Treatment

The treatment choice depends on the clinical type of the onychomycosis, the number of affected nails, and the severity of nail involvement.

The onychomycosis severity index (OSI) was developed in 2011 and provides a fast and effective way to evaluate the extent of onychomycosis and may provide an objective measurement on which to base treatment (Carney et al. 2011). Furthermore, the OSI scoring system demonstrates excellent interobserver reliability. The categories assessed when calculating the OSI are area of involvement, proximity of disease to matrix, and the presence of dermatophytoma or subungual hyperkeratosis greater than 2 mm. First, the area of involvement is determined as the percentage of the nail that is onychomycotic. Involvement is categorized as 1–10 %, 11–25 %, 26–50 %, 51–75 %, or 76 % or greater with scores ranging from 0 to 5, respectively. Next the proximity of disease to matrix is assessed by visualizing the leading edge of disease proximally. The nail is divided transversely into quarters. Scores of 1 through 4 are assigned, with 1 for only distal quarter involvement and 4 for proximal quarter involvement. If the proximal edge extends into the nail fold or if the lunula is involved, a score of 5 is given. The third step is to assess the presence of dermatophytoma, defined as the presence of a patch or a longitudinal streak, or subungual hyperkeratosis greater than 2 mm. If either of these is present, a score of 10 is given. The OSI is calculated by multiplying the score for the area of involvement by the score for proximity of disease to the matrix and adding 10 if necessary from the third step. Scores range from 0 to 35 with higher numbers correlating with increased severity. Scores of 1–5 indicate mild onychomycosis, scores of 6–15 indicate moderate onychomycosis, and scores of 16–35 indicate severe onychomycosis. A score of zero indicates a cured state.

Topical Treatment

Penetration of a topical antifungal through the nail plate requires a vehicle that is specifically formulated for transungual delivery. The two most commonly used agents are amorolfine 5 % nail lacquer and ciclopirox 8 % nail lacquer. However, agents such as miconazole, tioconazole, ketoconazole, tolnaftate, naftifine, and tea tree oil have been tested with varying success rates in the past. Amorolfine nail lacquer is applied once a week, whereas ciclopirox nail lacquer is applied daily.

Fig. 21.2 Complete cure of the onychomycosis after 6 months of topical application of a nail lacquer containing ciclopirox with hydroxypropyl chitosan as vehicle

Nail lacquers are effective as monotherapy in the treatment of superficial onychomycosis, with patch infiltration, and of distal subungual onychomycosis, limited to less than 50 % of the distal nail (Hay and Baran 2011). Treatment duration should be 6–12 months (Fig. 21.2). Nail lacquers are also utilized in combination with systemic antifungals or nail avulsion in severe onychomycosis to reduce duration of treatment and increase cure rate.

Application of amorolfine nail lacquer once every 2 weeks after completion of treatment may be effective prophylaxis to prevent the recurrence of onychomycosis.

Recent studies on lipid diffusion enhancers and water-soluble biopolymers have shown promise (Baran et al. 2009; Hafeez et al. 2013). Terbinafine nail solution and a terbinafine spray using lipid-based vesicles currently under development, labeled TDT 067, may be viable treatment alternatives in the future (Elewski et al. 2013;

Table 21.1 New topical antifungal treatment options for onychomycosis

Drug	Nail involvement	Mycological cure	Clinical cure	Complete cure	Author
Efinaconazole	<50 %	53.4*–55.2 %*	–	15.2*–17.8 %*	Elewski et al. (2013)

Terbinafine nail solution	25–75 %	12.7–18.8 %*	2.3–3.5 %	1.2–2.2 %	Elewski et al. (2013)
Terbinafine spray (TDT 067)	–	90.1 %	–	–	Dominicus et al. (2012)
Terbinafine HCL with iontophoretic patch	25–75 %	84 %*	–	–	Amichai et al. (2010)

*Indicates statistically significant difference

Dominicus et al. 2012). Other formulations with terbinafine that are undergoing phase II trials include MOB-015 and TMI-358. Luliconazole has completed phase I and IIa testing for treatment of moderate to severe distal subungual onychomycosis with positive results (Jones and Tavakkol 2013). Refer to Table 21.1 for a comprehensive list of new topical antifungal treatment options for onychomycosis.

Treatments with photodynamic therapy (PDT) using photosensitizers may also prove to be effective treatment options in the future. Laser therapy is also currently being researched and may be effective in the treatment of onychomycosis. Food and Drug Administration (FDA)-approved lasers for onychomycosis include carbon dioxide laser, Nd:YAG laser, and the diode 870 nm, 930 nm laser. The carbon dioxide laser is the oldest laser and is infrequently used today. With the Nd:YAG laser, small clinical trials have demonstrated mycological cure rates as high as 87.5 % (Zhang et al. 2012). Similarly, the diode laser has shown some efficacy in small trials, with mycological cure rates as high as 38 % reported at 9-month follow-up (Landsman and Robbins 2012). Large randomized control trials need to be conducted to validate the efficacy of these lasers and PDT in the treatment of onychomycosis.

Systemic Treatment

Distal subungual onychomycosis that involves greater than 50 % of the nail, proximal subungual onychomycosis, and deeply infiltrating white superficial onychomycosis require systemic therapy. Systemic treatment with terbinafine or itraconazole produces mycological cure in more than 90 % of fingernail infections and in about 80 % of toenail infections. These success rates can be increased by associating a topical treatment with a nail lacquer to the systemic treatment. However, compared to itraconazole, terbinafine has a higher mycological and clinical cure rate and a lower rate of recurrence. Terbinafine can be administered as a continuous therapy at 250 mg per day for 12 weeks or an intermittent regimen of two pulses of 250 mg/day for 4 weeks on and 4 weeks off. Itraconazole is administered as pulse therapy at the dosage of 200 mg twice a day for 1 week a month. The treatment duration is 2 months for fingernails and 3 months for toenails.

Fluconazole is also used in onychomycosis but is less effective. The recommended dosage is 150 mg weekly for more than 6 months, especially for toenails. Posaconazole and albaconazole are newer drugs that could be alternative therapy options.

In cases of lateral nail plate involvement or dermatophytomas, surgical or chemical avulsion of the nail plate combined with topical or systemic treatment is indicated. Total dystrophic onychomycosis is an extremely recalcitrant entity. Surgical nail avulsion followed by topical therapy may not be enough to provide a cure in this situation; however, chemical avulsion with urea nail lacquer may be a viable treatment option. Sequential treatment with itraconazole and terbinafine has been utilized to increase cure rates: the suggested regimen is two pulses of itraconazole 400 mg/day for 1 week a month followed by one or two pulses of terbinafine 500 mg/day for 1 week a month.

Mycological cure can be evaluated at the end of treatment. Evaluation of clinical response, on the other hand, requires several months due to the slow growth rate of the nail. Recurrences and reinfection are not uncommon and vary with type of treatment (rates of 35.7 % reported with itraconazole). These may be prevented by the regular application of nail lacquers on the previously affected nails and topical antifungals on soles and toe webs.

Drug Hypersensitivity Reactions

22

Andrea Szegedi and Eva Remenyik

Abbreviations

AGEP	Acute generalised exanthematous pustulosis
DiHS	Drug-induced hypersensitivity syndrome
DRESS	Drug reaction with eosinophilia and systemic symptoms
HSS	Hypersensitivity syndrome
LTT	Lymphoblast transformation test
MDE	Maculopapular drug eruption
NSAIDs	Nonsteroidal anti-inflammatory drugs
SJS	Stevens-Johnson syndrome
SSSS	Staphylococcus scalded skin syndrome
TEN	Toxic epidermal necrolysis

Key Points

- In the therapy of drug hypersensitivity reactions at the time of the acute symptoms, the main tasks are to state the correct diagnosis, classify the reaction, score the severity, withdraw the suspected drug, treat the symptoms and prepare the drug history documentation properly, which can help the allergological examinations in the future.
- After the resolution of the symptoms, the physician's next duties are the identification of the eliciting drug and the treatment of sequelae if needed.
- Since morphology and distribution of the rash does not help in determining the responsible drug, allergological investigations should be performed on the basis of the patient's history.
- Allergological tests are best prepared between 3 weeks and 6 months after the incident.
- A detailed history is one of the most important assessments when a patient presents with drug hypersensitivity reaction.

Definition and Basic Concept of Pathogenesis

Adverse reactions caused by drugs can be divided into two main groups, type A and type B reactions. Type A reactions represent nearly 80–85 % of these side effects and are caused by predictable pharmacological actions of the drug, while type B reactions develop on the basis of individual predisposition (idiosyncratic reactions, immune-mediated and nonimmune-mediated hypersensitivity

Table 22.1 Pathogenesis and diagnostic steps in drug hypersensitivity reactions

Clinical manifestation	Potential pathogenesis	Diagnostic tests
Urticaria, angioedema	IgE mediated, pseudoallergy	Prick test, intradermal skin tests, specific IgE, basophil tests, LTT, provocation
Anaphylaxis	IgE mediated, pseudoallergy, rarely immune complex activation (C3a, C5a)	Prick test, specific IgE, basophil tests, serum tryptase measurement, LTT
MDE	T cell mediated (IVc)	Patch test, LTT
AGEP	T cell mediated (IVd)	Patch test, LTT
DRESS	T cell mediated	Patch test, LTT
	Viral reactivation?	
SJS and TEN	T cell mediated (IVc) and other nondrug-specific amplification mechanisms	Patch test, LTT (low sensitivity)

reactions) and account for 15–20 % of adverse effects. The skin is the organ most commonly, but not exclusively, affected in drug hypersensitivity reactions both in the immune-mediated (allergic) and in the nonimmune-mediated (pseudoallergic) forms; these reactions are observed in 2–3 % of hospitalised patients. Immune-mediated drug hypersensitivity reactions comprise a heterogeneous group of diseases which can be classified according to Gell and Coombs (antibody-mediated drug hypersensitivity reactions: type I, IgE; type II and III, IgG; and type IV, T cell mediated). After better understanding of T-cell functions and discovery of subgroups, the late type IV reaction has been further subdivided in the revised form of Gell and Coombs classification (type IVa, T helper 1; type IVb, T helper 2; type IVc, T cytotoxic mediated and type IVd). Nonimmune-mediated hypersensitivity reactions are the so-called pseudoallergic reactions, which usually imitate IgE-mediated reactions with wheal and oedema formation, but sometimes anaphylaxis can also develop. These pseudoallergic reactions tend to arise less rapidly than true IgE-mediated allergies, they require higher doses of the drugs and neither IgE nor T-cell reactions can be demonstrated later. Non-specific histamine release, arachidonic acid pathway activation, bradykinin pathway alteration and complement activation can be detected in the background. Nonsteroidal anti-inflammatory drugs (NSAIDs), plasma expanders and radiocontrast media are the most common causes of pseudoallergic reactions.

The therapy of drug hypersensitivity reactions comprises two fundamental steps. At the time of the acute symptoms, the main tasks are to state the correct diagnosis, classify the reaction, score the severity, withdraw the suspected drug, treat the symptoms and prepare the documentation properly, which can help the allergological examinations in the future. The second step is the identification of the eliciting drug and the treatment of sequelae if needed. Since morphology and distribution of the rash does not help to determine the responsible drug, according to data of the history, allergological investigations should be done between 3 weeks and 6 months after the incident in order to find the causative agent (see Table 22.1). The recommended test type depends on whether the diagnosis of the rash was an immediate- or delayed-type reaction.

This chapter will deal with the most common and severe forms of drug hypersensitivity reactions like urticaria and anaphylaxis, maculopapular drug eruption (MDE), acute generalised exanthematous pustulosis (AGEP), drug reaction with eosinophilia and systemic symptoms (DRESS), Stevens-Johnson syndrome (SJS) and toxic epidermal necrolysis (TEN).

Clinical Presentation

Urticaria, Anaphylaxis

Urticaria and anaphylaxis are the two most common immediate-type drug hypersensitivity reactions and urticaria is the second most common cutaneous manifestation of drug allergy after MDE. In

urticaria, disseminated wheals (oedema in the upper part of the dermis) are limited to the skin and can be accompanied by angioedema (tense, non-pitting oedema of the deeper skin layers and mucosa). Anaphylaxis has been defined as a severe, life-threatening generalised or systemic hypersensitivity reaction that occurs immediately after drug intake and affects more than one organ, whether or not accompanied by hypotension (anaphylactic shock). Urticaria can be caused by immune-mediated hypersensitivity reactions (type I, IgE-mediated reaction, or less frequently type III, immune complex-mediated reaction) or by nonimmune-mediated, so-called pseudoallergic mechanisms. In the pathogenesis of anaphylaxis, immunological reactions involving IgE or rarely immune complexes and also nonimmunological mechanisms are detected (called as nonallergic anaphylaxis or anaphylactoid reaction). Many different drugs can cause urticaria or anaphylaxis, most commonly beta-lactam and non-beta-lactam antibiotics, nonsteroidal anti-inflammatory drugs (NSAIDs), radiocontrast media, general anaesthetics and latex.

Clinical Features

In drug-induced acute urticaria, symptoms appear usually within 1 h after drug intake. Rapidly emerging, migrating and extensively itching wheals occur on large body parts (see Fig. 22.1). The lesions typically disappear in hours in one location without leaving any remnant signs. Pruritus, urticaria and angioedema may also present as initial or partial symptoms of full-blown anaphylaxis. In anaphylactic patients, flushing, itching and pruritus of the palms and soles, together with generalised urticaria and angioedema, are followed by respiratory symptoms (in up to 70 % of patients) and by gastrointestinal symptoms (in up to 40 % of patients). Asphyxia due to laryngeal oedema is probably the main cause of lethal anaphylaxis. Laryngeal swelling

Fig. 22.1 Clinical signs of urticaria and angioedema

may be suspected in case of difficulty of speaking or swallowing and if the voice becomes hoarse. Hypotension, manifest as dizziness, tachycardia, shock and cardiorespiratory arrest, occurs in only 10–30 % of cases. Typically, anaphylactic symptoms start within minutes (seldom later than 20 min) after exposure to the causative drug. In the diagnosis, the physician should consider the wide spectrum of symptoms and the continuum of signs and symptoms.

Differential Diagnosis

The diagnosis of acute urticaria and anaphylaxis is based largely on history and physical findings at the time of the event. Usually skin biopsy is not needed, only if urticaria vasculitis has to be distinguished. Laboratory tests available to support the diagnosis of anaphylaxis have proved to be somewhat disappointing in the clinical practice. Transiently elevated plasma histamine level of >10 nM correlates with severity and persistence of cardiopulmonary manifestations or gastrointestinal manifestations, but as histamine needs to be measured within 1 h of the onset of anaphylaxis, this test is seldom used. Measuring serum tryptase level within 12 h is more widely used, although this method also has its limitations.

Treatment

Acute stage: In the majority of moderate drug-induced urticaria cases, stopping the causative agent and treatment with a non-sedative histamine H1 antagonist is sufficient. Locally corticosteroid-containing creams or lotions can be applied to decrease pruritus. In case of widespread lesions with oedema formation, oral corticosteroids provide symptomatic relief and attenuate the reaction. Patients with anaphylaxis should be lied down with their legs elevated and epinephrine should be administered at the first sign of respiratory failure or cardiovascular collapse. The intramuscular route for epinephrine administration is recommended when compared to the subcutaneous mode. The dose is usually 0.3–0.5 ml of a 1:1,000 dilution in adults and this dose can be repeated in every 5–15 min until symptoms improve. Intravenous epinephrine (1:10,000 dilution) should be reserved for extremely severe anaphylaxis with life-threatening hypotension because of the higher risk of cardiac arrhythmias, hypertension and myocardial infarction. The most common side effects of epinephrine are anxiety, tremor, palpitation and increased blood pressure. Beta-blockers may increase the severity of an anaphylactic reaction and antagonise the response to epinephrine; accordingly, the anaphylaxis of patients on beta-blockers can be severe and treatment resistant. Corticosteroids are often used to decrease the risk of recurrent or protracted anaphylaxis, but it is still not entirely clear how steroids work. If hypotension is severe or does not respond rapidly to therapy, 1–2 L of crystalloid fluid should be infused. Patients should be warned of the possibility of an early relapse and kept under observation for 8–24 h, particularly if the patient has asthma, has a history of biphasic response or may continue to absorb the drug. Oxygen should also be applied in respiratory or circulatory failure. In case of severe laryngeal oedema, in order to maintain the airway, endotracheal intubation or tracheostomy should be carried out.

Chronic stage: The main purpose is the identification of the eliciting drug. Since both urticaria and anaphylaxis can be the result of immune-mediated and also of nonimmune-mediated reactions, this often causes difficulties in the allergological investigations, which are recommended between 3 weeks and 6 months after the incident, when complete clearing of clinical signs and normalisation of laboratory values have occurred. In the case of acute urticaria, prick tests which are less sensitive but safer can be carried out if the intradermal skin test is negative. The negative result is not a guarantee that the drug is tolerated, because of the weak sensitivity of these tests. Whenever possible, one should carry out laboratory tests, such as drug-specific IgE measurements, basophil CD63 activation assay, basophil sulphidoleukotriene or histamine release assays or the lymphoblast transformation test (LTT). If these tests are negative, then a provocation test may be performed or in other words a graded challenge test. In the case of anaphylaxis, laboratory tests can be performed, whereas intradermal or provocation tests are usually not advised. Serum tryptase levels increase greatly after anaphylactic shock and anaphylaxis, but are

negative in anaphylactoid non-IgE-mediated reactions. The concentration of tryptase peaks 1–2 h after the onset of the reaction and remains elevated with a half-life of 1.5–5 h, so the samples for tryptase test should be collected within 6 h of initiation of anaphylaxis. In pseudoallergic reactions, skin tests and in vitro tests are also negative, since adaptive immune reactions are not involved to our present knowledge. Provocation tests can be informative but often negative suggesting that additional cofactors might be needed to develop clinical symptoms. Although it has been described with aspirin and penicillin, desensitisation is rarely performed, since the benefits are outweighed by the hazards. Patients may be advised to wear a MedicAlert bracelet and instructed on the use of a self-administration epinephrine device in the event of further episodes.

Maculopapular Drug Eruption (MDE)

The so-called exanthematous reactions, the MDEs, are the most common drug hypersensitivity eruptions affecting the skin and present 31 %–95 % of all drug-induced cutaneous reactions. Antimicrobials (beta-lactams, sulfamethoxazole, quinolones), anticonvulsants, NSAIDs, and allopurinol are the most frequently involved drugs, but it is important to know that any drug can play an initiating effect. There are a lot of cofactors in the development of MDEs, like viral infections, connective tissue diseases, older age and genetic factors. MDEs belong to the type B hypersensitivity reactions, so they are unpredictable and occur in individuals with personal susceptibility. Drug-specific, CD4+ cytotoxic T cells are the dominant effector cells, and MDEs are considered to be a Gell and Coombs type IVc, cell-mediated delayed-type hypersensitivity reactions.

Clinical Features

The clinical picture characteristic of MDEs consists of hyperaemic or pink-coloured papules and macules, which sometimes become confluent (see Fig. 22.2). The rash usually starts on the trunk and upper extremities and affects other body parts, like lower extremities, gradually. The palms, feet and mucous membranes are free and this can be an important differential diagnostic

Fig. 22.2 Generalized erythematous morbilliform macules and papules of MDE

feature. Moderate to severe pruritus can occur. In the uncomplicated forms, the skin lesions usually begin to evolve 4–14 days after the patient starts to take the causative drug and disappear 1–2 weeks after discontinuation. MDE often heals with desquamation. On the other hand, in some cases the primary maculopapules can represent the beginning of more severe drug reactions, like erythroderma, SJS, TEN or DRESS, so all patients should be monitored for markers of severe reactions (see Table 22.2). In late-type reactions, including MDE, certain laboratory tests (complete blood count, liver function test, CRP, serum creatinine) are recommended to assess severity.

Differential Diagnosis

In the differential diagnosis of MDE, the dermatologist should consider acute viral infections, collagen vascular diseases, acute graft-versus-host disease and secondary syphilis (see Table 22.3). Usually skin biopsy is not needed; anamnestic data, clinical picture and some laboratory tests are enough to state the diagnosis.

Treatment

Acute stage: The suspected drug should be withdrawn as the first step of treatment. Sometimes it is not easy to identify the causative drug. In these cases, all drugs that are not essential and were started in the last few weeks should be stopped. In mild–moderate cases, topical corticosteroid creams and systemic antihistamines can be used; in severe cases, systemic corticosteroids can be initiated and then gradually decreased when the symptoms disappear.

Chronic stage: After the patient became symptom free, the next step is to identify the causative drug, if there are several suspected medications in the history. The patch test and the LTT can be performed after recovery and after stopping antihistamines and corticosteroids. Patch tests are recommended to carry out within 6 months after the MDE, and they are not well standardised so false-positive and false-negative results can occur. LTT validation is also not well organised in different laboratories. Provocation tests after MDEs are questionable since they need longer time period and hold the risk of inducing a more severe reaction. Desensitisation may be considered in those cases where the drug is mandatory without available alternative.

Table 22.2 Markers of severe reactions in patients with MDE

1. Skin pain or burning
2. Widespread eruptions (i.e. confluent erythema)
3. Affecting more than 60 % of the body surface area
4. Dusky red or purpuric macules
5. Atypical target lesions
6. Blisters or epidermal detachment
7. Positive Nikolsky sign
8. Involvement of mucous membranes
9. Facial oedema
10. Lymphadenopathy
11. Arthralgia
12. High fever (>40 °C)
13. Laboratory findings: eosinophilia, atypical lymphocytes and abnormal liver function tests

Acute Generalised Exanthematous Pustulosis (AGEP)

AGEP is a T-cell-mediated, late type IVd hypersensitivity drug-induced skin reaction with a rapid and dramatic appearance, but with a benign course. It is a rare disease with an estimated incidence equal to severe bullous skin diseases. The main causative medications are aminopenicillins, cephalosporins, macrolides, celecoxib, diltiazem and antimalarial drugs such as hydroxychloroquine or chloroquine, but there are reports on the role of sulphonamides and terbinafine. Usually the onset of the skin reaction occurs a few days (3–5 days) after the initiation of the suspected medication. In the pathogenesis, drug-specific T lymphocytes are supposed to migrate into the epidermis, where keratinocytes and T cells secrete IL-8, which attracts neutrophils, and neutrophil recruitment will result in the formation of subcorneal pustules.

Table 22.3 Differential diagnosis of MDE

	Clinical picture/histology	Laboratory findings
1. MDE	Polymorphous clinical picture, frequent confluence, elderly age group	Eosinophilia in peripheral blood
2. Acute viral infections (paramyxovirus, togavirus, Epstein-Barr virus, enterovirus, CMV, parvovirus)	Younger age groups, concomitant general symptoms, dermal haemorrhage	Serological test for infections are positive, laboratory signs of infections (CRP, leukocytosis)
3. Collagen vascular diseases	General symptoms differ, epidermal atrophy, focal parakeratosis, thickening of the basement membrane zone on histology	Immunological alterations, (autoantibodies, complement serology)
4. Acute graft-versus-graft reactions	Specific anamnesis, epidermal atrophy, parakeratosis, necrotic keratinocytes on histology	
5. Secondary syphilis	Palmoplantar lesions, plasma cell-rich mononuclear infiltration in histology	Specific serology

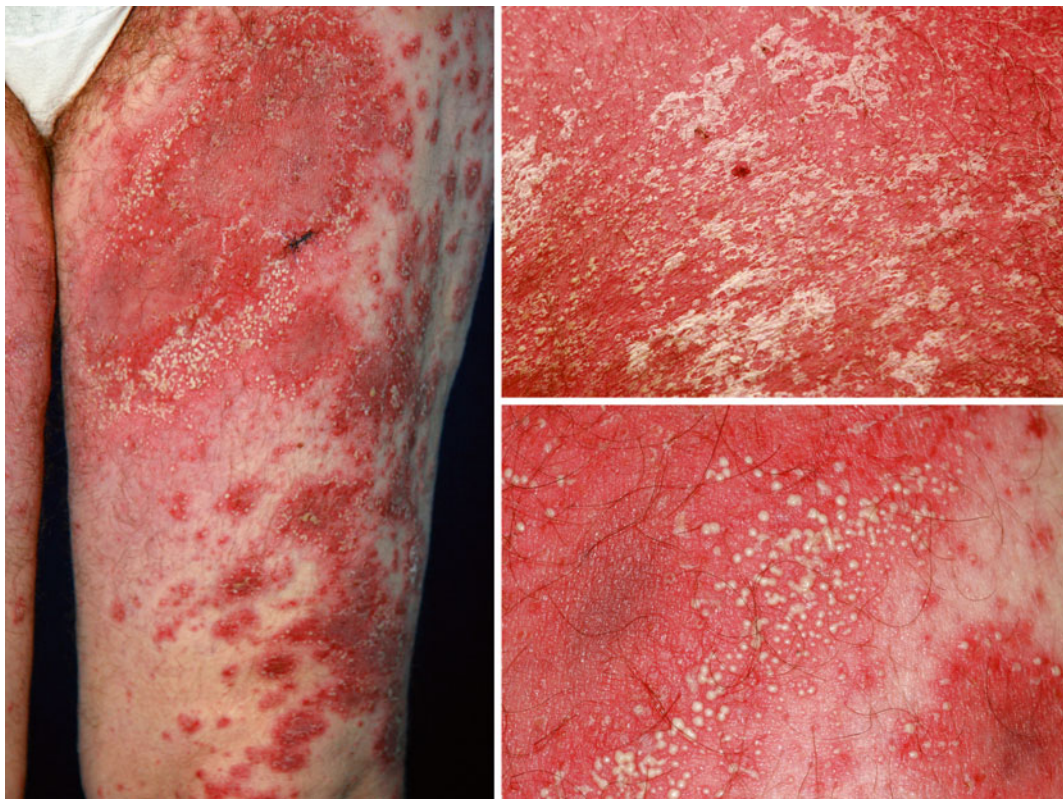

Fig. 22.3 Characteristic picture of AGEP with widespread small, non-follicular, sterile pustules

Clinical Features

In the course of AGEP, a widespread erythema suddenly occurs on the trunk and extremities, mainly affecting the flexural surfaces and skin folds. On the top of the erythema, a lot of small non-follicular sterile pustules develop rapidly (see Fig. 22.3)**.** Usually mucous membranes are not involved, but patients have fever and massive

neutrophilia. A diagnostic score for validation of AGEP was introduced and this system distinguishes definite, probable and possible AGEP diagnosis according to the final score. Spontaneous resolution in less than 15 days and post-pustular desquamation are also characteristics.

Differential Diagnosis

A pustular smear and culture should be taken to exclude infectious pustular disorders. A skin biopsy is also needed to differentiate other pustular skin diseases. Spongiform subcorneal and/or intraepidermal pustules and perivascular infiltrate of neutrophils with oedema of the papillary dermis are visible. Bacterial folliculitis, furunculosis, acne, acneiform eruptions, varicella, impetigo, Sweet syndrome and staphylococcal scalded skin syndrome (SSSS) are easy to differentiate from AGEP. On the other hand, psoriasis pustulosa generalisata and Sneddon-Wilkinson syndrome are rather difficult to distinguish. In the former, one history of psoriasis and histological signs of psoriasis can help; in the latter, one larger pustules with hypopyon formation and slower development are characteristics.

Treatment

Acute stage: Once the trigger was identified and discontinued, the disease has a self-healing resolution and symptomatic therapy is sufficient. In those cases with severe and widespread inflammation, a short course of systemic corticosteroids can be useful.

Chronic stage: During the latter allergological investigations patch test is recommended, since it is frequently positive in AGEP. The patch test reaction at 48 h imitates the early phase of the disease with T-cell infiltration; after 96 h pustules can be observed.

Drug Reaction with Eosinophilia and Systemic Symptoms (DRESS)

The term DRESS has been suggested in place of hypersensitivity syndrome (HSS) or drug-induced hypersensitivity syndrome (DiHS) which has long been used to describe drug reactions with internal organ involvements. Drug-specific T cells play a role in the pathogenesis of DRESS, but it is also suggested that virus reactivation may be important in the development of the disease. It is not clearly revealed whether reactivation of latent herpes viruses (HHV-6, HHV-7 and EBV) may play a causal role or just can be considered as complications. In Europe, elevated HHV-6 IgG levels are not yet included in the diagnostic criteria of DRESS. After the initiation of the suspected drug symptoms that can start up to 12 weeks, the disease often persists for a long time even after stopping the indicated drug and introducing the correct treatment. Most commonly registered causative drugs in the development of this disease are aromatic anticonvulsants (phenytoin, carbamazepine, phenobarbital), but there are reports on the triggering effect of minocycline, allopurinol, thalidomide and sulphonamides. Neurologists who often indicate anticonvulsants should be aware of DRESS as it might occur in 1:3,000 treated patients.

Clinical Features

The diagnosis of DRESS can be stated if at least three of the following criteria are fulfilled: skin rash, haematological abnormalities (marked eosinophilia, atypical lymphocytes in the peripheral blood), lymph node enlargement (minimum in two regions), hepatitis (liver transaminases show a more than twofold increase), interstitial nephritis (creatinine levels show more than 1.5-fold increase), interstitial pneumonia and carditis (CK, CK-MB and troponin levels are increased in these cases). In the beginning of the disease, the skin lesions have a morbilliform appearance, and facial oedema is quite common. As the disease progresses erythroderma develops with deeper infiltration, and purpuric lesions and sometimes exfoliative dermatitis occur. In the later stage, marked desquamation is visible. Fever accompanies the skin rash frequently.

Differential Diagnosis

During the development of DRESS, the initial rash has a maculopapular appearance, so MDE has to be excluded. In MDE, mild liver or kidney involvement can also occur, but prominent creatinine and

transaminase elevation and haematological abnormalities, which are characteristic to DRESS, cannot develop. As the skin lesions of DRESS progress, the infiltration become severe and erythroderma evolve. In this phase, lymphoma or pseudolymphoma should be taken into consideration. Acute viral infections should also be excluded in the differential diagnosis. During the diagnostic steps of DRESS, physicians have to keep in mind that skin changes and also histological findings are rather non-specific, the time period of the application of the causative drug is variable and the laboratory alterations can also develop in other diseases. Differential blood count, liver and kidney function tests and also serum CK, CK-MB, troponin and LDH levels should be determined.

Treatment

Acute stage: The first step in the management of DRESS is the immediate cessation of the offending medication. Systemic corticosteroid therapy in a minimum dose of 1.0 mg/kg/day is very effective both in the management of clinical and laboratory alterations. It is usually advised to decrease the systemic corticosteroid dose very slowly over 3–6 months in order to avoid relapse. Topical corticosteroids applied on the skin lesions can cause symptomatic relief. It is better to avoid empiric antibiotics or anti-inflammatory drugs, since they can exacerbate the symptoms. When DRESS is associated with severe exfoliative dermatitis lesions, the patients should be provided supportive care in an intensive care or burn unit. In some severe cases, other immunosuppressive medications should be considered (IVIG, plasmapheresis, cyclophosphamide, cyclosporine). Most patients recover completely, but chronic complications and mortality in about 10 % can occur, primarily from visceral organ failure.

Chronic stage: In order to determine the culprit drug in DRESS, patch test and LTT are used. Results of patch tests vary significantly based on the specific drug and the higher specificity was detected when antiepileptic medications (carbamazepine, phenytoin) were tested. In the case of LTT, positive values are more informative than negative ones.

Stevens-Johnson Syndrome (SJS) and Toxic Epidermal Necrolysis (TEN)

SJS and TEN, the latter also called as Lyell syndrome, belong to the most severe drug-induced hypersensitivity reactions with a high mortality rate. SJS has a mortality of 13 % and TEN of 39 %. SJS and TEN are considered to be end points of a single disease, differing only by their extent of skin detachment. Acute and disseminated epidermal necrolysis on large skin areas and on the full thickness of the epidermis is the hallmark of this disease group together with a relatively mild inflammatory cell infiltration. SJS and TEN are rare diseases affecting approximately one or two cases per million inhabitants per year. SJS and TEN are specific drug hypersensitivity reactions in which cytotoxic CD8+ T lymphocytes play a crucial role in the drug-specific immune response (type IVc), but the relative paucity of these infiltrating T cells suggests that nondrug-specific amplification mechanisms should accompany the immune reaction and cause the massive apoptosis of keratinocytes. On the basis of extensive research, the co-expression of the membrane form of the death ligand (FasL) and its cognate death receptor (Fas) on keratinocytes and a recently identified secretory granulysin (a cationic cytolytic protein secreted by Tc, NK cells and NKT cells) are key players in the amplification of keratinocyte apoptosis. Most cases occur 2 weeks (range 4–30 days) after the first exposure to the suspected drug. Recently a very strong association of HLA-B1502 with SJS/TEN provoked by carbamazepine and allopurinol was proved in Chinese patients and also to a lesser extent in other populations.

Clinical Features

Typically unspecific initial symptoms characterise TEN and SJS, like throat pain, fever, malaise and stinging eyes. Skin and mucous membrane lesions occur in a few days. Cutaneous manifestations are located first on the face and presternal region of the trunk and soon rapid progression and involvement of large body parts develop as characteristic features. The palms and soles are

Fig. 22.4 Clinical manifestations of: (**a**) SJS with <10 % extent of skin involvement, (**b**) SJS/TEN overlap with 10 %–30 % extent of skin involvement, (**c**) TEN with >30 % extent of skin involvement

Fig. 22.4 (continued)

often affected. Erythematous macules, patches, flaccid blisters and erosions are visible, and the spots have a grey to violet colour. The Nikolsky sign is positive since tangential mechanical pressure on erythematous zones induces epidermal detachment (detachable skin). These regions together with already detached regions (blisters, erosions) should be included in the evaluation of the extent of skin involvement. According to the degree of epidermal detachment, we can distinguish SJS (<10 %) (see Fig. 22.4a), SJS-TEN overlap (10–30 %) (see Fig. 22.4b) and TEN (>30 %) (see Fig. 22.4c). The mucous membranes are involved in 95 % of patients, most commonly the buccal, genital and ocular mucosa, and in some cases the respiratory and gastrointestinal tracts are also affected. Early oral lesions may resemble aphthae, but pain, rapid progression, skin lesions and fever are important signs of a severe systemic disease. The lesions progress for 1 week as a mean, and then re-epithelialisation starts; sometimes the bullae formation is still progressing on lower parts of the body. The most common acute complications are hypovolaemia, sepsis, shock and multiple organ failure, but destruction of epithelium of the trachea and bronchial tree or other epithelial surfaces can also occur. The most frequent and severe sequelae are the ocular complications. On the skin, hyper- or hypopigmentation will remain, but can fade with years if the patient pays attention to sun protection. Nail dystrophies are also common and may result in persistent nail abnormalities.

Differential Diagnosis

The diagnosis relies on clinical symptoms and on histological analysis. Characteristic clinical signs are erythematous, grey to livid macules on the skin, rapid progression with bulla formation, Nikolsky sign positivity (although it is not specific for TEN/SJS), simultaneous mucosal involvement, pain, anxiety and fever. These severe signs should alert the physician and rapid diagnostic confirmation is needed with the help of

skin biopsy. Histological evaluation of cryosections or formalin-fixed sections demonstrates widespread necrotic epidermis involving all layers. In the differentiation of SJS/TEN from autoimmune bullous diseases, direct immune fluorescent staining is carried out, and neither immunoglobulin nor complement deposition is detected. The main diseases that should be ruled out are linear IgA dermatosis, paraneoplastic pemphigus, pemphigus vulgaris, bullous pemphigoid, AGEP, disseminated fixed bullous drug eruption and SSSS.

Treatment

Acute stage: In the acute stage, severity and prognosis of the disease should be evaluated; the suspected drug(s) should be withdrawn and supportive care and specific therapy should be initiated.

Evaluation of severity: The validated SCORTEN disease severity scoring system is generally used to determine the severity and progression of the disease and to define the further management.

It consists in attributing 1 point to each of the following:

- Age >40
- Detachment larger than 10 % of body surface area
- Recent malignancy
- Tachycardia
- Serum urea >10 mmol/l
- Serum glucose >14 mmol/l
- Bicarbonate >20 mmol/l

Patients with a SCORTEN score of 3 or above should be managed in an intensive care unit because of the high mortality rate. The risk of dying is about 3 % at a score of 0–1, but nearly 60 % when it reaches 4.

Withdrawal of culprit drug(s): To suspend the offending drug is a crucial step, since it has been shown that the earlier the pathogenic medication is withdrawn, the better the prognosis. Two data can help to identify the culprit drug, the chronology of drug use and the registered potential of the drug to cause TEN/SJS. The overwhelming majority of cases occur in patients with normal metabolic pathways, after taking a normal dosage of medication for the first time and the development of TEN/SJS is between 1 and 4 weeks (mean 2 weeks), in case of agents with a long half-life even up to 6 weeks (allopurinol and some antiepileptics). Medications with high risk of inducing TEN/SJS are the following: allopurinol, sulphonamide antibiotics, carbamazepine, phenytoin, phenobarbital, oxicam-type NSAIDs, lamotrigine and nevirapine. Some authors underline the role of aminopenicillins, cephalosporins and quinolones as well.

Supportive care: Since TEN/SJS is potentially a life-threatening disease with extensive skin and mucous membrane lesions accompanied by serious acute complications, patients are advised to be undertaken in specialised intensive care units or in burn units and the best management is to place the patient on air-fluidised bed or on Metaline sheet. The basic element of symptomatic therapy is the fluid and electrolyte supplementation. Patients with TEN/SJS usually require less fluid replacement than burn patients, about two-thirds to three-quarters as much. For the purpose of volume substitution, electrolyte solutions rather than colloidal infusion are preferred in the moderately severe cases; in severe hypotension, the colloidal and electrolyte solutions should be used simultaneously. Purely prophylactic antibiotic usage can increase the risk of another hypersensitivity reaction and is not advised, but in case of definite infection or sepsis, targeted antibiotics must be initiated. To treat the wounds, it is usually advised to leave the necrotic epidermis in place, without skin debridement, to promote re-epithelialisation. Antiseptic solutions and nonadhesive wound dressings are used, but sulphonamide-based medications should be avoided. Antiseptic solutions and creams or dexpanthenol-based ointments are recommended for oral mucosa or lip lesions and also to treat genital erosions. Aggressive nutritional support should be initiated promptly to minimise protein loss and it is important to pay attention on warming of the environmental temperature. Mechanical ventilation is necessary in case of hypoxaemia and correction of any organ failure if needed.

Specific Therapy

Systemic corticosteroids: There have been a lot of doubts on the use of systemic steroids considering the risks and benefits, but a recent retrospective monocentre study found that a short course pulse of high-dose corticosteroids (dexamethasone) can exert good effect (Kardaun et al. 2007). One year

later another large retrospective multicentre study also found positive effect on the outcome of the severe skin reaction if corticosteroids were given briefly at the beginning of the reaction in moderate–high doses (100–500 mg). In this study compared to supportive treatment alone, the death rate was importantly, but not significantly, reduced in those who received corticosteroids too.

High-dose intravenous immunoglobulins (IVIG): The main mode of action that is supposed in the background of IVIG usage in TEN/SJS is the presence of antibodies with anti-Fas potential that can block Fas-mediated keratinocyte necrosis. Numerous case reports and noncontrolled clinical trials studied the effect of IVIG in TEN/SJS and the results are contradictory. Nearly all studies confirmed the excellent tolerability and low toxic potential of IVIG when used with precaution in patients with potential risk factors, but the efficiency is not clearly proven yet, so definite conclusion cannot be drawn. In spite of this, many practising physicians, based on clinical and laboratory evidences and also on the favourable effects of IVIG on infections and on fluid balance, prefer its use.

Thalidomide: In a double-blind, randomised, placebo-controlled study, thalidomide, an effective TNF-α blocker, was shown to have harmful effects when used in the therapy of TEN. In the thalidomide-treated group, higher mortality was observed and therefore this drug must be avoided for this indication.

TNF-α antagonists: So far only case reports have been published in the literature about the effect of TNF blockers, so data are insufficient to draw a conclusion.

Plasmapheresis: Current data are not enough to support the use of plasmapheresis in the therapy of TEN/SJS, due to the small number of treated patients and the variable treatment regimes.

Cyclophosphamide: Larger studies are needed to gain clear-cut data on the efficiency and also on the potential side effects of this agent in TEN/ SJS.

Chronic stage: In this stage, treatment of sequelae and allergological testing are recommended. The treatment of sequelae is an interdisciplinary task, and since ocular complications can become serious, referral to an ophthalmologist is important. In a lot of cases, several medications are candidates to be the causative drug and after recovery allergological testing is needed to identify the most likely candidate. Patch testing is an option, but because of the low sensitivity, only positive test is relevant, while negative result cannot rule out a sensitisation. The sensitivity of LTT test is also very low in SJS/TEN. Intradermal testing and provocation are not recommended because of the risk of another hypersensitivity reaction.

Drug Photosensitivity

23

Margarida Gonçalo and Ana M. Giménez-Arnau

Key Points

- Clinical manifestations of drug photosensitivity are polymorphic.
- Acute exaggerated sunburn and eczema of photoexposed sites are the main presentations of systemic photosensitivity.
- Pseudoporphyria, photoonycholysis, dyschromia and subacute lupus erythematosus are forms of subacute drug photosensitivity.
- It is not always easy to distinguish phototoxicity from photoallergy and both mechanisms can be involved in the final reaction.
- Main topical drugs causing photosensitivity are the NSAIDs, particularly ketoprofen.
- Photopatch testing, indicated mainly for the study of photoallergic contact dermatitis, can also be useful in systemic drug photosensitivity.

Definition and Epidemiology

Drug photosensitivity is an abnormal skin reaction to light, usually ultraviolet (UV) light, in individuals exposed to a drug, who, tolerate the same amount of light exposure in the abscence of the culprit drug.

Drug photosensitivity can present under a wide spectrum of acute or delayed clinical patterns, which are important to recognize and distinguish from idiopathic photodermatoses, in order to remove the offending drug or take the adequate measures to reduce this adverse effect.

Some drug phototoxic reactions presenting as acute sunburn or acute photoallergic eczema on sun-exposed areas are well recognized, but other reactions are often misdiagnosed, as the relation between drug and sun exposure may not be so obvious. The involvement of drug is certainly underestimated in drug-induced lupus erythematosus (LE) or in actinic keratosis and nonmelanoma skin cancer (NMSC) in patients exposed to photoactive drugs (Placzek et al. 1999).

More than 300 drugs from different pharmacological groups can cause photosensitivity, namely systemic or topical drugs and, occasionally, drugs manipulated in an occupational setting.

Many photosensitizers have been recognized and removed from the market (benoxaprofen, chlorproéthazine); premarketing studies regularly performed prevent the release of potential photosensitizing drugs; and when photosensitizers are used (lomefloxacin, vemurafenib), sun avoidance/protection is recommended (Gelot et al. 2013). Nevertheless, with the constant development of new photosensitizers, namely, for therapeutic purposes (photodynamic therapy), the introduction of new drugs with distinct mechanisms of action, namely, new targeted therapies, and more severe patients with concomitant diseases (immunosuppression), it is difficult to avoid this adverse drug effect.

Photosensitivity is still a field of intense research, with new mechanisms of drug photosensitivity and new aspects of their clinical presentation being recognized, which may also be important to understand diseases that course with photosensitivity, like HIV infection. Moreover, different pathomechanisms underlying drug photosensitivity may explain their clinical expressions and orient the choice of the most adequate diagnostic tests and therapeutic and preventive measures.

Basic Concept of Pathogenesis

Classically, drug photosensitivity is divided into phototoxicity (the more frequent) and photoallergy, but there are many overlapping situations and other immune-mediated or nonimmune-mediated mechanisms can also be involved. Most reactions occur within the UVA wavelength, although some can extend to visible light or, also, to UVB.

Immune-mediated reactions are mostly T-cell-dependent reactions, responsible for photoallergic contact dermatitis and systemic photoallergy. Drug-induced or drug-enhanced autoimmunity with photosensitivity involves autoantibodies and an inflammatory response with involvement of T cells.

Drug phototoxicity, on the other hand, does not involve specific immune hypersensitivity reactions. Frequently, acute reactions can be associated with enhanced photoimmunosuppression, photocarcinogenesis and photoaging, responsible for late reactions (premature skin aging, lentigines, actinic keratosis, NMSC and, even, melanoma) (Gonçalo 2012).

Solar Light and UVR in Drug Photosensitivity

Artificial light can be involved in drug photosensitivity (UV lamps used for aesthetic or therapeutic purposes or UV sources in occupational settings), but natural sun exposure is usually the cause. From the solar spectrum that reaches the earth, UV radiation, particularly UVA (320–400 nm), is responsible for most cases of photosensitivity. Some chromophores absorb in the UVB (290–320 nm) and UVB is more energetic, but UVA penetrates the skin more deeply and, particularly for systemic drugs, this is certainly the most important part of the solar spectrum involved in drug photosensitivity. Only exceptional cases of exclusively UVB-induced drug photosensitivity have been documented (Fujimoto et al. 2009).

Mechanisms of Acute Drug Phototoxicity

Photosensitivity develops when an abnormal chromophore is present in the skin, when a normal chromophore is present in exaggerated amounts or when there is failure of normal defensive mechanisms. The drug or a drug metabolite may be the exogenous chromophore that is excited in the skin or the drug may increase the quantity of endogenous chromophores in the skin, and these are, finally, responsible for the inflammatory reaction.

When a chromophore in the skin receives the energy of a UV photon, the electrons in the outer orbits increase their energy, and the molecules enter a short-lived excited state, singlet state, or can undergo more long-lived modifications into biologically more active molecules, triplet state. Excited molecules react with

neighbouring molecules in a photodynamic reaction, involving oxygen (type I) or other molecules (type II), and, ultimately, induce changes in bioactive molecules (unsaturated lipids of cell membranes, aromatic amino acids of proteins and pyrimidine bases of DNA or RNA). Eventually, free radicals or reactive oxygen species (ROS) are formed and expand the reaction in a cascade of events that progress in the absence of effective repair mechanisms (antioxidative defence mechanisms). This will result in damage of cellular organelles (mitochondria, lysosomes and cell membranes), cell aggression or cytotoxicity (apoptosis) of keratinocytes, melanocytes, dendritic cells in the epidermis and, eventually, other cells in the dermis. Injured cells liberate inflammatory mediators (prostaglandins, leukotrienes, IL-1, IL-6, TNF-alfa, IL-8/CXCL8, other cytokines and chemokines), and inflammatory cells are recruited causing visible skin lesions.

Other Mechanisms of Drug Phototoxicity

In rare cases, the drug increases the concentration of endogenous photosensitizers. Elevated erythrocyte porphyrins, namely, zinc protoporphyrin, seem responsible for acute photosensitivity from vemurafenib. Actually, transient skin burning shortly after sun exposure followed by erythema and oedema clearly limited by protective clothing, lasting a few days, simulates the genetic erythropoietic porphyria. Other kinase inhibitors that interfere with porphyrin metabolism, namely, vandetanib and, less often, imatinib and sorafenib, also cause acute photosensitivity.

Protoporphyrins, elevated during treatment with docetaxel, may also be responsible for photosensitivity.

Other porphyrins, namely, uroporphyrins, were increased in a case of photosensitivity from voriconazole associated with porphyria cutanea tarda, although voriconazole induces mostly pseudoporphyria with normal porphyrin levels.

Increased endogenous retinoids were explored as a possible cause of voriconazole photosensitivity, but this was not proved, although exogenous retinoids increase photosensitivity from this antifungal.

A decrease in defensive mechanisms, with reduced vitamin PP (niacinamide), may also contribute to vemurafenib photosensitivity.

Drug Photoallergy

In photoallergy, the energy of the photon transforms the drug into a stable photoproduct or enhances its combination with an endogenous peptide, forming a hapten or an antigen. Dendritic cells will uptake this antigen and combine it with HLA molecules, and in an adequate environment in skin-draining lymph nodes (cytokines/chemokines and HLA and co-stimulatory molecules), they stimulate and, eventually, sensitize naïve T cells. As in allergic contact dermatitis, drug-specific T cells will be mostly responsible for the effector response.

Mechanisms to explain how drugs enhance cutaneous LE, particularly the subacute variant, are not completely understood. Drugs may enhance UV-induced expression of the Ro/SSA antigen on the surface of keratinocytes and may interfere with apoptosis or cytokine production, promoting photosensitivity and the development of skin lesions in susceptible individuals.

Drug-Induced/Drug-Enhanced Photocarcinogenesis

Apart from the capacity to generate free radicals and cell death responsible for acute phototoxicity, several phototoxic substances, like psoralens, chlorpromazine, fluoroquinolones and ketoprofen, also enhance chromosomal damage in the presence of UVR, as shown both in *in vitro* and *in vivo* studies (Ray et al. 2013). These drugs are, therefore, photogenotoxic, photomutagenic and, consequently, photocarcinogenic. Moreover, this type of DNA aggression is also usually associated with photoimmunosuppression which further enhances photocarcinogenesis.

Epidemiological studies, reported since 1999, called the attention to the association between actinic keratosis and the exposure to potentially photosensitizing drugs (Placzek et al.1999), and

recent reports reinforce this association, namely, for diuretics and cardiovascular drugs, even if patients do not develop acute signs of photosensitivity (Jensen et al. 2008; Traianou et al. 2012). Nonmelanoma skin cancer (NMSC) and melanoma are also increased in humans chronically exposed to photoactive drugs, namely, psoralens, voriconazole and vemurafenib (Miller et al. 2010; Rinderknecht et al. 2013; Stern et al. 2012).

DNA damage in the presence of UVR and drugs may not be the only mechanism of voriconazole- or vemurafenib-enhanced photocarcinogenesis. Activation of alternative oncogenic intracellular pathways due to BRAF inhibition in vemurafenib and previous immunosuppression in voriconazole-treated patients may also contribute to enhancing carcinogenesis.

Drug Photosensitivity: Phototoxicity Versus Photoallergy

Although mechanisms involving T-cell-mediated photoallergy and nonspecific acute phototoxicity are well individualized, their participation in each case of drug photosensitivity is often more complex. Except for a few drugs, as piroxicam, which do not have an intrinsic phototoxic potential and induce only photoallergy, most substances can induce both photoallergic and phototoxic reactions.

In theory, in the clinical setting, it is easy to differentiate photoallergy from phototoxicity, but there are many overlapping aspects.

Classically, photoallergy develops only in a limited number in individuals and needs previous sensitization but occurs also with cross-reactive chemicals. It is not dose dependent, develops on low UV dose and appears as eczema that can spread to non-exposed sites, and on skin biopsy, there are mainly T-cell infiltration, spongiosis and vesicles. Phototoxicity is more frequent, develops in every individual and, as long as enough photosensitizer and sun exposure are simultaneously present, it occurs on a first contact with no particular aggravation on further contacts. It is not associated with cross-reactions, presents mainly as well-demarcated erythema, exclusively on sun-exposed areas (mimicking sunburn), resolves with hyperpigmentation and apoptotic keratinocytes (sunburn cells) are abundant on histology (Table 23.1).

These are the two polar aspects of photosensitivity, but many molecules may induce both phototoxic and photoallergic reactions, and, in the same patient, aspects that resemble phototoxicity may coexist with others that suggest photoallergy.

The highly phototoxic furocoumarins, contained in plant extracts ingested or used topically in "folk medicine" or during photochemotherapy, can induce photoallergy in some individuals

Table 23.1 Distinction between phototoxicity and photoallergy

	Phototoxicity	Photoallergy
Frequency	High	Low
Latency period/sensitization	No	Yes
Doses of UV/photosensitizer	High	Low
Cross-reactions	No	Yes
Morphology of lesions	Sunburn, polymorphic	Eczema, erythema multiforme
Sharp limits	Yes	No
Covered areas	Not involved	Possibly involved
Resolution	Quick[a]	May recur, persistent reactors
Residual hyperpigmentation	Yes	No
Histology	Sunburn cells	Eczema
Pathomechanism	DNA/cell damage	Type IV hypersensitivity
	ROS/inflammation	Photoproduct

[a]This relates only to the acute phototoxic reaction, but late effects as photoaging and photocarcinogenesis may also occur

(skin lesions developing at very low concentrations of psoralens and UV light). Also, phototoxic drugs like promethazine and lomefloxacin can induce photoallergy.

Very probably, photoallergens, as photoactive molecules, may also have some inherent phototoxic potential, like contact allergens that have some "irritant" capacity. In allergic contact dermatitis, most contact allergens induce "danger signals" that are recognized by innate receptors in skin cells and awaken the adaptive immune system, promoting sensitization. An innate inflammatory reaction generated in skin, in the presence of photoactive molecules and UVR, can also act as the "danger signal" necessary to initiate the sensitizing process.

Although phototoxicity can occur on a first contact and photoallergy needs previous sensitization, individuals previously sensitized to a structurally similar molecule can develop the reaction on a first exposure. This occurs in individuals with contact allergy to thiomersal and its moiety, thiosalicylic acid, who develop photoallergy to piroxicam on the first drug intake. Upon UVA irradiation, piroxicam is photodecomposed into a molecule antigenically and structurally similar to thiosalicylic acid that is responsible for the photoallergic reaction (Serra et al. 2008).

Also, patients with contact allergy to perfumes (cinnamic alcohol), octocrylene or benzophenones may have photoallergic contact dermatitis from ketoprofen on a first exposure or vice versa, as there are conformational similarities between these molecules.

Phototoxicity is considered to occur in every patient, as long as enough chromophore and sun are present at the same time, but even in drug phototoxicity, there are particularly susceptible individuals, even though mechanisms underlying this susceptibility have not been characterized.

Clinical Presentation

The clinical patterns of systemic drug photosensitivity vary from urticaria through eczema or subacute LE up to vitiligo-like lesions or NMSC. They can be very typical as in acute exaggerated sunburn, but sometimes, the diagnosis or even the suspicion of drug photosensitivity is not so obvious (Table 23.2).

Skin reactions can occur immediately after sun exposure in vemurafenib-induced photosensitivity, but skin lesions may be delayed 1 or 2 days in most phototoxic or photoallergic contact dermatitis or systemic photoallergy, several days or weeks in pseudoporphyria or subacute LE or even years in skin cancers associated with a long exposure to the sun and the photoactive drugs.

In systemic drug photosensitivity, the reaction usually involves, in a symmetric distribution, the face and forehead, the V-shaped area of the neck and upper chest, dorsum of the hands and forearms. Shaded areas in the face (upper eyelids, upper lip, deep wrinkles) are usually spared (Fig. 23.1) as well as retroauricular areas, submandibular areas (Fig. 23.2) and areas covered by the beard or scalp hair. In more extensive sun exposure, large body folds, like the axillae, groins, finger webs and areas covered by clothing or other accessories (watch strip, shoes) are also usually spared. Involvement of the shaded areas suggests an airborne dermatitis, which may occur in occupational exposure to photoactive drugs, in nurses and caregivers who crash tablets or during drug manufacture.

A different pattern in the distribution of skin lesions can occur when sun exposure is asymmetric, as in car drivers who only expose the left

Table 23.2 Clinical patterns of photosensitivity

Predominant in phototoxicity	Predominant in photoallergy
Exaggerated "sunburn"	Urticaria in sun-exposed area
Pseudoporphyria	Acute or subacute eczema
Photoonycholysis	Cheilitis
Hyperpigmentation	Erythema multiforme-like
Hypopigmentation (vitiligo-like lesions)	Lichenoid reactions
Telangiectasia	Subacute or chronic lupus erythematosus
Purpura	
Pellagra-like reactions	
Actinic keratosis and squamous cell carcinoma	

Fig. 23.1 Acute phototoxicity from amiodarone that mimics sunburn and spares the deep facial wrinkles

Fig. 23.2 Photosensitivity from systemic piroxicam, sparing the shaded submandibular area

Fig. 23.3 Photosensitivity from voriconazole with severe cheilitis and lip erosions

arm. Sometimes, in systemic photosensitivity, the lower lip is mainly or almost exclusively involved (Fig. 23.3), because of its higher exposure and, very probably, because the corneal layer is thinner and, therefore, more prone to photosensitivity.

In photoallergic or phototoxic contact dermatitis from topical drugs, lesions are coincident with the area of drug application and concomitant sun exposure, but distant lesions can occur in areas of accidental contact, as in a contralateral limb (kissing faces of the legs), or in areas of inadvertent spread by the hands or contaminated objects. Cases of connubial dermatitis have been described, mainly for ketoprofen and benzydamine (Devleeschouwer et al. 2008. When used in the mouth these NSAIDs induce mostly lip and chin dermatitis (Conti et al. 2012). Some topical drugs can be considerably absorbed through the skin, and lesional distribution can be similar to systemic photosensitivity.

Acute Patterns of Drug Photosensitivity

Immediate Reactions

Immediate urticarial reactions, like photocontact urticaria, have been described with chlorpromazine (Lovell et al. 1986) and with 5-aminolevulinic acid used in photodynamic therapy (Kerr et al. 2007).

Some phototoxic drugs, like amiodarone and benoxaprofen (already removed from the market), induce immediate prickling and burning with transient erythema.

Immediate burning upon sun exposure followed by well-limited painful oedema and erythema during a few days, mimicking erythropoietic porphyria, is being described in more than 50 % of patients under vemurafenib treatment for metastatic melanoma (Rinderknecht et al. 2013). Photosensitivity can be highly limitative but can be prevented by sun avoidance or sun protection, extending to the long UVA.

Acute Photosensitive Dermatitis

Exaggerated sunburn that develops within 12–24 h of sun exposure is the main presentation of drug phototoxicity (Fig. 23.1). Non-pruritic erythema with sharp limits can be associated with vesicles and bullae and progress to desquamation in large epidermal sheets within the next days and, thereafter, to residual hyperpigmentation.

In acute drug photoallergy, confluent or non-confluent eczematous lesions or erythema multiforme-like lesions on photoexposed sites (Fig. 23.2), with frequent extension to covered areas, are mostly observed. In the case of photoallergy to piroxicam, pompholyx is often associated with non-confluent papular or vesicular facial lesions (Serra et al. 2008).

Subacute Patterns of Drug Photosensitivity

Photosensitivity may develop within days or weeks after exposure to the drug and the sun. Some clinical patterns evoke mainly a phototoxic reaction, like pseudoporphyria, photoonycholysis, hyper- or hypopigmentation, telangiectasia and purpura, whereas annular lesions may suggest a drug-induced cutaneous subacute LE.

Pseudoporphyria

Drug-induced pseudoporphyria resembles porphyria cutanea tarda or pseudoporphyria associated with haemodialysis, both clinically and on histopathology (bullae formation below the lamina densa). It develops within weeks to months as chronic skin fragility with flaccid bullae on non-inflamed exposed skin, occasionally progressing to milia. Pseudoporphyria occurs in individuals with no inborn error in porphyrin metabolism and no increase of endogenous porphyrins, although some drugs like voriconazole may transiently increase uroporphyrin levels.

Pseudoporphyria was initially described with nalidixic acid, furosemide and naproxen, predominantly in children (Ferguson 1999), but more recently, many other drugs have been associated with this phototoxic reaction: celecoxib (Cummins et al. 2000), ciprofloxacin (Schmutz et al. 2008), voriconazole, torasemide (Pérez-Bustillo et al. 2008), metformin (Lenfestey et al. 2012), finasteride (Santo Domingo et al. 2011) and imatinib (Timmer-de Mik et al. 2009). Pseudoporphyria represents a typical phototoxic reaction where the drug, as the uroporphyrin in the hereditary disease, probably induces phototoxicity through the production of singlet oxygen.

Photoonycholysis

Photoonycholysis is a typical pattern of phototoxicity. It presents as a half-moon distal onycholysis of one or several nails, most often as the single manifestation of phototoxicity (Fig. 23.4). It appears late (2–3 weeks after drug intake and sun exposure) and is sometimes preceded by pain in the nail apparatus. It occurs mainly with tetracyclines (demethylchlortetracycline or doxycycline), psoralens and fluoroquinolones (Baran and Juhlin 2002).

There is no definite explanation for the single involvement of the nail: the nail bed, relatively unprotected from sunlight with less melanin, and the nail plate, working as a lens to concentrate the

Fig. 23.4 Photoonycholysis from doxycycline

UVR, may enhance the inflammation and induce detachment of the nail plate from the nail bed.

Drug-Induced Cutaneous Lupus Erythematosus

In a recent multicentre database analysis of the European Society of Cutaneous Lupus Erythematosus, drug-induced cutaneous LE was shown to represent 6 % among 1,002 patients with cutaneous lesions and 13.2 % of those with the subacute variant of cutaneous LE (Biazar et al. 2013). This form of drug-induced subacute cutaneous LE is usually associated with photosensitivity and mild systemic manifestations of LE. More than 80 % of patients have anti-Ro/SSA autoantibodies, the hallmark of photosensitivity in LE.

Cutaneous lesions usually develop weeks or months after drug exposure (medium of 6 weeks) and can resolve on drug suspension, without scarring. They are annular or papulosquamous lesions, clinically and on histopathology similar to the idiopathic form of cutaneous subacute LE. Lesions are localized in photoexposed areas (face, neck, upper chest and arms) but also in usually UV-shaded areas. Erythema multiforme-like lesions or, seldom, chronic cutaneous LE with more infiltrated plaques on the face or V of the neck can also be related with drugs.

Subacute cutaneous LE was described initially in association with thiazide diuretics, calcium channel blockers, ACE inhibitors and more recently terbinafine, the drug associated with the highest odds ratio for this adverse event, and a long list of other drugs, namely, proton pump inhibitors, antiepileptics, TNF-alfa antagonists and anticancer taxanes, paclitaxel and docetaxel (Grönhagen et al. 2012; Lamond et al. 2013).

Dyschromia

Hyperpigmentation usually follows acute phototoxicity due to the residual melanocytic hyperpigmentation. In rare occasions, like in flutamide-induced photosensitivity, vitiliginous lesions with sharp limits occur after the acute reaction (Gonçalo et al. 1999). Dyschromia with solar lentigines and other signs of photoaging have been recently described with voriconazole and vandetanib (Malani and Aronoff 2008).

Dyschromia from the accumulation of the photoactive drug or its metabolites in the dermis occurs in a smaller percentage of patients after acute phototoxicity from amiodarone, minocycline or phenothiazines. Some patients with lower phototypes also develop a golden-brown, slate grey or bluish colour on sun-exposed areas that persists longer after stopping the drug than residual melanocytic hyperpigmentation.

Other Clinical Patterns of Subacute Photosensitivity

Telangiectasia as a manifestation of photosensitivity has been reported with calcium channel blockers. A telangiectatic pattern of photoaging with lesions mainly in the lateral folds of the neck, sparing the shaded skin under the chin, is frequently observed in patients chronically exposed to the sun and photoactive drugs. In rare cases, petechial purpura with sharp limits on the transition to the shaded areas was described with ciprofloxacin (Urbina et al. 2006).

Pellagra is associated with the prolonged use of isoniazid that needs niacin for its metabolism, and pellagroid reactions were reported with the anticancer agents, like 6-mercaptopurin and 5-fluoruracil.

Delayed and Late Effects of Photosensitivity

Patients that are chronically exposed to photoactive drugs can also develop accelerated photoaging, actinic keratosis and skin cancers, which, at least partially, can be explained by the photogenotoxic effect of some drugs.

Accelerated skin photoaging occurs with voriconazole, including in children, and presents as dyschromia, lentigines and actinic keratosis.

There is a consensual agreement on the dose-dependent increased risk of skin cancers after long-time therapeutic exposure to PUVA phototherapy. Apart from psoralens, drugs like naproxen, chlorpromazine and the fluoroquinolones, particularly lomefloxacin, augment DNA aggression induced in vitro by UV and increase epidermal neoplasia in animals

(Klecak et al. 1997). Also, in humans, potentially photosensitizing drugs, like diuretics and cardiovascular drugs, are being associated with increased cutaneous precancerous lesions, and recent reports correlate human short-term exposure (weeks/months) to voriconazole and vemurafenib with an increased risk of developing actinic keratoses, keratoacanthoma-like NMSC and, even, malignant melanoma.

Main Topical and Systemic Drugs Causing Photosensitivity

There is a large and increasing list of drugs inducing photosensitivity (Table 23.3), either when used topically or upon systemic exposure. Drugs, like piroxicam, induce photosensitivity both by topical and systemic exposure, whereas other drugs, like ketoprofen, frequently induce photoallergic contact dermatitis, whereas upon systemic exposure the cutaneous concentration is usually too low to induce photosensitivity.

Drugs manipulated in an occupational setting can induce photosensitivity: carprofen, an NSAID for animal use, induced photoallergic contact dermatitis in workers manufacturing the drug (Kiely and Murphy 2010), and photosensitivity has been reported in nurses and family members who smashed the tablets of chlorpromazine to give to their patients/relatives.

Topical drugs are, by far, responsible for most positive photopatch tests in studies from the south of Europe and in the recent European multicentre photopatch test study (The European Multicentre Study PhotopatchTest (EMCPPTS) Taskforce 2012). Main topical drugs that cause contact photosensitivity are the NSAIDs, namely, ketoprofen and other arylpropionic acid derivatives, etofenamate, benzydamine and phenothiazine derivatives used as antihistamines or muscle relaxants.

The main systemic drugs inducing photosensitivity are antimicrobials, particularly tetracyclines, fluoroquinolones, sulphonamides and antifungals, NSAIDs, phenothiazines and cardiovascular drugs.

Table 23.3 Main drugs causing exogenous photosensitivity

1. Antimicrobials
Tetracyclines[a] (doxycycline, minocycline)
Sulphonamides (sulfamethoxazole)
Fluoroquinolones (lomefloxacin,[a] ciprofloxacin[a])
Voriconazole,[a,b] griseofulvin[a]
Efavirenz, tenofovir
Faldaprevir
2. Nonsteroidal anti-inflammatory drugs (NSAIDs)
Arylpropionic acids:
Ketoprofen[c,d], tiaprofenic acid,[a] suprofen
Naproxen, ibuprofen, ibuproxam, carprofen[d]
Piroxicam[c,d], etofenamate[c,d]
Benzydamine[d]
Celecoxib, diclofenac[d]
Azapropazone, phenylbutazone, indomethacin
3. Phenothiazines
Chlorpromazine,[d] thioridazine
Promethazine,[c,d] isothipendyl chlorhydrate[d]
Chlorproethazine[c,d]
4. Targeted therapies
Vemurafenib[b]
Imatinib, vandetanib
5. Antidepressants
Clomipramine, imipramine, sertraline
6. Cardiovascular drugs
Amiodarone,[a] quinidine
Furosemide, torasemide and thiazide diuretics
7. Anticancer agents
Paclitaxel, docetaxel
Methotrexate, 5-fluoruracil
Dacarbazine
8. Miscellaneous
Psoralens[b]
Fenofibrate, simvastatin
Sulfonylureas, sitagliptin, metformin
Flutamide, finasteride
Pirfenidone
Porphyrin analogues for photodynamic therapy
Retinoids (isotretinoin)
9. Plants (used as drugs)[a]
Hypericum perforatum (St. John's wort)
Ruta graveolens (common rue)[d]
Kava extracts

[a]Mainly phototoxic
[b]An increase of actinic keratosis, NMSC and, occasionally, melanoma have been related with these drugs
[c]Mainly photoallergic
[d]Often also from topical exposure or airborne exposure, mainly in occupational settings

Antimicrobials

Tetracyclines

Systemic tetracyclines, particularly doxycycline and minocycline, are highly phototoxic, induce photoonycholysis and pseudoporphyria and, the latter, can also induce a bluish persistent pigmentation (Vassileva et al. 1998). A case of photoallergic reaction with positive photopatch tests was, nevertheless, described with doxycycline.

Quinolones

The fluoroquinolones induce phototoxic reactions, in some cases presenting as pseudoporphyria, as initially described for the first quinolone antibiotic, nalidixic acid. Ciprofloxacin was also responsible for purpura in photoexposed areas. Phototoxicity is particularly important and frequent (4–15 % of treated patients) with fleroxacin, lomefloxacin, sparfloxacin and pefloxacin and less frequent with ciprofloxacin, norfloxacin, ofloxacin and enoxacin (Ferguson 1999). The recommendation to take the drug by the end of the day, therefore reducing drug concentrations in the circulation and in the skin during midday, can reduce this phototoxic reaction.

Although in vitro and in vitro tests prove the high phototoxic potential of fluoroquinolones, photoallergy has also been reported with lomefloxacin and enoxacin. Reactivity in photopatch tests and in photoprovocation tests with very low UVA doses, cross-reactions with other fluoroquinolones (ciprofloxacin and flerofloxacin), positive lymphocyte stimulation tests and identification of drug-specific Th1 cells that recognize skin cells combined with UV-irradiated fluoroquinolone document photosensitivity is immune-mediated (Tokura et al. 2001).

Fluoroquinolones also photosensitize DNA and are, therefore, photomutagenic and photocarcinogenic. A young male patient from our hospital on long-term ciprofloxacin therapy for multiresistant tuberculosis developed chronic photosensitivity and highly aggressive recurring and metastatic squamous cell carcinomas of the face (personal experience).

Sulphonamide and Derivatives

Sulphonamide antibacterials, as well as sulpha drug analogues (thiazidic diuretics, hypoglycaemic sulfonylureas and celecoxib) and dapsone (diaminodiphenylsulfone), have been reported to cause photosensitivity within the spectrum both of UVB and UVA. This side effect is not so frequent with cotrimoxazole (Vassileva et al. 1998).

Antifungals

Griseofulvin is a known phototoxic drug and can aggravate lupus erythematosus, as the more recent antifungal, terbinafine, which induces subacute lupus erythematosus in patients with anti-Ro/SSA antibodies.

Voriconazole, used mainly in patients with invasive aspergillosis or refractory candidiasis, therefore with immunosuppression from an underlying disease or from immunosuppressive drugs, is associated with severe photosensitivity, an adverse effect that is not extensive to other azole antifungals. Photosensitivity develops in susceptible patients, including children. Apparently it does not depend on the highly variable individual pharmacokinetic profile of the drug and its main metabolite (n-oxide voriconazole), on the drug-metabolizing capacity or on increased levels of endogenous porphyrins or retinoids. Cutaneous reaction is dependent on the broad UVA, extends to the visible solar spectrum, develops within 1–16 weeks of treatment and manifests as a burning sensation soon after sun exposure, with a sunburn-like reaction, cheilitis and erosions of the lower lip (Fig. 23.3), or as pseudoporphyria (Riahi and Cohen 2011). On relative short exposures, photoaging with solar lentigines and actinic keratosis develops, and these soon progress to multifocal invasive squamous cell carcinoma (Morice et al. 2010). Malignant melanoma has also been described in these patients.

Antiviral Drugs

Photosensitivity from antiviral drugs used in the treatment of HIV or HCV infection has been reported. Efavirenz induced mostly photodistributed papulosquamous annular lesions within a few

days or weeks of treatment. The combination of faldaprevir and deleobuvir caused photosensitivity in more than a quarter of patients involved in controlled clinical trials (Zeuzem et al. 2013).

Nonsteroidal Anti-inflammatory Drugs

Benoxaprofen, marketed between 1980 and 1982, called the attention to photosensitivity from this class of drugs, and this adverse event was reported with other arylpropionic derivatives (carprofen, naproxen, suprofen, tiaprofenic acid, ketoprofen and ibuprofen) and NSAIDs from other groups (azapropazone, diclofenac, piroxicam, phenylbutazone, celecoxib, benzydamine and etofenamate). The in vitro and in vivo phototoxic potential has been documented particularly for tiaprofenic acid, with phototoxic reactions in more than half patients tested with tiaprofenic acid (5 % pet) and 5 J/cm^2 of UVA (Gonçalo et al. 1992), but in other studies tiaprofenic acid was typically photoallergic (Pigatto et al. 1996), therefore calling the attention to the concomitancy of both patterns of photosensitivity with the same drug.

Most topically applied NSAIDs are absorbed through the skin and can cause distant lesions, resembling systemic photosensitivity. Benzydamine, widely used in the oral or genital mucosa, causes photosensitivity at distant sites. When used in the mouth, benzydamine can induce cheilitis and chin dermatitis as a manifestation of photoallergy, and when used in a vaginal solution, hand dermatitis has occurred.

Ketoprofen

Ketoprofen, particularly when used topically in a gel formulation, is responsible for severe photoallergic reactions, often with oedema, bullae or erythema multiforme-like reactions, extending well beyond the area of application. Reactions may recur on sun exposure with no further drug application, as the drug or its metabolites persist in the skin for several days (>2 weeks) (Sugiura et al. 2000). There are also cases of connubial or by proxy contact dermatitis, namely, from the contaminated hands of the dance teacher, reactions induced by contact with contaminated objects, even clothes after being washed, or from exposure to cross-reactive chemicals, like benzophenones or octocrylene in sunscreens or benzophenones from magazine inks.

Although such a high frequency might suggest phototoxicity, the clinical pattern with erythema multiforme, positive lymphocyte stimulation tests with ketoprofen-photomodified cells, animal studies with absence of phototoxic potential, the capacity to photosensitize and transfer photoallergy by $CD4^+$ and $CD8^+$ T cells, in vitro activation and maturation of antigen-presenting cells by ketoprofen and UVA and characterization of a stable photoproduct – 3-hydroxy-ethyl-benzophenone – highly support a photoallergic reaction (Hino et al. 2008).

Cross-reactions occur between arylpropionic acid derivatives that share the benzophenone structure, namely, tiaprofenic acid and suprofen, and are not extensive to naproxen or ibuprofen. Cross-reactions are also common with the benzophenone UV filters, mainly oxybenzone, the UV filter octocrylene and the systemic hypolipemic agent, fenofibrate, that also induces systemic photosensitivity with cross-reactions with ketoprofen.

Patients with photoallergic contact dermatitis from ketoprofen have positive photopatch tests with 1 % ketoprofen, even if the patch is applied only for 1 h, and apart from the frequent cross-reactions in the photopatch tests (oxybenzone, octocrylene, fenofibrate), more than half of the patients also have positive patch tests to perfume mix I, particularly cinnamic alcohol (Pigatto et al. 1996). Moreover, many patients with contact allergy to cinnamic alcohol have positive photopatch tests to ketoprofen, a relation which is still not completely explained.

The analogues of ketoprofen, piketoprofen and dexketoprofen have a similar behaviour, in which concerns photosensitivity. A new topical formulation of ketoprofen, in plaster, may reduce the UV exposure of the drug but does not completely hinder this side effect of ketoprofen.

Piroxicam

Piroxicam is a known photosensitizer since the 1980s. Although there was some initial enigma around this photoallergy that usually developed with the first intakes of piroxicam, soon a relation was established with previous contact sensitivity to thiomersal (Cirne de Castro et al. 1991) and one of its main sensitizing moieties, thiosalicylic acid. Actually, upon low UVA irradiation, piroxicam decomposes and gives rise to a stable photoproduct structurally similar to thiosalicylic acid which is responsible for photosensitivity: in vitro UVA-irradiated solutions of piroxicam induce positive patch tests in patients with photosensitivity and individuals with positive patch tests to thiosalicylic acid, and animals sensitized by thiosalicylic acid develop positive photopatch tests to piroxicam.

Photoallergy from piroxicam can occur both from topical application and systemic use. It is becoming less frequent as this NSAID is replaced by newer drugs but it is still observed in Southern Europe (Cardoso et al. 2009), and a few cases were still found in the recent European multicentre photopatch test study.

Systemic photosensitivity develops within 24–48 h as an acute eczema involving diffusely the whole face or, often, as scattered erythematous papules and vesicles on the face and dorsum of the hands and pompholyx.

These patients do not react, neither on photopatch nor on drug rechallenge, to tenoxicam, meloxicam or lornoxicam, as these oxicams do not share the thiosalicylate moiety. Nevertheless, cross-reactivity between piroxicam and these oxicams occurs regularly in fixed drug eruption.

Other Drugs as Photosensitizers

Systemic phenothiazines (chlorpromazine and thioridazine), typically phototoxic, can induce lichenoid lesions with residual pigmentation, but most recent cases of photoallergy to chlorpromazine have been reported in caregivers who smash the tablets (Cardoso et al. 2009).

Promethazine, a highly phototoxic drug still used as a topical antipruritic, often induces photoallergic contact dermatitis. Another phenothiazine derivate, also used as a topical antipruritic, isothipendyl chlorhydrate, caused photoallergy with a positive photopatch test to chlorpromazine. Chlorproethazine, another phenothiazine marketed for some time in France and the UK as Neuriplege® cream for muscle pain (Genevrier, Antibes, France), was a frequent cause of photoallergic contact dermatitis in these countries.

The antiarrhythmic amiodarone induces erythema and a bluish-grey hyperpigmentation in sun-exposed areas due to the accumulation of drug metabolites in the dermis (Ferguson et al. 1985) The list of drugs causing photosensitivity is very large and always increasing, namely, with the recent inclusion of new kinase inhibitors in oncology, vandetanib, imatinib and, particularly, vemurafenib. With this drug more about 50 % of patients suffer burning and oedematous erythema on sun exposure (UVA) due to increased protoporphyrins and develop actinic keratosis, keratoacanthoma and squamous cell carcinoma, often as early as 8 weeks after initiating therapy for metastatic melanoma.

"Folk" Drugs as a Cause of Photosensitivity

Sometimes patients use "folk" medicines, mostly based on plant extracts, some of them rich in photoactive furocoumarins, which induce topical or systemic photosensitivity.

Since the antiquity, these substances have been used in the treatment of vitiligo and, more recently, in PUVA photochemotherapy.

Very occasionally, systemic photosensitivity develops upon oral exposure to furocoumarin-rich plants or their extracts, namely, to "homemade" infusions of St. John's wort (*Hypericum perforatum L.*) or to extracts commercialized in some European countries and used as a folk drug to treat depression (Fig. 23.5). Also, these infusions are occasionally used topically as a "folk medicine" with impressive adverse effects, as in a report where an infusion of *Ruta graveolens*, applied topically to relieve pain in fibromyalgia just before going into the sun, induced severe sunburn with bullae (Arias-Santiago et al. 2009).

Fig. 23.5 Photosensitivity from consumption of infusion of *Hypericum perforatum* (St. John's wort)

Diagnostic Procedures in Drug Photosensitivity

Whenever a patient has a photosensitive eruption, a systematic inquiry for drugs should be conducted carefully.

Photopatch tests are indicated mainly for photoallergic contact dermatitis, but they can also be useful in the study of systemic drug photosensitivity. The recommended European baseline photopatch test series includes many drugs, namely, ketoprofen, etofenamate, piroxicam and benzydamine and also piketoprofen, dexketoprofen, ibuprofen, diclofenac, fenofibrate and chlorpromazine in the extended series (Gonçalo et al. 2013). Any other topical or systemic drug suspected of causing photosensitivity may be tested according to the general standardized procedures of photopatch testing. Briefly, allergens are applied in duplicate on the back, followed by skin irradiation of one of the sets of allergens at day 1 or day 2 with 5 J/cm2 of UVA, whereas the other set is shielded from light. Readings should be performed immediately after irradiation and also 48 and/or 72 h thereafter. Photopatch tests results have to be carefully interpreted. Positive reactions both in the irradiated and non-irradiated sites mean contact allergy that may be photoaggravated if the reaction is 1+ more in the irradiated site. A photopatch test is positive when erythema and papules covering the whole test area are observed only in the irradiated side. If the reaction is mainly erythema and oedema, without pruritus, exclusively limited to the test chamber area, with very sharp limits, begins shortly after irradiation, reaches its highest intensity by 24 h and regresses by 48/72 h (decrescendo reaction) with hyperpigmentation, it suggests a phototoxic reaction. A pruritic erythema with vesicles, diffuse limits extending beyond the chamber limit, increasing in intensity until 48/72 h after irradiation (crescendo reaction), suggests photoallergy. Often these patterns are not so typical, and the difficulties previously referred in the interpretation of clinical cases also occur in the interpretation of the photopatch tests.

In systemic photosensitivity, apart from photopatch tests, photoprovocation with irradiation after drug exposure or the calculation of the minimal UVA/B erythema dose when exposed to the drug and after drug withdrawal, may help identify the culprit.

In phototoxic reactions, both photopatch and photoprovocation tests are positive in the great majority of tested individuals; therefore, they are not particularly useful for confirming the aetiology of a phototoxic reaction, but they can disclose a hidden photoallergy.

General Principles of Treatment

Drug suspension and sun avoidance are recommended to resolve drug photosensitivity. When the drug is essential and life-saving, when there is no alternative drug or the alternative drug is not adequate, sun avoidance, protection from clothing and a broad-spectrum sunscreen that covers the UV spectrum of photosensitivity (mainly

within the UVA) may be adequate to improve photosensitivity. This protective effect of sunscreens can be helpful particularly in phototoxic reactions, as shown for voriconazole, vemurafenib and amiodarone. Broad-spectrum sunscreens may reduce both acute and long-term effects of photosensitivity, like photoaging and photocarcinogenesis, but they should always be associated with other sun-avoiding measures. Moreover, they should be recommended as preventive measures from the initiation of therapy with known photosensitive drugs. Nevertheless, it is important to recognize that chemical UV filters represent an important cause of contact photosensitivity, particularly in patients with previous dermatoses.

In cases of acute photoallergy from topical or systemic drugs, suspension of the culprit drug and sun avoidance will not resolve the skin lesions within a short time, and, therefore, active treatment may be necessary. Topical corticosteroids, in a formulation and potency adapted to the localization and severity of the dermatitis, may be prescribed for a few days. In severe reactions, as often observed with topical ketoprofen and systemic piroxicam, an additional short course of oral corticosteroids (24–32 mg of methylprednisolone, or equivalent, for a few days followed by a quick dose tapering) may be necessary to reduce acute symptoms and skin lesions.

In acute phototoxicity, presenting mainly as exaggerated acute sunburn, the efficacy of corticosteroids is highly questioned. Emollients and further photoprotection are advised for some time after resolution of acute photosensitivity.

Conclusion

Phototoxic, photoallergic and overlapping photosensitive reactions are still a frequent problem. They have a highly polymorphic clinical presentation, with different time courses and late consequences. Different responsible agents depend on geographic areas and, over time, depend on prescription habits. The dermatologist must be highly alert to search for a possible involvement of a drug in a photosensitive patient and try to confirm its contribution to photosensitivity. A correct questionnaire should be conducted and, although not so important in phototoxic cases, complementary tests including photopatch and photoprovocation tests may contribute to the final etiologic diagnosis. This is important in order to allow an adequate patient advice concerning further eviction of the photosensitizer and related chemicals.

Epidermolysis Bullosa

24

Maya El Hachem, Mauro Paradisi,
and Giovanna Zambruno

Key Points

- Epidermolysis bullosa is distinguished in:
  I. Inherited epidermolysis bullosa (EB)
  II. Acquired epidermolysis bullosa (EBA)
- Inherited epidermolysis bullosa (EB) is a heterogeneous group of genodermatoses, due to defects in epithelial adhesion and characterized by the development of mucosal and cutaneous bullous lesions, after minimal traumas.
- The new classification distinguishes four major groups, based on the site of blister formation: EB simplex (or epidermolytic: EBS), junctional EB (JEB), dystrophic (or dermolytic: DEB) EB, and Kindler syndrome.
- Many proteins are involved into the pathogenesis of all major EB types (plakophilin-1, desmoplakin, keratins 5 and 14, plectin, α6β4integrin, laminin-332, type XVII collagen, collagen VII, kindlin-1, etc.).
- Immunofluorescence and in some cases electron microscopy are necessary to identify the specific EB subtype.
- The prenatal diagnosis in families at risk of disease recurrence is possible through the molecular diagnosis; it could be performed when the mutation of the patient is already identified.
- The clinical pictures and course vary upon the EB type and subtype. The evolution is generally chronic; EBS, the evolution is chronic with improvement generally along the life; JEB, generalized severe (previously known as JEB-Herlitz), the clinical picture may be mild at birth and worsens dramatically in the first weeks/months of life; *severe generalized* recessive DEB (previously known as Hallopeau-Siemens RDEB) is the most important form because of multisystem involvement and the high risk to develop squamous cell carcinoma; other subtypes may be associated to extracutaneous abnormalities, e.g., *JEB with pyloric atresia* (JEB-PA), EBS-MD (EBS-muscular dystrophy).

- The treatment of EB patients requires a coordinated multidisciplinary approach. The management varies upon the age of the patient, the subtype of EB, the level of systemic involvement, and the complication.
- An adequate wound care is mandatory. The use of advanced dressings allows to delay the frequency of dressing change, in order to reduce pain and risk of infections and skin trauma. Caregivers should be trained specifically.
- Chronic wounds should be straightly followed in order to early detect carcinoma.
- Acquired epidermolysis bullosa (EBA) is a rare chronic autoimmune bullous disease of the skin and mucosa due to the formation of IgG autoantibodies directed against collagen VII.
- A genetic predisposition has emerged in some cases.
- The clinical diagnosis can be confirmed by ELISA, from IFD of salt-split skin and immunoelectron microscopy.
- Colchicine, dapsone, immunosuppressants, steroids, intravenous IgG and plasmapheresis, and rituximab are used as therapy with some success.

Definition and Epidemiology

Epidermolysis bullosa is distinguished in:

I. Inherited epidermolysis bullosa
II. Acquired epidermolysis bullosa

Inherited Epidermolysis Bullosa (EB)

Definition and Epidemiology

Inherited epidermolysis bullosa (EB) is a heterogeneous group of genodermatoses, due to defects in epithelial adhesion and characterized by the development of mucosal and cutaneous bullous lesions, after minimal traumas. Inheritance has a Mendelian pattern, autosomal dominant or recessive, depending on the forms. EB are rare diseases; epidemiological data are not homogeneous in all countries because of diagnosis and classification problems.

Table 24.1 The major epidermolysis bullosa types and subtypes

Major EB type	Major EB subtypes	Targeted protein (s)
EBS	Suprabasal EBS	Transglutaminase 5; plakophilin 1; desmoplakin; plakoglobin
	Basal EBS	Keratins 5 and 14; plectin; exophilin 5; bullous pemhigoid antigen 1

	RDEB	Collagen VII
Kindler syndrome	–	Fermitin family homolog 1 (kindlin-1)

From Fine et al. (2008, 2014)

Diagnostic criteria and classification of EB have been revised in 2008 and recently in 2014 by an international study group. These new revisions distinguish four major groups, based on the site of blister formation and proposed new nomenclature of some EB subtypes:

(a) EB simplex (or epidermolytic)
(b) Junctional EB
(c) Dystrophic (or dermolytic) EB
(d) Kindler syndrome

Each one is then subdivided into several subtypes as summarized in Table 24.1.

The major differences with the previous classification schemes are the inclusion of Kindler syndrome as a fourth major EB type, the subdivision of EBS into basal and suprabasal subtypes. In any case, this EB classification is not final and that further revisions are occurring.

Basic Concepts of Pathogenesis

Antigen mapping, ultrastructural images, and mutations identified until now, and their location contributed to understand that this group of

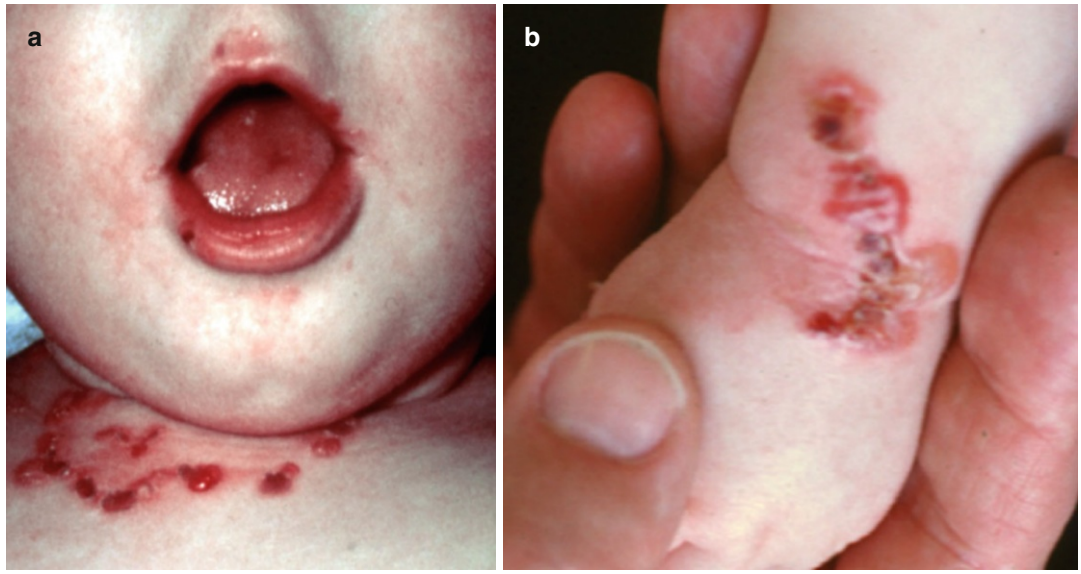

Fig. 24.1 (**a**, **b**) Hemorrhagic herpetiformis blisters in Dowling-Meara EB

diseases is the result of a defect in the adherence of the epithelium into the basement membrane zone. Although phenotype-genotype correlation is variable within the major EB types, the type of mutation, its location may suggest in some cases, even partially, the severity of different clinical manifestations. In Table 24.1 are listed the identified proteins involved into the pathogenesis of all major EB types.

Clinical Presentation

The clinical pictures and course vary upon the EB type and subtype.

EB Simplex (EBS)

Until now different subtypes have been identified. We limit the description to the particular or more frequent forms.

Localized EBS, known as EBS Weber-Cockayne, is the most common form of EBS. It is not present at birth and appears with the start of walking or during military service. The blisters are serious or rarely hemorrhagic and localized in particular at palms and soles; they usually heal without scarring. Teeth are normal; occasionally some nails may present dystrophies; oral mucosa involvement is transient. The association with hyperhidrosis is frequent, which contributes to the characteristic worsening of lesions in the summer.

EBS, generalized severe (previously known as EBS, Dowling-Meara) (Fig. 24.1a, b), known as EBS herpetiformis, appears at birth, and the blisters assume later on a characteristic herpetiform pattern, which are generally hemorrhagic affecting the entire body surface. The oral mucosa is frequently involved; in rare cases, it can spread to the tracheolaryngeal and esophageal mucosa. Nail dystrophy is usually observed. In the first year of life, the extensive involvement may, in rare cases, lead to systemic complications. Subsequently, there is a significant improvement of the clinical picture and development of palmoplantar hyperkeratosis. Patients with EBS-gen sev have a risk of developing basal cell carcinomas in adulthood.

EBS, generalized intermediate (previously known as EBS, Kobner), is characterized by blisters arising in particular at sites of friction. It appears usually at birth or in the first months of life. Nail dystrophies and lesions of the oral mucosa are mild and not constant; sometimes there are calluses and also palmoplantar keratoderma. The evolution is favorable, with an improvement in the clinical picture after puberty.

Table 24.2 Classification of EB simplex (EBS)

EBS major types	EBS subtypes
Suprabasal	Acral peeling skin syndrome (APSS)
	EBS superficialis (EBSS)
	Acantholytic EBS (EBS acanth)
	Skin fragility syndromes
	Desmoplakin deficiency (EBS-desmoplakin; skin fragility–wooly hair syndrome)
	Plakoglobin deficiency (EBS-plakoglobin; skin fragility–plakoglobin deficiency)
	Plakophilin deficiency (EBS-plakophilin; skin fragility–ectodermal dysplasia syndrome)
Basal	EBS, localized (EBS-loc)
	EBS, generalized severe (EBS-gen sev)
	EBS, generalized intermediate (EBS-gen intermed)
	EBS with mottled pigmentation (EBS_MP)
	EBS, migratory circinate (EBS-migr)
	EBS, autosomal recessive K14 (EBS-AR K14)
	EBS with muscular dystrophy (EBS-MD)
	EBS with pyloric atresia (EBS-PA)
	EBS-Ogna (EBS-Og)
	EBS, autosomal recessive-BP230 deficiency (EBS-AR BP 230)
	EBS, autosomal recessive-exophilin 5 deficiency (EBS-AR exophilin 5)

From Fine et al. (2008, 2014)

EBS with mottled pigmentation is rare; it is characterized by generalized bullous lesions associated with hyperpigmented macules, localized mainly at the trunk and extremities. Also, this form tends to improve spontaneously over time.

EBS with muscular dystrophy is characterized by an onset of generalized blisters at birth and associated with muscular dystrophy, which appears between the first year and the fourth decade of life and with a progressive clinical course. The cutaneous manifestation tends to resolve with atrophic scars and milia. Dystrophic nails and focal keratoderma of the palms and soles may be associated. Extracutaneous involvement is frequent: dental abnormalities, blistering in the oral cavity, inspiratory stridor, and breathing difficulties. The prognosis is related to the evolution of muscular dystrophy.

EBS, migratory circinate is very rare and characterized by migrating areas of erythema with multiple vesicles and small blisters at the advancing edge. The lesions heal with brown pigmentation without scarring (Table 24.2).

Junctional EB (JEB)

JEB, generalized severe (previsouly known as JEB_Herlitz) is characterized by the congenital presence of blisters and extensive erosions, on the skin and mucous membranes. The clinical picture may be mild at birth and worsens dramatically in the first weeks/months of life. Typical findings are exuberant granulation tissue formation in particular around nail folds and the involved site: perioral and periorbital areas, nose, shoulders, and buttocks. The involvement of mucous membranes may affect the entire respiratory, digestive, and less commonly genitourinary tract. The patients may require tracheostomy. The failure to thrive and severe infectious and respiratory complications are often responsible for the fatal outcome, occurring frequently within the first year of life.

JEB, generlaized intermediate (previously known as as JEB, non-Herlitz, generalized) is characterized by a clinical aspect similar to JEB, generalized severe but of lesser severity and therefore in most cases compatible with life. Skin blistering is generalized healing with atrophic scars or, less commonly, with exuberant granulation tissue. Nail dystrophy, hair loss, oral and nasal mucosa lesions, and teeth abnormalities are frequently present. Chronic anemia and growth delay are frequent. The course is relatively benign, with a gradual improvement up to adulthood. Adult patients with non-Herlitz JEB should be followed accurately for the increased risk of developing squamous cell carcinomas.

JEB with pyloric atresia (JEB-PA) appears generally at birth with widespread cutaneous and mucosal blistering and complete congenital pyloric. Congenital absence of skin (aplasia cutis congenita) is present in approximately 20 % of

cases. Nail dystrophy and dental abnormalities are constant features. This JEB type leads in most cases to early death; prognosis depends first of all on the prompt surgical correction of pyloric atresia. In some patients of this latter group, skins lesions improve gradually.

JEB, localized is characterized by localized disease, less severe than Herlitz and generalized JEB. It manifests at birth or soon thereafter with skin blistering on the hands, feet, lower legs, and face. Sometimes, mild nail dystrophy and dental abnormalities are associated (Table 24.3).

Dystrophic EB (DEB)

RDEB, generalized severe (previously known as Hallopeau-Siemens RDEB) is the most important form because of multisystem involvement. It appears at birth with widespread blisters and/or erosions of the skin and mucous membranes (Fig. 24.2). Nail involvement causes generally the permanent loss of nail plates of both hands and feet. The most affected areas are those subject to minimal traumas changing therefore with age. The recurrent lesions heal with milia formation and retracting scars: pseudosyndactyly, flexion contractures of the interphalangeal, metacarpophalangeal, and wrist joints, fusion of fingers and toes ("mitten deformities"), ankylosis of the limbs, scarring alopecia, chronic gingivitis, dental caries and enamel defect, microstomia, ankyloglossia, esophagus stricture, anal and perianal erosions, urogenital mucosa involvement, corneal opacity, and pannus formation (Fig. 24.3a, b). Most patients also present delayed puberty, osteopenia, osteoporosis, constipation, severe growth retardation, refractory anemia, hypoalbuminemia, and skin infections, which can cause post-streptococcal glomerulonephritis. Life expectancy and quality of life are significantly reduced. The most frequent cause of death remains squamous cell carcinomas that occur in areas of chronic skin wounds and scars and more often from the second-fourth decade of life, with frequent regional and distant metastases.

RDEB, generalized intermediate variant is the most common subtype of RDEB with onset at birth or in the first days of life and highly variable severity of the cutaneous and mucosal involvement. In some patients, the scarring phenomena can lead to a certain degree of pseudosyndactyly and loss of nail plates. Mucosal lesions are always present and affect the oral cavity, usually without the development of microstomia and

	JEB, late onset (JEB-LO)
	JEB with respiratory and renal involvement (JEB-RR)
JEB, localized	JEB, localized (JEB-loc)
	JEB, inversa (JEB-inv; JEB-I)
	JEB-LOC syndrome

From Fine et al. (2008, 2014)

Fig. 24.2 A newborn with large, multiple, painful, and hemorrhagic blisters, affected by RDEB

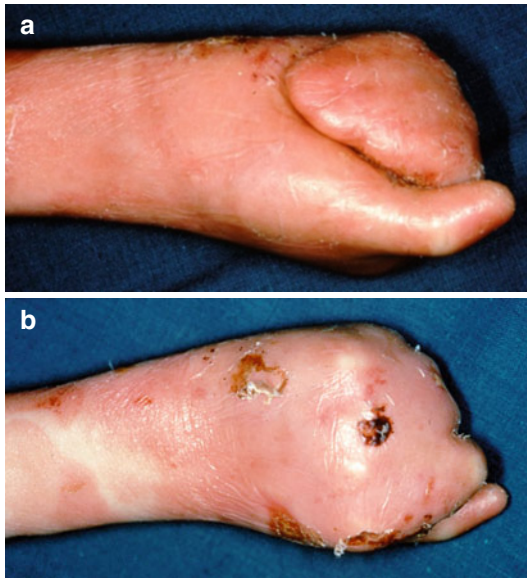

Fig. 24.3 (**a**, **b**) Digit fusion and pseudosyndactyly in a girl affected by RDEB

ankyloglossia; excessive dental caries are a common finding. The involvement of the esophagus, relatively frequent, is a major determinant of the severity of the clinical picture. In these patients too, chronic ulcerations, particularly of the limbs, are associated with an increased incidence of squamous cell carcinomas.

RDEB inversa is a rare but severe subtype of RDEB. After the first years of life, cutaneous lesions tend to localize mainly to folds. Nail dystrophies are typical but of variable severity. Lesions of the oral cavity, always present, can lead to microglossia and ankyloglossia, and esophageal involvement is often severe. Also common are lesions of the lowermost portion of the genitourinary tract, with possible development of vaginal strictures.

The *DDEB generalized* subtype manifests with blisters at the limbs and heal with formation of numerous milia and atrophic scars. Multiple papular and plaque lesions of ivory-white color, known as albopapuloid lesions, may occur and are most frequently localized on the trunk. Nail dystrophies and loss of nail plates are always present. Mucosal lesions are usually mild and limited to the oral cavity. Multiple dental caries are relatively frequent. The course is usually relatively benign, with improvement with age.

Table 24.4 Classification of dystrophic EB (DEB)

DEB, major subtypes	All subtypes
DDEB	DDEB, generalized (DDEB-gen)
	DDEB, acral (DDEB-ac)
	DDEB, pretibial (DDEB-pt)
	DDEB, pruriginosa (DDEB-pr)
	DDEB, nails only (DDEB-na)
	DDEB, bullous dermolysis of the newborn (DDEB-BDN)
RDEB	RDEB, generalized severe (RDEB-gen sev)
	RDEB, generalized intermediate (RDEB-gen intermed)
	RDEB, inversa (RDEB-inv; RDEB-I)
	RDEB, localized (RDEB-loc)
	RDEB, pretibial (RDEB-pt)
	RDEB, pruriginosa (RDEB-pr)
	RDEB, centripetalis (RDEB-ce)
	RDEB, bullous dermolysis of the newborn (RDEB-BDN)

From Fine et al. (2008, 2014)
DDEB dominant dystrophic EB, *RDEB* recessive dystrophic EB

The DDEB and RDEB pruriginosa variants are characterized by severe itching which appears frequently at adolescence or even adulthood. The characteristic features are the aspect and linear distribution of the lesions which may be papules, nodules, lichenoid, or hypertrophic at the extensor surfaces of the limbs.

DDEB and RDEB, bullous dermolysis of the newborn are characterized by generalized lesions with oral cavity involvement. The blisters heal within the second year of life with atrophic scars and milia. Nail dystrophies and mild skin fragility can persist in adulthood (Table 24.4).

Theresa Kindler Syndrome (KS)

KS is a rare autosomal recessive genodermatosis characterized by skin fragility and photosensitivity caused by recessive mutations in the *FERMT1* gene encoding for kindlin-1.

Clinically, KS is characterized by trauma-induced blisters localized most frequently at the

extremities, photosensitivity with erythema and photo-induced blisters, progressive poikiloderma, predominantly localized to the face and neck, partial pseudosyndactyly, and generalized skin atrophy. Additional features include oral, anal, urogenital, ocular, and laryngeal mucosa involvement, esophageal strictures, and an increased susceptibility to develop squamous cell carcinomas.

Diagnosis and Prenatal Diagnosis

Diagnosis of EB is generally clinical and easy for expert; however, the identification of specific subtype requires electron microscopy and/or antigen mapping in immunofluorescence, on a biopsy of a recent blister or, preferably, of one mechanically induced. Furthermore, specific monoclonal or polyclonal antibodies and immunofluorescence techniques are used to demonstrate the defective expression of specific protein components, which are altered in individual subtypes of EB.

Molecular diagnosis is possible by searching for mutations in different gene, such as the COL7A1 for DEB, LAMB3, LAMC2, COL17A1, and, less frequently, LAMA3 for JEB and allows to perform prenatal diagnosis in families at risk of disease recurrence.

General Principles of Treatment

The treatment varies upon the age of the patient, the subtype of EB, the level of systemic involvement, and the complication. In this chapter, we develop only the skin care.

General Measures

The care of EB requires a coordinated multidisciplinary approach; it should take into account the treatment of mucocutaneous lesions and systemic manifestations. Therefore, many specialists are involved (dermatologist: case manager, neonatologist/pediatrician, gastroenterologist, plastic surgeon, dentist, pain relief doctor, specialist nurse, dietitian, psychologist, etc.). An efficient treatment of EB patients encompasses information about the existence of patient association (DEBRA) and the advantages to become a member. DEBRA contributes to improve patient access to information, reference centers, and social services.

Management of EB Patients Since Neonatal Age

The fragility of the skin requires specific attention:

- Caregiver and patient education should be gradual and adapted to the sociocultural level of the family.
- Whenever possible, skin-to-skin contact with the mother and breast feeding should be encouraged.
- The baby should not be placed in an incubator unless needed.
- Handling and bathing the baby with extreme attention.
- There is no contraindication to immunization for infectious diseases.
- In case of hospitalization, a venous access should be guaranteed. Whenever required for a long term, an indwelling central venous catheter can be used for blood sampling, fluid/electrolytes, drug administration, etc.
- Whenever electrodes are needed, they should be of small size.
- Choosing clothes without seams and tags made by soft material and easy to put on and remove.
- Hard shoes with internal seams should be avoided.
- Toys should be in soft material without traumatic angles and frequently cleaned.
- Hobbies and sports should be at the lowest risk of skin trauma.
- Vulnerable skin sites, such as knees and elbows, should be protected when the child begins to walk and during sport activities or hobbies.
- Patient compliance and adherence to therapy should be regularly checked and if necessary supported by psychologist.
- Monitoring of EB requires periodically complete clinical examination and evaluation of nutrition status and infection through blood test and swabs for culture which should be taken from infected and critically colonized wounds.

- In recessive DEB patients, specific dressings of fingers and toes are required in order to prevent digit fusion and development of pseudosyndactyly. The separation should be performed by using easily modeled dressings such as soft silicone foams (e.g., Mepilex® or Mepilex Lite®, Mölnlycke®). in order to delay.

Wound Care

- The use of advanced dressings such as polymeric membranes, hydrogels, and hydrofiber allows to delay the frequency of dressing change, in order to reduce pain and risk of infections and skin trauma.
- New blisters should be lanced and drained in order to prevent their enlargement; the blister roof should be left in place
- Mechanical debridement, when necessary, should be performed gently with previous analgesia.
- Chronic wounds should be straightly followed in order to early detect carcinoma; in suspected lesions, biopsy is mandatory
- Topical antibiotics should be used only to treat infected lesions.
- The choice of dressings varies upon the availability and the type and site of the lesions.
- An adequate dressing retention should be provided in order to prevent slipping and further trauma (e.g., Elastomull®, Tubifast®, or Self-fix®).
- If available, Dermasilk® or other specifically designed garments, without silver, can also be useful to retain the dressings in place.

Exuding Wounds

- Nonadhesive soft silicone or lipido-colloid contact layers (e.g., Mepitel®, Adaptic® touch, Urgotul®), thin polyurethane foam-soft silicone (Mepilex® Lite), and hydrogels (Intrasite® Conformable) appear to be the most suitable in these types of lesions. Hydrogel dressings should be changed daily or as soon as they become dry. Others could be changed every 3 days. Hydrofiber dressings (e.g., Aquacel®) or soft silicone foam with super absorbers (Cutimed®Siltec) able to absorb the abundant exudates should be preferred. Soft silicone foam (Mepilex®, Mepilex®transfer) and polymeric membranes (PolyMem®) are indicated in heavy exuding wounds.
- Dressings containing silver (Mepilex® AG; Urgotul®silver/SSD; PolyMem®silver, Aquacel®Ag) may reduce the risk of skin infections. However, silver plasma level should be checked in case of large surface and/or prolonged treatment, because of the risk of silver absorption and its toxicity. Indeed in children, the use of those dressings should be very limited in time and treated surface.

Hyperkeratotic and Crusted Lesions

These lesions are itchy and may mask an underlying squamous cell carcinoma; thus they require an accurate treatment and follow-up. Emollient creams and bathing are indicated.

Exuberant Granulation Tissue

Very potent topical steroid ointments and silver dressings are effective.

Infected Wounds

- Wounds should be cleaned with mild antiseptics, such as chlorhexidine 0.1 %
- In case of lesions at risk of infection, the use of topical hydrogen peroxide (Crystacide®) is indicated. An aqueous solution of eosin (2 %) reduces the exudate.
- Topical antibiotics, which do not have a systemic formulation (e.g., fusidic acid, mupirocin), should be used for treatment of infected wounds and used for short periods.
- Treatment with systemic antibiotics is always indicated when the infected lesions are multiple and widespread. In malnourished and/or noncompliant patients and in infants, systemic therapy should be started at the first signs of infection.

Dressing Frequency

It depends on the type of material used and the type of the lesion:

- Paraffin-impregnated gauzes (e.g., Jelonet®) or medicated gauzes (e.g., Fitostimoline®) or hyaluronic acid (e.g., Connectivine®) dressing should be changed on a daily basis, increasing

wound manipulation, pain, and indirectly also the risk of infection. Furthermore, they adhere to the wound bottom.
- Advanced dressings could be kept in place for 2–4 days.
- Infected lesions should be dressed every day.

Acquired Epidermolysis Bullosa (EBA)

EBA is a rare chronic autoimmune bullous disease of the skin and mucosa due to the formation of IgG autoantibodies directed against collagen VII, the main constituent of anchoring fibrils. It generally affects adults but may occur in all ages. Clinically, it is characterized by skin fragility and subsequent formation of subepidermal blisters, predominantly in locations subjected to trauma, that heal with scar formation and milia, in a similar way to dystrophic epidermolysis. Nail loss may also occur. There are some variations, like inflammatory bullous pemphigoid or Brunsting-Perry pemphigoid-like and also IgA linear dermatosis. A genetic predisposition has emerged in some cases. The clinical diagnosis can be confirmed by ELISA, from IFD of salt-split skin and immunoelectron microscopy. Therapy is often frustrating because patients often do not respond to treatment with systemic steroids and immunosuppressive drugs, and there are no therapeutic guidelines. Medications that have been used with some success are colchicine, dapsone, immunosuppressants (cyclosporine, methotrexate, azathioprine, mycophenolate mofetil), steroids, intravenous IgG and plasmapheresis, and rituximab

Erysipelas

25

Maria Balabanova

Key Points

- Erysipelas is a distinctive type of superficial cellulitis of the skin with prominent lymphatic involvement.
- Its hallmark is a well-defined, raised edge reflecting the more superficial (dermal) involvement.
- Seventy to 80 % of the lesions are on the lower extremities and 5–20 % are on the face.
- Erysipelas is almost always due to beta-haemolytic streptococci group A (uncommonly *S. dysgalactiae* group G or *S. dysgalactiae* group C).
- Mild early cases of erysipelas in adult can be treated with intramuscular procaine penicillin (600,000 units once or twice daily), oral penicillin V (250–500 mg every 6 h) and erythromycin (250–500 mg every 6 h).
- More extensive erysipelas is treated with hospitalization and parenteral aqueous penicillin G (600,000–2,000,000 units every 6 h for 5–10 days); clindamycin should be added in case of septic shock.
- Extensive cellulitis or necrotizing fasciitis requires surgical debridement of the necrotic tissue and intensive care for the shock syndrome.
- Alternative treatment includes the other macrolides (roxithromycin, clarithromycin, azithromycin); they appear to be as effective as parenteral penicillin G. Cephalosporins also may be used as a second-line treatment. Quinolones are not indicated in the treatment of erysipelas.
- Prophylactic treatment includes benzylpenicillin benzathine (Tardocillin) 2.4 million units every 3 weeks for 1 or 2 years and erythromycin 250 or 500 mg twice a day. Of importance for prophylaxis is the rigorous disinfection of minor injuries that may provide a portal for bacteria.

Definition and Epidemiology

Erysipelas is a distinctive type of superficial cellulitis of the skin with prominent lymphatic involvement. It is more common in infants, young children and older adults. Its incidence has declined since the middle of the twentieth century, probably due to the greater use of antibiotics

M. Balabanova
Department of Dermatology,

and improved sanitation. Formerly the face was most commonly involved. Now the distribution of erysipelas has changed: 70–80 % of the lesions are on the lower extremities and 5–20 % are on the face. This is most probably because of the ageing population and risk factor such as lymphoedema.

Basic Concepts of Pathogenesis

Erysipelas is almost always due to beta-haemolytic streptococci group A (uncommonly *S. dysgalactiae* group G or *S.dysgalactiae* group C). Group B streptococci have produced erysipelas in newborns and may be the cause of abdominal or perineal erysipelas in post-partum women. *S. aureus*, *Pneumococcus* species, *Klebsiella pneumoniae*, *Yersinia enterocolitica* and *Haemophilus influenzae* type B have also been known to cause an erysipelas-like infection.

The portal of entry commonly includes skin ulcers, local trauma or abrasions, psoriatic or eczematous lesions or fungal infections; in the neonate, erysipelas may develop from an infection of the umbilical stump.

Predisposing factors include venous stasis, paraparesis, diabetes mellitus and alcohol abuse, lymphoedema and obesity. Other predisposing factors and ports of entry are surgical wounds, fissures of the nares, under the lobes of the ears, on the anus or penis, between or under the toes and athlete's foot.

Location and hepatic and renal disease are the most important risk factors, while diabetes is probably of less significance than previously suggested. Patients with the nephrotic syndrome are particularly susceptible. Erysipelas tends to occur in areas of pre-existing lymphatic obstruction or oedema (e.g. after a radical mastectomy). Also, because erysipelas itself produces lymphatic obstruction, it tends to recur in an area of an earlier infection. Over a 3-year period, the recurrence rate is about 30 %, predominantly in individuals with venous insufficiency or lymphoedema. An antecedent streptococcal respiratory tract infection preceded cutaneous involvement in about one-third of patients even though streptococci might not be found on culture at the time that the skin lesions become evident.

Clinical Presentation

Erysipelas has an abrupt onset of fever, chills, malaise and nausea. A few hours to a day later, these general symptoms are followed by a painful lesion with a bright red oedematous, indurated ('peau d'orange') appearance and an advancing, raised border that is sharply demarcated from the adjacent normal skin. The affected area is hot, tender and painful to palpation and may burn. A common form of erysipelas involves the bridge of the nose and the cheeks. Local clinical signs, without fever and inflammation, characterize the recurrent forms. Uncomplicated erysipelas remains confined primarily to the lymphatics and the dermis. Occasionally, the infection extends more deeply and produces cellulitis, subcutaneous abscess and necrotizing fasciitis. Other complications may include streptococcal bacteraemia which occurs in about 5 % of patients with erysipelas; when the infection resolves, desquamation and postinflammatory pigmentary changes may occur.

Diagnosis

The diagnosis is based on the:

- General symptoms.
- Local symptoms.
- Biopsy reveals diffuse oedema of the dermis and a dermal neutrophilic infiltrate. There is commonly dilation of lymph vessels, dermal foci of suppurative necrosis and a dermal–epidermal separation. There is no primary necrotizing vasculitis, thrombosis or leukocytoclasis.
- Gram or Giemsa stain, direct immunofluorescence, throat swabs, culture technique, swabs from the local portal of entry and serological tests.

Differential Diagnosis

- Early herpes zoster involving the second division of the fifth cranial nerve
- Contact dermatitis
- Giant urticaria
- Deep venous thrombosis
- Diffuse inflammatory carcinoma of the breast
- Erythema chronicum migrans
- An erysipelas-like skin lesion in patients with hypogammaglobulinaemia
- *Campylobacter jejuni* bacteraemia
- Lupus (butterfly pattern on the face)

General Principles of Treatment

Oral or parenteral penicillin is the treatment of choice. Elevation of the affected leg, bed rest and saline wet dresses are recommended.

Mild early cases of erysipelas in adult can be treated with:

- Intramuscular procaine penicillin (600,000 units once or twice daily)
- Oral penicillin V (250–500 mg every 6 h)
- Erythromycin (250–500 mg every 6 h)

More extensive erysipelas is treated as follows:

- Hospitalization and parenteral aqueous penicillin G (600,000–2,000,000 units every 6 h for 5–10 days).
- Clindamycin should be added in case of septic shock.
- Extensive cellulitis or necrotizing fasciitis requires surgical debridement of the necrotic tissue and intensive care for the shock syndrome.

Alternative Treatment

The other macrolides – roxithromycin, clarithromycin and azithromycin – appear to be as effective as parenteral penicillin G. Cephalosporins also may be used as a second-line treatment. Quinolones are not indicated in the treatment of erysipelas.

Although typical erysipelas can be readily distinguished from cellulitis (which can be of staphylococcal as well as streptococcal aetiology), differentiation may not be clear-cut in occasional circumstances. Under such conditions, particularly in an acutely ill patient, intravenous administration of penicillinase-resistant penicillin (nafcillin or oxacillin) or a first-generation cephalosporin is warranted.

Prophylactic Treatment

- Benzylpenicillin benzathine (Tardocillin) 2.4 million units every 3 weeks for 1 or 2 years
- Erythromycin 250 or 500 mg twice a day

Of importance for prophylaxis is the rigorous disinfection of minor injuries that may provide a portal for bacteria usually streptococci and the physical oedema therapy described by comprising manual lymph drainage and compression.

- Opinions differ about the duration of antibiotic prophylaxis. It has been established that recurrences are reduced, but the effect is not dramatic. Continuous antibiotic prophylaxis is indicated only in patients with high recurrence rate. Prophylactic antibiotic therapy should be considered as a long-term, even lifetime, treatment especially for certain predisposed subject (i.e. postphlebitic syndrome, lymphoedema, diabetes and immunocompromised hosts).
- Treatment of the local point of entry does not guarantee that there will be no recurrences. Recurrent episodes of erysipelas/cellulitis have also been associated with post-cellulitic oedema, which is a risk factor for recurrent disease. Reduction of the oedema would seem beneficial as well as a vigorous treatment of local factors.

Treatment Algorithm

First-Line Treatment

- Intramuscular procaine penicillin (600,000 units once or twice daily).
- Oral penicillin V (250–500 mg every 6 h); erythromycin (250–500 mg every 6 h).

- Hospitalization and parenteral aqueous penicillin G (600,000–2,000,000 units every 6 h for 5–10 days).
- Surgical debridement of the necrotic tissue and intensive care for the shock syndrome.
- In case of septic shock, clindamycin should be added.

Second-Line Treatment

- Macrolides – roxithromycin, clarithromycin and azithromycin.
- Cephalosporins also may be used as a second-line treatment.

Prophylactic Treatment

- Benzylpenicillin benzathine (Tardocillin) 2.4 million units every 3 weeks for 1 or 2 years
- Erythromycin 250 or 500 mg twice a day
- Rigorous disinfection of minor injuries

Erythema Multiforme

26

Kristina Semkova and Jana Kazandjieva

Abbreviations

CMV	Cytomegalovirus
DIF	Immunofluorescence
DNA (*pol*)	DNA polymerase
EBV	Epstein-Barr virus
EM	Erythema multiforme
GVHD	Graft-versus-host disease
HSV	Human herpesvirus
IBD	Inflammatory bowel disease
IFN-γ	Interferon-γ
PMLE	Polymorphous light eruption
SJS	Stevens-Johnson syndrome
SLE	Systemic lupus erythematosus
TEN	Toxic epidermal necrolysis
VZV	Varicella-zoster virus

Key Points

- Erythema multiforme (EM) is an acute, immune-mediated dermatological condition affecting the skin and mucous membranes. The most commonly identified triggering factor for EM is infection with human herpesvirus (HSV).
- A consensus clinical classification currently divides EM into EM minor and EM major. According to the frequency pattern, EM is classified into isolated cases, recurrent EM, and persistent EM.
- The characteristic clinical presentation is with typical target lesions with mainly acral, symmetrical distribution with or without mucosal erosions.
- Symptomatic therapy should be the mainstay in every patient with EM. Mild cutaneous involvement usually resolves without treatment within several weeks, but symptomatic improvement for occasional burning or pruritus may be achieved by using oral antihistamines or topical corticosteroids.
- Severe cases of EM major require special care for the mucous membranes to prevent complications.
- Early ophthalmologic consultation is important in the evaluation and management of eye involvement with daily examinations for signs of complications.
- Recurrent and persistent EM requires systemic therapeutic interventions. In HSV-associated or idiopathic EM, the first-line management is long-term prophylaxis with antiviral medications.

Definition

Erythema multiforme (EM) is an acute, immune-mediated dermatological condition affecting the skin and mucous membranes. It develops as a type IV hypersensitivity reaction to infections, medications, or other stimuli. The clinical presentation with target lesions and/or mucosal erosions with a history of exposure to a known trigger is usually sufficient for the diagnosis. Albeit self-limited in most cases, severe or recurrent forms of EM require systemic therapy.

EM was first described by Hebra in 1866 in his atlas of skin diseases (*Erythema Exudativum Multiforme typus benignus Hebra*). For many years, it was considered a variant from a continuous spectrum comprising EM, Stevens-Johnson syndrome (SJS), and toxic epidermal necrolysis (TEN). Studying an extensive number of cases allowed for a more precise understanding of these diseases and their evidence-based distinction as separate entities (Table 26.1). A consensus clinical classification currently divides EM into EM minor and EM major (Bastuji-Garin et al. 1993). EM minor is characterized by typical targets or raised, edematous papules with predominantly acral distribution, while EM major presents with typical targets or raised, edematous papules distributed acrally with involvement of one or more mucous membranes. Epidermal detachment in EM major should involve less than 10 % of the total body surface area.

Table 26.1 Consensus classification of EM, SJS, and toxic epidermal necrolysis and types of targetoid lesions (by Bastuji-Garin et al. 1993)

Consensus clinical classification	Types of targetoid lesions
EM – detachment of <10 % of BSA, localized typical or raised atypical targets	1. Typical targets
SJS – detachment of <10 % of BSA, widespread erythematous or purpuric macules or flat atypical targets	2. Raised atypical targets
SJS/TEN overlap – detachment of between 10 % and 30 % of BSA, widespread purpuric macules or flat atypical targets	3. Flat atypical targets
TEN with spots – detachment of >30 % of BSA, widespread purpuric macules or flat atypical targets	4. Macules with or without blisters
TEN without spots – detachment of >10 % of BSA, large epidermal sheets and no purpuric macules	

Epidemiology

The exact incidence of EM is not known but is estimated to be between 0.01 and 1 %. Young adults are most commonly affected with a slight male predominance. EM before the age of 3 and after the age of 50 is exceedingly rare.

Higher risk of EM was suggested in patients with HIV infection, corticosteroid treatment, bone marrow transplant, systemic lupus erythematosus (SLE), graft-versus-host disease (GVHD), and inflammatory bowel disease (IBD), as well as in patients on chemotherapy or radiotherapy.

Basic Concepts of Pathogenesis

The most commonly identified triggering factor for EM is infection with human herpesvirus (HSV). Other infectious agents and medications have been implicated as well. Nevertheless, about 50 % of cases remain idiopathic with no identifiable etiologic factor.

Infections

Infectious stimuli are linked to the majority of all cases of EM with known etiology.

HSV, primarily type 1, is the most common, especially in patients experiencing recurrent episodes of EM minor and in young adults. A study with PCR detection and genotyping of HSV in EM patients revealed that 66.7 % of the patients had HSV1, 27.8 % had HSV2, and 5.6 % had HSV1 and HSV2 co-infection (Sun et al. 2003). Some of the idiopathic cases are also believed to be induced by a subclinical or silent HSV infection. In a PCR study of skin

samples from 16 patients with idiopathic EM, HSV DNA was found in 25 % of single-episode idiopathic EM and in 50 % of recurrent idiopathic EM (Ng et al. 2003).

Other viruses that may induce EM include cytomegalovirus (CMV), Epstein-Barr virus (EBV), influenza, adenovirus, coxsackievirus B5, echoviruses, enterovirus, hepatitis A/B/C viruses (HAV/HBV/HCV), measles, mumps, paravaccinia, parvovirus B19, poliomyelitis, and varicella-zoster virus (VZV).

Many bacterial infections have been reported to precipitate EM, including *Mycoplasma pneumoniae*, borreliosis, cat-scratch disease, diphtheria, hemolytic streptococci, legionellosis, leprosy, *Neisseria meningitidis*, *Mycobacterium avium* complex, pneumococci, tuberculosis, *Proteus*/*Pseudomonas*/*Salmonella*/*Staphylococcus*/*Yersinia* species, *Treponema pallidum*, tularemia, *Vibrio parahaemolyticus*, and rickettsial and chlamydial infections.

Mycoplasma pneumoniae is of particular importance for the development of EM as it is the most common known trigger in the pediatric population.

Drugs

Drug-related EM comprises less than 10 % of all cases. Multiple drugs and substances can precipitate EM, the most common being nonsteroidal anti-inflammatory agents, sulfonamides, antiepileptics, and antibiotics.

Newer agents, such as biologics and human papillomavirus vaccines, as well as over-the-counter preparations, such as weight loss pills and herbal medicines, can also trigger EM.

Other Triggers

Multiple other factors have been linked to EM development: menstruation; high intake of food preservatives, especially benzoic acid and cinnamon; hair dye exposure; tattoo dermatitis; and physical or mechanical factors, such as radiotherapy, tattooing, cold, and sunlight. However, a recent study challenged the role of radiation, as EM was observed predominantly in patients with concomitant prescribed medications and only rarely in patients who were irradiated only.

Albeit rarely, EM has been described in association with malignancy, mainly leukemias and lymphomas. Solid organ tumors, such as gastric adenocarcinoma, renal cell carcinoma, and extrahepatic cholangiocarcinoma, have been reported in patients with persistent and treatment-recalcitrant EM. Thorough screening and physical examination may be thus warranted in these cases.

The pathogenesis of EM is not yet clearly understood. An autoimmune nature of the disease was recently refuted by an identified lack of specific humoral autoreactivity in sera from patients with EM major. Its occurrence in a small proportion of the whole population exposed to the known triggers suggests a genetic predisposition. Specific HLA associations reported in the literature include HLA-DQB1*0301, HLA-DQB1*0302, HLA-B35, HLA-B62, and HLA-DR53. Different genetic background accounts for the difference in presentation and severity, and HLA-DQB1*0302 is particularly linked to severe mucous membrane involvement.

Although HSV-induced and drug-induced EM are delayed type hypersensitivity reactions, they evolve via different pathways. In HSV-associated EM, the main reaction targets are the keratinocytes which express HSV DNA fragments. These fragments are transported to the skin by blood CD34+ Langerhans cells progenitors after phagocytosis of the active virus. Skin homing receptors and upregulation of E-cadherin expression enhance the binding of these cells to keratinocytes. Expression of HSV DNA polymerase (*pol*) and other genes on the surface of basal layer keratinocytes recruits CD4+T-helper cells, which produce cytokines and initiate an inflammatory cascade. The main effector cytokine in HSV-related EM is interferon-γ (IFN-γ). By contrast, the primary effector cytokine in drug-induced EM is TNF-α.

Clinical Presentation

According to the frequency pattern, EM is classified into isolated cases, recurrent EM and persistent EM. Recurrent EM is defined as multiple episodes of EM over a period of years with an average of six episodes per year and a mean duration of 6–10 years. The most common association of recurrent EM is with HSV infection and complex aphthosis, but literature reports incriminate other factors as well, including menstruation, vulvovaginal candidiasis, hepatitis C, *M. pneumoniae* infection, and acetaminophen and benzoic acid ingestion. About 70 % of patients have oral involvement and about 20 % report genital lesions.

Persistent EM is a rare variant characterized by continuous appearance of target and targetoid lesions without remissions. Its rarity impedes proper etiological identification, but association with HSV, Epstein-Barr virus, hepatitis C, influenza, cytomegalovirus, inflammatory bowel disease, and various neoplasms has been reported in the literature.

The clinical presentation of EM may be variable from one patient to another and even in the same patient. A detailed history is important to identify the potential trigger and any possible morphological changes in the clinical manifestation of the rash before the initial presentation to the clinician. The hallmark of EM is the target lesion, but early or atypical target lesions may not have the characteristic appearance.

Prodromal Symptoms

In EM minor prodromes are rarely observed and are usually mild, consisting of nonspecific upper respiratory tract infection-like symptoms within about 3 days before the onset of the rash.

In EM major prodromes are common, and about half of the patients experience influenza-like symptoms, including malaise, fever, cough, sore throat, vomiting, chest pain, and diarrhea. These symptoms usually present 1–2 weeks prior to the cutaneous eruption, but in many cases it is not known whether they represent a genuine prodromal period or are part of the infectious process that incites EM development.

Skin Lesions

Early EM presents with oval to round erythematous-edematous macules or papules that expand gradually over a period of 24–48 h. During the first few days, the initial lesions develop a raised, pale, and edematous peripheral ring, surrounded by a second cyanotic or violaceous ring, thus forming the typical concentric, "target" lesion (Fig. 26.1). The central area of the target lesion represents necrosis and may appear clinically as a dusty red area or blister (Fig. 26.2). During the course of the disease, the lesions may evolve to form polycyclic, geographic, or annular configurations. Post-inflammatory hyperpigmentation or hypopigmentation may follow the clearance of the eruption.

Fig. 26.1 Typical target lesions on the feet of a 32-year-old woman after an upper lip HSV infection

Fig. 26.2 Target lesions with bullous and hemorrhagic center

Atypical target lesions can also be observed, albeit uncommonly. They usually present as raised, edematous plaques that have only two concentric rings or poorly defined borders. In contrast, atypical target lesions in Stevens-Johnson syndrome are flat and not edematous.

The lesions are usually in a symmetrical distribution, affecting the acral extensor surfaces of the extremities. The eruption may spread to the trunk in a centripetal fashion. Palms, soles, and face are frequently involved (Fig. 26.1). Less commonly, other presentations, such as nail fold edema and grouping of lesions around the elbows and knees, may be observed.

The lesions may appear on areas of previous physical trauma or sunburn, suggesting a Koebner (isomorphic) phenomenon. Photo-sensitive variants of EM and distribution along the lines of Blaschko have also been reported.

Mucosal Lesions

Mucosal lesions are reported in as many as 60–70 % of EM patients. They usually appear simultaneously with skin lesions but can also precede or follow the cutaneous eruption within a time frame of several days. Isolated mucosal involvement is rare.

The most commonly affected mucous membrane sites are the oropharynx (lips, palate, and gingiva) (Fig. 26.3), conjunctivae, and the anogenital area, but potentially all mucosal sites may be involved. Initial presentation of mucosal EM is with erythema and edema, sometimes flaccid bullae, which rapidly progress to superficial erosions. Occasionally, the erosive areas may be extensive. When the lips are involved, they are covered by hemorrhagic crusts. Interestingly, a study in patients with recurrent EM with oral lesions showed that recurrent attacks have different site distribution from initial attacks, with a greater proportion having genital as well as skin and oral mucosal involvement.

The genital areas are affected in about 25 % of cases. The typical EM lesions at this site comprise painful, hemorrhagic bullae, and erosions.

Fig. 26.3 EM major in a child after *M. pneumoniae* infection

Eye involvement (9–17 %) is usually mild and may present as injection of the conjunctivae, chemosis, and lacrimation.

Clinical Course and Prognosis

Mild cases of EM are usually self-limited. In EM minor, the lesions develop over a period of 3–5 days and subside within 2–3 weeks without sequelae. The whole duration of the process is usually less than 4 weeks. Post-inflammatory discoloration may persist for several months after disease resolution. Scarring is not a feature, except after secondary infection. Despite the benign course, over one third of patients have repeating episodes over years (recurrent EM) or, rarely, a prolonged continuous disease without remissions (persistent EM).

EM major usually has a protracted course, and resolution may take up to 6 weeks. It is associated with higher morbidity, primarily due to the pain and functional impairment with poor oral and fluid intake. Dehydration may result from the impeded fluid intake, diarrhea from bowel mucosal involvement, increased sweating due to elevated body temperature, and evaporation through denuded areas of skin. Rare serious complications include conjunctival scarring and permanent visual loss in ocular involvement, genital synechiae, esophageal strictures, and upper airway erosions leading to pneumonia.

The mortality rate in EM major is less than 5 % and correlates with the affected total body surface area with sepsis being the principle cause of death. Advanced age, visceral involvement, increased serum urea nitrogen level, and previous bone marrow transplantation are poor prognostic factors.

Diagnosis

EM is primarily a clinical diagnosis with clue findings in the history and clinical presentation. The important points in the clinical history include acute presentation with episodic and self-limiting course, temporal association with infections, and use of new medications. The typical clinical presentation includes target lesions in mainly acral distribution with or without mucosal involvement.

There are no laboratory tests that confirm or refute the diagnosis. In severe cases an array of nonspecific findings, such as elevated ESR, leukocytosis, thrombocytopenia, and mild anemia, is expected. Electrolyte disturbance can also develop due to the dehydration.

Histopathologic examination of a biopsy specimen is useful to confirm the diagnosis of erythema multiforme (EM) and discriminate it from other clinically similar diseases in the differential diagnosis. Histologically, EM is characterized by basal cell hydropic degeneration with apoptosis of the keratinocytes and lymphohistiocytic infiltrate along the dermoepidermal junction and around the superficial vascular plexuses. Apoptotic keratinocytes may be focal in the basal layer or affect the whole epidermis. Pronounced basal cell hydropic degeneration may result in subepidermal clefting and vesiculation.

Histological presentation depends on the evolutionary stage of the lesion and the site of biopsy. In early lesions and from the periphery, the changes may be predominantly dermal with edema of the papillary dermis with chronic inflammatory cell infiltrate and red blood cell extravasation. Epidermal changes are more prominent in evolving lesions and from the central portions of the target lesions.

Blistering lesions with nonspecific histological features might require direct immunofluorescence (DIF) to exclude immunobullous disorders. In EM the DIF findings are usually nonspecific and include granular deposition of C3 and immunoglobulin M (IgM) at the dermoepidermal junction and around the superficial blood vessels. Homogeneous C3 and IgM can be observed in regions of epidermal necrosis.

Differential Diagnosis

In typical EM, the clinical presentation and history are usually sufficient for a straightforward diagnosis. Nevertheless, it is very important to exclude other possible diseases that can resemble EM but have a more serious prognosis. Mimickers of EM include SJS, fixed drug eruption, vasculitis, bullous pemphigoid, paraneoplastic pemphigus, Behcet's disease, Rowell's syndrome, polymorphous light eruption, and Sweet's syndrome.

SJS is a distinct entity with similar mucosal lesions but a different pattern of cutaneous involvement. In SJS the eruption is usually widespread and comprises erythematous or purpuric macules or flat atypical targetoid lesions. Acral predominance is not a feature. Medications are the main culprit for SJS. Timely diagnosis of SJS is essential as it may have function-threatening and life-threatening complications and may progress to toxic epidermal necrolysis.

Immunobullous disorders usually have insidious onset and protracted, chronic course. DIF is positive with a characteristic histological presentation. The Nikolsky sign is negative in EM and positive in the immunobullous disorders.

Fixed drug eruption may look like EM clinically and histologically, but usually there is one single or just a few lesions and the infiltrate extends deeper and contains sparse neutrophils with prominent melanin incontinence. History of starting new medication within the previous 2 months is usually present.

Rowell's syndrome is a rare clinical entity with lupus erythematosus and EM lesions. It is now believed to be a form of subcutaneous lupus

erythematosus presenting with EM-like lesions. In Rowells' syndrome, DIF shows continuous granular immunoglobulin and complement deposits, a speckled ANA pattern, and sometimes positive rheumatoid factor, anti-Ro, and anti-La antibodies. Chilblains are usually a part of the clinical presentation.

Polymorphous light eruption (PMLE) may present with EM-like lesions, and clinical and histological distinction is challenging. In PMLE the vacuolar interface reaction and epidermal necrosis are rarely seen. Photo-distribution, seasonal recurrence, and lack of prior HSV infection may be clue to the diagnosis, but it should be borne in mind that cases of photo-incited or photo-aggravated EM have also been reported in the literature.

General Principles of Treatment

The treatment strategy for a patient with EM would depend on the type, severity, site of involvement, and triggering factors, with special consideration for underlying conditions or age. The cause for EM development should be identified when possible. If a medication is suspected to be the inciting stimulus, it should be discontinued as soon as possible. This includes all drugs and herbal supplements introduced within 2 months of presentation. Suspected or known preceding infections should be treated accordingly after confirmatory cultures and/or serologic tests.

Symptomatic therapy should be the mainstay in every patient with EM. This includes oral antihistamines, analgesics, local skin care, and soothing mouthwashes. Mild EM is usually self-limited, and specific treatment is not required, unless recurrent or persistent. In severe cases of EM major, though, appropriate therapeutic and prophylactic measures are indispensable. Local supportive care for anogenital, upper respiratory tract, and ocular involvement is very important to prevent serious complications (Table 26.2).

Table 26.2 Treatment options for isolated, recurrent, and persistent EM

Type of EM	Treatment options (suggested dosage and treatment duration)
Isolated episode	Topical antiseptics
	Oral antihistamines
	Topical corticosteroids
	Systemic antibiotics (when bacterial infection present) (treatment dosage and duration should be according to the type of infection)
	Oral corticosteroids in severe mucous membrane involvement (40–60 mg/daily in tapering doses)
Recurrent and persistent EM	Antivirals (acyclovir 400 mg/2× daily, valacyclovir 500 mg/day, famciclovir 250 mg/2× daily) (treatment should continue for at least 6 months up to 2 years)
	Oral corticosteroids (1–2 mg/kg/day in slowly tapering doses)
	Dapsone (100–150 mg/daily)
	Azathioprine (100–150 mg/daily)
	Mycophenolate mofetil (≤2 g/daily)
	Cyclosporine
	Thalidomide (100 mg/daily for suppression of a recurrent episode or 50 mg/daily to maintain remission)
	Immunoglobulins

Isolated Episode of EM Minor

Isolated occurrence of EM is most commonly associated with HSV infection, but antiviral drugs do not change the course of an already developed post-herpetic EM. Mild cutaneous involvement usually resolves within several weeks, but symptomatic improvement for occasional burning or pruritus may be achieved by using oral antihistamines or topical corticosteroids. For erosions developing from bullous EM lesions, topical antiseptics and wound care are sufficient to prevent secondary infection, and analgesics are useful to manage the pain. In cases of extensive involvement, the use of liquid antiseptics, such as 0.05 % chlorhexidine, during bathing may also decrease the risk of superinfection.

Isolated Episode of EM Major

The treatment for cutaneous lesions should be the same as in EM minor. The approach to mucosal lesions should depend on site and severity. Minimal involvement, presenting as several painful erosions, can be managed with oral antiseptic washes, oral anesthetic solutions, and high potency corticosteroids in gel or spray form.

For extensive mucosal involvement, some authors recommend the use of systemic steroids (such as prednisone 40–60 mg with tapering over 2–4 weeks). However, this approach remains controversial, and others believe that systemic steroids protract the course of the disease. There are no controlled studies in the literature, and all data for application of systemic steroids in EM is based on personal observations. A study of 25 patients, randomized into two groups, one on supportive treatment plus systemic steroids and one on supportive treatment only, found no outcome difference in the two groups. To achieve maximum benefit and to avoid possible side effects, advocates of systemic steroids, however, emphasize on the early administration of a high dose for a short period of time.

Early ophthalmologic consultation is important in the evaluation and management of eye involvement with daily examinations for signs of complications. Local supportive care includes topical lubricants for dry eyes, sweeping of conjunctival fornices, and disruption of fresh synechiae with the help of lubricating or antibiotic eye drops. Administration of eye preparations should be at the discretion of the ophthalmologist, and all procedures should be carried out by the appropriate specialist.

Hospitalization is usually not required for EM patients, except in the rare cases of life-threatening complications such as dehydration, severe electrolyte imbalance, or secondary infection.

Recurrent and Persistent EM

Treatment of recurrent EM is a challenge for the dermatologist. In HSV-associated or idiopathic EM, the first-line management is long-term prophylaxis with antiviral medications. The treatment target for long-term acyclovir is the reduction of HSV recurrences and, consequently, of EM episodes. Several ways of administration have been used, including continuous oral therapy, intermittent oral therapy, and topical therapy, but continuous oral antivirals for at least 6 months remain the most effective approach. Topical application failed to reduce the frequency or severity of EM episodes.

Acyclovir at a dose of 400 mg twice daily is usually the preferred agent, but in acyclovir-resistant cases, other agents, such as valacyclovir at a dose of 500 mg once daily or famciclovir, can be a worth-to-try alternative. The treatment should continue for at least 6 months, and any extension should be according to the clinical response. Doses of antiviral drugs may be doubled in recalcitrant cases.

Once achieved, remission is usually difficult to maintain after treatment discontinuation. In case of relapse of EM, patients who responded well to treatment should restart the antiviral agent at the lowest effective dose and continue the therapy for 6–12 months.

Multiple therapeutic agents have been tried for recurrent EM resistant to prophylactic antiviral treatments. These include dapsone, azathioprine, mycophenolate mofetil, thalidomide, cyclosporine, hydroxychloroquine, and cimetidine. Unfortunately, the scarcity of literature data and the limited experience with these agents impede guidance on the most optimum period of treatment.

Dapsone is a drug with antibacterial, anti-inflammatory, and immunomodulatory effects. In a series of nine patients with treatment-resistant recurrent EM, eight had complete or partial remission with dapsone at a dose of 100–150 mg/day (Schofield et al. 1993). Another study identified ten patients at dapsone therapy (dose <200 mg/day) with three complete and two partial remissions (Wetter and Davis 2010). Isolated case reports claim dapsone is also effective in persistent EM. Dapsone treatment should be initiated after testing for glucose-6-phosphate dehydrogenase deficiency and requires close

monitoring for adverse events, including hemolytic anemia, methemoglobinemia, and agranulocytosis. Interestingly, dapsone was reported to induce EM with neutropenia in a patient with IgA linear dermatosis.

Azathioprine has been used with variable success in patients who are not responsive to antiviral therapy. Most of the patients reported in one study of recurrent EM had a dose-dependent remission (at doses 100–150 mg/day) but relapsed after treatment discontinuation.

Mycophenolate mofetil has also shown efficacy in the treatment of EM. Complete or partial remission was reported in about 75 % of patients treated with ≤2 g/day.

The clinical experience with *cyclosporine* for treatment of EM is limited. An intermittent short therapeutic course with initiation of treatment within 1–2 days of the onset of a new episode has been proposed as an effective and safe alternative to long-term treatment.

Thalidomide is effective to suppress a recurrent episode of EM at a dose of 100 mg/day or to maintain remission at a lower dose. It could be used as an intermittent therapy for new episodes of recurrent EM or as a continuous course in persistent EM.

Other treatments, such as antimalarials, immunoglobulin, and cimetidine, represented an effective treatment for isolated cases of patients with EM, but the controversial results and limited number of reports preclude correct analysis of the results and treatment recommendations.

Topical tacrolimus 0.1 % cream was used in one patient to achieve faster resolution of cutaneous lesions and induce remission.

Treatment of EM in Children

Treatment principles in children should follow the guidance for adults with age-dependent modifications in drug therapy and dosage. Supportive care is first-line in the management plan, and in almost all reported cases, it suffices on its own. Systemic steroids could be used in severe cases when the potential benefits outweigh the possible risks. Recurrent and/or persistent cases have not been reported in children, and immunosuppressive agents are not used to treat EM in this population group.

Erythema Nodosum

27

Eva Remenyik

Key Points

- Erythema nodosum is an inflammation of the subcutaneous tissue (panniculitis), usually appears in acute fashion. It may recur but is rarely chronic.
- Histopathologically the mixed inflammatory cells involve the septa of the panniculus without vasculitis.
- Erythema nodosum is a secondary hypersensitivity reaction to a known or unknown antigen.
- Underlining causes always have to be vigorously investigated.
- The diagnosis is mostly based on case history and the clinical picture. Deep biopsy is rarely needed to differentiate from other nodular inflammatory lesions mainly from vasculitides and other panniculitides.
- The first step of treatment is to eliminate the antigen (or aggravating factor) and treat the underlying disease.
- Symptomatic treatment is also indicated:
  - Physical: bed rest, elevation of the limbs, cold compresses, elastic bandage
  - Topical: anti-inflammatory (aluminum salt, NSAID)
  - Systemic: NSAID, antihistamines, corticosteroids, antibiotics, potassium iodine, colchicine, dapsone, hydroxychloroquine, thalidomide

Definition and Epidemiology

Erythema nodosum (EN) is typically characterized by suddenly symmetrically appearing deep painful red nodules on the pretibial area. It rarely recurs, but in some cases it becomes chronic. Histopathologically EN is a septal panniculitis without vasculitis. It is presumed a hypersensitivity reaction. The most common underlying causes are infections, inflammatory bowel diseases, sarcoidosis, drugs, and it can also be idiopathic. It is self-limited but reacts well and rapidly to anti-inflammatory therapy, healing without any remaining sign.

Basic Concepts of Pathogenesis

EN is probably a hypersensitivity reaction to a known or unknown antigen. Antigens from the underlying primary disease initiate the inflammatory process most likely via delayed-type hypersensitivity reaction, but the role of immune complexes is also suspected especially in inflammatory bowel disease-associated EN.

Table 27.1 Possible etiologic factors of erythema nodosum

			Incidence (%)
Unknown	Idiopathic		50–55
Physiological conditions	Gravidity		2–5
Drugs	Antibiotics	Sulfonamide, amoxicillin	3–4
	Oral contraceptive		
Diseases	Infective		
	Bacterial	Streptococcal infection (tonsillitis)	20–40
		Bacterial gastroenteritis: *Yersinia*, *Campylobacter*, *Salmonella*; other bacterial: *Mycobacteria*, *Rickettsia*, *Brucella*, *Bartonella*, *Treponema*	
	Viral	Mostly upper respiratory, but hepatitis B	
	Fungal	Coccidioidomycosis, blastomycosis	
	Parasitic	Giardiasis	
	Chronic inflammatory	Sarcoidosis	10–20
		Inflammatory bowel diseases mostly Crohn	1–4
		Neutrophilic dermatoses (Behcet's disease, Sweet syndrome)	
	Malignancy	Acute myelogenous leukemia	
		Hodgkin disease	

Histopathologically there is a mixed inflammatory infiltrate in the septa of the panniculus and the overlying dermis without evidence of vasculitis. Neutrophils may predominate during early septal edematous change but eosinophils may also be present. A characteristic feature is Miescher's granuloma (a group of histiocytes surrounded by neutrophils); giant cells are also frequently seen. Latter perivascular lymphocytic infiltration predominates with fibrosis.

A physician diagnosing EN always has to consider it as a secondary disease, and underlying causes must be sought. Possible initiating causes are shown in Table 27.1. Among them, streptococcal infection is the most common in children and adults besides sarcoidosis and inflammatory bowel disease.

Clinical Presentation

Suddenly appearing painful 2–5 cm-diameter red tender nodules develop symmetrically on the anterior shins (see Fig. 27.1). Pain can be

Fig. 27.1 Red painful nodules symmetrically on the shins

Fig. 27.2 Closer view of nodules

Fig. 27.3 Erythema nodosum, nodules in resolution stage: bluish color

disabilitating. The skin is usually elevated at the center of the nodule with poorly defined borders and more intensive bright red color in the middle during the acute eruptive phase (see Fig. 27.2). The color of the nodules may at times also be violaceous especially during the resolution phase turning to yellow, resembling a bruise (see Fig. 27.3). Suppuration and ulceration never develop. Sometimes only one nodule appears, but more often simultaneously and consecutively multiple lesions appear. Although extensor surface of the lower extremities is the typical site of the lesions, it is not rare for the nodules to present on thighs and arms or other body areas. Regional lymph node enlargement does not accompany the deep inflammation. Half of the patients experience joint pain mainly at the early development of the skin symptoms or preceding them. Signs of systemic inflammation like fever, flu-like syndromes can precede and/or accompany the development of skin symptoms. Nodules can spontaneously resolve, but frequently patients seek medical care. Skin symptoms heal without scar formation. The nodules recur in a third of the patients (mainly in idiopathic cases), and rarely they may also remain chronic. The later the discoloration of the affected area takes place, usually the more brownish the nodule becomes and the less elevated the central portion of the nodule will be. These lesions also show a tendency for centrifugal spread.

Regardless of the initiating cause, the skin symptoms of EN are the same, but systemic complaints sometimes are modified by the symptoms of the underlying conditions.

Differential Diagnosis

In typical cases, the clinical picture is characteristic, and the diagnosis can be established without the need for biopsy and histopathology. If biopsy is needed it has to be deep enough to reach the subcutaneous fat and provide optimal amount of tissue sample from the inflammatory site. Usually incisional biopsy is preferred, but a double punch, with a larger-diameter superficial punch biopsy followed by a deeper smaller punch of the subcutis, may prove sufficient.

In everyday clinical settings on the first examination, erysipelas/cellulitis, thrombophlebitis, insect bite, or sometimes urticaria are the most common differential diagnoses. After ruling out these diseases, other panniculitides and vasculitides have to be considered (see Fig. 27.4). EN leprosum is a separate disease characterized histopathologically with small vessel vasculitis.

General Principles of Treatment

EN is usually self-limited, and its outcome is not independent of the course of the underlying disease. Therefore the therapy is often only symptomatic besides eliminating or treating aggravating causes. These latter interventions include discontinuation of possible aggravating drugs and initiation of adequate antimicrobial treatment if infection is suspected and intensification of regimen for underlying chronic uncontrolled diseases.

Physical pain relief methods (bed rest and cooling the inflamed skin) are the bases of symptomatic care. EN quickly responds to systemic steroid, but in most cases its use is neither recommended nor necessary. Therapeutic options consist mainly of nonsteroidal anti-inflammatory drugs (NSAID) but are also influenced by the underlying conditions.

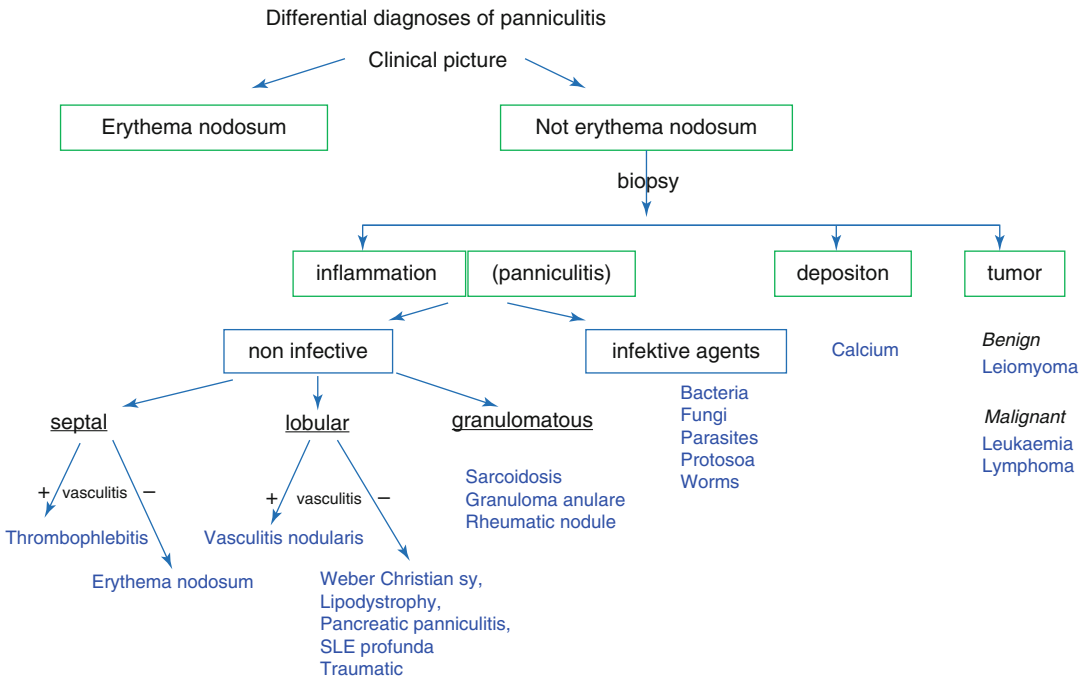

Fig. 27.4 Differential diagnosis of erythema nodosum after emergency

Topical Treatments

Given the experienced pain, patients usually intuitively find relief in bed rest. Nevertheless physicians have to counsel patients to avoid physical activity and potential trauma. Moreover physical cooling of the inflamed area with cold compresses or ice packs helps also reduce subjective complaints. Elastic bandages or low pressure compression stockings are also recommended. Solutions with aluminum salt in cold compress and also in barrier creams further increase anti-inflammatory effects of topical therapy. Topical NSAIDs may also be used but their higher sensitizing potential has to be considered. Potent topical corticosteroids can also be applied. Some reviews mention intralesional injection of corticosteroids, but only based on anecdotal evidence. In resolving phase Ichthyol can enhance the healing process, but its effect is also based on only personal clinical experiences.

Topical Treatments at a Glance

- Bed rest
- Cold compress
- Elastic bandage

Systemic Treatments

It is crucial to *treat the underlying disease*. However, in most EN cases systematic therapy is needed to reduce pain and speed up recovery even before the initiating factor is identified.

Salicylates and other *NSAID*s are the most commonly recommended drugs. Their main effect is inhibition of cyclooxygenase enzyme producing pro-inflammatory mediators like prostaglandins. NSAIDs modify cytokine production of T cells. They are recommended in the regular anti-inflammatory dose. Pain and subjective symptoms react quicker than inflammation. Continuous treatment is necessary for a few weeks, sometimes for an even longer period. The most frequently observed side effects are gastrointestinal, including hyperacidity, impairment of renal function, and also allergic reactions.

Important warning! NSAIDs have to be avoided in inflammatory bowel disease-associated EN, because they may trigger exacerbation of bowel symptoms or compromise maintenance therapy.

Systemic Corticosteroids As potent anti-inflammatory drug with immunosuppressive effects, corticosteroids effectively control EN. Clinical symptoms react very well and rapidly to systemic administration of corticosteroids. The severity of the symptoms of EN and the underlying diseases determine their indication. It is recommended if NSAIDs fail to reduce pain and inflammation. Concomitant infection should be ruled out or treated with suitable anti-infective agent (antibiotics, antimycotics, antimycobacterials). Usually 0.5 mg/kg body weight prednisone-equivalent dose substantially alleviates the symptoms within 24 h. The dose should be gradually tapered according to the clinical symptoms and also to the underlying disease. Meanwhile other causative agent-dependent treatment can also be recommended. Well-known side effects of systemic steroid therapy have to be considered and preventive management has to be initiated.

The use of *potassium iodine* solution is another systemic therapeutic option in EN. Daily dosage is 300–1,500 mg orally for adults. For better palatability dissolving the recommended amount in fruit juice or water is recommended. Its exact effect is not well established. It is thought to help in EN by suppression of neutrophil ROS release and chemotaxis and by inhibition of cell-mediated immunity via induction of heparin release from mast cells. For the onset of therapeutic benefit, usually at least 2 weeks is needed. Thyroid gland function before and during the application has to be checked. Acute side effects are nausea,

bitter taste, excessive salivation, and allergic reactions (urticaria, cutaneous small vessel vasculitis). Occasionally chronic side effects also can be seen. These include enlargement of salivary and lacrimal glands, acneiform eruptions, and hypothyroidism or rarely hyperthyroidism.

Colchicine is an antimitotic agent and arrests cell division by interfering with microtubule and mitotic spindle formation, and it also has direct anti-inflammatory effect by reducing neutrophil chemotaxis and adhesion to endothelial cells by decreasing expression of adhesion molecules. It is widely used in acute gout. There is empirical evidence that Behcet's disease-associated EN reacts well to colchicine and recurrences are also decreased by this medication. It can also be effective in EN associated with other conditions. Close monitoring is required during the therapy because colchicine has relatively low therapeutic index. Kidney failure contraindicates its usage. Hematological side effects are relatively common (anemia, neutropenia) and peripheral neuropathy can occur.

Dapsone (diaminodiphenyl sulfone) is an antibacterial drug commonly used in the treatment of leprosy in combination with other agents. It inhibits bacterial synthesis of dihydrofolic acid via direct structural competition for dihydropteroate synthetase. It also has anti-inflammatory and immunomodulatory effects most likely by inhibiting myeloperoxidase in neutrophils. Dapsone is mainly used in EN leprosum, but it can be considered in classical EN refractory to conventional therapy, especially EN in Behcet's disease. Hematologic side effects are the most pronounced including methemoglobinemia, aplastic anemia, leukopenia, agranulocytosis, eosinophilia, and macrocytic anemia. Hemolytic anemia is more likely with doses greater than 200 mg/day or in patients with glucose-6-phosphate dehydrogenase (G6PD) deficiency. Before initiation of the drug, G6PD activity should be determined; if it is not available, closer monitoring of the red blood cell count, methemoglobin level, and evidence of hemolysis should be performed besides monitoring for clinical symptoms of peripheral neuropathy. Dizziness, vertigo, blurred vision, and headache have also been reported as side effects of dapsone.

Hydroxychloroquine is an antimalarial agent also used in rheumatoid arthritis, lupus erythematosus, and some other photosensitive and inflammatory skin conditions. Its anti-inflammatory mechanisms are broad, involve immunocomplex production and T cell-mediated immune response, inhibit lysosomal enzymes, reduce ROS and nucleic acid synthesis, and also reduce antigen presentation by macrophages. It is mainly used and indicated in EN associated with Behcet's disease and EN leprosum. Hydroxychloroquine is usually well tolerated. Leukocytopenia and gastrointestinal and eye side effects rarely appear. During a long-term use, minimum yearly ophthalmologic examination has been previously advised, although recent evidence questions the cost-effectivity of this practice, and after good triage of patients for risk, less frequent follow-up is acceptable.

Thalidomide Launched as a hypnosedative drug in the 1950s, thalidomide later turned out to induce birth defect and was withdrawn from the market due to its teratogenicity. After the discovery of its excellent effect in EN leprosum, it was relicensed in some countries and since has proven its therapeutic efficacy in several autoimmune and inflammatory diseases. Thalidomide has FDA approval only for treating EN leprosum and multiple myeloma. Thalidomide can directly inhibit angiogenesis induced by bFGF or VEGF, also inhibit IL-6 and TNF alpha secretion, activate apoptosis, and increase NK-dependent T cell cytotoxicity. It has immunomodulating effects on the innate and adaptive immune system, as well as on tumorigenesis and angiogenesis. A wide variety of diseases, several dermatological conditions among them (Kaposi sarcoma, lupus erythematosus, prurigo nodularis, erythema nodosum, Behcet's syndrome, Langerhans cell histiocytosis, graft-versus-host disease, cutaneous sarcoidosis, erythema multiforme, Jessner-Kanof lymphocytic infiltration of the skin, lichen planus, melanoma, pyoderma gangrenosum, and uremic pruritus), have been successfully treated

with thalidomide. Due to its teratogenicity, proper contraception (two different methods) is inevitable during its use. In everyday practice, neuropathy is the most limiting side effect, but prescribing physicians need to also be aware of the relative frequency of anemia, leukopenia, constipation, and susceptibility to deep vein thrombosis. With close monitoring and good counseling, several patients may benefit from thalidomide therapy.

TNF-a Inhibitors TNF alpha is a key cytokine in granulomatous inflammation. Its inhibitors reduce chronic inflammation in rheumatoid arthritis and psoriasis. Moreover, it has been published to be effective in EN refractory to conventional therapy. Receptor antagonist etanercept in sarcoidosis-associated EN and chimeric immunoglobulin G1 monoclonal antibody (infliximab) in inflammatory bowel disease-associated EN had therapeutic benefit according to some reports.

Other immunosuppressants and chemotherapeutic agents (azathioprine and methotrexate, cyclosporine) have also been shown to have benefit in some forms of EN.

From the treatment choices, physicians should choose the best according to the possible or proven underlying/aggravating agent (*see in* Table 27.1) *and also consider that most of the drugs recommended based on case reports and personal experiences are off-label.*

Systemic Treatments at a Glance

Treat underlying infection or disease

- NSAID
- Corticosteroids
- Potassium iodine
- Colchicine
- Dapsone
- Hydroxychloroquine
- Thalidomide
- TNF alpha inhibitors

Erythrasma

28

Alexander Yu. Turkevych

Key Points

- Erythrasma is a chronic superficial infection of the intertriginous areas of the skin that causes brown, scaly skin patches. It occurs most often between the third and fourth toes, but it can also frequently be found in the groin, armpits, and under the breasts.
- Erythrasma is caused by the Gram-positive bacterium *Corynebacterium minutissimum*, which usually is present as a normal human skin inhabitant.
- The diagnosis can be made on the clinical picture alone.
- Erythrasma can be treated with topical fusidic acid or topical erythromycin gel or clindamycin solution twice a day for 2 weeks. Extensive infection may benefit from the treatment with systemic macrolides.

Definition and Epidemiology

Erythrasma is a chronic superficial infection of the intertriginous areas of the skin that causes brown, scaly skin patches. It presents as a slowly enlarging area of pink or brown dry skin. It occurs most often between the third and fourth toes, but it can also frequently be found in the groin, armpits, and under the breasts. Because of the color and location, it is often confused with a fungal infection like jock itch.

It is usually reported in the literature that the incidence could be over 20 % in general population. Erythrasma is caused by the Gram-positive bacterium *Corynebacterium minutissimum*, which usually is present as a normal human skin inhabitant. This may coexist with the dermatophyte fungi or with *Candida albicans*. It is prevalent among diabetics and the obese and also in warm climates. Wearing occlusive clothing can worsen erythrasma.

Clinical Presentation

The patches of erythrasma are initially pink but progress quickly to become brown and scaly (as skin starts to shed), which are classically sharply demarcated. Erythrasmic patches are typically found in intertriginous areas (skinfold areas – e.g., armpit, groin, under breast). The slightly webbed spaces between toes (or other body region skinfolds) can be involved, making it

A.Yu. Turkevych

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_28, © Springer-Verlag Berlin Heidelberg 2015

difficult to distinguish from various tineas. The patient is commonly otherwise asymptomatic. Occasionally, itching, or burning sensation, may start because of sweating. Without treatment, lesions can persist for months, with exacerbations during the summer.

Diagnosis

The diagnosis can be made on the clinical picture alone. However, to tell the difference between erythrasma and a fungal infection is to do a Wood's lamp examination on the rash. Under the UV light of a Wood's lamp, erythrasma turns a bright coral red, but fungal infections do not. Some other tests that may help include Gram stain (Gram stain of erythrasma shows delicate Gram-positive rods and filaments in the cornified layer), hematoxylin-eosin stains (there is orthokeratosis within which blue-staining organisms in the form of delicate rods and filaments can be found), and KOH test (test used to identify fungal elements and might be done to confirm that there is no fungus present). Also skin biopsy can be done, if necessary. In the case of erythrasma, the bacteria can be seen in the upper layer of the specimen.

Erythrasma can easily be missed on routine histopathologic sections as the inflammatory response is typically minimal; well-established lesions will reveal a sparse superficial perivascular infiltrate of lymphocytes.

Differential Diagnosis

The main differential diagnoses are with the diseases involving intertrigo, tinea cruris or pedis, and candidal intertrigo.

Pityriasis versicolor – *Malassezia* (formerly known as *Pityrosporum*) yeasts colonize the stratum corneum and also fail to elicit much of an epidermal response. The yeast forms are larger than *Corynebacteria* and fail to stain with Gram stain.

Pitted keratolysis – this may be indistinguishable from erythrasma without clinical correlation.

Also erythrasma may be confused with impetigo, contact dermatitis, inverse psoriasis, and seborrheic dermatitis.

General Principles of Treatment

General Recommendations

Regular washing with antiseptic is helpful during the treatment and may prevent relapses.

Given the fact that there is a pronounced tendency to recurrence, the intertriginous areas should be kept dry, with the use of suitable powders, while clothes and/or shoes should be appropriate.

Topical Treatments

Erythrasma is treated with topical fusidic acid or topical erythromycin gel or clindamycin solution twice a day for 2 weeks.

Systemic Treatments

Extensive infection can be treated with systemic macrolides:

- Erythromycin 250 mg four times a day for 7–10 days
- Clarithromycin 1 g once
- Azithromycin 1 g once

There is no sure way of knowing which of the above treatments should be preferred. It seems that systemic treatment is more effective. The disappearance of the red-coral fluorescence confirms the efficacy of the treatment. A brownish hyperpigmentation can persist for a while.

Erythroderma

29

Annalisa Patrizi and Michela Venturi

Key Points

- Erythroderma (E), also named exfoliative dermatitis, is a rare severe skin disease and represents an extreme state of skin irritation involving the whole or most (more than 90 %) of the skin surface. The resulting failure of the skin functions can coexist with other organ failures, so E is potentially life-threatening.
- E may arise from or be caused by a preexisting dermatosis, a drug-induced reaction, a malignancy, an infection, a miscellaneous of rare diseases or may represent an idiopathic disorder. In this last case, the term "red man" may be used when no primary cause can be found, despite serial examinations and tests.
- Idiopathic E begins as a patch(es) of erythema accompanied by pruritus. The patch(es) enlarges and coalesces to form extensive areas of erythema which eventually spread to cover the whole or most of the skin surface. E is also associated with profuse scaling, which has its onset 2–6 days after the erythema with individual variations. In the acute form of E, the formation of large scales is typical, while the chronic form is frequently characterized by small scales. The skin is notably dry, hot, and indurated. Mild to severe pruritus is usually present. Malaise and fever may occur.
- Since E is mainly a secondary process, it is mandatory to establish its etiopathogenesis in order to facilitate its correct management. The diagnosis is mainly based on histology; immunocytochemistry (ICC) and molecular biology techniques can be helpful.
- E is a serious disease; in fact the mortality rate is around 18–64 % on the basis of its different etiology. The management frequently requires hospitalization, as well as general and local treatment.
- *The treatment of E* varies according to the underlying condition and includes systemic treatment as systemic corticosteroids, antihistamines, and systemic antimicrobials. Moreover, according to the underlying condition, systemic specific treatment is added.

Definition

Erythroderma (E), first described by Hebra in 1868, is a reaction pattern, characterized by diffuse and confluent erythema with desquamation

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_29, © Springer-Verlag Berlin Heidelberg 2015

affecting most of or the entire body surface. E is usually accompanied by systemic manifestations including several metabolic changes. E may be the morphologic presentation of a variety of cutaneous and systemic diseases or, ultimately, the culmination of different skin disorders.

Its phenotype varies from mild skin symptoms to lethal forms.

E and exfoliative dermatitis are quite synonyms; however, E is the term currently preferred. Nonetheless, it is imperative to define both conditions. E is characterized by extensive and pronounced erythema with diffuse slight scaling, whereas exfoliative dermatitis presents a more conspicuous and marked scaling. The prerequisite to make the clinical diagnosis of E is a ≥90 % involvement of the skin surface.

Epidemiology

The overall precise incidence of E is difficult to define as most reports are retrospective.

E is surely a rare condition and its estimated annual incidence can vary from 1–2 per 100,000 general patients per year to 35 per 100,000 dermatologic outpatients, depending on the series. E accounts for about 1 % of all hospital admissions with dermatologic conditions. In adults a male predominance has been reported, with a male/female ratio from 2:1 to 4:1 with no racial predilection. The most frequent reported age range is from 40 to 60 years, in the published series excluding children, but any age group may be affected; however, the affected patients are usually over 45 years of age (excluding hereditary disorders/atopic dermatitis), with an average onset age of 55 years. On the Indian subcontinent, the onset age is slightly lower.

Even though E usually represents an adult disease, it shows another incidence's peak in the pediatric age. Pediatric E has a mean onset age of 3.3 years, with a male/female ratio of 0.89:1.

Basic Concepts of Pathogenesis

Adults

E may be idiopathic when the personal and family history, the physical examination, and the laboratory data are inconclusive, or E may be due to different preexisting dermatoses, drug adverse reactions, malignancies, and systemic disorders. E is considered idiopathic in 9–47 % of cases, while it may be linked to an exacerbation of a preexisting dermatosis in more than 50 % of cases; therefore, patients should be carefully evaluated for an underlying skin disease.

The subtle/sudden generalization of a preexisting dermatosis to E is an intriguing dilemma and may reflect individual variations. A detailed outline of the patient's history is important to understand the possible triggering events as infections, drugs, sun/ultraviolet light exposure, vitamin deficiency, and other factors.

In adults, the most common causes of protracted E are preexisting dermatoses, drug intake, pre-lymphomatous conditions, and occult malignancies. The underlying diseases that more frequently can cause E are eczema (40 % of cases), psoriasis (25 %), lymphomas and leukemias (15 %), drug intake, vitamin deficiency (10 %), and, more rarely, other dermatoses or skin infections and infestations (2 %) (Tables 29.1 and 29.2).

When considering a patient affected with E, the list of drugs assumed should always be asked, as E's pathogenesis may involve many drugs (Table 29.2).

Topical and systemic drugs are notorious for triggering E. The agents that mainly and most frequently induce E are calcium channel blockers, carbamazepine, phenytoin, and phenobarbital. Other medications include antibiotics, corticosteroids, diaminodiphenyl sulfone, NSAIDs, phenothiazines, antihypertensive drugs, cimetidine, lithium and gold, synthetic antimalarials, sulfonamides, peptic ulcer drugs, sulfasalazine, allopurinol, thalidomide, cytokines, trimethoprim, sodium clodronate, zidovudine, and codeine.

in E induced by other causes. A different situation is E accompanied by systemic drug hypersensitivity reactions (DRESS, Drug Rash with Eosinophilia and Systemic Symptoms) due to antibiotics, anticonvulsants, and allopurinol. DRESS develops within 2–5 weeks after the start of treatment and may persist for weeks despite stopping the medication. Edema, fever, leukocytosis with marked eosinophilia, lymphadenopathy, organomegaly, and liver and renal dysfunction are characteristic of DRESS. Drug-induced E due to dapsone/antileprosy drug hypersensitivity may appear quite similar to a cutaneous T-cell lymphoma in the clinical features and histopathology. Anyway, it disappears after the withdrawal of the drug and the administration of a supportive therapy.

Lymphomas and leukemias may cause E, for instance, Hodgkin's and non-Hodgkin's lymphomas, myeloid and lymphoid leukemias, and myelodysplasia. Cutaneous T-cell lymphomas (mycosis fungoides, Sezary syndrome) are one of the most common malignancies associated with E. E may derive from a previous cutaneous T-cell lymphoma as a marker of progression and may appear simultaneously, or its onset may be antecedent to the cutaneous T-cell lymphoma lesions. When E precedes cutaneous T-cell lymphoma lesions, the interval between E's appearance and cutaneous T-cell lymphoma's manifestations ranges from months to years.

Acute and chronic leukemia could cause E. The relative risk of leukemia inducing E is not well definite, varying from 11 to 50 %.

Reticular cell sarcoma and malignant histiocytoses are a few other implicated conditions.

E may ultimately be one of the clinical expressions of reticuloendothelial neoplasms and internal malignancies. Malignant E invariably affects older individuals, and in the elderly age E is considered to be a cutaneous marker of an internal malignancy. Its incidence is around 1 % and about 1 % of all cases of E are due to visceral malignancies.

The suspicion of an underlying malignancy may arise when the development of E is insidious, the patient becomes progressively debilitated, no previous skin diseases are recognized, and the lesions resist to standard therapies.

In the literature, eosinophilic E is suggested to be a paraneoplastic syndrome.

Children and Neonates

In children, E due to atopic dermatitis is the most frequently observed.

Other causes of children's E are ichthyosis, Netherton syndrome, primary immunodeficiency syndromes (PIDS), and metabolic diseases in neonates (aged less than 1 month of life). Psoriasis, Omenn syndrome, seborrheic dermatitis, and atopic dermatitis usually appear after the first month of life.

The pathogenesis of E is not clarified. A complex interaction of cytokines and cellular adhesion molecules, such as interleukins 1, 2, and 8, intercellular adhesion molecule-1 (ICAM-1), and tumor necrosis factor (TNF), is considered to be responsible for E, causing a strong increase in the epidermal turnover rate. In patients with this disorder, the mitotic rate and the absolute number of germinative skin cells are higher than normal. Moreover, the time required by the cells to differentiate and travel through the epidermis is shorter. This compressed maturation process results in an overall greater loss of corneocytes, which clinically appears as scaling and shedding. Normal epidermis undergoes some exfoliation

every day, but the lost scales contain little, if any, important viable material, such as nucleic acids, soluble proteins, and amino acids. In patients with E, several pathological alterations appear, in particular regarding thermoregulation, metabolism, and water balance; in addition some laboratory parameters show abnormal values.

E causes a severe aberration of the body's metabolism. The increased skin blood flow leads to higher skin temperature and heat loss. This elicits a cold sensation that induces a higher compensatory basal metabolic activity. The patient's dehydration derives from the elevated transepidermal water loss (TEWL) and skin evaporation. Otherwise, hypoproteinemia is due to protein loss (because of the desquamation) and to the significant exudation. Hence, changes in laboratory parameters include hypoalbuminemia (brought by increased protein loss in the skin, decreased synthesis, and increased catabolism of proteins), anemia, electrolyte disturbances (hypernatremia), serum urea increase, and all alterations due to dehydration; lymphocytosis, possible eosinophilia, elevated inflammatory markers, and polyclonal gammaglobulinemia may be also observed. In specific forms of E, increased IgE serum levels or Sezary cells may be found.

Clinical Presentation

Adults

E's phenotype varies from less severe skin symptoms to lethal forms. E can erupt simply with erythrodermic features or can be the aggravation of a preexisting dermatosis. The underlying disease is hidden by the erythrodermic nonspecific inflammatory manifestations, although it could emerge again during regression. Nonetheless, E's clinical profile varies consequently to the nature of the underlying disease.

A clinical classification distinguishes three different types of E:

1. Dry with large scales E (Wilson–Brocq) (Figs. 29.1 and 29.2)
2. Dry with small scales E (Hebra)
3. Vesiculo-edematous E (Fig. 29.3)

From the clinical point of view, erythema is the first stage of primary E. It often erupts as single or multiple pruritic patches, localized most

Figs. 29.1 and 29.2 Erythroderma with large scales and skin dryness (Wilson–Brocq)

Fig. 29.3 Vesiculo-edematous E

frequently in the head, trunk, and genitalia. In a few days or weeks, they tend to spread, and an erythematous, pruritic eruption comes to cover a great part of the skin. The palms, the soles, and the mucous membranes are usually not involved. The nose and the paranasal area are sometimes not affected. This is generally referred to as the "nose sign." Two to six days after the appearance of erythema, scaling begins.

The erythema has a variable intensity and scales are dandruff-like or lamellar, large in acute forms or small in chronic cases of E. Skin failure, that is, the inability to maintain homeostatic functions, may occur. Edema is due to extravasation of proteins into the tissues because of the vasodilation. In E, the edema can be generalized or localized only on the lower limbs. In some cases, and exudation may occur.

In long-standing E, clinical presentation encompasses injuries due to scratching, dyschromia as hyperpigmentation or hypopigmentation, and palmar-plantar fissurated keratoderma when palms and soles are involved. The patient's face can present a leonine appearance and/or ectropion. Changes in skin appendages may also be observed. Alopecia and eyebrow and eyelash thinning are frequently part of the clinical profile. Nails can appear thickened, corrugated, yellowish, and friable with transverse grooves. Some alterations may involve mucous membranes: cheilitis, conjunctivitis, and stomatitis could develop. Even lymph nodes may be moderately enlarged, hard-elastic, and painless (dermopathic lymphadenopathy).

Itching, skin tension sensation (feeling tightness on the skin), and cold feeling are the subjective most frequently referred symptoms.

E may be complicated by some general signs and symptoms, such as fever, chills, asthenia, fatigue, myalgia, shortness of breath, weight loss, insomnia, gynecomastia, splenomegaly, hepatomegaly, and pedal edema.

Psoriasis is a frequent cause of E. Chronic plaque psoriasis precedes psoriatic E in more than 80 % of patients. An identifiable/unidentifiable triggering factor drives to the transition from chronic plaque psoriasis to a more extensive involvement, characterized by the onset of an inflammatory phase; here, there are predominant erythema and limited scaling, as well as pruritus and burning. Triggers include sudden stopping of methotrexate, topical or systemic corticosteroids, the use of topical irritants as tars, systemic medications (antimalarials, lithium, terbinafine, gold, antimalarials, etc.), systemic illness, phototherapy burns, local and systemic infections (as HIV), pregnancy, and emotional stress.

This unstable psoriasis could become a whole-body disease. Pustular and erythrodermic psoriasis (Figs. 29.4, 29.5, 29.6, 29.7, and 29.8) are the most severe clinical variants of the disease spectrum.

In the erythrodermic psoriasis, generalized erythema, superficial scales, and loss of psoriatic clinical features are observed. Hence, psoriatic E is very similar to E due to other causes. Sometimes scales do not look like those of chronic plaque psoriasis that are thick and adherent. Erythema involves the whole skin surface and derives from vasodilation, inducing a high heat loss. E can regress to extensive

Figs. 29.4, 29.5, 29.6, 29.7, and 29.8 Erythrodermic psoriasis

plaque psoriasis but erythrodermic psoriasis recurs in 15 % of patients after an initial clearing.

In some patients, generalized pustular psoriasis may lead to erythrodermic psoriasis when there is no more pustular formation.

E can follow pityriasis rubra pilaris. It often appears as a seborrheic dermatitis-like eruption of the scalp and, in a short time, evolves into a widespread erythema with islands of sparing. An early prominent feature is keratoderma. Pink papules may affect the hair follicles in the dorsal fingers, wrists, and elbows.

Blisters and erosions are helpful for the diagnosis of E secondary to immunobullous diseases. Ruptured blisters may be highlighted by impetigo-like erosions or collarettes, leading to the recognition of superficial pemphigus, and tense blisters are usually indicative of an erythrodermic bullous pemphigoid.

E associated with dermatomyositis is rare, and in half the cases it is associated with digestive neoplasia (stomach and liver). Moreover, erythrodermic dermatomyositis may present Gottron's papules, heliotrope rash, poikiloderma, periungual telangiectasias, and muscle weakness.

E associated with mycosis fungoides (Fig. 29.9) is preceded by patches, plaques, or nodules, or there can be an E ab initio. An immunophenotypic study using advanced antibody panels may be required to distinguish it.

Sezary syndrome, the leukemic variant of mycosis fungoides, is characterized by itching, infiltration of the skin, enlarged lymph nodes, hepatosplenomegaly, and circulating Sezary cells.

Fig. 29.9 E associated with mycosis fungoides

A rapidly progressive E can be associated with lymphomatoid granulomatosis, a rare EBV-associated lymphoproliferative disorder. It affects mainly males in an immunodeficiency state. Clinical superficial lymph node swelling, subcutaneous nodules, and lung involvement are characteristic. The central nervous system is frequently involved. The diagnosis is based on histology.

Children and Neonates

Atopic dermatitis may occur with E at birth but, more frequently, it develops in infants or small children. Atopic dermatitis presenting as E is usually observed after the first months of life. Skin lesions consist of vesicles or exudative areas mainly on the face and flexures. They can overlap those of infantile seborrheic dermatitis in smaller children. After the age of 1 year, the disease is often complicated by itch sensation and excoriations or overinfections (Figs. 29.10, 29.11, 29.12, and 29.13).

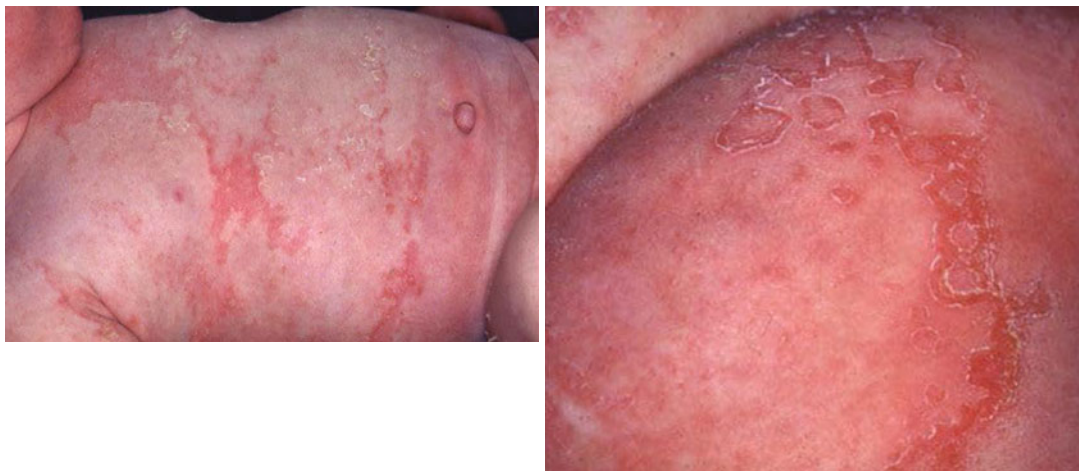
E due to psoriasis is rare in children. It usually starts on the napkin area, but sometimes it may be yet observed at birth. Erythrodermic psoriasis should be differentiated by pityriasis rubra pilaris when it starts with erythematous scaly plaques.

In neonates with E, a delay in reaching the correct diagnosis can be fatal. Clinical evaluation, knowledge of familial anamnesis, and laboratory tests are key points in the differential diagnosis of E. A skin biopsy is essential.

In particular, microscopy, histology, and immunohistochemistry could be useful tools for the distinction of severe diseases, such as PIDS and Netherton syndrome.

Several varieties of ichthyoses can manifest as E in neonates or infants (see Chap. 44). Netherton syndrome is a rare skin disease classified within ichthyoses (Figs. 29.14 and 29.15). It has a recessive inheritance pattern. In small children with Netherton disease, scaly E is associated with fragile hair with trichorrhexis invaginata (named "bamboo hair"), immunological abnormalities of varying severity, IgE-mediated allergic reactions, infections, and defective temperature regulation.

Figs. 29.10, 29.11, 29.12, and 29.13 E in atopic dermatitis



Figs. 29.14 and 29.15 E in Netherton syndrome: with picture of ichthyosis linearis circumflexa. Notice the characteristic serpiginous erythematous plaque with double-edged scale at the margin

E of Netherton syndrome can be noted at birth or during the first weeks of life; it often induces retarded growth and development of the newborn.

Neonatal E can be the early manifestation of PIDS such as Omenn syndrome.

Omenn syndrome is a rare, autosomal recessive disease. Severe combined immunodeficiency, infections, E, alopecia, hypereosinophilia, hepatosplenomegaly, lymphadenopathy, hypogammaglobulinemia and elevated IgE serum levels, chronic diarrhea, and failure to thrive are characteristic of this condition.

Diagnosis

The diagnosis of E is usually easy, but finding the underlying disease of E is a hard work. Unfortunately, the clinical profile of E is not contributive and certain clues such as scaling or

pruritus cannot be related to a specific cause. So, the clinical picture does not always contribute to the underlying skin disease's diagnosis. Patients with dermatologic disorders resistant to the therapy may develop E during a flare-up. In such cases, the etiologic diagnosis of E is easy; otherwise, its origin remains a diagnostic challenge. Long-duration E may cause hair loss and/or nail dystrophy regardless of its origin, so these changes are sometimes nonspecific. In erythrodermic patients, clinic-pathologic correlation is usually insufficient, because the specific skin changes due to dermatoses or drug reactions are masked by the nonspecific changes induced by the inflammatory erythrodermic process.

The diagnosis of E is mainly based on histology; immunocytochemistry (ICC) and molecular biology techniques can be helpful. Conclusive clinic-pathologic correlation may require multiple and repeated skin biopsies. The histopathology of E varies, according to the underlying pathology. Therefore, in a skin bioptic sample, it is important to perform a careful examination of all the skin layers. Anyway, specific diagnostic features are not found in biopsies in about one third of erythrodermic cases. Furthermore, only a half of histopathologic examinations are indicative of the underlying disease. Histopathology shows a context of nonspecific subacute or chronic dermatitis, even if there has been a previously well-known dermatosis, whose specific features are no more evident. The main histologic findings found in E are parakeratotic hyperkeratosis, acanthosis, spongiosis tending to vesiculation, exocytosis, dermal edema, and perivascular infiltrates mainly composed by lymphocytes with or without eosinophils (Fig. 29.16).

The stage of the disease can make changes in the histopathologic features; the acute stage is mainly characterized by spongiosis and parakeratosis, while the chronic stage presents acanthosis and elongated rete ridges.

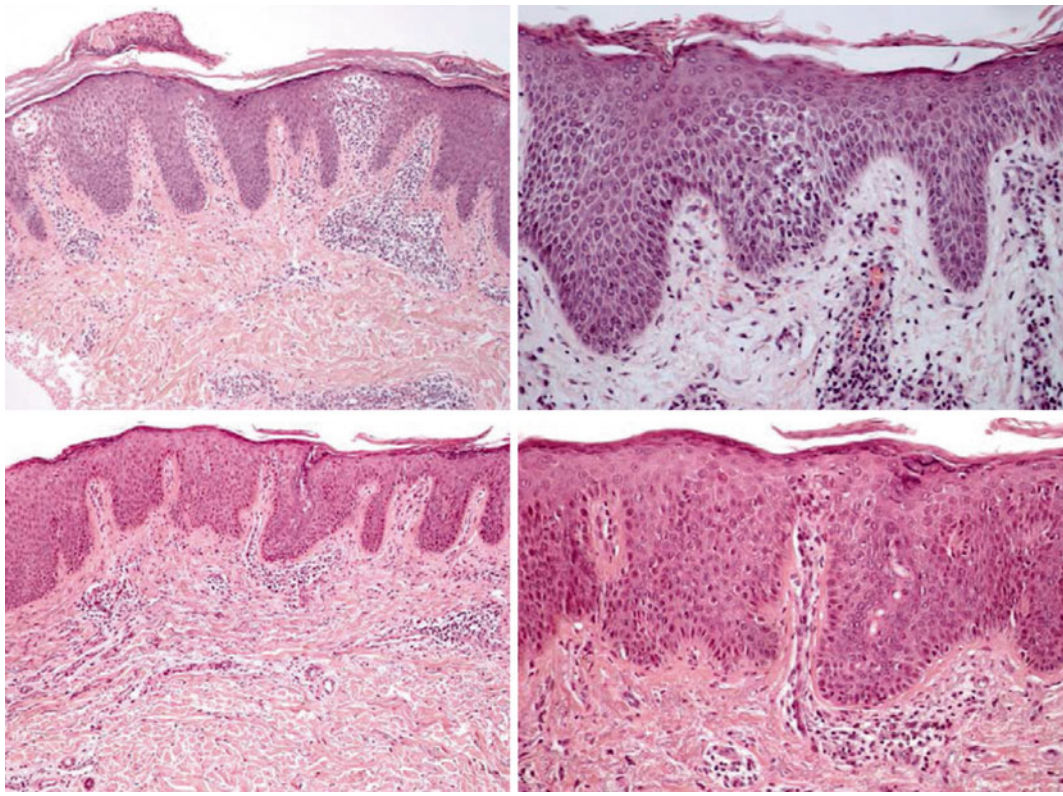


Fig. 29.16 Histopathology of E. Parakeratotic hyperkeratosis, acanthosis, spongiosis tending to vesiculation, exocytosis, dermal edema, and perivascular infiltrates mainly composed by lymphocytes

Drug-induced E may often show a lichenoid interfacial dermatosis at the histopathologic evaluation.

In E due to lymphoma, the infiltrate may progressively come to be polymorphic until it reveals its diagnostic aspects. A lymph node biopsy shows a histiocytic infiltrate in the place of the previous perifollicular lymphatic (dermopathic lymphadenopathy). In E due to epidermotropic T-cell lymphoma, histopathology presents a band-like lymphoid infiltrate in the superficial dermis, intraepidermal exocytosis, cerebriform cells, and Pautrier microabscesses. Sometimes, in this kind of E, some aspects of chronic dermatitis coexist, and in the case of benign E, there are aspects of lymphoma. Thus, the ICC is not always decisive, nor it is even the molecular biology.

Taking care of E, basic investigations include monitoring vital parameters as temperature, weight, pulse, and respiratory rate charting. Laboratory tests should explore a complete blood cell count and morphology, total and differential leukocyte counts, absolute platelet count, erythrocyte sedimentation rate, liver and kidney function tests, total and fractionated protidemia, serum electrolytes, fluid intake/output charting, and scheduled urine macro- and microscopy. Moreover, electrocardiogram and chest radiograph should be performed. Furthermore, disease-specific investigations are required:

- Scabies/skin mycosis: skin scrapings/KOH
- Allergic contact dermatitis, photoallergic contact dermatitis, and airborne contact dermatitis: patch test
- Atopic dermatitis: serum immunoglobulin E testing, RAST, and prick tests
- Multiple myeloma: serum and urine protein electrophoresis
- Sarcoidosis: angiotensin-converting enzyme levels and serum calcium level
- Bacterial overgrowth or herpes simplex virus: microbiologic cultures
- Acquired immunodeficiency syndrome: screening for human immunodeficiency virus 1 and 2
- Immunological disorders: antinuclear antibodies, anti-DNA antibodies, and rheumatoid factor
- Lymphoma/leukemia: lymph nodes examination, CD4/CD8 ratio, fine-needle aspiration cytology, bone marrow examination, immunophenotyping, flow cytometry, and B-cell and T-cell gene rearrangement analysis
- Pemphigus, pemphigoid, lichen planus, lupus erythematosus, and graft-versus-host disease: cutaneous direct and indirect immunofluorescence
- Occult malignancy: stool search for occult blood, prostate examination, cervical smear ultrasonography of the abdomen, chest radiograph, computed tomography scan, mammography, and sigmoidoscopy

About 10–25 % of patients with E do not receive a specific etiologic diagnosis. In these cases, E is defined as primary or idiopathic. In patients with primary, idiopathic E, laboratory abnormalities frequently comprise leukocytosis, anemia, raised erythrocyte sedimentation rate, lymphocytosis, eosinophilia, and hypergammaglobulinemia with elevated IgE serum levels. Other findings are increased creatinine level, hyperuricemia, and hypoalbuminemia. Eosinophilia is not diagnostic for the E's etiology. In Sezary syndrome, more than 20 % of circulating Sezary cells is a diagnostic point, whereas less than 10 % is a nonspecific finding. This lower count of Sezary cells can in fact be found in different benign dermatoses.

A diagnostic algorithm for an erythrodermic patient is presented in Fig. 29.17.

Complications and Prognosis

In E, some complications may occur such as pressure ulcers, pneumonia, venous thrombosis, heart or renal failure, depressive syndrome, and side effects of systemic corticosteroids and immunosuppressors. Loss of fluid and electrolytes develops from leaky capillaries. E increases protein loss by 25–30 % in psoriatic E and by 10–15 % in non-psoriatic E. This protein loss causes hypoalbuminemia, with fatigue, edema, and muscle wasting.

Systemic complications include alteration of fluid and electrolyte imbalances, thermoregulatory disturbance, high-output cardiac failure, and acute

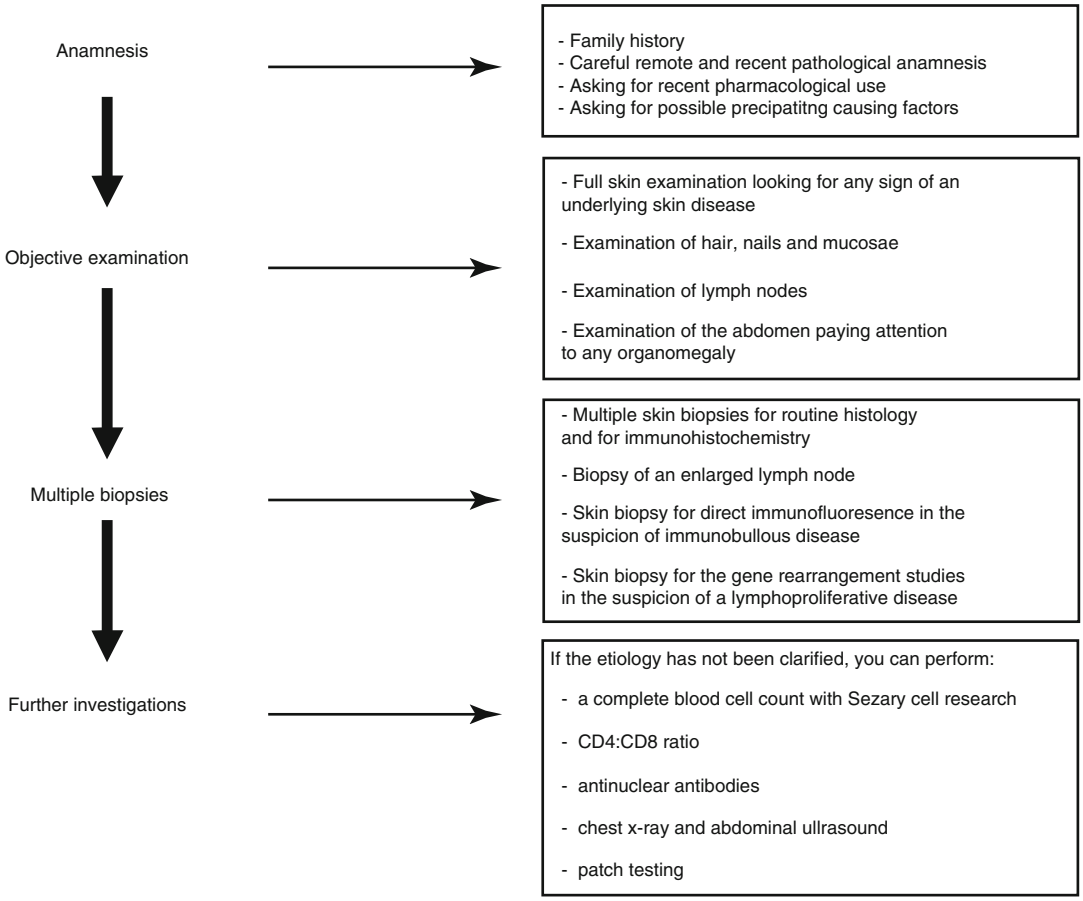

Fig. 29.17 Diagnostic algorithm for an erythrodermic patient

respiratory distress syndrome. The inflamed, fissured, and excoriated skin is susceptible to impetiginization, and sepsis may occur. Staphylococcal sepsis is especially a risk for patients with cutaneous T-cell lymphoma and/or HIV positive.

The clinical course of E is variable, but many patients have a bad prognosis; in fact E is a severe disease, the mortality rate ranges from 18 to 64 % of cases on the basis of the underlying disease. Pneumonia, septicemia, and heart failure represent the most common causes of death. In patients who develop complications (e.g., infection, fluid and electrolyte abnormalities, cardiac failure), the mortality rate increases. Death from sepsis, cardiac failure, adult respiratory distress syndrome, and capillary leak syndrome continues to be present. The prognosis has improved with the advent of the innovative dermatologic therapies (e.g., cyclosporine and synthetic retinoids, biologic therapies) and the advances in the management of systemic manifestations.

A high index of suspicion for complications must be maintained to facilitate an early medical intervention. The long-term prognosis is better in patients with drug-induced disease, whereas the course tends to remit and relapse in idiopathic E, although in some of these cases spontaneous resolution occurs. The prognosis of cases associated with malignancies depends on the outcome of the underlying cancer.

Post-inflammatory hypopigmentation or hyperpigmentation may occur. Generalized vitiligo or pyogenic granulomas have also been reported after drug-induced acute E. Alopecia, nail dystrophy, nevi, and keloid formation rarely follow E.

General Principles of Treatment

Treatment approach should include discontinuation of any potentially causative medications and a search for any underlying malignancy. The initial management of E of any etiology includes paying attention to nutrition, fluid and electrolyte replacement, and the institution of gentle local skin care measures. All cases should be considered as a dermatologic emergency and patients should preferably be hospitalized for treatment. Hospitalization is usually necessary for initial evaluation and for the administration of the general therapy.

When dealing with a patient with E, local and systemic treatments are necessary (Table 29.3). First of all, bed rest and sedation of patient

Table 29.3 Treatment of E

	Treatment	Remarks (dose and period of treatment)
General	Hospitalization	
	Fluid intake monitoring	
	Electrolyte balance check	
	Temperature measuring	
	Hyper-proteic diet	
	Nutritional implementation	
	Stop of any unuseful drug	
Specific (topical)	Lukewarm bath every day	
	Wet dressing with topical steroids and emollients (triamcinolone acetonide cream, 0.025–1.0 %)	Every 2–3 h and slowly decrease frequency
Specific (systemic)	Sedative antihistamine	Hydroxyzine hydrochloride, 25–50 mg per os every 4–6 h
	Systemic antimicrobials	First- or second-generation cephalosporins or semisynthetic penicillins for 7–10 days, or macrolides, or clindamycin
		Because of the subsequent infection by *S. aureus*
		Prudence due to the worsening of a drug-induced erythroderma
	Systemic steroids	Prednisone 1 mg/kg/24 h, then gradually decreased
	Acitretin	0.3–0.75 mg/kg
	Cyclosporin	Initial mean dose 4 mg/kg/day slowly reduced after remission by 0.5 mg/kg every 2 weeks
Specific disease		
Psoriasis	Systemic corticosteroid	It is better to avoid
	Methotrexate	Initial dose 10–25 mg/week, maintenance
		Dose 7.5–15 mg/week
	Cyclosporin	Initial mean dose 4 mg/kg/day slowly reduced after remission by 0.5 mg/kg every 2 weeks
	Acitretin	0.3–0.75 mg/kg
	Phototherapy	UVB, UVA, PUVA
	Etanercept	50 mg subcutaneous injection twice a week, reduced 50 mg/week after 3 months
	Infliximab	5 mg/kg i.v. at week 0, 2, 6, and later every 8 weeks
		Can be combined with methotrexate or acitretin
	Ustekinumab	45/90 mg (according to the weight) at week 0.4 and later every 12 weeks
	Adalimumab	80 mg at week 0, 40 mg at week 1, later 40 mg every 2 weeks

(continued)

Table 29.3 (continued)

	Treatment	Remarks (dose and period of treatment)
Atopic dermatitis	Systemic steroids	Prednisone 1 mg/kg/24 h, then gradually decreased
	Antimicrobials	First- or second-generation cephalosporins or semisynthetic penicillins for 7–10 days, or macrolides, or clindamycin, etc.
	Cyclosporin	Initial mean dose 5 mg/kg/day, slowly reduced after remission by 0.5 mg/kg every 2 weeks
	Phototherapy	Broadband UVB (280–320 nm)
		Narrowband UVB (311–313 nm)
		UVA (320–400 nm), UVA1 (340–400 nm), PUVA
		Balneo PUVA
		Possibility of combination of phototherapy (UVA/UVB) with corticosteroids
	Azathioprine	100–200 mg/day slowly reduced after remission
	Methotrexate	10–25 mg/week slowly reduced after remission
	Mycophenolate mofetil	1–2 g/day slowly reduced after remission
	Intravenous immunoglobulins	2 g/kg/month for 3–6 months
	Other	Interferon (50 g/m^2/day for 12 week)
		Rituximab
		Alefacept
Pityriasis rubra pilaris	Acitretin	0.3–0.75 mg/kg/day slowly reduced after remission
	Methotrexate	10–25 mg/week slowly reduced after remission
	Systemic steroids	Prednisone 1 mg/kg/24 h, then gradually decreased
Toxic epidermal necrolysis	Intravenous immunoglobulins	High dose (1 g/kg/day for 3 days)
	Systemic steroids	Prednisone 1 mg/kg/24 h, then gradually decreased
Lymphoma	Extracorporeal phototherapy, PUVA, alkylating agents	
Scabies	Topical permethrin, 5 %	Once a day for 5 consecutive days
	Oral ivermectin	200 μg/kg/day

should be suggested with monitoring of temperature, fluid intake, and electrolyte balance. A nutritional support should be added.

A local therapy with daily tepid baths, emollient creams, and soothing, in addition to low-power corticosteroids, is indicated. The maintenance of the skin hydration and avoiding of scratching and precipitating factors are mandatory as well as the treatment of the underlying cause of E (e.g., scabies) and of its complications (overinfections). As antipruritic agents, mild topical steroids/emollients can be used as well as wet wrap dressing.

Systemic therapy is usually necessary to achieve a good improvement of E. Oral, i.m., or i.v. sedative antihistamines are frequently added. In severe cases, systemic corticosteroids are the first-choice drug. They reduce itching and improve the general status, but they have many side and rebound effects. To increase the skin improvement, further treatments can be used depending on the E's etiology. Antimicrobials can be used to control secondary infections. Any hemodynamic or metabolic abnormalities must be correctly treated.

The outcome is unpredictable in idiopathic E and the course is marked by multiple exacerbations, so prolonged steroid therapy is often needed.

Erythrodermic psoriasis and eczematous E are usually severe; thus patients should be treated

with systemic drugs. Acitretin, cyclosporine, methotrexate, and biologic drugs (e.g., tumor necrosis factor-alpha blockers) are the treatment options in E due to psoriasis (see Chap. 81). E due to eczema usually improves within several weeks to several months, although chronic cases of atopic or contact eczematous E are not uncommon.

E secondary to cutaneous T-cell lymphomas or to other malignancies is often long-standing and refractory to treatment.

Complete remission occurs in one third of patients with idiopathic E, while 50 % of these patients demonstrate only partial remission. Patients where idiopathic E shows a chronic course are at high risk to evolve to cutaneous T-cell lymphomas.

Therapy for lymphomatous E includes PUVA, re-PUVA, total body electron beam irradiation, topical nitrogen mustard, chemotherapy, and extracorporeal photopheresis.

Treatment of Erythroderma in Childhood

Also in childhood, and in particular in neonatal and infantile period, E could be a severe condition. The connection between the pediatrician and the dermatologist is essential in this situation, and a prompt diagnosis of the underlying disease is fundamental to avoid any circumstance that could lead even to the death of the young patient. In the literature, the infantile mortality is quite high (16 %), due to primary dermatosis or to the complications. As a matter of fact, different life-threatening complications of E can occur; in particular, neonates with E have a higher risk of severe systemic infections, hypernatremic dehydration, hypoalbuminemia, hyperpyrexia, or hypothermia. These complications are more evident in collodion baby, severe lamellar ichthyosis, harlequin ichthyosis, Netherton syndrome, and Omenn syndrome. The skin fragility, fissures, cracks, erosions, or immunodeficiency of these conditions can lead to severe septicemic infections, resulting in high morbidity and mortality.

Hence, a child with E requires a proper supportive management, because it is necessary to correct the metabolic, hematologic, and biochemical imbalance. It is important to monitor the vital signs, check electrolyte balance, and provide an adequate fluid, caloric, and protein intake (per os or parenteral), according to the hypermetabolic state and requirements of normal growth. To obtain a normal weight gain of 15 g/kg/day, an estimated energy intake of 120–130 kcal/kg/day is necessary. In stressful situations, the energy intake can be increased by 10–30 %. The physician should pay attention also to the prevention of infections. The results of skin culture, hemoculture, and antibiogram should allow the choice of the correct antibiotics. In neonates, parenteral antibiotics are preferred.

In general, topical emollients such as petrolatum or white soft paraffin and antifungals or topical steroids are recommended, with wet dressing, to maintain the barrier function of the stratum corneum. When the diagnosis of the underlying disease is established, the specific therapy must be started.

The prognosis for an erythrodermic patient would vary because it depends on the primary etiology of the E. With an adequate treatment, children affected by E due to staphylococcal scalded skin syndrome, infantile seborrheic dermatitis, or nutritional deficiencies can be completely cured. A short administration of systemic steroids (1 mg/kg/day) could be necessary in case of atopic dermatitis and drug-induced E, while systemic methotrexate or acitretin (0.5 mg/kg/day) could be helpful in psoriatic E. Some more difficulties could be found in ichthyotic E, because a long-lasting therapy with retinoids may be required.

Erythroplasia of Queyrat

30

Konstantinos Krasagakis

Key Points

- Erythroplasia of Queyrat is a carcinoma in situ involving the mucosal surface of the penis.
- Treatment includes surgical procedures and either local or systemic medical treatment.
- Treatment of choice is surgical excision with microscopically controlled surgical margins. Defects depending on the size are managed by primary closure or reconstructive plastic surgery.
- Alternative surgical treatment includes laser vaporization by neodymium:YAG or carbon dioxide.
- Topical drug treatment in cases where surgery is not selected can be performed with 5-fluorouracil or imiquimod.
- Photodynamic treatment gives moderate results with efficacy ranging to 50 %.
- Close control is required when treatments other than excision with controlled or safety margins are chosen due to the risk of recurrence.

Definition and Epidemiology

Erythroplasia of Queyrat (EQ) is a carcinoma in situ of the mucosal surface of the penis. It is clinically distinctive from other forms of carcinoma in situ of the penis as Bowen's disease and bowenoid papulosis. The terminology regarding these entities is sometimes confusing and discrimination is not always done. Erythroplasia of Queyrat is a lesion with sharply defined borders and a red, smooth surface, involving the glans and the inner surface of the prepucial skin of the penis. Bowen's disease of the penis should be used to describe red, sometimes slightly pigmented, scaly patches and plaques of the keratinized penis, whereas bowenoid papulosis is described as multiple warty lesions, often pigmented in keratinized sites, and more numerous and more inflamed at mucosal sites (Bunker and Neil 2010). The histological features of erythroplasia of Queyrat and Bowen's disease are almost identical.

Basic Concepts of Pathogenesis

The etiology of erythroplasia of Queyrat remains unknown. Since it affects the mucosal surfaces of uncircumcised men, local factors such as poor hygiene and local irritation from retained

smegma or trauma have been all postulated as potential risk factors. More solid appears the presence of a coinfection of HPV type 8 with high-risk HPV-16. Wieland et al. (2000) reported that the presence of HPV-8 may discriminate EQ from Bowen's disease.

Clinical Presentation

The disease preferentially affects non-circumcised men older than 50 years. The typical presentation of erythroplasia of Queyrat is a well-demarcated, velvety red plaque of variable size, having a smooth surface, which involves the glans penis or the inner surface of the prepucial skin (Fig. 30.1). The lesion is flat or with slight infiltration, and multiple lesions are possible as well. Some authors use the term to describe squamous intraepithelial neoplasia in other mucosal localizations such as the conjuctiva, the oral mucosa, and the vulva. The disease progresses slowly, but if the lesion becomes increasingly indurated or ulcerated, this might be a sign for progression to an invasive SCC. The rate of progression to SCC is between 10 and 33 % (Graham and Helwig 1973). Rarely, cases of metastatic disease to the lymph nodes in the absence of an invasive component have been reported (Kim et al. 2007).

Fig. 30.1 Erythroplasia of Queyrat involving the glans penis

Diagnosis

Histology is necessary to discriminate EQ from other benign conditions mentioned above and to establish the diagnosis. Histologically, the lesion shows a hyperkeratotic epidermis with acanthosis and focal parakeratosis. Keratinocyte polarity and maturation have been lost. The cell nuclei are hyperchromatic and bizarre; multinucleated cells and atypical mitoses are seen. The basement membrane is not affected. In the upper dermis a dense infiltrate is found with mononucleated cells often having many plasma cells.

Differential Diagnosis

A variety of dermatological diseases may be considered in the differential diagnosis of EQ. These include conditions like psoriasis or lichen planus that may rarely manifest at the penis only, or even coexist with EQ. In such a case proper diagnosis may be delayed. Typically, Zoon's balanitis plasmacellularis, lichen sclerosus et atrophicus, and candida balanitis are more common conditions in this specific region. Rarely, sexually transmitted diseases such as syphilis or granuloma inguinale may be confused with EQ.

General Principles of Treatment

Large, well-designed studies on the treatment of EQ are missing, and much information is derived from studies on therapy for carcinoma in situ of the penis. Treatment of choice for EQ is surgical excision of the lesion. Concerns exist regarding remaining functionality from such an excision or even from a partial amputation of the penis, depending on the size of the lesion. Such considerations may pose limitations to the extent and radicality of surgery. Safety margins of 5 mm are generally acceptable for excision, which however result on most occasions in large defects. Therefore, Mohs micrographic surgery is suggested as an effort to spare unaffected tissue.

Neodymium:YAG or carbon dioxide laser therapy or the application of 5-fluorouracil cream

or imiquimod cream is also possible as an alternative to surgery in order to preserve function and not to affect sexual activity.

Local Excision

Local excision (with or without circumcision) remains the gold standard. Recurrence rates for carcinoma in situ of the penis may vary from 13 to 33 % (Cripsen and Mydlo 2010). The surgical excision of the lesion often has to be completed with coverage of the defect with skin from the body of the penis or with free skin transplantation. This is necessary when a safety margin of 0.5–1.0 cm is taken. Reports for cure rates are very sparse for these margins, even though it is a generally accepted safety limit. Also when these margins have been kept, the risk of recurrence is not negligible, and follow-up is recommended (Angerer-Shpilenya et al. 2010). Mohs micrographic surgery, when feasible, combines the benefit of excising the lesion with a sparing of uninvolved tissue, which is important for preventing disfigurement of the glans penis.

Some authors advocate total glans resurfacing as a surgical alternative for managing intractable EQ after failure to control disease with topical 5-FU cream or imiquimod (Hadway et al. 2006). According to this technique, the glans and subcoronal epithelial and subepithelial tissues are completely excised and replaced with healthy skin from an extragenital site. The penis is also circumcised. The graft, usually from the lateral thigh, is secured with several absorbable sutures to delineate the coronal sulcus, the external meatus, and the shaft skin ends. This technique, as reported in a study of ten patients, had not affected their sensation and had improved the quality of their sexual life in most of them giving a high overall patient satisfaction.

Laser Treatment

An alternative to surgical excision is the treatment of EQ with a laser source. Laser vaporization allows the adequate destruction of the lesion and limits the depth of penetration and the unnecessary destruction of healthy tissue. The preferred type of laser is the neodymium:YAG compared to other laser sources such as the carbon dioxide laser, but selection may depend upon the availability of the device and the experience of the user. Carbon dioxide laser has been suggested for treatment of penile carcinoma, alone or in conjunction with neodymium:YAG, as a penis-preserving surgery with reported cosmetically and functionally excellent results (Malek 1992; Conejo-Mir et al. 2005). Laser therapy also carries the risk of recurrences, and relapse rates of 0–33 % for carcinoma in situ have been reported (Malloy et al. 1988; Tietjen and Malek 1998; Schlenker et al. 2010). Invasive squamous cell carcinomas or even lymph node metastases have been observed after laser surgery (Frimberger et al. 2002; Meijer et al. 2007). Disadvantages are prolonged time for healing and the absence of histological control for clearance from the tumoral tissue.

Other Ablative Methods

Curettage and cautery is another treatment modality, widely used for therapy of basal cell cancer and Bowen's disease, which can also be applied for treatment of erythroplasia of Queyrat (Bunker and Neill 2010). A disadvantage compared to laser ablation is the risk of disfigurement.

Cryosurgery is included among the ablative treatments for erythroplasia of Queyrat. It is considered as a minimally invasive treatment able to offer good results as reported in two cases (Sonnex et al. 1982), but the selection of this type of treatment should be individually considered, and a close follow-up has to be ensued. Other authors do not recommend cryosurgery because of the lack of consistent depth of treatment (Crispen and Mydlo 2010).

In Bowen's disease of the skin, a comparison of curettage and cautery with liquid nitrogen cryotherapy showed a superiority of the curettage procedure (Ahmed et al. 2000).

Photodynamic Therapy

Photodynamic treatment (PDT) gives moderate results with overall efficacy ranging to 50 %. In a study with methyl aminolevulinate PDT for carcinoma in situ of the penis, excellent cosmetic results have been reported, but three out of ten patients had histopathologically residual disease (Axcrona et al. 2007). Also, Paoli et al. (2006) found initially a response to photodynamic therapy in seven out of ten patients treated with delta-5-aminolevulinic acid or methyl aminolevulinate PDT. Four of these patients presented no recurrences during a mean follow-up of 35 months and were completely cleared after two to eight treatments (mean 4.5 treatments). Three patients presented recurrences after treatment. Typically methyl aminolevulinate can be applied for 3 h under occlusion with a condom, and illumination is performed under regional anesthesia with 1 % Xylocaine. Side effects include mild swelling, redness, and pain (Lee and Ryman 2005). PDT may be useful in erythroplasia of Queyrat of the penis where tissue sparing is important, but several cases refractory to this modality have been reported with development of squamous cell carcinoma (Stables et al. 1999; Varma et al. 2000).

Topical Treatment

Topical treatments may be as well used for EQ. The 5-FU cream has been used since several decades as alternative to surgical therapy with success. The protocol includes the twice daily application of 5 % 5-FU cream to the lesion and the immediately adjacent area under occlusion with the foreskin or a condom. If the irritative reaction with pain, erythema, and edema, which usually appears after few days, is too strong, frequency of application can be reduced or treatment can be subsided for a few days before reinstituted again. In most cases a treatment period of 4–5 weeks is necessary to achieve clearance (Goette and Carson 1976). The inflammatory reaction often poses limitations to this type of treatment. Other protocols describe initially the application of lower concentrations of 5-FU cream (i.e., 2–3 %), and if the reaction is not strong enough, then the higher concentration of 5 % can be used. After treatment, close follow-up is necessary, with biopsies in case of any suspicion of inadequate response to the primary therapy or relapse.

Imiquimod is an immune-response-modifying agent with both antiviral and antitumor properties indicated for topical treatment of actinic keratosis, superficial basal cell carcinoma, and condylomata acuminata. Few anecdotal reports and a small open-label case series suggest a role for treatment in EQ, considering that besides its antineoplastic activity, imiquimod possesses efficacy against benign HPV conditions. Some authors consider 5-FU as the first-line and imiquimod as the second-line topical chemotherapy agent in penile carcinoma in situ (Alnajjar et al. 2012).

Other Treatments

The advent of radiation therapy is debatably discussed, since some authors prefer to avoid its use. A study of 11 cases with carcinoma in situ treated with primary radiotherapy reported complete responses without recurrences (McLean et al. 1993). Nevertheless, radiotherapy is used for therapy of more advanced cancerous lesions when surgery is not selected. In the case of erythroplasia of Queyrat, 8–10 fractions of single doses of 4 Gy may be used.

Follow-Up

There are presently no evidence-based recommendations on the frequency or the duration of the follow-up examinations. Recommendations are largely based on the knowledge that despite adequate therapy, erythroplasia of Queyrat still carries a risk for relapse depending on the type of treatment, as mentioned above. Close control is required when treatments other than excision with controlled or safety margins are chosen, due to the risk of recurrence. In the case of

complete local resection with histologically controlled excision margins and eventually circumcision, the risk of local relapses is rather small, but when other methods are selected, the risk can become higher. A tight clinical follow-up is recommended, i.e., a first visit after 3 months to evaluate for signs of persistent or recurrent disease. The National Comprehensive Cancer Network® panel suggests for penile cancer clinical exams every 3 months for the first 2 years, thereafter every 6 months until the fifth year, and then once per year for the next 5 years.

Factitial Dermatitis

31

Razvigor Darlenski and Nikolay Tsankov

Abbreviations

FD	Factitial dermatitis
SISL	Self-inflicted skin lesions
SSRIs	Selective serotonin reuptake inhibitors

Key Points

- Factitial dermatitis (FD) has been classified as part of the so-called self-inflicted dermatoses.
- A factitious skin disorder refers to artificial or faked, self-provoked or alleged skin diseases, without clear external incentives. In these cases the behavior responsible for the somatic damage is denied or kept "secret" by the patient.
- Lesions are most often found at skin sites accessible by the patient, with sharp demarcation borders and geometrical figures.
- A multidisciplinary psychocutaneous team is required in FD treatment.
- Dermatological care for FD includes topical bland therapy, antiseptics, and epithelizing agents.
- Nondrug psychological approaches include psychosomatic primary care (complaint diary), psychoeducation (no confrontation), relaxation techniques, and deep psychological therapy with the inclusion of behavior therapy concepts (aversion therapy, systemic desensitization, operant conditioning).
- As factitial dermatitis is often accompanied by psychiatric comorbidity, psychoactive drugs such as antidepressants, neuroleptics, and anxiolytics are used as adjunctive therapy.

Definition and Epidemiology

Factitial dermatitis (FD), also named dermatitis artefacta, artifact dermatitis, and factitious dermatitis, is an interdisciplinary problem that often involves dermatologists, general practitioners, and psychiatrists/psychologists (Dourmishev and Kazandjieva 1999). Historically there has been confusion with regard to terminology and classification of this pathologic condition. Recently a position paper (Gieler 2013). classified FD as a part of the so-called self-inflicted

dermatoses. Many terms have been used overlapping clinical correlations and disregarding some nuances between conditions such as neurotic excoriations, psychogenic excoriations, skin pickling syndromes, pathomimicry, and malingering. The panel suggests that instead of "FD," the term "factitious disorders in dermatology" should more appropriately be used, as this clinical entity is not always concurrent with "dermatitis."

Self-inflicted skin lesions (SISL) are defined as skin lesions actively and directly produced by the patient on his/her skin or mucosa that are not better explained as a consequence of another physical or mental disorder. In the narrower sense, a factitious skin disorder refers to artificial or faked, self-provoked or alleged skin diseases, without clear external incentives. In these cases the behavior responsible for the somatic damage is denied or kept "secret" by the patient. Dermatitis para artefacta can be regarded as disorder of impulse control, often as manipulation of an existing specific dermatosis (often semiconscious, admitted self-injury) (Ehsani 2009).

The prevalence of SISL ranges from 0.03 to 9.4 % (reviewed in Gieler et al.). Many cases of FD are underreported; that is why the real incidence cannot be critically estimated. It is clear that females are more commonly affected with male-to-female ratio of 1:3–20, and no race predominance could be established. The most common age of onset is in adolescence and early adulthood.

Clinical Presentation

Classically when there is no dermatological diagnosis that could explain the lesions upon physical examination, this could lead to the diagnosis of FD. Lesions are most often found at skin sites accessible by the patient (Figs. 31.1, 31.2, and 31.3). The morphology is in a way bizarre with sharp demarcation borders, geometrical figures, linear tracks, superficial erosions, deep ulcers, excoriations, crusts, papules, hyperpigmentations, and purpuric lesions.

Triggers such as emotional stress can precipitate the course of FD, but the lack of one cannot rule out internal, unconscious determinants (Nielsen 2005). Child physical, sexual, or psychological abuse or neglect is quite frequent in the history of these patients.

Self-mutilations are often observed in a spectrum of primarily psychiatric diagnoses, e.g., anxiety, depression, personality disorder, dissociative disorder, body dysmorphic disorder, post-traumatic stress disorder, autism, schizophrenia, delusion of parasitosis, Munchausen's syndrome (and by proxy), and mental retardation (Baranska-Rybak 2011).

Differential Diagnosis

FD is primarily a psychological disorder, but the clinical picture could mimic many different dermatoses: neurotic excoriations, pruritic lesions in underlying systemic disease, friction blisters, insect bites, impetigo, and impetiginized atopic or contact dermatitis, erythema multiforme, basal cell carcinoma, cutaneous lymphoma, and pyoderma gangrenosum.

General Principles of Treatment

The disease management is complex, and establishing a confident doctor-patient relationship is important. Often the induction behavior is kept secret until an appropriate relationship with the physician is established. In accordance with this, early referral to a psychiatrist may result in loss of confidence of the patient (Mohandas 2013). At this point, open-ended questions are more suitable instead of the direct: "Did you make these skin lesions by yourself?" The main motivation is assumed to be a method for coping with a severe psychological background and a preference for the sick role. In everyday setting FD can be regarded as "cry for help" with regard to the psychological comorbidity.

In the best way, a multidisciplinary psychocutaneous team is required in FD treatment, particularly as the patient is likely to require psychological intervention (to facilitate the resolution of the precipitant) in addition to dermatological (diagnosis setup and to exclude organic

Fig. 31.1 Erosions, excoriations, and ulcerations on the patient's body and upper extremities

Fig. 31.2 Lesions distributed on accessible sites of the patient's back

Fig. 31.3 Closer view of the skin lesions on the upper limb

disease) and psychiatric (to management of psychiatric comorbidity) help.

Dermatological care for FD includes topical bland therapy, antiseptics, and epithelizing agents. Occlusive dressing may be used to prevent from further self-infliction. When discussing the cutaneous lesions, it may be helpful to emphasize on stress or depression as a possible mediator in order to avoid counterproductive confrontation about the disease origin.

Nondrug psychological approaches include psychosomatic primary care (complaint diary), psychoeducation (no confrontation), relaxation techniques, and deep psychological therapy with the inclusion of behavior therapy concepts (aversion therapy, systemic desensitization, operant conditioning).

Pharmaceuticals are mainly used to treat psychiatric comorbidities (Tamakuwala 2005). Selective serotonin reuptake inhibitors (SSRIs) such as fluoxetine, sertraline, paroxetine, and fluvoxamine, in relatively high doses, are typically first-line treatment for self-injurious behavior (Koblenzer 2010). These can be combined with atypical antipsychotics (pimozide, olanzapine,

or risperidone), or the latter can be used alone. When anxiety is dominating, anxiolytics such as benzodiazepines and buspirone can be introduced.

Definition

A furuncle (*boil*) is a deep, necrotizing form of folliculitis with involvement of the subcutaneous tissue. It occurs as the follicular infection progresses deeper and extends out of the follicle. Several furuncles may coalesce to form *a carbuncle* with several pustular openings. *Staphylococcus aureus* (*S. aureus*) is the causative agent.

Basic Concepts of Pathogenesis

The initial pathophysiological event involves *S. aureus* colonization of the skin surface and proliferation with spread within follicles. The organism may spread through follicular walls to the dermis or can be inoculated through cuts and scratches into the dermis leading to the formation of a furuncle. The attraction of polymorphonuclear leukocytes by the *S. aureus* chemotactic factors and the elaboration of several enzymes by the microorganism result in clinical inflammation. These enzymes include enterotoxins, proteases, hemolysins, and leukocidins.

Clinical Presentation

A furuncle is manifested by a tender, round subcutaneous *nodule*, which is usually capped with *a small pustule*. It is a firm or fluctuant mass of walled-off purulent material. The follicular abscess enlarges, becomes fluctuant, and then softens and ruptures spontaneously to discharge a core of necrotic tissue and pus and may result in scarring. Furuncles may occur anywhere on the body but have a predilection for hairy parts of areas exposed to friction and maceration, especially the *face*, *scalp*, *buttocks, and axillae*.

A carbuncle forms a deep, swollen, erythematous, and painful mass with multiple draining sites and is found commonly on the neck, back, and thighs.

Predisposing factors are obesity, diabetes, prolonged sitting, tight irritating pants, or immunodeficiencies.

Systemic symptoms, such as fever and malaise, are more frequently present with carbuncles. When infection occurs in the nasolabial area, extension via the vein draining into the cavernous

sinus may lead to thrombosis. Perinephric abscess and osteomyelitis are other complications.

Recurrent furunculosis is the sequential occurrence of many furuncles over a period of months or even years in the same patient and sometimes develops in patients in whom there is no evidence of harboring specific staphylococcal strains or having any deficiency in their host defense mechanism. Panton-Valentine leukocidin (PVL) is the primary virulence factor of community-associated methicillin-resistant *Staphylococcus aureus* (CA-MRSA) and is associated with recurrent furunculosis. Such patients, who suffer from repeated infections, are usually nasal carriers of the infecting strain. It has been estimated that nasal carriage of *S. aureus* is the primary risk factor for recurrent furunculosis and accounts for 60 % of the cases. Therefore, nasal colonization with CA-MRSA interspersing the PVL toxin is a very strong risk factor for recurrent furunculosis. The anterior nares can serve as a reservoir for spread into the skin and subsequent reinfection. Less common reservoirs for the pathogenic staphylococci may be found in the axillae or perineum.

Differential Diagnosis

Furuncles must be differentiated from other bacterial infections, such as *anthrax* and *tularemia,* or from some other infections of the follicles, such as *conglobate acne* and *hidradenitis suppurativa*. In the last case, the location and the multiplicity of lesions usually lead to the correct diagnosis.

General Principles of Treatment

Furuncles or carbuncles associated with fever or located on the face are better to be treated with *a systemic antibiotic*. Isolated lesions on other areas of the body can be treated with only local care and, sometimes, *surgical drainage of pus*.

Eradication of recurrent lesions is often difficult. Prolonged antibiotic therapy, along with adjuvant measures, is often necessary. It is important to consider modifiable exogenous risk factors like hyperhidrosis, tight clothing, or obesity, which cause local moisture and occlusion, thus promoting local bacterial growth and injury to the hair follicle contributing to repeat infection. Endogenous risk factors like underlying acquired immune dysfunctions must also be taken into account. These include diabetes mellitus, human immunodeficiency virus, alcoholism, and malnutrition. If no skin colonization is detected, neutrophil dysfunctions should be investigated.

Recommended Therapies

(a) Systemic antibiotics
(b) Local treatment

Systemic Antibiotics

Antibiotics systemically are given in furuncles or carbuncles associated with surrounding cellulitis or those >5 cm diameter and/or associated with fever or located on the forehead, nose, cheeks, or upper lid. Patients with recurrent furunculosis and immunocompromised patients are also treated with systemic antibiotics.

Due to lack of clinical trials with many patients, treatment guidelines for furuncles and carbuncles are often based less on evidence and more on expert opinion. Knowledge of antibiotic sensitivity of the responsible organism is desirable for the selection of treatment. If this is hard to pursue, it is reasonable to begin with a semisynthetic penicillinase-resistant penicillin by mouth, such as cloxacillin at a dose of 250 mg every 4–6 h or dicloxacillin at a dose of 500 mg every 6 h for 10 days. For penicillin-sensitive patients, erythromycin (500 mg every 6 h for 10–15 days), clindamycin (300–600 mg every 6–8 h for 10–15 days), or fusidic acid (500 mg 8-hourly) is suggested. For CA-MRSA cases, empiric therapy with penicillins or cephalosporins may be inadequate. MRSA sensitivities vary according to geography, but co-trimoxazole, clindamycin, and doxycycline are the most likely oral agents to be effective empirically against MRSA and most non-MRSA too.

We prefer to start with azithromycin, one of the relatively newer macrolides, at a dose of 500 mg on day 1, followed by 250 mg on days 2–5. We believe that patient compliance is better with this dose schedule. If the organism is resistant to macrolides, we consider oral therapy with a cephalosporin such as cefaclor or one of the newer quinolones, such as ciprofloxacin.

In *recurrent furunculosis*, which represents a difficult therapeutic problem, the organism's antibiotic sensitivity should be assessed. The appropriate drug, most often a semisynthetic penicillin, is usually given for 1–3 months, but it can be administered for longer periods (6–12 months), if necessary. Rifampicin (300–600 mg 12-hourly) or rifabutin (300 mg daily), because of the potential for fewer than rifampicin drug interactions and greater tissue penetration, can be given for 7–10 days, along with a semisynthetic penicillin. In especially stubborn cases, their administration for longer periods, alone or in combination with other antibiotics, can be considered. A proposed treatment regimen for recurrent disease is the so-called CMC regimen that consists of skin disinfection with chlorhexidine for 21 days, nasal mupirocin ointment for 5 days, and oral clindamycin 1,800–2,400 mg for 21 days.

Local Treatment

Topical therapy consists of the application of warm normal saline compresses (1 teaspoon of table salt in 2 cups of tap water) followed by the application of an antibiotic ointment. A daily bath with antimicrobial soap is advisable. Incision and drainage, needed in 80 % of cases, are particularly helpful to relieve the pressure and pain associated with furunculosis and usually suffice if lesions are <5 cm diameter.

Local anesthetics are usually not required before small furuncles are incised. Spray anesthesia is in most cases adequate to provide enough local analgesia. The use of a number 11 blade with its sharp-tapered end is preferable, and, initially, a small (2–4 mm) rather than lengthy incision is better to prevent unsightly scarring. If the furuncle has been present for a long time or is large, a longer incision may be required. Care should be taken to not incise deeper than the pseudo capsule that has been built at the site of infection. Pressure is then applied to the abscess, but with caution, because sudden rupture of intrafollicular loculi may shoot purulent material from the wound. Sometimes, it is necessary to probe into the abscessed cavity with a curved mosquito forceps or curette to break these loculi, but only after injecting a small amount of 2 % lidocaine into the skin overlying the abscess.

In *recurrent furunculosis*, topical antibiotic ointment should be applied to the potential reservoir areas, e.g., the nostrils, axillae, and perineum. However, decolonization regimens are not always used due to fears of encouraging mupirocin and other resistance. Special measures for maintaining topical hygiene have been also proposed in repeated infections. It is not clear whether these measures add anything of benefit to the care of such patients. According to these instructions, patient and family should bathe and shampoo one to two times daily, nails should be clipped short to avoid scratching, precautions should be taken during shaving to soak the beard with hot water and discard or boil the blade, and clothing, including underwear, should be changed daily and laundered thoroughly.

Alternative and Experimental Treatments

Interferon gamma, iron supplements, zinc sulfate, levamisole, pentoxifylline, and vitamin C have been used in the treatment of furunculosis in clinical and experimental settings.

Long-standing improvement of recurrent furunculosis was noted in patients with HIV, following the administration of interferon-γ. It was given at a dose of 50 μg on days 1, 2, and 3 of the first week, with a new cycle every 4 weeks.

Human immunoglobulin has been administered intramuscularly, at monthly intervals, in patients with recurrent, nonresponding to conventional treatments furunculosis with promising results. Once a period without new lesions was achieved, treatment was discontinued, and if new lesions developed, treatment was reinitiated.

Treatment with iron supplements for a period of 4 weeks was very beneficial in patients with

furunculosis and hypoferremia without anemia. Recurrences of furunculosis were prevented after treatment with oral zinc sulfate, in cases with low serum zinc levels.

Pentoxifylline 400 mg t.i.d. for 2 months was successful in reducing recurrences in patients with chronic furunculosis.

Vitamin C has been found to be effective in the treatment of recurrent furunculosis in patients with impaired neutrophil function. It was administered alone at a dose of 500–1,000 mg per day for at least 30 days, or in combination with levamisole at a dose of 2.5 mg/kg for 3 days per week.

The excision of carbuncles with primary split-thickness skin grafting has been published in the recent literature as a new treatment modality aiming to the shortening of the recovery time and alleviation of pain.

Clinical data on the potential usage of new antimicrobials such ceftobiprole, ceftaroline, and oritavancin are expected.

Granuloma Annulare

33

Rolland Gyulai and Ágnes Kinyó

Key Points

- Granuloma annulare (GA) is a benign, usually self-limited granulomatous dermatosis.
- While localized forms can usually be managed with topical treatments, disseminated variants generally require systemic therapy.
- Topical high-potency glucocorticosteroids (both as ointments or intralesional injections) and macrolide immunomodulators (such as tacrolimus and pimecrolimus) are most commonly recommended for localized GA.
- Isotretinoin, anti-tumor necrosis factor (TNF) biologic agents, and fumaric acid esters are the most frequently recommended systemic treatments for generalized GA.
- Cryotherapy and light-based treatment modalities (such as PUVA, lasers, and photodynamic therapy) may be used with success in both localized and generalized clinical forms.
- Combination treatments are often proposed to enhance effectiveness and tolerability.

Definition

Granuloma annulare is a benign, usually self-limited granulomatous dermatosis affecting predominantly children and young adults. Clinically, GA typically occurs as localized or disseminated annular, skin-colored or erythematous plaques or individual papules. Lesions are most common on the extremities (especially on the dorsa of the hands and feet); however, in generalized forms, the trunk is frequently affected. Subcutaneous and perforating forms are rare GA variants. Although GA is usually self-limited and asymptomatic, patients often need treatment for cosmetic reasons.

Basic Concepts of Pathogenesis

Although GA has been reported to be triggered by several factors (such as insect bites, sun exposure, viral infections, etc.), the etiology of the disease remains largely unknown. It is generally accepted that a delayed-type hypersensitivity reaction leads to matrix degeneration and elastic tissue damage in the skin and, ultimately, to granuloma formation. GA has been associated with several systemic diseases, including diabetes mellitus, malignancy, thyroid disease, viral infections (such as HIV, hepatitis B and C), and rheumatoid arthritis.

Clinical Presentation

GA can be classified based on the extent of the disease and the morphology of the individual lesions. Localized GA occurs primarily in children and young adults and is characterized by less than ten skin lesions, typically localized to the distal extremities (Fig. 33.1). Disseminated GA forms (Fig. 33.2), developing in about 15 % of patients, are often chronic and difficult to treat. Apart from the typical erythematous-violaceous annularly arranged papules and plaques, GA may present as rare clinical variants as well. Subcutaneous GA is characterized by large, skin-colored, deep-dermal or subcutaneous nodules, whereas in perforating GA lesions develop central umbilication, crusting, or ulceration.

Fig. 33.1 Solitary granuloma annulare lesions on the hands

Differential Diagnosis

The differential diagnosis of GA is determined by the type and number of skin lesions. Biopsy is often required to establish a firm diagnosis when GA is suspected.

Localized forms should be distinguished from:

- Tinea: epidermal surface change; cultures for fungi are positive.
- Erythema migrans: history of tick bite, spontaneous resolution within weeks, "migration."
- Nummular eczema: epidermal involvement, severe itch, ill-defined borders.
- Discoid lupus erythematosus: epidermal surface change, involvement of skin appendages.

Generalized forms should be distinguished from:

- Sarcoidosis: usually less erythematous; biopsy is required.
- Necrobiosis lipoidica: typical (pretibial) localization, association with DM; biopsy is required.
- Disseminated lichen planus: epidermal involvement, mucous membrane lesions.

Subcutaneous forms should be distinguished from:

- Rheumatoid nodules: presence of joint symptoms; biopsy is required.

Fig. 33.2 Disseminated form of granuloma annulare on the lower extremities

General Principles of Treatment

Patients should be advised about the potentially self-limited nature of localized GA, as well as about the often chronic and treatment-resistant

course of disseminated disease. Therefore, treatment is not always necessary in localized variants; however, most patients request therapy for cosmetic reasons or symptomatic lesions. Disseminated GA presents significant therapeutic challenge, as evidence-based treatments and well-established recommendations are lacking. In most disseminated cases, systemic drug administration is recommended; however, risk of adverse drug reactions must be weighed against the benefit of treatment. The presence of comorbidities (both as potential trigger factors and treatment contraindication), prior therapies, gender, age, as well as the adherence to treatment must be taken into account when designing the therapeutic plan. Camouflage should also be considered in cases of recalcitrant, cosmetically disturbing lesions. Although the development of GA has been historically linked to type 2 diabetes mellitus, convincing evidence is still missing to establish this association. Therefore, GA patients will most likely not benefit from antidiabetic diet.

Topical Treatments

Topical Corticosteroids

Medium- to high-potency topical glucocorticosteroid (e.g., clobetasol propionate, betamethasone dipropionate, mometasone furoate, fluticasone propionate) preparations are the most commonly used treatments in localized GA. Although their efficacy and safety in GA have not been assessed by randomized clinical trials, there is ample clinical experience to justify their use as first-line treatment. Topical corticosteroids are relatively safe; however, patients should be advised about potential side effects, such as hypo/hyperpigmentation, atrophy, and development of striae distensae. Therefore, once- or twice-daily continuous application of topical corticosteroids should be continued only for a maximum of few weeks, and special attention should be paid to sensitive skin areas, such as the face or genitals. Intermittent application (such as once every 2–3 days, once a week, etc.) is recommended if long-term treatment is necessary to maintain results.

Topical Calcineurin Inhibitors

Topical calcineurin inhibitors (tacrolimus 0.1 % ointment and pimecrolimus 1 % cream) have been reported to be effective in localized GA. The mode of action of these macrolide immunosuppressants is through a nonsteroidal pathway; therefore, the use of these medications is associated with significantly less side effects than corticosteroids. Tacrolimus and pimecrolimus should be applied twice daily, and usually 4–8 weeks of treatment is required to achieve clinically meaningful improvement. Topical calcineurin inhibitors may also be used sequentially in order to maintain long-term control after other therapeutic interventions (e.g., corticosteroids or cryotherapy).

Topical Imiquimod

Imiquimod, a Toll-like receptor agonist, is licensed for the treatment of external genital warts and cutaneous neoplasia. The efficacy of imiquimod in GA has been reported in one case report and a case series of four patients (Kuwahara and Skinner 2002; Badavanis et al. 2005). Imiquimod 5 % cream was used once daily for 6–12 weeks, and the medication was left on the lesional skin for 10–12 h without occlusion and was then removed by washing. Complete remission and no recurrence for 10–18 months were reported in all patients. Based on these results, imiquimod may be used as a second-line therapy in localized GA.

Intralesional Corticosteroid Injection

Triamcinolone, in a dose of 5 mg/ml, is commonly used for localized GA, especially in treatment-resistant, more infiltrated, or deeply localized forms. As treatment is often associated with relatively intense pain, it is generally

recommended to combine the corticosteroid with 1–2 % lidocaine in the same syringe. Attention should be paid to corticosteroid side effects, especially skin atrophy. Frequent administration, therefore, should be avoided. Combination with lidocaine also helps to distribute the medication to a wider area, which, in turn, may further decrease the risk of local skin atrophy.

Intralesional Interferon Gamma

Intralesional injection of low-dose recombinant interferon gamma has been reported to be effective in localized granuloma annulare in a case series. Also, a few more recent case reports describe the disappearance of granuloma annulare upon interferon treatment of concomitant hepatitis B or C infection. On the other hand, interferon treatment reportedly can also lead to the development of generalized GA. It is, therefore, possible that interferon treatment is only effective in cases associated with hepatitis infection.

Topical Therapies at a Glance

- Localized GA is potentially self-limited, and treatment is not always necessary.
- Medium- to high-potency topical glucocorticosteroid preparations are the mainstay of the treatment in localized GA.
- Topical calcineurin inhibitors (tacrolimus 0.1 % ointment and pimecrolimus 1 % cream) are almost similarly effective and are associated with fewer side effects.
- Imiquimod cream, intralesional corticosteroid, and interferon gamma injections could also be tried with success if other therapies fail.

Cryosurgery

Cryosurgery is one of the most commonly used treatments in localized GA, although there has been only one prospective study proving its efficacy (Blume-Peytavi et al. 1994). In this report lesions resolved after a single freeze-thaw cycle in 25 of 31 patients (80.6 %). Relapse occurred in only 1 of 11 patients who were followed up for more than 2 years. The optimal dosing, duration, and frequency of freezing cycles have not been defined and generally depend on the experience of the treating physician.

Psoralen Plus UVA (PUVA) and Narrowband (NB) UVB Phototherapy

Cream PUVA treatment for localized GA was reported in a case series of five patients (Grundmann-Kollmann et al. 2001). Treatments were repeated four times a week; the mean number of treatments was 26, and the mean cumulative UVA dose was 55.9 J/cm^2. Complete clearance of the localized GA lesions was achieved in four patients and significant clinical improvement in one patient.

The efficacy of systemic PUVA therapy in GA was recently assessed by a retrospective analysis (Browne et al. 2011). This report analyzes the data of 33 patients treated with PUVA for generalized GA. Sixty-six percent of courses resulted in clearance of disease or in good improvement, 25 % had moderate benefit, and 9 % had a poor outcome. Of the patients that cleared, 79 % remained in remission at 6 months but only 32 % were still clear 12 months following treatment. PUVA treatment is usually administered three to four times per week, and on average 20–30 treatment sessions are required. Side effects, especially the long-term risk of skin cancer development, should be considered and weighed against the benefit of treatment.

Despite its frequent use in clinical practice, there is only very limited published evidence supporting the use of NB-UVB in the treatment of localized or disseminated GA. One case report describes the complete resolution of generalized symptoms after once weekly NB-UVB administration for 24 weeks. Therefore, frequency, dose,

and duration of sessions should be individually assessed by the provider for each patient.

Photodynamic Therapy

The use of photodynamic therapy (PDT) has been reported in both localized and generalized GA. Both 5-aminolevulinic acid and methyl aminolevulinate PDT resulted in complete or significant resolution of symptoms in the majority of the participating GA patients. The number and frequency of PDT sessions differed considerably in these trials; however, it seems that even in disseminated GA few treatment sessions may lead to significant clinical improvement.

Lasers

Different types of lasers (CO_2, 585 nm pulsed dye, 308 nm excimer, Nd:YAG) were reported in individual case reports as effective treatment modalities in GA. Session numbers differed according to laser types, and remission was complete or near complete and lasted for several months after the therapy.

Systemic Treatments

The use of systemic therapy is indicated for generalized GA. Although several different therapeutic approaches have been proposed, none is effective in more than 50 % of patients, and some of these treatments may have severe side effects (Table 33.1). Current treatment modalities are based on case series and consensus, as randomized controlled studies are missing.

Fumaric Acid Esters

Fumaric acid esters (FAEs) have been used with success in several inflammatory skin disorders, including GA. FAEs have been shown to suppress tumor necrosis factor (TNF)-α and other Th1 cytokine production via NF-κB-dependent mechanisms. As TNF-α and Th1 cytokines are required for granuloma formation, the therapeutic effect of FAEs in GA may be due to this phenomenon.

FAEs are administered in tablets using two formulations differing in strength. The tablets contain a mixture of dimethyl fumarate (DMF) and three salts of monoethylfumarate (MEF) in different doses. In the standard therapy regimen, FAE therapy is started with one low-dose tablet, and dosage is increased weekly by one tablet per day up to three tablets per day. Dose escalation is done weekly with a final maximum dosage of six high-dose tablets. FAEs significantly improved disseminated GA in approximately two thirds of the patients. Clinically meaningful response may be seen as early as 4–6 weeks after initiating treatment; however, some patients may need a longer therapy (Weber et al. 2009).

Adverse events are generally mild, transient, and dose dependent. Nausea, diarrhea, flushing, leukopenia, lymphopenia, eosinophilia, and transient elevation of transaminases are the most common findings. Laboratory monitoring (blood count, differential blood count, transaminases, gamma-glutamyl transferase, serum creatinine, and urine analysis) before initiation of and during FAE therapy is recommended. FAEs are not available in all the European countries.

Retinoids

Etretinate, an aromatic retinoid, has been reported as a successful treatment modality in GA. It has been used at a dosage of 0.8–0.9 mg/kg/day in monotherapy and in combination with PUVA therapy. In one case report, short-term administration of etretinate was enough to achieve complete remission in monotherapy (Asano et al. 2006).

Isotretinoin may improve GA symptoms via its antiproliferative effect and inhibition of collagen synthesis. Several case reports describe the successful use of isotretinoin (in doses of 0.5–1 mg/kg/day, 30–50 mg once daily, or 30–40 mg twice

Table 33.1 Dosage and adverse events of systemic treatments in GA

Treatment type		Dosage	Side effects	Level of evidence	References
FAE		Variable	Nausea, diarrhea, flushing, leukopenia, lymphopenia, eosinophilia, and transient elevation of serum transaminases	C	Meissner et al. (2012), Eberlein-König et al. (2005), Weber et al. (2009)

	Rifampin+	600 mg/month	Epigastric burning, abdominal discomfort, nausea, vomiting	D	
	Ofloxacin + minocycline	400 mg/month			
		100 mg/month			
Corticosteroids		0.5–1 mg/kg/day	Weight gain, elevation of blood pressure, elevation of serum glucose level	D	
Antimalarials	Chloroquine	Variable	Retinopathy, aplastic anemia, liver toxicity	D	Cannistraci et al. (2005)
	Hydroxychloroquine				
Cyclosporine		4 mg/kg/day × 4 weeks, then tapered by 0.5 mg/kg/day every 2 weeks	Elevation of blood pressure, elevation of serum creatinine level	D	Fiallo (1998), Spadino et al. (2006)

daily for 8–16 weeks) in disseminated GA. Potential adverse effects are elevated serum transaminase levels, elevated cholesterol and triglyceride levels, blood count abnormalities, and teratogenicity. Laboratory controls are recommended frequently to control for potential side effects. Some patients require dosage reduction due to drug-related adverse reactions.

In summary, retinoid treatment is effective in disseminated GA; however, its use is limited by its unfavorable adverse event profile and the requirement for frequent monitoring.

Antitumor Necrosis Factor (TNF)-α Biologic Agents

Tumor necrosis factor (TNF)-α inhibitors are approved for the treatment of rheumatoid arthritis, psoriatic arthritis, moderate to severe plaque psoriasis, ankylosing spondylitis, Crohn's disease, and juvenile idiopathic arthritis. This group of drugs has sporadically been reported to be effective in granulomatous diseases. Interestingly, the occurrence of granulomatous skin symptoms has also been reported during anti-TNF therapy. The complete mechanism by which anti-TNF therapy works in granulomatous disease is uncertain. It is, however, well established that TNF-α plays essential role in granuloma formation. Thus, blocking TNF-α prevents the organization of newly forming granulomas and helps to dismantle existing lesions.

Infliximab, an antitumor necrosis factor-α monoclonal antibody, administered intravenously at a dosage of 5 mg/kg at weeks 0, 2, and 6 and thereafter at two monthly intervals resulted in initial improvement of GA lesions in 4–8 weeks and total resolution in a few months. The standard adalimumab treatment is 80 mg initially, followed by 40 mg every other week. A quick response was noted often within 1–3 weeks, and only postinflammatory hyperpigmented maculae remained after a few weeks. Histopathologic examination revealed significant reduction in the interstitial histiocytic infiltration and the precipitations of mucin. Etanercept has shown mixed results: only one patient showed improvement after a 12-week treatment, and a later series reported no improvement or worsening disease after treatment.

Methotrexate

Methotrexate (MTX) is an antimetabolite used in the treatment of many chronic inflammatory diseases. Several pharmacological mechanisms for MTX action have been proposed, both in respect to its immunomodulatory and anti-inflammatory effects. The dose of methotrexate can be adjusted between 10 and 20 mg/week. Side effects are gastrointestinal symptoms, liver toxicity, and blood count abnormalities.

Cyclosporine

Cyclosporine A (CsA) inhibits cell-mediated immunity by downregulating T-lymphocyte responses. A cycle of systemic cyclosporine therapy (started at a dose of 4 mg/kg/day for 4 weeks, subsequently reduced by 0.5 mg/kg/day in every 2 weeks) results in a good therapeutic response in GA in 3–6 weeks. The dosage of the drug and the period of treatment may be modified according to the therapeutic response and therapy-related side effects. Complete response can be achieved in disseminated GA with 3 mg/kg CsA daily for 12 weeks or 200 mg daily for 7 months. Close monitoring of blood pressure and laboratory control of renal function (serum creatinine) and blood counts are recommended with this drug.

Antimalarials

Antimalarial agents, including hydroxychloroquine and chloroquine, are used widely and successfully in the treatment of several connective tissue disorders and granulomatous diseases. They have been presumed effective because of their immunosuppressive and anti-inflammatory properties. Chloroquine is administered in a dosage of 250 or 500 mg daily; hydroxychloroquine is administered in a dosage of 200 mg/day for months. Possible side effects are retinopathy, aplastic anemia, and liver toxicity.

Corticosteroids

Oral steroids (prednisolone, methylprednisolone) are effective in the treatment of disseminated GA. Lesions cleared after a course of steroids (0.5–1 mg/kg/day), but the disease recurs quickly when the drug is discontinued.

Antibiotics

Dapsone is a sulfone antibiotic with many dermatologic indications, and it has been reported to be effective in disseminated GA (Martìn Saez et al. 2008). Its mechanism of action involves an anti-inflammatory effect, although the pathways by which it acts are not yet understood. The recommended dosage of the drug is 100 mg/day. Improvement may be seen between 4 and 12 weeks of treatment, and there is no recurrence after suspension of the drug. The main side effects are methemoglobinemia and hemolytic anemia. Blood dyscrasias, heart, liver and kidney abnormalities, pregnancy, and glucose-6-phosphate dehydrogenase or folic acid deficiency should be ruled out with laboratory tests before beginning treatment. During treatment, blood and urine tests should also be performed every week for the first month and every month thereafter.

Tetracyclines are broad-spectrum antibiotics that interfere with protein synthesis, inflammation, immunomodulation, cell proliferation, and angiogenesis. Doxycycline 100 mg administered twice daily for 12 weeks is effective in the treatment of GA. Adverse effects are gastrointestinal symptoms and photosensitivity.

The rationale for using rifampin + ofloxacin + minocycline (ROM) therapy for treating disseminated GA is based on the morphologic and histologic similarities between GA and tuberculoid leprosy. In addition to its antimicrobial effects, rifampin has also proved to influence antibody formation and cellular immune response, specifically delayed-type hypersensitivity. Minocycline has anti-inflammatory effects that are likely related to its antioxidant activity. It also interferes with lymphocyte (especially T cell) proliferation and reduces collagenase activity.

The standard regimen in paucibacillary leprosy for adults is as follows: rifampin (600 mg), ofloxacin (400 mg), and minocycline hydrochloride (100 mg). This regimen is administered for 3 months in disseminated GA (Marcus et al. 2009). Complete clearance of the plaques is achieved 3–5 months after the initiation of treatment. Some patients experience postinflammatory hyperpigmentation. Adverse effects most commonly include gastrointestinal tract symptoms: epigastric burning, abdominal discomfort, nausea, vomiting, and orange-red discoloration of urine.

Other Treatment Options

Pentoxifylline

The clinical efficacy of pentoxifylline is based on the hypothesis that an immune-mediated vasculitis may be involved in the pathogenesis of GA. Pentoxifylline is thought to reduce blood viscosity via effects on all major blood components. Although the standard pentoxifylline therapy (400 mg twice daily) offers a well-tolerated treatment option, the efficacy of the therapy is unclear.

Allopurinol

Allopurinol, a urate-lowering drug, has been successfully used in granulomatous diseases, such as sarcoidosis. A higher dose of the drug (300 mg twice daily) results in improvement of skin lesions in disseminated GA. The use of allopurinol significantly increases the incidence of serious drug hypersensitivity reactions, and in some patients allopurinol can also induce GA.

Niacinamide

The participation of delayed hypersensitivity reaction in the pathogenesis of GA suggests a possible efficacy of niacinamide. Niacinamide is a reasonably safe drug; even relatively high doses (1,500 mg/day) are associated with low incidence of side effects. Liver toxicity is an

important side effect; liver enzymes should be monitored during therapy.

Vitamin E and Zileuton

Oral vitamin E in monotherapy or vitamin E (400 IU) in combination with zileuton (2,400 mg) daily is a safe and probably effective treatment in patients with prolonged generalized GA.

Calcitriol

Oral calcitriol (0.25 γg/day) is also a safe and probably effective treatment in GA. Serum calcium levels should be monitored.

Defibrotide

Defibrotide is a deoxyribonucleic acid derivative derived from cow lung or porcine mucosa. It has been shown that defibrotide has protective effects on vascular endothelial cells, particularly those of small vessels. It has extensive beneficial pharmacological effects owing to its antithrombotic, anti-inflammatory, and anti-ischemic properties. Intramuscular use of defibrotide in a dosage of 400 mg/day results in improvement after 7-month administration. Frequent control of coagulation tests is recommended.

Combination Therapy

Fumaric Acid Esters (FAE) Plus PUVA

FAE should not be combined with other systemic drugs (methotrexate or cyclosporine A), but a better response was reported for FEA in combination with PUVA than in PUVA only.

PUVA Plus Prednisolone

PUVA therapy combined with 10 mg prednisolone every other day has also been effective in one case report.

Isotretinoin Plus Topical Pimecrolimus

Oral isotretinoin combined with topical pimecrolimus 1 % cream has been reported as a successful treatment.

Systemic Treatments at a Glance

- Isotretinoin is recommended as a first choice in disseminated or refractory GA alone or in combination with PUVA therapy.
- FAE is second-line treatment if previous treatments have failed or to enhance PUVA therapy. Adverse effects do not require discontinuation of the drug; dose reduction may be enough.
- Triple therapy with rifampin, ofloxacin, and minocycline has a positive outcome with a relatively few side effects.
- TNF-α inhibitors, mainly adalimumab, demonstrated a good clinical response in disseminated GA, but further well-designed clinical trials are needed to better direct treatment.

Future Perspectives

Treatment is often challenging for GA, especially because of the often recalcitrant nature of the disease and a lack of evidence-based therapy. Future investigations should focus on the evaluation of larger cohorts, not only to establish treatment recommendations in randomized, placebo-controlled trials but also to reach a greater understanding of disease pathogenesis and clinical-pathological presentation.

Guidelines for Treatment of GA

The treatment of choice should be individualized for the patient on the basis of dissemination of the symptoms, comorbidities, blood evaluations, drug interactions, compliance, adverse effect profiles, and reproductive status. In localized GA topical treatments are recommended as first-line therapy; in refractory cases phototherapy or

lasers could be applied. Systemic treatment in localized forms should be avoided of unnecessary side effects. In case of prolonged cosmetic disfigurement, systemic therapy can be attempted. Generalized forms of GA require systemic treatment in monotherapy or in combination with topical treatment. An algorithm of GA treatments is summarized in Fig. 33.3.

Grover Disease

34

Bengu Gerceker Turk and Sibel Alper

Key Points

- Grover disease is an acquired pruritic papulovesicular disease which is characterized by acantholysis on histology.
- The pathogenesis of the disease is unclear.
- The first step is the avoidance of the exacerbating factors including heat, exercise, sweating, and ultraviolet (UV) radiation.
- Topical agents including corticosteroids, synthetic retinoids, and vitamin D analogues are recommended for localized disease.
- Antihistamines may obtain symptomatic relief.
- For recalcitrant and generalized disease, oral retinoids (isotretinoin, acitretin), systemic steroids, methotrexate, etanercept, Psoralen-UVA, or UVB phototherapy may be used.

Definition

Grover disease (GD), namely, "transient acantholytic dermatosis," is an acquired disease which is characterized by pruritic papulovesicular rash on the trunk and extremities.

Basic Concepts of Pathogenesis

The main histologic feature is the acantholysis with dyskeratosis. The obstruction of damaged eccrine ducts, leakage of the sweat, or the small molecules seeping through the ductal epithelium have been proposed to induce the acantholysis in GD. Heat is also blamed directly to cause acantholysis. However, the pathogenesis remains largely unknown.

The acantholysis in GD shows six patterns including: pemphigus vulgaris like, pemphigus foliaceus like, Darier like, Hailey–Hailey like, spongiotic, and mixed. Additional patterns also have been observed. Recent electron microscopic evaluation showed poorly developed tonofibrils in the basal cells. The number of the desmosomes was observed as increased without any change in the structure. These poorly developed tonofibrils are suggested to cause the acantholysis in GD.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_34, © Springer-Verlag Berlin Heidelberg 2015

Clinical Features

GD usually affects older white men (male-to-female ratio: 3/1) with significant photo damage. Its frequency is estimated to be 0.1 %. Prolonged fever and the bed rest are predisposing factors. Thus the disease's frequency increases in bedridden and hospitalized patients to 0.8 %. Exacerbations are induced by heat, exercise, sweating, xerosis, and ultraviolet (UV) radiation. Some drugs including sulfadoxine-pyrimethamine, recombinant human interleukin-4, an aromatase inhibitor (namely, anastrozole), RAF inhibitors such as vemurafenib and dabrafenib, cetuximab, ribavirin, and penicillamine may trigger GD.

The disease is characterized by pruritic papulovesicles or keratotic papules that mainly affect the trunk. Lesions may disseminate to the neck, arms, or thighs. Scalp, mucosa, and palmoplantar areas are usually spared. Unusual presentations of GD include bullous, follicular papules and eczematous plaques. GD may appear along the Blaschko lines or in herpetiform and zosteriform distribution. The size of the lesions ranges between 1 and 3 mm in diameter. Lesions may arise on preexisting lentigines. Pruritus may be absent in approximately 40 % of the patients with GD and cancer. On the other hand, pruritus may be the only symptom of the disease which presents without a cutaneous eruption.

Although the disease is self-limited, recurrences and persistency may be observed. On follow-up, the disease resolves within weeks or months in 43 % of the patients, shows recurrences in 46 %, and persists in 11 % of the patients. Complete remission may be observed between the recurrent attacks. Patients usually have typical flares in summer or winter months.

GD is also reported to be associated with malignancies in 8 % of the patients. Chemotherapy for various malignancies and immunodeficiency conditions, including HIV infection, ionizing radiation, and transplantation, may also associate with the disease. Its incidence has been found as 6 % in acute myelogenous leukemia patients and 1.8 % in bone marrow transplants. Dermatoses such as asteatotic eczema, allergic contact dermatitis, atopic dermatitis, irritant contact dermatitis, and psoriasis may accompany GD in 11 %.

Differential Diagnosis

Grover disease should be differentiated from:

- Darier disease: Involvement of scalp and nails; onset in adolescence or early adult life.
- Hailey–Hailey disease: Onset in younger patients; the flexural involvement including the axilla, groin, perianal region, and lateral aspects of the necks together with the family history.
- Folliculitis: Reveals positive bacterial culture; follicular localization of pustules.
- Acne vulgaris: Earlier presentation with comedones and pustules.
- İmpetigo: Positive bacterial culture and typical crusting.
- Herpes zoster: Multinucleated giant cells on Tzanck smear.
- Scabies: Tunnels on the interdigital spaces; involvement of the glans and the nipples.
- Seborrheic keratoses: Typical dermoscopic features including milia-like cysts, comedo-like openings, brain-like appearance, and light brown fingerprint-like structures.
- Syphilis: Positive serologic tests.
- Pemphigus: Positive characteristic directs immunofluorescence deposition in a fishnet pattern.
- Galli–Galli disease: It is the acantholytic variant of Dowling–Degos disease. Focal reticulated pattern together with generalized involvement of the body including the hands. Skin biopsy lacks acantholytic patterns seen in Grover disease.

General Principles of Treatment

Since GD may regress spontaneously, there are no placebo-controlled trials and no guidelines for the treatment. Patients should be instructed to avoid exacerbating factors.

Soothing baths, emollient bath oils, colloidal oatmeal, regular use of emulsions, zinc oxide lotion, mentholated or calamine lotion, and pramoxine-containing preparations help to control the pruritus. Irritant products should not be used to avoid an isomorphic response. Antihistamines may obtain symptomatic relief. But they do not effect development of new lesions. Topical retinoids may be prescribed. Systemic therapy should be considered for recalcitrant, generalized cases. Treatment modalities are given in Table 34.1.

Table 34.1 Treatment modalities in GD

Topical
Corticosteroids
Calcipotriol
Tacalcitol
Tretinoin
Phototherapy
PUVA, narrowband UVB, UVA1
Systemic
Vitamin A
Corticosteroids
Retinoids
Methotrexate
Alternative
Medium-depth chemical peel (TCA)[a]
Red-light 5-aminolevulinic acid photodynamic therapy (ALA-PDT)

Modified from Kouba et al. 2006

[a]Trichloroacetic acid

Topical Treatments

Topical Steroids

Highly potent steroid creams are usually prescribed for localized disease. Topical steroids are successful in approximately 50 % of the cases.

Calcipotriol

It is the synthetic analogue of calcitriol and the bioactive form of vitamin D3. It has got immunomodulatory effects, regulates keratinocyte differentiation, and inhibits proliferation of keratinocytes. It is used alone or in combination with topical steroids such as betametasone ointment. Another vitamin D3, tacalcitol, has been reported as effective in a case report of GD.

Systemic Treatments

Oral Vitamin A

Oral vitamin A, 50,000 1U, may be administered three times per day for 2 weeks. The dosage is then reduced to 50,000 IU daily for a maximum of 12 weeks.

Corticosteroids

Systemic steroids suppress inflammation and pruritus. After the control of the disease, a minimum maintenance dose is recommended. Relapses may occur after cessation of systemic steroids.

Retinoids

Isotretinoin 40 mg/day has been used for 2–12 weeks. After improvement, it is suggested to taper the dose to 10 mg/day. Acitretin 0.5 mg/kg/day has been prescribed alone or in combination with calcipotriol ointment.

Methotrexate (MTX)

MTX 25 mg/week has been used. It has been found effective in some refractory cases.

Phototherapy

Psoralen-UVA, bath PUVA, and medium-dose UVA1 cold-light irradiation therapy have been used with success in GD. However, flare may be observed during the phototherapy.

Etanercept

Etanercept has been used 50 mg subcutaneously, twice weekly in a patient of GD for 6 weeks with success.

Alternative Treatments

Alternative treatment approaches should be used when the systemic therapies fail for the recalcitrant cases of GD. This includes trichloroacetic acid (TCA).

TCA

This method is based on the ablation of the affected epidermis to clear the pathologic process by reepithelialization. The standard concentration of TCA, 20–30 %, has been used successfully for the treatment in a recalcitrant GD patient.

ALA-PDT

Red-light 5-aminolevulinic acid photodynamic therapy has treated a recalcitrant case of GD after a single treatment session.

Hailey-Hailey Disease (Familial Benign Pemphigus)

35

Carmen Maria Salavastru and George-Sorin Tiplica

Key Points

- Hailey-Hailey disease is a rare autosomal dominant skin disease due to mutations in the *ATP2C1* gene.
- The diagnosis is sustained by the clinical manifestations (recurrent erythematous plaques with erosions and fissures in the intertriginous areas) and the histopathological elements (acantholysis, "dilapidated brick wall" structure of epidermis).
- Topical antibiotic/antifungal therapy and topical corticosteroids are indicated in the mild form of the disease. In severe cases systemic antibiotics/antifungals and systemic corticosteroids can be used. Other treatments include: botulinum toxin injections, retinoids and laser CO_2 ablation.
- The patients have a poor quality of life, and in spite of different treatment attempts, both topical and systemic, the results are unsatisfactory.

Definition

Hailey-Hailey disease (familial benign chronic pemphigus, familial acantholytic dermatosis) is a rare skin disease with autosomal dominant transmission characterised by recurrent eruption of acantholytic blisters manifested in early adulthood.

Basic Concepts of Pathogenesis

ATP2C1 is the defective gene in Hailey-Hailey disease. This gene, located on 3q21-24, encodes the related human secretory pathway Ca^{2+}/Mn^{2+} ATPase (hSPCA1). hSPCA1 is located in the Golgi apparatus and is involved in the cytosolic and intra-Golgi Ca^{2+} and Mn^{2+} homeostasis. The decrease of Ca^{2+} or Mn^{2+} concentrations in the Golgi apparatus is inducing alterations in the construction of desmosomal components and other proteins involved in keratinocyte adhesion. More than 80 mutations in the ATP2C1 gene were described, but there is no correlation between genotype and phenotype.

C.M. Salavastru • G.-S. Tiplica (✉)
2nd Clinic of Dermatology, Colentina Clinical Hospital – "Carol Davila" University of Medicine and Pharmacy, Bucharest, Romania
e-mail: tiplica@upcmail.ro

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_35,

Clinical Presentation

The disease debut is in early adulthood and consists of oval erythematous plaques covered with vesicles and post-vesicular lesions (erosions, fissures), scales and yellow crusts. The lesions are distributed symmetrically on the flexures (mainly involving the axillae and the groin) and friction sites. The flexural lesions are wet and can become hypertrophic and malodorous (Figs. 35.1 and 35.2) – a sign of secondary infection with bacteria or fungi. At the beginning the lesions are itchy and become painful when erosions and fissures develop. The lesions occur in recurrent eruptions, more severe during the hot seasons. Longitudinal white lines are formed on the fingernail plate (Fig. 35.3). Oral or genital eroded lesions can rarely occur. Few cases were described with segmental lesions (e.g. along Blaschko lines).

The disease is autosomal dominant with variable phenotypic expression, from mild forms (e.g. limited eczematous lesions, nail changes only) to severe forms (e.g. multiple painful flexural lesions).

Fig. 35.1 Hailey-Hailey disease: right axillary area

Fig. 35.2 Hailey-Hailey disease: right groin

Diagnosis: Histopathology

The histopathologic examination of the skin shows suprabasal clefting with acantholytic cells. Keratinocytes in stratum malpighii show few intercellular connections, mimicking a "dilapidated brick wall". Also present are discrete dyskeratosis and moderate perivascular lymphocytic infiltrate in the superior dermis (Fig. 35.4). The direct immunofluorescence examination is negative.

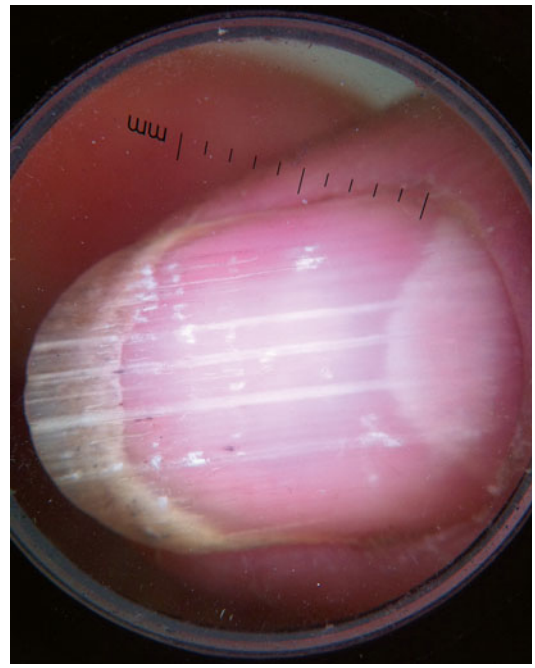

Fig. 35.3 Hailey-Hailey disease: fingernail plate with longitudinal *white lines* – dermatoscopic view

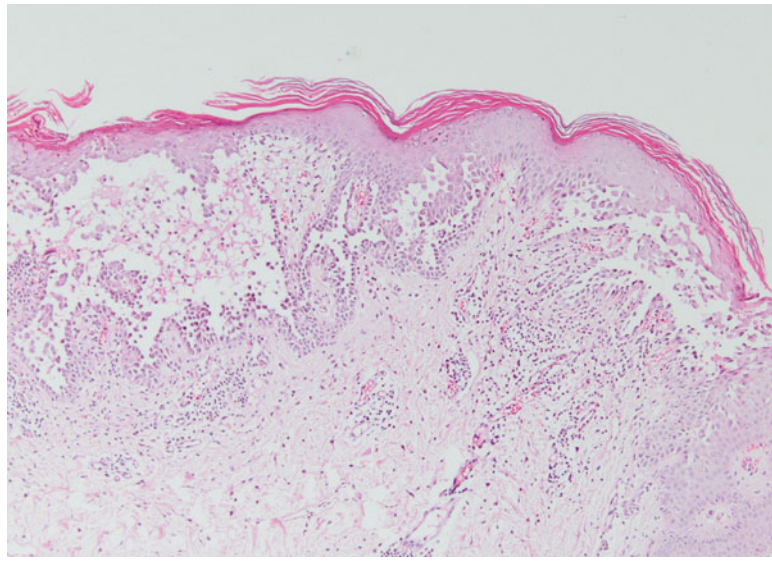

Fig. 35.4 Hailey-Hailey disease: "dilapidated brick wall" aspect (H-E, 10×) (Courtesy of A/Prof. Sabina Zurac, "Carol Davila" School of Medicine, Bucharest)

Differential Diagnosis

The autosomal dominant transmission of the disease and the adult onset of acantholytic blisters in the flexures are guiding elements for a positive diagnosis. Hailey-Hailey disease should be differentiated from:

- Darier-White disease
- Galli-Galli disease
- Eczema (contact dermatitis)
- Bacterial infection (impetigo, erythrasma)
- Fungal infection (dermatophytic or *Candida* spp. intertrigo)
- Viral infection (herpes simplex, varicella-zoster virus)
- Pemphigus vulgaris
- Pemphigus vegetans
- Epidermolysis bullosa simplex
- Inverse psoriasis vulgaris
- Extramammary Paget disease

General Principles of Treatment

Hailey-Hailey disease has no specific treatment. Most of the literature reports are limited to small series of cases. The Hailey-Hailey patient has a reduced quality of life and must constantly avoid mechanical trauma, skin maceration in the folds and exposure to ultraviolet light. Maintaining a normal weight and wearing comfortable clothing are recommended for moisture and friction prevention.

Topical Treatments

In patients with a mild form of Hailey-Hailey disease, the topical therapy is efficient for the remission of the inflammatory plaques and concomitant infection. Disinfectant measures (compresses or baths) can be used daily for the infection control: $AgNO_3$ 1 % solution, chlorhexidine, diluted bleach, etc. Local antibiotics will better treat the bacterial infection: gentamicin (also proven of value in selected patients with nonsense mutation in *ATP2C1* due to the read-through inducing capacities of aminoglycosides), clindamycin, neomycin and bacitracin. Azoles (clotrimazole, bifonazole, ketoconazole) are also recommended for controlling the mycotic infection.

Topical corticosteroids of mild potency (e.g. betamethasone dipropionate, fluticasone propio-

nate, mometasone furoate, triamcinolone acetonide, fluocinolone acetonide) are recommended for treating the inflammation. Combination of topical products including corticosteroids, antifungals and antibiotics can also be used when secondary infection is suspected.

In patients with frequent limited recurrences or in low-response cases, benefits can be obtained from topical retinoids or tacrolimus cream or calcipotriol cream.

Systemic Treatments

Systemic treatments are useful in severe forms of Hailey-Hailey disease. Systemic antibiotics are used according to the culture results. Long cures of erythromycin or cyclines (tetracycline, doxycycline, minocycline) can also be used for the anti-inflammatory effect. Systemic acyclovir will be used in case of herpes simplex virus infection. Systemic corticosteroids (e.g. prednisone 0.5–1 mg/kg) in short cures can reduce the skin inflammation. Systemic retinoids are not as effective as in Darier-White disease. Acitretin (25 mg/day) and also isotretinoin, etretinate and alitretinoin were reported as useful in some patients.

Other systemic treatments that can be used in severe or recalcitrant cases with different efficacy results are cyclosporine (2.5–3.5 mg/kg*day), dapsone (100 mg/day), thalidomide, methotrexate, systemic calcipotriol and etanercept.

Other Treatment Options

The reduction of sweating by botulinum toxin local injection was reported by many authors as beneficial in Hailey-Hailey patients. Surgical excision and skin grafting were also a successful treatment option for some patients. Of benefit in the case of patients with localised recalcitrant Hailey-Hailey disease was the destruction of lesions by dermabrasion with sterile sandpaper or CO_2 laser or selective tissue removal with Alexandrite laser or erbium:YAG laser. Photodynamic therapy with 5-aminolevulinic acid was reported as efficient in some patients.

Treatment Algorithm for Hailey-Hailey Disease Treatment (Fig. 35.5)

Future Perspectives

The developments in Hailey-Hailey disease pathogenesis can generate personalised therapy in selected patients. Aminoglycosides and non-aminoglycoside compounds that induce read-through of nonsense mutations can be of benefit in Hailey-Hailey patients with this type of mutation. As a disease produced by a single gene mutation, Hailey-Hailey disease is a candidate for gene therapy.

Hand Dermatitis

36

John English, Angelo Massimiliano D'Erme, and Massimo Gola

Key Points

- Hand dermatitis, also known as hand eczema (HE), is the most common skin disorder affecting the hands. It is not a homogeneous disease, and it can occur in many and various forms either for clinical presentation or for severity.
- As shown in multicenter studies, (chronic) HE is associated with an inability to work and job loss, and the quality of life (QoL) is clearly compromised.
- Usually HE may be triggered by the contact with exogenous factors, and depending on them, it is possible to distinguish *irritant* and *allergic* contact dermatitis, or the influence of phenotypic factors, as in atopic dermatitis, can be predominant. During the normal practice, it is very common to observe mixed forms where development of HE involves multiple factors that may be present at the same or at different times.
- Chronic hand eczema (CHE) is not a uniform disease. It can be described as persistent HE (with own etiology and clinical manifestation) over 3 months or returns twice or more within 12 months.
- Successful basic therapy requires proper skin hydration; use of emollients; identification and avoidance of irritants, allergens, and specific trigger factors; antimicrobial treatment; skin protection measures; and educational programs. They have to be personalized according to the features of HE.
- The specific and proper use of topical corticosteroids (TCS) remains the first-line anti-inflammatory treatment of HE. They are fast acting and very effective in the short term (few weeks) for controlling the disease when the disease severity is mild to moderate.
- Phototherapies (mainly UVA1 and narrowband UVB) can be useful in moderate to severe forms, as well in HE unresponsive to TCS, including also very potent TCS.
- The management of severe *chronic hand eczema* (CHE) is often *challenging*, difficult, and unsatisfactory, further worsen by a not adequate response to local therapy. The therapeutic options for these

patients are extremely limited. There is a clear medical need for an effective intermittent, long-term therapy to treat this chronic condition.

- Alitretinoin (9-cis-retinoic acid) has been specifically developed for the (long-term) management of CHE. The efficacy, safety, and tolerability of alitretinoin have been proved by multicenter trials and physician experiences. There are two traded formulations of alitretinoin: 10 and 30 mg. A 75 % improvement of clinical scores of CHE after 24 weeks was observed (48 % of patients achieve "clear" or "almost clear" hands within 12–24 weeks). The highest response was obtained in cases of hyperkeratotic CHE.

Definition and Epidemiology

Hand dermatitis, also known as hand eczema (HE), is the most common skin disorder affecting the hands. It is not a homogeneous disease, and it can occur in many and various forms either for clinical presentation or for severity. A wide range of clinical presentation has been reported: from mild, acute, and self-limiting forms to chronic and severe, refractory to treatment.

The clinical presentation includes scaling, lichenification, vesiculation/blistering, erythema, edema, hyperkeratosis, fissures, pruritus, and pain.

For these reasons a comprehensive differential diagnosis is often necessary.

The annual prevalence of hand eczema (HE) in the general population is between 7 and 12 % in Central and Northern Europe and the incidence at about 5 per 1,000.

Studies have reported a higher incidence of HE in female patients, which is most likely because of environmental factors.

The commonest causative factors and/or cofactors are a combination of irritants, mainly in domestic or working environment, and contact allergens with phenotypic factors (i.e., atopy, barrier deficit (i.e., filaggrin), and psoriasis).

A lot of affected people are workers and use their hands in their jobs.

High-risk professions are those where the job is made in a wet work environment: hairdressers, bakers, florists, healthcare workers, barman, metal workers, etc.

The annual rate of new hand eczema(s) is about 0.7 new cases per 1,000 workers in Germany: probably this rate may be higher due to the unreported cases.

Chronic hand eczema (CHE) has been defined as either a long-lasting, relapsing course of HE or HE unresponsive to standard treatment with topical corticosteroids (and basic therapy).

The proportion of chronic severe hand eczema (CHE) is estimated to be 5–7 % of all cases of HE, and 2–4 % are those refractory to topical treatment.

CHE has a poor long-term prognosis. It is very costly (most of the affected people are workers), and it has negative repercussion on people's quality of life.

Thus CHE is a very important issue in health economics and social medicine, as pointed out by several studies in the last years.

As shown in multicenter studies, (C)HE is associated with an inability to work and job loss. As a consequence, the (C)HE has a considerable economic impact on the patient, his or her employer, and the responsible insurers.

For example, painful rhagades, fissures, and erosions can severely restrict manual activities, causing significant impairment at work, in daily activities, and in social interactions. In Sweden up to 8 % of patients suffering from CHE have been forced to change jobs because of their disease. In Europe, the economic impact of HE has been estimated at €11 billion per year, only considering direct medical costs (cost for treatment, medication, visit, etc.). The direct nonmedical costs (as travel, informal care, etc.) and the indirect nonmedical costs (as loss of productivity, reduced performance at work, worsening of quality of life) were not considered in the total amount.

Furthermore, the quality of life (QoL) is clearly compromised. Hands are needed for a proper communication, expression, and working.

A lack of understanding of the disease and a suspicion of the people that the disease is contagious contribute further to the problem. HE is associated to psychological repercussions as shame, low self-esteem, anxiety, depression, withdrawal, and phobias.

Pruritus can increase the psychological stress (and vice versa), and they can lead to sleeplessness.

It has been shown that severe CHE is associated with a significant lowering of quality of life on par with that of generalized eczema or psoriasis.

About 50 % of all patients with hand eczema receive dermatological treatment, and about 5 % of them are off work due to the disease.

Basic Concepts of Pathogenesis

There is currently no universally accepted classification for HE. There is no single "hand eczema," but it includes different forms of disease.

HE is an inflammatory, noninfectious skin eruption whose pathogenesis can involve a combination of constitutional factors and exogenous factors. Undoubtedly, the impaired skin barrier function is a key factor in the pathogenesis of eczema. The dysfunction can be caused by a genetic predisposition (e.g., atopic skin diathesis, skin barrier component dysfunction, etc.) and environmental factors as irritants (low humidity, low or high temperatures, sweating, long-term application of topical corticosteroids, etc.), allergens, and exogenous proteases from house dust mites and *Staphylococcus aureus*.

Skin barrier dysfunction further increases the risk of penetration of irritants and allergens and the inflammation among the time.

During a clinical history, it is often possible to observe several causes (from exogenous to endogenous), heterogeneous morphological appearances (i.e., acute to chronic eczema, dyshidrosiform, hyperkeratotic-rhagadiform or "psoriasiform," nummular, etc.), and different manifestation sites (e.g., dorsal, palmar, interdigital, localized only at hands or more diffuse, etc.).

Usually HE may be triggered by the contact with exogenous factors, and depending on them, it is possible to distinguish *irritant* and *allergic* contact dermatitis, or the influence of individual factors, as in atopic dermatitis, can be predominant. During the normal practice, it is very common to observe mixed forms where development of HE involves multiple factors that may be present at the same or at different times. Thus the classification of hand eczema is challenging and it can be carried out according to etiological and morphological criteria as well as the affected location as reported in Table 36.1.

Severity can be evaluated according to the physician global assessment (PGA) (Table 36.2).

Table 36.1 Classification of hand eczema

Etiology (types of hand eczema)
Irritant HE
Allergic HE
Atopic HE
Other (vesicular/pompholyx type, protein contact dermatitis, idiopathic hyperkeratotic-rhagadiform, etc.)
Location
Dorsal surface of hands
Palmar surface of hands
Lateral margins of fingers
Fingertips
Interdigital folds
Wrists
One hand involved (or more involved than the other one)
Morphology
Redness, scaling
Acute exudative
Lichenified
Dyshidrosiform (vesicular)
Hyperkeratotic-rhagadiform (or psoriasiform)
Nummular
Severity (PGA)
Clear
Almost clear
Mild
Moderate
Severe
Duration
Acute
Chronic (>6 months or two relapse in 12 months)

From Diepgen et al. (2009) modified

Table 36.2 Physician global assessment (PGA)

PGA severity	Features	Intensity	Area involved
Severe	Erythema, scaling, hyperkeratosis/lichenification	At least one moderate or severe	>30 % of affected hand surface
	Vesiculation, edema, fissures, pruritus/pain	At least one severe	
Moderate	Erythema, scaling, hyperkeratosis/lichenification	At least one mild or moderate	10–30 % of affected hand surface
	Vesiculation, edema, fissures, pruritus/pain	At least one moderate	
Mild	Erythema, scaling, hyperkeratosis/lichenification	At least one mild	Less than 10 % of affected hand surface
	Vesiculation, edema, fissures, pruritus/pain	At least one mild	
Almost clear	Erythema, scaling, hyperkeratosis/lichenification	At least one mild	Less than 10 % of affected hand surface
	Vesiculation, edema, fissures, pruritus/pain	Absent	
Clear	Erythema, scaling, hyperkeratosis/lichenification	Absent	Not detectable
	Vesiculation, edema, fissures, pruritus/pain	Absent	

From Ruzicka et al. (2008)
The area involved does not apply to patients with eczema localized to fingertips. In the evaluation, the surface that refers to the surface area of the more severely affected side of the more affected hand has to be considered

Another commonly used scale is the modified total lesion symptom score (mTLSS).

HE varies in severity. Especially for CHE, a validated photographic guide has been carried out to better classify the CHE together, the PGA, and mTLSS scales.

Almost clear to mild HE heals quite quickly. Moderate eczema can persist for several weeks despite adequate dermatological therapy and cooperation of the patient. Severe eczema of the hands can be very difficult and challenging to treat.

At the moment, we can distinguish four main types of HE: irritant (subtoxic-cumulative) HE, allergic HE, atopic HE, and other forms of HE.

All these kinds of eczemas can become chronic with a chronic relapsing course (chronic hand eczema, 5° type).

The etiopathogenesis and clinical features of the "five main" types and of the CHE are reported in Table 36.3.

Table 36.3 Characteristics of irritant, allergic, and atopic hand eczema, other forms, and chronic hand eczema

1. Irritant (subtoxic-cumulative) hand eczema (IHD) (Fig. 36.1)
Etiopathogenesis
It is the result of repeated irritating harmful substances over a longer period of time in concentrations too low to produce an acute and immediate reaction
When the irritant is within the work environment, an improvement during the weekend (and healing possible with extended periods away from work) has been reported
Constitutional factors, as atopic skin diathesis and hyperhidrosis, promote its development
Location
Backs of the hands, fingers, exposed areas of the forearms, and, later, the inner surfaces of the hands are the most commonly involved areas
Skin symptoms are limited to the hands
Morphology
At the beginning, skin is raw, dry, and scaly. Acute manifestations are usually rare
After prolonged or repeated exposure to one or more irritants, there is development of redness, infiltration, and lichenification
Lastly, painful rhagades development and hyperkeratotic plaques interspersed with rhagades (hyperkeratotic-rhagadiform eczema)
Lesions present relatively well-defined borders and are not so itchy (as in allergic contact dermatitis)
2. Allergic hand eczema (AHD) (Fig. 36.2)

Clinical Presentation

Chronic Hand Eczema (CHE)

Chronic hand eczema (CHE) is not a uniform disease. There is no universally accepted

Table 36.3 (continued)

Etiopathogenesis
It is the result of delayed contact hypersensitivity (type IV hypersensitivity) to one or more allergens in a sensitized individual (verification with patch test is mandatory)
Protein contact dermatitis is also reported (rarely)
In occupational causes, the development and exacerbation occur in the working environment. An HE improvement during the weekend, up to a good improvement to healing on vacation, and a new relapse within days of returning to work are often reported
Location
The affected site corresponds to the area of exposure to the allergen
Involvement of exposed areas is typical (airborne dermatitis)
Spread of the dermatitis around the site of the exposure (d.d. irritant hand eczema)
Morphology
Acute exudative phase: it is possible to observe redness, vesicles, exudation, and excoriation. Severe pruritus is often reported
Chronic stage: hyperkeratosis, scaling/lichenification, infiltration, rhagades
Irregular border around the exposure sites (different from IHD)
3. Atopic hand eczema (Fig. 36.3) (AE)
Etiopathogenesis
Result of atopic eczema or atopic skin diathesis
Quite common involvement of hands in adult atopic dermatitis(AD)
Frequently unrelated to occupation but it is worthy to remember that irritant or occupational factors can trigger skin manifestation
Location
Often involves the backs of the hands (especially the dorsal site of the fingers)
Involvement of the nails can be present
Hand eczema can be the only site of AD involvement, or the hand can be a site of an AD spreader involvement (as flexor surfaces, face, neck)
Involvement of the wrist and of the "snuff box"
Morphology
Vesicles (dyshidrosiform morphology) in palmar and interdigital surfaces
Poorly bordered lichenified patches at the backs of the hands, mainly fingers and flexor surfaces of wrists
Scaling and rhagades in the lichenified patches on backs of the fingers
Sometimes nummular lesions on backs of hands

Table 36.3 (continued)

4. Other forms of eczema
Vesicular (dyshidrosiform), hyperkeratotic-rhagadiform (discussed in CHE), and nummular eczema
In this group it is possible to highlight an irritant, allergic, and/or atopic etiology or a combination of thereof
4.1 Vesicular (dyshidrosiform)
An atopic skin diathesis is common to observe
Location
Solitary blisters (pompholyx) mainly in the interdigital lateral spaces
Severe itching
Morphology
Solitary blisters (pompholyx) accompanied by severe inflammatory redness around and severe itching
4.2 Nummular eczema (Fig. 36.4)
An atopic skin diathesis and a history of AD are common to observe
Location
Dorsum of the end
Other lesions can be present on the wrist and arms and spread on the body
Morphology
Round-to-oval erythematous plaque on the back of the hands
5. Chronic hand eczema (CHE) (Fig. 36.5)
It can be the result of the IHD, AHD, AE, or other forms becoming chronic
Differences in etiology, morphology, and course explain the heterogeneity in the clinical manifestation and in the course of CHE
The hyperkeratotic-rhagadiform, vesicular, and mixed pattern HE are the most common manifestation
Location
Palmar and dorsum site
Tendency to recur at the same site
Morphology
Irregularly bordered, symmetrical, hyperkeratotic, lichenified lesions with painful rhagades
Absence or mild pruritus
The absence of vesicular eruptions is characteristic

classification for etiologically and clinically heterogeneous disease group. It can be described as persistent HE (with own etiology and clinical manifestation) over 6 months or returns twice or more within 12 months.

Differences in etiology, morphology, and severity make accurate diagnosis difficult and challenging.

Fig. 36.1 Irritant contact eczema

Fig. 36.2 Allergic contact eczema

Fig. 36.3 Atopic dermatitis of the hands

The environment and individual factor interactions explain the different manifestations during the course.

The correct diagnosis is further hampered by the lack of a systematic classification system. It is based on etiology when possible and morphology when necessary.

Foot involvement is considered a distinguishing feature for idiopathic eczema if no other criteria (allergic or irritant contact dermatitis or atopic eczema) explain the plantar involvement.

Diagnosis

Given these limitations, accurate diagnosis of the disease is challenging and should be based on a careful patient history and on clinical examination (morphology and distribution of the lesions) (Fig. 36.6). Differential diagnoses, as psoriasis, infections, or other causes, must be excluded.

Diagnostic patch testing with the standard series, supplemented with additional specific

Fig. 36.4 Nummular eczema of the hands

Fig. 36.5 Chronic (hyperkeratotic) hand eczema

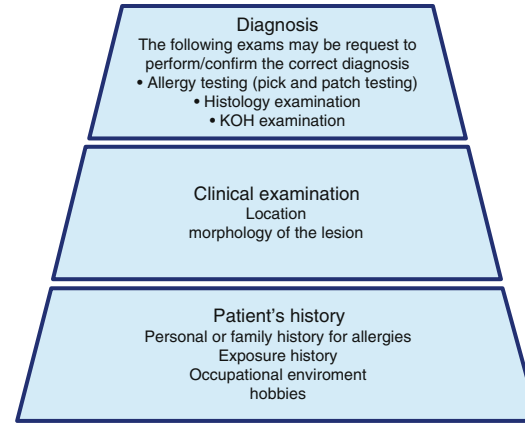

Fig. 36.6 Diagnosis of HE

series, other relevant allergens, and products used by the patient, according to the patient's exposure should be considered as a mandatory step.

The positivity of patch test(s) has to be relevant for the disease activity of CHE (as emerged from careful clinical history). Thus the diagnosis of allergic contact hand eczema can be made.

In a small studied group (22 patients with CHE and positive patch tests), the most common allergens are nickel (6), fragrance (3), medicaments (3), chromium (2), preservatives (2), permanent hair dye (2), and *Compositae* (1).

If no contact allergy is found and the patient has had relevant exposure to irritants (emerged from careful medical history), the dermatitis can be classified as irritant contact dermatitis. To confirm the diagnosis, an improvement of dermatitis with education and irritant avoidance has to be registered.

Lastly, a history of atopic dermatitis and other AD involvement can help in the diagnosis of AE.

The combination of irritant, allergen factors and atopic constitution contributes to led the

disease severe and chronic, the diagnosis difficult, and the management challenging. The clinical presentation varies greatly, making allergic and irritant types of eczema of the hands difficult to distinguish clinically and histologically.

Especially the correct diagnosis of hyperkeratotic-rhagadiform eczema can be very difficult due to its clinical and histological similarity to acral psoriasis.

It is important to remember that allergen avoidance may improve the eczema considerably but rarely leads to a complete cure underlying the multifactorial causes and features of HE. Even with the individualization and the avoidance of irritant/allergen factors, HE develops into a chronic condition as other dermatological skin diseases. Moreover the treatment is challenging and often unsuccessful despite adequate dermatological therapy and patient compliance.

Differential Diagnosis

Psoriasis, lichen ruber, and tinea manuum, in particular, can often be difficult to differentially diagnose and are sometimes mistakenly treated as eczema. Secondary infection of hand dermatitis with *S. aureus* is common.

Histological analysis is suggested in any skin disorder of uncertain cause or where the clinical diagnosis is doubtful.

Unfortunately, also histological examination cannot represent a valuable tool for the physician to distinguish clinically acral psoriasis from hyperkeratotic-rhagadiform eczema (whose similar clinical features are reported in Table 36.4). Table 36.5 lists diseases which should be considered as differential diagnoses. An accurate diagnosis of hand eczema leads to better management.

Table 36.4 Different features of psoriasis and hyperkeratotic-rhagadiform eczema. The clinical manifestations can be similar to each other

Psoriasis	Hyperkeratotic-rhagadiform eczema
Not usually itchy	Often itchy
Painful fissuring	Painful fissuring
Dry, silvery scale	Vesicular, scaly
Well-defined lesions	More diffuse lesions (border)
Nail and knuckle involvement	Nail can be involved
Koebner phenomenon	No Koebner phenomenon
Can be symmetrical	Often symmetrical
Often the palmar site is first involved	The palmar and dorsal site can be involved
Chronic relapsing	Often chronic relapsing

From English et al. (2009) modified

General Principles of Treatment

Although there are different therapeutic strategies for each group of HE, all patients should be educated and should adhere to skin protection measures and lifestyle changes to minimize exposure to allergens or irritants.

Allergen avoidance may also be beneficial, but not all contact allergies are clinically relevant. Table 36.6 lists measures that should be considered.

In Fig. 36.7 the general recommendation for HE according to its severity is reported.

Despite that HE is not a uniform disease, the basic therapy represents the first step in the long-term management of HE.

The treatment of hand eczema must take into account the following features in order to perform the correct management and therapy:

- Disease etiology (atopic, allergic, irritant, vesicular)
- Acuteness (acute vs. chronic eczema)
- Morphology (redness, scaling, lichenification, blistering, hyperkeratosis, rhagades, pruritus, etc.)
- Location (dorsal aspects of hands, interdigital spaces, palms)

Despite lots of literature data and clinical experience with various therapies, randomized controlled trials (RCT) are still lacking.

HE of recent onset should be treated promptly and vigorously in order to prevent the vicious circle of CHE. In fact the barrier damage and inflammation favor the penetration of irritants and allergens that further damage the skin barrier.

Table 36.5 List of diseases which should be considered in differential diagnosis with HE

Disease	Differential diagnoses	Notes
Psoriasis vulgaris	Personal or family history and clinical examination	Patch test and histological examination can help sometimes
Psoriasis pustulosa	Personal or family history and clinical examination. Sterile pustules	Neutrophils in the pustules
Acrodermatitis continua of Hallopeau	Personal or family history and clinical examination	
Tinea manuum	KOH examination	
Lichen planus	Different location (wrist) and morphology lesions (papules)	
Mycosis fungoides	Personal or family history and clinical examination	
	Histological examination	
Dermatitis (striata) pratensis	Personal history. Dermatitis bullosa and striata	
Palmar (and plantar) keratoderma	Personal or family history and clinical examination	
Scabies	Pruritus and clinical examination	
Fixed drug eruption	Personal or family history and clinical examination	
	Histology	
Pityriasis rubra pilaris	Other body sites affected	
	Histology	
Lupus erythematosus	Personal or family history and clinical examination	
Dermatomyositis	Personal or family history and clinical examination	
	Dorsum of the hand: Gottron papules	

Table 36.6 List of skin protection measures and lifestyle changes to minimize exposure to allergens or irritants

Short-term prophylactic measure of using gloves; however, do not use gloves for a long time as this will induce sweating of the hands. Use cotton liners or loosely fitting neoprene gloves
Short-term use of disposable gloves to avoid contact with irritants: washing powder, shampooing, dishwashing liquid, cleaning liquid such as toilet cleaner, etc.
Even the gloves themselves can sometimes aggravate the condition
Wash hands with mild, non-perfumed soap to reduce amount of skin bacteria
Avoid contact with certain food items: tomatoes, peeling of oranges, citrus fruits, and such like. Avoid juice from fish, meat, and certain vegetables. The patient's own experience will show what must be avoided
Reduce the amount of manual work at home and discuss where the partner could and should help, e.g., cleaning, dishwashing, helping the children with their baths, changing of the nappies, etc.
Avoid hair dying and potent allergens (i.e., *p*-phenylenediamine, acrylic compounds, nickel, etc.)
Complete avoidance of the triggering agent in patients who are sensitized to one or more allergens. Patients must be educated about the relevant contact allergens and where they are present and how to avoid or protect their skin with appropriate care measures
Emollient creams are the standard therapy, and they should be used alone or with all other treatments

Generally, *mild hand eczema* should be treated with anti-inflammatory drugs (topical corticosteroids (TCS)) together with a proper skin protection measures. This therapy, if performed quickly, is effective in controlling the symptoms in lots of these patients. Then a long-term management has to be performed with basic therapy. The short- and long-term management aims to prevent new relapses and to avoid the condition becoming chronic (which happens

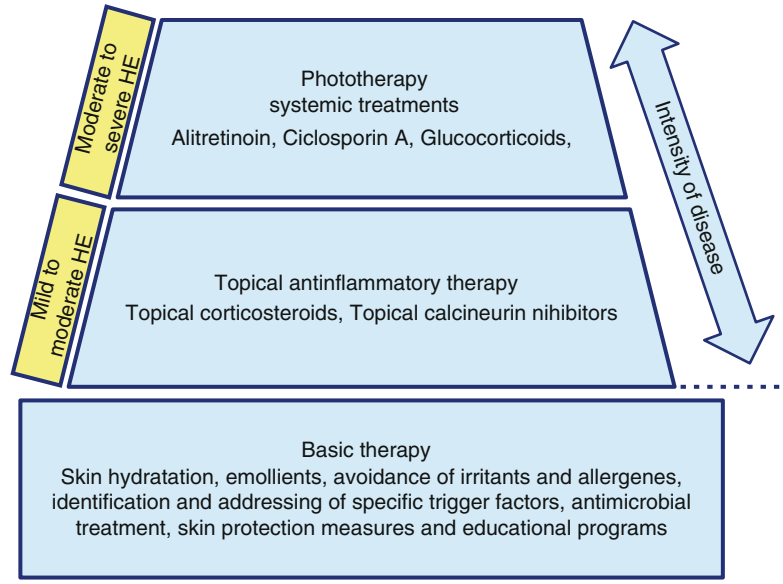

Fig. 36.7 General recommendation for HE according to its severity

in a considerable number of cases despite basic therapy and potent TCS).

It is important to note that a complete functional regeneration of the epidermal barrier requires several weeks or months after healing.

Chronic hand eczema is very difficult to treat and manage. They should be referred immediately and the treatment should not be delayed.

A successful management requires treatments that restore the skin barrier and control the inflammation.

Basic Therapy

Successful basic therapy requires proper skin hydration; use of emollients; identification and avoidance of irritants, allergens, and specific trigger factors; antimicrobial treatment; skin protection measures; and educational programs (as reported in Table 36.6).

Cleansing and Bathing

Patients with HE should follow a correct cleansing of the hands. As for atopic dermatitis, oil bath has to be preferred. The patient's washing habits have to be investigated. In fact excessive number of hand washing can be irritating for the hands.

Emollients

Consistent use of a moisturizing and emollient agent is key component in basic therapy. In particular, preparations should be free of any preservatives, fragrances, and perfumes (as well as for bath oils).

They should contain few ingredients (few or no potential allergens) in order to minimize a contact sensitization.

The vehicle of emollient is also important: In acute disease, dressings, lotions, or creams are preferred. On the other hand, in subacute, lichenified, and chronic stages, ointments are used with better efficacy.

Keratolytic substances can be useful in lichenified and in hyperkeratotic-rhagadiform eczema.

Salicylic acid (up to 20 %) and urea can be used with different concentration. Urea, at a concentration of 5–10 %, has a smoothing and water-binding effect, and it can be useful in lichenified and hyperkeratotic eczema. Sodium lactate, glycerol, sodium chloride, and other molecules can represent an alternative for water-binding and stratum corneum regulation.

Table 36.7 Topical therapy in hand eczema by morphology. They can be combined with the more appropriate pharmacological treatment

Morphology presumed effect of topical therapy (examples)
Vesicular ("*dyshidrosiform*")
Astringent solutions (i.e., potassium permanganate 0.025 %, eosin 2 %, boric acid 3 %)
Pasta exsiccans, zinc oxide barrier cream
When combined with hyperhidrosis, possible used aluminum chloride hexahydrate
Weeping/superinfection
Moisturizing (containing glycerol, urea 5–10 %, coal tar, etc.)
Astringent solution
Disinfectant and antibacterial (chlorhexidine, polyhexanide, povidone iodine, hydrogen peroxide, silver sulfadiazine, triclosan, etc.)
Treat immediately the superinfection (when it is clinically manifest) with pharmacological treatment
Hyperkeratosis
Keratolytic agents (salicylic acid-based ointments, ointments containing sodium chloride or urea)
Rhagades/fissures
Hydrocolloid dressings (rhagades)
Subacute eczematous reaction/lichenification
Anti-inflammatory substances (polidocanol (macrogol lauryl ether), glyceric acid, etc.)
Moisturizing (containing glycerol, urea 5–10 %, coal tar, etc.)
Dry, *scaling*
Moisturizing (containing glycerol, urea 5–10 %, coal tar, etc.)

From Diepgen et al. (2009), modified

Creams containing these molecules have to be used properly, because excessive or incorrect dosages can cause skin irritation and burning. They are also poorly tolerated on the rhagades.

A list of the emollient recommendation has been reported in Table 36.7.

Lastly, as for atopic dermatitis, educational programs and psychological counseling aim to improve the adherence in eczema management, the itch/scratching cognition, and the clinical and psychological condition.

Basic Therapy at Glance

Successful basic therapy requires proper:

- Skin hydration
- Use of emollients
- Identification and avoidance of:
  - Irritants
  - Allergens
  - Specific trigger factors
- Antimicrobial treatment
- Skin protection measures
- Educational programs

They have to be personalized according to the features of HE.

Topical Treatments

The specific and proper use of topical corticosteroids (TCS) remains the first-line anti-inflammatory treatment of HE.

They are fast acting and very effective in the short term (few weeks) for controlling the disease when the disease severity is mild to moderate. The use is limited by rebound flare-ups, tachyphylaxis, and lack of efficacy in severely affected patients. Despite their efficacy in the short term, long-term TCS use should be avoided because of their side effects. In particular, skin atrophy may contribute to further weakening of the skin barrier and further inflammation.

The choice of the potency of corticosteroids and the duration of treatment depend on the morphology, location, and severity of hand eczema.

As reported above (see atopic dermatitis chapter), corticosteroid concentration and its efficacy may be different when the preparation and the vehicles change.

It is commonly suggested to use immediately a potent to very potent steroid (according to the severity of the disease and the age of the patient) once or twice a day, followed by a less potent preparation for few days.

In case of chronic hyperkeratotic-rhagadiform hand eczema, the first treatment recommended is a high-potency corticosteroid (as clobetasol).

In mild to severe forms of HE, TCS have to be combined with the basic therapy. It is worthy to remember that the hand barrier is not restored at all after the end of the treatment. Thus a continued use of a nonsteroidal topical therapy (emollient) is necessary together with a basic education

of the hand skin care in order to achieve a long-term remission.

The possible utility of proactive therapy in the long-term management of HE (mainly chronic) has not been evaluated yet.

Before starting a TCS therapy, the correct diagnosis has to be performed. Other diseases, especially contact sensitivity (also to topical steroids, mainly when the symptoms get worse) and fungal infection, must be ruled out.

Other Topical Treatments

Topical calcineurin inhibitors (TCI) have been studied long in atopic dermatitis, and they can be used in atopic HE. TCI are not licensed for, but have been investigated in, the treatment of mild to moderate CHE. Studies investigating their efficacy in HE are still lacking.

Despite their safe profile (atrophy and other corticosteroid side effects are not reported with TCI), their use in HE is considered a second-line treatment in patients refractory to topical corticosteroids (TCS) or where the TCS use is contraindicated.

Topical Therapy at Glance

- The specific and proper use of topical corticosteroids (TCS) remains the first-line anti-inflammatory treatment of HE.
- They are fast acting and very effective in the short term (few weeks) for controlling the disease when the disease severity is mild to moderate.
- Despite their efficacy in the short term, long-term TCS use should be avoided because of their side effects. In particular, skin atrophy may contribute to further weakening of the skin barrier and further inflammation.
- The choice of the potency of corticosteroids and the duration of treatment depend on the morphology, location, and severity of hand eczema.
- Despite the safe profile of topical calcineurin inhibitors, their use in HE is considered a second-line treatment in patients refractory to topical corticosteroids (TCS) or where the TCS use is contraindicated.

Phototherapy

UVA1, topical PUVA, and UVB have been studied in HE. Narrowband UVB or UVA1 devices as well as excimer laser represent a valuable therapeutic option in these forms of hand eczema. The topical phototherapies have the advantage to limit therapy to the hands without a body irradiation. In this way some side effects (from erythema to potential carcinogenic risks) can be limited.

Since this treatment cannot be easily undertaken at home, one of the major disadvantages is that the patient has to go to the hospital from three to five times a week for the treatment. From 15 to 30 treatments are usually needed to achieve good results. This treatment can also be useful in combination with other topical or systemic therapies. In the literature, there are few studies evaluating the efficacy of phototherapy strategies. It can be a therapeutic option in moderate to severe forms, as well as in HE unresponsive to TCS, including also very potent TCS.

Phototherapy at Glance

- Narrowband UVB or UVA1 devices as well as excimer laser represent a valuable therapeutic option in HE.
- This treatment can also be useful in combination with other topical or systemic therapies.
- It can be a therapeutic option in moderate to severe forms, as well as in HE unresponsive to TCS, including also very potent TCS.

Systemic Treatments

The proportion of severe CHE is estimated to be 5–7 % of all cases, and approximately 2–4 % of patients with severe CHE are refractory to topical treatment.

The management of severe *chronic hand eczema* CHE is often *challenging*, difficult, and unsatisfactory, further worsened by a not adequate response to local therapy. It interferes with social and working life, and it has important and severe negative repercussion on the patients' quality of life. Moreover the majority of patients are workers, and high negative economic repercussion can be shown.

The therapeutic options for these patients are extremely limited. There is a clear medical need for an effective intermittent, long-term therapy to treat this chronic condition.

These patients may benefit (are candidate for) a systemic therapy.

Alitretinoin

Alitretinoin (9-cis-retinoic acid) is a drug approved from 2008 in several European countries for treating severe, chronic hand eczema that does not respond or with an unsatisfactory response to topical corticosteroids.

Alitretinoin, isomer of isotretinoin (13-cis-retinoic acid), is an endogenous physiological retinoid, panaagonist of both vitamin A acid receptors (retinoic acid receptors (RARs) and retinoid X receptors (RXRs).

It has been specifically developed for the (long-term) management of chronic hand eczema.

The exact mechanism of action of alitretinoin in the treatment of CHE is unknown.

Alitretinoin's anti-inflammatory and immunomodulatory properties have led to high response rates with a favorable safety profile over the long-term management.

There are two traded formulations of alitretinoin: 10 and 30 mg.

The efficacy, safety, and tolerability of alitretinoin have been proved by multicentral and national trials and experiences (BACH study and others).

A 75 % improvement of clinical scores of CHE after 24 weeks was observed (48 % of patients achieve "clear" or "almost clear" hands within 12–24 weeks). The highest response was obtained in cases of hyperkeratotic CHE.

A relapse has been observed in a third of cases. Studies have demonstrated that patients who had achieved "clear" or "almost clear" hands and had relapsed within 6 months responded to a second course of treatment.

Patients who had not responded to an initial 24 weeks of alitretinoin treatment achieved "clear" or "almost clear" hands in half of the cases when an additional treatment course of alitretinoin 30 mg for up to 24 weeks was carried out.

A small Italian experience has highlighted the positive impact of the alitretinoin treatment on the quality of life of patients with CHE. This data is of considerable importance considering that the study included 15 people whose jobs required the use of their hands. Eleven of those (73 %) reported moderately to severely impaired at work. Significant improvement of the point 7 of DLQI has been reported in this study. This point covers issues at work or studying, with scores ranging from 0 (no problem at work or studying) to 3 (severe difficulties at work or studying).

The recommended standard dose of oral alitretinoin is 30 mg daily for 12–24 weeks or until healing. Due to the possibility of increased triglycerides, cholesterol, and transaminases and thyroid side effects, some patients should begin with 10 mg once daily.

The most common reported side effect is headache (in about 20 % of cases), within the first 10 days of therapy.

It is very important to remember that alitretinoin, as any other vitamin A acid derivative, is a strong teratogen. Adherence to pregnancy prevention measures is strictly requested from before the beginning of the therapy up to 40 days after the end of the treatment for women of childbearing potential.

In conclusion alitretinoin is an effective, systemic, intermittent treatment for the long-term

management of chronic relapsing disease. The treatment has to be combined with topical therapies.

Systemic Corticosteroids

Systemic corticosteroids are commonly used to treat CHE. Despite their large use, their side effect profile and the lack of clinical studies do not allow to use them for the treatment of this disease. An acute relapse of CHE can benefit from a short period of oral corticosteroids.

Cyclosporine

Cyclosporine is approved for atopic dermatitis (of hands), and it can be used in severe, treatment-refractory HE, as a second-line treatment in patients unresponsive to alitretinoin or where the use of alitretinoin is not possible or is contraindicated. The use of cyclosporine in hand eczema is off-label.

Other Systemic Treatment

The use of other treatments such as methotrexate and azathioprine is reserved (off label) in patients unresponsive to other systemic treatments. Clinical large studies regarding the efficacy of these drugs are lacking.

Systemic Treatment at Glance

- The management of severe *chronic hand eczema* (CHE) is often *challenging*, difficult, and unsatisfactory, further worsened by a not adequate response to local therapy.
- The therapeutic options for these patients are extremely limited.
- There is a clear medical need for an effective intermittent, long-term therapy to treat this chronic condition.
- Alitretinoin (9-cis-retinoic acid) has been specifically developed for the (long-term) management of CHE.
- The efficacy, safety, and tolerability of alitretinoin have been proved by multicenter trials and physician experience.
- There are two traded formulations of alitretinoin: 10 and 30 mg.
- A 75 % improvement of clinical scores of CHE after 24 weeks was observed (48 % of patients achieve "clear" or "almost clear" hands within 12–24 weeks). The highest response was obtained in cases of hyperkeratotic CHE.
- The most common reported side effect is headache (in about 20 % of cases), within the first 10 days of therapy, followed by increase of triglycerides, cholesterol, and transaminases.
- Alitretinoin, as any other vitamin A acid derivative, is a strong teratogen.
- Cyclosporine is approved for atopic dermatitis (of hands), and it can be used in severe, treatment-refractory HE, as a second-line treatment in patients unresponsive to alitretinoin or where the use of alitretinoin is not possible or is contraindicated.
- Despite the large use of oral corticosteroids, their side effect profile and the lacking clinical studies do not allow to use them for the treatment of this disease.

Conclusion

The therapeutic approaches are summarized in Fig. 36.8a–e.

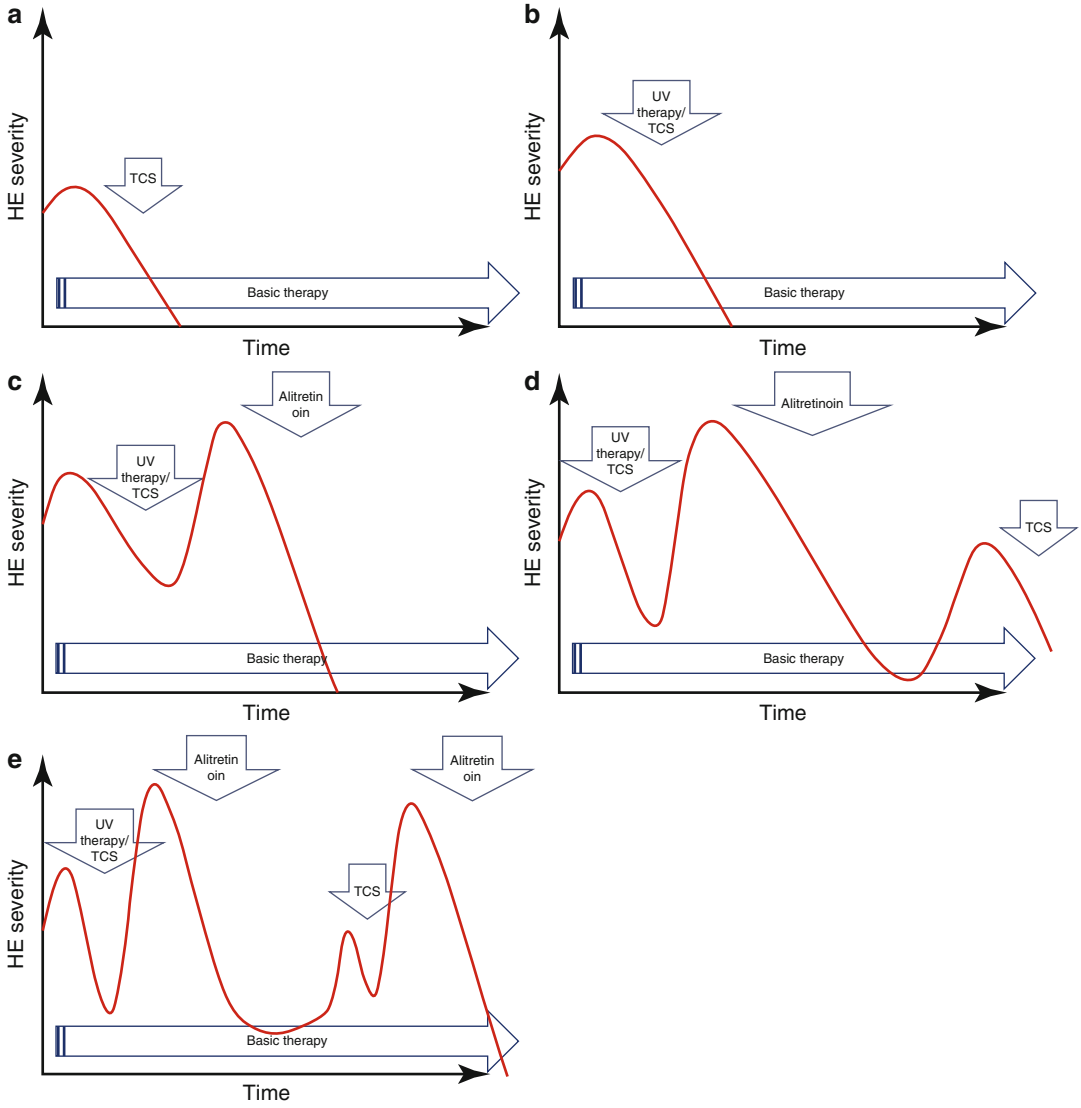

Fig. 36.8 (**a**) Mild and self-limiting HE, (**b**) moderate self-limiting HE, and (**c**–**e**) chronic moderate to severe HE. Topical and systemic treatments have to be combined during the time in order to achieve HE good improvement to remission

Herpes Genitalis

37

Angelika Stary

Key Points

- Genital herpes is a chronic viral infection caused by two types of herpes simplex virus (HSV-1, HSV-2), most cases of recurrent genital herpes caused by HSV-2.
- Clinical diagnosis of genital herpes is often insufficient, and unclear manifestations should be confirmed by laboratory diagnosis in order to enable appropriate treatment and counselling for the patient.
- Cell culture, antigen detection, and PCR are the preferred tests for individuals with potential clinical lesions.
- Antiviral treatment with nucleoside analogues offers clinical benefit to symptomatic individuals with first-episode or primary genital herpes as well as for recurrent herpetic episodes.
- Transmission of HSV to the partner and newborn can occur by viral shedding and should be prevented by antiviral therapy.

Definition and Epidemiology

Genital herpes is caused by the herpes simplex virus type 1 or 2 and is regarded as one of the most common sexually transmitted infections (STI) and the main cause of genital ulcer disease (GUD) in the developing world. HSV-2 infections are estimated to globally affect more than 500 million individuals with an annual incidence of 25 million cases among 15–50 years of age. It is a chronic infection and may last lifelong.

Herpetic lesions in the genital region have already been observed in the ancient period and were described by Greek scholars for a disease with creeping lesions. During the late eighteenth century, oral and genital herpetic lesions were recognised to be eventually associated with the same pathogenesis. Studies in the last century were able to demonstrate type-specific differences in the antigenic pattern between both HSV-1 and HSV-2.

Although most infections are mild or even subclinical, frequent recurrences are a persistent health and psychological burden for the individual with uncertainness concerning the danger of transmission to the sexual partner and newborn. In addition, erosive and ulcerative lesions have an impact on the transmission rate of the human immunodeficiency virus (HIV) and may lead to dangerous manifestations and treatment problems in immunocompromised persons. Only 10–25 % of persons infected with HSV-2 are aware of a genital HSV infection, mostly acquired

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_37, © Springer-Verlag Berlin Heidelberg 2015

from asymptomatic partners. The risk of sexual transmission correlates mainly on viral shedding in the large number of asymptomatic than symptomatic individuals. The risk of transmission of HSV infection to the neonate is high for infants born to mothers with clinical manifestations of first-episode genital herpes. Monitoring of first-episode or recurrent genital herpes during pregnancy is therefore an important preventive strategy for neonatal HSV infections. Potent antiviral agents offer clinical benefits in the treatment of first and recurrent episodes of genital herpes and have proven to reduce the frequency of recurrences when used as daily suppressive therapy. However, they cannot eradicate the latent virus infection and influence the transmission risk or recurrence rate after discontinuation.

Biology of HSV

Over 100 herpesviruses have been isolated in human beings who are the only known reservoir host. The herpes simplex virus type 1 (HSV-1) and herpes simplex virus type 2 (HSV-2) are listed among the group of *Alphaherpesvirinae* (Table 37.1).

The typical structure of herpesviruses is characterised by the double stranded linear DNA genome, an icosahedral capsid of approximately 120 nm, and an envelope with glycoprotein spikes called tegument. The DNA genome codes for about 80 different genes, which are either important for viral growth or infection and replication. The spikes on the tegument express a large number of viral enzymes, and some glycoproteins are responsible for the interaction with the host cell and the cytopathic effect on the infected cells as well as the ability to establish latent infections in the host.

Table 37.1 Classification of human herpesviruses

Alphaherpesvirinae:
Herpes simplex virus (HSV-1 and HSV-2)
Varicella-zoster virus (VZV)
Betaherpesvirinae:
Cytomegalovirus (CMV)
Human herpesvirus 6 (HHV-6)
Human herpesvirus 7 (HHV-7)
Gammaherpesvirinae:
Epstein-Barr virus (EBV)
Human herpesvirus 8 (HHV-8)

Basic Concept of Pathogenesis

Both virus types of the HSV enter the human body by the oral or genital mucosa or occasionally by small lesions in the skin.

The infection of the cell occurs by the binding of the virus to the cell surface followed by the activation of a viral-membrane-fusing complex of glycoproteins (gB, gH, gL), which play a major role in the initial binding to heparan sulphate chains on cell surface proteoglycans. After the initial infection the virus invades the sensory nerve endings within the epidermis and is then retrogradely transported along the axon to the sacral ganglion with production of the virus or restriction of viral replication entering an immediate state of "latency" within neurons. Latency can occur if the viral genome is maintained in the cell and only a small number of the DNA is replicated without protein expression during the period of latency (latency-associated transcripts, LATs). The detection of LATs is a good marker for latency of HSV in the cells. Activation of latent viral genomes to the replicating state can be induced by in vitro cultivation of the latently infected tissue after explantation.

The cells are not automatically killed by the virus, as it occurs in cell culture. A virion shut-off protein which is also introduced to the cell at the time of viral entry causes degradation of pre-existing cytoplasmic mRNAs and inhibits cell protein synthesis. It is assumed that cell fusion, typical for the presence of procaryocytes in infected epithelia, may be a different method for viral spreading and facilitate evasion from the immune response of the host.

In human beings, latent infections can be converted to productive infection by factors or stimuli, which have not yet been fully defined, and the mechanisms underlying reactivation are still a tool for investigation. Exposure to stress,

fever, colds, sunlight, pneumococcal infections, menstruation, mechanic stimuli, tissue damage, immunosuppression, etc. is known to reactivate the virus from the sensory neurons. However, sometimes the occurrence of productive infection does not depend upon inducing stimuli, and the reason for reactivation is inevident. The virus is subsequently transported along the axon to the nerve endings and crosses into the epidermis at the site of initial infection on the dermis or mucous membranes. There it causes the typical vesicular herpetic lesions which may also be inapparent or hardly recognised. The frequency and clinical manifestation of the recurrent lesion depends on the immunocompetence of the host and the severity of the primary infection. Interestingly, HSV-1 reactivates more readily from the cervical sensory ganglia, whereas HSV-2 recurs from the sacral ganglia.

It is an assumption that this might be in connection with differences in the cell type and the viral proteins needed for reactivation. The replication of HSV in the epidermal cell layers has a cytopathic effect on keratinocytes followed by destruction and the occurrence of clinical lesions. The lesions, mostly vesicles, contain a high number of viral DNA, interferons, and other cytokines. Macrophages and CD4 lymphocytes can control the viral replication after 2–4 days, when the viral titres in the vesicle decline. It depends on the interaction of the immune response of the host and the inoculum of the herpesvirus whether the infection results in an asymptomatic relapse and how often asymptomatic shedding occurs between clinical visible lesions. Obviously HSV is able to evade different host-dependent immune mechanisms: it has the capacity to downregulate MHC class I antigen expression on the surface of infected cells. It can also bind and inactivate complement and immunoglobulins by interactions with glycoproteins C, E, and I.

In summary, after the invading virus has caused a productive primary mucocutaneous infection with an infection of the ganglia, the basic pathogenesis of HSV-1 and HSV-2 follows the sequence of latency, reactivation, and recurrent infection.

Epidemiology of Genital Herpes

The incidence and prevalence of genital herpes vary considerably in countries and population groups, affecting 20–40 % of adults in the developed and in an even higher percentage of individuals in the developing world. The cumulative lifetime incidence of HSV-2 reaches 80 % in African-American women and 60 % in African-American men. Several reports showed an increase of the incidence during the last decades. In the USA, however, the most recent data show a decrease from 21.7 % in 1991 to 17 % in 2004 (Fleming et al. 1997).

In most cases, infected individuals have acquired the HSV infection subclinically and can be identified only by antibody detection. It is therefore difficult to make exact calculations about the infection rates in different population groups worldwide. Reported data differ according to the presence and detection of clinical symptoms and are dependent on the technology used for the diagnosis of an infection. Type-specific serology assays provide information on the occurrence of type-specific HSV-2 and HSV-1 infections. The predominant cause of genital ulcers is HSV-2 accounting for up to 80 % of diagnosed aetiologies of GUD. The frequency of HSV-2 antibodies is higher among persons from STI clinics or MSM compared with the general population. In the last decade, an increase of genital lesions caused by HSV-1 has been reported in the developed world. A shift from HSV-2 to HSV-1 has been reported predominantly in young women and MSM. Reasons for that are unclear and can only be assumptions like an increase of oral sex or a decrease of HSV-1 infections during childhood. In a study on the cause of HSV-1 in genital herpes and its impact on surveillance and prevention, it was demonstrated that genital HSV-1 may often be acquired through receptive oral sex.

Infections with HSV-2 types are nearly always sexually acquired, while HSV-1 is already acquired in most individuals during childhood.

However, these infections do not protect against an infection with type 2. HSV-1 is causing a high proportion of first episodes in young women and MSM, while recurrences and subclinical viral shedding are more frequently observed for HSV-2.

Risk factors associated with transmission of genital herpes include age (15–30 years), the number of sexual partners, black or Hispanic race, female gender, homosexuality, HIV positivity, and social status measured by lower income and education levels. HSV-2 is spread primarily by sexual contact through infected secretions via inoculation onto susceptible mucosal surfaces.

The overall risk of HSV-2 transmission to a seronegative partner is estimated to be 3–12 % per year and seems to be higher for women (17 %) than for men (4 %) and higher when clinical lesions are present compared to subclinical genital herpes. The reason for a higher risk for women is probably dependent on anatomic differences and a greater mucosal surface area compared with men. There is conflicting data on whether a past infection with HSV-1 has a protecting effect concerning the acquisition of an infection with HSV-2. The DNA of HSV could also be detected in the semen of men with genital HSV-2 infection which might also play a role in transmission of infection.

Clinical Presentation

Genital herpes infections have a wide range of clinical features and may occur subclinical or asymptomatic in most of the cases. Clinical manifestations are influenced by viral and host factors and differ between primary infections and recurrences.

Primary or First-Episode Genital Herpes Infection

In primary infections, symptoms typically occur within 3–7 days after exposure often with a prodrome of tender lymphadenopathy, malaise, anorexia, and fever with localised pain and burning, followed by typical clinical lesions with vesicles and erosions (Figs. 37.1 and 37.2). Primary genital herpes has prolonged local and systemic symptoms which usually reach a peak within the first 3–4 days after onset of lesions with massive local pain and edema. In women, lesions may involve the cervix and cause vaginitis, vulvitis, and dysuria. Genital lesions in men caused by a primary HSV infection are usually not as dramatic as in women. A history of primary genital herpes is often unknown and only reported in 50 % of symptomatic infections in individuals with HSV-2 seropositivity.

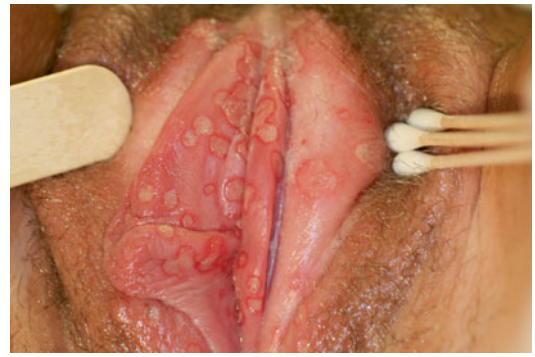

Fig. 37.1 First-episode genital herpes HSV type 1 in a 14-year-old adolescent, multiple erosions in the vulva region with urinary retention

Fig. 37.2 First-episode genital herpes type HSV-2 in an 18-year-old adolescent, multiple erosions on the penile shaft

HSV Cervicitis and Proctitis

Cervical herpetic lesions are clinical features which are seldomly observed and are therefore easily overseen and often underdiagnosed. They may be asymptomatic or may result in vaginal discharge. Cervical HSV is a possible site of shedding and important for transmission of the virus to newborns or the sexual partner.

HSV is the most frequent pathogen isolated in men with nongonococcal proctitis and is commonly associated with fever, bloody rectal discharge, and severe rectal pain. Both HSV-1 and HSV-2 have been isolated from the rectal area of MSM but can also occur in women and may result in subclinical viral shedding due to reactivation in latent sacral ganglia.

Recurrent Genital Herpes

The major problem of genital herpes is the reactivation of the virus resulting in recurrences over months or years with varying frequency. Reactivation of HSV-2 from the sacral nerve root ganglia is widespread over a large anatomic area. It is less frequently observed with HSV-1 compared with HSV-2 infection and occurs in about 60 % in the first year and 30 % in the second year after first-episode HSV-1 infection. In contrast to HSV-1 relapses, about 90 % of individuals with HSV-2 infections develop recurrences in the first year with a higher frequency in men than in women.

The frequency of recurrences correlates directly with the severity of primary infection with varying time intervals between relapses. Usually, recurrences are less severe, and a limited number of blisters will appear on the genitalia which will resolve within a week. Lesions may even be subclinical and unobserved (Fig. 37.3).

Fig. 37.3 Recurrent genital herpes with blisters on the labium major; HSV-2 positive

Genital Shedding of HSV

Asymptomatic viral shedding in patients with genital herpes is important for the understanding of transmission to the partner or newborn. It has been shown that besides shedding during symptomatic episodes of genital herpes, additional asymptomatic viral shedding occurs intermittently, mostly within a week of clinical recurrence. Individuals with more frequent recurrences had also more frequent subclinical shedding, as well as those who had recently acquired genital herpes. Viral DNA could be detected by PCR from the vulva, cervix, and rectum. These results may explain the viral transmission to partners of infected but asymptomatic individuals, unaware of eventually being a risk for their sexual partner. This has an important implication in terms of current or future relationships of individuals with genital herpes. In a multicentre study in the USA among individuals with symptomatic and asymptomatic genital HSV-2 infections, the frequency of genital shedding was evaluated (Tronstein et al. 2011). It could be demonstrated that persons with asymptomatic infections shed virus in the genital tract less frequently than persons with symptomatic infections, mainly because of a less frequent shedding from genital lesions. Even among persons with asymptomatic infection, shedding occurred in 10 % of days. The issue of infectivity is of concern for partner management and public health: The DNA load necessary for transmission is unknown, but there is an estimation that even a quantitatively moderate shedding may result in transmission. It is important to actively inform and advise the infected individual and offer methods such as condom use or daily antiviral medication to decrease the risk for transmission.

Diagnosis

In many infected individuals clinical symptoms of genital herpes may present as classical manifestations without the need of laboratory diagnosis. However, clinical diagnosis of atypical genital herpes should be confirmed or established by laboratory testing. Diagnostic procedures enable nowadays many more possibilities for both diagnosis of an acute infection and insight in the incidence and prevalence of HSV-1 and HSV-2 infections in different risk groups and in the general population. Multiple diagnostic methods are available for the detection of the virus, viral DNA, or viral antigen (Fig. 37.4). They include culture, direct fluorescent antibody assays (DFA), or molecular biological technology (Table 37.2). The Tzanck test is still often performed for rapid diagnosis in atypical clinical manifestations, but DFA is more sensitive and distinguishes between HSV and VZV. Cell culture had been used in the past for viral detection and is useful for resistance testing, but compared with molecular biological methods, the sensitivity is low and declines rapidly when the lesions start to heal. PCR is the most sensitive and the preferred method for the diagnosis of severe cases of HSV infections such as herpes simplex encephalitis or infections in newborns. It is recognised as the reference method for the detection of HSV in the cerebrospinal fluid and in brain biopsies and should be the method of choice for special questions concerning immediate treatment recommendations. This might be the case at the term of labour for decisions concerning caesarean section or for the diagnosis of HSV infection in the neonate. However, even amplification technology does not provide a 100 % sensitive test, and since viral shedding is intermittent, a negative result at the time of PCR testing does not exclude herpetic infections.

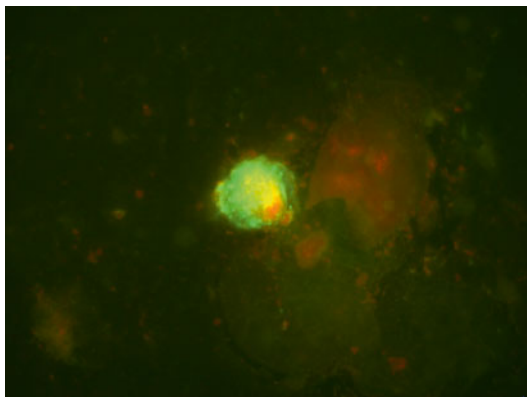

Fig. 37.4 Smear from the genital area of first-episode genital herpes. Direct fluorescence antibody assay: HSV-1 positive

Antibody detection for the differentiation between HSV-1 and HSV-2 antibodies in serological tests may be used for a better epidemiological insight. Type-specific antibody tests distinguish between both HSV types and are based on the type-specific glycoprotein gG-1 for HSV-1 and gG-2 for HSV-2 antibody detection. For prevalence or incidence studies and for prognosis and counselling, several reliable type-

Table 37.2 Diagnostic procedures for genital herpes

	Sensitivity	Specificity	Advantage	Disadvantage
Nucleic acid amplification NAATs	High	High, up to 100 %	Rapid different material	No resistance proof
				Expensive assays cross reactions
				Contamination
Virus culture	High, dependent on age of lesions	High	Allows sensitivity testing	Labour intensive
				Difficult transport
				Difficult storage
				Less sensitive
Antigen detection (EIA)	High, up to 80 %	High	Speed, costs	Less sensitive
				No viral typing
Antigen detection (immunofluorescence)	Lower, up to 50 %	High	Inexpensive	Less sensitive

and non-type-specific antibody detection assays are available. The Western blot represents the gold standard for serologic methods and is both highly sensitive and specific. However, it is still seldomly performed.

The use of diagnostic methods is especially recommended to exclude other infectious or non-infectious reasons for genital erosions or ulcerations (Table 37.3). In asymptomatic partners, CDC recommends type-specific serologic testing for HSV infection (2010).

General Principles of Treatment

The management of sex partners includes clinical and anamnestic evaluation, treatment recommendation, and counselling. Management and treatment of genital herpes have different targets which should be approached after the diagnosis is established and the patient had the opportunity for counselling.

In primary genital herpes it is of upmost importance to shorten the time of lesions and local and systemic symptoms and to prevent possible complications such as aseptic meningitis or urinary retention. After first genital episode or primary infection, the prevention of latency and the development of recurrences are further tools. In case of already established latency, the reduction or prevention of subsequent recurrences as well as the transmission of the disease to the partner or newborn is required. What has research contributed to these goals?

Antiviral drugs against HSV can partially control and reduce acute symptoms and the frequency of recurrent episodes. However, despite major advantages during the last 25 years, it is not possible to prevent latency or eradicate the latent virus from the ganglion or to reduce the frequency of episodes and the possibility of transmission after the preventive treatment is discontinued.

Antiviral treatment

Nucleoside Analogues

Antiviral treatment with nucleoside analogues offers clinical benefit to symptomatic individuals with first-episode or primary genital herpes as well as for recurrent herpetic episodes. Nucleoside analogues are also efficient in suppressing recurrent genital herpes in individuals with frequent episodes and are therefore recommended for long-term suppression in those with >6 episodes per year. Among FDA-approved oral antiviral drugs, acyclovir, valacyclovir, and famciclovir are the drugs of choice for the treatment of genital herpes. Oral administration is more efficient than locally applied antiviral creams.

1. Acyclovir
2. Valacyclovir
3. Famciclovir

Acyclovir (ACV)

ACV was the first guanosine analogue that was introduced as antiherpetic agent. It selectively inhibits the replication of HSV-1 and HSV-2 and of the VZV. It is phosphorylated by the virus-specific thymidine kinase in HSV-infected cells to acyclovir monophosphate and then by cellular enzymes to the active component, acyclovir triphosphate, which inhibits viral DNA synthesis by competing with guanosine triphosphate as a substrate for the viral DNA polymerase. ACV has potent in vitro activity against both serotypes of HSV and markedly reduces the duration and severity of lesions in animal models. It can be administered topically, orally, and intravenously, and all three options lead to reduction of viral

shedding and a quick healing of lesions and to a reduction of the duration of symptom. However, only the systemic treatment offers the benefit of accelerated improvement of general symptoms and avoids the development of new lesions. Therefore, oral treatment for both first-episode and recurrent genital herpes is recommended and eventually intravenous administration in acute primary genital herpes with severe general symptoms.

Numerous studies in primary and recurrent herpes have shown ACV to efficiently decrease the duration of symptoms and viral shedding, and in primary or first-episode infection, it rapidly reduces fever and systemic symptoms within 48 h. It is important to initiate the antiviral treatment as early as possible to have an immediate effect on viral shedding. The oral administration of 400 mg ACV twice daily has shown similar antiviral effect as a dosage of 5 × 200 mg. Higher dosage does not offer more benefit.

For recurrent genital herpes, the influence of ACV has also been studied concerning the frequency of recurrent episodes: daily ACV prevention reduces the number of recurrences and the rate of HSV detection on genital mucosa. However, it has no influence on the rate of recurrences if not permanently administered.

Beside the efficient impact of ACV on herpetic lesions in the introital region of the genital tract, it has also shown an improvement of herpetic proctitis in men having sex with men (MSM) and on cervical lesions in women with herpes cervicitis.

ACV has an excellent safety profile. Side effects are seldomly reported and might include nausea, headache, and rash. In case of renal dysfunction, the treatment schedule has to be modified. Resistance is seldomly observed and mostly only occurs in immunocompromised individuals. HSV resistance to ACV has been described in immunosuppressed individuals (mainly HIV-positive persons) in 2–9 %. In those cases, resistance is not restricted to ACV only, but also includes treatment with valacyclovir and famciclovir.

Valacyclovir

The main disadvantage of ACV is the low bioavailability of ACV with only a small fraction of the drug is absorbed. Valacyclovir, the L-valyl ester of acyclovir and a prodrug of ACV, is almost completely converted in the gastrointestinal tract by hepatic and intestinal enzymes, which increases the bioavailability of ACV from 10 to 20 % to more than 50 %. A dosage of 1,000 mg daily is similarly effective as intravenous ACV.

Valacyclovir and ACV have been compared in numerous studies, demonstrating a similar profile of activity in primary, first-episode, and recurrent genital herpes with a more convenient dosage frequency.

Different schedules of dosage for valacyclovir have been evaluated and compared with placebo or with ACV.

For the treatment of first-episode herpes, the recommendation of antiherpetic therapy with 1 g valacyclovir twice daily was similarly efficient as 200 mg ACV five times daily. However, in individuals with first-episode or recurrent herpes episodes, even the lower dosage of 500 mg valacyclovir twice daily was equally effective in the reduction of lesions and viral shedding as 1,000 mg twice daily and also comparable with 200 mg ACV five times daily or 400 mg daily (Gupta et al. 2004). Both drugs decreased the risk of viral isolation by 95 % and the rate of HSV detection by about 75 %.

Valacyclovir is also recommended for prevention of recurrent episodes in individuals with genital herpes.

It has been compared with placebo for the prevention of recurrences in genital herpes and viral suppression in 382 patients with at least eight recurrences per year for a period of 4 months: while about 70 % of drug recipients were recurrence-free, the corresponding data in the placebo group was about 10 %. Valacyclovir 500 mg once daily is therefore recommended for persons with nine or fewer recurrences per year. A different schedule of 250 mg twice daily or a higher dosage of 1,000 mg is recommended in individuals with ten or more recurrences per year.

Valacyclovir has also been evaluated whether it has an impact on viral shedding and the transmission of HSV-2 in between sexual partners: 500 mg once daily was able to reduce transmission of HSV-2 by 48 % (Corey et al. 2004).

To summarise, both drugs, ACV and valacyclovir, are equal in their profile of efficacy and side effects, with the advantage for valacyclovir of a more convenient dosage frequency. An early onset of therapy within 24 h is essential for a successful influence of the clinical course of genital herpes.

Famciclovir

Famciclovir is the prodrug of penciclovir, which inhibits the replication of both HSV types. It needs the viral thymidine kinase for phosphorylation to penciclovir monophosphate and – similar to ACV – is converted in the intestinal wall and liver to the active form penciclovir triphosphate. It has a high bioavailability of about 77 % and a much longer intracellular half-life (10 h versus 1 h). The antiviral drug is well tolerated with a very low profile of adverse effects. A reduced dosage is recommended in case of impaired creatinine clearance.

For the treatment of first-episode genital herpes, famciclovir showed comparable results with ACV, concerning symptom resolution, viral shedding, and lesion healing (Loveless et al. 1995). The efficacy of 125 mg famciclovir twice daily was evaluated in recurrent genital herpes and showed a significant difference to placebo with a shorter duration of lesions and a reduced viral shedding in all immunocompetent patients. A higher dosage did not show additional benefit. Famciclovir has also demonstrated to be effective in suppressing recurrent genital herpes in individuals with frequent episodes when compared to placebo (up to 90 % without episode within 4 months compared to 48 % in placebo group). Compared with valacyclovir, the first recurrences were reported earlier and suppression was not as efficient (Wals et al. 2006). The result of this study supposes that famciclovir was not as successful in HSV suppression and sexual transmission when compared to valacyclovir.

Resistance to Acyclovir

Resistance of HSV to ACV depends mainly on the deficiency of the viral thymidine kinase (TK) but can also be the result of altered TK or DNA polymerase. TK-deficient viral strains are less virulent but eventually can develop latency in the ganglion. ACV-resistant HSV are observed in about 3 % of isolates in immunocompetent individuals and may be detected even in persons who have never been treated with ACV and together with ACV-sensitive strains at the same time. It is interesting that despite the fact that ACV was used already for about 30 years, the frequency of in vitro resistance has not changed and does not happen more often in individuals treated over several years with this antiviral drug. It seems that in individuals treated with ACV, in vitro resistance of HSV may occasionally appear but is rapidly cleared by the immunocompetent host.

The majority of ACV-resistant strains have been isolated from immunosuppressed people undergoing multiple courses of ACV treatment in recurrent genital HSV infections. Patients with HIV infection or on immunosuppressive therapy for bone marrow or organ transplantations are especially exposed to severe HSV infections, and treatment failures are usually due to ACV-resistant HSV strains. The frequency of in vitro ACV resistance correlates with low CD4 count and topical ACV therapy. Since this is only described in about 5 % of isolates, routine testing for ACV resistance is not recommended.

Therapy in patients with ACV-resistant HSV strains may include high-dose oral or intravenous ACV or alternative drugs such as foscarnet, cidofovir, or other antiviral agents. As famciclovir is based on a similar antiviral mechanism, most ACV-resistant strains are also resistant to famciclovir.

Alternative Antiviral Therapy of ACV-Resistant Genital Herpes

The clinical management of genital herpes caused by ACV-resistant strains remains a challenge and needs to substitute ACV with alternative antiherpetic drugs.

Foscarnet

Foscarnet is a viral DNA polymerase inhibitor and is used in case of ACV resistance. Administration of foscarnet is usually intravenously or topical because of its poor oral absorption. Treatment is recommended by CDC (2010) as intravenous infusion (40 mg/kg every 8 h) until clinical resolution is observed. This dosage provides a high rate of clinical resolution in severe genital herpes and has proven to be more efficient than vidarabine (Safarin et al. 1991). Adverse reactions are frequent and may lead to renal insufficiency and metabolic disturbances but only rarely requires discontinuation of therapy.

Cidofovir

Cidofovir is an acyclic nucleoside phosphonate and is phosphorylated by cellular enzymes. It can therefore be implemented as alternative therapy in case of deficiency of viral TK. It is usually applied topically due to the potential of renal toxicity with IV administration. Since in long-term studies in animal models the development of tumours is reported as additional side effect, the drug is recommended only as an alternative drug in immunocompromised individuals.

Resiquimod and Imiquimod

Both drugs have partly shown a healing effect in herpetic lesions but have not proven substantial efficiency on the frequency of episodes in recurrent genital herpes. The antiherpetic potency was reported in few studies, but results were inconsistent.

There are several drugs tested for genital herpes but have demonstrated inefficiency against HSV: vidarabine, idoxuridine, isoprinosine, ether, 2-deoxy-D-glucose, BCG vaccine, chloroform, povidone iodine, topical surfactants, photodynamic dyes, topical IFN-alpha transfer factor, lysine, and nonoxynol-9. The long list reflects that despite the improvement in knowledge of management of genital herpes, treatment of recurrent genital herpes is still a management problem in this field of medicine.

A New Drug on the Horizon?

Pritelivir has been recently evaluated as a potential alternative antiherpetic agent in patients with a history of HSV-2 genital herpes (Wald et al. 2014). It is an inhibitor of the viral helicase-primase complex and has proven antiviral activity in vitro and in animal models. Pritelivir was administered in different schedules either daily in different dosages (5, 25, 75 mg) or weekly (400 mg). Compared with placebo, pritelivir administered in doses of 25 mg or more and once weekly, respectively, significantly reduced both the frequency of HSV shedding on the genital mucosa and the quantity of the virus detected. Also subclinical shedding of HSV was significantly reduced in both men and women. In addition the effect of pritelivir on genital lesions was evaluated, and a dose-related significant difference was observed between the antiviral drug and placebo group. It had an impact on the reduction of number of days of genital lesions at doses of 75 mg daily and the weekly administration with fewer recurrences. The drug was well tolerated, and adverse events were rare without safety problems and with no evidence of resistance. Although this was a short-term study of only 28 days, the outcome assumes that pritelivir provides a new alternative to the nucleoside therapeutic agents and may have the potential for combination therapy (Whitley and Prichard 2014).

Treatment of First Clinical Episode

Initial episodes of genital herpes include both anti-HSV-1/anti-HSV-2 antibody-negative primary herpes and anti-HSV1 or anti-HSV-2 antibody-positive first-episode genital herpes infection. First herpetic manifestations can cause prolonged clinical illness and concomitant systemic symptoms. Antiviral oral treatment should start as soon as possible after assumed diagnosis.

Recommended Regimens (CDC) (2010)

Acyclovir 400 mg orally three times a day for 7–10 days

Acyclovir 200 mg orally five times a day for 7–10 days
Famciclovir 250 mg orally three times a day for 7–10 days
Valacyclovir 1 g orally twice a day for 7–10 days

Recommended Regimens (IUSTI Europe)
Acyclovir 400 mg orally three times a day for 5 days
Acyclovir 200 mg orally five times a day for 5 days
Famciclovir 250 mg orally three times a day for 5 days
Valacyclovir 500 mg orally twice a day for 5 days

All drugs have shown to be effective, and the length of therapy should be extended if healing is incomplete, new lesions develop, or severe systemic complications are observed. Hospitalisation and intravenous application of antiviral drugs may be required with extraordinary clinical symptoms or if the patient is unable to tolerate oral treatment.

Concomitant counselling should include information on the natural course of the disease with the potential subclinical shedding, partner transmission, and recurrences. Screening on other STIs may be considered.

Treatment of Recurrent Episodes

Recurrent episodes are usually self-limited and require early initiation within 1 day of onset of lesions or prodromes. The reduction of healing of lesions may be 1–2 days. The patient should be provided with the drug with instructions for treatment to be started eventually, patient-initiated within the first hours of onset of symptoms. Treatment schedules differ in length and dosage. All antiviral drugs are effective for treatment of episodes, and head-to-head studies show no difference between the antiviral agents and length of therapy. Famciclovir may be less effective in the suppression of viral shedding. If symptoms are mild, patients may decide not to have antiviral therapy and may only need supportive advice.

Recommended Regimens (CDC)
Acyclovir 400 mg orally three times a day for 5 days
Acyclovir 800 mg orally twice a day for 5 days
Acyclovir 800 mg orally three times a day for 2 days
Famciclovir 125 mg orally twice a day for 5 days
Famciclovir 1,000 mg orally twice a day for 1 day
Famciclovir 500 mg orally once, followed by 250 mg twice a day for 2 days
Valacyclovir 500 mg orally twice a day for 3 days
Valacyclovir 1 g orally once a day for 5 days

Recommended Regimens (IUSTI Europe)
5-day therapy schedules:
Acyclovir 200 mg orally five times a day for 5 days
Acyclovir 400 mg orally three times a day for 3–5 days
Valacyclovir 500 mg orally twice a day for 5 days
Famciclovir 125 mg orally twice a day for 5 days
Short-course therapies:
Acyclovir 800 mg orally three times a day for 2 days
Famciclovir 1,000 mg orally twice a day for 1 day
Valacyclovir 500 mg orally twice a day for 3 days

Suppressive Therapy of Recurrent Genital Herpes

Suppressive therapy reduces the frequency of episodes by 70–80 % in patients with frequent relapses and is recommended in individuals with frequent and/or troubling recurrences. The decision for initiating suppression of genital herpes by the continuous treatment is very subjective and based on considerations including the frequency of relapses, the association with significant symptomatology and major psychosexual problems in the sexual relationship, costs, and the inconvenience of permanent drug administration. Suppressive treatment of recurrent genital herpes may lead to a significant improvement of life quality.

Where relapses are less frequent (<3–5 per year), intermittent episodic treatment may be preferable.

The safety and resistant data has been documented with ACV over 18 years and with other drugs for several years, and routine blood examination is not required.

The optimal dosage of ACV should be 800 mg daily. Breakthrough episodes may occur in approximately 20 % of patients and may lead to a modification or doubling of the schedule.

Individuals may experience at least a reduction of episodes compared to the situation without suppression and should be advised to include two recurrences to allow a view about discontinuation or change of dosages. Patients should be informed that despite treatment, viral shedding may occur and viral transmission to the partner may still be a risk. Suppressive therapy should be periodically discontinued and may be modified or stopped after 6–12 months to reassess the frequencies of relapses, since the frequency of recurrences decline over time.

Recommended Regimens (CDC)
Acyclovir 400 mg orally twice a day
Famciclovir 250 mg orally twice a day
Valacyclovir 500 mg orally once a day
Valacyclovir 1 g orally once a day

Recommended Regimens (IUSTI Europe)
Acyclovir 400 mg orally twice a day
Valacyclovir 250 mg orally twice a day
If >10 recurrences per annum
Valacyclovir 500 mg orally once a day
If <10 recurrences per annum
Famciclovir 250 mg orally twice a day

Management of Genital Herpes in Pregnancy

The therapy of genital herpes in pregnancy is complex and mainly concentrated on genital herpes near delivery in order to avoid transmission to the neonate. All women should be asked during pregnancy and at the onset of labour whether they ever had an episode of genital herpes. The incidence of neonatal herpes among asymptomatic women with the history of recurrent genital herpes or with genital herpes in the first half of pregnancy is low (<1 %) but increases to 30–50 % among women who acquire genital herpes near delivery (30–50 %) (Brown et al. 1997). Prevention of neonatal herpes is therefore concentrated on both avoiding first episode of genital herpes during late pregnancy and transmission of the virus during delivery.

Management of pregnancy with first-episode genital herpes during early pregnancy in the first and second trimester:

- Treatment of genital herpes of the pregnant woman in case of clinical symptoms
- Daily suppressive therapy with 400 mg acyclovir twice daily from week 36 to prevent recurrence
- Vaginal delivery if no lesions are present at the onset of labour

Management of pregnancy with first-episode genital herpes during late pregnancy in the third trimester:

- Treatment of genital herpes of the pregnant woman in case of clinical symptoms.
- Daily suppressive therapy with 400 mg acyclovir twice daily from week 36 to prevent recurrence.
- Intrapartal administration of intravenous acyclovir may be considered.
- Caesarean section should be considered in those with symptoms within 6 weeks of delivery.
- In case of vaginal delivery: no use of scalp electrodes and avoidance of prolonged membrane rupture.

Caesarean section in women without symptoms is under debate, and the risk to acquire herpes or the risk of a caesarean section has to be balanced from case to case.

Management of pregnancy with recurrent genital herpes:

- Vaginal delivery is indicated if no clinical lesions are present at onset of delivery.
- Daily suppressive therapy with 400 mg acyclovir twice daily from week 36 is recommended to avoid caesarean section in women with frequent recurrences.
- Caesarean section is only indicated if there are lesions at the onset of labour.

- Cultures or PCR diagnosis at term are not indicated.
- In early pregnancy continuous or episodic antiherpetic therapy is not recommended for women with recurrent genital herpes and should only be provided in case of severe and complicated recurrences.

General recommendations for pregnant women:

- Women without known genital herpes should abstain from sexual intercourse with partners known or suspected of having genital herpes.
- Information, whether a history of genital herpes is available.
- Careful clinical examination for herpetic lesions.
- ACV treatment late in pregnancy reduces the frequency of recurrences and – in consequence – the need for caesarean section.
- Antiviral treatment is not indicated among HSV-seropositive women without a history of genital herpes.

Neonatal Herpes Infection

Neonatal herpes infection is defined as infection in a newborn within 28 days after birth. Untreated, it is associated with a 40 % survival rate and can lead to long-term consequences in survivors (Corey and Wald 2009). Most neonatal infections result from exposure to HSV during delivery, although in utero and postnatal infections may also occur. The highest risk for the transmission of HSV to the neonate occurs from women who acquire genital HSV-1 or HSV-2 infections near term (50–80 %). It is remarkable that there is a discrepancy between a high shedding rate among women with HSV-2 infection and the low neonatal transmission rate with less than 1 % of neonates of mothers shedding the virus during delivery. This suggests a protective role of transplacental antibodies.

Congenital neonatal HSV infections are rare events with microcephaly, hydrocephalus, and chorioretinitis as the most common manifestations.

In neonatal infection, three different clinical pictures can be differentiated:

1. Manifestations of the skin, eyes, and mucous membranes account for about 45 % and need to be treated with high-dose intravenous ACV and have a good prognosis. Recurrences may occur in early childhood.
2. CNS-associated infections occur in about 30 % of infected neonates, and morbidity is higher in HSV-2 than in HSV-1 infections and may be associated with high rates of developmental problems and neurological abnormalities.
3. Disseminated HSV infections in neonates have a very bad prognosis with at least 30 % death despite ACV treatment. High-dose intravenous treatment with ACV is the drug of choice and has been systematically evaluated for neonatal infections.

Genital Herpes in HIV-Positive Individuals

Genital herpes plays a major role in HIV-positive persons, and with 60–90 % it is the most common cause of genital ulcer disease in this special risk group. Clinical manifestations range from minimal erosions to severe ulcerative symptoms. The infection may even stay unrecognised. Immunocompromised individuals may have prolonged or severe episodes of genital, anal, or oral herpes with often painful or atypical lesions. Viral shedding – independent from clinical symptoms – is increased and occurs on up to 30 % of days in HIV-infected individuals. Several studies reported the interaction of both viruses in immunocompromised individuals. It was demonstrated that in persons infected with both HIV and HSV, asymptomatic or symptomatic reactivation of HSV is associated with an increased level of HIV in the blood as well as in the genital tract (Schacker et al. 2002). Continuous suppressive therapy with ACV in persons with recurrent HSV infection reduces the severity and frequency of symptomatic recurrences and can also reduce the HIV levels. The initiation of retroviral therapy may worsen the clinical manifestations of genital herpes as part of the immune reconstitution syndrome.

In a study of the Prevention HSV/HIV Transmission Study Team performed in more than 3,400 heterosexual HIV-serodiscordant couples in Africa, it was investigated whether the ongoing suppression of HSV-2 with 400 mg ACV twice daily for 24 months may reduce the risk of HIV-1 transmission (Celum et al. 2010). It was disappointing that despite a significant reduction of the plasma level of HIV and a reduction in the occurrence of genital ulcers, daily ACV therapy did not reduce the risk of HIV-1 transmission to the sexual partner. The authors assumed that the lack of efficacy of ACV on the transmission rate may demonstrate that a greater reduction of HIV-1 plasma levels may have to be achieved.

Although resistance to nucleoside analogues is very rare, and the introduction of antiretroviral therapy has decreased the frequency of in vitro resistant HSV strains among HIV-infected individuals, it develops occasionally in HIV-positive individuals. This may lead to a difficult situation for the suppression of recurrences or the treatment of acute HSV infection, since treatment options for ACV-resistant strains of HSV are limited. However, new drugs on the horizon may be successfully implemented.

Herpes Simplex Virus Infection (Orofacial)

38

Theognosia Vergou

Key Points

- Herpes simplex virus type 1 (HSV-1) is among the most common human pathogens worldwide. Herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) are responsible for orofacial and genital herpes, respectively. Transmission takes place through direct contact with skin lesions, mucous membranes, and secretions (i.e., saliva). Transmission of HSV can occur during both asymptomatic and symptomatic periods of viral shedding.
- The symptoms of primary infection start 3–7 days after exposure. The prodromal symptoms are tender lymphadenopathy, malaise, myalgia, fever, burning sensation, localized pain, tenderness, and inability to eat. The most common clinical presentation of primary HSV-1 infection is gingivostomatitis in children and young adults.
- Most of the patients that develop a recurrent infection have some common prodromal symptoms, such as itching, pain, or burning sensation. The clinical symptoms start with a group of vesicles on an erythematous base, most commonly at the mucocutaneous junction of the lips. Other less common sites are the nasal mucosa, the cheek, the coccyx area, the buttock, and the upper surface of the fingers.

Definition and Epidemiology

Herpes simplex virus types 1 and 2 (HSV-1 and HSV-2) are responsible for orofacial and genital herpes, respectively. Worldwide it has been shown that almost 80 % of the adult population has antibodies against HSV-1. In children, 80–90 % of herpes simplex infections are attributed to HSV-1. HSV-2 is responsible for 70–90 % of genital herpes infections, even though HSV-1 might also be the cause of a genital infection, due to oral-to-genital transmission. HSV infections of both types are common in both the industrialized and developing worlds. The virus has the ability to successfully avoid the host immune system by entering a non-replicating state known as latency. This establishes a lifelong infection with periods of reactivation that are stimulated by various environmental cues. Prevention of infection is particularly difficult, as transmission between individuals often occurs during unrecognized and asymptomatic shedding during latency in the host individual.

Basic Concepts of Pathogenesis

In the majority of cases, orofacial HSV infections are caused by HSV-1, but HSV-2 have also been reported in sexually active persons and in HIV patients. Transmission takes place through direct contact with skin lesions, mucous membranes, and secretions (i.e., saliva). Transmission of HSV can occur during both asymptomatic and symptomatic periods of viral shedding. Replication of the virus takes place at the site of infected surface (i.e., mucocutaneous), and then it establishes latency until reactivation, after traveling to the sensory dorsal root ganglia (the trigeminal for orofacial HSV). The period of latency varies in individuals, and in most cases there are some factors that trigger the reactivation process, such as stress, cold weather, fever, immunosuppression, and ultraviolet light. The HSV viral envelope is composed of about a dozen viral glycoproteins in a lipid bilayer, many of which have the ability to use multiple alternative host cell receptors. In addition, the virus has multiple strategies to enter the cell, including using fusion or different forms of endocytosis.

Clinical Presentation

Primary Infection

It is very rare to have a newborn with herpetic primary infection, due to the fact that most babies have antibodies to HSV-1 at the time of delivery. After the first year of life, as soon as the antibodies titers start to decrease, the primary infection can occur. The symptoms of primary infection start 3–7 days after exposure. The prodromal symptoms are tender lymphadenopathy, malaise, myalgia, fever, burning sensation, localized pain, tenderness, and inability to eat. The most common clinical presentation of primary HSV-1 infection is gingivostomatitis in children and young adults. It may present together with pharyngitis. Multiple ulcers may appear on the anterior parts of the mouth and also significant edema and pain. In young adults, primary infection is most commonly characterized by the initial development of multiple, painful vesicles on an erythematous base that may progress to pustules and/or ulcerations. Resolution occurs within 2–6 weeks. The mouth and lips are most commonly involved in orofacial HSV-1 infection and the buccal mucosa and oropharyngeal membranes as well.

Recurrent Infection

Some of the most common triggering factors for reactivation have already been mentioned above. Most of the patients that develop a recurrent infection have some common prodromal symptoms, such as itching, pain, or burning sensation. The clinical symptoms start with a group of vesicles on an erythematous base, most commonly at the mucocutaneous junction of the lips. Other less common sites are the nasal mucosa, the cheek, the coccyx area, the buttock, and the upper surface of the fingers (Figs. 38.1 and 38.2). The vesicles in 3–4 days crust (Fig. 38.3), and after 7–10 days total healing will occur.

In most cases, three to four times/year is the common number of relapses, but some patients experience a recurrence even more often. Complications of recurrent orofacial HSV infection are eczema herpeticum (in patients suffering from severe atopic dermatitis), recurrent erythema multiforme, and disseminated HSV infection (in patients with Darier's disease, mycosis fungoides, ichthyosis vulgaris, pemphigus, or

Fig. 38.1 The characteristic group of vesicles on an erythematous base of HSV infection

Fig. 38.2 HSV infection on the neck

Fig. 38.3 Crusting of the HSV vesicles after 3–4 days of recurrent infection

Sezary's syndrome or in immunocompromised patients, such as HIV patients).

Keratoconjunctivitis is a situation that needs an ophthalmologist evaluation as soon as possible. Primary infection presents unilateral or bilateral, with significant eyelid edema, photophobia, tearing, and lymphadenopathy. Recurrent episodes with unilateral involvement are common.

Herpes encephalitis has a rate of mortality over 70 %, in untreated patients.

In immunocompromised patients, the lesions are larger, with persistent ulceration and crusting. In many cases, the infection is disseminated and severe.

Diagnosis

The Western blot method, for the detection of HSV antibodies, has very high sensitivity and specificity (99 %) and is one of the most valuable laboratory tests in order to diagnose HSV infections. Reliable serologic tests distinguish HSV-1 and HSV-2 antibodies. Tzanck smear reveals characteristic multinuclear, epithelial, giant cells (the technique is scraping the surface of early lesions). Viral cultures, PCR, and direct immunofluorescence for the detection of HSV antigens (very quick and reliable test, from the content of vesicles) are also available laboratory tests.

The histopathology reveals ballooning of the cytoplasm of keratinocytes, and this is a very characteristic and early sign of HSV infection. Another histopathology finding is the intranuclear inclusion bodies inside the degenerated nuclei. Spongiosis occurs in the epidermis, and intraepidermal vesicles are seen within the epidermis and dermis. Acantholytic keratinocytes are present, and a dense infiltration of lymphocytes, neutrophils, and eosinophils are seen in the dermis.

Differential Diagnosis

- Aphthous stomatitis
- EBV infections (i.e., pharyngitis)
- Stevens-Johnson syndrome
- Oral candidiasis
- Drug-induced mucositis

General Principles of Treatment

Primary infection with clinical symptoms in seronegative children and adults can be treated with oral antivirals as shown in Table 38.1. The dose for children is 15 mg/kg, five times/daily, for 7–10 days. In the majority of cases, only symptomatic, topical or oral antiviral treatment is enough for recurrent episodes. Patients with very frequent (more than six episodes/year) or severe and prolonged recurrences (including atopic patients) can be treated with suppressive oral antivirals, as shown in Table 38.1. Intravenous acyclovir is indicated for neonatal HSV infection, severe infections in immunocompromised hosts, and patients with systemic complications.

The fact that most current therapies target HSV-1 replication is not surprising, given that the initiation of replication is a very important process and any disturbance to this process adversely affects viral propagation. Acyclovir (ACV) is one of the oldest antiviral drugs used for HSV-1 treatment. ACV functions as a substrate for viral DNA polymerase, competing with deoxyguanosine triphosphate for incorporation into the elongation chain. It is a nucleoside analog with potent inhibitory effects and relatively low toxicity. ACV is selectively phosphorylated in virally infected cells by viral thymidine kinase, a process required for the activation of ACV. Valacyclovir, as a prodrug of ACV, enhances the bioavailability of ACV to levels threefold to fivefold higher than that obtained with oral ACV. Another drug developed during this period of antiviral development was famciclovir. Famciclovir, a synthetic acyclic guanine derivative, is a prodrug that, after oral administration, is rapidly metabolized to the highly bioavailable antiviral compound penciclovir via a two-step process of enzymatic hydrolysis and oxidation. Table 38.1 presents all therapeutic regimens for both HSV primary infection and recurrence.

Table 38.1 Therapeutic regimens for all oral antivirals for primary infection, recurrent episode, and suppressive treatment

Primary infection[a]/recurrent episode
Acyclovir: 200–400 mg, 5 times/day for 5 days
Valacyclovir: 500 mg, 2 times/day for 5 days or for recurrent episode 2 g, 2 times/day for 1 day
Famciclovir: 250 mg, 2 times/day for 5 days
Symptomatic therapy: topical antibiotics, NSAIDS
Recurrent infection (suppressive treatment)
Acyclovir: 400 mg, 2 times/day for 6 months
Valacyclovir: 500 mg, 1 time/day for 6 months
Famciclovir: 250 mg, 2 times/day for 6 months

[a]For primary infection, the therapeutic schedule can extend to 10 days, depending on the severity

N-Docosanol is an HSV-1 fusion inhibitor, and it functions by targeting the cell membrane and modifying the regions that many viruses utilize for entry. Through this modification, the fusion between a virus and its host cells is inhibited. Docosanol not only functions as an entry inhibitor, but also it interferes with the replication of HSV-1 and some other viruses. It is also administered in topical form and is mainly used for treating herpes labialis.

The entry of HSV into host cells is an intricate process that relies heavily on the ability of the viral glycoproteins to bind host cellular proteins and to efficiently mediate fusion of the virus envelope with the cell membrane. Acquisition of HSV-1 results in a lifelong latent infection. Because of the cycles of reactivation from a latent state, much emphasis has been placed until now on the management of infection through the use of DNA synthesis inhibitors as already mentioned above. However, new methods are needed to provide more effective treatment at earlier phases of the viral infection and to prevent the development of drug resistance by the virus. One of the most attractive candidates to assume this greater role in antiviral therapy is the targeting of glycoprotein-receptor interactions to inhibit the initial steps of viral entry, attachment, and fusion.

Herpes Zoster

39

Uwe Wollina

Abbreviations

BW	Body weight
DNA pol	DNA polymerase
HZ	Herpes zoster
TK	Thymidine kinase
VZV	Varicella-zoster virus (VZV)

Key Points

- Herpes zoster (HZ) is a common infectious disease caused by varicella-zoster virus (VZV).
- Diagnosis is primarily a clinical one. Cutaneous and extracutaneous manifestations of HZ are known.
- Treatment of choice is systemic acyclovir.
- Other antiviral drugs are available.
- For elderly people, VZV vaccine is an option in secondary prevention.

Definition and Epidemiology

Herpes zoster (HZ) is an acute segmental eruption of herpetiform-grouped vesicles due to endogenous reactivation of varicella-zoster virus (VZV) infection of nerval segments. In Germany the annual incidence is 5.8 per 1,000 patient years. The incidence of HZ increases with age: from 6.2 in the age group of 50–54 years to 13.2 for people ≥90 years. Similar figures have been reported from other European countries like Italy, Denmark, and the UK. There is no gender prevalence.

Patients at risk for HZ are those with inherited or acquired immunodeficiencies, immunosuppression, and lymphoproliferative disorders. HZ is low contagious.

Basic Concepts of Pathogenesis

The causative agent of HZ is VZV or herpes virus type 3 – an α herpes virus. Primary infection leads to varicella. During the viraemic period of primary infection (chickenpox), VZV infects sensible dorsal spinal nerve ganglia and/or cephalic nerve ganglia. VZV lies dormant in the nervous system – neurons and glia satellite cells – for years. Endogenous reactivation of viral infection occurs after impairment of immune surveillance. Trigger factors are immunosuppressive treatment, malignancy, trauma, and emotional stress. Approximately 70 % of solid organ transplant patients suffer from HZ. The risk for

e-mail: Wollina-Uw@khdf.de

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_39, © Springer-Verlag Berlin Heidelberg 2015

HZ is 4.8 times higher in patients with haematological malignancies. VZV spreads antidromically with secondary cutaneous involvement classically limited to unilateral dermatome(s). Destruction of the ganglion causes characteristic HZ pain. Neuronophagia results in sensible deafferentation and postherpetic neuralgia.

Clinical Presentation

After a prodromal phase of 1–5 days with malaise, fever, segmental pain, hyperesthesia, itch, and burning sensations, erythematous lesions develop. Within the erythema, multiple umbilicated vesicles arise with a diameter usually <5 mm. After a couple of days, vesicles evolve to pustules which desiccate within a week leaving crusts (Fig. 39.1). Extended prodromal phase has been observed up to 18 days (Zerngast et al. 2013). Aberrant vesicles are not uncommon, but bilateral or generalized HZ is less common and points to a more severe underlying pathology (Fig. 39.2a, b).

A necrotic variant is seen more often in the head and neck region leaving scars (Fig. 39.2c). When HZ affects not only the sensible but motoric nerves, palsy may result. HZ does not always produce cutaneous symptoms – HZ sine herpete. A late complication of HZ is Wolf's isotopic response, i.e. the appearance of other cutaneous disorders in the previously affected dermatome(s).

HZ can occur in various variants that run a peculiar course with characteristic symptoms.

Fig. 39.1 Typical herpes zoster. Cutaneous findings are limited to a unilateral dermatome

- Zoster ophthalmicus (first trigeminal branch) with affection of the forehead, capillitium, and eye. These patients need an urgent ophthalmological investigation. Bell's palsy is a possible delayed complication.
- Zoster of the second and third trigeminal branch can involve oral mucosa and tongue with aphthoid lesions and gingivitis.
- Cranial HZ may cause headache, neck stiffness, and nuchal lymphadenopathy.
- Central nervous (CNS) HZ is a severe complication developing meningitis, encephalitis, or CNS vasculitis.
- Zoster oticus with the risk of peripheral paresis of the facial nerve.
- Ramsay Hunt syndrome is due to affection of N. facialis and N. vestibulocochlearis. Typical manifestations include tinnitus, vertigo, and deafness. Patients with incomplete eye closure and dry eye at the beginning have a worse prognosis.
- Perineal HZ with severe pain, obstipation, and urinary retention.
- Visceral dissemination of HZ is a rare manifestation not restricted to immunocompromised hosts. These patients may develop multiple ulcers in the gastrointestinal tract.

HZ can cause cutaneous vasculitis and erythema multiforme. In rare cases postherpetic keloids may develop in former HZ lesions.

The neuropathic pain syndrome – postherpetic neuralgia – is a greatly feared complication leading to severe chronic pain over more than 4 weeks. The incidence of postherpetic neuralgia is between 0.4 and 1.3 per 1,000 patient years for individuals of ≥50 years. Other complications include loss of vision in zoster ophthalmicus and vasculitis that may require hospitalization.

Patients receiving tumour necrosis factor-α inhibitor therapy may run a protracted course with severe postherpetic neuralgia.

HZ-related mortality is estimated as 0.21 per 100,000 patient years.

Diagnosis

The diagnosis of HZ is primarily clinical based on rash and segmental distribution. In case of HZ

Fig. 39.2 More severe clinical types of herpes zoster. (**a**) Involvement of several dermatomes with haemorrhagic lesions. (**b**) Disseminated vesicles in generalized herpes zoster due to immune dysfunction of malignancy (here chronic lymphatic leukaemia). (**c**) Necrotic herpes zoster of the first trigeminal nerve branch

without rash, diagnosis is more complicated. Polymerase chain reaction has the best specificity (99 %) and sensitivity (95 %) compared to direct immunofluorescence staining (76 and 82 %) or virus culture (99 and 20 %). Tzanck test from vesicles or bullae is positive. Electron microscopy cannot differentiate VZV from herpes virus type 1 and 2.

Differential Diagnosis

The most important differential diagnosis is zosteriform herpes simplex. Other possible differential diagnoses include acute (contact) dermatitis, autoimmune bullous disease, bullous erysipelas, and eczema herpeticatum. Pain can be mistaken for intervertebral disc prolapse, myocardial infarction, pleurisy, abdominal disease, migraine, etc.

General Principles of Treatment

HZ needs to be treated systemically with antiviral drugs within 72 h of onset of the rash. If necessary, antibiotics, analgesics, and antipruriginous treatments may be added.

Systemic Treatments

HZ needs to be treated by systemic antiviral drugs. First-line treatment is acyclovir at a dosage of 10 mg/kg body weight (BW) three to five times a day for 5–7 days. The treatment should be 10 days in case of immunosuppressed patients. Orally applied acyclovir has a limited bioavailability. In children the dosage is 10 mg/kg BW three times a day with a maximum daily dosage of 2,500 mg. In patients with renal insufficiency, dose reduction is necessary. Nephrotoxicity is a rare but possible complication.

Acyclovir resistance of VZV has been reported in rare cases of immunocompromised patients. Both thymidine kinase (TK) and DNA polymerase (pol) gene mutations have to be considered in resistance testing. In a number of patients, resistance cannot be verified by virological methods.

Alternative oral drugs in immunocompetent adults include brivudine (125 mg once a day), famciclovir (3×250 mg/day), and valaciclovir (3×1,000 mg/day) for 7 days. In immunosuppressed adult patients, famciclovir can be used at doses of 3×500 mg/day. A multicentre, randomized, open trial in Japanese immunocompetent HZ patients suggested that famciclovir is superior to valaciclovir for acute pain relief (Ono et al. 2012). Another trial demonstrated equivalent efficacy of brivudine and famciclovir in HZ regarding resolution of symptoms and signs as well as prevention of postherpetic neuralgia (Wassilew et al. 2005). In contrast to acyclovir, brivudine has no nephrotoxicity. Brivudine is absolutely contraindicated in patients receiving 5-fluorouracil or other 5-fluoropyrimidines currently or within the last 4 weeks. The major active metabolite of brivudine, bromovinyl uracil, is a strong inhibitor of dihydropyrimidine dehydrogenase that can lead to a life-threatening accumulation of 5-fluoropyrimidines (Tables 39.1 and 39.2).

Table 39.1 Pharmacological treatment options in postherpetic neuralgia

Drugs	Examples
Tricyclic antidepressants	Amitriptyline (starting dosage 25 mg/day) Clomipramine 25–100 mg/day Desipramine – 150 mg/day Nortriptyline – 150 mg/day
Anticonvulsants	Carbamazepine 400–1,600 mg/day Gabapentin 900–3,600 mg/day Pregabalin 150–900 mg/day
Opiates	Oxycodone 10–400 mg/day Tramadol 200–600 mg/day
Topical anaesthetics	0.025 % capsaicin cream 5×/day 5 % lidocaine patch maximum 3 patches a day 8 % capsaicin patch (1 h with supervision)

Table 39.2 Treatment algorithms

Treatment algorithm for herpes zoster (HZ) in adults		
Uncomplicated HZ in immunocompetent hosts		
1st line	Acyclovir 800 mg five times a day for 7 days	
	Or brivudine 125 mg once a day for 7 days	
2nd line	Valaciclovir 1,000 mg three times a day for 7 days	
	Or famciclovir 500 mg three times a day for 7 days	
Uncomplicated HZ in immunocompromised hosts, complicated HZ in immunocompetent hosts		
1st line	Acyclovir intravenously 10 mg/kg three times a day	
Additional treatment for all patients: pain control		
Acute pain	1st line	NSAID like ibuprofen, aspirin, paracetamol or acetaminophen
	2nd line	Oxycodone
	3rd line	Opioids like tramadol

Topical Treatments

Topical treatment is symptomatic and includes soothing, drying, and antipruriginous effects. Typical ingredients are zinc oxide, cornstarch, clioquinol, menthol, or alcohol.

Crusted lesions benefit from ointments and wet dressings. Secondarily infected skin lesions may be treated with topical antibiotics like fusidic acid and antiseptics.

Topical acyclovir eye ointment is often used in zoster ophthalmicus although an add-on effect has never been established.

Vaccination

In Europe and the USA, a live attenuated vaccine for prevention of HZ and HZ complications has been approved for immunocompetent adults ≥50 years of age. The US Advisory Committee on Immunization Practices recommends vaccination for immunocompetent adults ≥60 years. A single vaccination results in HZ and postherpetic neuralgia incidence by 51 and 67 %, respectively. A booster may be necessary after 20–30 years. Depressed patients have a diminished VZV response to vaccination that can

Table 39.3 Treatment algorithm for postherpetic neuralgia

Line of Rx	Drugs	Examples	Dosage
1st line	Tricyclic antidepressants	Amitriptyline Nortriptyline Desipramine	10–75 mg at night
	Gabapentin		300–1,200 mg 3 time a day
	Pregabalin		50–300 mg twice daily
	Topical 5 % lidocaine patch		One patch every 12 h
2nd line	Opioids	Tramadol	50–400 mg/day
	Capsaicin cream		3 times a day
	8 % capsaicin patch		4 patches for 60 min every 3 months
3rd line	Centrally acting opioids	Morphine	30–360 mg/day

be improved with antidepressant therapy. Breakthrough HZ after active vaccination is possible but very rare.

Alternative and Experimental Treatments

FV-100 is a prodrug of the highly potent anti-VZV bicyclic nucleoside analogue CF-1743. Pharmacokinetics and safety have been evaluated in several trials. Oral doses of 400–800 mg/day were well tolerated.

KAI-1678 is an inhibitor of protein kinase C. The compound has shown no efficacy in acute postherpetic neuralgia in contrast to subcutaneous infusions of lidocaine.

Topical S-ketamine 1 % ointment has been evaluated in a double-blind, placebo-controlled, cross-over study to treat postherpetic neuralgia in 12 patients. After 15 days, pain-related findings improved with S-ketamine, but further investigations are necessary.

Intravenous vitamin C (7.5 g/50 ml) used as an adjuvant treatment for 2 weeks in an open trial seems to exert beneficial effects on fatigue, number of dermatomes and lesions, and pain. CNS vasculitis due to VZV infection may respond to intravenous pulses of cyclophosphamide.

Management of Postherpetic Neuralgia

The frequency of postherpetic neuralgia is reduced by early antiviral therapy and active vaccination. Elderly patients with deep pain at initial visit are at risk for this complication. Since its aetiology is complex and involves peripheral and central mechanisms, the combination of pharmacological treatments often is more efficacious than single agents.

The addition of short-term systemic corticosteroids to antiviral treatment is controversial, and a recent Cochrane review found no evidence for corticosteroids to prevent postherpetic neuralgia (Chen et al. 2010).

First-line treatments of postherpetic neuralgia include tricyclic antidepressants, gabapentin, pregabalin, and topical 5 % lidocaine patch. Second- and third-line therapies include opioids, tramadol, capsaicin cream, and 8 % capsaicin patch (Table 39.1). Invasive procedures like sympathetic blockade, intrathecal steroids, and implantable spinal cord stimulators can be used in patients refractory to conservative pharmacological interventions (Table 39.3).

Hirsutism and Hypertrichosis

40

Clio Dessinioti and Andreas D. Katsambas

Key Points

- Hirsutism is defined as the excessive growth of terminal hairs in androgen-dependent areas in females.
- Hypertrichosis is defined as the generalized excessive growth of hair that is not limited to androgen-dependent hair.
- The causes of hirsutism and hypertrichosis include heritable factors, endocrine disorders (usually the polycystic ovary syndrome (PCOS) and more rarely nonclassical adrenal hyperplasia, androgen-secreting ovarian, or adrenal tumors), or medications.
- An effective management of hirsutism should aim to diagnose and treat any underlying hormonal disease while reducing excessive hair.
- Evidence-based data regarding the use of systemic treatments for hirsutism is lacking.
- As idiopathic hirsutism is mainly a cosmetic problem, topical treatments and hair removal methods are preferred.
- Combined oral contraceptives are a first-line therapy for hirsute women with PCOS.
- Eflornithine hydrochloride 13.9 % cream is an FDA-approved treatment indicated for the reduction of unwanted facial hair in women.
- Different cosmetic and hair removal methods include chemical depilation, bleaching, physical methods, electrolysis, thermolysis, and laser hair removal/photoepilation.
- An interdisciplinary approach comprising a dermatologist, an endocrinologist, and/or a gynecologist may provide optimal management to the hirsute woman.

e-mail: katsabas1@ath.forthnet.gr

Definition and Epidemiology

Hirsutism is defined as the presence of excessive terminal hair in females in androgen-dependent areas such as the mustache area, chin, neck, arms, upper and lower abdomen, upper and lower back, and inner aspect of the thighs. In these body areas, hair growth is controlled by androgens that transform vellus to terminal hairs. In particular, the androgen dihydrotestosterone (DHT) acts in the skin via androgen receptors in the dermal papilla and increases the hair follicle size.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_40, © Springer-Verlag Berlin Heidelberg 2015

Hirsutism, together with acne, seborrhea, and alopecia, represents cutaneous manifestations of hyperandrogenism. Hirsutism affects approximately 5–10 % of women of reproductive age in the general population. Also, 70–80 % of patients with androgen excess demonstrate hirsutism, with the most common cause of androgen excess (hyperandrogenemia) being the polycystic ovary syndrome (PCOS). The prevalence of hirsutism in PCOS has been reported to be 40–92 % in European and American women. The prevalence of nonclassical congenital adrenal hyperplasia (CAH) among women with hirsutism varies from 1 to 12 %, depending on the ethnic group. On the other hand, in less than 20 % of hirsute women, hirsutism may be idiopathic, with normal serum androgen levels and normal ovulatory function. Idiopathic hirsutism may be due to the hypersensitivity of the hair follicle to androgens.

In contrast to hirsutism, hypertrichosis is defined as the generalized excessive hair growth that is not limited to androgen-dependent hair. Hirsutism and hypertrichosis may have considerable psychological consequences, causing severe distress and a significant negative impact on the quality of life.

Basic Concepts of Pathogenesis

The hair follicle is only found in mammals, and its growth cycle is regulated by hormones, mainly androgens. There are three main types of hair: lanugo, vellus, and terminal. Lanugo hair is the fine hair covering the fetus that is shed during the neonatal period. Vellus hair is the nonpigmented fine hair. Terminal hair shafts are coarser and darker. Vellus hair changes to terminal hair at puberty, while terminal hair changes to vellus hair in androgenic alopecia. Hirsutism usually results from the transformation of vellus hair into terminal hair in androgen-sensitive body areas.

Hirsutism is often the result of an underlying ovarian, adrenal, or central endocrine abnormality. Also, increased bioavailability of testosterone and increased sensitivity of hair follicles to androgens can contribute to the pathogenesis of hirsutism. The primary androgen involved in the development of hirsutism is dihydrotestosterone, which is synthesized from testosterone by the enzyme 5α-reductase type 2 in the hair follicle. Hirsute women have increased 5α-reductase activity in their hair follicles, which is stimulated by hyperandrogenemia and by high levels of insulin and/or insulin-like growth factors. The most common endocrine cause of hirsutism is PCOS which is characterized by ovarian androgen excess.

Hypertrichosis may be related to familial factors, metabolic disorders (such as hypothyroidism, anorexia nervosa, and malnutrition), or medications (including glucocorticoids, phenytoin, minoxidil, diazoxide, and cyclosporine).

Clinical Presentation

Hirsutism presents with excess hair on androgen-sensitive body areas, such as the face (Fig. 40.1), chest, abdomen, and/or thighs. In hypertrichosis, hair growth is not mediated by androgens, and the excess hairs are not distributed in an androgen-sensitive (male) pattern.

The degree of hirsutism in most studies is objectively quantified by a modified Ferriman–Gallwey (F-G) scoring system (Fig. 40.2), first introduced in 1961. Nine regions are assessed and given a score of 0 (no terminal hair) to 4 (extensive terminal hair). Hirsutism is generally

Fig. 40.1 Hirsutism of the face in a 22-year-old woman

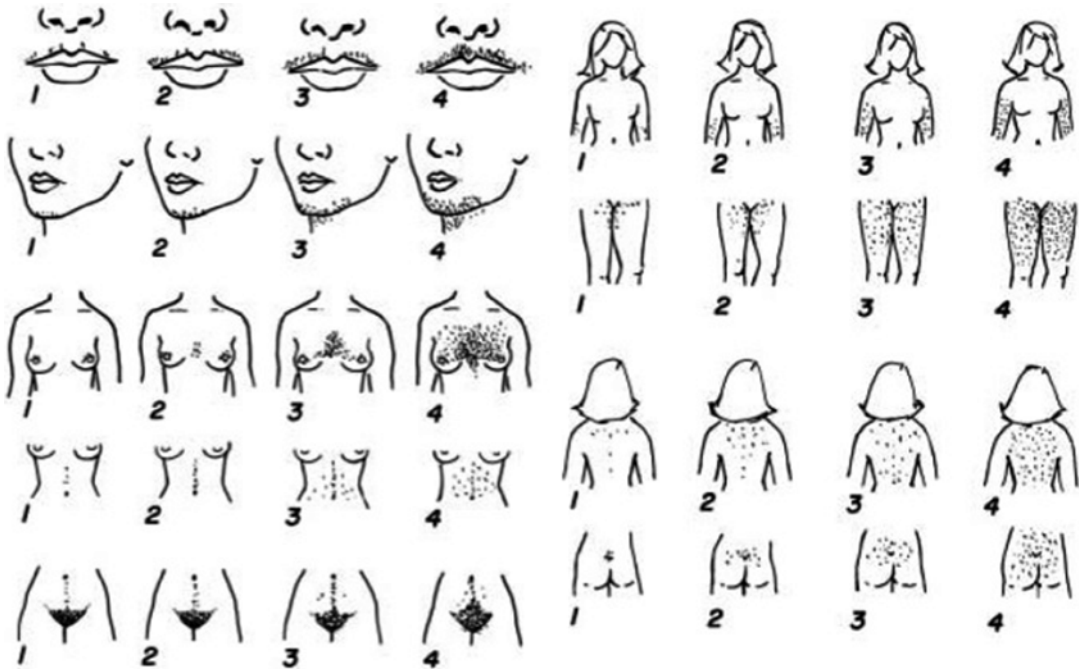

Fig. 40.2 Modified Ferriman–Gallwey hirsutism scoring system. Each of the nine body areas is assigned a score from 0 (no hair) to 4 (frankly virile) (Reproduced with permission from Hatch et al. (1981). ©Elsevier)

defined as a score of 8 or above. Mild hirsutism is defined as an F-G score of 8–15, moderate hirsutism as an F-G score of 16–25, and severe hirsutism as an F-G score >25.

Hirsutism can be a presenting sign of PCOS, nonclassical CAH, Cushing's syndrome, or androgen-secreting tumors.

PCOS is a multifactorial polygenic disorder of unknown etiology. It is the most common cause of hirsutism, even in the presence of normal menstrual cycles. It has therefore been suggested that the presence of hirsutism in women should prompt the evaluation for PCOS. The diagnosis of PCOS is currently based upon an international agreement (the 2003 Rotterdam Consensus Group) and is defined by the presence of at least two out of three of the following criteria: (1) oligomenorrhea or amenorrhea, (2) clinical hyperandrogenism or serum androgen excess, and (3) polycystic ovaries by a pelvic ultrasound. Cutaneous signs of hyperandrogenemia in PCOS include hirsutism, acne, seborrhea, and androgenic alopecia. In particular, the following symptoms or signs indicate high risk for PCOS and should prompt further evaluations:

- Moderate or severe hirsutism
- Resistant acne
- Menstrual irregularities
- Acanthosis nigricans and obesity
- Mild hirsutism, acne, or acanthosis nigricans associated with any other feature of PCOS

CAH is an autosomal recessive disorder with a reported prevalence for nonclassical (late-onset) CAH ranging from 0.6 to 10 % depending on the ethnic group. CAH can present with premature pubarche (appearance of sexual hair before 8 years of age in girls and 9 years in boys), hirsutism, acne, adult-type apocrine odor, tall stature in children, and advanced skeletal maturation. Growth can be assessed by review of growth charts, and skeletal maturation can be assessed by a bone age X-ray (X-ray of the left hand in children ≥2 years and hemi-skeleton in children <2 years of age). Nonclassical CAH is a progressive disorder, with the prevalence of hirsutism increasing with age in individuals >10 years old. Among 270 Spanish

women with hirsutism, acne, androgenic alopecia, or irregular menses, nonclassical CAH was diagnosed in six women (2.2 %).

Idiopathic hirsutism (hirsutism without hyperandrogenemia) accounts for about half of mild hirsutism and for a smaller fraction of moderate/severe hirsutism.

The term "SAHA syndrome" was coined in 1982 by Professor Orfanos to characterize the association of seborrhea, acne, hirsutism, and androgenic alopecia in women. In approximately 20 % of patients, all four major signs of SAHA syndrome are present; seborrhea is always present and androgenic alopecia occurs in 21 %, acne in 10 %, and hirsutism in 6 % of patients. The SAHA syndrome is classified into idiopathic, ovarian, adrenal, and hyperprolactinemic types, depending on the underlying associated disorder.

Diagnosis

The diagnostic evaluation of the hirsute woman should include a detailed medical history of the time of onset and rate of progression of hirsutism and of menstruation and fertility and a family history of PCOS, diabetes, obesity, and hyperandrogenism. The physical exam should include evaluation for hirsutism, androgenic alopecia, acne, seborrhea, galactorrhea (a sign of possible hyperprolactinemia), and acanthosis nigricans; signs of virilization (such as clitorimegaly, deepening of voice, or increasing muscularity) suggest marked hyperandrogenemia due to androgen-secreting adrenal or ovarian tumors. Also, hormonal evaluations and a pelvic ultrasound examination should be performed in patients suspected to have PCOS (Table 40.1). Referral to an endocrinologist to exclude PCOS and other hormonal causes should be considered.

The hormonal evaluations should be performed in the early follicular phase. In women under hormonal contraception, this should be ideally discontinued for at least 8–12 weeks before the hormonal evaluation. There is some disagreement as to whether hormonal evaluations are necessary in women with mild hirsutism. The 2008 Endocrine Society Guidelines by Martin et al., on the evaluation and treatment of hirsutism in premenopausal women, do not recommend this testing, whereas Barbieri and Ehrmann, as well as Escobar et al., suggest measuring testosterone (as a marker of ovarian androgens) and DHEA-S (as a marker of adrenal androgens) in all hirsute women. 17-Hydroxyprogesterone can assist in the diagnosis of NCCAH. Very high levels of testosterone (>150 ng/dl or 5.2 nmol/l) or DHEA-S (>700 μg/dl or 18.9 μmol/l) should raise suspicion of an ovarian or adrenal tumor, respectively, and should prompt referral to an endocrinologist for further evaluation including imaging.

Table 40.1 Diagnostic approach to hirsutism

Personal and family history: hirsutism (timing, rate, and psychological impact), menstruation, fertility, PCOS, diabetes, hyperandrogenism
Physical exam: hirsutism (modified Ferriman–Gallwey score), androgenic alopecia, acne, seborrhea, galactorrhea, acanthosis nigricans, and signs of virilization such as clitorimegaly, deepening of voice, and increased muscularity
Laboratory evaluations: LH, FSH, PRL, E2, DHT, SHBG, DHEA-S, 17-OH P, androstenedione, TSH
Pelvic ultrasound

LH luteinizing hormone, *FSH* follicle-stimulating hormone, *PRL* prolactin, *E2* estradiol, *DHT* dihydrotestosterone, *SHBG* sex hormone-binding globulin, *DHEA-S* dehydroepiandrosterone sulfate, *17-OH P* 17-hydroxyprogesterone, *TSH* thyroid-stimulating hormone

Differential diagnosis in patients with hirsutism or hypertrichosis includes the following:

- PCOS: diagnosis based on the Rotterdam criteria
- Nonclassical late-onset congenital adrenal hyperplasia: elevated 17-OH progesterone, diagnosis confirmed by ACTH stimulation test
- Cushing's syndrome: elevated and/or non-suppressible cortisol plasma or urine levels, hypertension, abdominal striae, and easy bruising
- Hyperprolactinemia: mild hyperandrogenism/hyperandrogenemia, oligomenorrhea/amenorrhea, and galactorrhea
- Primary hypothyroidism: elevated TSH, decreased thyroxine levels, menstrual irregularities, mild hyperandrogenism or/and hyperandrogenemia, cold intolerance, and goiter
- Acromegaly: elevated IGF-1 serum levels, non-suppressible growth hormone levels, oli-

gomenorrhea/amenorrhea, acral enlargement, coarse facies, prognathism, and macroglossia
- Virilizing adrenal or ovarian androgen-secreting tumors: rapid onset of hirsutism, extremely elevated plasma androgen levels, signs of virilization (clitorimegaly, deepening of voice, increased muscularity), and tumor confirmed with imaging (ultrasound or computed tomography)
- Drugs: androgens (danazol), glucocorticoids, minoxidil, valproate, and cyclosporine
- Hypertrichosis lanuginosa acquisita: rare, sudden appearance of long, fine, nonpigmented lanugo hairs that can grow to extraordinary length, mostly on the face and ears; occasionally associated with glossodynia or taste alterations; can be a paraneoplastic condition (breast and uterine adenocarcinomas, lymphomas, urinary bladder carcinomas), but may also be seen in anorexia nervosa and thyrotoxicosis

General Principles of Treatment

An effective management of hirsutism should aim to correct any underlying hormonal disease while reducing excessive hair. The management of women with hirsutism may require pharmacological systemic or topical treatments (Table 40.2), adjunct cosmetic methods of hair removal, and lifestyle modifications. The main rationale behind the medical treatment of hirsutism consists in suppressing ovarian or adrenal androgen secretion or blocking androgen action at the hair follicle.

For mild hirsutism, simple, inexpensive methods, such as bleaching, shaving, and waxing may suffice. Eflornithine hydrochloride cream may be prescribed for the topical treatment of facial unwanted hair (or used off-label for focal hirsutism in other body areas). A combination of pharmacological treatment regimens and direct methods to reduce and remove hair including electrolysis and photoepilation (laser or intense pulsed light) can yield better results.

Several factors should be taken into account during the therapeutic approach to hirsutism, including efficacy, safety, convenience, potential pain, and expense. The choice of therapy should be based on the degree of hirsutism, potential underlying hormonal disorders, the impact on the individual's quality of life, and the desired degree of unwanted hair reduction.

Table 40.2 Overview of systemic and topical pharmacological treatments for hirsutism

Systemic treatments	Topical treatments
Combined oral contraceptives[a]	Eflornithine hydrochloride
Antiandrogens	
Spironolactone, cyproterone acetate, finasteride[b], flutamide[b]	
Insulin-lowering drugs	Finasteride[b]
Metformin[b], rosiglitazone[b]	
Glucocorticoids[b]	

[a]EE 35 μg/CPA 2 mg is the only contraceptive pill approved by the European Medicines Agency (EMA) for the treatment of hirsutism
[b]The 2008 Endocrine Society Guidelines suggest against the routine use of these treatments for hirsutism

As idiopathic hirsutism is mainly a cosmetic problem, topical treatments and hair removal methods are preferred. A consensus statement by the Androgen Excess and Polycystic Ovary Syndrome Society published by Escobar-Morreale et al. mentions that the subjective perception of the patient, and not only the absolute extent of hair growth, may also be taken into account to guide the decision for appropriate treatment.

Specific recommendations and suggestions for and against certain drugs and other treatment methods by the 2008 Endocrine Society Guidelines (Martin et al.) on the evaluation and treatment of hirsutism in premenopausal women are outlined in the following section; for women with patient-important hirsutism despite cosmetic measures, either pharmacological therapy or direct hair removal methods were suggested (weak recommendation, very low quality evidence). Women with hirsutism should be adequately informed about the potential risks associated with COC use.

Healthy eating, regular exercise, and weight reduction are encouraged in all patients with PCOS to reduce the risk of cardiovascular disease and type 2 diabetes. By decreasing insulin

resistance, weight loss and exercise may also decrease androgen levels and normalize ovulation.

Systemic Treatments

Evidence-based data regarding the use of systemic treatments for hirsutism is lacking. Systemic treatments suggested by the Endocrine Society for patient-important hirsutism in premenopausal women include hormonal therapies (oral contraceptives and antiandrogens). However, this was a weak recommendation based on very low quality evidence.

Because with any systemic therapy it takes several months to reduce hirsutism, the efficacy should not be evaluated before 6 months of treatment, and no changes in dose or addition of second agents should be done before that time. In the meantime, concomitant adjunct treatment such as waxing, bleaching, electrolysis, and laser therapy may be beneficial.

Antiandrogens and insulin-sensitizing agents are not currently approved for the treatment of hirsutism by the European Medicines Agency (EMA).

Combined Oral Contraceptives

Combined oral contraceptives (COC) generally contain ethinyl estradiol (EE) and a progestin. The main progestins with antiandrogenic properties used in COC formulations are cyproterone acetate (CPA) and drospirenone.

The beneficial effects of COC for hirsutism are mediated by several mechanisms: (1) they inhibit FSH and LH release by the pituitary, thereby reducing ovarian androgen production; (2) they decrease the levels of free testosterone by stimulating the hepatic synthesis of SHBG; (3) certain progestins inhibit adrenal androgen production by inhibiting the activity of steroidogenic enzymes; and (4) certain progestins like CPA and drospirenone exert antiandrogenic actions as antagonists of the androgen receptor (antiandrogens).

COC are a first-line therapy for hirsute women with PCOS. COC containing cyproterone acetate and those containing drospirenone or desogestrel are generally effective in improving mild-to-moderate hirsutism in PCOS when used for more than 12 cycles. Of note, EE 35 μg/CPA 2 mg is the only COC approved by the EMA for the treatment of hirsutism in premenopausal women.

In a randomized, physician-blinded study, Batukan et al. showed a comparable improvement in hirsutism in 100 women with COC containing EE 30 μg/drospirenone 3 mg (median F-G score of 3 at 12 months compared to 15 at baseline) versus EE 35 μg/CPA 2 mg (median F-G score of 4 at 12 months compared to 16 at baseline) after 12 months.

A prospective randomized trial by Oner et al. reported similar efficacy of oral 0.03 mg ethinyl estradiol/3 mg drospirenone 21/7 regimen or 0.02 mg ethinyl estradiol/3 mg drospirenone 24/4 regimen, for 6 months, in 47 women with moderate-to-severe hirsutism ($p<0.05$). An improvement in the F-G scores for hirsutism was observed in Group 1 (mean ± SD) (17.3 ± 5.2 to 8.7 ± 2.5, $p<0.001$) and in Group 2 (17.5 ± 4.8 to 7.9 ± 2.8, $p<0.001$). There was a significant decrease of total and free testosterone in both groups.

Women should be counseled that it takes several months to obtain an improvement in hirsutism.

COC have potential serious side effects, including an increased risk of venous thromboembolism (VTE), stroke, and myocardial infarction. These risks are increased in patients with a history of hypertension, diabetes, or migraine and in cigarette smokers. There are contraindications to COC therapy, including women with a history of clotting disorder, thrombophlebitis, cerebrovascular disease, coronary occlusion, abnormal vaginal bleeding, impaired liver function, migraine, smokers over age 35, and women at increased risk of breast cancer. An evaluation by an endocrinologist or a gynecologist can be useful when the use of COC is contemplated for hirsutism, and women with hirsutism should be adequately informed about the potential risks associated with COC use.

Antiandrogens

Antiandrogens, or androgen receptor blockers, are defined as agents that inhibit directly the binding of dihydrotestosterone (DHT) to its receptor in a competitive way. They include cyproterone acetate, spironolactone, flutamide, and finasteride. Antiandrogen monotherapy without contraception should be avoided due to the teratogenic effect. So, antiandrogens are usually employed as second-line therapy, adjunctive to COC. If the response to COC is suboptimal after 6 months of treatment, an antiandrogen can be added.

A systematic review and meta-analysis by Swiglo et al. included 12 eligible studies of at least 6 months of antiandrogen therapy in women with hirsutism. Antiandrogens reduced F-G scores by 3.9 (95 % CI 2.3–5.4) compared to placebo. Spironolactone reduced hirsutism scores by 1.3 (95 % CI 0.03–2.6) compared to metformin. Spironolactone or finasteride combined with contraceptives (1.7, 95 % CI 0.1–3.3) was superior to monotherapy with contraceptives. The authors concluded that weak evidence suggests antiandrogens are mildly effective for the treatment of hirsutism.

Cyproterone acetate (CPA 10 mg, 50 mg) is a progestational antiandrogen that blocks the androgen receptor. CPA is the only antiandrogen that also has an antigonadotrophin action by inhibition of ovulation. It is used either as the progestin component of COC (at a low dose of 2 mg) or alone at higher doses of 12.5–100 mg given over the first 10 days of the menstrual cycle. A study by Kelekci et al. reported that the combination of 35 μg of EE/2 mg of CPA plus 100 mg of CPA daily for 6 months in 45 women showed the same improvement in hirsutism with 30 μg ethinyl estradiol (EE)/3 mg drospirenone plus 100 mg CPA ($n=45$) or 30 μg of EE/3 mg drospirenone plus 100 mg of spironolactone ($n=44$). The most frequent side effect of CPA monotherapy is amenorrhea or oligomenorrhea. Other side effects of CPA include nausea, vomiting, fluid retention, headache, liver dysfunction, and blood clotting disorders.

Spironolactone is an analogue of aldosterone that acts as an antagonist of the mineralocorticoid receptor but also of the androgen receptor, thus competing with dihydrotestosterone (DHT). In addition, it inhibits enzymes involved in androgen biosynthesis. A systematic review by Brown et al. reported that in two trials comparing 100 mg of spironolactone with placebo, there were significant differences in subjective improvement in hair growth (OR 7.18, 95 % CI 1.96–26.28), but not in the F-G score. The authors concluded that due to the scarce number of studies, the small number of included patients, and differences in study design, results cannot be generalized. Spironolactone may cause hyperkalemia, menstrual irregularity, breast tenderness, headache, and fatigue. It is contraindicated during pregnancy as it may lead to feminization of a male fetus (abnormalities of the male fetal genitalia, such as hypospadias).

Flutamide is a nonsteroidal antagonist of the androgen receptor used to treat prostate cancer. It has been associated with hepatotoxicity, for which reason its use for hirsutism is not recommended.

Finasteride has no direct effect on the androgen receptor or the pituitary. Rather, it inhibits in hair follicles the activity of 5α-reductase type 2, the enzyme that converts testosterone to the highly active DHT. However, of the two isoforms of the enzyme, finasteride targets only 5α-reductase type 2, thus exerting a partial effect. It is also more expensive than spironolactone and has a higher potential teratogenic effect; thus, its routine use for hirsutism is not recommended.

Antiandrogens are not currently approved for the treatment of hirsutism by the European Medicines Agency (EMA).

Insulin-Sensitizing Drugs: Metformin

Compensatory hyperinsulinemia is associated with insulin resistance in PCOS. Metformin is an insulin-sensitizer that reduces insulin resistance, insulin secretion, and hyperinsulinemia.

A double-blind placebo-controlled crossover study by Kelly et al. in 16 women with PCOS and hirsutism reported a significant improvement of hirsutism F-G score with metformin compared to placebo (F-G score 15.8 ± 1.4 vs 17.5 ± 1.2, $p=0.025$).

In the prospective randomized controlled trial of Rezvanian et al. in 70 women with PCOS, the addition of metformin 1,500 mg daily to intense pulsed light (IPL) therapy during 6 months resulted in significantly better control of hirsutism compared to five sessions of IPL alone ($p = 0.009$).

Adverse effects with metformin include nausea, vomiting, diarrhea, myalgia, palpitation, flushing, reduced vitamin B12 levels, and lactic acidosis. Metformin is contraindicated in case of renal disease/dysfunction due to increased risk for lactic acidosis.

Insulin-sensitizing agents are not currently approved for use in women with hirsutism or PCOS. There are no adequate evidence-based data regarding the effects of metformin for hirsutism, and the 2008 Endocrine Society Guidelines suggested against its routine use for hirsutism.

Studies Evaluating Metformin Compared to COC in Women with Hirsutism

Harborne et al., in a randomized study in 52 women with PCOS, compared metformin (500 mg, three times daily) to EE 35 μg/CA 2 mg, for 12 months. They reported that both treatments significantly reduced the F-G score, with metformin showing a significantly greater degree of reduction in the F-G score (25 %) compared with EE/CA (5 %) ($p < 0.01$).

Ibanez et al., in a randomized, open-label trial, compared the effects of 35 μg ethinyl estradiol/mg cyproterone acetate (EE/CA) versus a low-dose combination of pioglitazone (7.5 mg/day), flutamide (62.5 mg/day), and metformin (850 mg/day) (PioFluMet) for 18 months, in 34 nonobese adolescent girls with hyperinsulinemic androgen excess. After 18 months of treatment, the mean reduction in the hirsutism score compared to baseline was 6.5 with PioFluMet ($p < 0.001$) and 4.7 with EE/CA ($p < 0.001$). At 24 months follow-up, there was a more significant reduction with PioFluMet compared to EE/CA, with a mean reduction in the hirsutism score of 6.8 and 3.8, respectively ($p < 0.01$).

A Cochrane review of metformin versus oral contraceptives in PCOS evaluated 4 randomized controlled trials involving 104 subjects and reported no evidence of a difference in effect between COC and metformin on hirsutism, with both treatments resulting in a standardized mean difference of −0.18 ($p = 0.48$). The dose of metformin was 500 mg three times daily in one trial and 500 mg twice daily for the first 3 months increasing to 1,000 mg twice daily for the next 3 months for three of the trials. The COC type was EE 35 μg/CA 2 mg in all trials. The duration of trials ranged from 4 to 12 months.

Topical Treatments

Eflornithine Hydrochloride Cream

Hair follicles in the anagen (growth) phase are characterized by the highest activity of ornithine decarboxylase (ODC), the rate-limiting enzyme of polyamine biosynthesis. Eflornithine hydrochloride is an inhibitor of ODC, and eflornithine hydrochloride 13.9 % cream (Vaniqa) has been clinically shown to slow the growth of unwanted facial hair in women. It is FDA-approved for the reduction of unwanted facial hair in women; it is available by prescription and is applied twice daily. Eflornithine cream is not indicated for use during pregnancy (FDA pregnancy category C).

Eflornithine cream may be combined with laser hair removal methods. Smith et al. reported more rapid hair removal when eflornithine cream was combined with laser treatment (alexandrite or Nd:YAG) in 54 women with unwanted facial hair for 34 weeks. Hamzavi et al. reported higher rates of complete or almost complete hair removal in 31 women treated for unwanted hair on the upper lip, for 26 weeks with eflornithine cream combined with long-pulsed alexandrite laser (93.5 %) versus laser alone (67.9 %) ($p = 0.021$). The Endocrine Society Guidelines suggest the use of eflornithine cream for women who desire a more rapid response to laser therapy.

Finasteride

Stimulation of 5α-reductase in hair follicles causes male pattern hair to grow on the face and body and to be lost on the scalp. Topical finasteride (a type 2, 5α-reductase inhibitor) has been used for treating hirsutism with inconsistent results.

In a double-blind, randomized, placebo-controlled study of 77 women with excess facial hair, Farshi et al. reported that the addition of 0.5 % finasteride solution for 6 months to intense pulsed light/radiofrequency (four sessions) may result in greater reduction of facial hair (by 1/cm^2).

Given that the data overall show little or no benefit in hirsutism, the Endocrine Society Guidelines suggest against the use of topical finasteride.

Hair Removal Methods

Different cosmetic and hair removal methods include chemical depilation (removal of hair above the skin surface), bleaching (to lighten hair color), physical depilation (trimming), or epilation (removal of hair with its bulb by tweezing, by waxing, or by the use of electric rotating epilating devices), electrolysis, thermolysis, and laser hair removal or photoepilation.

Chemical and Physical Methods

With chemical depilation, chemicals such as sulfur compounds of calcium, arsenic, antimony, barium, and strontium are applied to dissolve the hair through reduction of disulfide bonds. The depilatory creams are mostly based on thioglycolates 2–4 %. Disadvantages include allergic or contact dermatitis. Bleaching lightens the color of excessive hair to make it less visible. Bleaching is quick, easy, painless, and inexpensive. Disadvantages include skin irritation due to peroxide/sulfates contained in bleaching products and possible sensitization. For any bleaching or chemical depilation, it is advised to first perform it on a small test area.

Trimming of hair is safe, and it does not accelerate hair regrowth. Tweezing or plucking is a temporary method of epilation that is used for small areas of excess hair. Disadvantages include pain, folliculitis, postinflammatory hyperpigmentation, and potential scarring. Waxing involves the application of melted wax to hair-bearing skin which, upon drying, is rapidly peeled away from the skin. Disadvantages include pain, folliculitis, sensitization (to the colophony resin), and the possibility of thermal skin burns caused by the hot wax. Electric rotating epilating devices for home use or waxing techniques are based on hair shaft epilation leading to longer-lasting hair-free effects (2–6 weeks). Disadvantages include pain, skin irritation, and folliculitis.

Electrolysis-Electroepilation

Electrolysis is performed by passing direct or galvanic current through an epilation probe introduced into the hair follicle opening, leading to a chemical reaction and destruction of the hair follicle. This is a time-consuming method. In thermolysis (electroepilation), high-frequency alternating current is used to destroy the hair follicle by heat. The "blend method" combines both types of currents. Disadvantages include pain, hyperpigmentation, risk of scarring, and transmission of infection if the electrolysis needles are not properly sterilized.

Laser/Photoepilation

Wavelengths in the red and near-infrared spectra (600–100 nm) are suitable for hair removal, providing sufficient energy absorption by melanin, and decreased absorption from other skin chromophores such as oxyhemoglobin, and by water. Lasers used to treat unwanted hair include the long-pulsed ruby laser (694 nm), the long-pulsed alexandrite laser (755 nm), the diode laser (800–810 nm), and the long-pulsed Nd:YAG laser (1,064 nm). The intense pulsed light (IPL) is a non-laser, polychromatic, noncoherent light (590–1,200 nm) used in photoepilation.

The effects of laser systems used for hair removal are based on the principle of selective photothermolysis to selectively cause thermal damage

to the target (pigmented hair follicles) by using the melanin of the hair shaft as a chromophore, without damaging the surrounding tissue. A component of photothermolysis is the thermal relaxation time. This is used to determine the pulse width for laser light, so that the heat generated within the target owing to absorption of photon energy does not cause damage to the surrounding tissue.

In the retrospective study of Kutlubay, the effect of a millisecond alexandrite hair removal laser (755 nm) in 2,359 subjects was evaluated. Patients were treated in 3–15 sessions per anatomic site. A mean hair reduction of 61–86 % was reported, with lighter skin types showing better results. Complications were reported in 2.2 % of subjects, including transient hyper- or hypopigmentation, folliculitis, blistering, pruritus, and excoriations.

In general, the reported short-term efficacy with lasers ranges between 30 and 70 % up to 6 months after the final treatment, depending also on the treatment settings. Long-term hair removal efficacy beyond 6 months postoperatively has been reported with the alexandrite laser, the diode laser, and the long-pulsed Nd:YAG laser, with an average of approximately 50 % hair reduction at 6–20 months after treatment.

Two studies (McGill et al. and Goh) compared IPL to either the long-pulsed alexandrite laser or Nd:YAG laser and reported the IPL to be inferior to laser devices for hair removal.

Treatment parameters that must be individualized include wavelength, pulse duration, spot size, fluence, and number of sessions. Other key components with laser hair removal include proper patient selection, informed consent, and understanding of the principles of laser safety. The treatment outcome depends on skin type, hair color and density, and hormonal status. Blond, red, and white hair is not suitable for laser epilation, whereas dark hair in a fair-skinned subject is the ideal scenario. To minimize the risk of skin pigmentation side effects in patients with darker skin type (Fitzpatrick phototypes IV), it is suggested to use lower fluences of alexandrite and diode laser wavelengths or a long-pulsed Nd:YAG laser. Complications include hypo- or hyperpigmentation and rarely scarring and paradoxical hypertrichosis, the latter defined as the induction of terminal hairs after treatment of vellus hairs, especially on the cheeks and chin.

Patients should be informed that permanent and complete hair removal is not likely, but that significant long-term reduction can be achieved with multiple treatments. In females with hirsutism owing to hormonal disorders, laser hair removal may have lower efficacy, and continued maintenance sessions may be required. As mentioned, concurrent hormonal treatment may be beneficial in this setting.

Topical anesthesia (lidocaine/prilocaine cream) may be applied in limited body areas 1 h prior to laser treatment. Protective eye goggles by the patient and the treating physician should be used during laser treatment, and it is advised not to treat a patient within the bony orbit. Sun exposure should be avoided after laser treatment to avoid postinflammatory hyperpigmentation.

Conclusions

In conclusion, an effective management of hirsutism should aim to diagnose and treat any underlying hormonal disease while reducing excessive hair. Evidence-based data regarding the use of systemic treatments for hirsutism is lacking. As idiopathic hirsutism is mainly a cosmetic problem, topical treatments and hair removal methods are preferred.

According to current official guidelines and accepted practices, combined oral contraceptives (COC) or laser/IPL epilation is suggested for premenopausal women with patient-important hirsutism. Combined oral contraceptives are the first-line therapy for hirsute women with PCOS. If COC are chosen, treatment efficacy should be evaluated after no less than 6 months. Women with hirsutism should be adequately informed about the potential risks associated with COC use. When laser/IPL epilation is chosen, it can be combined with eflornithine hydrochloride cream for a more rapid result. The routine use of other topical or systemic medications for hirsutism is not suggested.

An interdisciplinary approach comprising a dermatologist, an endocrinologist, and/or a gynecologist may provide optimal management to the hirsute woman.

HIV Infection and AIDS: Antiretroviral Therapy

41

Vassilios Paparizos and Sofia Kourkounti

Key Points

- HIV infection is now considered to be a chronic disease with a long life expectancy.
- The treatment of HIV infection consists of newer drugs that have easy dosing schedules and fewer side effects.
- There are currently three regimens that drugs are co-formulated into a single tablet, administrated once per day, and more similar regimens are expected.
- Increased comorbidity, associated with the long-term survival, is a new therapeutic challenge.
- Initiation of treatment is recommended in earlier stages, even in asymptomatic patients with high levels of CD4 T-lymphocytes.
- Early treatment of HIV may help prevent or manage comorbidities and reduce risk of transmission.
- The high cost of treatment still remains a major obstacle.

Definition and Epidemiology

Human immunodeficiency virus (HIV) infection remains a major public health problem in Europe and around the world. Approximately 2.3 million people were living with HIV in Europe at the end of 2010, according to the Joint United Nations Programme on HIV/AIDS (UNAIDS), and this number continues to grow. The prevalence of HIV/acquired immunodeficiency syndrome (AIDS) in different regions of the continent varies widely, from less than 0.1 % in parts of Central Europe up to more than 1 % in parts of Eastern Europe. Ongoing developments in antiretroviral therapy (ART) have provided the means for those affected to live longer and healthier lives than would have been possible in the first years of the epidemic. With new developments in therapy, however, have come new challenges, and, like the virus itself, HIV/AIDS treatment will continue to evolve and adapt.

Basic Concepts of Pathogenesis

HIV/AIDS is caused by a human retrovirus named human immunodeficiency virus-1 (HIV-1) and, in a very few cases (predominantly in West Africa, rarely in Europe), human immunodeficiency virus-2 (HIV-2). HIV-1, which was discovered in 1983, is a ribonucleic acid (RNA) virus with two RNA chains organized into nine genes. The virus contains enzymes such as

reverse transcriptase, which enables the transcription of viral RNA into DNA; integrase, which aids the integration of viral DNA in the host cell's DNA; and proteases, which assist in the formation of structural and functional viral proteins from high molecular weight precursor proteins.

In the initial step in the interaction between HIV and cells, the viral surface glycoprotein, gp120, is bound to the CD4 receptor molecule and a co-receptor. The co-receptor is a chemokine receptor, usually CCR5 for macrophage-tropic strains (M-tropic or R5-tropic) or CXCR4 for T-cell line-tropic strains (T-tropic or X4-tropic). The complex of virus and receptors leads to exposure of the viral glycoprotein gp41 and then fusion of the viral and cellular membranes, allowing the virus to enter the target cell.

Each of these steps, and every other point in the life cycle of HIV and its enzymes, is a potential target for antiretroviral drugs.

General Principles of Treatment

In its first decade, beginning in 1987, the treatment of HIV infection depended on nucleoside analogue reverse transcriptase inhibitors (NRTIs), including 2,3-azidothymidine (AZT; also called zidovudine). In 1996, protease inhibitors (PIs) became available, and triple therapeutic combinations were introduced. Because HIV quickly and easily mutates, it would rapidly develop resistance to the administration of a single antiretroviral drug. Triple combinations, dubbed highly active antiretroviral therapy (HAART), were able to achieve strong suppression of viral replication, yielding much better and longer-lasting results than monotherapy had been able to achieve.

In order for HAART to achieve its main objective, that is, strong, long-lasting suppression of HIV, a patient's viral load, as reflected in the number of RNA copies per millilitre of blood plasma (plasma HIV RNA), must be reduced by more than 0.5 log copies/mL 4–8 weeks after therapy is initiated and to undetectable levels (<50 copies/mL) no later than 6 months after beginning treatment. According to the 2012 European AIDS Clinical Society (EACS) guidelines, a detectable HIV RNA level 6 months after initiation of treatment is the definition of virologic failure.

Successful treatment and strong viral suppression enable the reconstruction of the human immune response. Immune reconstitution is both quantitative and qualitative and includes an increase in the CD4 T-cell count and the restoration of these cells' repertoire. Such reconstruction is only partial, since HIV-specific responses, which shut down during the initial infection, do not reset. The degree to which CD4 T-cells increase during immune reconstitution depends on many factors, including the patient's viral load, treatment compliance, age, and lowest CD4 T-cell count (CD4 nadir) prior to treatment.

Although these improvements are incomplete, the vast majority of patients treated for HIV/AIDS experience viral load reduction and immune restoration. This enormous achievement has led to a significant reduction, in the affected population, of opportunistic infections such as Kaposi's sarcoma and other clinical manifestations of AIDS (AIDS conditions). These therapeutic successes have also led to a decreased need for hospitalization and an improvement in patients' quality of life and involvement in productive and social activities. According to several studies, the life expectancy of HIV patients has exceeded 30 years post infection. Life expectancy in the uninfected population is still higher, but patients with CD4 T-cell counts >500 cells/mm^3 who receive ART have mortality rates equal to that of the general population. In present-day Europe, most deaths in HIV-infected patients are not due to AIDS.

In addition to all of these treatment effects, ART is an important means of prevention, since the reduction in viral load reduces but does not

eliminate completely the infectivity of treated subjects. From a public health perspective, the reduction in the viral load of a community as a whole can lead to diminished virus spread. Thus, the main objectives of ART today can be summarized as follows:

- Maximum and long-term suppression of viral load
- Restoration of immune function
- Reduction of HIV-associated morbidity and prolongation of survival with improved quality of life
- Limitation of the transmission

Initiation of ART

Antiretroviral therapy (ART) for the treatment of HIV infection has improved steadily since the advent of potent combination therapy in 1996. New drugs, with their new mechanisms of action, improved efficacies, better safety, and fewer side effects, are broadening therapeutic horizons. Co-formulated, single-tablet, once-daily drugs are facilitating tolerance and improving patient adherence.

However, HIV/AIDS medications are meant to be taken for life, which means that the virus may develop resistance and patients will certainly endure side effects. As a response to these problems, intermittent therapy and 'drug holidays' have been trialled but have failed and are now contraindicated. Successful treatment, then, depends on the patient making a firm decision and committing to a course of action after appropriate counselling. Such counselling partly involves a discussion of the potential negative effects of each option and an investigation of potentially complicating factors, including health-related factors like comorbid depression, substance abuse, or other mental disorders, and system-related factors such as the restrictions of any relevant health insurance, the availability and cost of drugs, and the existence or lack of social support.

The best time to initiate ART remains controversial. The rapid reduction in viral load, subsequent reduction of infectiousness, and possible decrease in non-HIV comorbidity led some experts to advocate early initiation of treatment. The US Department of Health and Human Services (DHHS, USA) and the International Antiviral Society, USA (IAS, USA), panel recommended, in 2012, the immediate initiation of treatment in all patients, regardless of the CD4 T-cell counts. On the other hand, some experts have recommended tempering the rush into immediate ART, citing the need for lifelong commitment and the long-term toxicity and high cost of the drugs.

The EACS guidelines, meanwhile, recommend starting treatment in:

- All patients with clinical symptoms (stage B or C in the CDC classification system)
- All asymptomatic patients with a CD4 T-cell count <350 cells/mm^3

The EACS guidelines also recommend earlier initiation of treatment under specific conditions such as the presence of HIV-associated kidney disease, neurocognitive disorder, Hodgkin lymphoma, cancer associated with the human papillomavirus, hepatitis B requiring treatment, pregnancy, etc. (see Table 41.1).

Antiretroviral (ARV) Drugs

At present, there are many ARV drugs from six different classes used for the treatment of HIV/AIDS (see Table 41.2). These classes include:

1. Nucleoside or nucleotide reverse transcriptase inhibitors (NRTIs)
2. Non-nucleoside reverse transcriptase inhibitors (NNRTIs)
3. Protease inhibitors (PIs)
4. Integrase inhibitors
5. Fusion inhibitors
6. Entry inhibitors – CCR5 co-receptor antagonists

Table 41.1 Initiation of antiretroviral treatment

According to EACS guidelines 2013:
A. ART initiation is recommended in:
1. Symptomatic HIV disease (CDC B or C conditions)
2. All patients with CD4 count below 350 cells/mm^3
3. Regardless of CD4 T-cell count, HIV patients with:
HIV-associated kidney disease
HIV-associated neurocognitive impairment
Hodgkin lymphoma
HPV-associated cancers
Pregnancy
Hepatitis B requiring anti-HBV treatment
4. Patients with CD4 T-cell counts between 350 and 500 cells/mm^3 with:
Hepatitis C virus (HCV) co-infection
B. Use of ART should be considered in:
Asymptomatic patients with primary HIV infection
Non-AIDS-defining cancers requiring chemo- and/or radiotherapy
Patients at high risk for CVD (>20 % estimated 10-year risk) or history of CVD
Patients with hepatitis B not requiring anti-HBV treatment and CD4 count 350–500 cells/mm^3
Patients with CD4 count >500 cells/mm^3 and hepatitis C for which anti-HCV treatment is not feasible
Patients with CD4 count >350 cells/mm^3, to reduce HIV transmission
Patients with CD4 count >350 cells/mm^3, individualized, especially if patient is requesting ARV therapy and is ready to start
DHHS USA and IAS – USA panel, 2012, recommends initiation of antiretroviral therapy in all patients, regardless of CD4 T-cell count:
In order to reduce the risk of disease progression
For the prevention of transmission of HIV, through HIV RNA load reduction

Antiretroviral Regimens for the Initiation of Therapy

The plethora of ARV drugs allows patients and clinicians to choose an optimal combination that is compatible with the needs and characteristics of the individual patient. The choice of regimen is usually based on guidelines developed by an expert panel, which recommend preferred medicines and offer alternative choices when the preferred medicines are not ideal or practicable for a given situation. Such guidelines, issued by international and national organizations, are frequently revised or updated (see Table 41.3).

Nucleoside/Nucleotide Reverse Transcriptase Inhibitors (NRTIs/NtRTIs)

NRTIs and NtRTIs (also called nucleoside/nucleotide analogues or even 'nukes') inhibit HIV's reverse transcriptase function by preventing

Table 41.3 Initial combination regimen for antiretroviral-naive adult patients

According to EACS guidelines 2013:
A. Preferred regimens
The initial regimen consists of two NRTIs, preferably combinations of TDF/FTC or ABC/3TC, plus one of the following
NNRTI (recommended: EFV or RPV)
Ritonavir-boosted PI (recommended: ATV/r or DRV/r)
Integrase inhibitor (recommended: RAL)
B. Alternative regimens
Alternatively, the regimen may consist of two NRTIs – TDF/3TC, ZDV/3TC, ddI/3TC, and ddI/FTC – plus a third drug, such as:
Ritonavir-boosted PI (LPV/r, SQV/r, or FPV/r)
NNRTI (NVP)
CCR5 inhibitor (MVC)
Integrase inhibitor (EVG + Cobicistat)
According to DHHS guidelines 2013:
(a) Preferred NRTI regimen is only TDF/FTC and the only alternative combination is ABC/3TC
(b) Preferred NNRTI is only EFV. RPV is included in alternative regimens and NVP is not
(c) Preferred PIs are ATV/r και DRV/r. LPV/r is included in alternative regimens and SQV/r is not

transcription of the viral RNA into DNA. These act as alternative substrates that compete with physiological nucleosides/nucleotides. The integration of NRTIs/NtRTIs in the chain formation of viral DNA interrupts its composition, since the virus can no longer create phosphodiester bonds with the 'fake' nucleoside/nucleotide. In order to be incorporated into the DNA chain, NRTIs must first be phosphorylated in the cell with three phosphate groups (while NtRTIs, which already contain one phosphate group, require two more), forming triphosphate analogues, the active form of the molecules. NRTIs were the first antiretroviral drugs; AZT, introduced in 1987, was used as monotherapy for many years. Today, a combination of two NRTIs/NtRTIs forms the backbone of HIV/AIDS treatment, which is usually completed with a third drug from another class.

Although tolerance is very good, NRTIs/NtRTIs have been associated with long-term toxicity. Their main long-term side effects include myelotoxicity (particularly with AZT), hepatotoxicity, lactic acidosis, rhabdomyolysis, pancreatitis, peripheral neuritis (especially with stavudine [d4T] and didanosine [ddI]), and lipoatrophy. Many of these side effects are related to mitochondrial toxicity. The incorporation of false nucleosides leads to inhibition of mitochondrial DNA polymerase-c, resulting in impaired synthesis of mitochondrial enzymes that generate ATP by oxidative phosphorylation.

Non-nucleoside Reverse Transcriptase Inhibitors (NNRTIs)

NNRTIs inhibit HIV's reverse transcriptase activity by binding a hydrophobic pocket close to the enzyme's active site, locking the site in an inactive conformation. These drugs are very potent, but they have a low genetic barrier; a single primary mutation can create an HIV strain able to resist them. In many cases, a single mutation (e.g. the K103N mutation) can cause cross-resistance, making more NNRTIs ineffective. However, when patient adherence to treatment is very high, these mutations are not easily or quickly selected.

The main side effects of NNRTIs are hepatotoxicity, drug eruption (especially with nevirapine [NVP]), and central nervous system (CNS) disorders (associated with the use of efavirenz [EFV]). As these drugs are metabolized by cytochrome CYP3A4, particular attention to interactions with other drugs or substances (e.g. methadone) is required.

Protease Inhibitors (PIs)

PIs inhibit HIV proteases by binding to their active sites, preventing the cleavage of Gag and Gag-Pol precursor proteins. When proteolytic splicing is prevented, incomplete and non-infectious virions are produced. Since 1995, PIs inaugurated the HAART era, revolutionizing the treatment of HIV/AIDS. All PIs have strong antiviral activity and high genetic barriers; a sum of many mutations is required to develop resistance to them, especially to the newest drugs. PIs, however, have many side effects, both short-term and long term. Short-term side effects are mainly gastrointestinal disturbances such as nausea, abdominal upset, flatulence, and diarrhoea, while long-term side effects include lipodystrophy, metabolic disorders such as hyperlipidaemia, insulin resistance, atherosclerosis, and an increased risk of cardiovascular disease and osteoporosis-osteopenia. While these side effects affect the entire class, some additional side effects are specific to certain drugs: atazanavir and indinavir (IDV) are associated with hyperbilirubinaemia and nephrolithiasis, and IDV is associated with skin dryness and nail dystrophy.

PIs are metabolized in the liver and are potent inhibitors of cytochrome CYP3A4. PIs may interact with many other drugs so careful co-administration is required.

Meanwhile when ritonavir is co-administered with other PIs, it leads to a considerable increase in several pharmacokinetic parameters, including Cmax (maximum concentration) and Ctrough (trough levels). This phenomenon, known as 'boosting', is indicated on labels by the notation '/r' after the drug name and simplifies daily regimens by reducing dose frequency and pill burden.

Integrase Inhibitors

Integrase inhibitors are designed to inhibit one of the functions of the viral integrase. Integrase is involved in multiple steps of the path of the viral DNA, from the production in the cytoplasm to the transfer to the core and the final incorporation into the DNA of the host cell. The currently available integrase inhibitors (raltegravir and elvitegravir) inhibit the final step, the binding of the viral DNA into the cellular DNA (strand transfer inhibitors). Integrase inhibitors are well tolerated; their side effects are relatively rare and mild. The most common adverse events associated with these drugs are transient mild-to-moderate headaches and fatigue.

Because integrase inhibitors are metabolized by glucuronidation via UDP-glucuronyltransferase 1A1 (UGT1A1) and not by cytochrome p450, interactions with other drugs are minimal. Drugs that are strong inducers of glucuronidation enzyme UGT1A1 though, such as rifampicin, significantly reduce concentrations of raltegravir. Integrase inhibitors are considered to have a relatively low genetic barrier, and there is cross-resistance between raltegravir and elvitegravir. However, in clinical practice they have demonstrated superiority over other drugs as a first-line therapy.

Currently, two integrase inhibitors are available: raltegravir, which must be administered twice a day, and elvitegravir, which exists only as a co-formulation with emtricitabine, tenofovir, and cobicistat.

Entry Inhibitors: Fusion Inhibitors

The fusion of the HIV membrane with the membrane of the target cell is an essential step for the entry of the virus. After connecting the viral gp120 with the CD4 receptor and co-receptor (CCR5 or CXCR4), viral gp41 undergoes a conformational change that exposes the hydrophobic region of gp41 to the cell membrane. This allows the two heptad repeat sequences (HR1 and HR2) of gp41 to interact, resulting in the formation of a hairpin structure that brings the virus and cell membranes together, mediating the fusion of virus and cell.

At present, there is only one fusion inhibitor: enfuvirtide (T-20). T-20 exerts its action by binding to HR1 and disrupting its interaction with HR2, so that the fusion of the two membranes is

no longer possible and the virus cannot enter the cell.

T-20 is only available in the form of a twice-daily subcutaneous injection. Its most frequent adverse reactions are injection site reactions, including pain, erythema, itchiness, nodules, cysts, or granulomas. Other adverse reactions are rare but include coughing, dyspnoea, arthralgia, insomnia, depression, and infections, notably bacterial pneumonia. T-20 is a synthetic peptide with a high molecular weight (4,492 Kd), making it difficult to develop a non-injectable formulation.

Entry Inhibitors: CCR5 Co-receptor Antagonists

There is currently only one drug, maraviroc (MVC), in the class of co-receptor antagonists. MVC binds to the CCR5 co-receptor, which is a chemokine receptor, inducing conformational changes and leading to the inhibition of its binding to the viral gp120. MVC has no activity against HIV strains that use the CXCR4 receptor (X4-tropic strains) or those that can use both receptors (dual-tropic), and there are currently no CXCR4 co-receptor antagonists. However, in most patients, strains that bind to the CCR5 co-receptor (R5-tropic strains) prevail in the early stages of the disease; R5-tropic strains are found in 80–90 % of treatment-naïve patients; CCR5 antagonists, therefore, probably need to be given earlier in the course of the disease. X4-tropic strains of HIV, on the other hand, are almost exclusively found in advanced stages of the disease.

So far, a shift in virus tropism from R5- to X4- or dual-tropic during treatment with MVC has not been observed. In any case, before administering MVC, tropism testing should be performed to exclude patients with X4- or dual-tropic strains. MVC is very well tolerated, with usually few and relatively mild side effects, including gastrointestinal disorders, headaches, dizziness, and joint pain.

MVC is metabolized by cytochrome CYP3A and thus enzyme inhibitors such as PIs increase the level of MVC in the blood, while inducers, as EFV or etravirine (ETR), may substantially decrease maraviroc concentrations. In practice, the dosage of MVC depends on which antiretroviral drugs are co-administered.

Changing Antiretroviral Therapy

Change Due to Virologic or Immunologic Failure

As previously noted, virologic failure, according to EACS guidelines, is defined as HIV RNA levels >50 copies/mL 6 months after starting therapy (initiation or modification). ARV drugs should be changed in patients experiencing virologic failure, especially when there is resistance mutation substantiated by genotypic testing. The new regimen must contain at least two and preferably three fully active drugs. However, in all cases of virologic failure, the degree of the patient's adherence to therapy and possible factors affecting compliance should be investigated thoroughly. If the viral load is more than 500–1,000 copies/mL, it is necessary to perform drug resistance genotype testing. Therapy should also be changed in the case of immunologic failure, which is defined as failure to achieve and maintain an adequate CD4 T-cell response despite virologic suppression, especially when the CD4 T-cells remain firmly below 200 cells/mm^3. No consensus exists, however, on how best to change the antiretroviral regimen in the event of immunologic failure.

Change Due to Toxicity

Change in the ARV regimen is sometimes necessary due to adverse reactions, both those appearing shortly after initiation of treatment (commonly hypersensitivity, gastrointestinal disorders, myelotoxicity, hepatotoxicity, and CNS disorders) and those that occur with long-term use (commonly renal dysfunction with tenofovir use, depression related to efavirenz use, nephrolithiasis, lipodystrophy, hyperlipidaemia, etc.).

Change to Simplify or Modernize Therapy

Regimen simplification usually aims at reducing pill burden and dose frequency in order to improve adherence to therapy. New less-toxic or co-formulated drugs and single-tablet regimens offer options for modernizing and simplifying more complex, older combinations. Occasionally such an update will be compelled when an older drug becomes unavailable (as occurred with nelfinavir) or becomes only available in a new formulation (as occurred when Viramune (a brand of NVP) changed its formulation to Viramune XR).

Special Issues

Adherence/Drug Resistance

The effectiveness of ART is determined by the treatment duration and the efficacy of each of the drugs. Both of these factors depend on the drugs' genetic barriers (i.e. the number of mutations of HIV required for the development of drug resistance) and the ease of selection of the mutations. When such drug resistance develops, treatment response decreases, and viral replication increases. Resistance mutations are detected by genotypic resistance tests that must be performed before the start of therapy and in the event of virologic failure. Based on the results of these resistance tests, any failed drugs are replaced with active agents.

Such drug failures are most commonly caused by a lack of patient adherence to treatment; frequently missed doses, arbitrary dose reduction, and discontinuation of therapy lead to increased viral replication in the presence of the drugs' genetic information, which encourages the selection of resistance mutations. When virologic failures are repeated and new mutations constantly appear, treatment options decrease and subsequent regimens are usually more complex and may include more drugs with more side effects and limited efficacy. Thus, patient adherence to treatment is particularly important for its success. Factors commonly associated with poor adherence include depression, use of alcohol or recreational drugs, and patients' personal perceptions of medications, all of which should be investigated before therapy is initiated.

Genotypic resistance tests, at the time of initial diagnosis, detect mutations that are there due to transmission of resistant strains during the initial infection or during reinfection, and the likelihood that a patient will acquire a drug-resistant virus is not rare; in Europe, 8–10 % of patients have transmitted resistance.

Ageing

The prolongation of survival has led to increased patient age and the emergence of comorbidities associated with ageing. It is likely that after 2015, 50 % of HIV patients will be over 50 years old. Thus, patients who are treated with antiretrovirals have increased risk for several non-AIDS complications, many of which are commonly associated with ageing. The most common complications in treated subjects are related not directly to AIDS but to hypertension, diabetes mellitus, cardiovascular disease, osteopenia-osteoporosis, liver or kidney failure, neurocognitive disorders, and increased incidence of cancers. The emergence of these disorders occurs in patients younger than expected and contributes to a phenotype of frailty.

Due to the changing spectrum of HIV-associated diseases, the medical management of HIV infection is evolving; a lower proportion of time is now spent managing drug resistance and short-term toxicities and a higher proportion is spent managing these premature age-associated complications.

These disorders are related to the incomplete correction of immunological function, the persistent defects, and the presence of low-level inflammation which acts on the endothelium of blood vessels and at cellular level.

The occurrence of events which are not directly related to HIV infection creates the need for further treatment. The multi-morbidity leads to polypharmacy and requires increased attention

to the selection of these drugs and antiretroviral therapy, in order to avoid drug interactions.

HIV Co-infection with Hepatitis B (HBV) or Hepatitis C (HCV)

HIV co-infection with HBV or HCV is common. In Western Europe, the incidence of HBV in HIV patients has been found to be 6–14 % overall. Its prevalence is estimated at 9–17 % in men who have sex with men (MSM), 7–10 % in injectable drug users (IDU), and 6.4 % in heterosexuals. HCV-HIV co-infection has been found to be 25–30 % overall: 72–95 % in IDUs, 1–12 % in MSM, and 9–27 % in heterosexuals. HIV infection has been associated with a more rapid progression of viral hepatitis. HIV patients with HBV or HCV have greater levels of HBV or HCV viraemia, faster progression to cirrhosis, and severe hepatic impairment and suffer more frequently from hepatocellular carcinoma. Furthermore, HIV patients with viral hepatitis exhibit rapid progression to AIDS. The increase of CD4 T-cells and the improvement of the immune response associated with ART also improve the course of viral hepatitis. Moreover, NRTIs such as emtricitabine, lamivudine, and tenofovir are potent drugs against HBV. Accordingly, the 2012 EACS guidelines for the treatment of HIV infection recommend the rapid onset of ART in co-infected patients, particularly those who need or are receiving treatment for hepatitis (see Table 41.1).

HAART Optimism

Excessive optimism from the effectiveness of HAART, deemed 'HAART optimism', involves inaccurate beliefs about susceptibility to HIV transmission, a reduction in the use of condoms, frequent unprotected sexual contacts, an increase in the number of sexual partners, and a general resurgence of high-risk behaviour. HAART optimism has been associated with an increased incidence of sexually transmitted diseases such as syphilis, particularly among MSM. HAART optimism remains a controversial topic, though many studies conclude that risky behaviour is a factor in the growth of HAART optimism and not the reverse. However, it is clear that the causal relationship can act in both directions, each perhaps due to differences in individuals or populations.

Lipodystrophy

HIV-associated lipodystrophy is a syndrome that represents a group of disorders observed in HIV patients under treatment. It includes morphological changes, such as the loss or redistribution of subcutaneous fat (in the form of lipoatrophy and/or adiposity [lipohypertrophy]), and other physical and metabolic disorders. The metabolic disorders are diverse and are primarily associated with hyperlipidaemia and insulin resistance. HIV-related changes in the distribution of subcutaneous fat often coexist with metabolic abnormalities, but these may exist independently of one another.

Lipoatrophy is characterized by loss of subcutaneous fat through the face (cheeks, temples, nasolabial regions), the upper and lower extremities, and the buttocks. These changes appear as sunken cheeks, prominent temporal veins, and increased wrinkling in the face. Lipoatrophy has been associated more with long-term use of NRTIs, particularly derivatives of thymidine (e.g. d4T and zidovudine). Lipohypertrophy, on the other hand, is mainly associated with the use of PIs and is characterized by increased fat deposition in the abdomen, breasts, and, more rarely, shoulders and neck (sometimes referred to as 'buffalo hump'). Lipohypertrophy may occur as multiple subcutaneous lipomas, but this is a rare presentation. The two forms of lipodystrophy can coexist in the same patient. Lipoatrophy, particularly of the face, and/or the development of buffalo hump, can be cosmetically disfiguring, significantly reducing the patient's quality of life. Facial lipoatrophy carries a social stigma and is undoubtedly one of the most distressing side effects for HIV patients.

The HIV-related metabolic disorders, meanwhile, include hyperglycaemia, reduced glucose

tolerance, and elevated triglycerides and total cholesterol. Other metabolic symptoms include increased levels of low-density lipoprotein, very low-density lipoprotein, and apolipoprotein B (which is considered an independent risk factor for atherosclerosis) and slightly decreased levels of high-density lipoprotein. Other metabolic abnormalities that are associated or may coexist with lipodystrophy are a disturbance in calcium metabolism, osteoporosis and osteopenia, and aseptic bone necrosis.

The pathogenesis of lipodystrophy is not yet adequately understood. Some evidence suggests that NRTIs may cause mitochondrial toxicity, leading to reduced energy production, increasing insulin resistance, and dyslipidaemia. PIs are also implicated, as they compete with enzymes involved in the metabolism of retinoic acid and lipoproteins or directly affect adipocytes' life cycles. In addition, HIV infection itself causes dyslipidaemia and lipodystrophy, especially in its advanced stages.

Overall, risk factors for developing lipodystrophy involve the course of HIV/AIDS, the duration of treatment, the types of medication used, the CD4 nadir, and the patient's race and gender (white patients and female patients experience higher risk). As long as the offending drug is being administered, a patient's lipodystrophy will continue to evolve. Switching from thymidine analogues to other NRTIs or from PIs (particularly older ones such as IDV and lopinavir/ritonavir) to other drugs (NNRTIs, integrase inhibitors, newer PIs such as darunavir), if feasible, may help. However, such have been shown to result in only limited and slow improvements in appearance.

Managing the metabolic disorders (e.g. diabetes, hyperlipidaemia) is essential for the treatment of lipodystrophy. Many drugs, such as anabolic steroids, human growth hormones, and naltrexone, have been tested in clinical trials for treating lipodystrophy. However, at present, only tesamorelin has been approved by the USA's Food and Drug Administration (FDA) for the treatment of lipodystrophy.

Approaches using plastic surgery, such as liposuction or lipectomy, have achieved moderate success in treating lipohypertrophy, as have commercial fillers or implants (e.g. poly-L-lactic acid, hyaluronic acid, calcium hydroxyapatite, and injectable collagens). Autologous fat grafting from lipohypertrophy areas to areas of lipoatrophy has also been used.

Drug Eruptions

Adverse cutaneous drug eruptions are very common in HIV-infected patients and occur 10–100 times more frequently than in the general population. Such drug eruptions can range from extremely mild to very serious and life threatening, and they usually occur within 6–14 days of therapy initiation. The typical form in the vast majority of cases is maculopapular morbilliform rash, with or without pruritus. Systemic symptoms (e.g. fever or headache) may occur with the rash. Other forms of eruption include urticaria, erythema multiform, fixed drug eruption, drug reaction with eosinophilia, Stevens-Johnson syndrome, and toxic epidermal necrolysis.

The pathogenesis of this phenomenon is unknown. Suggested related factors include advanced immunosuppression or immune activation, differences in the expression of cytokines, complex medication interactions, disturbances in the metabolism of compounds such as glutathione deficiency, liver dysfunction, and individual factors. The drugs that are most commonly responsible for rash are trimethoprim-sulphamethoxazole, NNRTIs, and semi-synthetic penicillins. Trimethoprim-sulphamethoxazole is administered to all patients who have CD4 T-cell counts <200 cells/mm^3 as chemoprophylaxis against *Pneumocystis jirovecii* pneumonia and toxoplasmosis, but its use and resulting eruptions were more frequent before the HAART era. NNRTIs are often responsible for hypersensitivity reactions, and 12.5–20 % of NVP-treated patients experience an exanthematous eruption. The NRTI abacavir (ABC) may also cause a hypersensitivity reaction, which manifests within the first 6 weeks of treatment as rash, fever, fatigue, nausea, abdominal pain, and respiratory symptoms such as pharyngitis, dyspnoea, or

coughing. If ABC is discontinued due to hypersensitivity, it must not be used again because of the risk of recurrence of immediate hypersensitivity in a much more intense, life-threatening form. Because ABC hypersensitivity is strongly associated with the HLA-B*5701 allele, all treatment guidelines recommend HLA-B*5701 testing before initiating ABC treatment. PIs, meanwhile, particularly older agents such as IDV, may cause retinoid-like effects, including xerosis, desquamative cheilitis, paronychia, and onychodystrophy. In some cases of mild rash, the responsible drug may be continued under close monitoring, and the eruption may resolve, but drug discontinuation is usually required. A re-challenge test may be performed for mild NVP, but not ABC, hypersensitivity.

Drug Interactions

HIV/AIDS patients receive a combination of three or four drugs (including boosters) for the treatment of their disease. They often have to take other medications for comorbid disorders (co-infection with hepatitis, depression, etc.) or to address the effects of ageing (hypertension, hyperlipidaemia, etc.), and many patients also take methadone, alternative medications, and recreational drugs. Such a proliferation of substances significantly increases patients' risks for drug interactions.

Most drug interactions in HIV/AIDS patients are associated with PIs or NNRTIs, both of which are metabolized by cytochrome p450. The most common isoenzyme is CYP3A4, followed by CYP2C19 and CYP2D6. Drugs that inhibit, induce, or act as a substrate for p450 alter the metabolism of other drugs, resulting in higher drug levels and an increased potential for toxicity or lower drug concentrations and decreased efficacy. Drugs such as rifampicin, azoles, methadone, anticonvulsants, hypolipidemics, and many others that are also metabolized by the same enzyme system should be used with caution. A thorough medication history must be taken for every patient before initiating ART or other drug treatments, and each visit should include a review of all currently used drugs. Extensive appendices of interactions between ARVs and other drugs are listed in international and national guidelines, and they are widely available and frequently updated on the websites of international organizations.

Pregnancy

The administration of ART in pregnant HIV-infected women has two aims: treating the patient and preventing perinatal transmission of HIV. This is achieved:

- By reducing the viral load in the mother's blood
- By reducing the viral load in genital secretions
- By achieving high protective drug levels in the foetus due to the passage of the drugs across the placenta

Thus, the objective of HAART in pregnancy is the maximum suppression of the viral load, at least in the last trimester and especially during the labour. However, ART during the whole pregnancy is better than therapy only in the third trimester. Given that HIV is transmitted through breastfeeding, the mother is not allowed to breastfeed.

The probability of transmitting HIV to the foetus when the mother receives full ART throughout pregnancy is less than 2 %. According to the 2012 EACS guidelines, a pregnant HIV-positive woman must:

- Continue therapy, if she is already receiving treatment
- Start therapy after the completion of the first trimester, if she has not started treatment because she had not yet had indication for receiving ART
- Start therapy immediately, if the diagnosis is made after the first trimester, especially after the 28th week

Generally, the choice of antiretroviral drugs for treating HIV-infected pregnant women should be made with the same criteria as in non-pregnant patients. Most antiretroviral drugs have not been associated with teratogenicity in humans, and their administration is associated with a much

stronger potential benefit than potential risk. Neither EFV nor NVP should be initiated as a component of a pregnant woman's regimen, each for different reasons. If the pregnant woman is already taking these drugs, however, it is acceptable to continue them. Combinations that are contraindicated in pregnancy, such as d4T and ddI, or regimens with three NRTIs are to be avoided in all pregnant women. Preferred PIs for pregnant women are those for which there is more recorded data. In addition, administration of additional intravenous zidovudine during labour is recommended, although its necessity when the viral load is undetectable (<50 copies/ml) is in dispute. The performance of a caesarean section is no longer considered necessary when the viral load is undetectable at the end of pregnancy. In any other case, however, a caesarean section is imperative. According to the 2012 DHHS–USA guidelines, a child born to an HIV-infected mother should receive postexposure prophylaxis with zidovudine immediately after birth, for a duration of 6 weeks.

Outlook

The treatment of HIV infection has developed faster than treatment for any other disease in history. This progress has been the result of intensive research, which has yielded side benefits for the treatment of other infections, such as reverse transcriptase inhibitors for HBV, protease and DNA-polymerase inhibitors for HCV, and drugs for *Cytomegalovirus*.

As a result of all of these advancements, HIV/AIDS is no longer the same undefeatable spectre the world faced with a sense of hopelessness and terror in the 1980s. However, a large number of old and new issues remain. Time and research will reveal the potential long-term toxicities of newer drugs, strategies for treating comorbidities, the possibility of reducing HIV incidence by the immediate initiation of treatment ('test and treat'), and the effects of economic crises on the epidemiology and treatment of the disease. The definitive eradication of the virus from an infected individual, moreover, does not appear to be feasible in the near future. A high priority remains, then, on limiting the spread of HIV, largely through the concerted prevention efforts of international and local organizations and governments.

Hidradenitis Suppurativa

42

Clio Dessinioti and Christos Zouboulis

Key Points

- Hidradenitis suppurativa/acne inversa (HS) is a chronic, multifactorial, debilitating, inflammatory skin appendage condition of the hair follicle.
- HS is a common disorder with a point prevalence of 1.0 % and a female preponderance.
- Management of HS should encompass the education of the patient regarding the nature of the disease, general measures, pharmacological topical or systemic treatment and surgical therapy.
- Antibiotic, immunosuppressive, anti-inflammatory, antiandrogenic and surgical treatments, as well as laser and light sources, have been used for the management of HS, although few randomised, controlled trials exist to provide evidence-based data on their efficacy for this condition.
- Topical clindamycin 1 % is the only studied topical antibiotic for HS.
- Systemic treatments that have been used for HS include antibiotics, retinoids (acitretin), biologic agents, antiandrogens, zinc gluconate, dapsone, colchicine, corticosteroids, ciclosporin and metformin.
- The combination of clindamycin and rifampicin is indicated for active inflammatory HS.
- The treatment choice will depend on the severity and extent (localised or widespread disease) of HS.
- The combination of different treatment modalities may be required to achieve improvement.

Definition and Epidemiology

The definition of hidradenitis suppurativa (HS) relies on clinical criteria. According to the 'Dessau definition' of HS, it is a chronic, inflammatory, recurrent, debilitating skin disease that usually presents after puberty with painful, deep-seated, inflamed lesions in the apocrine gland-bearing areas of the body, most commonly the axillary, inguinal and anogenital regions (First International Conference on Hidradenitis suppurativa, March 30–April 1, 2006, Dessau, Germany).

Although HS was considered a rare disease in the past, its prevalence has been estimated to be 1–4 %. It presents as a sporadic or familial form.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_42, © Springer-Verlag Berlin Heidelberg 2015

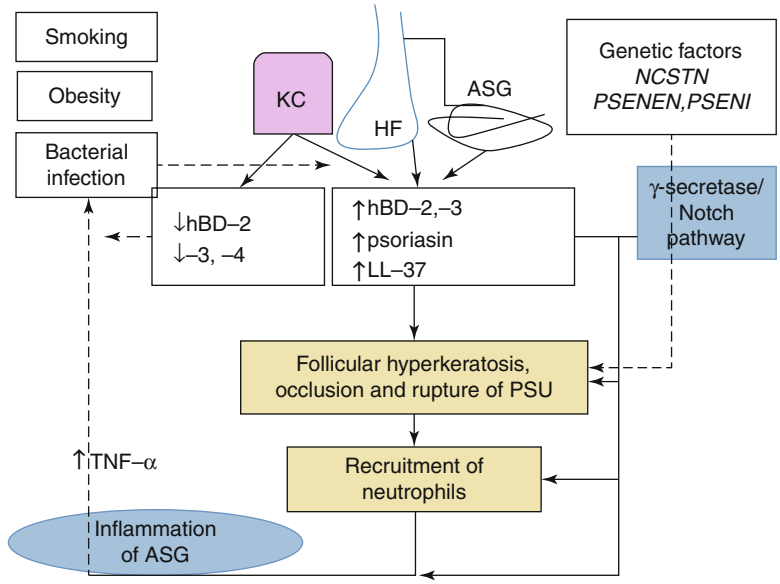

Fig. 42.1 Schematic pathophysiology of HS (Dessinioti et al. 2013)

HS affects more women than men, with a female-to-male predominance as high as 4:1. The disease occurs almost always after puberty and before the age of 40 years.

The chronicity, relapses and sequelae of the disease, including dermal contraction, scarring, restricted limb mobility, lymphoedema and fistula formation, contribute to the long-term burden of the disease and have a considerable negative impact on the patients' psychology, sex health and quality of life.

Basic Concepts of Pathogenesis

The pathogenesis of HS has not yet been elucidated, but it is considered to be a multifactorial disease. Current theories implicate the hyperkeratosis of the follicular epithelium as the morphological hallmark of HS pathogenesis, leading to occlusion of the apocrine glands with subsequent follicular rupture, inflammation and possible secondary infection. Genetic factors, hormones, smoking, obesity, bacterial infection and alteration of antimicrobial peptides (AMPs) that regulate cutaneous innate immunity have been implicated in the multifactorial pathogenesis of HS (Fig. 42.1).

It is clear that bacterial infection is not the primary cause of HS. However, bacteria, their products and immune responses raised against bacterial antigens may influence the clinical phenotype of HS lesions as well as the course of HS in any given patient (Zouboulis et al. 2012). In terms of natural immunity, patients with HS may respond abnormally to these bacteria (e.g. *Propionibacterium acnes*), whose products stimulate Toll-like receptors, producing pro-inflammatory cytokines such as IL-1α and giving rise to abnormal keratinisation (Zouboulis et al. 2012).

Current smoking has been associated with HS, with a highly significant association in multivariate analysis (OR = 12.55) (Hana et al. 2007). It has been suggested that smoking affects polymorphonuclear cell chemotaxis. Obesity and being overweight are frequent in HS and could represent a risk factor. Two case-control studies by Revuz et al. showed an association of HS with body mass index in medically assessed patients ($n = 302$) (odds ratio = 1.12 [1.08–1.15]) for each increase of 1 U of BMI. However, HS may also develop in low or normal body mass index.

Clinical Presentation

The clinical lesions of HS consist of primary lesions including painful nodules and abscesses and secondary lesions including sinus tracts,

Fig. 42.2 Hidradenitis suppurativa Hurley grade I

hypertrophic scars and multiparous or uniporous 'tombstone' open pseudo-comedones. In contrast to acne, there is no hyperseborrhoea or closed comedones in HS.

The topography of involvement may be explained by the distribution of apocrine glands and shearing forces, which originate in large skin folds, especially of overweight patients. The location of HS lesions is along the 'milk line' of apocrine and mammary tissues that have the same embryonic origin.

For each affected body site, the severity of the disease can be classified in three grades according to the Hurley classification (Figs. 42.2, 42.3 and 42.4) that provides a simple but static assessment (Table 42.1). The Sartorius score is also used as a more complex, dynamic score to assess severity of HS, mainly in the context of clinical studies, grading the number, size and extent of individual lesions.

Recently, Canoui-Pointrine et al. reported three distinct HS phenotypes in 618 patients, including the 'axillary-mammary' class (48 %) that had a high probability of breast and armpit lesions and hypertrophic scars; the 'follicular' class (26 %) that were more often male, current smokers and with more severe disease and had a high probability of breast, armpit, ear, chest, back or leg lesions and follicular lesions and a family history of HS; and the 'gluteal class' that were less often obese and had less severe, with gluteal involvement, papules and folliculitis.

Complications of HS include lymphatic obstruction and lymphoedema of the anogenital area; the development of squamous cell carcinoma in 2–4 % of patients, especially in men and in the buttock area; and serious infections, anaemia or hypoproteinaemia.

Fig. 42.3 Hidradenitis suppurativa Hurley grade II

Fig. 42.4 Hidradenitis suppurativa Hurley grade III

Several diseases have been reported in association with HS, including Crohn's disease, the synovitis-acne-pustulosis-hyperostosis-osteitis (SAPHO) syndrome, pyoderma gangrenosum, acne and suppurative hidradenitis (PASH) syndrome, pyoderma gangrenosum, Adamantiades-Behçet's disease, spondyloarthritis without or with follicular occlusion triad signs, genetic keratin disorders associated with follicular occlusion (pachyonychia congenita, steatocystoma multiplex, Dowling-Degos disease without and with arthritis), keratitis-ichthyosis-deafness (KID) syndrome and Down syndrome.

The follicular occlusion tetrad includes HS, acne conglobata, pilonidal sinus and dissecting cellulitis of the scalp; these conditions are characterised by follicular occlusion as the initial event.

Table 42.1 Severity classification of hidradenitis suppurativa according to Hurley staging

Stage I	Abscess formation, single or multiple, without sinus tracts and cicatrisation
Stage II	Recurrent abscesses with tract formation and cicatrisation, single or multiple, widely separated lesions
Stage III	Diffuse or near-diffuse involvement or multiple interconnected tracts and abscesses across the entire area

Diagnosis and Differential Diagnosis

The diagnosis of HS is clinical and a biopsy is not necessary for diagnosis. The following three diagnostic criteria must all be met:

1. Chronicity and recurrences
2. Typical lesions, i.e. deep-seated painful nodules: 'blind boils' in early lesions; abscesses, draining sinus, bridged scars and 'tombstone' double-ended pseudo-comedones in secondary lesions
3. Typical topography, i.e. axillae, groins, perineal and perianal region, buttocks and infra- and inter-mammary folds.

Closed comedones in HS are never present. The apparently open comedones are never closed; they are double-ended 'pseudo-comedones', i.e. literally scars.

Histologically, HS is a disease of the hair follicle, with follicular occlusion leading to the occlusion of the apocrine gland and subsequent follicular rupture, associated with lymphohistiocytic inflammation, inflammation, granulomatous reactions, sinus tracts and scarring. The early lesions of HS demonstrate follicular hyperkeratosis. The deep part of the follicle appears to be involved. Dermal features include perifolliculitis, active folliculitis or abscess, sinus tract formation, fibrosis and granuloma formation.

HS should be differentiated from:

- Folliculitis: it presents with follicular pustules. Comedones are absent.
- Furuncles (boils): may be confused with the early solitary, painful nodules of HS. In HS, nodules are more deeply seated, they are located on the characteristic anatomic sites affected by HS and there are recurrences and progression to abscesses and scars over time.
- Crohn's disease: cutaneous CD mimicking HS has to be taken into consideration in case of sole perianal lesions. Metastatic CD cannot be easily differentiated from HS. There is associated intestinal Crohn's disease.
- Acne vulgaris: there are always closed comedones and different topography of the lesions.

General Principles of Treatment

Management of HS includes the education of the patient regarding the nature of the disease, general measures, pharmacological topical or systemic treatment and surgical therapy.

The education of the patient by the treating dermatologist is pivotal, so that he/she understands that HS is usually a chronic disease, with exacerbations and remissions, and that it may necessitate long-term therapies. Also, the patient should be reassured that HS is not contagious and that it is not caused by an infection of the skin or by the lack of hygiene.

General measures and lifestyle changes may contribute to the better management of HS. Friction should be avoided by wearing loose-fitting clothes. Although no data exist for the improvement of HS lesions after reduction of weight and cessation of tobacco smoking, the general expert opinion (EDF) is that cigarette smoking and overweight have to be avoided.

Antibiotic, immunosuppressive, anti-inflammatory, antiandrogenic and surgical treatments, as well as laser and light sources, have been used for the management of HS, although few randomised, controlled trials exist to provide evidence-based data on their efficacy for this condition. A systematic review on the use of immunosuppressive treatments and systemic retinoids for HS evaluated 87 papers including 518 HS patients treated with biologics, colchicine, ciclosporin, methotrexate, dapsone, acitretin or isotretinoin and graded the level of evidence. The authors reported that infliximab, adalimumab and acitretin were the most effective systemic agents, with 89, 79 and 95 % of patients, respectively, responding to treatment (however, the quality of

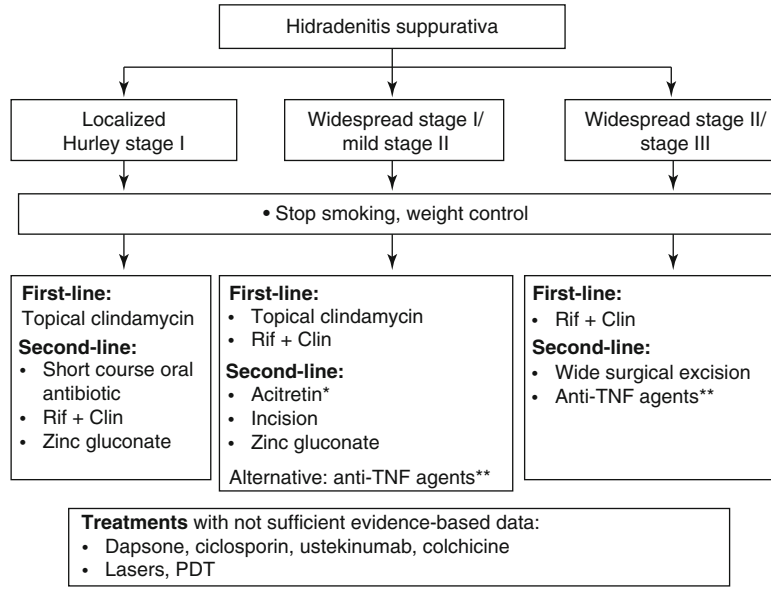

Fig. 42.5 Algorithm of treatment for hidradenitis suppurativa. *Rif+Clin* rifampicin plus clindamycin, * strictly contraindicated for women of childbearing potential, ** off-label therapies

evidence was lower for acitretin) (Matusiak et al. 2009). Nonsteroidal anti-inflammatory drugs (NSAIDs) may be proposed as analgesics for the symptomatic therapy of pain.

Based on the severity of HS, for Hurley stage I, topical or systemic drugs are proposed; stage II may benefit from medical treatment and from limited excisions of locally recurring lesions; and stage III requires radical surgery (Zouboulis et al.). The severity of HS, and whether it is localised or more widespread, should be taken into account before determining optimal treatment. The combination of different treatment modalities may be required to achieve improvement (Matusiak et al. 2009). A proposed algorithm of treatments is presented in Fig. 42.5.

Topical Treatments

Topical Antibiotics: Clindamycin

Topical clindamycin is the only antibiotic that has been studied in HS. A randomised, placebo-controlled study by Clemmensen et al. in 27 HS patients showed that topical clindamycin 0.1 % was superior according to patients' assessments and improved lesion counts. Another randomised trial by Jemec et al. compared topical clindamycin 1 % solution twice daily with oral tetracycline 500 mg twice daily, for 3 months, with response and no significant difference in efficacy between topical and oral treatment (Brocard et al. 2007). Topical clindamycin may be applied twice daily for 3 months or longer if clinically indicated.

Resorcinol 15 %

Resorcinol 15 % cream twice daily has been described for flares of lesions in patients with Hurley stage I or II HS.

Intralesional Steroids

Intralesional injection of triamcinolone acetonide may be used for individual early HS lesions.

Topical Treatments at a Glance

- Topical antibiotic treatment with clindamycin is indicated for localised Hurley stage I or mild stage II disease.

Systemic Treatments

The use of systemic treatments is indicated for more severe or widely spread lesions. Systemic treatments that have been used for HS include antibiotics, retinoids, biologic agents, antiandrogens, zinc gluconate, dapsone, colchicine, corticosteroids, ciclosporin and metformin.

Antibiotics

Antibiotics may be used as a short-term treatment to provide a rapid control of an exacerbation of the disease or as a long-term therapy with the aim to provide improvement as well as sustained remission.

For an acute flare of HS, a short course of an oral antibiotic such as amoxicillin/clavulanic acid, cephalosporin or clindamycin may be proposed.

For long-term continuous therapy, the combination of clindamycin and rifampicin is useful.

Clindamycin and Rifampicin

Although HS is not primarily an infectious disease, the combination of two antibiotics, rifampicin and clindamycin, is one of the most useful regimens in cases of inflammatory lesions. The combination of clindamycin and rifampicin for the treatment of HS has been evaluated in three retrospective studies, including a total of 118 patients. A response was reported in 96 patients (81.36 %), with 32 (27.11 %) achieving complete remission (Van der Zee et al. 2009, 2010; Mendonca and Griffiths 2006). Most reported side effects were gastrointestinal and affected 23 of 104 (22.11 %) patients (Gener et al. 2009).

Another prospective study of Bettoli et al. in 23 patients with HS treated with oral clindamycin (600 mg daily) and rifampicin (600 mg daily) for 10 weeks reported improvement (a Sartorius score improvement higher than 25 %) in 85 % of patients. Side effects were reported in three patients (13 %) and included nausea and vomiting.

Oral clindamycin should not be used in patients with intestinal inflammatory disease. The development of marked diarrhoea should prompt its immediate discontinuation, as it may progress to pseudomembranous colitis caused by *Clostridium difficile*. Liver function evaluation and complete blood count should be carried out during prolonged treatment.

Oral rifampicin at very high doses has been shown to have teratogenic effects in animals. There are no well-controlled studies with rifampicin in pregnant women (FDA pregnancy category C). Rifampicin causes an orange coloration of urine, swat, sputum and tears. Monitoring of hepatic function is necessary during treatment with oral rifampicin, and liver function evaluation, bilirubin, serum creatinine and complete blood count should be carried out.

The EDF guidelines recommend this combination for any stage active inflammatory HS.

Retinoids

Isotretinoin

Systemic isotretinoin (13-*cis* retinoic acid), a vitamin A derivative, has been used as an off-label treatment for HS, but it is ineffective in the treatment of HS, as this agent primarily works on sebaceous glands, which are not involved in the pathogenesis of HS (Zouboulis et al.; Matusiak et al. 2009).

The systematic review of Blok et al. reported seven papers evaluating the use of isotretinoin for HS in a total of 174 patients. Daily dosages were 0.5–1.2 mg/kg and treatment duration was 4–12 months. There was no response in the majority of patients (112 patients, 64 %), while 30 patients (17 %) had moderate improvement and 32 patients (18 %) had significant improvement.

Oral isotretinoin is a known teratogen for women (FDA pregnancy category X). Before treatment initiation, women of childbearing age should be informed about teratogenicity of isotretinoin and the absolute need of avoidance of pregnancy and effective contraceptive measures throughout treatment and for 1 month after treatment completion.

Acitretin and Etretinate

Retinoids have antiproliferative and immunomodulatory properties. Etretinate is a prodrug of acitretin. Acitretin is converted in vivo to etretinate

by re-esterification. Acitretin also has anti-inflammatory actions and may target the process of hyperkeratosis of the infundibular follicular epithelium, normalising epithelial cell proliferation and differentiation (Matusiak et al. 2009).

In the study of Boer et al., 12 patients with HS Hurley stage II/III were treated with acitretin (mean dose 0.59 mg kg once daily) as monotherapy for 9–12 months (mean 10.8). Overall, an improvement was noted in all 12 patients. Nine patients achieved marked or complete remission after one course of acitretin therapy, and the other three patients showed mild or moderate improvement. Follow-up showed that nine patients had a long-lasting improvement, with remissions ranging from 6 to 45 months (mean 24.9). A systematic review evaluated six available studies on the use of acitretin and etretinate for HS that included 22 patients. Used doses were 0.35–1.1 mg/kg for etretinate and 0.25–0.88 mg/kg for acitretin for a period of 2–29 months. Significant improvement was reported in 16 of 22 patients (73 %), moderate improvement in 5 (13 %) and no response in 1 (5 %). Within a follow-up of 6 months, there was recurrence in 6 of 17 patients (35 %), while 8 patients (47 %) relapsed later than 1 year after discontinuation of treatment.

The EDF guidelines recommend acitretin for early HS stages (Hurley I or mild II) and for the chronic stages of HS with recurrent abscesses with sinus tracts and/or scarring.

Retinoids, including etretinate and acitretin, are potent teratogens, leading to strict requirements for pregnancy prevention during their use and after their discontinuation. In the case of acitretin (FDA pregnancy category X), women of childbearing potential have to use adequate contraception measures during therapy and for 24–36 months after discontinuation, depending on local regulations.

Biologic Agents

Anti-TNF-α Agents: Adalimumab, Etanercept, Infliximab

Tumour necrosis factor alpha (TNF-α) is a pro-inflammatory cytokine produced by many cell typesı, including macrophages, monocytes and T cells. It is expressed in the basal layer of the epidermis, sweat glands and hair follicles. The rationale for the use of anti-TNF agents for the treatment of hidradenitis was based on the clinical observation of improvement of HS in patients with concomitant Crohn's disease, as well as on experimental evidence that TNF-α may play a key role in HS. TNF-α serum concentration in 54 HS patients was significantly higher than healthy controls ($p = 0.006$), although it was not associated with the severity of the disease. Van der Zee et al. showed elevated TNF-α production after culture of biopsies of lesional and perilesional skin of 20 HS patients compared to skin of six healthy controls and similar TNF-α levels with that of the skin of seven psoriasis patients. Also, the −238 G⁄A SNP at the promoter region of the TNF gene was significantly more frequent in HS patients than in healthy controls ($p = 0.027$), and a certain haplotype of the TNF gene seems to be associated with a greater reduction of disease severity after treatment with TNF agents.

Adalimumab is a fully anti-TNF monoclonal antibody that binds with high affinity and specificity to soluble and membrane-bound TNF-α. It is administered subcutaneously. In the systematic review of Blok et al., adalimumab was evaluated in 15 papers in 68 HS patients, with only one being a randomised, double-blind, placebo-controlled design (evidence level A). Dosing regimens varied from 40 to 80 mg, in a frequency ranging from weekly to every other week. In total, 30⁄68 patients (44 %) showed a significant response to adalimumab, 24 patients (35 %) had a moderate response and 14 patients (21 %) did not respond. Relapse of HS was reported in 23 out of 35 responders (66 %) within 3–10 months after discontinuation of treatment, while 7 patients (20 %) relapsed during treatment but improved with an increase in the dose of adalimumab.

Etanercept is a soluble fusion protein comprising a TNF-α receptor and the Fc component of human immunoglobulin G1. It is administered subcutaneously. Etanercept was evaluated in nine papers in 54 patients, with only one being a randomised, double-blind, placebo-controlled design (evidence level A). Dosing schedules varied from

25 to 50 mg once or twice weekly to 100 mg weekly. In total, 21⁄54 patients (39 %) showed a significant response to etanercept, nine patients (17 %) had moderate improvement and 24 patients (44 %) did not respond. Relapse of HS was reported in 18 out of 30 responders (60 %) within immediately up to 8 months after discontinuation of treatment.

Infliximab is a chimeric (mouse/human) anti-TNF monoclonal antibody that binds both soluble and transmembrane TNF-α. It is administered intravenously. Infliximab was evaluated in 42 papers in 147 patients, with only one being a randomised, double-blind, placebo-controlled design (evidence level A). Dosing schedule was 5 mg kg^{-1} at weeks 0, 2 and 6 and every 6–8 weeks thereafter. In total, 74⁄147 patients (50 %) showed a significant response to infliximab, 57 patients (39 %) had moderate improvement and 16 patients (11 %) did not respond. Relapse of HS was reported in 26 out of 131 responders (20 %) 2 weeks to 3 years after discontinuation of treatment.

Anti-IL12/23 Agents: Ustekinumab

Ustekinumab is a human monoclonal antibody against interleukin 12/23 (IL 12/23). It is administered subcutaneously. The systematic review of Blok et al. reported two papers in four patients evaluating ustekinumab for HS (both evidence level C). Dosing schedule was 45 mg at weeks 0, 4 and 12 and every 3 months thereafter. In total, two out of four patients showed a significant response to ustekinumab, one patient had a moderate response and one patient did not respond. Relapse of HS was reported in two out of three responders.

Antiandrogens

The rationale for the use of antiandrogens for HS was based on the female preponderance of HS, its development after puberty and its association with PCOS.

On the other hand, the usual absence of clinical signs of hyperandrogenism and the normal levels of serum androgens do not support a role for androgens. This may explain the limited effect of anti-androgen treatments for HS.

Zinc Gluconate

Zinc acts via inhibition of polymorphonuclear cell chemotaxis. Its anti-inflammatory activity could be related to a decrease in TNF-α production and the modulation of the expression of integrins and the inhibition of Toll-like receptor 2 (TLR2) surface expression by keratinocytes.

In a pilot study of Brocard et al., 22 patients with Hurley grades I and II were treated with 90 mg/day zinc gluconate. Complete remission was noted in eight patients and partial remission in 14 patients. Four out of 22 patients experienced side effects of gastrointestinal upset.

The EDF guidelines recommend zinc gluconate as maintenance therapy for HS Hurley stages I and II.

Dapsone

A systemic review of Blok et al. reported three studies in 34 patients treated with dapsone at dosages of 25–100 mg daily during 0.5–48 months. There was a significant improvement seen in 12 of 34 patients (35 %), moderate improvement in 7 patients (21 %) and no response in 15 patients (44 %). It was reported that there was a rapid recurrence after treatment discontinuation in all patients.

The EDF guidelines recommend dapsone as third-line treatment for mild to moderate HS (Hurley stage I or II).

Colchicine

Colchicine is a natural product that can be extracted from plants of the lily family. It inhibits neutrophil expression of cell adhesion molecules and decreases neutrophil degranulation, chemotaxis and phagocytosis.

There is a report by van der Zee et al. of eight patients with refractory HS treated with

colchicine 0.5 mg twice daily for up to 4 months that reported that six patients (75 %) did not respond, while there was a moderate response in the remaining two patients. Adverse events were nausea and diarrhoea. The authors suggested that higher doses may be needed for clinical efficacy and that colchicine treatment should start with 1 mg followed by 0.5 mg every 2 h with a cumulative maximum of 5 mg, followed by 1 mg daily (Boer et al. 2011).

The EDF guidelines recommend that colchicine should not be used for the treatment of HS.

Corticosteroids

Systemic steroids may provide relief from pain and inflammation and be used as an alternative or in combination with oral antibiotics. Steroids may be used for a short period of time and tapered rapidly.

Ciclosporin

Ciclosporin is a calcineurin inhibitor with potent immunosuppressive activity. It targets T lymphocytes and it inhibits the production of TNF-α and IL-2.

Ciclosporin at a dose ranging from 2 to 6 mg/kg/day has been studied in four patients for 4–16 months, with a significant response in three patients and a moderate response in the remaining two patients.

Metformin

Metformin improves insulin insensitivity and has antiandrogenic properties. Verdolini et al. studied metformin in 25 patients with HS, at a starting dose of 500 mg once daily for the first week, increased to 500 mg twice daily for the second week, with a maximum dose of 500 mg three times daily for a total of 24 weeks. There was improvement in 18 patients, while seven patients (28 %) showed no response. Only minor gastrointestinal side effects were reported.

Systemic Treatments at a Glance

- The combination of clindamycin and rifampicin is indicated for any stage active inflammatory HS.
- A systematic review evaluating immunosuppressive treatments and oral retinoids for hidradenitis suppurativa reported that infliximab, adalimumab and acitretin were the most effective systemic agents, with 89, 79 and 95 % of patients, respectively, responding to treatment (however, the quality of evidence was lower for acitretin).
- Oral acitretin should be reserved for male patients and sterilised or postmenopausal women due to its long-term teratogenic side effects.
- Oral isotretinoin was shown to be ineffective for hidradenitis suppurativa.
- There are a limited number of studies in a small number of patients on the efficacy of ustekinumab, colchicine, dapsone, ciclosporin and zinc gluconate.
- There is limited data on long-term results and relapse rates with systemic treatments for HS.

Surgical Therapy

The surgical approach for HS Hurley stage I is incision and drainage; for stage II, deroofing and secondary healing; and for HS stage II/III, wide surgical incision and healing with secondary intention or skin graft.

Surgical incision and drainage is indicated as means of symptomatic relief of pain, e.g. as an analgesic for a fluctuating abscess. Incision does not affect the course of the disease nor does it provide clearance of the incised lesion.

A simple technique consists of unroofing under local anaesthesia and debridement of the scars, abscesses, cysts and sinuses. In the study of van der Zee et al., 44 patients with mild to moderate HS were treated with the surgical deroofing technique, with no recurrence in 83 % of treated lesions after a median follow-up of 34 months.

Traditional surgery for hidradenitis suppurativa (HS) consists of en bloc wide excision followed by primary closure or healing by secondary

intent. Mapping of sinus tracts with methyl blue intra-operatively is crucial. In one series of 106 patients, there was a 70 % recurrence rate requiring subsequent operation in the primary closure cohort and no recurrence in the split-thickness graft and flap groups. In general, the recurrence rate with wide excision has been reported to be less than 30 %. However, poor surgical outcomes (scarring) have been associated with surgery (van der Zee and Prens 2011).

Other Treatment Options

Lasers and Light Sources

There is scarce data on the use of laser and light sources for the treatment of HS.

Long-pulsed neodymium:yttrium-aluminium-garnet (Nd:YAG) laser is a laser hair reduction device. The rational for treating HS was based on the role of follicular occlusion as the initiating event in the pathogenesis of HS. The proposed mechanism of action included the release of obstruction of the hair follicle and photothermolysis.

A prospective, randomised study of Mahmoud et al. in 22 patients with HS evaluated the efficacy of Nd:YAG laser, clinically and histopathologically. Topical benzoyl peroxide wash 10 % and clindamycin 1 % lotion were used on both sides of the face. Laser treatment consisted of four monthly sessions. The reported fluence was 40–50 J/cm^2, pulse duration was 20 ms and spot size was10 mm, whereas for skin types IV–VI, the fluence used was 25–35 J/cm^2, pulse duration was 35 ms and spot size was 10 mm. The percent improvement was 72.7 % on the laser treated side and 22.9 % on the control side ($p<0.05$). Similar results were reported by Xu et al. in 19 patients with HS Hurley stage II, treated with two monthly sessions of long-pulsed 1,064-nm Nd:YAG laser. The percentage change in HS severity after two sessions of laser treatment was −31.6 over all anatomic sites ($p<0.005$).

Photodynamic therapy (PDT) as treatment for HS has been recently described in three small case series, but it is neither established nor has it been standardised.

Primary Hyperhidrosis

43

Benedetta Brazzini and Sana Sultan

Key Points

- Hyperhidrosis is excessive sweating which goes beyond the normal physiological reaction that occurs in response to fluctuations in temperature.
- It affects 3 % of the population and can be a severely disabling condition with a significant negative impact on quality of life.
- Several treatment modalities are available and are broadly divided into medical and surgical.
- Medical treatments include topical medication, iontophoresis, systemic anticholinergic medications and botulinum toxin injections.
- Surgical treatments include retro-dermal curettag, liposuction and thoracoscopic sympathectomy.

Definition and Epidemiology

Sweating is a normal physiological reaction that occurs in response to fluctuations in temperature. It mainly occurs from cutaneous eccrine glands that are widely distributed throughout the whole body at an average of 100–200 per cm^2 but more concentrated on the palms, axillae, soles and forehead.

Hyperhidrosis is excessive sweating in certain parts of the body and is thought to have a prevalence of 3 % in the population. It can be severely distressing for patients due to the negative perception of sweating and body odours by the majority of cultures throughout the world. For this reason hyperhidrosis can have a debilitating psychosocial element and can have a significant negative impact on quality of life.

Hyperhidrosis can be classified as primary or secondary. Primary hyperhidrosis is an emotional stress response that causes excess sweating particularly affecting the palms, axillae, soles and forehead and, in a small proportion of patients, the whole body surface. Excess sweating is a result of overstimulation of the eccrine glands. However, the exact mechanism of this overstimulation remains unclear but is thought to be due to a dysfunction in the neuro-exocrine interplay between the sympathetic nervous system and the eccrine sweat glands. The sweating tends to be bilateral and symmetrical, and in the absence of a secondary cause, the history will be sufficient for making a diagnosis.

Secondary hyperhidrosis implies an underlying cause and encompasses a range of conditions that precipitate excess sweating such as fevers, neurological diseases (Parkinson's, syringomyelia and Riley-Day syndrome), endocrinopathies (diabetes mellitus, hypoglycaemia, thyrotoxicosis and hyperpituitarism), trauma (medullary accidents and Frey's syndrome) and various other disorders (drug and alcohol withdrawal, dumping syndrome, carcinoid, Hodgkin's disease, menopausal state, anxiety, congestive heart disease and obesity).

General Principles of Treatment

Several treatment modalities exist for hyperhidrosis and will be explored in this chapter. Figure 43.1 clearly demonstrates that there are differences in the treatment of palmar-plantar and axillary hyperhidrosis. These will all be explored within the text.

Topical Treatments

Perfumes, Deodorants and Antimicrobials

Perfumes have been used for centuries to hide unpleasant body odours. However, the successors of perfumes, deodorant soaps and cosmetic deodorants are not strong enough to hide bad odour for a long period of time. Antimicrobial fragrances have been used to suppress the microorganism responsible for bromhidrosis. However, products such as antiseptic benzalkonium chlorides and quaternary ammonium compounds, are inactivated very rapidly and therefore rendered useless. Other antiseptics like triclosan and triclocarban are effective over longer periods of time but are very irritating and therefore poorly tolerated by patients.

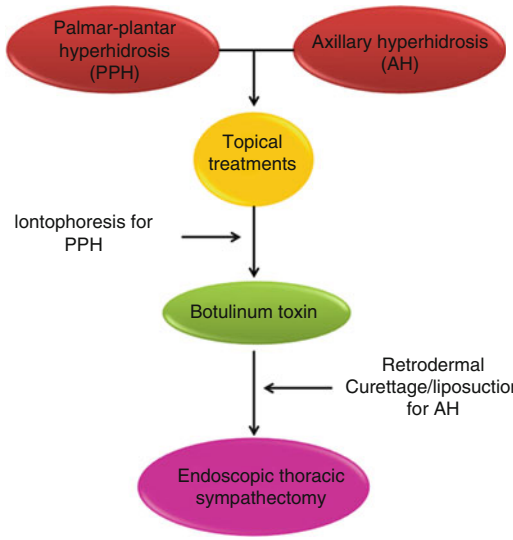

Fig. 43.1 Treatment options available for different types of hyperhidrosis

Antiperspirants

Satisfying results have been obtained with topical antiperspirant salts. In particular, aluminium chloride hexahydrate is reported to be the most effective topical treatment and acts by diffusion into the ducts of the eccrine glands. It will then complex with metal ions and mucopolysaccharides, thus causing reversible damage to the surface of the non-cornified cell causing temporary occlusion to the sweat gland ducts, which becomes reversed during normal regeneration of the skin.

The best results are obtained with topical applications of aluminium salts at night when the eccrine sweat glands are largely inactive. The side effects of treatment include irritation, soreness and pruritus. Traditionally, it has been thought that optimum concentration of aluminium chloride is dependent upon body area affected. Therefore, higher concentrations of aluminium chloride were recommended for palmar-plantar (up to 30 %) than for axillary (10–15 %) hyperhidrosis. However, Streker et al. (2012) recently conducted a study on 20 patients comparing the efficacy and safety of two different concentrations (12.5 and 30 %) of aluminium chloride hexahydrate for the treatment of plantar hyperhidrosis and found that both concentrations were equal in efficacy and safety. The effect of aluminium chloride treatment is optimal and lasts for several days in patients with moderate hyperhidrosis, but in severe cases it remains ineffective.

Aqueous solutions of glutaraldehyde (glutaraldehyde 10 % in a buffered solution pH 7.5) are effective in controlling palmar-plantar hyperhidrosis. The mechanism of action is not entirely

clear; however, it is thought to act by partial occlusion of the sweat ducts. At the beginning it must be applied on alternate days until control is achieved. Thereafter, it can be decreased to a once-weekly application or used only when needed. However, commonly reported side effects include a yellow coloration of the skin and clothes, irritation and allergic reactions. Also 10 % methenamine, which is hydrolysed to ammonia and formaldehyde when applied to the skin, is effective in mild hyperhidrosis and rarely produces allergic reactions. Finally, topical glycopyrrolate (glycopyrronium bromide) has been shown to be an appropriate treatment for hyperhidrosis with particular benefits seen in head and neck hyperhidrosis.

Anticholinergic Topical Drugs

Topical anticholinergic drugs are absorbed sufficiently to produce a beneficial local effect without producing systemic side effects, but none of those available at present can be relied upon.

Iontophoresis

Tap water iontophoresis is a simple and effective treatment for mild to moderate palmar-plantar hyperhidrosis. Its use extends back to 1952 where the principle of tap-water iontophoresis was first introduced for the treatment of hyperhidrosis. Since then it has become an established method of treatment for hyperhidrosis, and its efficacy has been proved by several studies with a significant reduction in sweating in about 90 % of patients.

The procedure consists of applying moisturised paddles to the affected areas and passing a 15–20 mA electrical current. The current is conducted through tap water to cause reversible disruption of ion channels that leads to blockage of sweat glands. Better results are obtained if a diluted solution of an anticholinergic drug is used as it causes blockage at the neuro-glandular junction, thus reducing sweat production.

The duration of each session varies between 10 and 40 min, with an accepted average of 20 min. Usually a euhydrotic state can be achieved with an intensive treatment regimen that consists of two to six sessions a week until euhydrosis has been achieved. The euhydrotic state is then maintained with treatments repeated every 3–6 weeks. The interval between the two sessions should be constant because there is no structural alteration in the sweat glands. In theory the treatment should be carried out indefinitely, although the pathology generally decreases with age.

Iontophoresis is a non-invasive well-tolerated treatment, which can be carried out in the comfort of one's home using the Drionic or Idrostar units. A recent study by McAleer and Collins (2013) showed that patients perceive an 85 % improvement with home therapy. Nonetheless, hospital iontophoresis is thought to be better because patients tend to apply lower currents in the home than those used in the hospital environment.

The conventional iontophoresis treatment is through the use of a direct current, which is associated with side effects such as pain and discomfort. In recent years it was shown that the use of alternating current iontophoresis is just as effective with fewer reported side effects. This approach is still being developed, and clear treatment guidelines are yet to be agreed upon.

There has been no report of adverse side effects following long-term iontophoresis therapy; however, some of the short-term side effects include discomfort (burning and tingling sensations), skin irritation, erythema and vesicles and deep burning (defective devices and badly protected electrodes). Contradictions to treatment include pregnancy, cardiac pacemaker and metal orthopaedic implants. Iontophoresis is an effective treatment, but the fact remains that it only offers symptomatic relief and therapy has to be continued on a maintenance schedule over many years. This has a negative impact on the patient, as it affects lifestyle due to multiple follow-up appointments, and is economically draining and time consuming for clinical staff.

Systemic Treatments

Anticholinergic Drugs

In theory anticholinergic drugs are effective against hyperhidrosis; however, in reality they carry a large number of side effects that are

poorly tolerated by patients. In Germany two anticholinergic drugs have been licensed for the treatment of hyperhidrosis: methantheline bromide (Vagantin®) and bornaprine hydrochloride (Sormodren®). In a multicentre randomised clinical trial carried out by Müller et al. (2012), it was shown that methantheline bromide is an effective and safe treatment for axillary hyperhidrosis when given at a dose of 50 mg three times daily.

Oxybutynin is an anticholinergic drug that is commonly used to treat urological disorders; however, an observed side effect of the drug includes significant reduction in sweating. Wolosker et al. (2013) carried out a study on 30 patients suffering from plantar hyperhidrosis who were treated with oxybutynin (starting from 2.5 mg daily up to 5 mg twice a day, for 12 weeks). More than 70 % of patients reported improvements in symptoms with significant positive impact on their quality of life in general.

Bornaprine hydrochloride is an antiparkinsonian drug with some anticholinergic properties, which led to its use in the treatment of hyperhidrosis. In 80 % of patients treated, there was a marked sweat reduction within 2 weeks of treatment; however, there were several adverse side effects such as dry mouth, tachycardia, disturbance in accommodation, disturbed micturition and inability to concentrate. This, unsurprisingly, leads to cessation of treatment (Togel et al. 2002).

Others

Psychoactive drugs, tranquillisers, sedatives and β-blockers have all been used to treat hyperhidrosis; however, no controlled clinical trials exist to prove the efficacy and safety of these treatments. Often they are administered on an individual case basis to treat a pronounced emotional factor suggesting secondary rather than primary hyperhidrosis.

Botulinum A Toxin Subcutaneous Injection

Clostridium botulinum is a gram-positive rod-shaped anaerobic bacteria, which is best known for producing the botulinum toxin. There are currently seven serotypes of the botulinum toxin labelled A–G which act by inhibiting the presynaptic release of acetylcholine by disrupting the Ca^{2+}-dependent K^{+}-evoked release mechanism that ultimately causes a flaccid paralysis to ensue. Both neuromuscular junction and eccrine sweat glands utilise acetylcholine as the primary neurotransmitter; therefore, disruption of transmission leads to reduction in sweat volume. Of the seven serotypes mentioned, only types A, B, E and F are poisonous to humans, and only types A and B are used therapeutically for the treatment of hyperhidrosis.

Botulinum toxin is approved in many countries to treat spasticity, including blepharospasm, focal dystonia, achalasia and chronic anal fissures. Botulinum toxin A is available in Europe and in the United States. In terms of clinical efficacy in humans, 1 U of Botox® is estimated to be equal to 3–4 U of Dysport®. Botulinum toxin B is available in Europe as NeuroBloc® and is used in those patients who are unresponsive to the botulinum toxin A injections.

To this day administration of botulinum toxin injections for the treatment of hyperhidrosis is slightly variable and practitioner dependent. Some practitioners will administer Minor's iodine-starch test which helps to visualise the area for treatment, whilst others will prefer to inject around the hair distribution in the axilla or following a grid in the palm and feet without Minor's test. In addition the botulinum toxin injections can be painful, particularly for the palms and the soles, and thus a deterrent for seeking treatment. However, there are a number of anaesthetic options available such as oral or IV sedation, Dermojet®, topical anaesthetic creams, nerve block (radial and ulnar), Bier's block and cryoanalgesia.

A reasonably effective dose of the botulinum toxin A (Botox) is 50, 100 and 150 U for each axilla, palm and sole, respectively. The difference in units of the botulinum toxin used is related to the differences in surface area of the regions affected. Before the injections are administered, they must be diluted using 1 ml of normal saline for each 25 U of botulinum toxin (Botox). Twenty-six or thirty gauge needles are then used to administer the botulinum toxin in subdermal injections.

Studies for the efficacy of botulinum toxin have demonstrated a high patient satisfaction rate

with treatments lasting 4–11 months. Treatments are not permanent, and there is a high recurrence rate of hyperhidrosis possibly because symptom-free patients become intolerant of sweating or, according to some authors, due to antibody formation against the toxin leading to reduced efficacy of treatment. Contraindications of the treatment are disorders of neuromuscular function including myasthenia gravis, Eaton-Lambert syndrome or amyotrophic lateral sclerosis. Also pregnant or lactating women or those with a severe blood clotting disorders are isolated from treatment.

Surgical Treatments

In some patients with moderate to severe hyperhidrosis, surgery may be indicated where all medical treatments have been unsuccessful. Currently, there are two surgical interventions available: retro-dermal curettage and liposuction, which is used for axillary hyperhidrosis and thoracoscopic sympathectomy for the treatment of axillary, palmar-plantar and facial hyperhidrosis.

Retro-dermal Curettage and Liposuction

Retro-dermal curettage involves a small incision at the posterior, inferior and caudal aspects of the axillary hair distribution area of the skin. Blunt dissection of the area is then carried out, and the curette is used to scrape against the skin, thus removing the sweat glands from the dermal layers. Before skin closure, a washout is performed and a suction drain is placed, which can only be removed when sweat output is less than 10 ml. Liposuction follows the same principle, and instead of using a curette, a liposuction syringe is used to scrape of the underside of the dermis with 15–20 strokes of the cannula.

Despite the lack of long-term follow-up data, both retro-dermal curettage and liposuction appear to be a safe and effective method of treatment. They show a significant reduction in sweat production that lasts for up to 6 months in 80–90 % of patients; however, relapse does occur in 7–8 % of patients (Proebstle et al. 2002; Rompel and Scholz 2001). There are some post-operative complications that have been noted, and these include wound infection, skin necrosis, bleeding, haematoma formation and induration. Some of the longer-term potential complications include partial alopecia, skin discoloration, scar formation, wound contracture, paraesthesia and pain with arm movements.

Thoracoscopic Sympathectomy

The nerves innervating the sweat glands are the sympathetic postganglionic fibres, which consist of unmyelinated C fibres. The sympathetic nerves to the arm arise from spinal cord segments T_2–T_6 and leave the spinal canal in the corresponding ventral rami to synapse or pass through the second to sixth thoracic sympathetic ganglia. All postganglionic sympathetic fibres to the hand, forearm and arm except the axilla run with the somatic nerves of the brachial plexus. Consequently, division of the sympathetic trunk between the first and second thoracic ganglia will interrupt all the sympathetic innervation to the arm, comprising preganglionic and postganglionic fibres.

The procedure is performed under general anaesthesia and the patient placed in a semi-sitting position with the arm at 90° abduction. To begin with, patients will be intubated using a single- or double-lumen endotracheal tube, which will then be clamped. Access to the thorax is achieved through 5 or 10 mm ports, and once a pneumothorax has been established, the sympathetic chain will then be visualised. The mediastinal pleura will be opened allowing dissection of the sympathetic chain from T2 to T4.

This operation is not without risk and indeed some of the minor complications include wound infections, hematoma and pain on movement of the arms. However, rare but more serious complications include pneumothorax, haemothorax, atelectasis, radial nerve paralysis and Horner's syndrome (T1 nerve root damage). The commonest post-operative complication reported (86–100 % of patients) is compensatory hyperhidrosis, which is excess sweating in a previously

unaffected area such as the face, foot, trunk, buttocks and popliteal fossa. Currently, there is no medical treatment for compensatory hyperhidrosis, and the only available treatment is surgical reconstruction of the sympathetic chain, which is a risky operation with limited efficacy. For plantar hyperhidrosis, sympathectomy of L_2 and those nerves of the lower lumbar extremities are thought to relieve symptoms efficaciously. However, lumbar sympathectomy has no place in the treatment of pedal hyperhidrosis since ejaculatory impotence and anorgasmia are almost certain consequences.

In view of the post-operative complication, thoracoscopic sympathectomy should be considered for moderate to severe palmar or axillary hyperhidrosis once all other therapies have been explored. In a retrospective study conducted by Dumont et al. (2004) on long-term follow-up for thoracoscopic sympathectomy, 90 % were reportedly satisfied with the outcome. Currently, this procedure is considered the surgical gold standard for treatment of palmar and axillary hyperhidrosis.

Ichthyoses

44

Mauro Paradisi, Maya El Hachem, Andrea Diociaiuti, and Alberto Giannetti

Abbreviations

ARCI	Autosomal Recessive Congenital Ichthyosis
TGM1	Transglutaminase 1 gene
ABCA12	gene ATP-binding cassette, sub-family A (ABC), member 12
ALOXE3	gene arachidonatelipoxygenase 3
ALOX12B	gene arachidonate 12-lipoxygenase, 12R type
FLJ39501	gene

Key Points

- The ichthyoses represent a large heterogeneous group of Mendelian disorders of keratinization (cornification), clinically characterized by the presence of scales on the skin.
- They may manifest at birth or later on, and they could be isolated or associated with extracutaneous anomalies.
- The classification of ichthyoses has been recently revised in (a) non-syndromic ichthyoses and (b) syndromic ichthyoses and in congenital and later onset.
- The choice of treatment depends on the type of ichthyoses, age of the patient, the involved areas, and the extent of the disease.

Definition and Epidemiology

The ichthyoses represent a large heterogeneous group of Mendelian disorders of keratinization (cornification), clinically characterized by the presence of scales on the skin. They may manifest at birth or later on, and they could be isolated or associated with extracutaneous anomalies.

The classification of ichthyoses has been recently revised during a consensus conference of experts based on clinical aspects (Oji et al. 2010; Fleckman et al. 2013) in (a) non-syndromic ichthyoses and (b) syndromic ichthyoses (Fig. 44.1) and in congenital and later onset (Fig. 44.2). This classification represents an intermediate step toward a new classification based on the molecular diagnosis, whenever they will be all identified.

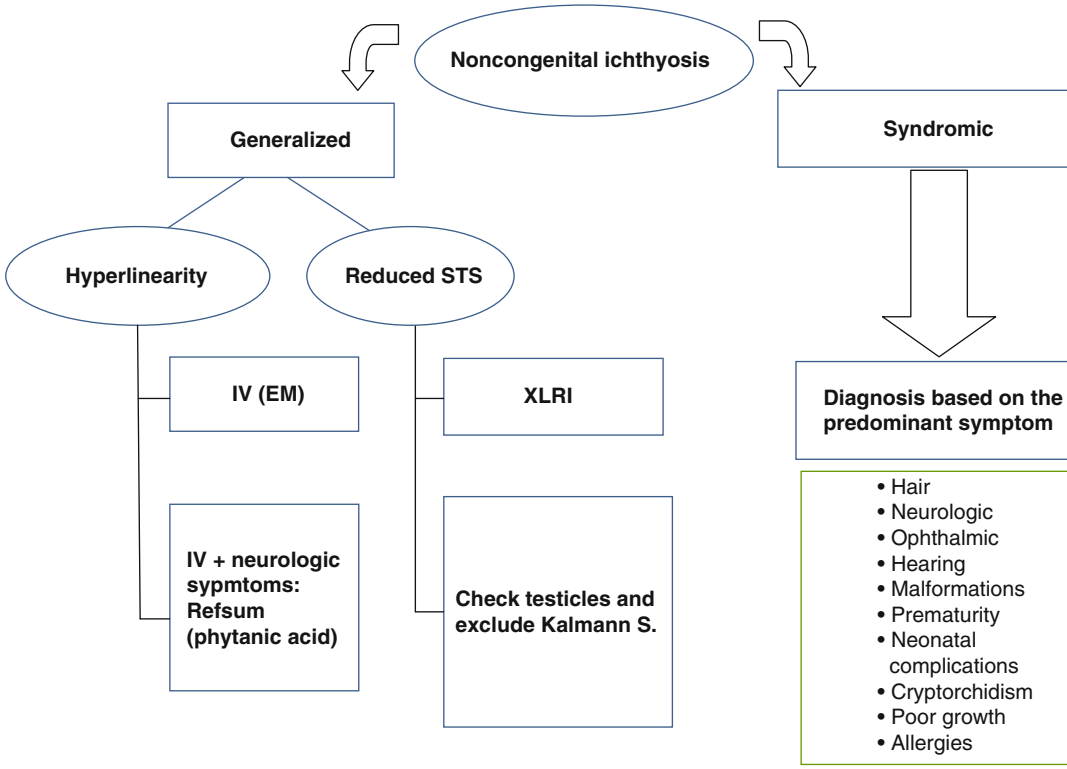

Fig. 44.1 Classification of non-congenital ichthyoses. *IV* Ichthyosis vulgaris, *EM* Electron Microscopy, *STS* steroid sulfatase enzyme, *XLRI* Recessive X-linked Ichthyosis

The epidemiology varies upon the type of ichthyosis, from a common form such as ichthyosis vulgaris (1:300) and recessive X-linked ichthyosis (1:6,000) to the rare autosomal recessive congenital ichthyosis, ARCI, (1:300,000) and other extremely rare forms such Harlequin fetus, Dorfman-Chanarin Syndrome, etc.

Traditionally, the keratinopathic ichthyoses, once called epidermolytic ichthyosis, are also included between the ichthyoses (Fig. 44.3). The incidence varies from 1:200/300,000 for the generalized epidermolytic ichthyosis to extremely rare for other forms such as ichthyosis hystrix, Curth-Macklin type. They are transmitted in an autosomal dominant trait.

Basic Concepts of Pathogenesis

Ichthyoses are due to mutations of many genes (identified until now six, Fig. 44.4), codifying for proteins and lipids involved in the different stage of the cornification. The pathophysiology may be related to a disorder in keratinocyte proteins, proteases, lipid metabolism (assembly or transport), or connexins.

Clinical Presentation

I. Ichthyosis vulgaris (Fig. 44.5a, b), the most common type of genetic ichthyoses, is characterized by small, gray-white scales mainly on the extensor surfaces without fold involvement. There is a strong association with atopy, keratosis pilaris, and palmar hyperlinearity. It improves with age.

II. Recessive X-linked ichthyosis affects males, and the clinical feature is characterized by large brown scales, fold involvement, and asymptomatic corneal opacity.

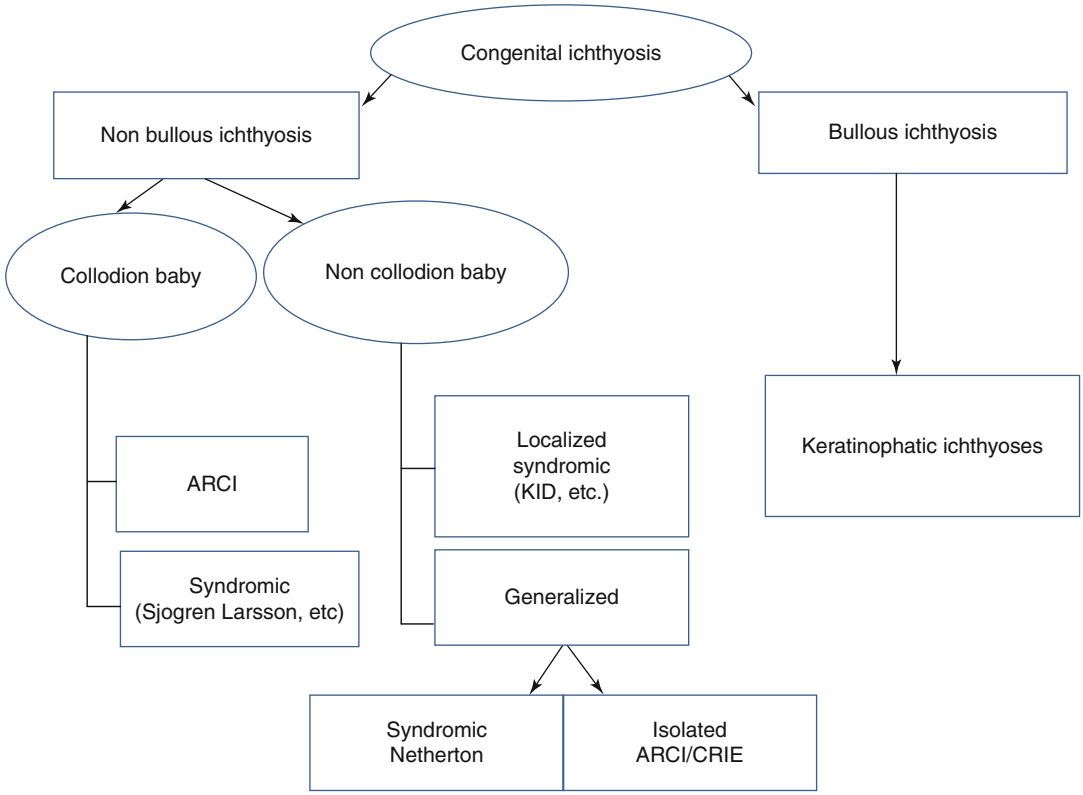

Fig. 44.2 Classification of congenital ichthyoses. *ARCI* Autosomal Recessive Congenital Ichthyosis, *KID* Keratitis, Ichthyosis, Deafness syndrome, *CRIE* Congenital Reticular Ichthyosiform Erythroderma

III. ARCI represents a wide heterogeneous group. Until now, some genes (TGM1, ABCA12, ALOXE3, ALOX12B, Ichthyin, FLJ39501) were identified as the cause of ARCI, but others have yet to be discovered. The most common form manifests initially as collodion baby and evolves successively in ichthyosis with or without erythroderma congenital ichthyosiform erythroderma (CIE) and lamellar ichthyosis (LI). The scales are generally flat, thick, large, and brown. Ectropion and electrolytes imbalances are also frequently associated. The most severe and lethal form is Harlequin fetus.

IV. Keratinopathic ichthyoses (Fig. 44.6a, b) are characterized by erythroderma, blistering, erosions, and desquamation since birth. The skin is easily macerated with consequent bad smelling and itching. We distinguish generalized or localized forms.

Syndromic Ichthyosis

The first group is represented by:

I. Recessive X-linked ichthyosis syndromes with hypogonadism:

IFAP: ichthyosis follicularis, atrichia, photophobia

Conradi-Hunermann-Happle syndrome: severe ichthyosiform erythroderma clearing after a few months, lifelong linear hyperkeratosis, follicular atrophoderma, chondrodysplasia punctata, skeletal and eye anomalies, and unilateral hypoplasia of the face.

II. Autosomal ichthyoses with prominent hair abnormalities:

Netherton syndrome (Fig. 44.7) is the most severe form of this group and is characterized by erythroderma, severe atopic manifestations, trichorrhexis invaginata which may not be present during the first months of life, and hypernatremia.

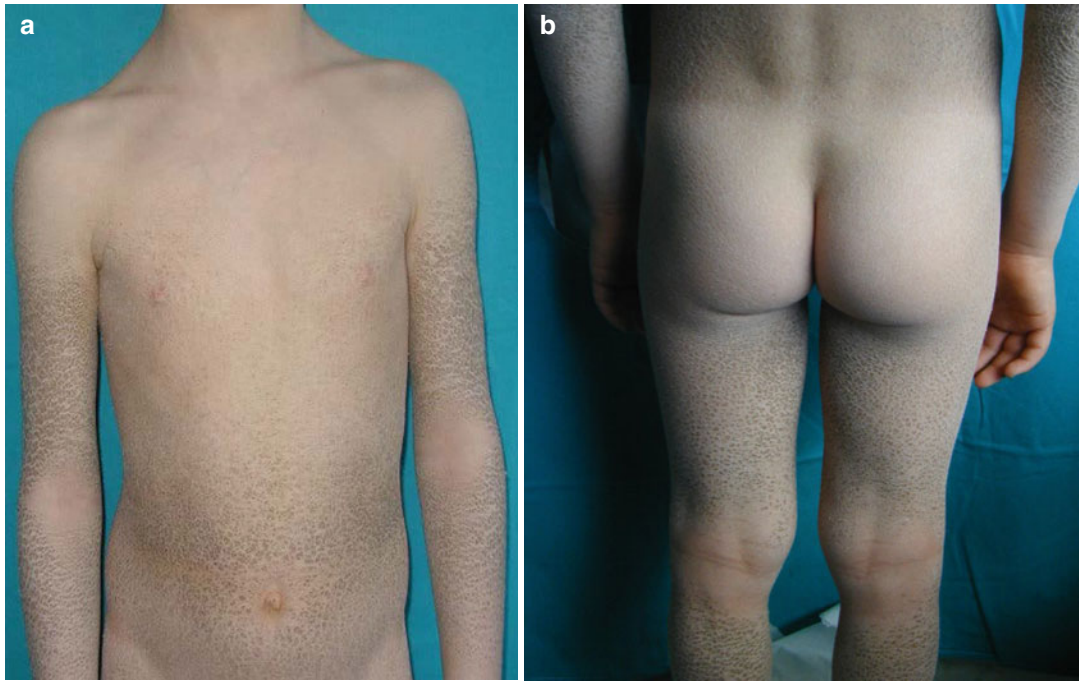

Fig. 44.5 (**a**, **b**) Ichthyosis vulgaris

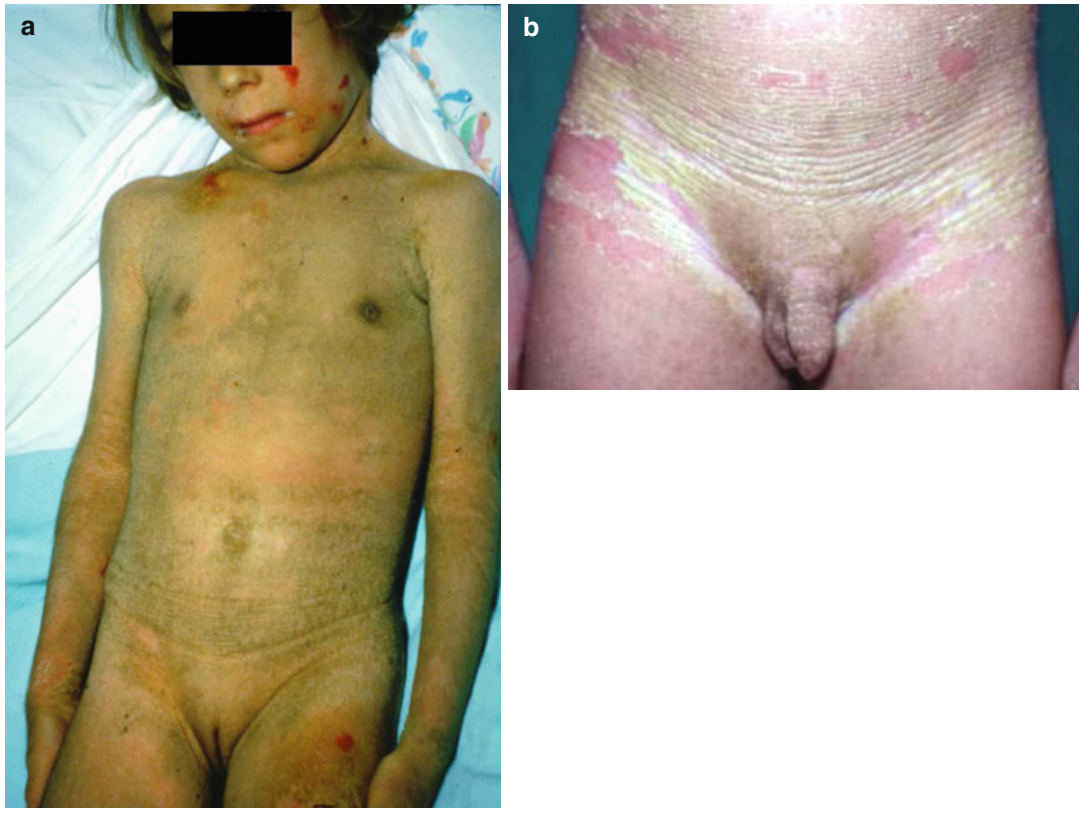

Fig. 44.6 (**a**, **b**) Keratinopathic ichthyoses

Trichothiodystrophy (TTD) (collodion baby (Fig. 44.8) or not, with or without photosensitivity, cataracts, hair fragility with low content of sulfur, tiger tail).

III. Autosomal ichthyosis with prominent neurologic signs such as Sjogren-Larsson (congenital ichthyosis, palmoplantar keratoderma, spastic paraplegia, reduced aldehyde dehydrogenase) and MEDNIK (mental retardation, entheropathy, deafness, neuropathy, ichthyosis, keratoderma)

IV. Autosomal recessive ichthyosis with fatal course, such as

ARC (arthrogryposis, renal dysfunction, and cholestasis) and CEDNIK (cerebral dysgenesis, neuropathy, ichthyosis palmoplantar keratoderma)

V. Autosomal ichthyosis with other associated signs such as KID (keratitis, ichthyosis, and deafness), neutral lipid storage disease with ichthyosis, and ichthyosis prematurity syndrome

Fig. 44.7 Netherton syndrome

Diagnosis

See flow chart (Fig. 44.9).

General Principles of Treatment

The choice of treatment depends on the type of ichthyoses, age of the patient, and severity of the clinical picture. In fact in the mild forms of ichthyoses, such as ichthyosis vulgaris or X-linked ichthyosis, a local treatment is sufficient; in the severe forms, i.e., ARCI, complex syndromic ichthyoses, or generalized epidermolytic ichthyosis, an associated systemic therapy is necessary.

Fig. 44.8 Collodion baby

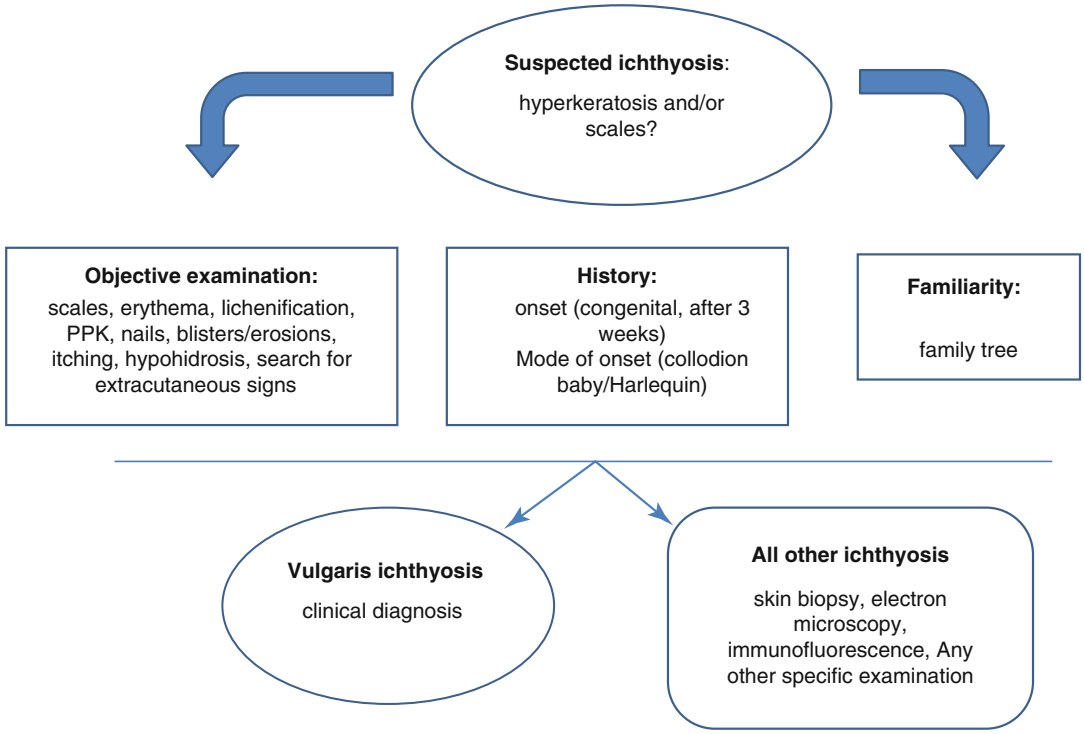

Fig. 44.9 Ichthyoses diagnosis algorithm

The treatment must clearly be linked to the patient's age, the involved areas, and the extent of the disease. The total dosage of the drug absorbed through the skin depends on the relationship between the cutaneous layer and the weight of the patient; this relationship is higher in newborns and infants than in adults; therefore, it is better to avoid, particularly in childhood, the use of potentially toxic drugs. For example, the use of salicylic acid as a keratolytic at concentrations varying between 5 % and 10 % previously in vogue has recently been excluded because of the risk of toxicity both in adults and children. In children acute toxicity (tinnitus, hyperthermic convulsions, respiratory depressions) can be lethal. Topical products based on urea may cause skin sensitivity in children, mostly on the folds; in newborns and collodion babies, there is the risk of nephropathy due to systemic absorption. *Collodion baby* (Fig. 44.8) is used to define a particular phenotype in which the neonate is encompassed in a cellophane-like membrane stretched over the skin at birth. This transient condition spontaneously heals with desquamation within 2 weeks to 3 months, revealing the true underlying disease, ARCI most frequently and rare ichthyosis such as Netherton syndrome or seldom Gaucher disease in some cases. A complete recovery can be observed (self-healing collodion baby) in 10 % of patients. A more severe and usually lethal form due to mutations in gene ABCA12 involved in lipid transport in epidermal keratinocytes is called *Harlequin ichthyosis*. In both conditions, ectropion, eclabion, and contractures of joints and fingers are common. The very compromised skin barrier enhances the risk of dehydration, electrolytic imbalances, and sepsis. The use of simple emollient, such as vehicle cream or Vaseline, can contribute to lubricate the skin, restore the cutaneous barrier, and minimize the risks. The use of emollient as glycerol or paraffin has been proven effective and safe in neonate and children with ichthyosis, especially the vulgaris type.

Particular attention must always be paid to extracutaneous problems in severe forms of congenital ichthyoses (Fig. 44.10) (collodion baby and erythroderma) such as the risk of sepsis, hydroelectrolytic imbalances, sunstroke, and alter-

Fig. 44.10 (**a**, **b**) Congenital ichthyoses

ation of the thermoregulation; therefore, the newborn should be placed in incubator in an adequate temperature and humidity in order to reduce the trans-epidermal water loss (TEWL), generally high in ichthyosis patients. In keratinopathic ichthyoses the treatment of infected bullous lesions with antiseptics and antibiotics is mandatory.

An adequate treatment has the aim to improve hydration, obtain keratolysis, modulate keratinization, and prevent systemic complication.

Recommended Therapies

(a) Therapies that normalize keratinization
(b) Keratolytic substances that improve hydration

Therapies That Normalize Keratinization

Systemic Retinoids

The systemic retinoids like etretinate and its active metabolite acitretin produce good results in the treatment of ichthyoses because of their capacity to operate selectively on the keratinization disorders. Etretinate was the retinoid first used for serious cases of ichthyosis with the dosage of 0.5–1 mg/kg per day at the initial stage, for 1–3 months, with a successive reduction. Acitretin is more effective, manageable, and better tolerated than other retinoids. The therapeutic index of retinoids restricts their use to the most serious forms of ichthyosis. Above all they are found

most useful in the treatment of lamellar and erythrodermic ichthyosis and less in epidermolytic hyperkeratosis in which retinoids can increase the cutaneous fragility acting on the interkeratinocyte adhesion causing more bullous lesions. It is therefore advisable to begin with lower dosages (0.1–0.5 mg/kg per day) always associated with topical treatment. They have also shown very little evidence of success in Netherton syndrome. The side effects are dose dependent; part of them appears regularly: cheilitis, xeroderma and cutaneous desquamation, photosensitivity, cutaneous fragility, and sometimes paronychia. Other possible side effects include migraine; reversible alopecia; transient increase in transaminases, bilirubin, cholesterol, and triglycerides; modification of night vision; epistaxis; arthromyalgia; and occasionally intracranial hypertension and skeletal anomalies. The latter (e.g., hyperostosis, osseous condensation, extra-skeletal calcification of the soft tissues and the ligaments) are always present after 4–6 years of therapy, whereas the total bone growth and development is normal even if an early closure of the epiphysis has been registered. The potential bone damage caused by retinoids has however been reviewed in the last few years. To diminish the incidence of such a risk, it is advisable, when possible, to alternate cycles of therapy with periods of abstention from the treatment, above all during the summer in which there is a greater cutaneous photosensitivity caused by the retinoids. Radiographic monitoring of children doesn't seem to offer significant advantages in comparison to clinical observation. Bone X-ray is advisable only in symptomatic cases. However, before beginning the treatment with systemic retinoids, laboratory analyses should be performed to investigate eventual dyslipidemia, liver diseases, and pregnancy; in these cases the therapy cannot be indicated. A lipidic balance and hepatic function will be repeated monthly in the initial phase of the treatment and, after that, at greater intervals.

The main side effect of systemic retinoids is teratogenicity. An informed agreement should be signed by the women of fertile age, and measures of contraception are necessary during the treatment until 2 years after its end.

Topical Retinoids

Topical retinoids are suggested to avoid side systemic effects, and they are useful in mild forms of ichthyosis. Some recent studies show the effectiveness of the retinoic acid 13-cis (isotretinoin) cream 0.1 % because of its capacity to reduce desquamation and to improve cutaneous smoothness.

Although the use of the trans-retinoic acid (tretinoin) can produce less irritation, it is not recommended in the erythrodermic form and in the presence of atopic dermatitis.

The topical receptor-selective retinoid (tazarotene 0.05 or 0.1 % gel) has been proved effective in multiple recent studies in congenital ichthyosis in children and adults and in some cases of ectropion ichthyosis related. The most common side effect is a local sensitivity; thus a dilution with a simple moisturizing cream can be suggested mostly in children. An international multicentric trial is ongoing to test the tolerability of tazarotene cream 0.05 %.

Topical calcipotriol, the biologically active form of vitamin D3 (1.25-dihydroxy vitamin D3), is effective in the treatment of lamellar and epidermolytic ichthyoses because of its capacity to stimulate the terminal differentiation of the epidermal keratinocytes and to inhibit their proliferation. Topical application of calcipotriol cream 0.05 % twice a day for at least 12 weeks is found to be moderately effective and well tolerated. It is also possible to treat 15–20 % of the cutaneous surface, not exceeding the weekly dose of 120 g in order to prevent the risk of hypercalcemia.

Keratolytic Products

I. Urea Cream or Ointment

Urea cream ointment at 5–20 % is effective in the treatment of ichthyoses and psoriasis. The mechanism of the action is partially known; it seems linked to proteolytic and keratolytic activity (at 6–30 %) and keratolytic; furthermore it increases links between water and the stratum corneum, induces epidermal differentiation, and reduces epidermal hyperproliferation. Urea is also available in many concentrations till 40 % which is useful in adults in areas with

thick scales. Urea should be used carefully in young children and infants for the risk of increased blood urea nitrogen level, and it may cause burning and irritation. In adults it is generally well tolerated.

II. The α-Hydroxy Acids (AHA)

These simple organic hydroscopic acids present an oxydrile in their chemical structure that links to the carbon atom in the alpha position. Among the numerous AHA, for example, lactic, pyruvic, malic, and glycolic acids, the first is the most effective in ichthyoses. They act in a different way from the normal keratolytic; they reduce the cohesion of the corneocytes at the deep stratum corneum level without exercising any effect on the more superficial cells. They stimulate the turnover of the epidermis and also favor the penetration of other associated substances. This action explains the greater effectiveness of the lactic acid in the treatment of recessive X-linked ichthyosis.

Creams with lactic acid (8 %) are effective in reducing the hyperkeratosis associated with ichthyoses and in increasing the hydration of the stratum corneum.

The following formula with lactic acid base is simple and effective:

- Lactic acid 5 g
- Water 40 ml
- Ethanol 35 ml
- Propylene glycol 20 g

This preparation should be applied four times a day for 1–3 weeks. Afterwards the medication is reduced to once or twice a day, depending on the clinical situation.

III. Propylene Glycol

Propylene glycol at the concentration of 40–70 % in water is effective in removing the scales with occlusive medication at bedtime (covering the treated parts with a layer of impermeable film). It is however necessary to avoid the use on extensive skin surface, particularly in children. It can be used in lesser concentration associated with other substances. It has also a moistening effect which increases the content of water in the stratum corneum, which can however cause cutaneous irritation and contact dermatitis even at low concentrations.

Alternative Therapies

(a) PUVA

This therapy seems useful in the treatment of Netherton syndrome. Some studies have reported an association between etretinate and PUVA which has resulted in patients responding positively to this combination but only poorly to etretinate when given alone.

(b) Liarozole

This is a new hymidazolic derivative recently used as topic in the treatment of various forms of ichthyoses. It acts by inhibiting the hydroxylation in position 4 of the retinoic acid that depends on cytochrome P-450, responsible for its physiological degradation. Oral administration is also convenient (150 mg twice a day for 12 weeks), with undesired subjective effects similar to those of the retinoids.

Impetigo

45

Stefano Veraldi and Ermira Çuka

Key Points

- Impetigo is a superficial infection of the skin caused by staphylococci and/or streptococci.
- It is the most frequent bacterial dermatitis in infancy: it occurs mainly in preschool-aged children, particularly during the summer.
- Impetigo actually consists of two distinct entities from the aetiopathogenetic and clinical point of view: non-bullous impetigo and bullous impetigo.
- Non-bullous impetigo may be caused by staphylococci or streptococci or both. It is at first characterized by vesicles surrounded by an erythematous halo. These vesicles can rupture, resulting in erosions, or they may remain intact; however, the fluid becomes purulent, with formation of a pustule. Subsequently, both erosions and pustules dry up and become crusts. Uncovered areas are characteristically affected, particularly the nose, cheeks, lips and chin; covered areas can be involved by self-inoculation.
- Bullous impetigo is always caused by *Staphylococcus aureus*. It is characterized clinically by vesicles and/or blisters which may be widespread on the face, trunk and skinfolds.
- Diagnosis of impetigo is basically clinical.
- The treatment is based on the use of topical antibiotics (fusidic acid and mupirocin).

Definition and Epidemiology

Impetigo is a superficial infection of the skin caused by staphylococci and/or streptococci. It is the most frequent bacterial dermatitis in infancy: it occurs mainly in preschool-aged children, particularly during the summer. The disease is contagious: it is not rare to observe minor epidemics in kindergartens.

DOI 10.1007/978-3-662-45139-7_45,

The transmission is prevalent by direct person-to-person contact and is favoured by:

- Environmental factors:
  - High temperatures
  - High humidity
  - Overcrowding
  - Poor hygiene
- Personal factors:
  - Malnutrition
  - Poor hygiene
  - Abnormalities in humoral or cellular immunity
  - Presence of debilitating diseases
  - Previous or concomitant systemic therapies with antibiotics, corticosteroids, immunosuppressives or antitumourals

Impetigo often develops on a pre-existing skin disease characterized by more or less severe pruritus: atopic dermatitis, other allergic diseases, chickenpox, pediculosis, scabies, arthropod stings and bites. In these cases it is more appropriately referred to as secondary impetigo or impetiginization.

Basic Concepts of Pathogenesis

The term "impetigo" actually consists of two distinct entities from the aetiopathogenetic and clinical point of view: non-bullous impetigo (or contagiosa or vulgaris or pustular impetigo) and bullous impetigo.

Non-bullous impetigo may be caused by staphylococci or streptococci or both. In the past, streptococcal aetiology was most common. Group A β-haemolytic streptococci (*Streptococcus pyogenes*) are usually isolated. The infections caused by groups B, C, D and G are very rare. In Western countries, staphylococcal infections are currently more frequent (approximately 65 % of cases).

Bullous impetigo is always caused by *Staphylococcus aureus* (phagic II group in approximately 80 % of cases); furthermore, about 60 % of staphylococci are of types 55 and 71. These staphylococci synthesize some exotoxins with lytic and exfoliative properties both in vitro and in vivo. These toxins induce a detachment of keratinocytes of the granular layer of the epidermis, with consequent development of vesicles and blisters.

Clinical Presentation

Non-bullous impetigo is at first characterized by the appearance of one or more round vesicles, small in size, containing a clear fluid, and surrounded by an erythematous halo (Fig. 45.1). These vesicles can rupture, resulting in erosions, or they may remain intact; however, the fluid becomes purulent, with formation of a pustule (Fig. 45.2). Subsequently, both erosions and pustules dry up and become crusts: these are rather thick, poorly adherent, yellowish in colour, similar to honey, and surrounded by an erythematous halo. Their removal shows an underlying surface which is erythemato-erosive, moist and bright red in colour (Fig. 45.3). Uncovered areas are characteristically affected, particularly the nose, cheeks, lips and chin; covered areas can be involved by self-inoculation.

Bullous impetigo presents with isolated vesicles and/or blisters which may be widespread on the face, trunk and skinfolds. These lesions are round, sometimes large (some centimetres in diameter) and flaccid, containing initially a clear fluid which becomes frankly purulent, surrounded by very mild or no erythema. The removal of the roof reveals moist erosions which eventually become yellow-brown crusts.

Both varieties of impetigo are asymptomatic or accompanied by mild pruritus.

General health is good: only in chronic and/or diffuse infections fever may be sometimes observed. Regional lymphadenitis is also rare.

Fig. 45.1 Impetigo of the ear. Notice the yellow crust

Fig. 45.2 Pustular and crusted lesions of impetigo

Fig. 45.3 Vesicular and erosive lesions of impetigo

Both varieties of impetigo can resolve spontaneously within some weeks; with adequate therapy, the duration usually is 5–7 days. The disease heals without leaving scars; transitory hyper- or hypopigmentation may persist for some weeks.

Complications (lymphangitis, lymphadenitis) are extremely rare. Glomerulonephritis is rare today compared to the past. It is caused by strains of nephritogenic streptococci, mainly M49 and less frequently 55 and 57. Glomerulonephritis usually occurs 3–4 weeks (up to 7 weeks) after the appearance of the skin lesions and is at first characterized by proteinuria and microhaematuria.

Recurrences of impetigo are possible if bacterial foci are not adequately eradicated in the patient, in his/her family and in the community.

Diagnosis

Diagnosis of impetigo is clinical.

Bacteriological examination of the fluid or the pus removed from a vesicle, blister or pustule and then Gram stained allows the observation of both extracellular and intracellular (particularly in the cytoplasm of neutrophils) Gram-positive cocci, which are arranged in bunches or chains.

The same modality of collection may be followed for bacterial culture and antibiogram.

Antistreptolysin and antistaphylolysin titres increase in an inconstant and delayed fashion. Anti-DNAse B antibodies are slightly more specific.

Laboratory abnormalities are rare and aspecific: mild leucocytosis with neutrophilia and increase in inflammatory tests (erythrosedimentation rate, C-reactive protein, alpha1-acid glycoprotein).

Three to 4 weeks after cure, it is helpful to perform urinalysis to exclude a post-streptococcal glomerulonephritis.

Differential Diagnosis

- Herpes simplex: small grouped vesicles on an erythematous base, which always recur at the same sites
- Irritant/allergic contact dermatitis: tiny vesicles on an erythematous base, accompanied by more or less severe pruritus
- Herpetiform dermatitis: papular-vesicular lesions at typical sites (shoulders, elbows, lumbosacral region, buttocks, knees) accompanied by intense pruritus
- Tinea corporis: erythematous-vesicular borders and scaling in the centre of the lesion

General Principles of Treatment

An early diagnosis and an adequate therapy limit the extension of the infection and its diffusion within the family and the community.

The therapy must be preceded or accompanied by a careful search in the patient, in his/her family and in his/her contacts for any possible infective reservoir:

1. For staphylococci:
   - Nostrils
   - External auditory canal
   - Major skinfolds (axillae, inguinal, intergluteal and perineal folds)
2. For streptococci:
   - Pharynx
   - Tonsils
   - External auditory canal
   - Major skinfolds

During the course of the disease, the patient must use personal underwear, towels and bed sheets.

It is necessary to open vesicles, blisters and pustules with the tip of a scalpel or a needle.

It is then helpful to wash and disinfect the erosive lesions. This can be achieved with several cleansers/antiseptics:

- 5 % benzoyl peroxide.
- 0.4 % chlorhexidine digluconate.
- 1–5.16 % hydrogen peroxide.
- Potassium permanganate [250 mg in 2–3 l of water (dilution, 1:10,000, approximately)]. Since potassium permanganate is toxic, maximum caution must be taken by the patient: its use on the face must be avoided.
- 3 % urea peroxide.

All these antiseptics may be used two to three times/day for 7–10 days. However, the last Cochrane review on impetigo, published in 2012, stated that there is a lack of evidence for the benefit of antiseptics (Koning et al. 2012). Therefore, they should be considered as a complementary treatment in impetigo.

In the same Cochrane review, a total number of 68 trials, based on 5,578 evaluable patients, reporting on 50 different treatments, including placebo, were considered as clinically and statistically evaluable. Topical antibiotics showed better cure rates than placebo in six studies on 575 patients. There is good evidence that topical fusidic acid and mupirocin are equally, or more, effective than oral antibiotics. In four studies on 440 patients, fusidic acid and mupirocin showed to be of similar efficacy. In ten studies on 581 patients, topical mupirocin was shown to be slightly superior to oral erythromycin. Furthermore, penicillin was inferior to erythromycin in two studies on 79 patients and cloxacillin in two studies on 166 patients. The reported number of side effects was low, and most of these were mild. Side effects (in particular gastrointestinal side effects) were more common for oral antibiotics compared to topical antibiotics. Worldwide, bacteria causing impetigo show increasing resistance rates for commonly used antibiotics. However, no cases of resistance have yet been reported for retapamulin. In our personal clinical experience, also gentamicin sulfate is effective in bullous impetigo; furthermore, it is very well tolerated and resistance is rare, in spite of the fact that this drug was marketed many years ago. Topical antibiotics should not be used for more than 14 days, with the aim of minimizing the possibility of development of resistant strains (particularly staphylococci). Other topical antibiotics (amikacin, bacitracin, chlortetracycline, clindamycin, meclocycline, neomycin, polymyxin B) are considered ineffective for the treatment of impetigo. Five per cent benzoyl peroxide gel may be used as a cleanser for the prevention of recurrences (two to three cleanings or baths/week).

Therapeutic Algorithm

- Localized impetigo – A topical antibiotic (fusidic acid or mupirocin or retapamulin or gentamicin) and a topical antiseptic (benzoyl peroxide or chlorhexidine or hydrogen peroxide or potassium permanganate or urea peroxide)
- Widespread impetigo or impetigo resistant to topical antibiotics – An oral antibiotic (erythromycin or clarithromycin or amoxicillin or amoxicillin/clavulanic acid)

Kaposi's Sarcoma

46

Erwin Tschachler and George-Sorin Tiplica

Key Points

- Kaposi's sarcoma (KS) is a multifocal tumor of endothelial cell origin which occurs in four clinical variants: (1) classic KS, (2) endemic African KS, (3) KS in therapeutically immunosuppressed patients, and (4) AIDS-associated KS.
- The diagnosis is established by the clinical aspect, histopathology, and demonstration of HHV-8 in tumor lesions.
- The therapeutic approach is dependent on the clinical variant and on the extent of the lesions and comprises local destructive measures or systemic chemotherapies.
- Localized cutaneous KS treatment includes surgical excision or lesion destruction with radiotherapy, liquid nitrogen, laser, photodynamic therapy, and topical therapy with 9-cis-retinoic acid.
- AIDS-associated KS responds to liposomal anthracyclines: liposomal doxorubicin or liposomal daunorubicin. KS in organ transplant patients benefits from replacement of calcineurin inhibitors with rapamycin in their immunosuppressive regimen.
- Classic KS with widespread skin lesions responds to chemotherapeutic drugs (doxorubicin, bleomycin, vincristine, etoposide, dacarbazine) as well as to liposomal anthracyclines.
- In AIDS patients, it is pivotal to combine KS therapy with antiretroviral therapies.

Definition and Epidemiology

In 1872, the Austro-Hungarian dermatologist Moritz Kaposi described five patients with multicentric cutaneous and extracutaneous neoplasms that primarily affected older individuals. Kaposi's sarcoma (KS) was originally described as "idiopathic multiple pigmented sarcoma" and was later named after its first describer. Based on distinct epidemiological features and clinical evolution, there are four clinical variants of KS. All of those variants have comparable histopathology, and in all of them the human herpesvirus type 8 (HHV-8), also known as Kaposi's sarcoma–associated herpesvirus, plays a causative role.

Fig. 46.1 Classic Kaposi's sarcoma lesions in typical locations on the distal extremities

Fig. 46.2 Advanced Kaposi's sarcoma, nodular lesions surrounded by pitting edema

Clinical Presentation

Classic KS

Classic KS preferentially occurs in Caucasians over 60 years of age with a Mediterranean or Jewish background. The male to female ratio is 3:1–5:1. Classic KS lesions manifest on the skin as unilateral or bilateral violaceous (hematoma-like) macules and plaques with acral disposition, frequently on the distal portions of the lower extremities (Fig. 46.1). These lesions progress slowly into coalescent firm plaques and nodules surrounded by pitting edema (Fig. 46.2) and, subsequently, into nodules, while additional lesions start to arise in the surroundings or at distant sites. This clinical variant is usually slowly progressive, and patients may live with slowly progressive disease for many years. However, also in classic KS, ultimately dissemination to other body sites such as lymph nodes, mucous membranes, and inner organs, in particular the gastrointestinal tract, may occur. Since classic KS mostly affects elderly patients, death from other causes may precede its full spread.

The higher incidence of KS in countries surrounding the Mediterranean Sea has led some authors to speak of a Mediterranean KS variant as a separate entity. Since the clinical course and the epidemiology are comparable to the classic KS, the authors prefer to not separate classic and Mediterranean KS.

African Endemic Kaposi's Sarcoma

An increased frequency of Kaposi's sarcoma in black Africans in Central Africa was reported already in the 1950s. This clinical form is more prevalent in male patients, with ratios ranging from 3:1 in children up to 18:1 in adults. In some Equatorial African countries, endemic KS comprises up to 10 % of all malignancies in men. The age at onset is lower than in classic KS, with a peak at 25–39 years in women and 35–39 years in men. There are four clinical variants of the African endemic KS: nodular, florid, infiltrative, and lymphadenopathic. The florid and infiltrative variants are showing an aggressive behavior, and the lesions may extend deeply into the muscle and bone. The lymphadenopathic variant is mainly seen in children and young adults and may rapidly progress.

Kaposi's Sarcoma in Patients Receiving Immunosuppressive Therapies

After organ transplantation had become a routine procedure in the 1970s, a high incidence of KS was reported for organ-transplant recipients undergoing immunosuppressive therapy. The occurrence of KS has been reported, less frequently, in patients who receive therapeutic immunosuppression for other reasons such as the treatment

Fig. 46.3 HIV-associated Kaposi's sarcoma, multiple lesions on the trunk

of autoimmune diseases. Transplantation-associated KS is observed predominantly in kidney allograft recipients, while in recipients of other solid organs and bone marrow allografts, it is rarely seen. An important risk factor for KS development is the dose and type of the immunosuppressive drug. The risk in association with cyclosporin A is higher than with glucocorticoids and azathioprine, and the disease onset is earlier. Discontinuation of immunosuppressive therapy was followed in some cases by the regression of KS lesions.

The clinical course of KS in therapeutically immunosuppressed patients may be slowly progressing like in the classic variant or rapidly disseminating like in AIDS-associated KS. Skin lesions are present in more than 85 % of the patients with transplantation-associated KS, while the remaining 15 % of patients have visceral disease without skin involvement.

AIDS-Associated KS

Rapidly progressing, multifocal KS occurring in young homosexual men was one of the diseases which alerted health authorities in the USA on the advent of a new disease, i.e., the acquired immunodeficiency syndrome (AIDS). KS is considered an AIDS-defining illness. At the beginning of the AIDS pandemic, KS was seen in more than 20 % of HIV-1–infected patients. In recent years, it is in a strong decline due to efficient anti-HIV drugs. AIDS-associated KS is more frequent in homosexual or bisexual men and less common in injection drug users or transfusion recipients. In Europe and the USA, the AIDS-associated KS is seen mostly in males, whereas in Africa, it is encountered in high numbers in HIV-1–infected women and children.

Fig. 46.4 Involvement of the oral mucosa. Nodular Kaposi's sarcoma lesions on the hard palate

AIDS-associated KS evolves with multifocal dissemination and undergoes a more rapid course than classic KS. The KS lesions in AIDS are asymptomatic, are elliptical, and occur along the skin tension lines, frequently on the face (nose, eyelids, ears) and on the trunk (Fig. 46.3). Over time, KS lesions may unite to form large plaques that can interfere with the normal movements of the limbs. Mucosal lesions occur early in the disease. Hard palate (Fig. 46.4), gingival,

and pharyngeal lesions may easily ulcerate and result in difficulties of eating, speaking, and breathing.

AIDS-associated KS involves rapidly all visceral sites. Tumors are frequently found in lymph nodes, gastrointestinal tract, lungs, liver, pancreas, heart, bone marrow, etc. Involvement of the gastrointestinal tract may cause severe clinical symptoms including extensive bleeding, ileus, malabsorption, nausea, vomiting, and abdominal pain. Pulmonary involvement can be manifest with coughing, chest pain, hemoptysis, bronchospasm, and progressive respiratory insufficiency.

Diagnosis of KS

The diagnosis of KS is based on the clinical aspect and confirmed by the histological examination. To assess the dissemination of KS and the coexistence of other diseases, laboratory and imaging studies are needed.

Histopathology is similar for the different clinical forms and depends on the stage of KS lesions. Early patch lesions show a discrete increase in dermal vessels, which may appear slightly irregular and may form slits and clefts in the papillary dermis. The dermis also shows hemosiderin deposits and extravasated erythrocytes. In the plaque stage, extensive vascular proliferation can be seen at all levels of the dermis with dilated and angulated vascular spaces dissecting the collagen and leaving a spongy network. At this stage, solid cords and fascicles of spindle cells arranged between the vascular channels may be already present. On further progression to the nodular stage, bundles of spindle cells delineating irregular slit-like vascular spaces without endothelial linings become predominant. In these advanced lesions, pronounced pleomorphism, nuclear atypia, and mitotic figures are frequently present. In all stages of the KS lesions, a moderate inflammatory infiltrate consisting of lymphocytes, histiocytes, plasma cells, and, sporadically, neutrophils is regularly present. On immunophenotyping KS tumor cells are $vWF^{+/-}$, $PAL\text{-}E^{-}$, $CD31^{+}$, $CD34^{+}$, and$VEGFR3^{+}$ which characterizes them as part of the lymphatic endothelial differentiation lineage.

Laboratory studies include a complete blood count (CBC) and blood chemistry tests together with screening for sexually transmitted infections including HIV tests. In HIV-positive patients, CD4 T-lymphocyte count and plasma HIV viral-load studies should be performed.

Imaging Studies

- Conventional radiology of the chest is nonspecific in case of pulmonary KS showing diffuse reticulonodular infiltrates, lymphadenopathy, pulmonary nodules, and pleural effusion.
- Computerized tomography (CT) of the thorax can also identify nonspecific lesions in pulmonary KS: nodules (poorly defined), bronchovascular infiltrates, lymphadenopathy, or pleural effusions. Contrast CT scan can detect liver KS nodules.
- Magnetic resonance imaging (MRI) can identify KS lesions with better contrast resolution than CT. MRI findings can be suggestive for pulmonary KS and for cardiac or bone involvement.
- ^{99}Tc scintigraphy (planer or single photon emission computerized tomography (SPECT)) can detect KS lesions and can be used in combination with ultrasound to indentify KS lymph node involvement or with ^{67}Ga scintigraphy to differentiate lung infection.

Medical procedures can be used to identify KS lesions in internal organs and take tissue samples for histopathologic examination: bronchoscopy, upper endoscopy, or colonoscopy.

KS and Human Herpesvirus Type 8 (HHV-8)

Epidemiological data and electron microscopic studies had suggested the involvement of an infectious agent in the etiology of KS for a long time. Finally, in 1994 Chang and colleague set the stage for a viral cause of KS when they discovered and characterized a novel human herpesvirus: HHV-8. This virus is present in all KS variants. HHV-8 is a member of the γ-Herpesviridae subfamily, genus *Rhadinovirus*. Several of the HHV-8 regulatory genes are homologous to human genes

involved in regulation of apoptosis, cell proliferation, and angiogenesis, and some of them have been shown to transform cells. It is therefore generally accepted that HHV-8 is a transforming herpesvirus and plays a direct role in the development of KS. In addition to KS, HHV-8 has been implicated in the pathogenesis of pleural effusion lymphoma, a rare B cell neoplasm seen primarily in AIDS patients, and in multicentric Castleman's disease. The routes of HHV-8 transmission are not yet entirely known. Epidemiological studies have confirmed that sexual transmission occurs during oral-genital and oral-anal contacts. In areas where the virus is highly prevalent, such as in Mediterranean countries and Africa, nonsexual transmission is possible as the HHV-8 can be shed in saliva.

The prevalence of HHV-8 is largely overlapping with that of KS. In regions of low KS incidence such as the USA and Northern Europe, HHV-8 prevalence is below 0.1 %, whereas in regions with high KS incidence such as in Southern Italy and Central Africa, HHV-8 prevalence reaches 20 and 70 %, respectively. In HIV-1–infected patients in the USA and Northern Europe, HHV-8 prevalence is highest in homosexual and bisexual men and reflects the incidence of KS in this risk group.

Differential Diagnosis

The violaceous lesions of KS can be sometimes misdiagnosed, mainly in patients with few skin or mucosal lesions:

- Bacillary angiomatosis
- Pseudo-Kaposi's sarcoma (acral angiodermatitis)
- Blue rubber bleb nevus syndrome
- Pyogenic granuloma
- Hematoma
- Tufted angioma
- Melanocytic nevi
- Melanoma
- Angiokeratoma
- Stewart-Treves syndrome
- Nodal angiomatosis
- Glomus tumor
- Lymphangioma
- Arteriovenous malformations (pseudo-KS)
- Severe stasis dermatitis (pseudo-KS)
- Skin metastasis of other tumors (e.g., renal cell carcinoma)
- Erythema elevatum et diutinum
- Insect bites

General Principles of Treatment

The treatment of KS depends on the clinical variant, on the extent of the skin lesions, and on the internal organ involvement (Table 46.1). Despite the presence of the oncogenic herpesvirus HHV-8, the treatment with modern anti-herpetic drugs did not prove to be effective.

Localized Cutaneous Disease

Regardless of the clinical variant, if a patient presents with limited disease confined to the skin, local therapies aimed for the destruction of individual

Table 46.1 Treatment options for Kaposi's sarcoma

Localized disease
Surgical excision
Cryotherapy
Topical 9-cis-retinoic acid
Photodynamic therapy
Radiation therapy (on regions not easily accessible for surgery)
For patients with AIDS: initiate HAART
Disseminated disease/internal organ involvement
For AIDS patients not responding to HAART alone – systemic cytotoxic chemotherapy (and continuation of HAART)
Liposomal anthracyclines (e.g., liposomal doxorubicin 20–40 mg/m^2
every 2–4 weeks)
Paclitaxel (100 mg/m^2 every 2 weeks)
For patients with classic KS
Liposomal anthracyclines (e.g., liposomal doxorubicin 20–40 mg/m^2 every 2–4 weeks) (preferred treatment of the authors)
Vinblastine (6 mg IV once a week)
Doxorubicin/bleomycin/vincristine (20–30 mg/m^2, 10 mg/m^2, 1–2 mg, respectively, every 2–4 weeks)
Interferon alpha (3–30 million units daily to 3 times a week)
For patients on immunosuppressive therapy – reevaluate drug regimen and further treatment depending on the immunosuppressive regimen and the degree of organ involvement

lesions are recommended as first-line treatment. These include surgical excision or local destruction with liquid nitrogen, laser or photodynamic therapy, and topical therapy with 9-cis-retinoic acid. Radiotherapy can be used at body sites difficult to reach by other local therapies such as on the nose and in the oral mucosa. Radiation therapy may be given as low-voltage (100 kV) photons or electron-beam radiotherapy. For localized skin lesions, electron beam therapy can be used once weekly in 4 Gy fractions. In patients with widespread skin involvement, extended-field electron beam radiation therapy was reported to be effective. The treatment is maintained for 6–8 weeks/cure.

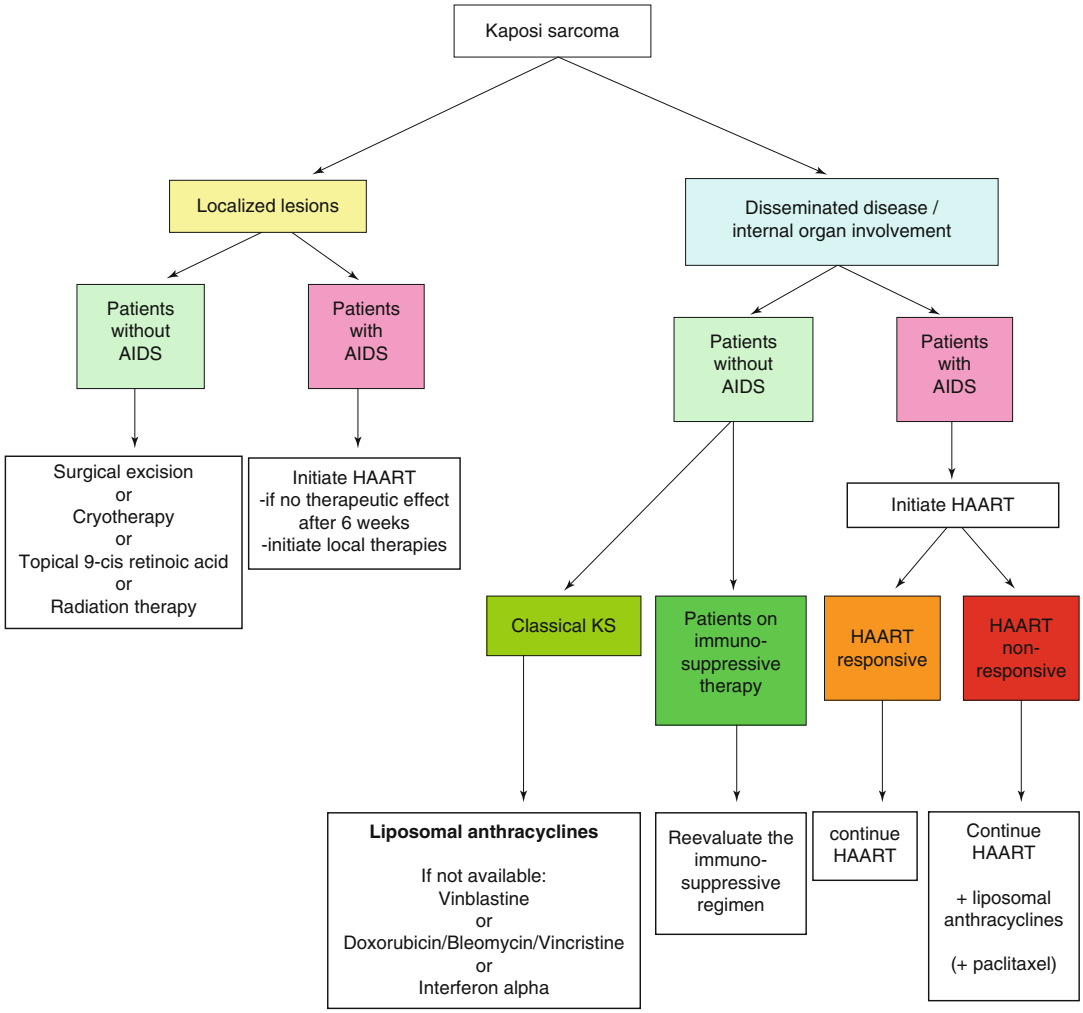
Although recurrence rates are high, local therapies might be satisfactory for years in slowly progressing classic KS. By contrast, in the other clinical variants, it is necessary that additional measures such as change of the immunosuppressive therapy in transplantation-associated KS and initiation of HAART in patients with AIDS-associated KS.

Progressive Cutaneous Diseases and Involvement of Other Organs

AIDS-Associated KS. The advent of highly active antiretroviral therapies (HAART) had led to a decrease of AIDS-associated KS incidence, and remission of early KS lesions occurred after initiating HAART. However, advanced KS cannot be controlled or reversed by HAART but requires chemotherapy. Among several chemotherapeutic regimens used in the past decades, liposomal anthracyclines emerged as more efficient and better tolerated than the combination therapies of bleomycin with vincristine or both combined with doxorubicin. *Liposomal doxorubicin* is an anthracycline antibiotic liposome encapsulated with polyethylene glycol coating that has a preferential concentration in the skin. Doxorubicin inhibits DNA and RNA synthesis by intercalating between DNA base pairs. Liposomal doxorubicin is recommended for the treatment of AIDS-related KS in IV administration: *20 mg/m^2 once every 2–3 weeks*. The treatment continues as long as the patient is responding and tolerating it. The doses need adjustments in case of hepatic impairment. Bone marrow suppression may occur during the treatment, and CBC monitoring is recommended before each drug administration. Leukopenia is usually transient. Neutropenia may result in superinfection and hemorrhage may occur due to thrombocytopenia. Doxorubicin may cause cumulative, dose-related myocardial toxicity that may lead to congestive heart failure as the cumulative dose of liposomal doxorubicin approaches 550 mg/m^2. Left ventricular ejection fraction is used to evaluate the cardiac function prior to treatment and periodically during treatment. Other adverse reactions include peripheral edema, fever, palmar-plantar erythrodysesthesia (hand-foot syndrome), transient alopecia, nausea, and stomatitis. Doxorubicin may potentiate the toxicity of cyclophosphamide and mercaptopurine, may diminish the therapeutic effect of inactivated vaccines, and may enhance the adverse effect of live vaccines. Liposomal doxorubicin may diminish the therapeutic effect and enhance the adverse effect of zidovudine. The adverse effects of liposomal doxorubicin may be enhanced by taxane derivatives or tacrolimus.

Daunorubicin is another anthracycline antibiotic with antineoplastic activity, first obtained from *Streptomyces peucetius*. Cell structure studies have demonstrated the drug rapid cell penetration and perinuclear chromatin binding, rapid inhibition of mitotic activity and nucleic acid synthesis, and induction of mutagenesis and chromosomal aberrations. Encapsulating daunorubicin in liposomes maximizes the drug selectivity for solid tumors. *Liposomal daunorubicin* is indicated as a first-line cytotoxic therapy for advanced HIV-associated KS at a dose of *40 mg/m^2 administered* IV *at 2 weeks' interval*. Treatment is maintained as long as KS lesions are not progressing (over 25 % new or evolving lesions) or HIV disease complications do not impose the discontinuation. Due to the liposomal daunorubicin myelosuppressive effect, CBC monitoring is performed before each administration, and therapy is postponed when the total neutrophil count is less than 750 cells/mm^3. Other side effects include cardiac toxicity (cardiomyopathy), back pain, flushing, chest tightness, and temporary hair loss. Echocardiographic monitoring is performed at a total cumulative dose of liposomal daunorubicin of 320 mg/m^2 and afterward at every 160 mg/m^2.

Table 46.2 Flow diagram for KS treatment



For patients with anthracycline-refractory AIDS-associated KS, paclitaxel has been recently advocated as potential rescue therapy. It is important to keep in mind that HAART needs to be continued during chemotherapy of KS in HIV-infected patients. Interferon alpha which was the most frequently used drug for AIDS-associated KS treatment during the 1980s and early 1990s still holds some promise for AIDS patients with early disseminated KS who simultaneously receive highly active antiretroviral therapy.

KS in organ transplant patients may respond well to a reduction or change of the immunosuppressive therapy. Replacement of calcineurin inhibitors by rapamycin may lead to dramatic therapeutic effects with complete remission of advanced KS lesions. This effect seems to be not only due to the modulation of the immune response by the change of therapy but also to direct antitumor effects of rapamycin.

Classic KS. Chemotherapeutic drugs including doxorubicin, bleomycin, vincristine, etoposide, and dacarbazine alone or in combination had been administered also to patients with progressive or widespread classic KS in particular in those with involvement of inner organs. However, large prospective studies are not available. Data from the literature (Martin-Carbonero, 2004) as well as the authors' experience shows that liposomal anthracyclines are efficient as in the AIDS-associated KS.

Flow Diagram for KS treatment (Table 46.2).

Keloids and Hypertrophic Scars

47

Ivana Binic

Key Points

- Keloids and hypertrophic scars are benign, localized proliferations of connective tissue of the skin and are the result of abnormal wound healing.
- Hypertrophic scarring usually occurs within 4–8 weeks after some traumatic skin injury, has a rapid growth phase for up to 6 months, and then gradually regresses over a period of a few years. Keloids appear as firm, mildly tender tumors, pink or purple, with shiny surface and sometimes telangiectasia.
- The most important factor in hypertrophic scar and keloid formation is prevention. Before any surgical procedure, patients should be asked if they have had previous problems with scarring.
- Multiple studies on hypertrophic scar and keloid formation have led to a plethora of therapeutic strategies to prevent or attenuate keloid and hypertrophic scar formation. The current arsenal of treatment methods includes surgical, medical, physical, and radiologic therapies, often used in combination. In the present, no existing single method is superior to others as an effective solution for all hypertrophic scars and keloids.

Definition

Keloids and hypertrophic scars are benign, localized proliferations of connective tissue of the skin and are the result of abnormal wound healing. Excessive scars may develop following any injury of a deep dermis, including burns, surgery, abrasion, piercings, vaccinations, and lacerations.

Hypertrophic scars are raised, but they stay within the boundaries of the original wound, and there is a possibility of spontaneous regression. Keloids are also raised, but spread beyond the original wound boundaries, invading the surrounding skin. They may continue to grow over time and often recur following excision. Hypertrophic scars usually are more responsive to different treatment modalities than keloids.

Basic Concepts of Pathogenesis

Despite advancements in knowledge of the mechanisms of wound healing and scar formation, the etiology and pathophysiology of hypertrophic scarring are not fully understood. Keloids and hypertrophic scars represent an exaggerated fibroproliferative response of the dermis. There is imbalance of matrix degradation and collagen synthesis, resulting in excess accumulation of dermal collagen, fibronectin, and glycosaminoglycan content and increased collagen turnover. It is shown that the dermal fibroblasts under the influence of persistently high levels of fibrogenic cytokines play a major role in stimulating matrix production. Also, it is found that keloid-derived fibroblasts show a rate of fibronectin biosynthesis that is four times higher than that of fibroblasts from normal scars and normal skin. Experiments on cells isolated from keloid tissue demonstrate numerous alterations on their function such as in proliferation, apoptosis, and/or expression of growth factors and matrix molecules.

In the normal maturation phase of wound healing, the connective tissue elements regress after the third week. In keloids, the collagen synthesis is approximately 20 times as great as that in normal skin and 3 times as great as in hypertrophic scar. Also, it is shown that not only high collagen production matters, but the ratio of type I to type III collagen is also high.

Histologically, hypertrophic scars display a nonspecific dermal fibroblastic proliferation, thickened dermis, and atrophy of the epidermis. Hypertrophic scars are more cellular than keloids, which in contrast display characteristic hypocellular, glassy, hyalinized, eosinophilic collagen fibers.

Clinical Presentation

Hypertrophic scarring usually occurs within 4–8 weeks after some traumatic skin injury (infection, wound closure with excess tension, burn), has a rapid growth phase for up to 6 months, and then gradually regresses over a period of a few years. Eventually, hypertrophic scars may finish like flat scars with no further symptoms. Keloids, in contrast, may develop up to several years after minor injuries. They persist, usually for long periods of time, and do not regress spontaneously.

Keloids appear as firm, mildly tender tumors, pink or purple, with shiny surface and sometimes telangiectasia. The borders of the tumor are well demarcated, but irregular in outline. A hypertrophic scar has a similar appearance but is usually linear if following a surgical scar or papular or nodular if following inflammatory lesions. Both types of scars are very often pruritic, but keloids may be the source of significant pain and hyperesthesia.

In most cases, hypertrophic scars develop in anatomic locations with high tension, as the shoulders, sternum, knees, neck, and ankles. Keloids are more often found on the skin of the anterior chest, earlobes, cheeks, upper arms, and shoulders. Less affected locations are the eyelids, cornea, mucous membranes, genitalia, palms, and soles, but both can occur at any anatomic location. Risk factors for the development of hypertrophic scars or keloids include trauma, mechanical forces (namely, increased wound tension or stretching), infection, inflammation, and foreign body reaction.

The incidence of keloids and hypertrophic scars is highest in the second to third decade of life, and their occurrence has equal sex distribution. Incidence rates of hypertrophic scarring vary from 40 to 70 % following surgery to up to 91 % following burn injury, depending on the depth of the wound. Patients with keloids often report a positive family history, unlike patients suffering from hypertrophic scarring, and the concept of a genetic predisposition to keloids has long been suggested. Keloid formation is seen in individuals of all races, except albinos, but dark-skinned individuals have been found to be more susceptible to keloid formation, with an incidence of 6–16 % in African populations.

Diagnosis and Differential Diagnosis

A clinical finding of flesh-colored to erythematous fibrotic plaque, together with history of recent surgery or trauma, is sufficient to make

diagnosis. Biopsy is unnecessary. In the absence of supportive findings, malignant tumors, including dermatofibrosarcoma protuberans, and giant cell fibroblastoma, along with infections and sarcoidosis, should be considered in the differential diagnosis.

In some cases clinical differentiation between hypertrophic and keloid scars is of central importance before the initiation of any treatment, because of a different course and prognosis.

Prevention

The most important factor in hypertrophic scar and keloid formation is prevention. Before any surgical procedure, patients should be asked if they have had previous problems with scarring. Avoiding all unnecessary wounds, elective surgical operations, especially in keloid-prone patients, remains an obvious but incomplete solution. Risk factors that promote the development of hypertrophic scars and keloids and that can be limited by physicians are attention to the early care of wounds, mechanical force (stretching tension) on the wound, wound infections, and foreign body reactions.

Anything that accelerates wound healing and reduces skin tension (e.g., postsurgical taping for 12 weeks) will diminish the risk of abnormal scar formation. Surgical closure of an open wound should take into account the tension on the wound, incisions should not cross joint spaces, midchest incisions should be avoided, and incisions should follow skin creases whenever possible.

General Principles of Therapy

Multiple studies on hypertrophic scar and keloid formation have led to a plethora of therapeutic strategies to prevent or attenuate keloid and hypertrophic scar formation. The current arsenal of treatment methods includes surgical, medical, physical, and radiologic therapies, often used in combination. In the present, no existing single method is superior to others as an effective solution for all hypertrophic scars and keloids. Patients usually are treated with several treatment modalities combined depending on the patient's special circumstances and the clinician's experience with each specific treatment method.

Hypertrophic scars and keloids are benign skin lesions, but very often they are associated with pain and/or pruritus with different degrees of discomfort; sometimes they cause functional problems (e.g., contraction/mechanical irritation due to elevation) and also cause cosmetic-aesthetic concerns which may lead to psychological stress and functional disabilities that ultimately affect the patient's daily life.

The ultimate goal of hypertrophic scar and keloid management is to prevent function impairment and maintain a cosmetically acceptable appearance; therefore, thorough treatment should include different therapeutic options that are appropriate for the patient.

The therapy goals must be set on an individual basis and be oriented to the complaints of the patient. Depending on the treatment option, marked improvement should be achieved after three to six treatments or after 3–6 months (e.g., volume reduction by 30–50 %, symptom reduction >50 %, and/or sufficient satisfaction of the patient).

Treatment modalities for keloids and hypertrophic scars include pressure therapy, radiation, intralesional injections, cryotherapy, silicone-based products, surgical excision, lasers, and different combinations of two or more treatments.

Pressure Therapy

Pressure therapy has been the preferred conservative management for both the prophylaxis and treatment of hypertrophic scars and keloids since the 1970s, when physicians noted that pressure stockings used on lower extremity burns resulted in scars that matured more rapidly, with less erythema and thickness. Currently, pressure garments are predominantly used for the prophylaxis of hypertrophic burn scar formation, despite controversial data regarding their value in reducing excessive scarring and little scientific evidence supporting their use.

The compression phenomenon is not well understood, but theories include the following: decrease in blood flow with a resultant decrease in a2-macroglobulin and a subsequent increase in collagenase-mediated collagen breakdown, normally inhibited by a2-macroglobulin; hypoxia leading to fibroblast degeneration and collagen degradation; lower levels of chondroitin 4-sulfate, with a subsequent increase in collagen degradation; and decreased scar hydration, resulting in mast cell stabilization and a subsequent decrease in neovascularization.

Histologic examination showed that pressure therapy in hypertrophic scars partly restores the extracellular matrix organization, like that observed in normal scar tissue, and induces the disappearance of a-SMA-expressing myofibroblasts, probably by apoptosis.

Recommendations for the amount of pressure and the duration of the therapy are based merely on empirical observations, and continuous pressure of 15–40 mmHg for at least 8–24 h a day is recommended for the first 6 months while the scar is still active. Pressure therapy should be started immediately after reepithelialization of the wound. The success rate depends largely on patient compliance.

Radiation Therapy

The first use of x-rays in the treatment of scars was at the beginning of the last century. Later evidence showed that radiation therapy used as monotherapy is inadequate for the treatment of keloids, and therefore the use of radiation therapy was started as an adjunct to surgical excision.

Ionizing radiation has two effects on pathological scars: (1) an antiproliferative effect due to inhibition of new cell formation by delay of mitosis or the mitosis-induced cell death and (2) an antiinflammatory effect due to lymphocyte apoptosis and induction of differentiation of fibroblasts/fibrocytes. The result is a hypocellular, poorly vascularized, and hypoxic tissue, less new fibroblasts formation, decreased amount of collagen production, and finally inhibition of keloid development. An adequate radiation dose establishes the balance between scar formation and excessive cell growth without influence on wound healing.

Surgical excision in combination with radiotherapy is considered the most effective treatment available in severe keloids. Surgical excision as a sole treatment of keloids has a very high recurrence rate, between 45 % and 100 %. Surgical excision followed by radiation therapy for the treatment of keloids provides the highest reported regression rates.

Electron beam irradiation is usually started 24–48 h after keloid excision, and the total dose is limited to 15–20 Gy over the course of several treatments. Response rates ranged from 65 to 99 %, and recurrence rates ranged from 21 to 72 %, with most occurring within 13 months of radiation treatment. Risk factors for increased recurrence after adjuvant radiation therapy include a keloid with a diameter greater than 2 cm, prior treatment of the keloid, and male gender. Also, one of the advantages of radiation therapy is the amelioration of pruritus and tenderness often associated with keloid lesions.

Adverse effects include hypo- and hyperpigmentation, erythema, telangiectasia, ulcerations, and atrophy. Radiation-induced malignancies from scar treatments are rare. The total-body radiation dose from a superficial low-voltage radiotherapy technique is low, and it is difficult to definitively implicate this kind of treatment as the cause of neoplasm. There is concern regarding the use of radiation in pregnant women and children as well as in regions of the body with high carcinogenic potential (i.e., breast, thyroid).

The selection of radiation type, i.e., a conventional radiotherapy (RT), brachytherapy or electron therapy, or fractionating, should be made individually by the treating radiation therapist. The current use of radiotherapy for keloids in routine practice is limited both because of the nonavailability of the modality in most centers and also a general understanding about its use. Treatment should preferentially be performed in specialized clinics with interdisciplinary consultation (dermatology, surgery, nuclear medicine). It may be an effective option for recalcitrant and large keloids not responding to other treatments.

Intralesional Therapy

Corticosteroids

Intralesional corticosteroid injections are one of the most common approaches in therapy of hypertrophic scars and keloids. Most of the known effects of corticosteroids are thought to result primarily from its suppressive effects on the inflammatory process in the wound. In addition corticosteroids reduce the excessive growth of the scar by diminishing collagen synthesis as well as glycosaminoglycan synthesis and inhibiting fibroblast proliferation.

The most used corticosteroid is triamcinolone acetonide (TAC, 10–40 mg/mL, maximally 5 mg/cm^2), pure or diluted with 0.9 % NaCl or lidocaine 1:2–1:4, injected strictly intralesional. The concentration of triamcinolone acetonide depends upon the size and site of the lesion and age of the individual. It is important to inject the steroid at a correct depth in the mid-dermis; otherwise, it may lead to irreversible atrophy. A blanching effect signals the endpoint of the infiltration. Further injections are performed as needed at 3–4-week intervals, and usually two or three sessions are sufficient. Occasionally, injections are continued for 6 months or more. The total number of injections depends on the response and possible side effects. Response rates have been highly variable, ranging from 50 to 100 %, and a recurrence rate is reported to be 9–50 %.

When used alone, intralesional corticosteroid injections have the best effect on younger keloids, which can become completely flattened. In older hypertrophic scars and keloids, corticosteroids can soften and flatten the scars only to some degree and can provide symptomatic relief. Injections may be used alone or combined with other therapies, of which the combination with cryotherapy or surgery is the most widely used modality in clinical practice.

Side effects include dermal atrophy, telangiectasia, and pain at the site of injection. The latter can be averted by topical anesthesia and/or regional injections of local anesthetic around the scars. With available evidences, intralesional steroids should be considered as the first-line treatment for early keloids and a second-line treatment for early hypertrophic scars if other easier treatments have not been efficacious.

5-Fluorouracil (5-FU)

Recent data suggest that intralesional 5-FU injection is a safe new efficient tool in the ongoing battle against keloid scars. This treatment is increasingly becoming popular, because of good results. As a nucleotide analog (pyrimidine analog) that incorporates into DNA in place of uracil, 5-fluorouracil (5-FU) inhibits DNA synthesis, especially in rapidly proliferating cells, and has been shown to inhibit fibroblast proliferation in vitro and in vivo. It also has an inhibitory effect on type I collagen gene expression in human fibroblasts through inhibition of TGF signaling.

5-FU alone is effective in the treatment of keloids, but there are recommendations that for better results, it can be combined with surgical excision, as it prevents recurrence after excision in a majority of patients. Also, there is evidence that a combination of triamcinolone and 5-FU results in less skin atrophy and telangiectasia than triamcinolone alone. Recommended doses vary from different authors, from 50 mg per session (total exposure 50 mg) to 150 mg per session (total exposure 1,200–2,400 mg). Further work to determine appropriate doses should be initiated. Adverse effects of 5-FU include skin ulceration, burning, pain, and hyperpigmentation.

Bleomycin

Bleomycin is a polypeptide antibiotic isolated from a strain of *Streptomyces verticillus* with antitumor, antibacterial, and antiviral properties. In addition to blocking the cell cycle, bleomycin also directly inhibits collagen synthesis via decreased stimulation transforming growth factor β1 and induces fibroblast apoptosis. It was first investigated in the mid-1990s as a scar-reducing agent.

Only few relevant studies have investigated the efficacy of bleomycin in the treatment of hypertrophic scars and keloids. It can be administered

either by intralesional injections or by multiple punctures. A recent technique for delivering bleomycin to these lesions is called bleomycin tattooing in which multiple punctures are made on the keloid or hypertrophic scar with a 25-gauge needle and bleomycin (2 mL/cm^2) is dripped onto the lesion. In one randomized controlled trial, the relative mean resolution score in the bleomycin tattoo group was approximately 88 %, with a complete response observed in 47 % of patients.

Locally applied bleomycin results in minimal side effects, with transient hyperpigmentation and mild to moderate local pain among the most common. Systemic toxic effects of intralesionally administered bleomycin seem to be uncommon. Bleomycin may thus be a promising agent for the therapy of keloids and hypertrophic scars; however, further investigation and efficacy trials are needed before this agent is included in future treatment protocols.

Interferons (INF)

Interferons are cytokines secreted by T-helper cells that, apart from other properties, interferes with collagen synthesis and fibroblast proliferation, increases collagenase activity, and inhibits overproduction of collagen and glycosaminoglycans by fibroblasts. All interferon isoforms (a, b, g) have been shown to have these effects, but most of them have been applied only experimentally and in small numbers of patients.

Specifically, IFN-alfa-2b has been proposed to have antiproliferative properties, and it may improve the pathologic features of dermal fibrosis directly or by antagonizing the effects of TGF-β. It can be used as monotherapy or as adjunctive therapy. Conclusions from trials of interferon as monotherapy have shown inconsistent results, but as postoperative therapy or in combination with other treatment methods, interferon seems to be more promising, with lower recurrence rates and better outcomes. However, contradictory results have also been reported, so current evidence is therefore not sufficient to recommend the routine use of interferons. It may be used in selected cases, particularly when the other treatment modalities have failed. Adverse effects are common with the use of interferons and include flu-like symptoms (fever, chills, night sweats, fatigue, myalgia, and headache) and pain on the site of injection.

Cryotherapy

Cryotherapy has been used as monotherapy and in conjunction with other forms of treatment for both hypertrophic scars and keloids. The low temperature induced by cryogens causes vascular damage leading to anoxia, thrombosis, and consecutive ischemic cell death.

Cryotherapy delivery methods include contact, sprays, and intralesional needles. Response to cryosurgery has been reported as high as 80 %, but newer keloids that are more vascular are more susceptible to this kind of therapy than chronic, older keloids. Also, there is a better response in smaller keloids. Success rates in studies in which contact or spray cryosurgery with liquid nitrogen was used varied between 32 and 74 % after two or more sessions, with higher response rates of hypertrophic scars compared with keloids. Treatment recommendations include two 15- to 20-s thaw cycles performed on each visit every 3/4 weeks for a total of eight to ten visits. Recently, the intralesional-needle cryoprobe method has been assessed in the treatment of hypertrophic scars and keloids and has been demonstrated to have successful results. Compared with that obtained with contact/spray probes, there is shorter reepithelialization time, and it requires fewer treatments to achieve results.

Cryotherapy is often used in combination with intralesional corticosteroids, and this combination is superior to either treatment alone. Cryotherapy is used directly before the administration of intralesional corticosteroid injections, because success rates seem to be increased with this sequence. One study found that this combination therapy produced an 84 % positive response rate. Lesions treated with combination therapy require fewer procedures and have lower recurrence rates.

Immediate local complications associated with cryotherapy include pain, stinging sensation, edema, and bulla formation. Other adverse effects include atrophy, necrosis, and hypopigmentation and hyperpigmentation. The risk for pigment abnormalities is related to the duration of freezing as well as the number of sessions. A freeze/thaw time that exceeds 25 s may lead to destruction of the cold-sensitive melanocytes, thereby causing hypopigmentation, and should be avoided to achieve cosmetically successful results.

Silicone-Based Products

Silicone therapy was first reported in the early 1980s, and since than an effective and well-established therapy has become the noninvasive standard of care for scar management. The mechanism of action remains not completely determined. Presumed effects include hydration of the stratum corneum, increased skin surface temperature, development of a static electric field, reduction of evaporation, and oxygen transmission. Also, it is likely that silicone products act on the epidermis to initiate signaling cascades that affect dermal fibroblasts.

Silicone is available as cream, gel sheet, strip, spray, and foam. To be effective, silicone sheet must be used over the scar for 12–24 h per day for 2–3 months, with removal for routine hygiene. The sheets can be reused until they start to disintegrate. Silicone gel is better for areas of consistent movement, where sheeting will not conform, and should be applied twice daily. Positive effects from silicone products that have been reported include reduction of erythema, pigmentation, and induration and an improved overall appearance. Silicone products may be especially useful in patients who cannot tolerate the pain associated with other treatment procedures.

Results from numerous randomized controlled trials demonstrate that silicone is safe and effective for the treatment of hypertrophic scars and keloids with consistent treatment effects. In the past years, more and more studies have supported the use of silicone gels for prophylaxis of abnormal scarring. In a Cochrane Review the benefit of silicone use in scar prevention in patients with a predisposition to developing keloids after surgery was confirmed.

In patients who are known to have predisposition to form hypertrophic scars, application of topical silicone gel sheets should begin as soon as reepithelialization is finished, and daily application for at least 12 h is recommended. It is unknown what exact duration of treatment is needed for maximum benefit.

The efficacy of silicone gel dressings depends on the location of the scar, early commencement, the grade of response, and patient compliance. Side effects are minimal and very rare; however, rashes, pruritus, maceration, and dryness of the skin have been reported.

Surgical Excision

Although surgical excision is the most practical, effective, and traditional treatment for keloids and hypertrophic scars, it is very important before starting any surgical intervention to clearly differentiate the type of scar.

In case of hypertrophic scars, the timing of surgical intervention is an important consideration in the treatment protocol. This type of scar is formed during a period of at least 1 year, and in the course of that year, the scar can show decreased contractures along with flattening, softening, and repigmentation. Surgical excision thus might not be needed, even though postexcisional recurrence rates of the original hypertrophic scar are usually low.

In contrast, recurrence rates of keloids, after excision, range between 45 and 100 %, and surgical removal is not recommended as monotherapy. Excising the abnormal keloid tissue creates a new wound where new collagen begins to form; unfortunately, a larger and more aggressive keloid can recur in its place. Ideally surgical excision of keloid should be avoided as far as possible. Sometimes surgery can be used to treat keloids in order to reduce keloid mass (remove infected regions and provide symptomatic improvement).

In combination with other different treatment modalities, the recurrence rate is lower, between

8 and 50 %. Adjuvant therapy for surgical intervention for keloids can be the preoperative and/or postoperative use of intralesional corticosteroids, pressure therapy, interferon injections, and radiation therapy; these combinations all have shown promising results.

There are many methods for scar removal, including simple scar revision, resurfacing with skin grafts, local or distant flaps, intrascar excision, geometric broken line closure, and dermabrasion. Tangential shaving leads to better healing and reepithelialization, better cosmetic outcomes, and less recurrence rates, and it is a method of choice for earlobe keloids. Z-plasty, W-plasty, and V-Y and Y-V advancement flaps are some of the techniques currently used to remove keloids.

Lasers

Since the introduction of laser treatment for keloids in the mid-1980s, various lasers have been evaluated for the treatment of hypertrophic scars and keloids, with varied success. Current data is difficult to compare due to different laser systems, too small case numbers, too short follow-up periods, lack of information on the age and activity of the scars, and lack of differentiation between hypertrophic scar and keloids. Commonly used ablative lasers include the CO2 and erbium:YAG (Er:YAG) lasers, and nonablative lasers include the pulsed dye laser (PDL) and the Nd:YAG laser.

CO2 lasers emit light at a wavelength of 10,600 nm, which is strongly absorbed by water in the tissue, producing vaporization. In hypertrophic scars and keloids, the CO2 laser causes focal necrosis, which leads to collagen remodeling and lesion contraction. The CO2 laser may be used as monotherapy, but optimal treatment occurs when used in conjunction with intralesional corticosteroids. Intralesional steroids injected at regular 3- to 4-week intervals for up to 6 months demonstrated a lower recurrence rate compared to irregular-interval injections. Adverse events associated with the CO2 laser include erythema, reversible hyperpigmentation, and permanent hypopigmentation.

The Er:YAG laser emits infrared light at a wavelength of 2,940 nm and is more strongly absorbed by water than the CO2 laser. A randomized clinical trial found the Er:YAG laser to be effective in improving the elevation and vascularity of hypertrophic scars, with fewer side effects than the CO2 laser.

The use of the long pulsed 1,064-nm Nd:YAG laser, which selectively inhibits collagen production based on in vivo and in vitro studies, in the beginning demonstrated softening and flattening of keloids. Results, however, were transient and scar recurrences were common. Side effects were mild and included a prickling sensation during treatment and post-treatment erythema. Nevertheless, more studies are necessary to elucidate the effect of an Nd:YAG laser for the treatment of hypertrophic scars and keloids.

Until today, the most encouraging results have been obtained with the 585-nm pulsed dye laser (PDL), which has been recognized as an excellent therapeutic option for the treatment of younger hypertrophic scars and primarily keloids. Research studies since the mid-1990s have shown evidence of improvement in scar erythema, texture, height, pliability, and associated symptoms using the flashlamp-pumped 585-nm PDL for treating both hypertrophic scars and keloids, with low recurrence rates and a low adverse effect profile. Several theories have been proposed on the mechanisms by which this laser achieves clinical effects. By causing tissue hypoxia via destroying blood vessels, the 585-nm PDL therapy is believed to induce neocollagenesis, collagen-fiber heating with disruption of disulfide bonds, resulting in reorganization and realignment of collagen fibrils. Irradiation with the flashlamp-pumped 585-nm PDL may also affect collagen remodeling through cytokine stimulation and reduce extracellular matrix expression by reducing transforming growth factor β1. Adverse effects include transient hyper- or hypopigmentation and blistering. The most common adverse side effect of 585-nm PDL treatment is postoperative purpura, which can persist for 7–10 days.

The recommended protocol for the treatment of hypertrophic scars and keloids with the 585-nm PDL is the use of nonoverlapping laser pulses at fluences ranging from 6.0 to 7.5 J/cm^2 (spot

size 5–7 mm) or from 4.5 to 5.5 J/cm^2 (spot size 10 mm). Lower fluences should be applied at initial treatment sessions, with upward adjustments. Two to six treatments may be necessary to successfully improve scar resolution.

Onion Extract

Onion extract is found in numerous scar treatment products. It is currently believed that the flavonoids (quercetin and kaempferol) in onion extract play the main role in reducing scar formation. This "botanical" ingredient exhibited anti-inflammatory, bacteriostatic, and collagen downregulatory properties in a rabbit ear model, but in humans the results are controversial. Quercetin, a dietary bioflavonoid, has been recently shown to inhibit fibroblast proliferation, collagen production, and contraction of keloid and hypertrophic scar-derived fibroblasts. But former clinical studies are contradicting, regarding its efficacy, so the role of onion extract remains questionable.

Imiquimod

Imiquimod is a topical immune response modifier and is approved for the treatment of basal cell carcinomas, actinic keratoses, and genital warts. Imiquimod stimulates interferon alfa, a proinflammatory cytokine, which increases collagen breakdown. Therefore, imiquimod 5 % cream has been used after excision in an attempt to reduce keloid recurrence, and it was reported to have positive effects on the recurrence rate of keloids. However, there are contradictory data in other studies, so additional investigations with a larger sample size and longer follow-up are necessary to determine the role of imiquimod 5 % cream in hypertrophic scar therapy.

Combination Therapy

Numerous therapeutic strategies have been described for prevention and reduction of hypertrophic scars and keloids, but none of the treatments is effective in all patients. No universal consensus in treatment regimen has been established, and there is limited evidence-based literature to guide the correct management. There is a great need for additional clinical studies, well-designed, double-blind, placebo-controlled, and randomized with objective and standardized evaluative measures. A polytherapeutic approach to the treatment of abnormal scars has a best chance to help, and the right combination of treatments designed for each individual patient is the goal of every therapist.

Keratoacanthoma

48

Rodrigo Roldan, Josep Malvehy, and Susana Puig

Key Points

- Keratoacanthoma probably lies within the spectrum of intraepidermal keratinocyte neoplasia and is possibly related to squamous cell carcinoma. The majority of lesions regress spontaneously. There are both surgical and chemotherapeutic treatment options.
- Keratoacanthoma is a lesion that usually undergoes three phases: rapid growth, maturation and regression.
- There are several forms of solitary keratoacanthomas as well as syndromes involving multiple lesions. Some of these syndromes are familial.
- The major risk factor for developing this lesion is sun exposure.
- The specific aetiology of keratoacanthoma formation and regression, including the potential role of infectious, environmental and genetic factors, is not yet known.
- Keratoacanthoma shares several histologic features of squamous cell carcinoma. There are various features that usually distinguish keratoacanthoma from squamous cell carcinoma; however, no one architectural or histopathological marker clearly delineates between the two.

Definition

Keratoacanthoma (KA) is an epidermal neoplasm of the skin and mucous membranes that exhibits rapid growth, maturation and regression. It occurs most often on the sun-exposed areas of fair-skinned adults and is thought to arise from cells in the hair follicle. The exact biologic behaviour of keratoacanthoma remains controversial. In the past it had been considered a reactive condition or pseudomalignancy which could be treated expectantly. Now the favoured view is that KA is a malignant tumour with low, but not negligible, metastatic potential, which in many cases will regress. Even those that ultimately involute can cause considerable

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_48, © Springer-Verlag Berlin Heidelberg 2015

destruction before they regress. The regression may be partially mediated by immunity, but takes the form of terminal differentiation. The exact course of these tumours is unpredictable. Recently, the clinical behaviour of KA was retrospectively reviewed in 445 cases published in 113 articles. In all cases follow-up and outcomes had been reported, and none of these resulted in death or distant metastases. Yet, in the immunosuppressed patient, any lesion with histologic features of keratoacanthoma should be managed as a squamous cell carcinoma, with complete eradication.

There are four types of keratoacanthomas: solitary, multiple, eruptive and keratoacanthoma centrifugum marginatum.

Epidemiology

The incidence of solitary keratoacanthoma is highest in fair-skinned individuals, and the majority of the lesions occur on sun-exposed areas of the body. In 1963, Ghadially documented that KA occurs twice as often in men than in women and that the most frequently affected age group was 60–65, while the average age was 56. From this group, 90 % of the lesions were on sun-exposed skin with the cheeks, nose and dorsa of the hands being most commonly affected. In 1984, Kligman and Callen noted that the majority of the lesions occurred on sun-exposed skin and were accompanied by actinic damage, including a "leathered" aged appearance, actinic keratosis, other cutaneous neoplasms, solar lentigines, poikilodermas or a combination of these findings.

The incidence of Japanese Hawaiians seeking care for KA between 1983 and 1987 was 22.1/100,000, while the incidence in white Hawaiians was 104/100,000 and the incidence in Japanese residing in Japan was approximately 0.1/100,000. Dufresne et al. in Rhode Island, an area with marked seasonal variation in temperature and daylight hours, noted a statistically significant increase in the presentation of keratoacanthoma during the summer months. More recently, other authors also found differences in the seasonal appearance of KA; the tumour occurred more frequently in the winter months in Houston, Texas, versus June, November and December in Minneapolis, Minnesota.

Multiple keratoacanthomas of the Ferguson-Smith variant are an autosomal dominant disorder in which lesions may be numerous (up to hundreds) and both men and women are equally affected. Although lesions can begin as early as infancy, the mean age of onset is 25.5 years for women and 26.9 for men (Schwartz 1994).

Basic Concepts of Pathogenesis

A single cause for keratoacanthoma is unknown. The lesion occurs most often on hair-bearing, sun-exposed skin, but can occur on non-hair-bearing, sun-protected skin as well. For instance, keratoacanthoma has been reported on the hard palate, tongue, gingiva, lip (Fig. 48.1), nasal mucosa conjunctiva, anal mucosa, vulva, palms and soles.

Several proposed aetiologic mechanisms include:

Sun Exposure

The fact that most KAs occur on sun-exposed skin and occur more often in individuals who spend more time in the sun implies a connection between solar radiation and the lesion's pathogenesis. The

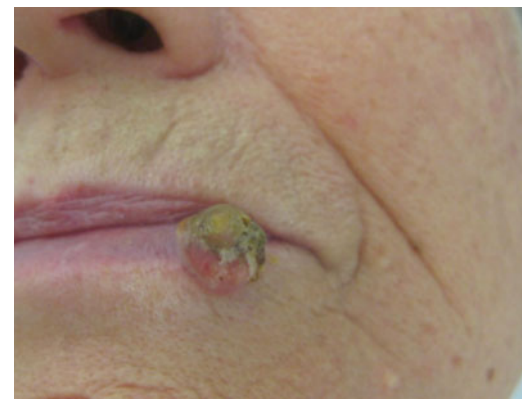

Fig. 48.1 Large keratoacanthoma of the lip

specific mechanism is unclear. Filipowicz et al. have demonstrated that the apoptotic mediator CD95 (Fas) is downregulated in two-thirds of keratoacanthoma lesions developing on sun-exposed skin. This data suggests that loss of the protective apoptotic mechanism may be one path to keratoacanthoma formation. A similar downregulation of CD95 was also seen in other lesions such as actinic keratosis, squamous cell carcinoma and basal cell carcinoma, and indeed these lesions have been described as occurring in the same patients and the same sun-exposed areas of the skin as KA.

Other Radiation-induced Forms

There have been case reports of keratoacanthoma occurring after cutaneous exposure to radiation therapy. Shaw et al. described the development of several keratoacanthomas on the face of a woman shortly after radiation therapy to her sinuses for a squamous cell carcinoma. There have also been case reports of psoralen and ultraviolet A (PUVA) therapy inducing keratoacanthoma. Brazzelli et al. reported keratoacanthoma arising in a vitiligo lesion after a prolonged course of UVB narrowband (UVB-NB) therapy.

Trauma

There have been numerous reports of keratoacanthoma developing at sites of skin trauma, even in young patients. Several specific case reports describe KA formation at the margins of excisions and skin grafts. Keratoacanthomas have also developed at the site of thermal burns and CO2 laser resurfacing. Kaptanoglu and Kutluay described a keratoacanthoma developing in previous cryotherapy sites for actinic keratosis.

Viral

There have been numerous studies suggesting a possible viral aetiology in the formation of keratoacanthoma. Specifically, HPV DNA has been demonstrated in several keratoacanthomas by various techniques including in situ hybridisation and PCR. Stockfleth et al. suggested that HPV infection does not cause KA formation in all people, but may be one predisposing factor in some patients and a cofactor for malignant transformation.

Hair Follicle Cycling

Ghadially proposed pathways by which keratoacanthomas develop from cells in the hair follicle. The cyclic nature of hair growth – anagen (growth phase), catagen (regression phase) and telogen (resting phase) – presents a similarity to the rapid growth, maturation and regression of most keratoacanthomas. The mechanism of formation of lesions on the mucosa and other non-hair-bearing skin is not known. It is also interesting to note that KA arising in the subungual area may arise from cells in the nail bed which grow constantly and do not cycle; thus, it seems logical that keratoacanthomas arising in this area would rarely show spontaneous regression. In fact keratoacanthomas of the subungual area often continue to grow, without regression, causing severe local tissue and bone destruction.

Immune Factors

Patel et al. demonstrated significant differences in the profiles of immune cells invading keratoacanthomas and squamous cell carcinomas. The infiltrates of KAs were demonstrated to be higher in CD3+ and CD4+ cells as well as cells expressing the interleukin-2 receptor and the adhesion molecule, CD36.

Keratoacanthomas tend to develop more frequently in immunosuppressed patients, and the lesions tend to be more locally aggressive in this population. These differences suggest that there is an immunologic role in KA regression, although a specific mechanism has not been elucidated.

Genetics

Several forms of keratoacanthoma express specific genetic patterns. KAs are found in conjunction

with sebaceous skin tumours and internal malignancies in Muir-Torre syndrome. This syndrome is a variant of the hereditary nonpolyposis colon cancer (HNPCC) syndrome and is inherited in an autosomal dominant pattern. Patients with Muir-Torre syndrome have germline mutations in their DNA mismatch repair genes. Several researchers have utilised microsatellite instability to document mutations in MSH-2 and MLH-1 mismatch repair genes in lesions from patients with both Muir-Torre syndrome and HNPCC (Machin et al. 2002).

DNA repair defects also characterise xeroderma pigmentosum, a syndrome in which keratoacanthomas are seen with actinic keratosis, basal cell carcinoma, squamous cell carcinomas and melanomas on sun-exposed skin.

Ferguson-Smith keratoacanthomas also demonstrate an autosomal dominant pattern of inheritance, and KAs of the Witten-Zak type have been reported in families.

Activated ras genes have been detected in several tumours including keratoacanthoma. RAS is a family of proteins involved in cell signal transduction that normally cycle between active and inactive states. Mutations in the ras gene can lead to proteins that are disproportionately active and thus tumorigenic. In a study by Peng et al., rabbits were altered to express human EJras, a RAS mutant, and all of these transgenic rabbits developed keratoacanthomas approximately 3 days after birth. Additionally, nearly all of these lesions spontaneously regressed. Clearly, mutations in this family of RAS proteins have the potential to explain KA formation in humans.

Vemurafenib, a fibrosarcoma kinase B (BRAF) inhibitor, is the first molecularly targeted therapy for the treatment of advanced-stage melanoma licensed in the USA and Europe. Its mechanism of action involves selective inhibition of the mutated BRAF V600E kinase that leads to reduced signalling through the aberrant mitogen-activated protein kinase (MAPK) pathway. Vemurafenib use can be associated with the development of cutaneous neoplasms such as squamous cell carcinoma and keratoacanthoma as a side effect. These lesions often arise weeks after initiation of therapy often in sun-exposed areas. The precise mechanism by which BRAF inhibition promotes the appearance of keratinocyte neoplasms is not yet fully understood (Fig. 48.2). However, the prevailing hypothesis is that in the context of a hyperactive mutant RAS gene and a normal BRAF gene, BRAF inhibitors, including vemurafenib, paradoxically activate ERK signalling by promoting the formation of CRAF-containing dimers, leading to hyperproliferation and tumour formation. Su and colleagues provide evidence supporting such a mechanism by showing that 60 % of the cSCCs and KAs in vemurafenib recipients had RAS mutations (mostly in HRAS) – a rate higher than the 3–40 % usually seen in sporadic cutaneous squamous cell carcinomas. Furthermore, cells overexpressing mutant RAS hyperproliferated in the presence of the drug, and skin tumours developed sooner in mice with Hras mutations induced by a vemurafenib analogue.

Clinical Presentation

Keratoacanthoma is a lesion that undergoes three phases: proliferation, maturation and regression. These phases correlate with both its clinical and histological appearances. In the early proliferative phase, KA appears as a flesh-toned to pink bud, dome- or berry-shaped papule that grows rapidly over the course of several weeks into a firm nodule that often has scale on top. During the maturation phase, a central, firmly embedded keratin plug develops (Figs. 48.1 and 48.2). This plug may appear verrucous, may grow to resemble a cutaneous horn (Fig. 48.2) or may become more darkly pigmented with the appearance of a necrotic centre. The firmly embedded keratinous plug cannot be dislodged with ease. The periphery of the lesion is often erythematous and slopes down to merge with the surrounding normal skin.

The tumour is usually not fixed to deeper structures. In the regression phase, the lesion involutes and eventually expels its keratinous centre. Regression usually results initially in a saucer-shaped depression when the plug is dislodged; this evolves into an atrophic, hypopigmented, depressed scar. KA often traverses its entire lifecycle within 2–6 months.

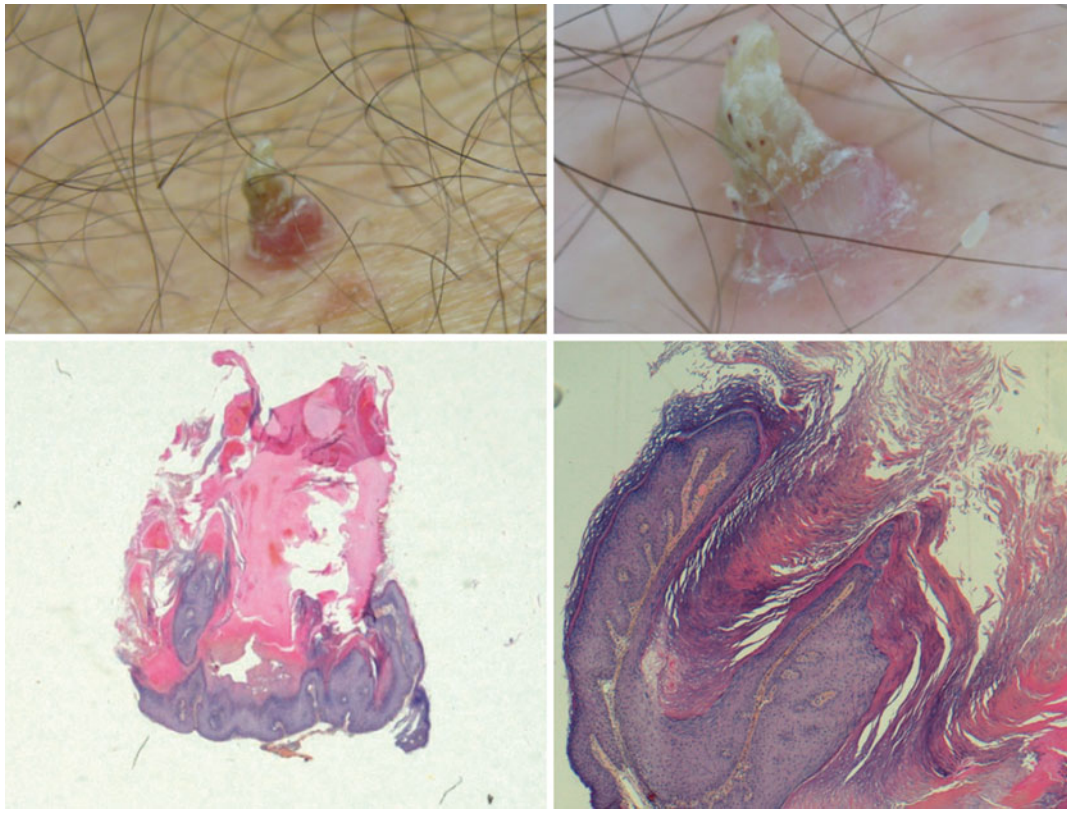

Fig. 48.2 Clinical (*upper left*) and dermoscopy (*upper right*) images of a keratinasing tumour induced during treatment with BRAF inhibitor. Clinically the lesion shows a bright pink elevated tumour with a central horn. Dermoscopy shows a lesion filled by keratin, hair pin vessels and blood spots. The histologic diagnosis is based on the architectural pattern of the lesion at scanning magnification (*down left*). The centre of the lesion shows a crater filled with eosinophilic keratin. Over the sides of the crater, a "lip" or "marginal buttress" of epithelium extends over the keratin-filled crater. At the base and sides of the crater (*down right*), the epithelium is acanthotic and composed of keratinocytes which are highly keratinised and have an eosinophilic, glassy cytoplasm with mild cytologic atypia

Under dermoscopy classical mature KAs are characterised by the presence of hairpin vessels surrounding the centre of the lesion filled by keratin. Hairpin vessels are surrounded by a whitish halo as in other keratinising tumours (Figs. 48.2 and 48.3). Recently, Rosendal et al. described the main dermoscopic criteria present in keratoacanthomas and squamous cell carcinomas, adding to the classical criteria the presence of white circles and blood spots. Central keratin was more common in keratoacanthoma than in SCC (51.2 % vs 30.0 %, $P=0.03$) with highest sensitivity for keratoacanthoma SCC (79 %), and white circles had the highest specificity (87 %). In a multivariate model, white circles, keratin and blood spots were independent predictors of SCC and keratoacanthoma.

Solitary Keratoacanthoma

Solitary keratoacanthoma is the most common form of this tumour. It occurs most often on the sun-exposed, hair-bearing skin, especially the face and dorsal hands, of adults with fair complexion. Solitary keratoacanthoma has the classic appearance of a rapidly growing hemispheric nodule (2–6 weeks) with a central keratin-filled crater that spontaneously regresses over a period of months. Lesions tend to be single, but there

Fig. 48.3 Clinical (*left*) and dermoscopy (*right*) images of a keratinasing tumour induced during treatment with BRAF inhibitor. Clinically the lesion shows a bright pink elevated tumour with a central horn. Dermoscopy shows a lesion filled by keratin, hair pin vessels and blood spots

can be several lesions or additional lesion formation over the course of the patient's lifetime. It has been estimated that some 5 % of treated lesions recur. Invasion along nerve trunks has been documented and may result in recurrence after a seemingly adequate excision.

Giant Keratoacanthoma

A KA is considered giant if it grows larger than 3 cm in diameter. Giant keratoacanthoma may be locally invasive and disfiguring or may remain superficially situated. In spite of its size, it can still demonstrate complete, spontaneous regression.

Keratoacanthoma Centrifugum

Keratoacanthoma centrifugum marginatum is a rare, most commonly solitary, large lesion demonstrating a plaque-like appearance with central clearing and scarring. The diameter is similar to or larger than giant KA, but the proportions have changed so that the lesion is flat and atrophic in the centre with a raised rim that grows outwards and demonstrates keratin production. The dorsum of the hands and pretibial regions are favoured sites. Keratoacanthoma centrifugum marginatum often does not regress and can pose a significant therapeutic challenge.

Subungual Keratoacanthoma

Subungual keratoacanthoma is a rare tumour derived from the nail bed. It causes significant tissue destruction and does not regress. These lesions, classically, cause cup-shaped osteolysis without periosteal reaction in the underlying distal phalanx due to pressure erosion. Other

symptoms include local swelling, erythema, pain, nail bed deformity and in some cases bacterial superinfection. It may occur on the proximal nail fold and may involve nails of the fingers or toes, although they are seen most often on the thumb, index and middle fingers of patients in the third through seventh decades.

Multiple Keratoacanthoma Syndromes

Ferguson-Smith-Type Keratoacanthomas

Multiple KAs of the Ferguson-Smith type are an autosomal dominant disorder seen most commonly in males (3:1 predominance) with an onset in the second and third decades of life. The lesions occur first in small crops and are self-healing with scar formation. Sun-exposed sites are favoured, especially the ears and nose, and in most cases scalp lesions occur. The lesions tend to recur periodically throughout life, and later developing lesions have a lower tendency to spontaneously regress.

Generalised Eruptive Keratoacanthomas of Grzybowski

Grzybowski first described a very rare and sporadic form of eruptive keratoacanthomas in which thousands of small 1–5 mm KAs appear simultaneously or progressively. The lesions are more concentrated on sun-exposed skin, but also involve the oral mucosa, larynx and intertriginous areas. The lesions can appear in groups or clusters and demonstrate Koebnerization. Because of the severe facial involvement and resultant scarring, patients exhibit masked facies and ectropion. This variant has been reported in white, Asian and black patients with equal incidence in men and women.

Witten and Zak-Type Keratoacanthomas

In Witten and Zak-type keratoacanthomas, there is a combination of both Ferguson-Smith-type lesions and the smaller eruptive Grzybowski-type lesions. This variant has been reported in multiple siblings of the same family.

Histology

The histologic diagnosis is based on the architectural pattern of the lesion, which is best evaluated at scanning magnification (Fig. 48.2). This is true at each stage of the lesion's evolution.

The centre of the lesion shows a crater filled with eosinophilic keratin, with orthokeratotic and parakeratotic cells. Over the sides of the crater, which seems to have been formed by the invagination of the epidermis, a "lip" or "marginal buttress" of epithelium extends over the keratin-filled crater. At the base and sides of the crater, the epithelium is acanthotic and composed of keratinocytes which are highly keratinised and have an eosinophilic, glassy cytoplasm. Mild cytologic atypia is common. Mitotic figures, necrotic and dyskeratotic keratinocytes and acantholytic keratinocytes are prominent. Microabscesses of neutrophils often admixed with eosinophils are noted within the hyperplastic epidermis.

The surrounding dermis has a moderately dense perivascular or lichenoid mixed inflammatory infiltrate composed of lymphocytes, eosinophils and plasma cells.

The most definitive histologic feature is evidence of terminal differentiation, where the scalloped outer border of the tumour has lost its infiltrative character and is reduced to a thin rim of keratinising cells lining a large keratin-filled crater.

There are no histologic findings proven to predict biologic behaviour. The number of mitotic figures, perineural invasion and extension into subcutaneous tissue do not appear to differentiate between those lesions that will involute spontaneously and those that will persist.

Some reported metastases of keratoacanthoma to the lymph node have retained the architectural and cytologic features of the primary fully developed lesion.

The differential diagnosis with well-differentiated squamous cell carcinoma is sometimes difficult. Unfortunately, there is no single diagnostic marker study to date that can reliably differentiate KA from SCC.

Interestingly, recently a study was carried out to assess syndecan-1 (CD 138) and Ki-67 expression to differentiate keratoacanthoma

(22 samples) from squamous cell carcinoma (17 samples). Syndecan-1 is an adhesion molecule whose expression appears to be inversely correlated with tumour invasiveness. Elevated Ki-67 expression is indicative of a high proliferation index, a feature of malignant tumours. According to the results of this study, syndecan-1 expression is markedly diminished, and Ki-67 expression is significantly increased in SCC compared to KA.

General Principles of Treatment

Although keratoacanthomas usually spontaneously involute, it is impossible to predict how long this will take. If no therapeutic intervention is implemented, the patient may be faced with a destructive growth of a tumour which has a limited tendency to metastasise. More importantly, SCC cannot always be ruled out. Therefore, excisional biopsy should be considered in most cases. Surgery limits the progression and invasion of the lesion and allows for definitive diagnosis. Mohs micrographic surgery has also met with good success in removal of lesions from the head and neck and of recurrent lesions.

Nonsurgical therapy may also be considered in certain anatomical sites to preserve function or to improve cosmetic outcome.

Preferred treatment options vary depending on size and location of the lesion, as well as experience by the physician with each modality.

Intralesional injection of 5-FU solution, 50 mg/mL at weekly intervals; bleomycin 0.5 mg/mL; or methotrexate 25 mg/mL can be effective. For a typical lesion four injections along the base at each pole are recommended.

Topical photodynamic therapy with delta aminolevulinic acid has been successful for solitary and giant KA.

Low-dose systemic methotrexate may be considered if there is no response to intralesional injection or if multiple lesions are present and there is no contraindication.

Both etretinate and isotretinoin in oral doses of 1 mg/kg/day have been reported with good outcome in the treatment of recurrent and multiple KA syndromes.

Topical 5 % imiquimod has been reported as another successful alternative for the treatment of keratoacanthoma.

Excision is recommended if there is not at least 50 % involution of the lesion after 3 weeks.

Markus Streit and Claudia Blazek

Abbreviations

ABI or ABPI	Ankle-brachial pressure index
DVT	Venous thrombosis
ESWT	Extracorporeal shock wave therapy
MPFF	Micronised purified flavonoid fraction
NPWT	Negative-pressure wound therapy
PAOD	Peripheral arterial occlusive disease
PG	Pyoderma gangrenosum
VAC	Vacuum-assisted closure
VAD	Venoactive drugs
wIRA	Water-filtered infrared A

Key Points

- A leg ulcer is a wound located on the lower leg caused by different underlying diseases.
- Vascular diseases dominate the variety of pathologies, but also dermatological, metabolic, haematological, infectious or other disorders can be causative.
- Leg ulcers tend to evolve as chronic wounds, which have failed to heal within an expected time.
- Clinical knowledge and assessment is imperative for correct diagnosis.
- Treatment of leg ulcers encompasses the treatment of the underlying disease and local wound care.

Definition and Epidemiology

Leg ulcers can be defined as any wound located above the foot and under the knee (1). Ulcers on the foot and toes should better be denoted as foot ulcers although they are often numbered among leg ulcers. Leg ulcers – and foot ulcers – most often are chronic wounds. Such wounds have failed to proceed through an orderly and timely process to produce anatomic and functional integrity. The time frame in which a wound is expected to heal is variably estimated by different authors, ranging from 3 weeks up to 3 months. The delay of wound healing can be explained by different factors (e.g. lack of oxygen, bacterial toxins, increased proteinase levels), which are the consequence of a disease that in general is also the cause of the wound.

There are a large number of diseases that can induce a leg ulcer: Vascular, dermatological, metabolic, haematological or infectious diseases can be the cause but also neuropathies, malignancies

and chemical or physical exposure. An overview of underlying diseases is shown in Table 49.1. A chronic wound can only heal if the underlying disease is controlled; therefore it is mandatory to know the cause of a wound and treat it correctly!

Most studies have shown that a venous aetiology (varicose or postphlebitic) is most common in leg ulcers (70–90 %). However a pure venous aetiology should not be overestimated: An additional arterial component can be found in 10–20 % of venous leg ulcers. A recent population-based study among 250,000 people in London found only 43 % pure venous ulcers but a multifactorial aetiology in 35 % (Moffat et al. 2004).

The prevalence of leg and foot ulcers was investigated in large epidemiologic studies in the 1990s analysing more than 230,000 people. An overall prevalence was found in up to 0.3 %, with a prevalence of venous ulcers of 0.16 %. More recent data from Germany have confirmed these data, showing a prevalence of an active venous ulcer in 0.1 % of a general population (more that 3,000 subjects) (Rabe et al. 2003). In elderly people the prevalence is higher (up to 0.3 % in the cited Bonn vein study) with a predominance of females.

Leg ulcers are a major public health concern, representing about 2 % of the UK healthcare budget with costs of £400 million. In Germany annual costs of over two billion Euros were calculated.

Due to the fact that leg ulcer is caused by a huge number of different diseases involving different medical specialities, a multidisciplinary approach is important. A close collaboration of dermatologists, angiologists, vascular and plastic surgeons, internists, rheumatologist and others is a precondition when dealing with leg ulcers.

But also the interprofessional aspect is of relevance: Wound nurses today are experts for the treatment of leg ulcers. Their suggestions for a treatment plan should be taken into account.

Diagnosis

All diagnostic measures should first aim to find the cause of leg ulcer and to establish the diagnosis of the underlying disease!

As most leg ulcers have a venous or arterial aetiology, the first step should always be to *confirm a venous origin and rule out an arterial involvement*. For this purpose, clinical characteristics are important and most helpful.

If a venous and/or arterial origin is not obvious or another aetiology is clinically suspected, diagnostic procedures have to be performed that allow diagnosis of suspected diseases.

Diagnostic steps include the following.

Medical History

Basic information should comprise duration of ulceration, date and modalities of onset, change of shape, characteristics of pain, history of previous ulcers and recurrences and former treatments.

To confirm *venous origin*, personal and family history of venous disease is of interest, e.g. occurrence of varicose veins, earlier venous thrombosis (DVT), former treatments (surgical interventions) and forms of compressions therapy.

To rule out *peripheral arterial occlusive disease* (*PAOD*), one has to ask for intermittent claudication (occurrence of crampy pain in the calf or thigh during walking) or rest pain in the legs (improvement with walking). Risk factors for vascular disease have to be recorded, e.g. arterial hypertension, diabetes mellitus, hypercholesterolaemia and nicotine consumption.

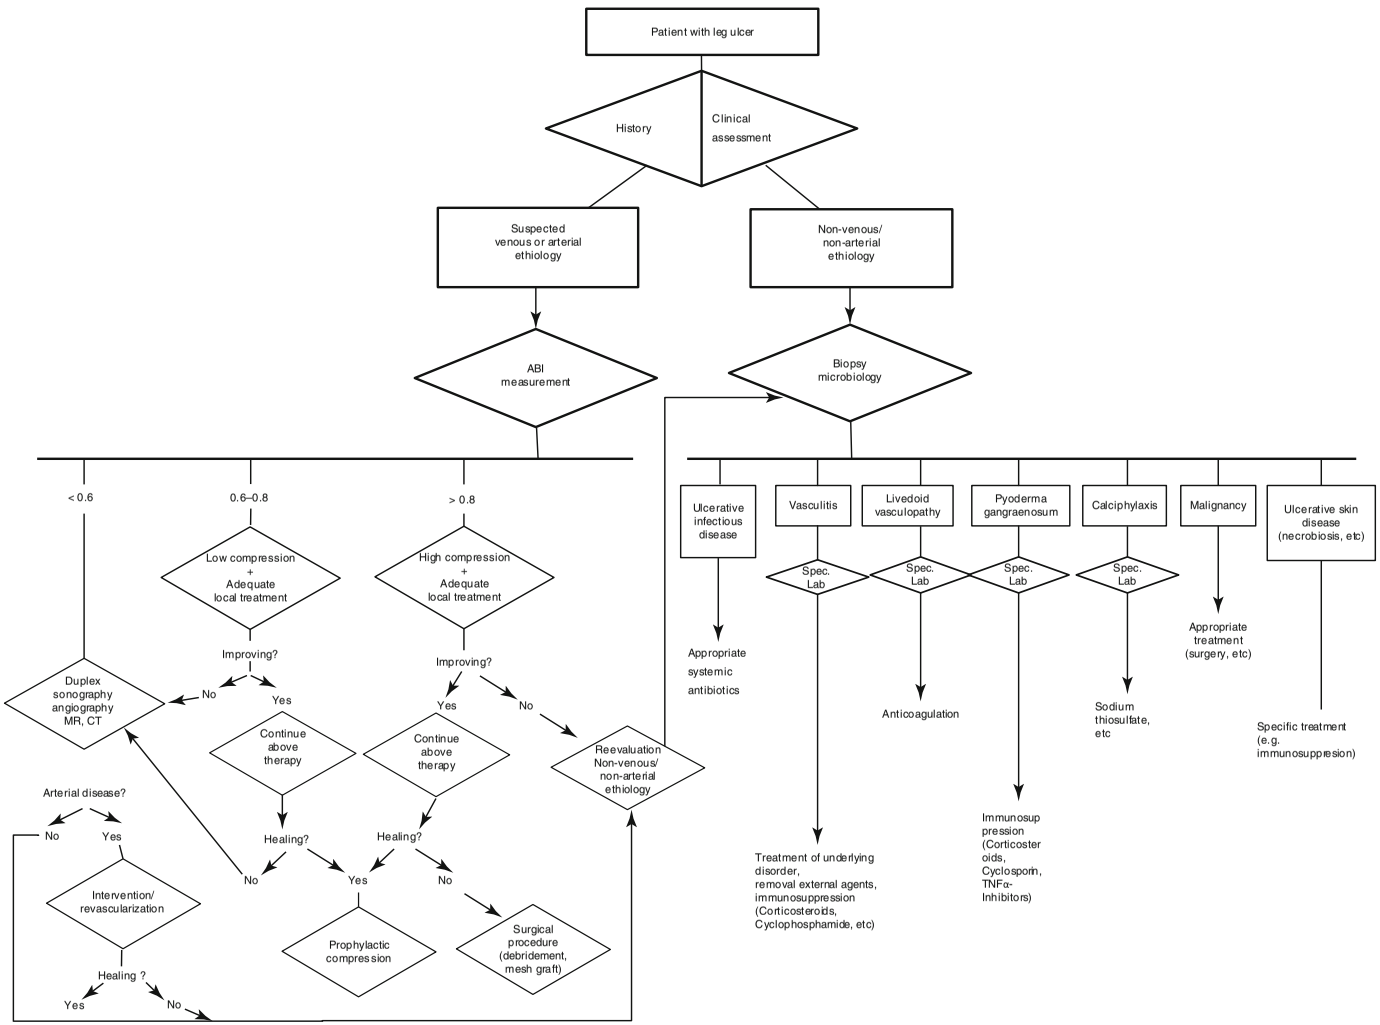
Recording of known diseases, allergies and drug intake is compulsory. Because patients with leg ulcers most often are elder people, information about life situation, impaired mobility and adequate nutrition is of great importance.

Clinical Assessment

The clinical aspect of a leg ulcer is often diagnostic for an underlying disease. Therefore it is crucial to be familiar with typical clinical signs:

- To confirm *venous origin* at a glance, localisation of ulcers is of primary interest: Venous ulcers are typically located around the medial ankle. Lateral or other localisation may occur, in particular in case of lesser saphenous vein insufficiency.
- Most helpful in diagnosing a venous origin of an ulcer are characteristic cutaneous signs of

Table 49.1 Algorithmic steps to achieve correct treatment of a leg ulcer. Rhomboid boxes: diagnostic step or intervention



chronic venous insufficiency, the underlying disease of venous ulcers. These skin changes on the lower leg were listed by Widmer in the 1970s in his classification of chronic venous insufficiency and define stages I and II of the disorder (Widmer and Wandeler 1978):

Look for ankle swelling, pretibial pitting edema and varicose veins, especially corona phlebectasia. Redness and dryness with scaling are signs of venous stasis eczema, small red and brownish spots are typical for purpura jaune d'ocre which can lead to hyperpigmentation. Diffuse redness resembling erysipela is indicative for hypodermitis. Dermatofibrosclerosis and atrophie blanche are typical for longstanding venous insufficiency. – The mentioned clinical signs also define clinical stages C1-4 of the CEAP classification that has been established in the nineties and is today widely accepted for the classification of chronic venous insufficiency (Ad hoc committee American Venous Forum. Classification and Grading of Chronic Venous Disease in the Lower Limbs: A Consensus Statement. Maui, Hawaii, 6th Annual Meeting February 22–25, 1994). (Eklof et al. 2004)

- Pathophysiologically chronic venous insufficiency results from venous hypertension induced by superficial and/or deep venous reflux. Both are mainly consecutive to valvular and/or perforator impairment (destruction in postphlebitic syndrome; incompetence due to venous dilatation) and dysfunction of muscular and articular pump (which supports recirculation of blood from foot to heart).
- Venous hypertension induces major microcirculatory disorders:
  - Dilatation, lengthening and microthrombosis of capillaries.
  - Distension of venular endothelial pores, allowing large plasmatic molecules to escape into the interstitial fluid and thereby inducing pericapillary deposits of fibrin. Increased oncotic pressure then favours the subsequent development of oedema, lymphatic overload and lymphangiopathy.
  - Accumulation and "trapping" of white blood cells in the distal medial part of the dependent legs of CVI patients, plugging of capillaries and releasing of cytokines as well as toxic metabolites.
  - Fibrosis and thickening of the fascia superficialis of the leg, histologically well demonstrated, altering calf muscle pump function.

Taken together, these alterations disturb oxygen diffusion and metabolic exchanges, inducing hypoxia, anoxia and leg ulcers.

- An *arterial involvement* has to be suspected when an ulcer is localised on the lateral aspect of the lower leg and when foot pulses are absent. Arterial ulcers are often more painful than venous ulcers.
- A very painful ulcer on the distal portion of the lower leg above the lateral malleolus with necrotic wound ground and livedoid borders is typical for *Martorell's ulcer* (*hypertensive leg ulcer*). Stenosing arteriolosclerosis is causative for the infarction of the skin that leads to ulceration; foot pulses may be palpable. Arterial hypertension and diabetes mellitus are underlying diseases.
- Ulcers with an atypical localisation, with rolled or everted wound edge, atypical granulation tissue (with hypertrophic, transparent aspect) and an increase of size despite adequate treatment are suggestive for *ulcerative malignancy*. Malignant neoplasias are the cause of a leg ulcer in up to 2.2 %. Basal cell carcinomas can be found most often. Squamous cell carcinoma can occur de novo or arise in long-standing chronic wounds due to "Marjolin transformation". In non-healing ulcers with no suspicious features, carcinoma can be found in 37.5 % (Miller et al. 2004).
- Disseminated necrotic lesions and ulcerations on both legs surrounded by flea bite-like, small red lesions are typical for *small vessel vasculitis*. The small red purple lesions that do not blanch when pressed are diagnostic: Such lesions (petechiae) are caused by extravasation of blood into the skin. This may result from hyper- and hypocoagulable states or vascular pathology. Petechiae that are palpable are indicative for vascular inflammation and therefore almost diagnostic for vasculitis afflicting small cutaneous vessels (palpable

purpura). Petechial lesions may become necrotic and ulcerate. Vasculitic ulcers usually are very painful.

- When ulcers are bizarrely shaped – often with a dendritic form – and surrounded by a purplish discoloration of the skin in a mottled reticulated pattern, *ulcerating livedo reticularis* can be diagnosed. The discoloration (reticular livedo) is caused by swelling of venules due to thrombotic obliteration of capillaries. A variety of diseases can lead to vasoocclusion of small vessels: haematological diseases (e.g. cryoglobulinaemia), autoimmune conditions with vasculitis (e.g. polyarteritis nodosa, systemic lupus erythematosus, etc.) and others.
- Reticular livedo together with atrophie blanche and episodic painful ulcers is diagnostic for *livedoid vasculopathy*. The disease is most often associated with coagulopathies.
- Livedo reticularis, painful panniculitis and large necrotic ulcers are the cardinal signs of *calciphylaxis*. In calciphylaxis pathological calcification of small arteries and fat tissue leads to thrombosis and skin necrosis. The disease most often occurs in patients on dialysis (stage 5 chronic kidney disease) and the term calcific uremic arteriolopathy (CUA) is equally used. However other risk factors have also been identified (elevated serum calcium and phosphate levels, hyperparathyroidism, obesity and type 2 diabetes mellitus, oral anticoagulation with coumarins, arterial hypertension and others). Calciphylaxis is extremely painful and necrosis and ulcerations can rapidly spread out.
- Another form of very painful ulcer that can occur on the lower leg shows undermined violaceous borders and a purulent, cleft wound ground, resembling dirty honeycombs. This corresponds to the classical picture of *pyoderma gangrenosum*, which typically has started with a small, red papule or pustule – looking like a bite reaction – changing into an ulcerative lesion with rapid centrifugal enlargement. Pyoderma gangrenosum is a non-infectious reactive neutrophilic dermatosis that is associated with inflammatory bowel disease, rheumatological and haematological disease and malignancy.
- Disseminated round, punched out lesions with a crusted necrotic surface are typical for *ecthyma gangrenosum*, an ulcerative infectious pyoderma of the skin caused by bacteria (*Pseudomonas*, *Streptococci*, *Staphylococci*). Patients often suffer from a haematological disease or receive immunosuppressive drugs. Diabetes and malnutrition may also favour occurrence of infection.
- Round ulcers with centrifugal enlargement over weeks and with a history of insect bite are suggestive for *leishmaniasis*. Infection is caused by protozoan parasites that are transmitted by the bite of sandflies.
- Round superficial ulcerations could be caused by bullous skin diseases even in the absence of visible blisters. *Bullous pemphigoid*, an autoimmunobullous disorder, can present solely on the legs. Autoantibodies against epidermal basal membrane induce bullous inflammation.
- Ulcerations occurring in well-circumscribed plaque-like areas on the shin with active, more indurated borders and waxy, strophic centres are typical for *necrobiosis lipoidica*. Initially, the underlying skin lesions are reddish brown but progressively become more yellow, shiny and atrophic in appearance. Necrobiosis lipoidica is a disorder of collagen degeneration.
- Ulcers on the feet and toes are typical for *diabetic foot syndrome*. As this article only deals with leg ulcers, the problem will not be discussed further.

Non-invasive Apparative Investigations

Ankle-Brachial Pressure index (ABI or ABPI)

In all leg ulcers at least this apparative investigation should be performed to exclude arterial disease. ABI stands for assessment of the ratio of blood pressure in the lower leg (ankle) to blood pressure in the arm (brachial): ABI = P leg/P arm.

It is a simple method that requires a Doppler ultrasound blood flow detector (Doppler probe) and a sphygmomanometer (blood pressure cuff). Ankle pressure is measured by slowly inflating

the blood pressure cuff around the distal lower leg and indicating at which pressure the pulse of distal pedal arteries ceases. For calculation of the ratio, the higher systolic reading of the left and right arm brachial arteries is generally used in the assessment and the higher of the two values of pressures measured in the posterior tibial artery and dorsalis pedis artery.

An ABI of less than 0.9 indicates an arterial disease. Of practical importance: Below a threshold of 0.8 compression therapy has to be performed with caution.

An ankle pressure of less than 50 mmHg demonstrates critical ischaemia. This is also the case with a toe systolic pressure below 30 mmHg.

Doppler and Duplex Investigation

Doppler probe offers a cheap and simple technique to diagnose alterations in the venous or arterial system; however sensitivity and specificity are low and therefore the Doppler is not advised any more in the diagnostic of leg ulcers for routine investigations (Guidelines for diagnostics and treatments of venous leg ulcers developed by the Guideline Subcommittee of the European Dermatology Forum 2013).

Duplex sonography (the combination of B-mode echography and Doppler sonography) in contrast has a high sensitivity and specificity in the diagnosis of venous or arterial thrombosis, arterial occlusion or stenosis and is most commonly used to visualise the superficial and deep venous system (e.g. venous directional flow, valve incompetence) of the leg. It is the preferred technique for patients with a vascular leg ulcer (Guidelines for diagnostics and treatments of venous leg ulcers developed by the Guideline Subcommittee of the European Dermatology Forum 2013).

A duplex sonography should be performed in all patients with venous or arterial ulcer when an intervention is a realistic option.

Pulse Volume Recording (PVR)

If arterial disease is suspected, this non-invasive diagnostic test can evaluate arterial circulation, which is measured at multiple sites of the leg according to the vascular segments. The test is based on pressure ratios and flow assessment and allows a more precise location of the arterial disease. The PVR may be non-diagnostic in patients with advanced vessel calcification as in diabetes or hypertension, due to atherosclerosis. In unclear cases, further tests like magnetic resonance imaging (MRI) are required.

Microbiology

All chronic wounds are contaminated or colonised by bacteria or yeasts. Therefore a routine swab from the wound ground for microbiological investigations is meaningless, if there is not a suspect of a critical colonisation that impairs wound healing or an obvious wound infection can be detected. In this case identification of microbes is important for the choice of antibiotics.

In countries with a high prevalence of methicillin-resistant *Staphylococcus aureus* (MRSA), routine swabs may be important to identify patients for hygienic reasons.

Histopathological Investigations

Ulcers with atypical appearance or inadequate response to treatment are suspicious for malignancy. A biopsy from the edge of the wound should be advocated for any ulcer that fails to respond to appropriate treatment to rule out malignancy.

A number of underlying diseases of leg ulcers can only be diagnosed histologically: This applies for all forms of vasculitis (especially small vessel vasculitis), calciphylaxis and ulcerating dermatoses (e.g. necrobiosis lipoidica, sarcoidosis). For other diseases like pyoderma gangrenosum, histopathological findings are important to support the clinical suspect.

Special investigations are required for some rare disorders: The diagnosis of leishmaniasis requires Giemsa's stain and/or polymerase chain reaction (PCR) assays from tissue; atypical mycobacteriosis can only be detected in Ziehl–Neelsen stain and by PCR. For the diagnosis of autoimmunobullous disorders, a direct immunofluorescence is mandatory.

These examples may underline the importance of clinical knowledge. Diagnostic investigations in the direction of rare diseases would not be performed without a corresponding clinical suspect.

Laboratory Investigations

It is debatable whether blood tests should be performed initially in all patients with leg ulcers.

It may be useful to have information from the beginning about a patient's blood count, C-reactive protein (CRP) levels, erythrocyte sedimentation rate (ESR), HBA1c, total protein and basic coagulation parameters.

In some cases laboratory findings however are imperative:

- In case of a wound infection (with erysipelas or phlegmon/cellulitis), differential blood count, CRP and ERS are relevant for diagnosis and monitoring of the course.
- In patients with PAOD, one should know the values of risk factors (cholesterol, glucose/HbA1c) and also values that are of interest for further interventions, e.g. angiography, angioplasty or surgery (creatinine and coagulation parameters/INR).
- When vasculitis is suspected, laboratory tests are important to diagnose the aetiology of vasculitis but also to assess acuteness and extent of the disease. Serological tests include titres of antinuclear antibodies (ANA), dsDNA, cANCA, pANCA and rheumatoid factor (RF); serology for hepatitis B and C; creatinine/urea, muscle enzymes (CK, aldolase), complement, evidence of cryoglobulins and antiphospholipid antibodies.
- If a vasoocclusive disease with hypercoagulable/hypocoagulable state is suspected (e.g. livedo vasculopathy), additional assessments are relevant to rule out coagulopathy (prothrombin time, partial thromboplastin time, proteins C and S, homocysteine, antithrombin III, APC resistance, lupus anticoagulant).
- Calciphylaxis requires special assessment of serum calcium and phosphate, parathormone, HbA1c and albumin.
- The diagnosis of pyoderma gangrenosum obliges to search for associated internal diseases.

Angiography: Arteriography and Phlebography

With angiography the inside of blood vessels can be visualised. This is performed by injecting a contrast agent into the blood vessel and imaging using X-ray–based techniques.

Phlebography is the technique in which contrast fluid is injected into the venous vascular system, either from distal (ascending phlebography) or from proximal by performing a Valsalva manoeuvre (descending phlebography). Phlebography has largely been replaced by duplex diagnostic and is not considered the diagnostic of first choice for venous leg ulcers. It should only be used for special indications (Guidelines for diagnostics and treatments of venous leg ulcers developed by the Guideline Subcommittee of the European Dermatology Forum 2013).

Intra-arterial angiography refers to the visualisation of the arterial system with access gained through an artery, most commonly through the femoral artery. Angiography is performed to show stenosis of arteries in suspected peripheral arterial occlusive disease, which can be treated in the same session with angioplasty. For pure diagnostic measures, arterial duplex has become popular and also CT and MR angiography.

General Principles of Treatment

Treatment of leg ulcers is based on two pillars: The first comprises *treatment of underlying disease*, and the second encompasses *local wound care*.

The first step in the management of leg ulcers should always target at recognition and treatment of underlying diseases. As mentioned above, wound healing is only possible if the cause of the wound is sufficiently controlled. In the treatment of venous ulcers, in a Cochrane review, evidence for faster healing has been demonstrated for compression therapy (O'Meara et al. 2012), which is the treatment of underlying chronic venous insufficiency. In contrast the type of dressing applied beneath compression had not been shown to affect ulcer healing in another Cochrane review (Palfreyman et al. 2006).

Dealing mainly with elder patients that suffer from other diseases, one should not forget to look for concomitant diseases. These may have an influence on wound healing and should be treated: cardiac insufficiency, diabetes, obesity,

malnutrition, hypertension arthropathies, autoimmune disorders and others.

Treatment of Underlying Disease

Venous Ulcers: Treatment of Chronic Venous Insufficiency

The underlying disease of venous ulcer is chronic venous insufficiency, which can be treated noninterventionally or interventionally. Noninterventional treatments include compression therapy and medical treatments; interventional treatment encompasses all forms of invasive procedures from endovenous ablation techniques to surgery.

Compression Therapy

Compression therapy is an empirically originated treatment: Bandages are applied to exert pressure on tissue. Compression therapy is indicated in all forms of chronic venous insufficiency; it is and will remain the keystone of treatment for chronic venous insufficiency. Compression therapy reduces oedema, leads to constriction of venous lumina and thus reduces venous blood capacity. It enhances blood velocity in both superficial and deep venous compartments, improves pump function and reduces venous reflux. Reduction of capillary pressure corrects microcirculatory dysfunction and improves skin changes like dermatosclerosis.

Compression treatment may be performed with different forms of bandages:

- *Elastic long-stretch bandages* exert almost constant pressure due to their elasticity regardless whether a person is moving, standing or lying.
- *Short-stretch bandages* are less elastic and work on the principle of applying a low amount of pressure when the muscle is resting/not active. When the calf muscle is working, however, high resistance is applied to the muscle, which is known as working pressure.
- Nonelastic bandages like *multilayer bandages* or *Unna's boot* (gauze bandage containing zinc oxide paste) generate most working pressure and support optimally function of calf muscle pump. *Compression stockings* (*hosieries*) are manufactured with elastic materials and are worn knee-high, thigh-high or as pantyhose. They exert a graduated compression, which is strongest distally around the ankle. For elder people they may be difficult to apply by themselves. Compression stockings are mainly indicated for prophylaxis and in practice are generally recommended when an ulcer has healed. In the last ten years, however, special forms of high-compression stockings have been developed that are provided for ulcer treatment.

In a Cochrane systematic review, it could be demonstrated that compression increases ulcer healing rates compared with no compression. Multicomponent systems were more effective than single-component systems, and those multicomponent systems containing an elastic bandage appeared to be more effective than those composed mainly of inelastic constituents. Patients receiving a four-layer bandage healed faster than those with short-stretch bandage, and more patients heal on high-compression stocking systems compared to short-stretch bandage (O'Meara et al. 2012).

Compression therapy is safe; however there are some contraindications: Elastic bandages may not be used in stage III or IV of PAOD and/or below an ABI of <80 mmHg. Nonelastic bandages can still be applied because they do not exert pressure at rest. In case of heart failure, especially in the presence of right heart insufficiency, compression therapy has to be performed with care due to the shift of fluid into central compartments.

With bandage or stockings worn, regular exercise such as walking is imperative. Stimulation of ankle mobility to induce calf muscle pump is essential. Additional application of a bolster to the ulceration may selectively enhance compression.

Medical Treatment: Venoactive Drugs (VAD) and Others

Venoactive drugs (VAD) are a heterogeneous group of medicinal products of plant or synthetic origin, which have effects on oedema and on symptoms related to chronic venous disease. Synonymously used but better discarded are the terms oedema-protective agents, phlebotonics, venotonics, vasoprotectors, phlebotropics and venotropics. VAD include flavonoids (secondary metabolites of plants), e.g. benzopyrones like diosmin, hesperidin or coumarin; rutosides (rutin) and troxerutin; saponins like escin (from horse chestnut); calcium dobesilate; etc. The

main mechanisms of action of VAD is an increase of venous tone that results in restoration of normal blood flow, dispersion of red cell aggregates and better oxygenation. In the treatment of venous leg ulcers, VAD are used adjuvantly together with compression therapy which has to be the first-line treatment.

Micronised purified flavonoid fraction (MPFF) with diosmin and hesperidin has shown an adjuvant effect on healing of leg ulcers in double-blind studies (Guilhou et al. 1997; Roztocyl et al. 2003) and one meta-analysis (Coleridge-Smith et al. 2005), when ulcers were larger than 5 cm^2 and existing for more than 6 months. Pain was relieved in all treated patients.

Long-term administration of rutosides did not prevent leg ulcer relapses in one study (Wright et al. 1991).

Oral anticoagulants, heparin, aspirin, pentoxifylline and prostaglandins have been suggested to improve microcirculation and stanozolol to reduce dermatofibrosclerosis.

Interventional Therapy

Superficial venous insufficiency is a major cause of leg ulcers; up to 60 % of venous ulcers result from greater and/or lesser saphenous insufficiency, as could be demonstrated by duplex investigations in recent series. Superficial venous insufficiency can be treated and corrected by different forms of interventions:

- *Phlebectomy*, *sclerotherapy*, *echo-guided sclerotherapy or endovenous ablation techniques* (*radiofrequency or laser ablation*) of a feeding vein in the neighbourhood of the ulceration are simple and cost-effective treatment that can be performed in an outpatient setting.
- *Flush ligation and stripping* of insufficient greater and/or lesser saphenous veins suppresses reflux and venous hyperpressure. Photoplethysmography (1,2) is useful to determine the impact of venous reflux and can predict the improvement to be achieved with surgical removal of the incompetent vein(s).

The question whether compression and surgery are better treatments for venous ulcers has been answered by the ESCHAR study (Barwell et al. 2004) where the combination of surgery and compression was compared to compression alone in a randomised controlled trial with 40 patients. Healing rates after 6 months were similar in both groups (65 % vs 65 %), but 12-month ulcer recurrence rates were significantly reduced in the combined compression and surgery group (12 % vs 28 %). It could be concluded that most patients with chronic venous ulceration benefit from the addition of simple venous surgery regarding recurrence of ulcer but not concerning healing of the present ulcer.

Some surgical procedures may be indicated in cases of long-lasting venous ulcers with chronic skin changes.

- *Paratibial fasciotomy*, as described by Hach, yields excellent results in post-thrombotic syndromes or in painful atrophie blanche ulcers. It now usually completes perforator dissection and is performed through the same incision. The fascia is split down to the malleolus with long scissors or with a fasciotome. The mode of action is not clearly understood, but it certainly compensates a chronic compartment syndrome, by reequilibrating sub- and epifascial venous pressure. Fibrotic alteration of the fascia induces a fatty degeneration of the muscles and impedes its effect on the venous return. These changes are partially reversible after fasciotomy. Post-operative improvement of the microcirculation is immediate, as demonstrated by tcpO2 measures.
- *Large excision of the ulcer* and surrounding tissues, including the fascia, associated if necessary to endoscopical dissection of perforators, stripping and fasciotomy may be the single solution to definitively heal refractory long-lasting ulcers, which become "autonomous". Long-term results are excellent.
- *Shave excision and grafting* are indicated in circular superficial ulcers on dermatofibrosclerosis.

Arterial Leg Ulcers: Treatment of PAOD

If arterial perfusion is not sufficient for healing, revascularisation is mandatory. It could be demonstrated that wound healing is impaired high above the threshold of chronic critical limb ischaemia. Leg ulcers with an arterial involvement and an ankle pressure below 110 mmHg that do not heal under conservative measures will benefit from revascularisation.

Revascularisation requires angioplasty (PTA or percutaneous transluminal angioplasty, if necessary with stent placement), if solitary occlusions in large arteries are present. Often bypass surgery is needed for arterial reconstruction to circumvent a seriously occluded area of the arterial vasculature.

In leg ulcers meeting the criteria of critical ischaemia, where arterial reconstruction is not possible, intravenous prostacyclin (Ilomedin, Iloprost®) or prostaglandin E (Prostavasin, Alprostadil®) should be considered before amputation is executed.

PAOD requires general measurements: Activity should be recommended, e.g. walking to the point of pain and alternate with rest periods. Risk factors should be minimised: Smoking has be stopped, and arterial hypertension needs medical control, as well as hypercholesterolaemia if dietary measures are not sufficient. Reduction of overweight is another goal. Daily aspirin is recommended for overall cardiovascular care.

Martorell's Ulcer

The most important is to recognise the disorder which is often mistaken for pyoderma gangrenosum or calciphylaxis (which shares identical histological features, e.g. calcified vessels). Best treatment is surgical debridement and split-thickness skin grafting.

Ulcerative Malignancy

Most often basal cell carcinoma and squamous cell carcinoma are the cause of malignant ulceration on the leg. Both are best treated with surgical excision, which normally requires skin grafting of the excisional wound. Radiotherapy is an alternative option when surgical treatment is not possible or reasonable.

Vasculitis

Cutaneous small vessel vasculitis (leukocytoclastic or hypersensitivity vasculitis) is the most common vasculitis seen in clinical practice that leads to vasculitic ulcers. It can be caused by different diseases (autoimmune disorders, systemic vasculitis, Henoch-Schönlein, infection, etc.) but also by external agents (e.g. drug reaction). In most cases (up to 50 %), no cause is identified. Treatment of vasculitis requires treatment of underlying disorder (when identified) or removal of external agents (e.g. drugs). The mainstay of symptomatic treatment is the use of anti-inflammatory/immunosuppressant agents, first of all corticosteroids. In ulcerative and necrotic vasculitis, systemic treatment is the rule, in dosages up to 60–80 mg/day of prednisolone equivalent. An infectious aetiology should always be ruled out before the introduction of immunosuppressive therapy. In severe cases, a combination of corticosteroids and other immunosuppressants like cyclophosphamide may be needed. Mild manifestations of vasculitis with only palpable purpura can be treated locally with steroid ointments/cream. Additional measures like leg elevation and compression of leg lesions may also be helpful (See Chap. 17).

For underlying collagenoses or systemic vasculitis, treatment should be performed according to actual recommendations (Sunderkotter and de Groot 2008).

Livedoid Vasculopathy

As a result of recent research (Kerk and Goerge 2013), livedoid vasculopathy has been defined as a coagulation disorder classified as a vasculopathy different from inflammatory vasculitis. To improve rheology, aspirin and pentoxifylline have been recommended earlier. In view of the basic coagulation disorder, systemic anticoagulation is suggested in recent recommendations (Sunderkotter and de Groot 2008). Treatment experience exists for the use of low molecular weight heparin (e.g. enoxaparin in a daily dosage of 1 mg/kg s.c.).

Calciphylaxis

The appearance of wounds in calciphylaxis with widespread necrosis is seductive for wide surgical debridement. In one of the largest series ($n=64$) in a retrospective study, in fact, 1-year survival was better in patients that received surgical debridement (Weenig et al. 2007). These data should be handled with care. In our own experience and according to other recommendations, wound care should be atraumatic. Extensive wound debridement is strongly discouraged, as even the slightest trauma, such as taking a biopsy, can lead to massive, new ulcerations leading to

new septic foci. The use of antibiotics however is important to prevent sepsis, which is the most dreaded complication of calciphylaxis and the main cause of death.

Another aim is to minimise risk factors: Reduction of serum concentrations of calcium and phosphate is mandatory. The impact of parathyroidectomy is discussed controversially, as there are data that show a benefit (Duffy et al. 2006), whereas others do not (Weenig et al. 2007). Oral anticoagulants should be avoided.

Intravenously applied sodium thiosulphate has become the most favoured treatment in calciphylaxis with documented good outcome. Sodium thiosulphate acts as a calcium-chelating agent which allows for successful mobilisation and clearance of the vascular and soft tissue calcium deposits.

Cinacalcet, which inhibits the production of parathormone by negative feedback, is another therapeutic option, which is often used in combination with sodium thiosulphate.

Bisphosphonate is the third treatment option with documented therapeutic success in many reports.

Pyoderma Gangrenosum (PG)

In active PG – due to pathergy phenomenon – surgical interventions, including aggressive debridement, have to be avoided because of the likely occurrence of new lesions at surgical sites and worsening of the original lesions.

In almost all cases of PG, systemic treatment is indicated. In 2005, an evidence-based review of the literature based on more than 350 patients (Reichrath et al. 2005) recommended only three medical treatments as first-line therapies for PG: daily oral corticosteroids, medium- to high-dose (0.5–1 mg methylprednisolone/kg/day) and pulsed-dose methylprednisolone 1 g/day for 1–5 days and oral daily cyclosporine 5 mg/kg/day. All other medical treatments that are documented in literature for the treatment of PG were considered to be of "experimental" nature in this review: dapsone, cyclophosphamide, mycophenolate mofetil, methotrexate, azathioprine, clofazimine, thalidomide and intravenous immunoglobulins. One exception was infliximab (TNF-alpha inhibitor) that was evaluated as a first-line therapy but only in cases of PG associated with Crohn's disease. A placebo-controlled trial 1 year later demonstrated that infliximab was superior to placebo in all types of treated PG (Brooklyn et al. 2006). Its application however is in "off-label use".

In small and early lesions and also when systemic treatment is not possible, primary local treatment can be considered. First-line therapy is the use of potent topical or intralesional corticosteroids. Topical tacrolimus and pimecrolimus are other options.

In addition to systemic therapies, local wound care can be conducted with dressings appropriate to wound stage. Alternatively used for local treatment are – among others – benzoyl peroxide, 0.25 % acetic acid and polyhexanide-containing wound solutions that all have an antimicrobial effect and prevent from secondary infection.

Ecthyma Gangrenosum

Appropriate systemic antibiotic treatment should be initiated. It is crucial to have microbiological evidence of causative bacteria.

Bullous Pemphigoid (BP)

Autoimmune bullous dermatosis generally requires an immunosuppressant treatment, lasting for months. Oral steroids are considered the standard treatment. In bullous pemphigoid however potent topical steroids have also proven to be effective. For ulcerative BP on the lower leg, oral steroids can be recommended, starting at a daily dosage of 0.75 mg prednisolone equivalent. To minimise corticosteroid-related adverse effects, adjuvant immunosuppressive drugs may be used (see Chap. 11).

Necrobiosis Lipoidica

There is no standardised treatment for necrobiosis lipoidica. Ulcerative forms are generally difficult to treat.

Systemic corticosteroids are not an attractive option because most patients are diabetics.

Successful treatment has been documented in several case reports for the use of cyclosporine A and for TNF-alpha inhibitors. Topical calcineurin inhibitors are also promising.

Other treatment options are phototherapy (PUVA) and chloroquine.

Local Wound Treatment

In the last century, local wound treatment was performed for decades by applying dry gauze on the wound ground, allowing the wound to dry and to develop a hard crust.

In 1962, in an epochal article in *Nature*, Winter could demonstrate that epithelialisation is retarded by the dry scab which covers a superficial wound, and if the formation of the scab is prevented, the rate of epithelialisation is markedly increased.

Winter's change of paradigm that wound healing is accelerated in a moist wound environment led to the "golden age of moist wound treatment" which went along with the development of new dressings that were applied on the wound to keep it optimally moist: Hydrocolloids, hydrofibre, alginates, foams and many others have become standards in local wound care in the last 50 years.

Recent reviews however have disclosed that the effectiveness of these dressings might be overestimated and evidence for their efficacy is poor: In a systematic Cochrane review assessing the effectiveness of wound dressings for the treatment of venous leg ulcers, no evidence was found for a better efficacy of a special form of wound dressing nor that the type of dressing applied beneath compression did affect ulcer healing (Palfreyman et al. 2006).

In another critical review of the literature on the efficacy of modern dressings in healing chronic and acute wounds, no evidence was found that any of the modern dressings were better than another or better than saline or paraffin gauze (Chaby et al. 2007). And finally two very recent systematic reviews found no current evidence that either alginates or foam dressings were more effective than other wound dressings to treat venous leg ulcers (O'Meara and Martyn-St James 2013a, b).

Despite these findings, the impact of local wound care with regard to wound healing cannot be emphasised enough. Local wound care is more than just applying a wound dressing: Each wound is different and requires an individual approach to care.

For a structured approach to wounds, an international group of wound healing experts has provided a framework for a structured approach to wound bed preparation more than 10 years ago (Schultz et al. 2003); this approach represents a basis for optimising the management of open chronic wounds. The concept of wound bed preparation can be described by the acronym TIME, which stands in today's definition for Tissue management (T), Inflammation and infection control (I), Moisture balance (M) and Epithelial (edge) advancement (E) (European Wound Management Association (EWMA). Position Document. 2004).

TIME has become an internationally accepted approach to chronic wounds in the last 10 years and is also the topic of a position paper of the European Wound Management Association (EWMA) (2004).

TIME Framework: An Approach to Treat Chronic Wounds

T = Tissue Management

Tissue management means removal of non-viable tissue (debridement). The presence of necrotic or compromised tissue is common in chronic non-healing wounds, and its removal has many beneficial effects. It takes away non-vascularised tissue, bacteria and cells that impede the healing process. Unlike acute wounds, which usually only require debridement once, chronic wounds may require repeated debridement.

The balance of necrotic burden can be achieved with different forms of debridement:

- For *sharp superficial debridement*, curettes, scalpel or scissors are used. Local anaesthesia may be required. With a ring curette, it could be demonstrated that a single treatment accelerated healing of venous leg ulcers.
- *Surgical debridement* with removal of deep structures has to be executed in an operating theatre in general or regional anaesthesia.
- *Hydrosurgical debridement* with fluid jet technology is comparable to sharp and surgical debridement. Most often local anaesthesia is required.
- Other physical forms of debridement include *ultrasound* and *CO2 laser*.
- *Autolytic debridement* is performed with dressings with a high water content, such as hydrogels and hydrocolloids. Enzymatic activity in wound fluid leads to lysis of fibrin

or necrotic tissue. Autolytic debridement is slow and often not effective.

- *Enzymatic debridement* can be induced by proteolytic enzymes in ointments or solutions. Proteases are derived from animals, plants or bacteria. Clostridiopeptidase A, a bacterial collagenase, and streptokinase, an inducer of plasmin which degrades fibrin, are both commercially available.
- For *biosurgical debridement*, maggots (fly larvae of *Lucilia sericata*) are used that produce proteolytic enzymes. Maggots are raised in a sterile environment and are placed on the wound, under a loose bandage in a cagelike dressing, where they selectively degrade dead or dying tissue. To reduce pain, maggots can be placed in a bag or pouch on the wound to avoid direct contact to the wound ground. The efficacy of maggot debridement therapy has been demonstrated in leg ulcers (Dumville et al. 2009), pressure ulcers (Sherman 2002) and diabetic foot ulcers (Sherman 2003). The treatment is safe, but acceptance of patients may be problematic.

I = Inflammation and Infection Control

All chronic wounds are colonised by bacterial or fungal microorganisms. Bacteria may stimulate a persisting inflammation and lead to the production of inflammatory mediators and proteolytic enzymes, thus promoting chronicity of wounds. Evidence shows that a bacterial burden of 10^5 organisms or more per gram of tissue seriously impairs healing.

A bacterial overload with $>10^5$ microorganisms/gram tissue – in the absence of systemic signs of infections – is referred to as critical colonisation. As mentioned previously, microbiological investigations (swab) should be limited to situations where there is a clear indication that the bacterial load is implicated in delayed healing.

In all chronic wounds, non-specific antimicrobial measures are reasonable to restore bacterial balance: This includes removing of nonvital tissue, exudate control, regular cleansing with sterile saline and/or superficial debridement.

If a critical colonisation is suspected, specific antimicrobial treatment is indicated and is most often performed with antiseptics like polyhexanide, octenidine or silver-containing wound dressings, even if evidence from systematic reviews is low (Storm-Versloot et al. 2010).

Biguanide antiseptics polyhexanide and octenidine, both with bactericidal effect against gram-positive and gram-negative bacteria and also fungicidal properties, can be used as solution: When changing dressings, a moist compress is applied and kept on the wound for 3–5 (octenidine) or 10–15 min (polyhexanide). Both antiseptics can also be applied together with modern wound dressings (hydrofibres, alginates, foam substances).

Silver, which demonstrates good antimicrobial efficacy against gram-negative and gram-positive bacteria, can be applied on wounds as silver nitrate solution or silver sulphadiazine cream. Most frequently used today is silver incorporated in any form of wound dressing (e.g. foam, hydrofibre, hydrocolloid).

Antiseptic treatment can also be conducted with iodine-containing products (PVP-iodine/povidone-iodine as solution or as a hydrosomal wound gel or cadexomer-iodine), honey or honey-containing dressings or acetic acid solution (<1 % applied for 3–5 min).

Systemic antibiotics may occasionally be indicated in critical colonisation, when local antiseptic treatment is insufficient. An uncontrolled use increases bacterial resistance. Symptomatic infection with erysipelas, cellulitis, fever and systemic signs in laboratory investigation has to be treated with systemic antibiotics. For the selection of appropriate antibiotics, a microbiological diagnosis is relevant.

M = Moist Control

Dressing

In the course of normal healing, a wound goes through different phases (inflammation–proliferation–reparation/maturation/remodelling). In these phases a varying amount of exudate is produced, with the peak in the inflammatory phase. Chronic wounds – due to chronic inflammation – produce chronic exudate, which causes the breakdown of extracellular matrix proteins and growth factors, prolongs inflammation, inhibits cell proliferation and leads to the degradation of tissue matrix. Chronic exudate delays healing and causes

maceration of the surrounding skin. The management of exudate therefore is crucial.

Compression therapy is one important measure to reduce exudate, not only in venous ulcers, but in the treatment of all chronic wounds – if there is no relevant arterial involvement.

To control exudate, selection of an appropriate dressing is relevant. Modern dressings are all able to keep a wound moist, but they differ in the degree of absorbing exudate. As exudate production correlates with the wound stages, the aspect of the wound ground may be helpful to estimate exudate release: A yellow colour and a sloughy wound ground are typical for the inflammatory phase which may go together with heavy exudate production. Red colour means granulation tissue and less exudate, while pink is the colour of epithelialisation.

Wounds with high exudate production (early inflammatory phase) can be treated with foams, hydrofibre dressings and alginates. They all have a good capacity to absorb exudate.

- *Foam dressings* are sheets of foamed polyurethane or silicone. They have a variable thickness and structure and are highly absorbent but can transmit moisture vapour and oxygen. In many countries they have become most popular in modern wound care.
- *Hydrofibre* dressings are almost entirely composed of sodium carboxymethylcellulose fibres. They absorb exudate immediately and form a soft coherent gel. They retain exudate within their structure even under compression and do not allow horizontal spreading of fluid, thus protecting the surrounding skin from maceration.
- *Alginates* are biodegradable fibre products derived from brown seaweed. Alginates can absorb 15–20 times their weight of fluid. They partly dissolve on contact with wound fluid to form a hydrophilic gel.

If relevant bacterial load is suspected, silver-impregnated foam, hydrofibre or alginate dressings may be considered.

Wounds with less or little exudate can be treated with hydrocolloid dressings, low-adherent dressings or films:

- *Hydrocolloids* consist of a layer of hydrophilic colloidal gel-forming particles, made of sodium carboxymethylcellulose, gelatin, pectin, elastomers and adhesives that are bonded to a carrier of semipermeable film or a foam sheet. Hydrocolloids absorb liquid and form a gel on the wound surface that maintains an optimal moist environment. This promotes granulation, mediates local fibrinolysis, stimulates capillary proliferation, enhances the concentration of growth factors within the wound fluid and increases the rate of re-epithelialisation. Hydrocolloids should be left on the wound for at least 2–3 days. When dressings are changed, the gel in the dressing, which may be yellow and malodorous, may be mistaken for infection.
- *Low-adherent dressings* are designed to reduce adherence at the wound bed. They are manufactured in the form of tulles, which are open-weave cloth soaked in soft paraffin or chlorhexidine. They allow exudate to pass through into a secondary dressing.
- *Semipermeable films* consist of sterile plastic sheets of polyurethane coated with hypoallergenic acrylic adhesive and are used mainly as a transparent primary wound cover. Although they are impermeable to fluids and bacteria, they are permeable to air and water vapour.

Dressings have to be changed according to the stage of the wound. In exudative ulcers, they should be changed quite regularly, whereas in later healing stages, it is preferable to avoid frequent changes of dressing, as this interferes with healing and may compromise newly formed tissue, disturb the patient's life and enhance the costs of treatment.

Negative-Pressure Wound Therapy (NPWT) or Vacuum-Assisted Closure (VAC)

NPWT or VAC can be used on almost any wound and provides optimal exudate control and promotion of granulation. The primary intention is to remove chronic oedema and fluid from exudative wounds, stimulate granulation, increase local blood flow, impede nosocomial infection of the wound and isolate infected ulcers. A foam dressing under hermetical occlusion is applied on the ulcer and connected with an aspirating device assuring a controlled continuous or intermittent sub-atmospheric pressure (between 55 and 200 mmHg below ambient pressure). This technique may induce granulation in refractory

venous ulcers, decubitus, infected wounds or even in arterial ulceration.

Surrounding Tissues

When exudate is not sufficiently controlled, maceration may occur around the margins of the wound. It is manifested as white, soggy tissue. For protection, zinc paste may be used or liquid film-forming acrylate.

If contact dermatitis is observed, local corticosteroids are indicated for a short-term use. Patients with leg ulcers frequently acquire clinically relevant contact sensitisation. In patch testing, sensitisation can be found in up to two-thirds of patients. Sensitisations are often found for balsam of Peru, amechol, fragrance mix, wool wax alcohols and rosins but also to wound dressing materials.

E = Edge Effect

Effective healing requires the re-establishment of an intact epithelium. If the epidermal margin fails to migrate across the wound bed, there are many possible reasons, including hypoxia, infection, desiccation, dressing trauma, overgrowth of hyperkeratosis and callus at the wound margin. Careful clinical observation can help to determine the cause.

Surgical Local Wound Treatment

Skin grafting can dramatically shorten the time to complete healing. The wound has to be well conditioned, with a good granulation tissue in the wound ground.

Pinch grafting (or Reverdin graft) may be performed in outpatients. Small bits of partial- or full-thickness skin from a healthy area are obtained by elevating the skin with a needle and cutting across its base. The pinch is removed and seeded in the site to be covered.

Split-thickness and meshed grafts are indicated in large ulcers, where healing by secondary intention would last for months. Meshed grafts are also used to cover a wound after deep debridement or large excision of a fibrotic ulcer bed.

Advanced Wound Treatments

Besides conventional local wound treatment, a number of new therapeutic modalities exist that can be summarised as advanced treatments. Some of them have been used for years while others are still experimental. We will focus on treatments that have been established and are already widely used:

Growth Factors

Growth factors are of great importance in normal wound healing. They are produced by many cells involved in different wound phases. It is suggested that in chronic wounds, degradation of growth factors by up-regulated proteases is one factor that is responsible for the delay in healing.

In a number of experimental approaches, exogenous growth factors were supplied to the wound microenvironment to stimulate healing. An efficacy in wound healing could only be demonstrated for platelet-derived growth factor (Wieman et al. 1998). Until today a recombinant form of PDGF-BB (becaplermin) is the only growth factor that was licensed and distributed for topical application in diabetic ulcers.

Protease Inhibition

A new generation of wound dressings was developed to interact with the wound to stimulate healing. Examples are protease-modulating dressings, which stimulate healing by inactivating excess of proteases (Cullen et al. 2002).

Tissue-Engineered Skin Equivalents

For years wound research has tried to create "artificial" living skin substitutes. A number of epidermal, dermal or bi-layered skin equivalents have been developed. Most of them are meant for acute wounds, especially burn wounds. For the treatment of leg ulcers, two skin equivalents are commercially available:

- *Apligraf* is a living bilayered skin equivalent that consists of an epidermal layer derived from human keratinocytes and a dermal layer containing human fibroblasts and bovine collagen. It was demonstrated that the skin equivalent that can be easily applied on a conditioned wound improves wound healing in venous leg ulcers and diabetic foot ulcers (Falanga et al. 1998; Veves et al. 2001).
- EpiDex is an autologous epidermal equivalent containing keratinocytes from the patient's own outer root sheath (ORS). To cultivate epidermal

equivalents, the necessary cells are extracted by plucking the patient's anagen head hairs. The outer root sheath of isolated hair follicles contains precursor cells for epidermal keratinocytes. It could be shown that EpiDex was as effective as split-thickness skin autografting in the promotion of healing and complete closure of recalcitrant vascular leg ulcers (Tausche et al. 2003; Ortega-Zilic et al. 2010).

Water-Filtered Infrared A (wIRA)

Water-filtered infrared A (wIRA) radiation can improve the healing of acute and chronic wounds both by thermal and thermic as well as by non-thermal and nonthermic effects. wIRA increases tissue temperature, oxygen partial pressure and perfusion. Application of wIRA proved to be effective for the treatment of chronic venous stasis ulcers.

Extracorporeal Shock Waves

Extracorporeal shock waves are a sequence of sonic pulses characterised by high peak pressure over 100 MPa, fast pressure rise and short life-cycle. In urology, extracorporeal shock wave lithotripsy (ESWL) has been successfully used for years for the treatment of urolithiasis. Extracorporeal shock wave therapy (ESWT) can also be used for recalcitrant skin ulcers. Several studies in the last 10 years have shown that ESWT promotes angiogenesis, increases perfusion in ischaemic tissues, decreases inflammation, enhances cell differentiation and accelerates wound healing (Stieger et al. 2013).

Future

In adult organisms, stem cells that can divide and differentiate into specialised cell types act as a repair system for the body. It sounds promising to apply stem cells in a wound where they can differentiate into cells that are required for the respective wound stage. It was demonstrated that application of stem cells derived from bone marrow aspirate – delivered in a fibrin spray – was able to accelerate wound healing (Falanga et al. 2007). Another interesting approach is application of stem cells in a biomatrix to treat wounds (Vojtassák et al. 2006).

Finally there are high expectations in gene therapy: This treatment uses DNA that encodes a protein required for treatment of a disease. To get the DNA inside cells of the body, DNA is packed within a vector. Inside the cells, DNA becomes expressed and starts producing the therapeutic protein. To treat wounds, locally applied genes will induce production of growth factors and cytokines in cells of the wound. This has been demonstrated for PDGF-B, PDGF-A, VEGF and EGF (Eming et al. 2007).

The future of wound treatment looks promising (Figs. 49.1, 49.2, 49.3, 49.4, 49.5, and 49.6).

Leishmaniasis

50

Meltem Onder and Mehmet Ali Gürer

Key Points

- Leishmaniasis usually affects the face and leaves a depressed scar.
- Leishmaniasis is diagnosed by the presence of the leishmania parasites in a superficial smear or biopsy of the ulcer.
- Treatment depends on the clinical form of the disease.
- Intralesional antimonial (0.2–0.4 ml sodium stibogluconate intradermally three times a week for a total of 15 injections) is advocated.
- 20 % paromomycin sulfate is a topical medication.
- Cryotherapy with liquid nitrogen (−195C) can be applied once or twice weekly up to 6 weeks. The combination of superficial cryotherapy and intralesional antimony is more effective than each technique used alone.
- Thermotherapy with radio-frequency waves is effective as antimony therapy.
- Systemic use of antimonials, amphotericin-B, dapsone, allopurinol, and rifampicin has shown effective activity against leishmania.
- The most successful therapy is intralesional therapy because of its efficacy, absence of toxicity, and low cost.

Definition and Epidemiology

Leishmaniasis is a protozoan disease with different clinical manifestations depending both on the infecting species of leishmania and on the immune response of the host. Its transmission occurs through the bite of a sandfly infected with leishmania parasites. It occurs in two forms, visceral and cutaneous leishmaniasis. Visceral leishmaniasis, also known as *kala-azar*, is a systemic disease, and it is usually diagnosed by the presence the organisms in the spleen, lymph gland, or bone marrow aspirates. Cutaneous leishmaniasis usually occurs in the form of an ulcerated nodule on the skin.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_50, © Springer-Verlag Berlin Heidelberg 2015

It is seen in all races and both sexes. It is a common disease especially in the south-east of Anatolia in Asia. Approximately 400,000 new cases occur each year, and 400 million people are at risk of the disease.

Basic Concepts of Pathogenesis

Leishmaniasis is caused by parasites of the *genus Leishmania*. Sandflies from the *genus Phlebotomus* transmit the disease. Only the female sandflies are bloodsucking, and they prefer to feed at night. The leishmania parasite exists in two forms, the promastigote or leptomonal form and the amastigote or leishmanial form. The first one is seen in the gut of the sandfly. It is flagellated and extracellular. The amastigote form occurs in the human host where the organism exists intracellularly and nonflagellated. The transmission occurs when the exposed area of the skin is bitten by an infected sandfly; at that time, the organism is engulfed by dermal macrophages. The sandfly becomes a vector by either biting the lesions of infected humans or feeding on animals which harbor the organism.

Clinical Presentation

Leishmaniasis usually affects the face, neck, and arms and legs which are easily bitten by a vector (Figs. 50.1, 50.2, and 50.3). The bite commonly presents as a solitary red papule which enlarges to a plaque or nodule. The lesion often develops into an ulcer, which is well demarcated. Itching pain is very mild. After approximately 6–12 months, the ulcer spontaneously regresses. It leaves a depressed scar with hypo- or hyperpigmentation. The wound may become superinfected, leading to misdiagnosis. A generalized papular eruption may also develop representing a hypersensitivity reaction.

In AIDS patients, atypical manifestations of cutaneous leishmaniasis occur as an opportunistic infection. One to 3 % of AIDS patients in endemic areas suffer from visceral leishmaniasis.

Fig. 50.1 Leishmaniasis (Courtesy of Prof Dr. Hamdi Memisoglu Adana, Turkey)

Fig. 50.2 Leishmaniasis in a child (Courtesy of Prof Dr. Hamdi Memisoglu Adana, Turkey)

Fig. 50.3 Leishmaniasis (Courtesy of Prof Dr. Hamdi Memisoglu Adana, Turkey)

Diagnosis

Leishmaniasis is diagnosed by demonstrating the organisms in a superficial smear or biopsy of the ulcer. The smears stained with Giemsa or Wright's

stain are often not satisfactory, because the lesion usually contains secondary infection. Moreover, the parasites are found much deeper in the tissue.

Skin biopsy reveals epidermal or dermal changes depending on the type and stage of the disease. Epidermal changes are hyperkeratosis, parakeratosis, and follicular plugging. Epidermal atrophy, acanthosis, may be seen. The basal layer may be degenerated. In the dermis, there is predominantly a mononuclear infiltrate consisting primarily of lymphocytes and histiocytes. The histiocytes may be filled with leishmaniasis bodies.

In suspected cases, both biopsy and touch preparation (imprint) from a biopsy specimen improve the sensitivity of diagnosis.

The intradermal leishmanin test (Montenegro reaction) and other serologic tests are of little value in regions where the disease is endemic because of previous exposure to the parasite. Immunofluorescence studies should be interpreted with caution and only if antibody levels are very high. Cultures of aspirated material from the lesions on NNN (Nicolle, Novy, MacNeal) blood agar were found to be moderately sensitive monoclonal antibodies to parasite surface antigens and have been used to identify leishmania species. Polymerase chain reaction (PCR) can be used to distinguish between the different species of *Leishmania*.

Differential Diagnosis

The natural history of cutaneous leishmaniasis is characteristic. It should be suspected in any patient with chronic inflammatory skin lesions who has visited or resided in the areas where leishmaniasis is endemic. The disease is on the rise due to travel, immigration, and military activity. The differential diagnosis may differ depending on the location of skin manifestations. Lip leishmanias is fairly common. It resembles herpes labialis, syphilitic chancre, squamous cell carcinoma, and fixed drug eruption. The differential diagnosis can be summarized in Table 50.1.

General Principles of Treatment

- Leishmaniasis is a worldwide health problem and there is no ideal therapy. It depends on the clinical form of the disease.
- The important measures to control leishmaniasis in areas where it is endemic are health education, elimination, or control of reservoir and hosts and vectors and early treatment of patients.

- Patients with lesions on the face or another cosmetically important area should be treated to reduce the size of the resultant scar.
- The most successful therapy is intralesional therapy. Systemic chemotherapy is recommended for very extensive lesions. Uncomplicated lesions do not need to be treated aggressively. Simple excision, cryosurgery, and topical therapy are usually sufficient.

Recommended Therapies

(a) *Systemic chemotherapy*
- I. Antimonials
  - Sodium stibogluconate (Pentostam®)
  - Meglumine antimoniate (Glucantime®)
- II. Amphotericin-B, dapsone, allopurinol, rifampicin, and isoniaside
- III. Pentamidine
- IV. Azole derivatives
  Ketoconazole-itraconazole-terbinafine
- V. Others
  Trimethoprim-sulfamethoxazole
  Metronidazole
  Monomycin
  Methyluracil
  Mebendazole
  Levamisole
  Furazolidone
  Miltefosine

(b) *Intralesional therapy*
- I. Antimonials
- II. Emetine hydrochloride
- III. Mepacrine
- IV. Hypertonic sodium chloride solution

(c) *Topical therapy*
- I. Paromomycin
- II. Diminazene aceturate
- III. Chlorpromazine
- IV. Local application of meglumine antimoniate under occlusive dressing

(d) *Local measures* (*physical*)
- I. Cryotherapy
- II. CO_2 laser
- III. Excision
- IV. Localized heat
- V. Photodynamic therapy

Systemic Chemotherapy

Antimonials have been used to treat most forms of leishmaniasis. They inhibit the amastigote's glycolytic activity and fatty acid oxidation. Two available preparations of pentavalent antimony are sodium stibogluconate (Pentostam ®) and meglumine antimoniate (Glucantime ®). The recommended dosage is 20 mg/kg per day for 20 days intravenously or intramuscularly. The parenteral route of administration is expensive and impractical in rural areas in which leishmaniasis is so prevalent. Moreover, the side effects, such as arthralgias, reversible elevations of hepatocellular enzymes, leukopenia, thrombocytopenia, and electrocardiogram changes, make systemic antimonials an unattractive choice for the treatment. All side effects resolve spontaneously after treatment. Glucantime remains the first-line treatment for cutaneous leishmaniasis.

Several oral agents have been tried instead of the parenteral antimonials. Amphotericin-B, dapsone, and allopurinol have shown effective activity against leishmania organism. Rifampicin 1,200 mg/day in two divided doses is well tolerated. It is simple to administer, cheap, more effective, and less toxic than other available oral drugs.

Pentamidine at a dose of 3–4 mg/kg once weekly for at least 4 months may help in diffuse cutaneous leishmaniasis.

A 600 mg dose of ketoconazole has been shown to be effective. Itraconazole 7 mg/kg per day for 4–8 weeks has been encouraging, but it cannot be used as the single agent.

Miltefosine is an alkyl phospholipid (hexadecylphosphocholine); at a dose of 50–100 mg/day, it can be used for 28 days. The limitations are relatively high cost, gastrointestinal side effects, and occasional hepatotoxicity and nephrotoxicity.

Intralesional Therapy

Intralesional antimonial regimen involves the application of 0.2–0.4 ml sodium stibogluconate intradermally three times a week for a total 15 injection. The recurrence rate with this regimen is only 4 %. It is advocated,

because of its efficacy, absence of toxicity, and low cost.

Topical Therapy

Today topically applied drugs are being used to minimize systemic toxicity and concentrate medication of the specific sites on the skin. Recently paromomycin sulfate 20 % was found to be a promising topical medication. It is an aminoglycoside and has an antibiotic spectrum. It is applied twice daily for 10–20 days. Some redness and irritation can be seen.

Local Measures

Cryotherapy, local excision, CO_2 lasers, and localized heat have all been tried with variable results. Freezing the lesions for 30–60 s until 2 mm margins are obtained has proved lethal to leishmania organisms. Liquid nitrogen is a relatively simple and safe alternative with few or no systemic adverse effects.

Thermotherapy, using radio-frequency waves (three treatments of 50 °C for 30 s at 7 day intervals), is effective, although the device is expensive.

Photodynamic therapy

After curettage of the lesion, topical application of methyl-amino-oxo-pentanoate (MAOP) for 3 h, followed by photodynamic red light, is used effectively.

Alternative and Experimental Treatments

Interferon

More recently subcutaneous injection of IFN-γ has proved effective for regression of lesions by stimulating the macrophages of the Th1 line.

Vaccination

It has been performed on animal models and human beings with virulent promastigotes. Reduced rates of subsequent injection have been noted in the vaccinated populations. The development of an effective, noninfectious vaccine is problematic.

Immunotherapy

The mixture of heat killed cultured leishmania promastigotes plus live lyophilized Bacille de Calmette et Guérin (BCG) can be combined for chemotherapy. It is recommended as a single intradermal injection and applied every 6 weeks.

Sitamaquine (WR 6026)

This is a primaquine analogue, *an 8-aminoquinoline derivative*, *is a once-a-day oral treatment for visceral leishmaniasis that* has shown effectiveness in animal models (Loiseau et al. 2011).

Liposomal Amphotericin

This has proved effective, but it is undergoing clinical trials.

Oral Zinc Sulfate

5 mg/kg of zinc sulfate orally can be recommended in the prophylaxis of cutaneous leishmaniasis (Sharquie et al. 2001).

A Therapeutic Algorithm

Global incidence of leishmaniasis is estimated at two million cases per year; approximately three fourths are cases of cutaneous leishmaniasis (CL). Treatment of CL should be decided by the clinical lesions and etiological species (Table 50.2). There are number of therapies for various forms of leishmaniasis and the preferences for first line and second line vary on the type of disease and are often guided by regional practice. In Table 50.3 recommended treatment dose, duration, main side effects, and risks are summarized. Basic treatment options regarding childhood, pregnancy, and lesions type like simple and complex may change.

Table 50.4 summarizes these options.

The growing resistance of parasite to antileishmanial drugs suggests that the currently used monotherapy needs to be reviewed. Local cryotherapy can be combined with intralesional treatment options and oral treatments. Combination

Table 50.2 Leishmanial parasites and treatment regimens

Species	Treatment
L. Major (Middle East and Africa)	Local
	Cryotherapy
	Topical paromomycin
	Intralesional stibogluconate(Sb)
	Intralesional Sb+cryotherapy
	Heat therapy
	Systemic
	Fluconazole
	Systemic stibogluconate
	Systemic stibogluconate+pentoxifylline
L. Tropica (Middle East and the Mediterranean)	Local
	Topical paromomycin
	Intralesional stibogluconate(Sb)
	Intralesional Sb+cryotherapy
	Systemic
	Systemic stibogluconate
	Systemic stibogluconate+pentoxifylline
	Amphotericin
	Allopurinol
All species and recurrences	Amphotericin or liposomal amphotericin
	Systemic stibogluconate
	Topical imiquimod
	Miltefosine
	Immunotherapy

Table 50.3 Dosage recommended period of treatment

Treatment	Dose	Duration	Risks, side effects
Local injection of pentavalent antimonials	IL, IM 1 ml/cm^2	Per week until recovery	Local side effects,
Meglumine antimoniate (Glucantime^R)	For infants 10 mg/kg/day		Hepatic renal failure
Stibogluconate (Pentostam^R)			Drug resistance
			Contraindication: pregnancy
Doxycycline	200 mg/day	15–30 days	Phototoxicity
Azithromycin	500 mg/day	5 days/4 months	Recurrence
Pentamidine	IM 2–4 mg/kg	3 days per week	Hypertension
			Tachycardia
			Skin rush
			Renal failure
			Pancreatic toxicity
Paromomycin	15 mg/kg/day	20 days	Erythema
Pentoxifylline	400 mg/oral/day	30 days	Recurrence (combination requires)
Allopurinol	20 mg/kg/day	30 days	Cardiotoxicity, elevation of liver test values
Metronidazole	1.5 g/day	15–30 days	Recurrence (combination requires)

Table 50.3 (continued)

Treatment	Dose	Duration	Risks, side effects
Amphotericin B	2.5–5 mg/kg/day	15–30 days	Renal insufficiency, electrolyte problem
Ketoconazole	100–400 mg/day	28 days	Hepatotoxicity
Fluconazole	200 mg/day	6 weeks	Hepatotoxicity
Itraconazole	400 mg/day	8 weeks	High costs and recurrence risk
CO_2 laser	Pulse 0.5–5 s	Every week	Local anesthesia is required
Electrotherapy	5–15 miliamper, 40 W	4–6 weeks	Local side effects
Cryotherapy	15–20 s freezing	2–3 months weekly	Hypopigmentation, satellite lesion
Imiquimod	5 % cream	20 days	Expensive in poor countries
Thermotherapy	39–40 °C	20 days	Painful
Miltefosine	50–100 mg/kg/day	30 days	Digestive troubles, increasing transaminases
			Abortion in pregnant women, high cost

Table 50.4 Basic treatment options

Simple lesion	*Complex lesion*
Cryotherapy	Amphotericin B
Thermotherapy	Ketoconazole, itraconazole, fluconazole
Intralesional antimonials	Miltefosine
Childhood	*Pregnancy*
Cryotherapy	Only local treatment
Intralesional antimonials	
Miltefosine (up 3 years)	

therapy with amphotericin B and miltefosine is also recommended.

Prevention

The preventive treatment is collective, and it is based on the eradication of the vector, eradication of the reservoir, and protection against the bite of sandfly. Eradication of the reservoir is important with the diagnosis and treatment of affected humans and killing the infected dogs in endemic zones. The use of powerful insecticides is recommended. Avoidance of outdoor activities during which the Phlebotomi are most active, wearing protective clothing, and installing mosquito nets around beds, doors, and windows are also very important.

Lentigo Maligna

51

Jean Kanitakis

Key Points

- Lentigo maligna is a form of melanoma in situ appearing on chronically sun-exposed areas in elderly patients. It may progress, albeit slowly, to an invasive melanoma (lentigo maligna melanoma). The diagnosis of lentigo maligna requires adequate biopsy and histological examination.
- High levels of evidence based on prospective studies or randomised controlled trials are not available to establish definite recommendations for the management of lentigo maligna.
- The preferred treatment ensuring the lowest rate of recurrences is surgical excision with tumour-free margins. This can be performed as standard local excision with predefined safety margins, staged surgical excision or Mohs micrographic surgery (traditional or "slow"). The latter margin-controlled techniques are associated with the lowest recurrence rates.
- Nonsurgical treatments can be applied when surgical excision is incomplete or not possible because of anatomic/functional concerns, patient's age and/or comorbidities. They include mainly imiquimod, radiotherapy and cryotherapy. These options do not allow histological verification of margin clearance and have therefore higher recurrence rates.

Definition and Epidemiology

Lentigo maligna (LM), also known as malignant freckle, Hutchinson's melanotic freckle and melanosis circumscripta precancerosa of Dubreuilh, is a clinicopathologic subtype of malignant melanoma (MM), accounting for 4–15 % of all MM cases. Although its precise prevalence is unknown, this seems to be increasing as a consequence of population ageing and increased sun exposure over the past decades. LM has long been considered as a precursor of MM, but the current trend is to consider it as a type of MM in situ in a radial growth phase. Clinically, it manifests as an asymmetric flat macule with irregular contours. It is light or dark brown in colour, often with several hues including black or whitish areas, reflecting partial regression, and may

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_51, © Springer-Verlag Berlin Heidelberg 2015

exceptionally be completely amelanotic. It develops on chronically sun-exposed body zones, typically the face (cheeks, forehead, temple, periocular skin) and more rarely on extrafacial sun-exposed body zones (arms, legs) of middle-aged and elderly patients with fair skin showing signs of sun damage (Fig. 51.1). LM may be difficult to distinguish clinically from solar lentigo, early seborrheic keratosis, pigmented actinic keratosis and lichen planus-like keratosis. Although the vast majority of solar lentigos are benign, they may rarely progress to LM. LM expands radially over months or years and may in the long term invade the dermis (vertical growth phase), thereby progressing to lentigo maligna melanoma (LMM), which has potential for metastatic spread and can cause death. This progression manifests clinically with the development of a thickened zone or a raised nodule. The rate of progression is poorly quantified. The lifetime risk has been reported to be as low as 5 % and as high as 50 %. The time to progression may vary from a few months to over 30 years; therefore, this progression may be unlikely within the lifespan of elderly people.

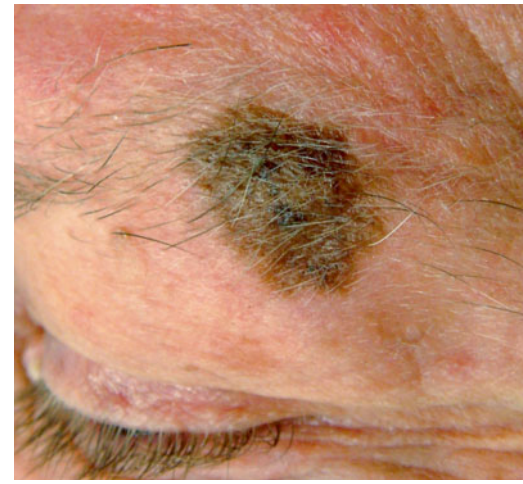

Fig. 51.1 Lentigo maligna: acquired pigmented macule with irregular contours and heterogeneous-speckled brown colour on the forehead of a skin type II Caucasian man

Diagnosis

The diagnosis of LM (and LMM) can be suggested clinically and may be supported by non-invasive imaging techniques such as dermatoscopy and in vivo reflectance confocal microscopy. By dermatoscopy, LM shows asymmetrical pigmented follicular openings, zones of rhomboidal pigmentation, annular-granular structures and grey pseudo-network. In vivo confocal reflectance microscopy shows epidermal disarray, pagetoid infiltration by large (>20 μm) round refractile cells and non-edged dermal papillae. Even though non-invasive imaging methods are useful in the diagnosis of LM, biopsy and histological examination are required to establish a definitive diagnosis. Although for suspicious lesions an excisional biopsy is recommended because it is easier to interpret pathologically and minimises the risk of missing the worst area of the tumour (including LMM), this is often not feasible for large lesions located on the face, as is often the case of LM. An incisional or punch skin biopsy is acceptable and should be taken from the clinically most suspicious area (most infiltrated/palpable, darkest or with the highest pigmentary irregularity). Biopsy of more than one site can reduce the risk of missing subclinical dermal microinvasion (LMM). Indeed, up to 22 % of cases diagnosed as LM by incisional biopsy are reclassified as LMM upon examination of the completely excised lesion. Non-invasive imaging techniques (such as Wood lamp illumination, dermatoscopy and in vivo reflectance confocal microscopy) are helpful to define the most informative area wherefrom the biopsy should be taken and to define the infraclinical limits of the lesion, which is useful for the further surgical treatment of the lesion as atypical melanocytes characteristic of LM may extend far beyond the clinically visible limits of the lesion.

Histopathological examination of LM shows a lentiginous proliferation of atypical, often spindle-shaped melanocytes within the basal epidermal layer; these often have a vacuolated

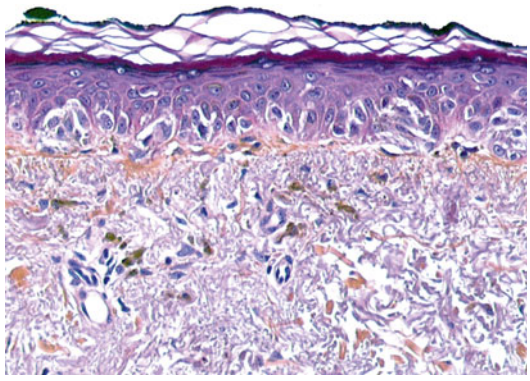

Fig. 51.2 Lentigo maligna: microscopic examination shows a lentiginous proliferation of atypical melanocytes in the basal cell layer of the epidermis, tending to form small nests. Note the presence of epidermal atrophy (manifesting with flattening of the dermal-epidermal junction), heavy elastosis and melanophages in the dermis (haematoxylin-eosin-saffron stain)

cytoplasm and a basophilic nucleus that may be pycnotic or multiple (Fig. 51.2). Atypical melanocytes are also found in the basal layer of the epithelial sheath of hair follicles and are responsible for recurrences following superficial treatment modalities that do not penetrate deeper than the epidermis. In more advanced stages, atypical melanocytes cluster in irregular nests that initially locate in the basal epidermal layer and later may invade the upper epidermis and eventually also the dermis (vertical growth phase, LMM) (Fig. 51.3). Associated histologic findings include an atrophic epidermis with a flattened dermal-epidermal junction, actinic elastosis in the underlying dermis (reflecting chronic sun exposure) and the presence of melanophages along with a mild lymphocytic infiltrate in the papillary dermis. LM should be differentiated from simple (non-malignant) atypical melanocytic hyperplasia, often noted in chronically sun-exposed facial skin of elderly people; this distinction is often difficult, especially in the initial stages of LM.

LM most commonly carries mutations in the *c-kit* gene, unlike other commoner forms of melanoma (SSM, nodular) that have activating mutations in the BRAF gene.

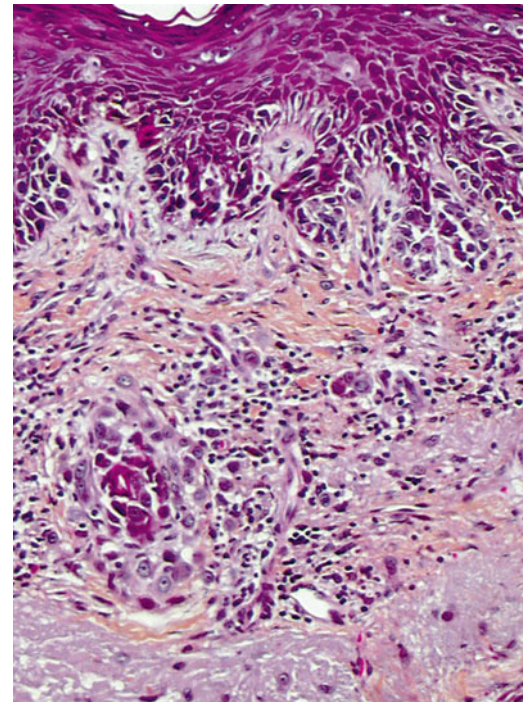

Fig. 51.3 Lentigo maligna melanoma: note similar findings as those seen in Fig. 51.2, along with the presence of atypical melanocytes invading the dermis (haematoxylin-eosin-saffron stain)

Workup

After a diagnosis of LM is established, a thorough history should be obtained and a complete physical examination performed, including total body examination and palpation of lymph node basins, both regional and distant. In asymptomatic patients with localised in situ MM (including LM), baseline routine laboratory tests and imaging studies are generally not recommended and should only be performed in the presence of clinically suspicious signs and symptoms.

General Principles of Treatment

There are no prospective studies or randomised controlled trials allowing to establish definite guidelines for the management of LM. It is however generally admitted that the best treatment of

LM is complete surgical excision. This allows histological examination of the whole tumour, therefore minimising the risk of missing an invasive zone, and allows examination of the margins to ensure that they are tumour-free. Surgical excision achieves thereby the lowest risk for disease recurrence. However, clinical factors such as the age of the patient, the patient's life expectancy and comorbidities and the size and location of the lesion may impact on the way LM is managed. Alternative destructive or medical therapeutic modalities can be proposed when surgery is not a feasible option. The best treatment should be tailored to each individual patient, possibly in the setting of a multidisciplinary oncology team, the aim being to obtain the best risk-benefit ratio in each case.

Surgical Excision

As with all clinicopathologic subtypes of MM, complete surgical excision with clear histologic margins is considered the best treatment of LM as it achieves the highest clearance rates. The definite surgical excision should preferably be performed within 4–6 weeks following diagnosis. The challenge is to excise the lesion completely (i.e. with tumour-free margins) while respecting the anatomy of the face and conserving a maximum of healthy tissue, so as to obtain the best possible aesthetic and functional results. Surgical excision can be performed with technical variations, such as standard excision with adequate safety margins, and margin-controlled techniques, such as staged surgical excision (SSE) and Mohs micrographic surgery (MMS).

Standard excision is a one-stage excision using predefined safety margins. It is suitable for well-defined, relatively small LM. The size of safety margins has been debated. Most consensus guidelines (Australian-New Zealand, European, National Comprehensive Cancer Network (NCCN), British Association of Dermatologists (BAD)) recommend for in situ MM (to which LM belongs) excision margins of 5 mm around the visible lesion. However, LM often shows subclinical extension of atypical melanocytes, which may be present several cm beyond the visible lesion, so that 5 mm margins are often insufficient to achieve histologically negative margins. A recent study found that surgical margins larger than 5 mm are required in 26.5 % of primary and in 69.2 % of recurrent LM. Another study using MMS found that margins of 6 and 9 mm achieved complete excision of in situ MM in 86 and 98.9 % of cases, respectively, and therefore suggested 9 mm excision margins. Another study found that the mean total surgical margin required for complete LM excision was 7.1 mm. On the basis of these observations, the NCCN recommends for large in situ MM (LM-type) surgical margins greater than 5 mm to achieve histologically negative margins. The AAD recommends margins 5–10 mm for in situ MM. The French Standard, Options and Recommendations guidelines recommend lateral excision margins of 10 mm; when this margin is unfeasible because of anatomic or functional limitations, a margin of 5 mm is acceptable, pending strict microscopic control of the entire tumour margin, either using SSE or MMS prior to definitive wound closure. The deep margin should include the subcutis but not the aponeurosis since removing this structure does not improve the rate of recurrence or survival. With simple surgical excision, the clearance rates range from 24 to 70 % and recurrences from 8 to 20 % of cases.

Margin-controlled excisions (SSE and MMS) are indicated in the case of large LM with ill-defined clinical borders. They are associated with the lowest recurrence rates for LM. SSE comprises several consecutive stages of excision, with each subsequent stage defined by the histologic findings of the previous stage. The first stage(s) consist(s) in excision of peripheral margins, if necessary in multiple steps, until histologically tumour-free ones are obtained. Various techniques of margin examination have been developed, such as square/geometric, perimeter, contoured and total circumferential margin control. The "spaghetti" technique is a recent variation of SSE that does not require specific training

of surgeons and pathologists and does not leave patients with an open wound before final reconstruction. The last stage of SSE consists in excision of the central portion of the tumour, after tumour-free margins have been excised. After complete excision the reconstruction is usually performed with flaps or grafts. Recurrence rates with SSE are reportedly lower than 10 %, and in one comparative study they were significantly lower than those obtained with MMS.

MMS is a specialised form of SSE using (conventionally) frozen sections for immediate histologic analysis or permanent, formalin-fixed-paraffin-embedded sections, offering better tumour cell visualisation (called "slow Mohs"). Immunohistochemical stains for melanocytic antigens (such as MART1/Melan-A and HMB-45) can be used to improve visualisation of atypical melanocytes, especially when frozen sections are used (intraoperatively). MMS allows smaller initial margins than standard excision and therefore has the advantage of sparing healthy tissue (although in the case of LM the difference with SSE regarding postsurgical lesion size may not be significant); furthermore, the traditional MMS involves real-time assessment of tissue samples and therefore allows complete tumour excision in 1 day. The recurrence rate in most studies is lower than 7 %, usually in the order of 4–5 %.

Nonsurgical Treatments

Although surgical excision is the mainstay of LM treatment, this may be challenging because LM frequently develops near critical anatomical structures of the face. Therefore, nonsurgical treatments may be envisaged in some clinical scenarios, namely, for unresectable tumours where complete excision would entail unacceptable mutilations or in elderly or frail patients when comorbidities or advanced age render surgery impossible. These nonsurgical modalities carry a higher risk of recurrence, mostly because of the lack of histological tumour assessment, a fact also exposing to the risk of missing invasive MM (LMM).

Imiquimod (IMQ)

IMQ (1-(2-2methylpropyl)-1H-imidazo[4,5-c] quinolin-4-amine) is a synthetic Toll-like receptor 7-agonist approved for the topical treatment of genital warts and superficial (pre)malignant keratinocytic neoplasms, i.e. actinic keratoses and superficial basal cell carcinomas. It acts as an immune-response modifier by stimulating skin macrophages to secrete cytokines (including TNFα, IFN-α, IFN-γ, IL-6, IL-1b, IL-8, IL-12, GM-CSF, G-CSF) directed against tumour cells. Local side effects (severe inflammatory reaction, burning sensation, erosions) are frequent but can usually be managed, if necessary, with local anti-inflammatory products.

IMQ has been used with variable results in the treatment of LM as a primary treatment when surgery is not realisable (e.g. for periocular tumours), before SSE, or as an adjuvant treatment in selected patients with positive margins after optimal surgery or after laser ablation. The dosing scheme is application of IMQ 5 % cream from daily to three times weekly over several weeks (6–44), with treatment margins up to 2 cm around the visible lesion. Complete clinical responses have been reported in 40–93 % of patients, although histological clearance rates are lower (persistent disease is found in approximately 25 % of patients). Furthermore, the follow-up time in most studies was rather short (less than 3 years). Progression to LMM has also occurred under IMQ treatment. The development of an inflammatory reaction to IMQ seems to be a predictor of clinical and histological clearance, contrary to treatment duration and lesion size. Long-term follow-up (at least 5 years) and post-treatment biopsies are recommended, even in the absence of a clinical recurrence.

IMQ can be associated with local applications of tazarotene 0.1 % gel (twice weekly). This has resulted in a slightly better (although statistically nonsignificant) rate of clearance (78 % vs. 64 %), probably due to a decrease of stratum corneum cohesion, thereby allowing better penetration of IMQ. IMQ can also be used in association with laser ablation or cryotherapy ("cryo-immunological treatment").

Radiotherapy (RT)

RT is rarely indicated as a primary treatment in MM in general but may be envisaged in elderly patients with surgically unresectable disease. It may also be used as adjuvant treatment after surgical excision when tumour-free margins have not been obtained. RT has the advantage over surgery in conserving normal tissue within the treatment field, therefore achieving good functional and cosmetic results. Either low-energy Grenz rays or superficial RT can be used, administered in fractionated doses so as to take advantage of the difference in repair capacity between normal and neoplastic cells. The total dose varies from 35 to 160 Gy and is delivered in 5–20 fractions. The radiation field must be large enough to avoid recurrences, in the order of 10–20 mm around the visible lesion. The radiation should be penetrating enough so as to reach deeply seated melanocytes (namely, those within hair follicles), as radiation energy attenuates with increasing depth; 5 mm is considered to be adequate in most cases. The recurrence rate of RT (infield or marginal) is 5–10 % at 3 years. Salvage is possible in the majority of these cases by further RT, surgery or other therapies. Progression to LMM has been observed in 1.4 % of cases at 3 years, and the outcome in these cases is poor. RT is well tolerated; however, side effects (such as fibrosis with possible ectropion, hypopigmentation, telangiectases and alopecia) may occur.

Cryotherapy/Cryosurgery

This technique involves application of a cryogenic agent, usually liquid nitrogen, to the skin in order to destroy superficially located pathologic cells. In LM, the treatment relies on the fact that melanocytes are sensitive to freezing and are destroyed at temperatures between −4 and −7 °C, i.e. higher than those destroying keratinocytes (−20 to −30 °C). The liquid nitrogen can be applied with a cotton swab or as spray. Most studies have involved small patient series. Two to three freeze–thaw cycles (occasionally under local anaesthesia) and 5–10 mm lesion margins are usually applied. A clinical clearance rate of 60 % or higher has been achieved, although data are insufficient to determine a histological clearance rate. On the other hand, even with "aggressive" cryotherapy, the recurrence rates may be high (up to 40 %). This treatment may make subsequent progression difficult to detect and may be complicated by the development of amelanotic MM. Side effects include hyper- or hypopigmentation of the treated area. Cryosurgery can be combined with continuous treatment with IMQ ("cryo-immunological treatment").

Other Treatments

Other treatment modalities have been tried for LM but are not included in current consensus recommendations. They include:

Laser therapy: several types of lasers (argon, carbon dioxide, Q-switched ruby, Q-switched neodymium-doped yttrium aluminium garnet, alexandrite lasers and various combinations) have been used. Potential advantages of laser treatment include less pain, better cosmetic results compared with surgery, speed of therapy and less post-treatment care. Despite lateral margins of 5 mm, the recurrence rates are rather high (23–38 %), probably because the laser beam may not reach a sufficient depth to destroy deeply seated atypical melanocytes, namely, within hair follicles. This drawback outweighs the advantages of laser therapy that may nevertheless be proposed as an alternative treatment in patients in whom surgery or RT is declined or carries significant morbidity. The combination of ablative laser therapy followed by IMQ has recently been advocated.

Curettage and electrosurgery have been used in a limited number of patients. Not surprisingly, high recurrence rates were observed.

Topical azelaic acid (AZA) is a dicarboxylic acid that competitively inhibits tyrosinase in vitro. It has been used to treat LM (applications of 15–20 % cream for up to 3 months) with local disease control; however, progression to invasive melanoma has also been reported.

Topical 5-fluoro-uracil is an antineoplastic pyrimidine analogue used locally for the treatment of actinic keratoses and superficial basal cell carcinomas. Limited data exist for its use in LM

treatment (twice daily application of 5 % cream for 6–13 weeks). Efficacy is very limited because recurrences are very common.

Topical cidofovir 1% is an acyclic nucleoside analogue of deoxycytidine monophosphate that can be used topically for the treatment of DNA virus-induced infections (molluscum contagiosum, HPV warts, herpes simplex). It has proven effective in a small number of basal and squamous cell carcinomas and has also been successful in two cases of recurring LM; it may act by blocking DNA synthesis.

Finally, elderly patients with facial LM that are not suspicious of containing an invasive zone, and who cannot be treated by surgery or alternative nonsurgical methods because of comorbidities or complexity of wound repair, may be carefully monitored with non-invasive techniques (macroscopic and dermatoscopic photography, in vivo reflectance microscopy). Biopsy should be performed if changes in size or pigmentation are noted.

Treatment of Lentigo Maligna Melanoma (LMM)

LM that has progressed into the invasive phase (LMM) behaves as other MM subtypes and therefore should be treated similarly to other MM forms, although the localisation on the face and the often large size of the lesion often poses difficult functional and anatomic problems. The therapeutic decision should be taken on an individual patient, preferably after discussion in the setting of a multidisciplinary oncology team.

Follow-Up

The aim of follow-up in MM is early detection of recurrences or disease progression, early diagnosis of new primary MM (reportedly occurring in 10 % of patients), psychosocial support and providing education on self-examination of the patient and his first-degree relatives. The frequency and extent of follow-up examinations depend on the risk of each individual patient. Since LM has no risk of metastasis, some advocate that no follow-up is necessary, apart from a return visit after complete excision to check the whole skin for further primary MM and to teach self-examination for a new primary MM. However, most guidelines recommend patient monthly self-skin examination and at least annual skin examination for life for all patients diagnosed with in situ MM. The frequency of this examination may be increased (up to four times per year) depending on the individual risks of the patient to develop recurrences and/or new MM, such as personal or family history of MM and the patient's ability and awareness to detect signs and symptoms of the disease.

Leprosy (Hansen's Disease)

52

Clio Dessinioti and Andreas D. Katsambas

Key Points

- Leprosy (Hansen's disease) is a chronic granulomatous bacterial infection caused by the bacillus *Mycobacterium leprae* (*M. leprae*).
- The transmissibility of *M. leprae* is low.
- The disease mainly affects the skin and the peripheral nerves.
- Lepromatous leprosy (LL) is characterized by positive bacteriology and negative Mitsuda reaction due to the absence of specific cell-mediated immunity.
- Tuberculoid leprosy (TL) is stable, rarely contagious, and may even be self-limiting. There is negative bacteriology and positive Mitsuda reaction, and granulomas are typically found on biopsy.
- The duration and type of drug therapy is based on the classification of leprosy as paucibacillary or multibacillary.
- Leprosy is curable.
- Multidrug therapy (MDT) treatment is a highly effective cure for leprosy.
- Reversal reactions and erythema nodosum leprosum (ENL) can be treated using oral corticosteroids.
- For severe ENL, thalidomide is the treatment of choice.

Definition and Epidemiology

Leprosy is a chronic granulomatous bacterial infection that primarily affects the skin and peripheral nerves. It is one of the world's oldest documented diseases with the first known written mention of the disease dating 600 BC. Leprosy is also called Hansen's disease after Gerhard Henrik Armauer Hansen (1841–1912), a Norwegian physician known for the identification of *Mycobacterium leprae* (*M. leprae*), an obligate intracellular, acid-fast, rod-shaped bacillus, as the causative agent of leprosy in 1874. *M. leprae* multiplies slowly (approximately every 12 days) and the incubation period of the disease is about 5 years. Symptoms can take as long as 20 years to appear.

By 2005, the global prevalence of leprosy had fallen to about 300,000 due to the available multidrug therapy. As reported by WHO, official figures from 115 countries showed the global registered prevalence of leprosy at 189,018 at the end of 2012, and during the same year, 232,857 new cases were reported. Elimination of leprosy globally was achieved in the year 2000 (i.e. a prevalence rate of leprosy

less than 1 case per 10,000 persons at global level). High endemicity still remains in some areas of many countries, including Angola, Bangladesh, Brazil, China, Democratic Republic of Congo, Ethiopia, India, Indonesia, Madagascar, Mozambique, Myanmar, Nepal, Nigeria, the Philippines, South Sudan, Sri Lanka, Sudan, and the United Republic of Tanzania.

Basic Concepts of Pathogenesis

M. leprae is an acid-alcohol-fast, gram-positive obligate intracellular bacillus that shows tropism for cells of the reticuloendothelial system and peripheral nervous system. It preferentially infects cold areas of the body such as the skin, nasal mucosa, and peripheral superficial nerves.

The transmissibility of *M. leprae* is low. The mode of transmission and infection with *M. leprae* remains unclear, but it has been postulated to occur from person to person via respiratory droplets, from the nose and mouth, during close and frequent contacts with untreated cases. Household contact studies have shown that multibacillary (MB) cases with a higher bacillary load display a higher transmission potential as compared to paucibacillary (PB) cases.

Leprosy displays a wide spectrum of clinical forms depending on the immunological status of mainly T-helper (Th) type cell-mediated immunity. The cytokine interferon-gamma (IFN-γ) plays an important role in the activation of natural killer (NK) cells and the induction of Th1 cells. A meta-analysis by Silva et al. included 1,573 patients and 1,914 controls and reported that carriers of the IFN-γ +874T allele (12q14.1), which has been correlated with high interferon-γ levels, may be protected from developing leprosy (pooled OR = 0.83, 95 % CI 0.72–0.96, $p = 0.011$). Familial aggregation studies and segregation analyses support a genetic basis for the human susceptibility to leprosy. A two-stage model has been proposed with a first set of genetic factors controlling susceptibility to preclinical disease and a second set of genes controlling the clinical polarization into PB or MB leprosy.

Clinical Presentation

Leprosy is a multi-organ infectious disease that can cause severe disability. The development of skin, nerve, and eye lesions and other symptoms can delay for 20 or more years after the onset of infection.

Clinical forms of leprosy are a part of a disease spectrum. In 1966, Ridley and Jopling have proposed a classification of leprosy into five groups based on clinical, histological, bacteriological, and immunological criteria (Fig. 52.1). Lepromatous leprosy (LL) is considered to be at the systemic and infectious end of the spectrum and correlates with an absence of an immune response to *M. leprae* antigens. LL affects the skin and peripheral nerves and presents with annular infiltrated, usually anaesthetic plaques. The lepromatous pole of the spectrum (lepromatous leprosy and borderline lepromatous cases) is characterized by confluent papules and nodules; marked, diffuse infiltration of the skin; leonine facies; and madarosis (Fig. 52.2). Lesions are usually symmetrical and bilateral. The lepromatous pole is characterized by greater nerve involvement and more severe disability. Histoid leprosy is a variant of lepromatous leprosy, presenting with shiny, skin-coloured or erythematous papules, nodules, or plaques. It may occur after inadequate antileprosy treatment or due to dapsone-resistant mutation or de novo.

Tuberculoid leprosy (TT) form correlates with cell-mediated immunity to *M. leprae*. The borderline forms [borderline tuberculoid (BT), borderline borderline (BB; also termed mid-borderline), and borderline lepromatous (BL)] have some cell-mediated immunity and are often immunologically unstable. At the tuberculoid pole (tuberculoid and borderline tuberculoid cases), there are a few well-defined, hypopigmented anaesthetic macules or plaques with elevated, erythematous borders and sometimes atrophic centres. This form is associated with anhidrosis and loss of adnexal structures. Since there is adequate immune response, lesions are not usually large or numerous and TT may resolve spontaneously.

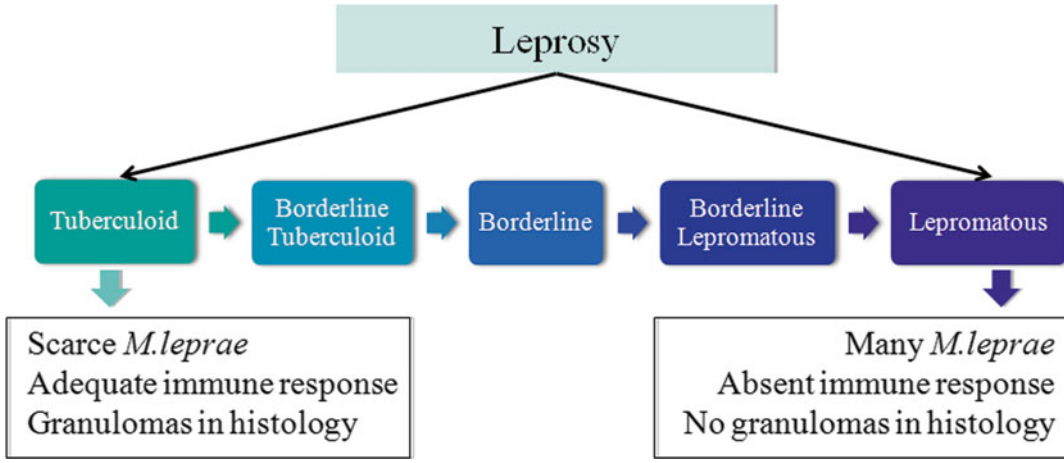

Fig. 52.1 Forms of leprosy

Fig. 52.2 Lepromatous leprosy with leonine face

Leprosy may affect cutaneous peripheral nerves, primarily the posterior tibial, cubital, medial, and lateral peroneal nerves, making them palpable during physical examination. There may be numbness, anhidrosis, and motor and thermal sensory impairment. Other affected organs in leprosy include the musculoskeletal system (95 %) with osteoporosis and non-specific symptoms due to nerve damage, the testis with atrophy and acute orchitis in patients with the lepromatous form, and the eye with lagophthalmos, keratitis, entropion, optic nerve damage, or loss of vision (Table 52.1).

Leprosy is classified into two subtypes, paucibacillary (PB) or multibacillary (MB) leprosy with MB patients manifesting a greater number of lesions, extent of nerve involvement, and bacillary load.

All types of leprosy have been reported in patients with HIV infection.

Leprosy Reactions

Leprosy may be complicated by episodes of immunological instability, such as those caused by antileprosy medication, stress, or pregnancy, termed 'reactions'. During reactions, leprosy patients are at higher risk of developing nerve damage. Type 1 reactions are caused by delayed-type hypersensitivity to *M. leprae* antigens, while type 2 reactions (erythema nodosum leprosum) by immune complex formation. If these reactions occur during MDT, the treatment should be continued and additional therapy for the reactions is advised.

Table 52.1 Clinical manifestations of leprosy

Skin	In tuberculoid leprosy: few anaesthetic erythematosquamous lesions
	In lepromatous leprosy: numerous symmetrical, annular, papulonodular lesions
Cutaneous peripheral nerves (posterior tibial, cubital, medial, and lateral peroneal)[a]	Thickening and palpable during physical examination
	Numbness
	Anhidrosis
	Motor and thermal sensory impairment
	Deformities
Musculoskeletal system (95 %)[b]	Non-specific findings
	Fractures
	Deformities due to nerve damage osteoporosis
Upper respiratory tract[b]	Nose deformities
	Mouth
	Larynx
	Pharynx
Testis[b]	Testicular atrophy
	Acute orchitis (lepromatous leprosy, erythema nodosum leprosum)
Eye[b]	Lagophthalmos
	Keratitis, iritis, uveitis
	Entropion
	Damage of the optic nerve
	Vision loss

[a]In tuberculoid leprosy, rapid, serious, asymmetrical nerve involvement; in lepromatous leprosy, slow and symmetrical nerve involvement
[b]Affected in lepromatous leprosy

Type 1 Reactions

Type 1 reactions include upgrading or reversal reactions and downgrading reaction. Reversal reaction is a delayed type IV hypersensitivity reaction that arises when borderline leprosy shifts towards borderline lepromatous leprosy during treatment. Type 1 reactions are due to the development of an appropriate immune response and the production of tumour necrosis factor-alpha (TNFα) and IFN-γ. The reaction is characterized by oedema and erythema of existing skin lesions, development of new skin lesions, neuritis, and additional sensory and motor loss.

The downgrading reaction occurs in untreated borderline patients and is characterized by appearance of new skin lesions and a shift towards the lepromatous pole.

Treatment of type 1 reaction includes nonsteroidal anti-inflammatory drugs (NSAIDs) and oral corticosteroids with tapering after clinical improvement is achieved.

Type 2 Reactions (Erythema Nodosum Leprosum)

Type 2 leprae reaction manifests clinically as erythema nodosum leprosum (ENL). It is a Th2-mediated type III hypersensitivity reaction due to immune complex deposition associated with systemic toxicity and elevated tumour necrosis factor levels. ENL is due to immunological response to high loads of *M. leprae* in skin tissue, and it develops mainly in leprosy patients classified as BL or LL, belonging to the multibacillary (MB) group, as defined by WHO. Incidence rates of ENL in person years at risk (PYAR) have been reported to range from 1 to 8 per 100 PYAR. In their systematic review, Voorend et al. reported that in most studies, the incidence of ENL during multidrug therapy (MDT) was at least twice as high than at the time of the initial diagnosis and was the highest during the first year of MDT. Other risk factors for the development of ENL include a bacteriological index (BI) of six (associated with up to 8.6 times higher risk), lepromatous leprosy, pregnancy, and lactation. ENL presents with fever and painful subcutaneous nodules on the face or the extensor surfaces of the limbs, while there may also be nerve and eye lesions. Neuritis, iritis, iridocyclitis, arthralgia, and glomerulonephritis may occur. ENL is often recurrent and may become chronic.

Thalidomide is the drug of choice for severe ENL, with its beneficial effect being attributed to anti-TNFα action. Due to the documented teratogenic effects of thalidomide, it is not proposed for women of childbearing potential. Short

courses of oral corticosteroids may be used in cases of moderate ENL or contraindication for thalidomide use. In the case of recurrent or chronic ENL, clofazimine may be beneficial.

Leprosy of Lucio and Latapí

Leprosy of Lucio and Latapí is prevalent in Mexico and the Caribbean. It is considered to be the most anergic form in the immunologic spectrum of the disease, and it is characterized by generalized infiltration of the skin and absence of nodules. Lucio's phenomenon is a late stage reaction in which haemorrhagic infarcts occur due to heavy colonization of endothelial cells by *M. leprae* in infarcted and clinically normal-appearing skin.

Diagnosis

Under the global initiative for eradicating leprosy in countries where the disease is endemic, diagnosis is based on clinical signs and smear tests, although other methods, such as serology, have become available.

The WHO case definition of leprosy is *M. leprae* infection in an individual who has not completed a course of treatment and has one or more of the following:

- Hypopigmented or reddish skin lesions with loss of sensation
- Involvement of the peripheral nerves as demonstrated by their thickening and associated loss of sensation
- Skin smear positive for acid-fast bacilli

Laboratory studies include the following:

- Skin biopsy, nasal smears, or both are used to assess for acid-fast bacilli using Fite stain.
- Serologic assays can be used to detect phenolic glycolipid-1 (specific for *M. leprae*).

The smear test has a specificity of 100 % and a sensitivity of 50 %. A smear can be obtained from the nasal mucosa, an ear lobe, and/or skin lesions and stained with Ziehl-Neelsen stain. The current system for classifying patients as either paucibacillary or multibacillary is based on skin smears. Ridley's logarithmic scale, or bacterial index (BI), is used to interpret the smear test results. Patients with negative smears at all sites are classified as having paucibacillary leprosy, while those with positive smears at any site are classified as having multibacillary disease.

Histologically, the morphology and cellular composition of the infiltrate in cutaneous leprosy lesions depends on the intensity of cell-mediated immunity. In TL, there are granulomas of activated macrophages (epithelioid cells) with CD4+ T cells in the centre of the aggregates of epithelioid cells and CD8+ T cells surrounding the granuloma. By contrast, in LL, both T-cell types are diffusely distributed without a specific organization.

The intradermal lepromin test uses inactivated *M. leprae* extracted from lepromas. After intradermal injection of 0.1 mL of the antigen (lepromin) in the flexor surface of the forearm, the reaction is interpreted. The early (Fernández) reaction is read at 24 or 48 h. The late (Mitsuda) reaction is read at 21 days and indicates resistance to the bacillus. A nodule measuring more than 5 mm indicates positivity. These tests are not diagnostic, and they are used for classification and prognostic purposes.

PCR detection of the bacillus is a highly specific and sensitive but expensive technique.

LL is characterized by positive bacteriology and negative Mitsuda reaction due to the absence of specific cell-mediated immunity. TL is stable and rarely contagious and may even be self-limiting. There is negative bacteriology and positive Mitsuda reaction, and granulomas are typically found on biopsy.

Differential Diagnosis

Leprosy should be differentially diagnosed from other granulomatous skin diseases such as sarcoidosis, cutaneous tuberculosis (lupus vulgaris), and other skin disease with infiltrated plaques/nodules such as cutaneous T-cell

lymphoma (mycosis fungoides) and deep fungal infections:

- Sarcoidosis: may present with annular plaques and/or nodules. However, there is a different histology.
- Lupus vulgaris: it is caused by *M. tuberculosis*, different histology.
- Mycosis fungoides: different histology, immunohistochemistry.
- Deep fungal skin infections: histology, culture and stains for fungi.
- Leishmaniasis: histology, culture for *Leishmania*.
- Molluscum contagiosum: histology.
- Primary amyloidosis: histology.
- Hereditary neuropathies: nerve biopsy.

Table 52.2 Standard MDT regimens for adults proposed by WHO

Multibacillary (MB) leprosy	
Rifampicin	600 mg once a month
Dapsone	100 mg daily
Clofazimine	300 mg once a month and 50 mg daily
Duration	12 months
Paucibacillary (PB) leprosy	
Rifampicin	600 mg once a month
Dapsone	100 mg daily
Duration	6 months
Single-skin-lesion paucibacillary leprosy	
Rifampicin	600 mg
Ofloxacin	400 mg
Minocycline	100 mg
Taken as a single dose	

General Principles of Treatment

Leprosy is curable and early treatment can prevent disability. Untreated, leprosy can cause progressive and permanent damage to the skin, nerves, limbs, and eyes. Standard treatment is multidrug therapy (MDT), including the combination of the antibiotics rifampicin and dapsone, with or without clofazimine, depending on the bacillary load. Since the introduction of multidrug therapy in 1981 by the World Health Organization (WHO), the global burden of leprosy has steadily declined. The duration and type of drug therapy is based on the classification of leprosy as paucibacillary or multibacillary (Table 52.2). When classification is in doubt, the patient should be treated as having multibacillary disease.

First-Line Drugs

Rifampicin is derived from *Streptomyces* fungi. It has antibacterial action and inhibits RNA synthesis. It is given once a month. It causes red coloration of urine, sweat, tears, and faeces.

Clofazimine binds DNA, generates cytotoxic superoxide radicals, and has anti-inflammatory properties. It is most active when administered daily. It causes a reversible brownish black discoloration and dryness of skin. Its use is associated with a lower incidence of erythema nodosum leprosum.

Dapsone is a sulphonamide whose antibacterial mechanism relies on p-aminobenzoic acid (PABA) antagonism and inhibition of folate synthesis. It is associated with haemolysis (mainly in patients with glucose-6-phosphate dehydrogenase deficiency), peripheral neuropathy, and erythema nodosum leprosum. Resistance to rifampicin and to dapsone has been described.

The daily combination of dapsone and clofazimine is highly bactericidal. This combination is capable of eliminating any rifampicin-resistant mutants in an untreated MB leprosy patient within 3–6 months. Based on results from several studies showing that MB leprosy patients who received less than 24 monthly doses of MDT responded as favourably as those who received 24 or more doses of MDT, the 7th WHO Expert Committee considered that the duration of MDT treatment of MB leprosy can be reduced to 12 months.

According to WHO, MB patients starting with a high BI may have a higher risk of developing reactions and nerve damage during the second year than those patients starting with a low bacterial index. High-BI patients who do not show improvement, with evidence of deterioration, will need an additional 12 months of MDT for multibacillary leprosy.

After completion of the WHO MDT regimens, the risk of relapse is considered to be negligible, and it is proposed that it is not necessary to continue active post-MDT surveillance. Patients should be taught to recognize early signs of possible relapses and to report promptly for treatment. Relapse in MB leprosy is defined as the multiplication of *M. leprae*, suspected by the marked increase (at least 2+ over the previous value) in the BI at any single site, usually with evidence of clinical worsening (new skin patches or nodules and/or new nerve damage).

Household contacts of patients with leprosy are at risk for the development of the disease and they should be examined for evidence of leprosy. Chemoprophylaxis with rifampicin or other antileprosy drugs is not recommended by WHO for contacts of leprosy patients in leprosy control programmes.

Supportive Measures

In order to improve the functional ability in patients with leprosy, supportive measures include physical therapy, reconstructive surgery, nerve and tendon transplants, and surgical release of contractures.

Vaccines

In some regions the BCG vaccine is administered to children under the age of 12 years who are in contact with relatives who have leprosy.

Lichen Planus

53

Alfredo Rebora

Key Points

- Lichen planus (LP) is an acquired chronic disease characterized by small cutaneous papules and mucosal striae affecting 0.3–0.8 % of the population.
- Topical treatments are usually employed on limited lesions, especially the oral ones. The most useful medications are corticosteroids and tacrolimus.
- Systemic treatments are rarely needed. Oral cyclosporine is probably the most active.
- Biologics are interesting but only exceptionally needed.

Definition and Epidemiology

Lichen planus (LP) is an acquired chronic disease characterized by small cutaneous papules and mucosal striae. It affects 0.3–0.8 % of the population, occurring in all races and both genders. Children are rarely affected.

A. Rebora
University of Genoa, Genoa, Italy
e-mail: rebdermo@unige.it

Basic Concepts of Pathogenesis

LP is a specific pattern of cell-mediated cutaneous hypersensitivity to a variety of antigens expressed on keratinocytes (possibly on other epitheliocytes as well), which are the target of CD8 lymphotoxicity. Antigens may be viruses (hepatitis C and hepatitis B virus in the Mediterranean countries, the USA, and Japan), drugs, and contact antigens. LP may associate with visceral diseases, in particular chronic active hepatitis, primary biliary cirrhosis (in the UK), and ulcerative colitis and with other autoimmune disorders of the same cell-mediated nature, like alopecia areata.

Clinical Presentation

Lesions are small violet, polygonal papules, which coalesce into larger papules and plaques. On their surface, a whitish reticulum can be observed. On the skin, a typical site is the volar aspect of the wrist, but widespread lesions are not uncommon. Mucosae are often involved, usually by the whitish reticulum, more rarely by erosions (Figs. 53.1 and 53.2). Nail plates may be dystrophic. Clinical features vary according to the body region. On the shins, LP is verrucous, while on the scalp it presents as a scarring alopecia plaque. Unusual varieties include:

- Annular LP of the scrotum
- Ulcerative form of the sole
- Lichen planopilaris

Fig. 53.1 Nonerosive oral lichen planus. Note the whitish irregular plaques on the dorsal surface of the tongue

Fig. 53.2 Erosive oral lichen planus. Gums are intensely erythematous and deepithelialized

- Vesicobullous lichen
- Pigmentary forms (lichen actinicus, lichen pigmentosus)

The course is chronic, accompanied by pruritus of varying severity. Mucosal erosion may result in squamous cell carcinoma.

Diagnosis

Diagnosis is mainly clinical. Histopathology may help in doubtful cases but is mandatory in erosive forms. It reveals a typical mononuclear infiltrate (CD4-positive initially then CD8-positive), which impinges the keratinocyte basal line, disorganizing the epidermal architecture. Immunofluorescence shows an IgM deposit at the dermoepidermal junction.

Differential Diagnosis

- Lichenoid drug eruptions: they show parakeratosis and eosinophils in the infiltrate.
- Lupus erythematosus: a lupus band in direct immunofluorescence is distinctive, but there may be overlapping cases.
- Secondary syphilis: lymph nodes are constantly involved and serology is distinctive.
- Psoriasis: there are parakeratotic scales and a typical histopathology.
- Leukoplakia: often asymmetrical, with a rough velvet surface and dysplasias on histopathology.
- Candidiasis: whitish patches are easily removed; there is a severe immunodeficiency.
- Erythema multiforme: skin lesions are target-like and histopathology is distinctive.
- Bullous diseases: histopathology and direct immunofluorescence are distinctive.

General Principles of Treatment

Usually, LP is a chronic but benign and often symptomless disease, which does not require systemic treatment. As an immune disease, LP responds to all immunosuppressants. Those should be used only if a severe visceral involvement is documented or whenever the mucosal erosions prevent eating and speaking.

Topical Treatments

A number of medications have been tried and recommended. They are summarized in Table 53.1.

Topical Corticosteroids

Corticosteroids are in most cases the treatment of choice, but there is no convincing evidence of their efficacy in the literature (Cribier et al. 1998). Class I and II corticosteroids should preferably

Table 53.1 Treatments

Corticosteroids	Retinoids	Calcineurin inhibitors	Physical	Others
Triamcinolone acetonide	Tretinoin	CyA A	Laser therapy	Aloe vera
Fluocinolone acetonide	Tazarotene	Pimecrolimus	Photodynamic therapy	Hyaluronic acid
Fluocinonide	Isotretinon	Tacrolimus		Calcipotriol
Clobetasol proprionate	Fenretinide	Sirolimus		Mesalazine
Fluticasone proprionate				Thalidomide
Betamethasone phosphate				Amlexanox
Mometasone furoate				Tetracycline
				Herbal medicines
				Extracorporeal photochemotherapy

be employed. Occlusive dressings with class I drugs are recommended on verrucous plaques. Intralesional preparations have been advocated, but they should be used only in very resistant verrucous plaques. They have been useful in pitted nails, but discomfort discourages the patients. In any case, injectable triamcinolone, properly diluted, is preferable (5–0 mg per mL injection and 0.5–1 mL per 2 cm lesion). On lichen planopilaris of the scalp, corticosteroids may be more useful at the periphery of the plaque rather in its center, which is usually scarring. Foamy preparations of betamethasone or clobetasol are useful in this particular location.

Oral mucosal lesions (OLP) occur in 50–70 % of the patients with LP, affecting 2 % of the population with the highest incidence in women (2:1), in the age range from 40 to 70 years. It is understandable therefore that most of the literature is devoted to oral lesions rather than to other locations. Topical steroids are still the widely accepted first-line therapy for erosive OLP. A recent Cochrane collaboration systematic review found, however, only weak evidence for their effectiveness (Thongprasom et al. 2011). The lack of good-quality well-conducted trials and the small number of participants prevented good evidence to be obtained. In any case, none of the studies involved genital or oesophageal disease.

Several side effects are reported. With topical corticosteroids, the main side effects are oral candidiasis and dyspepsia, but even a severe neuropsychiatric disorder has been reported due to the exceeding absorption of clobetasol through the oral mucosa. Fluticasone propionate spray caused nausea, swollen mouth, bad taste and smell, dry mouth, and a sore throat in a small proportion of participants.

Anecdotal reports describe the efficacy of the injections of triamcinolone within the lesion of OLP. In a study of 11 patients with lichen of the nail plate (Abell 1973), 5 mg/mL were injected in the posterior nail fold at intervals of 2–4 weeks. Seven of them greatly improved, but eight experienced relapses after about 1 year.

Retinoids

A recent literature review (Petruzzi et al. 2013) of data on topical retinoids in patients with OLP found 16 studies with 280 patients topically treated with different classes of retinoids. Isotretinoin 0.1 % gel is the most frequently employed one, but tretinoin (0.025 %), tazarotene, and fenretinide have been also tried.

In a double-blind study, ten patients with biopsy-proven OLP were treated for 4 months with 0.1 % isotretinoin gel and another ten patients with placebo. All patients treated with isotretinoin showed a significant improvement of the oral lesions, whereas in the placebo group, the size of the lesions remained the same (Piattelli et al. 2007). The best concentration has been also studied in 70 OLP patients who were randomly divided into two groups with 0.05 and 0.18 % drug concentrations. None of the cases of reticular LP improved, while in 26 patients with the

atrophic-erosive forms (at 0.18 % concentration) and in nine patients (at 0.05 % concentration), the erosions or ulcers disappeared both clinically and histologically. The disappearance of dysplastic phenomena was observed at 0.18 % concentration. Topical application of the drug was accompanied by a transitory increase in soreness and pain, as well as greater sensitivity to hot foods. The presence of dysplastic features, however, raises some doubts on the correct diagnosis (Scardina et al. 2006).

Tretinoin in an oral base 0.05 % was compared in a randomized controlled study with fluocinolone acetonide 0.1 % in the treatment of atrophic and erosive OLP. Of 33 patients, 18 improved with fluocinolone acetonide, whereas 15 patients receiving topical retinoic acid showed little change. The difference was significant. In a randomized, placebo-controlled study, 12 patients with OLP were randomly treated with tazarotene gel 0.1 % b.i.d. or with placebo for eight consecutive weeks. The tazarotene group had their lesions significantly reduced as compared with the control group (Petruzzi et al. 2002).

Fenretinide was used in a small heterogeneous study (eight patients) and two of them had complete remission after 1 month.

Cyclosporin A

Four controlled trials evaluated topical CyA (Eisen et al. 1990; Sieg et al. 1995; Lopez Lopez and Rosello Llabrés 1995; Harpenau et al. 1995). Three washes per day (1,500 mg/day) proved beneficial in 16 OLP patients. In another trial, no difference between CyA and triamcinolone paste was noted in 13 patients. Likewise, there was no difference in comparing an oil-based CyA solution (50 mg three times daily) with an aqueous 1 % triamcinolone acetonide solution in 20 patients. A significant difference was instead found when 14 patients with erosive OLP treated with 5 mL of CyA (500 mg) were compared with placebo after 4 weeks of treatment.

Multiple, small, uncontrolled trials studied topical CyA on OLP, while only one evaluated its effect under occlusion in chronic hypertrophic LP. The different forms of OLP, the different modalities of application (mouthwash, manual administration with local massage), the different doses (50–1,500 mg/day), and vehicles all bias the results. Those are favorable in most studies, although poor efficacy was also reported in three. Also genital LP seems to benefit from topical CyA, but a case of squamous cell carcinoma was registered during treatment. Efficacy seems to be dose dependent (1,550 mg/day), but not blood level dependent. CyA A solution significantly reduced pain in erosive OLP over 0.1 % triamcinolone acetonide in orabase; the study, however, was very small (11 patients). A significant difference was seen in favor of the 1.5 % CyA gel compared to 0.025 % clobetasol propionate gel. However, seven patients with long-standing atrophic/erosive OLP were treated for 4 weeks with CyA A as a mouthwash. At the end of the 3-month follow-up period, no improvement was recorded. In any case, the evidence to support the contention that topical cyclosporine reduces pain and clinical signs of oral lichen planus has been defined as weak and unreliable (Le Cleach and Chosidow 2012).

Calcineurin Inhibitors

A recent systematic review for calcineurin inhibitors examined 5 double-blind studies, 1 investigator-blinded study, 10 open prospective studies, 6 retrospective studies, and 28 case reports (Cheng et al. 2012).

Strong evidence (double-blind and open studies) (level A) has been found for tacrolimus ointment in OLP, with efficacy at least equal to topical clobetasol propionate 0.05 % ointment. Blood levels of tacrolimus are demonstrable but without clinically significant adverse events. Strong evidence (level A) has been also found for pimecrolimus 1 % cream with efficacy equal to that of topical triamcinolone acetonide 0.1 % paste. For vulvovaginal LP, pimecrolimus was superior to placebo in one double-blind study but less active than clobetasol (Goldstein et al. 2011). Only case reports support the efficacy of topical calcineurin inhibitors in cutaneous LP.

Topical rapamycin (1 mg/ml) was studied in an open prospective study involving seven women with oral and vulvar erosive lesions twice a day for 3 months. Complete remission was obtained in four women. Only one had stopped treatment due to local discomfort. Only one woman had detectable blood sirolimus level (Soria et al. 2009).

Other Topical Preparations

Calcipotriol

Eighteen LP patients applied calcipotriol ointment twice daily. Of the 16 patients that completed the study, 5 obtained complete clearing of the lesions, while 4 had partial improvement. No improvement was observed in seven. In a randomized open-label trial, 15 LP patients were given calcipotriol 50 μg/g and 16 betamethasone 0.1 % ointment twice daily for 12 weeks. Calcipotriol was no more effective than betamethasone (Theng et al. 2004).

Mesalazine

Mesalazine (5-aminosalicylic acid) 5 % was compared with clobetasol propionate 0.05 % in 25 patients with OLP. Both preparations were active without statistical difference. Mesalazine resulted in total remission in 57 % of patients. Only 9 % of patients had no benefit (Sardella et al. 1998).

Thalidomide

In a randomized double-blind, positive-control trial, 24 patients received thalidomide 1 % paste vs. dexamethasone 0.043 % paste of controls. After 1 month of treatment, 66.7 % of thalidomide patients had fully healed. The erosive area size and the Visual Analogue Scale scores were similar between groups. Only two patients in each group experienced discomfort with treatment (Wu et al. 2010).

Amlexanox

Amlexanox is an anti-inflammatory drug which selectively inhibits TBK1 and IKK-ε. It has been studied in a randomized, positive-controlled clinical trial in which 20 patients with erosive OLP received amlexanox paste and 18 dexamethasone paste. After 7 days of treatment, both groups showed significant reduction in erosive area. None of the patients had severe adverse reactions (Fu et al.2012).

Aloe Vera

Aloe vera gel was tried in a randomized, double-blind study involving 40 patients with OLP (18 erosive, 14 atrophic). After 8 weeks of therapy, aloe vera gel proved more effective than triamcinolone acetonide (Choonhakarn et al. 2010). In another double-blind, placebo-controlled trial, 27 patients with OLP applied *Aloe vera* twice daily for 8 weeks. Lesions disappeared in two patients treated with *Aloe vera* vs. none of the placebo group.

Hyaluronic Acid

In a blinded parallel-group randomized clinical trial (Woo 1985), a local hyaluronic acid preparation (0.2 %) was evaluated in 120 patients with erosive OLP four to five times daily for 28 days. In patients treated with hyaluronic acid, a decrease of pain for up to 4 h post application and a reduction of ulcerative areas were registered (Nolan et al. 2009).

Tetracycline

A 78-year-old woman with erosive OLP gargled a 0.25 % tetracycline solution three times a day. Within a week there was a considerable relief from pain, and after 6 weeks the erosions had disappeared.

Herbal Medicines

Zheng et al. investigated the concomitant administration of the Chinese herb *Liuwei Dihuang* and retinoic acid cream in 43 patients with OLP with more effective results than retinoic acid cream alone, particularly in patients with a shorter history of lichen. Lichen pemphigoides, however, has been reported to occur after Chinese herb medication.

Physical Treatments

Laser Therapy

A diode laser (940 nm) was also successfully used to relieve symptoms in a single case of LP.

The excimer laser 308 nm UVB was used in 8 patients with OLP with 9–32 applications and fluency 75–175 mJ/cm^2. Six patients improved, with

complete remission in two. One patient relapsed after 4 weeks (Köllner et al. 2003). Also Trehan and Taylor (2004) successfully managed nine patients with the excimer laser therapy (initial fluencies 100 mJ/cm^2). Unsatisfactory results have been instead reported in four patients treated with the 308 nm excimer laser twice a week for 12 sessions. The lowest dose was 50 mJ/cm^2, increased by 50 mJ/cm^2 every two sessions up to 200 mJ/cm^2. Only one patient showed positive results.

A total of 82 lesions of OLP of 30 patients were treated in an open study (Cafaro et al. 2013) with low-level laser therapy delivered with a 980 nm gallium-aluminum arsenide diode laser. Eighteen patients (60 %) obtained a total resolution of the clinical signs, ten patients (33.3 %) a partial resolution, and two patients (6.6 %) did not respond at all. In another study, low-level laser therapy proved as effective as topical corticosteroid therapy without any adverse effects.

The CO2 laser was investigated in 39 superficial OLP lesions (1.5–2.0 J/mm^2). During a mean follow-up period of 8 years, 24 lesions showed no more signs of pain or burning sensation. In all patients, the treatment led to complete epithelialization in 3 weeks (Van der Hem et al. 2008).

Photodynamic Therapy

Twenty-three patients with OLP were submitted to photodynamic therapy performed using a semiconductor laser, with power up to 300 mW and a wavelength of 660 nm. After treatment, improvement was observed in 39 sites, including 14 with complete regression. The reduction in the size of lesions was statistically significant in both genders and in smokers and nonsmokers. On the gums and tongue, the effect was slighter and not statistically significant.

Extracorporeal Photochemotherapy

Extracorporeal photochemotherapy (ECP) or photopheresis efficacy has been studied in four patients with erosive OLP. All patients improved their symptoms and lesions after seven to nine cycles. Guyot et al. (2007) submitted 20 patients with erosive OLP to ECP twice weekly for 3 weeks while the following sessions were planned according to clinical improvement. All patients reported clinical improvements. In another study ECP has been used successfully in the treatment of two patients with erosive OLP and cortico-resistant LP.

The Problem of Carcinogenicity of Calcineurin Inhibitors

Approximately 1–5 % of oral LP lesions will develop squamous cell carcinoma (SCC) of the mouth. Also about 1–3 % of vulval LP lesions develop into SCC and a small, but unknown, percentage of penile LP lesions transform into SCC. High-risk factors include smoking, excessive alcohol ingestion, erosive or atrophic clinical types, presence of erythroplakic lesions (reddened patches with a velvety surface found in the mouth), and sites involving the tongue, gingival, or buccal mucosa. No risk factors are known for progression of vulval LP into SCC. In a 7-year prospective study on 327 OLP patients, 8 patients developed an SCC in OLP areas (0.36 %/year) during a mean follow-up of 81.7 months, especially in women.

In 2006, the Food and Drug Administration warned about the potential cancer risk with topical calcineurin inhibitors tacrolimus and pimecrolimus. The reasons were an animal study indicating a risk for malignant transformation and lack of long-term studies on the safety of tacrolimus in treatment of atopic dermatitis. The advice to physicians was to use tacrolimus only as a second-line agent for short-term and intermittent treatment. The European Medicines Agency followed the same strategy.

Such strategy raised a discussion in which the reliability of the OLP diagnosis and whether the lesion would have become malignant even without tacrolimus were debated.

As Eisemberg (2000) put it, often "the microscopy not only fails to confirm the given diagnoses of antecedent OLP, but also it depicts previously unappreciated maturation abnormalities that augur malignant potential." In other words, "if the reported carcinomas evolved from atypical or dysplastic lesions that were confused with OLP at outset, the

case for malignant degeneration in OLP is decidedly undermined." I came recently across a case in which a patient was treated for OLP on the basis of a microscopic description and developed SCC. Further histological sections demonstrated that the original "OLP" was in fact already SCC. The asymmetry of the clinical lesions is against OLP diagnosis as they are the presence of dysplasia and the absence of persistent reticular striations in the periphery. As for the second point, the problem is whether or not tacrolimus may enhance SCC risk. Fleischer (2006) emphasized that not a single SCC case has been found in data from randomized control studies and that the risk is smaller than with use of topical steroids. In fact, topical steroids, which are usually recommended in OLP, are not free from risk of cancer (about 5 % in lichen sclerosus), and the incidence of lymphomas in the general population is far higher than in patients treated with topical tacrolimus. In conclusion, OLP, especially in its erosive variety, compromises the quality of life of the patient and even prevents any social activity (pain, severe dysphagia, fetid breath) demanding a treatment. Calcineurin inhibitors could be regarded at least as safe as topical steroids.

Systemic Treatments

Rarely LP requires systemic treatment. In the office patients, lesions are usually limited in size and spread; pruritus is hardly a real problem and the quality of life is commonly preserved. That is probably the reason why large controlled studies are scarce in the literature. Nonetheless, a number of systemic drugs have been proposed (Fig. 53.3).

Corticosteroids

Corticosteroids are the treatment of choice for most dermatologists, but surprisingly enough until recently, there were no double-blind placebo-controlled randomized studies to support such a practice. Two large studies have been recently conducted. In the first study by Kelett and Ead (1990), 38 patients received either prednisolone (30 mg/day) or placebo for 10 days. After 2 years, LP cleared in 18 weeks with prednisolone and, surprisingly, also in 29 weeks with placebo. Only three failed to clear with placebo. Probably because the treatment was stopped without tapering, severe relapses occurred. In the second study (Pitche et al. 2007), 73 patients with generalized cutaneous LP received three injections of betamethasone every 2 weeks. At 6 weeks, 84 % cleared and 8 % partially remitted. The failure rate was of 8.2 %. At 6 months, the relapse rate was 31.5 %. No major side effects were reported.

Cyclosporin A

Being specifically aimed at cell-mediated hypersensitivity reactions, systemic CyA is expected to be the drug of choice on severe cutaneous LP. It may be surprising therefore that only four small uncontrolled series and one anecdotal case are available. In a total of 21 patients treated with 1–6 mg/kg/day, the lesions cleared in a mean of 6 weeks. No relapse were noted after several months of follow-up in most patients. Lower doses 1–2.5 mg/kg/day proved to be equally effective.

Azathioprine

Azathioprine (50–100 mg/day) may be used in erosive OLP with chronic active hepatitis. Usually, transaminase level and oral lesions improve simultaneously. If the patient is hepatitis C virus positive, however, immunosuppressive treatments should be avoided to prevent hepatocarcinoma to develop. In any case, favorable therapeutic effects for LP found in the literature reach only a low quality of evidence (level C).

Thalidomide and Analogues

Oral administration of thalidomide seems to be effective in two short series and in anecdotal reports. Moura et al. (2009) treated eight patients with cutaneous LP with 100 mg/day. Five (62.5 %)

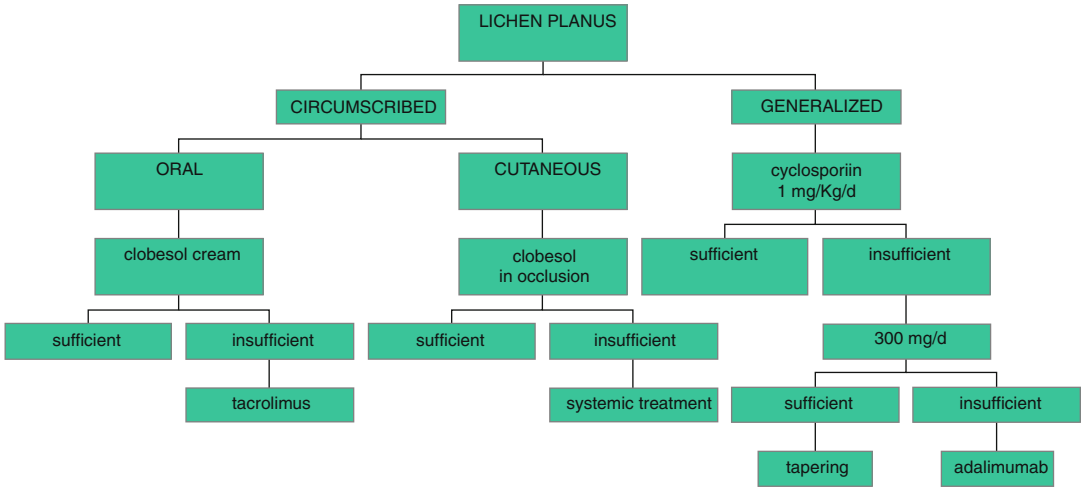

Fig. 53.3 Therapeutic algorithm

patients completed the trial. Three withdrew mainly due to neuropathy affecting the legs and weakness after the first days of treatment. These symptoms spontaneously regressed within days after treatment was stopped. Mean time for complete remission was 3 months. No recurrences were seen at follow-up 1 and 6 months after the end of treatment.

Macario-Barrel et al. (2003) used thalidomide in six patients with severe erosive OLP resistant to oral corticosteroids. They started at 50–100 mg/day to taper to the minimal effective dose. Complete healing of erosive lesions was observed in four patients after a mean duration of 4 months.

Perez reported a patient with generalized LP who, after treatment with thalidomide (initial doses 300 mg/day for 2 weeks and 200 mg/day for further 10 weeks), had his lesions cleared. Naafs and Faber (1985) treated one patient with oral LP in whom clearance was achieved. Another patient with generalized LP failed.

Dereure et al. (1996) treated two patients with severe erosive OLP with 150 mg thalidomide per day with impressive improvement in 4 months in the first case and with nearly complete healing in 3 months in the second. Tapering to 50 mg did not cause relapse. Side effects were minimal, except a mild reduction of T lymphocytes in the first case. Camisa and Popovsky (2000) used thalidomide in a patient with mild OLP at a starting dosage of 50 mg/day for 2 weeks and gradually increased the dosage over 3 months to 200 mg/day. Improvement was noted after 4 months. At the 11th month, the desquamative gingivitis and striae were nearly cleared. Dizziness, edema of the lower extremities, and a mild rash of the face and trunk recommended decrease to 100 mg/day.

Hydroxychloroquine

Although well known to include LP as adverse effect, hydroxychloroquine has been used in OLP at 200–400 mg/day for 6 months as a monotherapy in ten patients. Nine had an excellent response to therapy. Erosions required 3–6 months to clear. There were no adverse effects.

A 9-year-old girl with actinic LP was treated with hydroxychloroquine 200 mg daily for 3 months with complete and no relapse in the following years. The study was biased by the addition with 0.1 % methylprednisolone aceponate ointment for 2 weeks and with photoprotective measures (Ramírez et al. 2012).

A retrospective review by Chiang et al. (2010) of 40 patients with lichen planopilaris (or frontal fibrosing alopecia) who had been treated with hydroxychloroquine for up to 12 months found that after 6 months, 69 % had reduced symptoms and signs, a percentage that rose to 83 % at 12 months.

Retinal adverse effects should be considered, however, as they are often unpredictable and should be thoroughly monitored.

Retinoids

Etretinate provides more side effects than benefits. Five open studies have tested the efficacy of etretinate 0.6–1 mg/kg per day in 58 cases of oral LP (Miyagaki et al. 2013). Results were good in four of the five studies. In a series of ten patients, the benefits were minimal. In the only small controlled trial, 28 patients with OLP were treated with 75 mg/day etretinate vs. placebo for 2 months followed by crossover with etretinate in nine cases. Six stopped the treatment prematurely because of side effects. This therapy improved 93 % of lesions vs. 5 % of control lesions in the control group. Relapses occurred, 3 months after the end of treatment, in 66 % of cases.

In addition, scattered anecdotal reports can be found. A 68-year-old woman with oral and cutaneous LP and thymoma underwent thymectomy. Cutaneous LP lesions subsided spontaneously while oral lesions did not. Oral lesions responded well to oral etretinate therapy. No information on dosage are provided (Miyagaki et al. 2013). Another Japanese woman with ulcerative LP of the sole and Sjogren syndrome was treated with etretinate 30 mg/day for 2 months with nearly resolution of the ulcer (Tsuboi and Katsuoka 2007).

Oral tretinoin has been studied by three open studies. Doses ranged from 10 to 60 mg/day (Ott et al. 1996). Favorable results have been reported, but clinical data and criteria of efficacy are scantily mentioned; dosages are diverse, and topical tretinoin has been added, all biasing the assessment of tretinoin efficacy.

Oral isotretinoin has been reported anecdotally (Handler 1984), and in two small series, the dosage was 0.5 mg/kg/day and was effective in two cases. Benefits were minimal in the series of six patients.

Systemic therapy with acitretin 25 mg daily should be considered for patients with severe refractory LP. In the only placebo-controlled double-blind trial published so far, 65 patients with cutaneous LP were treated with 30 mg/day acitretin for 8 weeks. Sixty-four percent of them significantly improved vs. 13 % of controls. Clearance was doubtful, however, as papules persisted in most patients as one figure clearly shows. The trial had some defects as neither criteria for remission and improvement were detailed nor the duration and the extent of the lesions. Six of eight patients with LP treated with 50 mg/day acitretin for 8 weeks had a dramatic improvement, as did a boy with exanthematous LP (Brockowet al. 1997). A case of refractory hypertrophic LP, reported by Jaime et al. (2011), was treated with acitretin 40 mg/day and achieved total resolution on the upper limbs and partial resolution on the lower limbs after 9 months of therapy.

Because of the systemic side effects, acitretin has been replaced by oral alitretinoin. In one anecdotal report, a patient was treated with 30 mg/day with good results within 4 weeks. No severe side effects were registered, but oral striae and dysphagia recurred during treatment and LP relapsed after 4 months (Kolios et al. 2013).

Recently, some reports of recalcitrant lichen planus successfully treated with alitretinoin have been published (Kolios et al. 2013; Brehmer et al. 2011).

Temarotene obtained complete or nearly complete remission after 2–3 months in 10/13 patients. Dosage was 800–4,800 ng for between 31 and 441 days. Nausea and vomiting, with a transient increase of transaminase blood levels, afflicted six patients (Bollag and Ott 1989).

Dapsone

Dapsone (50–150 mg/day) proved to be more effective than topical corticosteroids in a prospective trial with 75 patients and in 2 isolated cases of recalcitrant erosive oral LP (Chopra et al. 1999). Attention should be paid to older patients for dapsone systemic side effects (hemolysis, methemoglobinemia). Its use is recommended in children and in bullous cases.

Methotrexate (MTX)

Only small retrospective series are available in the literature. Eleven patients with generalized

LP were treated with MTX 15–20 mg/week. Mucocutaneous lesions and pruritus improved within the first month in all patients, and complete response was achieved in ten patients at the end of the first month. Only one patient discontinued MTX because of intolerable adverse effects (nausea and fatigue) at the fourth week (Turan et al. 2009).

Adverse effects are in fact common, but they have been found only mild in a double-blind controlled study (Hazra et al. 2013) on 44 patients with LP treated with MTX (10 mg) (23 patients) or mini-pulse betamethasone (5 mg) (21 patients). Anemia (14.2 %), edema (57.1 %), dyspepsia 15 (71.4 %), acne 10 (47.6 %), mooning face 8 (38.1 %), striae 8 (38.1 %), menstrual abnormality (71.4 %), and hypertrichosis 4 (19.0 %) developed only with betamethasone. Intermittent diarrhea, headache, nausea, and fatigue were complained with both drugs but more often with betamethasone. Abnormality in platelet count and SGPT were registered only with MTX.

Tetracycline

In an open-label clinical trial, 15 patients with LP were treated with tetracycline 500 mg or doxycycline 100 mg, both twice daily. Of the 13 subjects who completed the study, 6 (46 %) reported no response to either doxycycline or tetracycline, 6 (46 %) a partial response, while only 1 experienced a complete remission in a mean treatment period for responders which was 3.6 months (range 1–6) (Hantash and Kanzler 2007).

An anecdotal report of a woman with lichen pemphigoides suggested the efficacy of doxycycline 200 mg/day and nicotinamide 1,500 mg/day, though the therapy included also intralesional triamcinolone.

Griseofulvin

Griseofulvin was largely studied in the past though no definitive conclusions were allowed. Griseofulvin, 1,000 mg/day, was given for 1–10 months in 15 patients with cutaneous LP and in 25 patients with cutaneous LP (Levy et al. 1986). In the first open study, 12 % of the patients improved and 12 % experienced exacerbation of the disease. In the second study, 86 % of the patients had complete disappearance of the lesions after a 3-month delay. A study included two groups of 17 patients receiving either placebo or griseofulvin for 4–6 weeks. A partial regression was observed in 71 % of griseofulvin-treated patients vs. 30 % of controls. In the second study, 44 patients with cutaneous LP were treated with griseofulvin, 1 g/day or placebo for 8 weeks. Griseofulvin resulted in "complete improvement" in 82 % of patients and partial remission in 18 %, whereas partial remission occurred in only 23 % of placebo-treated patients. A case of intensely pruritic acute eruptive LP in a 51-year-old male failed to respond to griseofulvin, and of seven OLP cases treated with 500 mg/day griseofulvin for more than 2 months, none improved and four worsened.

Levamisole

Levamisole hydrochloride has been tried in two studies, but in one it is not known whether the patients improved and in another it was associated with prednisolone (Lu et al. 1995).

Curcuminoids

Curcuminoids (diferuloylmethane) are components of turmeric (*Curcuma longa*) that has anti-inflammatory properties and has been used in Indian traditional medicine for centuries. A randomized, double-blind, placebo-controlled clinical trial on 20 OLP patients compared 6,000 mg/day curcuminoids in three divided doses to placebo. The curcuminoids group showed a greater and significant reduction in erythema and total modified Oral Mucositis Index score and proportion showing improvement in the numerical rating scale of OLP signs and symptoms and total Modified Oral Mucositis Index score. Adverse effects were uncommon in both groups (Chainani-Wu et al. 2012).

Metronidazole

As LP is a standard Th1 cell-mediated reaction to a variety of antigens, it is of no surprise that cutaneous and oral lesions improved as the results of treatment of intestinal giardiasis with oral metronidazole. In an open-label trial (Rasi et al. 2010), 49 LP patients were given metronidazole, 750 mg/day. Forty-one percent of lesions fully cleared, 33 % had partial healing, and 26 % did not improve. In mucosal lesion, the overall response was 67 %. In another open study, 19 LP patients were treated with 1 g metronidazole for 20–60 days and were followed up for a period of 5–36 months. Complete response was observed in 13 patients. Lesions worsened in 1 of the 4 nonresponders.

Itraconazole

A prospective, open-label study of itraconazole 400 mg/day for 1 week of each month for 3 months in 16 patients with severe LP reported complete cessation of new lesions in 77.7 %, complete relief of pruritus in 55 %, and complete flattening of lesions in 33 %. The mechanism of action is believed to be due to the immunomodulatory effects of itraconazole (Khandpur et al. 2009).

Fumarate

In a retrospective study, two of three LP patients showed complete clearance of their lesions after being treated with fumarate (max three tablets a day for 8 months). In one case, side effect led to discontinuation.

Biologics

As the serum levels of TNF-alpha is higher in LP patients, some TNF-alpha inhibitors have been tried in particularly severe LP patients. Results are in general encouraging, although some relapses and even a rebound effect have been registered at the drug withdrawal (Table 53.2). Another apparent contradiction rests on the fairly frequent occurrence of LP as side effects of TNF-alpha inhibitors used for other reasons. Less understandable is why B-cell inhibitors like rituximab and mycophenolate mofetil can work in a Th1-mediated disease as LP. In any case, biologics should be used only as ultima ratio when all other therapies have failed or cannot be used.

UV Phototherapy

Narrowband UVB

Twenty patients with disseminated LP were included in a retrospective study treated with narrowband UVB thrice a week according to the standard protocol for psoriasis. Complete response was obtained in 11 patients and partial response in 4 after 3 months, with an accumulated dose of UVB of 36 ± 4.8 J/cm^2. Another retrospective analysis of 43 patients with generalized LP treated by narrowband UVB revealed that complete response was achieved in 70 % of cases. In a randomized study, 46 patients with generalized LP were treated with either systemic prednisolone 0.3 mg/kg for 6 weeks or narrowband UVB (max 9 J/cm three times a week for 6 weeks). Narrowband UVB was significantly more effective than systemic steroids (Iraji et al. 2011).

PUVA

In a retrospective study, 28 patients with disseminated LP treated with PUVA and 13 treated with UVB-311 nm were compared. All 15 patients treated with oral PUVA had a complete (10) or partial (5) clinical response. The ten patients treated with UVB-311 nm showed complete (4) or partial (6) clinical response. The initial response to PUVA was significantly superior. After a mean follow-up period of 20.5 and 35.7 months, respectively, the disease relapsed in 7 of 15 PUVA-treated patients in 3 and 3 of 10 UVB-311 nm-treated patients (Wackernagel et al. 2007).

Table 53.2 Biologics in LP

Drug	Author	Year	Cases	Type of LP	Dose	Duration (wks)	Result

[a]+systemic steroids

Conclusions

Generalized LP is rare and commonplace patients do not need particular treatments. This is probably the reason why most of the studies are based on very small populations. Recruiting larger populations and following them up for a long time is not a cheap endeavor. As a consequence, one may suspect that the few studies existing in the literature, which may be considered of level A, are probably supported by the firm that manufactures the studied drug. A conflict of interest may bias their results.

Keeping this on mind, acitretin is the first line of treatment for cutaneous LP. Systemic corticosteroids are the second-line treatment, and all other drugs or procedures, including PUVA and narrowband UVB, are still awaiting rigorous placebo-controlled randomized trials.

Oral LP, instead, especially in its erosive form, is the real therapeutic challenge, since it is painful, prevents eating and speaking, exhales a fetid odor, and, therefore, compromises the quality of life of the patient. In addition, it carries a non-negligible risk of carcinogenicity. This is the reason why a large literature exists, mostly by stomatologists, but there is a lack of strong evidence supporting the efficacy of any therapy for OLP, with the possible exception for calcineurin inhibitors. In OLP, topical corticosteroids are the first line of therapy, a choice which has been recommended by several studies (Cribier et al. 1998). The second line is represented by calcineurin inhibitors, which have replaced topical cyclosporine A. A number of other treatments, including biologics, require further rigorous studies.

Lichen Simplex Chronicus

54

Mary Gantcheva and Valentina Broshtilova

Key Points

- Lichen simplex chronicus (LSC) is an acquired, severely itching chronic dermatosis with circumscribed lichenified lesions, which are due to skin rubbing and scratching.
- The key point of therapy is to introduce an individualised therapy regimen according to the patient's age, pre-existing diseases, medications, quality and intensity of pruritus.
- Explanation of the basic itch-scratch mechanisms and their relationship to the disease course is extremely helpful, because the patient realises his key role in the induction of the pathological process.
- General pruritus-relieving measures are simple and helpful approaches for long-term application that should be recommended to the patients. These measures include wet and cold wraps and application of lotio alba, a short-time localised heat.
- Systemic therapy aims to relieve itch. New therapeutic modalities such as opioid agonists and antagonists, gabapentin and leukotriene antagonists are being administered together with conventional antipruritic drugs to reduce itching and improve quality of life of patients.
- Topical therapy is introduced on a long-term basis due to its anti-inflammatory, antiseptic and antipruritic properties. Different topical modalities are used according to the stage of the disease.

Definition and Epidemiology

Lichen simplex chronicus (LSC) is an acquired, severely itching chronic dermatosis of circumscribed lichenified lesions, which are due to rubbing and scratching of previously normal looking skin. It follows a self-perpetuating scratch-itch cycle, which begins with rubbing and scratching of the skin to form areas of thickened, leathery, brownish lesions. Often there is no known predisposing skin disorder and underlying cause of the

development of the lichenification. However, itch may be associated with chronic eczema, atopic dermatitis, psoriasis, or other pre-existing skin conditions, as well as nervousness, anxiety, depression or any other psychological disorders. It is common in children, who chronically scratch insect bites or other areas, especially in mentally retarded individuals with chronic repetitive movements.

Variants in clinic morphology, size and location have led to several clinical variants, which affect the population worldwide. LSC is particularly common in Orientals and is comparatively rare in black people. Women are predominantly affected with the peak incidence between 30 and 50 years.

LSC frequency demonstrates a high burden and an impaired quality of life. As a consequence of the diversity of possible underlying diseases, no single therapy concept can be recommended. Each form of LSC has to be considered individually. There is a significant lack of randomised controlled trials that can be explained by the diversity and complexity of LSC symptoms, multifactorial aetiologies and the lack of well-defined outcome measures. However, new therapies for improved medical care have been suggested.

Basic Concepts of Pathogenesis

Lichenification may occur secondary to many pruritic dermatoses, and some authors suggest that LSC is a minimal variation of atopic eczema in adults with a personal or family history of atopic disorders. Others suppose that the occurrence of the disease is related to internal disorders such as gastrointestinal or liver cholecystopathies, diabetes mellitus or constipation. Lichenification also develops in the course of other irritant dermatoses or complicates persistent skin lesions of many types, such as chronic contact dermatitis, seborrhoeic and stasis dermatitis, lichen planus, pruritus ani et vulvae and rarely psoriasis.

Pruritus seems to be the cause and not just a symptom of LSC. It is the main factor for the development of the lichenification and probably results from mediator release or proteolytic enzyme activity. Nervous stress and psychovegetative disorders unlock an unconscious habit of rubbing and repeated scratching, which lead to thickening of the skin with accentuation of the skin markings. Sometimes nodular lesions appear as a consequence of prolonged rubbing. The increase in neuropeptides, calcitonin gene-related peptide and substance P immunoreactive nerve fibres can be related to prolongation and refractive course of LSC with secondary formation of nodular lesions. Other patients (e.g. black people) develop papular and follicular lichenification. Presumably, there is a native predisposition to the development of lichenification and its persistence.

LSC is classified, based on the presumptive aetiology, into (I) “dermatological”, (II) “systemic”, (III) “neurological”, (IV) “various”, including “somatoform”. The latter LSC variant should be defined as lichenification where psychiatric and psychosomatic factors play a critical role in the initiation, intensity, aggravation or persistence of the lesions.

Clinical Presentation

Pruritus is severe and paroxysmal and usually occurs at night. It is often out of proportion to the extent of the objective changes. The original lesion is usually isolated and a three-zone structure could be distinguished: central, infiltration and flat lichenification; middle, closely set lichenoid papules; and peripheral, slight thickening and pigmentation. There are different forms of lichenification with their own features depending on the localisation and duration. In early lesions the two external zones may be absent. In some cases leucoderma can be seen accompanied by vitiligo-like macules and depigmented area of infiltrated plaques. Rarely, LSC is presented with isolated lichenoid papules without central lichenification.

Almost every skin area may be affected, but the most common locations are those that are conveniently reached: the nape of the neck, scalp, extensor aspect of forearm, sacrum, inner thighs,

lower legs and ankles, vulva, pubis and scrotum (Fig. 54.1).

Lichen nuchae occurs on the back of the neck (Fig. 54.2) particularly in women under emotional stress or in patients with atopic dermatitis. This area is easily reached and patients may scratch it intensively. In both cases the disease is characterised by scaly psoriasiform plaques that are frequently impetiginised.

Nodular neurodermatitis of the scalp presents with pruritic and excoriated papules. The epidermal thickening of the scalp in this situation is enough to form nodules.

Giant lichenification of Pautrier presents with warty, cribriform plaques. Usually it affects the genitocrural region. The pruritus is persistent for many years. Sharply demarcated patches of verrucoid hyperplasia can be elevated above the surrounding surface, and tumour-like plaques may be formed.

The clinical evidence of "pebbly" lichenification is presented by plaques of coalescing smooth papules or discrete small nodules resembling lichen planus. They could also be seen in patients with atopic dermatitis, photodermatitis and seborrhoeic dermatitis.

The course of LSC is chronic and the lesions persist indefinitely depending on individual variation.

Fig. 54.1 Circumscribed lichenified lesions on the skin of the scrotum in a man with lichen simplex chronicus

Fig. 54.2 Lichen simplex chronicus on the back of the neck

Diagnosis

A patient's history should always include all current and recent medications, infusions and blood transfusions. Severe pruritus can lead to considerable psychological distress. This should not be underestimated by the physician and should be addressed directly. Examination of patients includes a thorough inspection of the entire skin including mucous membranes, scalp, hair, nails and anogenital region. The distribution of primary and secondary skin lesions should be recorded together with skin signs of systemic disease. General physical examination should include palpation of the liver, kidneys, spleen and lymph nodes. A skin biopsy specimen shows some variations with site and duration. Hyperkeratosis and acanthosis are constant. The rete ridges are lengthened. Sometimes spongiosis is present and small areas of parakeratosis are seen. Hyperplasia is everywhere.

Differential Diagnosis

- Atopic dermatitis: onset at childhood, presence of atopic stigmata, symmetrical lichenified lesions of predilection, positive radioallergosorbent test (RAST) or skin prick tests, elevated serum immunoglobulin E (IgE)
- Nummular eczema: absence of lichenified plaques
- Psoriasis: usually no itch, presence of psoriatic lesions elsewhere, thick adherent white scales and positive clinical symptoms, distinct histology on skin biopsy

- Lichenified chronic eczema: presence of more inflammatory changes, distinct histology on skin biopsy
- Hypertrophic lichen planus: involvement of the mucosa in about 50 % of patients, Wickham's striae
- Lichen amyloidosis: infiltrated itchy papules with typical ripple appearance, no plaque formation, symmetrical distribution, histology verification
- Prurigo nodularis Hyde: single nodules on normal skin
- Tinea (dermatophyte infection): microbiology, typical Wood's light features
- Contact dermatitis: patient's history, usually symmetric involvement, positive patch testing
- Drug reactions (gold, trimethoprim sulphamethoxazole diflunisal, bupivacaine, quanidine, quinacrine): history of drug intake
- Cutaneous T-cell lymphoma: distinct histology and immunohistochemistry.
- Stasis dermatitis: skin lesions on the lower legs in the presence of chronic venous insufficiency

General Principles of Treatment

An individualised therapeutic regimen according to the patient's age, pre-existing diseases, medications, quality and intensity of pruritus should be established. Elderly patients, pregnant women and children need special attention. As the care of LSC patients often extends over a long period, frustration regarding the failure of past therapies and general psychological stress frequently occurs. Some patients need a psychiatric consultation and in such cases psychotherapy is recommended. These are usually individuals who feel themselves emotionally distributed or have functional complaints. The diagnostic procedures and therapy should be discussed with the patient in order to achieve best possible compliance.

Patients should be given treatment for any underlying stress. The lesions worsen during periods of fatigue and emotional tension and improve with relaxation. In most cases the rubbing and scratching exist as a reflexive and unconscious habit. Explanation of the itch-scratch mechanism and its relationship to the disease course could be helpful.

Pruritus-Relieving Measures

There are simple and helpful measures such as wet and cold wraps and application of lotio alba. Application of short-time localised heat has shown promising itch-relieving results in case reports and an experimental study. Cool to tepid baths are another commonly used method of reducing itching. During active treatment, patients must avoid washing the involved areas with soaps and detergents and should have their nails cut.

Topical Treatments

(a) *Glucocorticosteroids.* External therapy without steroid treatment is not conceivable, although there are side effects associated with them. High-potency glucocorticosteroids tend to relieve the itching and infiltration of the lesions. Very potent topical steroids as a local application and under occlusive dressings are recommended for a short time. If the lesion is located in the genital area, it is preferable to use mild-potency steroids. Intralesional applications of triamcinolone acetonide (crystalline suspension – 10 mg/mL, 1: 4 dilution in 1 % local anaesthetic) should be tried in small lesions. Care must be taken to avoid the risks of atrophy and depigmentation. Injection should not be made into excoriated or infected lesions.

(b) *Tar.* The anti-inflammatory property of tar and tar products is well known. Liquor carbonis detergents or pure coal tar could be prescribed for a few days. It is better if combined with emollients because tar dries the skin. Photosensitisation, contact dermatitis and folliculitis may also occur as side effects. Combined therapy is well tolerated, including steroids and tar with or without salicylic acid.

(c) *Urea.* Urea preparations have been applied with great success in LSC therapy, follow-up and prophylaxis. Efficacy is based on its properties to increase the water-binding capacity of the corneal layer, on its keratoplastic abilities, anti-pruriginous effect and proliferation-suppressing action. The combination of hydrocortisone and urea may prove useful in the treatment of LSC.

(d) *Doxepin.* Topical application of 5 % doxepin cream has significant antipruritic activity in patients suffering from LSC. Doxepin cream provides pruritus relief with transient and mild adverse effects, such as stinging at the side of application.

(e) *Others*

Local anaesthetics. Local anaesthetics act via different groups of skin receptors. They can be used for pain, dysaesthesia and pruritus. Benzocaine, lidocaine, pramoxine as well as a mixture of prilocaine and lidocaine are widely used topically but have only a short-term effect. Intralesional application has also been used in persistent and therapy-resistant cases.

Capsaicin. Topical application has significant antipruritic activity with long-term effect. It is easy to use and highly effective. Only a few side effects have been described such as stinging and drowsiness at the side of application.

Cannabinoid receptor agonists. Since 2003 topical cannabinoid receptor agonists are used as antipruritic and analgesic substances for localised pruritic lesions.

Tacrolimus and pimecrolimus. The effects of tacrolimus and pimecrolimus on pruritus are mediated both through their immunological and neuronal properties. They can be used on a long-term basis for coping with the inflammation in LSC. Patients should be aware that transient irritation and burning at the site of application can appear.

Zinc, menthol and camphor. Although zinc oxide, menthol and camphor have been used in dermatology for over 100 years, due to their anti-inflammatory, antiseptic and antipruritic properties, their efficacy and safety are not proven in double-blind placebo-controlled study. However, prescriptions in creams, liniments, lotions, ointments and pastes are widely used and favoured in coping localised forms of pruritus, especially in children.

Mast cell inhibitors. Pruritus in atopic dermatitis responds to topical sodium cromoglycate and may exert favourable effect in LSC.

Topical Treatments at a Glance

- General pruritus-relieving methods are highly effective in coping with itch and discomfort in LSC.
- Topical corticosteroids are main stones of therapy. They may be applied alone or in combination with other agents to exert more favourable effect.
- Emerging topical regimens include local anaesthetics, capsaicin, cannabinoid receptor agonists and macrolide immunomodulators. Unfortunately, most can cause irritation and burning sensation at the site of application and often have only a short-term effect.
- No fixed-dose combination topical formulations for LSC exist. The therapeutic regimen should be strictly individualised and referred to the patient's general psychological condition.

Systemic Treatments

(a) *Antihistamines.* Antihistamines are the most widely used systemic antipruritic drugs in dermatology. First-generation antihistamines, such as chlorpheniramine, clemastine, cyproheptadine, diphenhydramine, hydroxyzine and promethazine, bind not only to H1-receptors but also to muscarinic, α-adrenergic, dopamine or serotonin receptors, thus exerting a central sedative effect. Therefore, their use is nowadays restricted and reserved only for cases with self-accentuation and obsession-compulsion syndromes. Second-generation antihistamines like cetirizine, levocetirizine, loratadine, desloratadine, ebastine, fexofenadine and rupafine have minimal activity on non-histaminic receptors, little sedative effect and a longer duration of action compared to

the first generation. Higher doses of second-generation antihistamines enhance their activity and may also be beneficial. Antihistamines are widely used as first-line drugs in patients with symptomatic LSC due to systemic diseases such as chronic renal failure, cholestasis, haematopoietic diseases and thyroid disorders.

(b) *Glucocorticosteroids.* There are no studies investigating the efficacy of the exclusive use of systemic glucocorticosteroids in LSC. Thus, systemic glucocorticosteroids should not be considered a therapeutic option and should not be prescribed in LSC cases. Systemic corticosteroids can be used as short-term treatment in severe cases for no more than 2 weeks.

(c) *Opioid receptor agonists and antagonists.* Experimental and clinical observations have demonstrated that pruritus can be evoked or intensified by endogenous or exogenous μ-opioids. This phenomenon can be explained by activation of spinal opioid receptors, mainly μ-opioid receptors. Therefore, μ-opioid antagonists may inhibit pruritus. The opposite is true for k-opioids. Their binding to μ-opioid receptors leads to inhibition of pruritus. Nalmefene, naloxone and naltrexone have exhibited high antipruritic potency and can be used in LSC therapy. High state of precaution is needed on administration of these drugs due to their broad side-effect profile.

(d) *Gabapentin and pregabalin.* Gabapentin is an antiepileptic drug also used in neuropathic disorders causing pain or pruritus. The mechanisms of action of the 1-aminomethyl-cyclohexane acetic acid, which is a structural analogue of the inhibitory neurotransmitter γ-aminobutyric acid (GABA), remain unclear. It is used in postherpetic neuralgia, especially with paroxysmal pain or pruritus. Anecdotal indications are brachioradial pruritus and cutaneous T-cell lymphoma. Off-label use of gabapentin and pregabalin can be recommended in some cases of LSC.

(e) *Antidepressants.* Psychoemotional factors are known to modulate the "itch threshold". Under certain circumstances, they can trigger or enhance LSC. Itch is a strong stressor and can elicit psychiatric disease and psychological distress. Depressive disorders are present in some patients with LSC. Consequently, depressive symptoms should be treated in these patients, and some antidepressants may also exert an effect on pruritus through their pharmacological action on serotonin and histamine.

(f) *Leukotriene receptor antagonists.* Leukotriene receptor antagonists (e.g. montelukast, zafirlukast) influence the pathogenesis of pruritus. They have been used in combination with antihistamines as antipruritic therapy. They may be considered, but due to the lack of evidence, cannot be recommended in the treatment of LSA.

(g) *Cyclosporin A.* Pruritus in atopic dermatitis and prurigo nodularis responds to treatment with cyclosporin A. It should have beneficial effect on LSC lesions as well. However, no controlled double-blind studies exist.

(h) *Aprepitant.* Substance P has a dominant role in pruritus induction in the skin. Via binding to the neurokinin 1 receptor (NKR1) on keratinocytes, blood vessels and mast cells, substance P is increased in skin lesions with nerve fibre hyperplasia. Presumably, inhibition of the corresponding receptor should cope with the itch sensation and relieves the LSC symptoms. There are only anecdotal reports on the beneficial effect of aprepitant in cases of cutaneous T-cell lymphoma, solid tumours and drug-induced pruritus. It may be considered a second-line option in therapy of refractory cases with persistent pruritus.

Systemic Treatments at a Glance

- Second-generation antihistamines are recommended as first choice for the treatment of long-lasting LSC, refractory to topical modalities.
- Oral medications should always be combined with topical itch-relieving modalities and general antipruritic measures.
- The beneficial effect of oral LSC therapy is not proven in double-blind placebo-controlled studies, and this lack of evidence

restricts the therapeutic choice to individualised approach of patient's systemic involvement and pre-existing conditions.
- Highly refractory LSC cases may require a short-term therapy of different class medication groups.

Alternative and Experimental Treatments

Alternatively, topical photochemotherapy (PUVA) three times weekly (3–5 J/cm/sq.m) is recommended to 20 therapeutic sessions per course.

Bulgarian dermatologists have been pioneers in the successful treatment of LSC using high-mountain climatotherapy. Itching is reduced by a cooling off in the atmosphere at 2,000 m above sea level. Pathologically changed reactivity of the organism modifies to a state of hyposensibilisation. The beneficial effects of high-mountain climatotherapy are based on the relative cleanliness of the air, the abundance of ultraviolet radiation and the low partial pressure of O2, stimulating the hormonal activity of adrenal glands.

- Acupuncture is also helpful in the relief of pruritus and could be recommended on a follow-up basis.

Guidelines for LSC Treatment

The treatment choice should be individualised and should take into account the age and medical history, the course and severity of the disease, the underlying systemic conditions and the impact of the dermatological problem on the quality of life of the patient. Topical regimens should be used as first-line therapy. Mild-to-moderate topical corticosteroids are found to have highest efficacy. The potent corticosteroid medications, even under occlusive dressings, should be used only in refractory cases.

Combined topical regimens are not fixed and depend on physician's own judgement, routine and skilfulness. The individual patient's characteristics and pre-existing conditions should always be taken into consideration.

Systemic drugs should be used only on a short-term basis in patients with systemic involvement and a protracted disease course.

Alternative therapeutic options such as high-mountain climatotherapy, acupuncture and topical photochemotherapy may provide safe and beneficial option in the combined therapeutic regimen.

An algorithm of treatment according to LSC clinical forms is suggested:

Cutaneous findings	Pre-existing dermatosis	No underlying skin condition
	Treatment of the main clinical entity	Topical corticosteroids
	Leukotriene antagonists in atopic patients	Tacrolimus and pimecrolimus
	Zink, menthol, camphor	Combination of topical preparations with oral antihistamines in refractory cases
	Mild corticosteroid tars

Future Perspectives

Future perspectives include various psychodynamic techniques, new preparations for itch relief and combined regimens of alternative curative methods such as thalassotherapy, high-mountain therapy, traditional Chinese medicine approaches and orthomolecular treatment with natural substances, enzymes and vitamins. New electrophysiological, ultrasound, cavitation and synergic methods of reflexotherapy should also be taken into consideration.

Double-blind placebo-controlled trials on the efficacy of newly introduced antipruritic drugs are needed to provide control and introduce the principles of good medicine practice in the everyday care of patients with LSC and general itch.

Lupus Erythematosus

55

Annegret Kuhn and Aysche Landmann

Key Points

- Therapeutic agents are applied off-label for patients with cutaneous lupus erythematosus (CLE), mainly based on the experience of experts.
- Topical corticosteroids are the mainstay of treatment for all different subtypes of the disease, but they are of limited value because of their well-known side effects, such as skin atrophy and telangiectasia.
- A safe and effective alternative topical treatment for CLE are the calcineurin inhibitors tacrolimus and pimecrolimus.
- Irrespective of the subtype of the disease, antimalarials, such as hydroxychloroquine or chloroquine, are the first-line systemic treatment for disfiguring and widespread skin manifestations.
- Systemic steroids can be used additionally in patients with highly acute and severe skin lesions but should be time limited due to the common side effects, such as osteoporosis.
- In contrast to immunosuppressive agents, such as azathioprine, cyclophosphamide, and cyclosporine, methotrexate has received more attention in the therapeutic management of skin manifestations of the disease.
- Further second-line treatment includes retinoids, dapsone, and mycophenolate mofetil. Other agents, such as rituximab and ustekinumab, have been used in single cases of therapy-refractory CLE and need to be evaluated in randomized controlled trials.

Definition and Epidemiology

The inflammatory autoimmune disease lupus erythematosus (LE) encompasses different clinical entities, reaching from a primarily cutaneous form (cutaneous lupus erythematosus, CLE) to a severe systemic disease (systemic lupus erythematosus, SLE). Only a small number of patients with CLE subsequently develop a systemic organ manifestation; however, cutaneous lesions can

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_55, © Springer-Verlag Berlin Heidelberg 2015

appear in 73–85 % of patients with SLE and may occur at any stage of the disease (Kuhn et al. 2009). In 1982, the American College of Rheumatology (ACR) developed a set of criteria for the classification of SLE that provides some degree of uniformity in classifying the patient population (Tan et al. 1982). However, the ACR criteria are of limited value to distinguish CLE from SLE as 4 of the 11 criteria are dermatological criteria; therefore, patients with primarily skin manifestations may be classified as SLE based on mucocutaneous lesions (Albrecht et al. 2004). Recently, the Systemic Lupus International Collaborating Clinics (SLICC) revised and validated these criteria in order to improve clinical relevance, meet stringent methodology requirements, and incorporate new knowledge regarding the immunology of SLE (Petri et al. 2012).

The classification of the cutaneous lesions into LE-specific and LE-nonspecific manifestations based on histological criteria of skin biopsy specimens was initially proposed by Gilliam in 1972 (Gilliam 1977). For example, vascular skin changes, such as urticarial vasculitis and livedo reticularis, are defined as LE-nonspecific skin lesions, which are mostly associated with active SLE, reflecting potentially systemic organ manifestations and serious complications (Costner et al. 2003). In contrast, the LE-specific skin lesions present the different subtypes of CLE, which are classified by the "Duesseldorf Classification 2004" (Kuhn and Ruzicka 2004); this classification subdivides the skin manifestations into acute CLE (ACLE); subacute CLE (SCLE); chronic CLE (CCLE), including discoid lupus erythematosus (DLE) as the most common form of CLE; and intermittent CLE (ICLE) (Table 55.1).

Up to date, no drugs have been approved specifically for the treatment of CLE, although several agents are licensed for systemic organ manifestations, such as lupus nephritis, or other immunological diseases. This is mainly due to the fact that only single randomized, controlled trials have been performed in CLE. According to the Cochrane Database of Systematic Reviews, two randomized, controlled trials are available for DLE (Jessop et al. 2009). Further randomized, controlled trials for other CLE subtypes were performed in the past years, i.e., comparing tacrolimus ointment with clobetasol propionate or the vehicle (Tzung et al. 2007; Kuhn et al. 2011a). Thus, topical and systemic agents in CLE are applied "off-label," mainly based on the experience of experts. In 2011, the novel monoclonal antibody belimumab, a B lymphocyte stimulator-specific inhibitor (Manzi et al. 2012), was approved for SLE based on two phase III trials (Furie et al. 2011; Navarra et al. 2011). This agent showed significant improvement for mucocutaneous manifestations, evaluated by the SLE Responder Index (SRI), but further prospective studies using a validated skin score are necessary to assess its efficacy in the different subtypes of CLE. In this article, recent information on therapeutic options and strategies for the treatment of skin manifestations of the disease is summarized (Table 55.2).

Topical Treatments

Topical Corticosteroids

Topical corticosteroids show a high efficacy in the treatment of localized skin lesions in CLE and SLE; therefore, class I to class IV corticosteroids

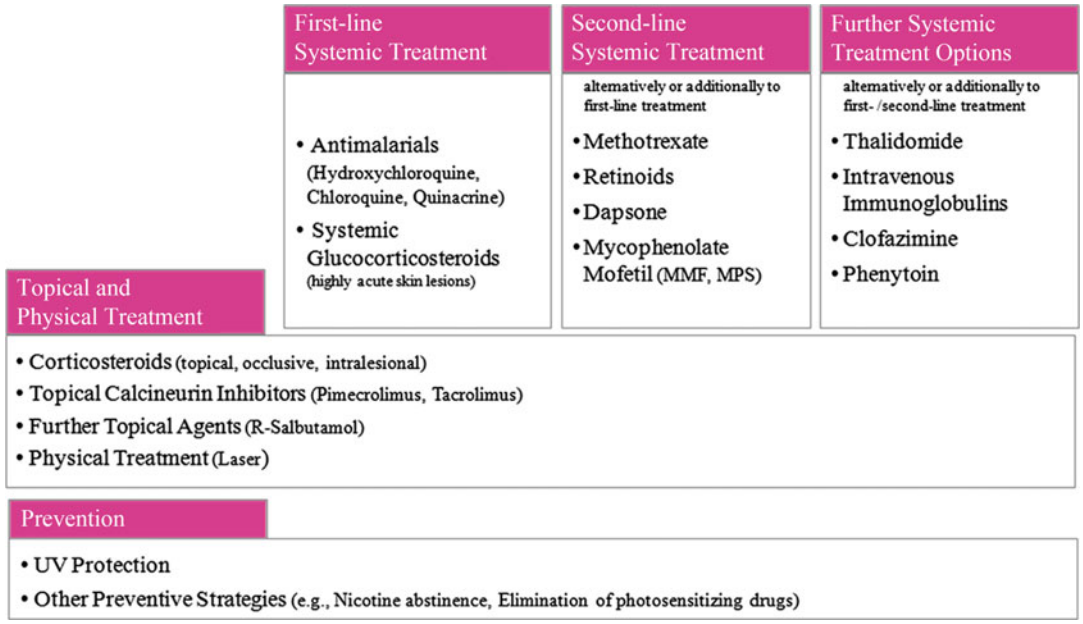

Table 55.2 Therapeutic Options of Cutaneous Lupus Erythematosus

are the mainstay of treatment in all disease subtypes. One randomized, controlled, 12-week crossover study exists, which compares 0.05 % fluocinonide, a potent corticosteroid cream, with 1 % hydrocortisone, a low-potency corticosteroid cream, in 78 patients with DLE (Jessop et al. 2009; Roenigk et al. 1980). This trial showed an improvement of skin lesions in 27 % of patients using fluocinonide and in 10 % of patients using hydrocortisone. However, corticosteroids are of limited value in the long-term topical treatment of facial and widespread skin lesions due to the well-known side effects, such as skin atrophy and telangiectasia (Kuhn et al. 2011b). Therefore, topical corticosteroids should be applied time limited and preferably intermittent. To increase penetration and efficacy of corticosteroids, occlusive techniques, such as plastic food wrap and adhesive gas-permeable surgical dressings, may be applied. Intralesional injection of corticosteroids (triamcinolone acetonide 5–10 mg/ml) has also proved very effective in skin lesions of localized DLE, but the risk of subcutaneous atrophy has to be considered (McCauliffe 2001).

Topical Calcineurin Inhibitors

The calcineurin inhibitors tacrolimus and pimecrolimus are approved for the topical treatment of moderate to severe atopic dermatitis in children and adults. Recently, various case series and reports have also shown topical calcineurin inhibitors to be effective for skin manifestations in CLE and SLE (Sardy et al. 2009; Wollina and Hansel 2008; Tzellos and Kouvelas 2008; Sticherling 2011). In a randomized, double-blind, bilateral comparison study, tacrolimus 0.1 % ointment was compared with 0.05 % clobetasol propionate in 18 patients with facial CLE lesions (Tzung et al. 2007). To improve the penetration of the agents into the skin, microdermabrasion was performed once weekly. Both agents were found to be efficient, but in contrast to clobetasol propionate, tacrolimus ointment showed no side effects, such as skin telangiectasia. In a retrospective study, Madan et al. (2010) assessed the efficacy of a specially formulated preparation of tacrolimus 0.3 % in clobetasol propionate 0.05 % ointment in 13 therapy-refractory CLE patients. Eleven of the patients demonstrated a better response to the

combined preparation compared to five patients who applied tacrolimus 0.1 % ointment as monotherapy. However, the combined preparation showed telangiectasia and acne in two patients. A multicenter, randomized, double-blind, vehicle-controlled trial demonstrated that tacrolimus 0.1 % ointment has a significantly higher efficacy in 30 patients with different CLE subtypes compared to the vehicle (Kuhn et al. 2011a). A high degree of improvement was observed in patients with LET, SCLE, and ACLE, who applied tacrolimus 0.1 % ointment, whereas patients with DLE showed the lowest response rate. Another group performed an open-label and uncontrolled study evaluating the efficacy of pimecrolimus 1 % cream in 11 patients with different subtypes of CLE (Kreuter et al. 2004). The agent was applied twice daily for 3 weeks (overnight occlusion with hydrocolloid dressings) and improvement was observed in all patients. In ten patients with DLE, who were treated with pimecrolimus 1 % cream twice daily for 8 weeks, similar results were obtained (Tlacuilo-Parra et al. 2005). In a further randomized double-blind pilot study, the efficacy of pimecrolimus 1 % cream was compared with topical betamethasone 17-valerate 0.1 % cream in ten patients with moderate to severe DLE of the face, and significant improvement was seen in both groups (Barikbin et al. 2009). Topical calcineurin inhibitors appears to be quite safe, with no potential of skin atrophy, and the most common adverse effect being a transient sensation of burning at the site of application (Czarnecka-Operacz and Jenerowicz 2012). In CLE, tacrolimus ointment and pimecrolimus cream are recommended particularly in atrophy-prone areas such as the face; however, randomized controlled phase III trials need to be performed.

R-Salbutamol

In 2005, a pilot study described the beneficial use of R-salbutamol 0.5 % cream in four SCLE and five DLE patients (Wulf and Ullman 2007). Consecutively, a multicenter, double-blind, randomized, placebo-controlled phase II trial was performed in 37 patients with DLE, and R-salbutamol 0.5 % cream was applied twice daily for 8 weeks (Jemec et al. 2009). Scaling/hypertrophy, pain, itching, and global patient assessment showed a significantly better result in the R-salbutamol-treated patients compared with the placebo-treated group. However, phase III trials still need to be performed to approve the efficacy of R-salbutamol in CLE.

Physical Therapy

Due to the possible induction of Koebner phenomenon, laser therapy, cryotherapy, and dermabrasion should only be used in CLE, especially in persistent DLE lesions, after risk–benefit analysis and evaluation of other possible therapeutic options (Kuhn et al. 2000; Ueki 2005). In single case reports, the use of argon laser (telangiectatic DLE) and carbon dioxide (CO_2) laser (disfiguring DLE) was reported to be successful (Kuhn et al. 2000; Nurnberg et al. 1996; Henderson and Odom 1986; Walker and Harland 2000). The pulsed dye laser was also applied in patients with different subtypes of CLE, resulting in clearance or significant improvement of active disease (Raulin et al. 1999; Erceg et al. 2009; Truchuelo et al. 2012; Diez et al. 2011).

Systemic Treatments

Antimalarials

The first-line treatment for widespread and disfiguring skin manifestations in CLE and SLE are antimalarials, including hydroxychloroquine (HCQ), chloroquine (CQ), and quinacrine (synonym: mepacrine) (Kuhn et al. 2011b). Antimalarials should be considered if (1) local therapy is ineffective or relapses occur soon after cessation of topical therapy, (2) lesions are disfiguring and mutilating, or (3) the extent of the lesions is too large for topical therapy, and (4) no contraindications exist (Kuhn et al. 2010a). In addition, treatment with antimalarials is associated with higher rates of remission and fewer relapses in SLE patients. Therefore,

antimalarials are recommended as standard treatment in all patients with a systemic manifestation of the disease (Bertsias et al. 2008). In the mid-twentieth century, large case series with a total of 771 DLE patients reported impressive improvement with quinacrine in 73–85 % of the patients (Dubois 1978; Wallace 1989). However, quinacrine was slowly replaced by HCQ and CQ due to their more convenient side effect profile, although the occurrence of irreversible retinopathy also limited the use of CQ and HCQ. This unwanted effect is primarily related to an excessive daily dosage but can mostly be prevented by adhering the maximal daily dosage of 3.5–4.0 mg for CQ and 6.0–6.5 mg for HCQ per kg adjusted to the ideal body weight (calculation for daily routine: males, body length in cm – 100 – 10 %; females, body length in cm – 100 – 15 %). Ophthalmological examinations are recommended before and during treatment (fundoscopy, visual field testing, testing of color vision, Amsler grid test) (Kuhn et al. 2009). A daily oral dose of 250 mg CQ or 400 mg HCQ leads to therapeutic plasma concentrations not before 3 weeks after start of treatment due to the long plasma half-life time. Initial higher doses, such as 2×250 mg/day CQ or HCQ up to 1,200 mg/day for 4 weeks, however, often cause unspecific side effects (nausea or gastrointestinal symptoms) (Munster et al. 2002). Therefore, higher dosages should only be given for a short period of time.

As quinacrine works synergistically with HCQ and CQ and does not further increase the risk of a retinopathy, a combination therapy with either agent may be effective in patients not responding to HCQ or CQ treatment. Several studies and case reports describe a high efficacy of a combination therapy in patients with DLE, SCLE, and lupus erythematosus profundus (LEP) (Chung and Hann 1997; Feldmann et al. 1994; von Schmiedeberg et al. 2000; Lipsker et al. 1995; Chang et al. 2011). In a recent prospective longitudinal cohort study, 128 patients with CLE were analyzed to evaluate the response to antimalarial agents. The results of the study demonstrated that a combination of HCQ with quinacrine shows good response in patients for whom HCQ monotherapy fails (Chang et al. 2011). However, oral doses of 100 mg/day quinacrine (one tablet) should not be exceeded and be reduced after achieving a good response (after 3–6 months). In case of adverse reactions, the daily dose can be tapered to 25–50 mg (Wallace 1989).

Up to date, only single randomized, controlled trials have been performed evaluating the efficacy of antimalarials (Kuhn et al. 2014) in patients with CLE. For example, a study comparing the efficacy of HCQ with acitretin (Ruzicka et al. 1992) has shown that overall improvement was observed in 50 % of patients when treated with HCQ and 46 % of patients treated with acitretin, but more side effects were seen in patients who applied acitretin. However, large case series studies suggest that smoking interferes with the efficacy of antimalarials and some mechanisms by which smoking may alter the antimalarial metabolism have been proposed (Kreuter et al. 2009). It has been suggested that nicotine inhibits CQ uptake in cultured cells and blocks the accumulation of antimalarials within lysosomes (Polet 1985). In contrast, recent studies assessing the efficacy of HCQ and/or CQ in CLE patients and smoking indicate that nicotine does not have any significant influence on the response to antimalarials (Wahie et al. 2011). Therefore, prospective studies are required to determine whether the efficacy of antimalarials is influenced by smoking (Dutz and Werth 2011).

Systemic Corticosteroids

The application of systemic corticosteroids is indicated in CLE patients with highly acute and severe skin lesions but only as a short-term treatment due to their well-known side effects, such as osteoporosis and type II diabetes. As described for patients with SCLE (Goldberg and Lidsky 1984), the usual dose of systemic corticosteroids is 0.5–1 mg/kg body weight/day orally over 2–4 weeks followed by tapering of the dose or 3-day intravenous (i.v.) pulse therapy.

Methotrexate (MTX)

The folic acid analog MTX has been primarily administered in patients with refractory SCLE (Kuhn et al. 2002; Boehm et al. 1998; Wenzel et al. 2005) and DLE (Wenzel et al. 2005; Boehm et al. 1998; Bottomley and Goodfield 1995; Goldstein and Carey 1994). A retrospective analysis of 12 patients with different subtypes of CLE assessed the efficacy of MTX in doses of 10–25 mg per week applied orally or i.v. (Boehm et al. 1998). Six of these patients showed complete remission, four partial remission, and two patients did not respond; five of the ten responding patients presented with a long-term remission. A further study including 43 patients with therapy-refractory disease confirmed this beneficial effect of MTX in CLE (Wenzel et al. 2005). Skin lesions of 98 % of patients improved with low-dose MTX, administered either orally or. i.v., and patients with SCLE and localized DLE showed a better improvement than disseminated DLE. In a follow-up study, MTX was applied subcutaneously (s.c.) in 15 of the 43 CLE patients and showed good acceptance by the patients due to easier and self-administered injection; the efficacy of the agent was comparable to the i.v. application (Huber et al. 2006). In addition to the recommended dose of 7.5–25 mg MTX once weekly, folic acid supplementation should be given up to 5 days a week, excluding the day of MTX application, to prevent gastrointestinal side effects (Kuhn et al. 2011c).

Retinoids

In 1985, Ruzicka et al. (1985) first applied etretinate (50 mg daily) in 19 patients with localized and disseminated DLE, SCLE, and one SLE patient with skin manifestations in an open prospective trial. A complete or almost complete clearing of the skin lesions was observed in 11 patients, and a moderate response or treatment failure was seen in 8 patients. In the following years, etretinate has been replaced by its major metabolite acitretin due to its shorter half-life and better safety profile. The efficacy of acitretin was evaluated in 20 patients with CLE; complete clearing or marked improvement could be observed in 75 % of the patients (Ruzicka et al. 1988). Moreover, acitretin (50 mg/day) was compared with HCQ (400 mg/day) in a randomized, double-blind, multicenter, controlled trial with 28 and 30 patients, respectively (Ruzicka et al. 1992). Both agents showed a similar good efficacy (acitretin 46 % and HCQ 50 %). Furthermore, one case report described the successful treatment of hyperkeratotic/verrucous refractory DLE on hands, feet, and legs with acitretin (Al-Mutairi et al. 2005). Treatment of DLE and SCLE with isotretinoin, a further compound of the retinoid family, was published in approximately 50 patients with an efficacy of up to 86.9 % (Newton et al. 1986; Vena et al. 1989; Furner 1990; Shornick et al. 1991; Richardson and Cohen 2000). The recommended dose for acitretin and isotretinoin in CLE is 0.2–1.0 mg/kg body weight/day (Bacman et al. 2004). Due to their relatively innocuous side effects, acitretin and isotretinoin are listed as "second-line" substances for CLE in the American Academy of Dermatology guidelines (Drake et al. 1996). Because of their high teratogenicity, effective contraception is highly important during and after treatment with retinoids (isotretinoin, 1 month; acitretin, 2 years).

In 2008, the vitamin A derivative alitretinoin has been approved for use in severe chronic hand eczema unresponsive to treatment with potent topical corticosteroids (Garnock-Jones and Perry 2009). Recently, a case report on three patients with different subtypes of CLE who received alitretinoin demonstrated a high efficacy of 30 mg alitretinoin in the treatment of the disease (Kuhn et al. 2012). Further studies are necessary to confirm the efficacy and evaluate the safety profile of alitretinoin in patients with different subtypes of CLE.

Dapsone

In the literature, dapsone has been described to be effective in several subtypes of CLE, urticarial vasculitis, oral ulcerations, and bullous rash of

SLE (Bacman et al. 2004; Ludgate and Greig 2008). In 1981, Ruzicka and Goerz (1981) reported on dapsone treatment in four patients with DLE and three patients with SLE, resulting in clearance of discoid lesions, oral ulcerations in DLE, and urticarial vasculitis in SLE, whereas widespread macular–papular eruptions of SLE and disseminated DLE did not respond to this agent. In two further studies, dapsone was applied in 44 patients with DLE and showed a clinical response in 24 patients, with an excellent result in eight of the patients (Coburn and Shuster 1982; Lindskov and Reymann 1986). Single case reports of successful treatment with dapsone in SCLE and LEP have also been described in the literature (Bohm et al. 1998; McCormack et al. 1984; Fenton and Black 1986; Holtman et al. 1990; Ujiie et al. 2006; Yamada et al. 1989). A recent case report on one patient with vesico-bullous SCLE, who received a combination of HCQ and dapsone, described a clinical improvement of skin lesions after 3 weeks of treatment and a clearance on continuous treatment (Pinto-Almeida et al. 2012). As the formation of new skin lesions already stopped after 5 days of treatment, the prompt clinical efficacy might have been due to dapsone. In CLE, dapsone is recommended in doses ranging from 25 to 150 (maximum 200) mg/day; however, the lowest effective dose should be applied to minimize possible side effects, such as hemolysis and methemoglobinemia (Duna and Cash 1995).

Mycophenolate Mofetil (MMF) and Mycophenolate Sodium (EC-MPS)

In single case reports of patients with CLE, such as SCLE, DLE, and chilblain lupus erythematosus (CHLE), the efficacy of the immunosuppressive drug MMF has been reported (Boehm and Bieber 2001; Goyal and Nousari 2001; Schanz et al. 2002; Cetkovska and Pizinger 2006). For example, a complete remission within 3 months of starting MMF was achieved in four patients with various manifestations of refractory CLE and smoldering systemic involvement (Hanjani and Nousari 2002). In contrast, MMF was not efficient in five of seven patients with various LE-specific and nonspecific skin diseases in the context of SLE, such as vasculitis and urticarial rash (Pisoni et al. 2005). MMF is recommended in doses of 2–3 g per day; the common dose of 2 g MMF is best tolerated and hematological side effects are rare. In a non-randomized, open-pilot study, the enteric-coated form of MMF (EC-MPS) was applied in ten patients with active therapy-refractory SCLE, showing a significant improvement of the cutaneous manifestations (Kreuter et al. 2007).

Thalidomide and Lenalidomide

Due to the immunomodulatory and anti-inflammatory characteristics of thalidomide, successful treatment in a high number of cases has been reported in particular in patients with DLE. First-case series with thalidomide were published in 1983 (Knop et al. 1983). High initial doses of 400 mg/day and a maintenance dose of 50–100 mg/day of thalidomide were applied in 60 patients with DLE. In 90 % of the patients, a complete or marked response was observed; however, although most patients relapsed after stopping thalidomide, the cutaneous manifestations were not as severe as prior to treatment. However, peripheral polyneuropathy appeared in 25 % of the patients. In a retrospective study with 48 CLE and SLE patients overall clinical response rate of 81 % has been shown in a retrospective study with 48 CLE and SLE patients (Cuadrado et al. 2005). Different dosages (100 mg/day, 50 mg/day, and 50 mg/day on alternate days) were applied; interestingly, there was no clear dose-dependent effect of thalidomide. Skin lesions relapsed in 67 % of 39 patients after discontinuation of thalidomide. In 13 (27 %) of the 48 patients, evidence of polyneuropathy (EMG abnormalities or symptoms) was observed, which were irreversible in a high number of patients. In four further studies, approximately 160 patients with CLE, such as DLE, LEP, and SCLE, as well as SLE with cutaneous manifestations were treated with thalidomide, confirming the efficacy of this drug (Briani et al. 2004; Kyriakis et al. 2000; Coelho et al. 2005; Cortes-Hernandez et al. 2012). In the recent prospective

study by Cortes-Hernandez et al. (2012), complete response to treatment with thalidomide (100 mg/day) was observed in 85 % of the CLE patients, but clinical relapse was frequent (70 %) and usually occurred 5 months after withdrawal or reduction of thalidomide. Patients with SCLE showed a long-term remission of skin lesions even after treatment discontinuation, whereas DLE tended to relapse and required a long-term maintenance dose of thalidomide. In addition to the teratogenic effect and the strict precautions for the use of this drug in women of childbearing potential, these studies confirmed the high relapse rate, the well-known side effects and, most importantly, the high risk of potential irreversible polyneuropathy. Therefore, due to high incidence of polyneuropathy, thalidomide should only be used to treat severe therapy-refractory cases of CLE.

Lenalidomide is a structural derivative of thalidomide with more immunomodulatory effects and lower risk of polyneuropathy (Braunstein et al. 2012). In 2009, two patients with refractory disseminated DLE were treated with lenalidomide (Shah et al. 2009). One patient showed good clinical response at a dosage of 10 mg per day, while no improvement was seen in the second patient; however, this patient received only 5 mg lenalidomide per day. Recently, five patients with refractory DLE or SCLE were treated with 5 mg lenalidomide daily, and in four patients, clinical improvement of skin lesions was observed (Braunstein et al. 2012). Even though lenalidomide showed a good efficacy, one patient developed new-onset proteinuria and an exacerbation of arthralgias. In addition, the same strict precautions as for thalidomide have to be applied for lenalidomide in women of childbearing potential (appropriate contraception), although the risk of polyneuropathy seems to be lower for lenalidomide. Therefore, further studies are required to assess the benefit–risk balance of lenalidomide in the treatment of patients with CLE.

Intravenous Immunoglobulins (IVIG)

Several case reports have shown a good response to IVIG in therapy-refractory patients with SCLE (Genereau et al. 1999; Kreuter et al. 2005; Lampropoulos et al. 2007), and a complete resolution was seen in most of the 17 patients with different subtypes of CLE (DLE, SCLE, bullous SLE) reported by Goodfield et al. (2004) and Piette et al. (1995). In addition, a recent case report demonstrated a good efficacy in a patient with LEP, who had not responded to any other previous treatment (Espirito Santo et al. 2010). However, this efficacy could not be confirmed in five patients with malar rash and oral ulcers in the context of SLE and two patients with SCLE, which were also treated with IVIG (De Pita et al. 1997). The SCLE lesions worsened and the cutaneous manifestations in the SLE patients did not show any response, even though some clinical and immunological parameters improved. Adverse reactions of IVIG include headache but also urticarial rash, cutaneous vasculitis, proteinuria, acute renal failure, deep venous thrombosis, embolia, myocardial infarction, stroke, and anaphylactic reactions. Additional clinical trials need to be performed in order to investigate the efficacy of this promising but highly expensive therapy in CLE.

Clofazimine

In 1974, clofazimine, an antibacterial substance for the treatment of leprosy, was applied in 26 refractory patients with DLE, and a remission of skin lesions was observed in 65 % of the patients (Mackey and Barnes 1974). A further randomized, comparative trial was performed in 33 SLE patients with active CLE lesions (ACLE, SCLE, and localized disseminated DLE) (Bezerra et al. 2005). The results of this study suggested that clofazimine has a similar efficacy as CQ in controlling cutaneous manifestations of SLE, but further studies are necessary to assess the efficacy of this agent in different subtypes of CLE and SLE.

Phenytoin

Despite promising data from earlier studies, treatment with phenytoin (93 DLE, excellent response in about 90 %) (Rodriguez-Castellanos et al.

1995) is historic and should only be used in therapy-refractory patients as a last alternative treatment due to the wide spectrum of side effects.

Azathioprine, Cyclophosphamide, and Cyclosporin

Immunosuppressive drugs, such as azathioprine, cyclophosphamide, and cyclosporine, are not recommended for CLE and skin manifestations in SLE, as poor efficacy in the treatment of cutaneous disease has been reported (Kuhn et al. 2009). However, these drugs are frequently used as basic or additional therapy in patients with systemic organ manifestations.

Biologicals

It is well known that TNF-alpha blockade leads to the formation of antinuclear antibodies including anti-dsDNA antibodies (Charles et al. 2000; Louis et al. 2003). Furthermore, induction of CLE subtypes (SCLE and DLE-like eruption, CHLE) and worsening of SCLE through infliximab have been reported (High et al. 2005; Vabre-Latre et al. 2005; Stratigos et al. 2004; Richez et al. 2005). However, other biologicals, such as ustekinumab, rituximab, and belimumab, are promising agents in the treatment of CLE.

Ustekinumab

Ustekinumab is a human monoclonal antibody against interleukin-12 and interleukin-23, registered for the treatment of psoriasis (Leonardi et al. 2008). Recently, three case reports on therapy-refractory patients with CLE, which were treated with ustekinumab have been published, describing a good efficacy of this agent. Winchester et al. (2012) described a patient with severe psoriasis and hypertrophic DLE, who received three doses of 45 mg and one dose of 90 mg ustekinumab i.v. within 16 weeks, resulting in a marked improvement of the skin lesions. In one patient with severe DLE and overlap to CHLE, ustekinumab was administered in four doses of 45 mg i.v., respectively, within 34 weeks (Dahl et al. 2013). The erythema on the face, scalp, and fingertips improved, and the ulcers on the fingertips healed, while the erythema on the toes remained unchanged. In a further case report, the efficacy of this agent was confirmed in a patient with SCLE treated with ustekinumab (De Souza et al. 2011). In none of the reported patients, any side effects were observed, suggesting that this agent may be an alternative treatment for CLE; however, randomized controlled studies are required to assess the efficacy and safety of ustekinumab in patients with the disease.

Rituximab

The chimeric monoclonal anti-CD20 antibody rituximab has been applied successfully in adults and children for refractory SLE, usually in combination with corticosteroids, immunosuppressives, antimalarials, or a combination of these agents (Garcia-Carrasco et al. 2009). In a case report by Risselada and Kallenberg (2006), two patients with SLE and cutaneous manifestations, such as urticarial vasculitis and diffuse generalized rash with painful erythema on hands and feet, were treated with $2 \times 1{,}000$ mg rituximab i.v. in combination with 100 mg methylprednisolone i.v. at an interval of 2 weeks. In both patients, skin manifestations cleared completely and persistently. A further recent case report described a 48-year-old patient with refractory SCLE in which rituximab (375 mg/m^2 i.v.) was administered weekly for 4 weeks, in addition to HCQ (600 mg daily) and topical clobetasol propionate 0.05 % (Kieu et al. 2009). The skin lesions improved after 16 weeks but recurred after 11 months of follow-up, and rituximab treatment was repeated with maintenance therapy every 8 weeks for 2 years, resulting in an ongoing disease remission. In a recent single-center, retrospective study, 14 patients with consecutive SLE, 1 patient with CCLE, and 2 patients with SCLE with recalcitrant skin involvement were treated with 2× rituximab 1 g and 1× cyclophosphamide 750 mg (Hofmann et al. 2013). Six months after B-cell depletion therapy, 9 of 17 (53 %) patients showed a complete or partial remission; however, relapses occurred in 12 patients. The results of this study demonstrate that B-cell depletion

therapy based on rituximab is well tolerated and may be effective in CLE, but further randomized, controlled trials are required to further assess the efficacy of this agent.

Belimumab

Belimumab, the first of a new class of immunomodulators with a novel mechanism of action, was approved for SLE in 2011 based on two phase III studies (Furie et al. 2011; Navarra et al. 2011). SLE therapy was assessed by the SLE Responder Index (SRI) at week 52 and belimumab was used in 1 and 10 mg/kg versus placebo. Belimumab plus standard SLE therapy showed a significantly higher efficacy than placebo plus standard therapy, also for mucocutaneous manifestations. In addition, a post hoc analysis was performed in these 1,684 autoantibody-positive SLE patients, and SLE disease activity was assessed by the "Safety of Estrogens in Lupus National Assessment-Systemic Lupus Erythematosus Disease Activity Index" (SELENA-SLEDAI) and the "British Isles Lupus Assessment Group" score (BILAG) (Manzi et al. 2012). A validated skin activity and damage score, such as the Revised Cutaneous Lupus Erythematosus Disease Area and Severity Index (RCLASI) (Kuhn et al. 2010b), was not applied to assess improvement of skin manifestations in SLE. Therefore, it is difficult to evaluate the positive results on mucocutaneous manifestations with regard to the different CLE subtypes. Future prospective studies using a validated skin score are required to assess the efficacy of belimumab on mucocutaneous manifestations of the disease.

Conclusion

Several agents are approved for the treatment of SLE, including the novel anti-BLyS monoclonal antibody belimumab. However, no drugs have been licensed specifically for the treatment of CLE. Thus, "off-label" topical and systemic agents are applied to skin manifestations of the disease, mainly based on expert opinions. Corticosteroids are the first-line topical treatment for patients with CLE, but they are of limited value because of their well-known side effects, such as skin atrophy and telangiectasia. In recent years, topical calcineurin inhibitors, such as tacrolimus and pimecrolimus, have been shown to be efficient in various CLE subtypes and are recommended particularly in atrophy-prone areas such as the face. Antimalarials, e.g., HCQ or CQ, are the mainstay of treatment for disfiguring and widespread skin manifestations, irrespective of the subtype of the disease. Both agents can be combined with quinacrine in refractory CLE, and systemic steroids can be added in acute exacerbations of the disease for short periods of time. In contrast to immunosuppressive agents, such as azathioprine, cyclophosphamide, and cyclosporine, methotrexate has received more attention in the treatment of cutaneous manifestations of the disease. Further second-line treatment includes retinoids, dapsone, and MMF/EC-MPS. Due to severe side effects or high costs, other agents, such as thalidomide or high-dose IVIG, respectively, are reserved for severe recalcitrant CLE. In addition to belimumab, other biologics, such as rituximab, have been evaluated to treat SLE in clinical trials and have also been shown to be efficient in single cases of CLE. In conclusion, several treatment options exist for patients with skin manifestations of the disease, but only single agents are supported by evidence from randomized, controlled trials.

Lyme Borreliosis

56

Jana Hercogová

Key Points

- Lyme borreliosis is an inflammatory disease caused by the spirochaete *Borrelia burgdorferi* which is transmitted by tick (mainly of the genus *Ixodes*).
- It is an anthropozoonosis which manifests itself as a multisystem disorder of the skin and other organs (joints, nerves, heart, eye, etc.).
- Cutaneous manifestations of Lyme borreliosis include erythema migrans, borrelial lymphocytoma and acrodermatitis chronica atrophicans.
- The diagnosis of Lyme borreliosis is based on the history of tick exposure, the characteristic clinical picture and confirmation of *B. burgdorferi* infection by serological tests
- Antibiotic therapy should be started as soon as possible after the diagnosis has been made. Borreliae are sensitive to four groups of antibiotics—penicillins, cephalosporins (third generation and cefuroxime axetil), tetracyclines and macrolides. The drugs of choice for oral treatment of Lyme borreliosis are doxycycline and amoxicillin and for parenteral treatment ceftriaxone, cefotaxime and penicillin G.

Definition and Epidemiology

Lyme borreliosis is an inflammatory disease caused by the spirochaete *Borrelia burgdorferi* which is transmitted by tick (mainly of the genus *Ixodes*). It is an anthropozoonosis which manifests itself as a multisystem disorder of the skin and other organs (joints, nerves, heart, eye, etc.).

Lyme borreliosis is the most common vector-borne disease in Europe and the USA. Ticks of the genus *Ixodes* are the vectors that transmit the infection to mammals in endemic areas—in the North American and Euro-Asian continents. In Europe, Austria, Slovenia, Sweden and the Czech Republic belong to the most endemic areas (incidence could raises to 100 cases per 100,000 inhabitants). *B. burgdorferi* has been isolated from patients worldwide. Cutaneous involvement

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_56, © Springer-Verlag Berlin Heidelberg 2015

is the most frequent manifestation of the disease: it represents 60–80 % of all reported cases. Concerning cutaneous symptoms, erythema migrans is the most prevalent (approximately 85 %), followed by acrodermatitis chronica atrophicans (10 %) and borrelial lymphocytoma (5 %). Concrete cutaneous manifestations affect different age groups—erythema migrans is mainly present in middle-aged adults (30–50 years), borrelial lymphocytoma is typical for children and acrodermatitis is a disease of the elderly.

Basic Concepts of Pathogenesis

The aetiological agent, *B. burgdorferi* sensu lato, has been subdivided into three genospecies causing the human disease: *B. burgdorferi* sensu stricto, *B. afzelii* and *B. garinii*. Strains of all three species have been isolated from patients in Europe, whereas only the first species is involved in the USA. Some studies show that *B. afzelii* represents a dominant human skin isolate in Europe. Antigenic differences of three genospecies may explain the variability of clinical manifestations in patients with Lyme borreliosis. Genetic analysis of *B. garinii* OspA serotype 4 strains is correlated with the development of neuroborreliosis. *B. afzelii* OspA serotype 2 closely correlates with the development of acrodermatitis chronica atrophicans.

After the tick bite, borreliae spread in the dermis causing cutaneous symptom of the early localized stage (erythema migrans and borrelial lymphocytoma). Antibody immune response could be demonstrated in 3–4 weeks in the IgM class and in 4–6 weeks in the IgG class. Haematogenic spread of borreliae follows weeks to months after the tick bite and can manifest itself as the early disseminated stage of the disease. The development of the chronic stage is a subject of ongoing studies. The question is whether the symptoms are a result of the host immune response against organism or even against tissue autoantigens. T-cell-mediated immunity might be responsible for inducing and exacerbating cardiac and joint symptoms. T-cell-mediated immunopathology may result from the antigenic specificity of T cell, the activation of a specific T-cell subset or ability of persisting antibodies to induce hypersensitive auto-reactive T cells in the joints and the heart. Auto-reactive B-lymphocytes as well as significantly raised concentrations of IgA rheumatoid factor were proven in the serum of patients with the chronic stage of Lyme borreliosis; production of these antibodies may be a result of B-cell auto-reactivity.

Clinical Presentation

Cutaneous manifestations of Lyme borreliosis include erythema migrans, borrelial lymphocytoma and acrodermatitis chronic atrophicans; morphoea and its initial stage, lichen sclerosus et atrophicus, are considered to be polyaetiological entities in which borreliae (*B. afzelii* and *B. garinii*) were isolated from morphoea lesions. Extracutaneous manifestations are variable (Table 56.1).

Erythema migrans is an early localized form of Lyme borreliosis. It appears 3–30 days after the tick bite and is defined as a red patch, bigger than 4 cm in diameter at the site of the tick bite which spreads centrifugally and can reach several decimetres in diameter. Three main clinical types are

Table 56.1 Clinical manifestations of Lyme borreliosis

Early stage
Localized infection
Erythema migrans (annular, macular, concentric)
Borrelial lymphocytoma (papular, infiltrative)
Disseminated infection
Multiple erythemata migrantia
“Flu-like” symptoms
Meningitis, manigoradiculoneuritis
Endocarditis, myocarditis, pericarditis
Arthritis, tenosynovitis
Hepatitis, keratitis, conjunctivitis
Chronic stage
Acrodermatitis chronica atrophicans (macular, telangiectatic, fibrotic, atrophic)
Chronic encephalitis, encephalomyelitis, polyneuritis
Chronic arthritis

known: (a) homogenous (a red, sharply demarcated patch without a central clearing), (b) annular (a red, sharply demarcated patch with a central clearing) and (c) iris-like (concentric annular patches). From time to time, also multiple or bullous types could be present. A central reddish macule, representing the site of the tick bite, may be apparent in any of these three clinical types.

Erythema migrans can be present anywhere on the body surface, but the lower extremities are the most frequent sites. In children, the head and neck are also usually affected.

Borrelial lymphocytoma is a bluish-red papule, nodule or plaque, 1–3 cm in diameter, localized on the ear lobe. The areola mammae, scrotum and nose are other typical sites.

Acrodermatitis chronica atrophicans starts as an inflammatory stage which evolves into an atrophic stage. Firstly, bluish-red, not sharply demarcated patch(es) or plaque(s) appear on the dorsal aspect of the foot or hand. Predilection sites include the skin above the bony prominences (on the lower extremities, the ankle, lateral aspects of the foot, fingers and knee and on the upper extremities, fingers and elbow). Lesions usually spread from distal to proximal sites, including the trunk and face. Four clinical types of the lesions can be differentiated: (a) erythematous lesions (bluish-red patches, plaques in cases of swelling), (b) telangiectatic lesions (telangiectasias predominately, red patches), (c) fibrous lesions (firm, bluish-red of skin-coloured nodules, mainly above the elbow, ulna or small joints of the hand) and (d) atrophic lesions (thin skin with wrinkles, prominent vessels).

Diagnosis

The diagnosis of Lyme borreliosis is based on the history of tick exposure, the characteristic clinical picture and confirmation of *B. burgdorferi* infection by serological tests (with the exception of early pathognomonic cutaneous manifestations of the disease, e.g. annular erythema migrans and borrelial lymphocytoma which is localized on the ear lobe and is present in children). Histopathological examination should be performed in acrodermatitis chronic atrophicans patients and in those where the diagnosis is not clear from a clinical point of view.

Direct proof of borrelial infection includes isolation (allowing the demonstration of live *B. burgdorferi*, e.g. in the skin, synovial fluid, myocardium) and histopathological detection of the microorganisms in the tissue by a modified Dieterle's stain or a modified Steiner's method, electron microscopy, DNA hybridization and polymerase chain reaction (nested PCR and quantitative PCR). PCR testing of cutaneous lesions is helpful to confirm the diagnosis in clinically atypical cases.

Indirect methods include enzyme-linked immunosorbent assay (ELISA) and immunoblotting. Two-step serological testing is recommended in which a serum specimen with a positive test result by the ELISA is further tested with immunoblotting. The standardization of an immunoblotting method for the diagnosis of Lyme borreliosis would require agreement on the strains used for antigen preparation. This approach would not be possible in Europe due to different local prevalences of genospecies of *B. burgdorferi* sensu lato and also to heterogeneity within those strains. To date, none of the serological tests should be termed as a "screening" test. Special attention should be given to patients in whom serological tests could be false positive (other spirochetal infections, autoimmune disorders) and/or false negative (immunocompromised patients).

Histopathological examination of the erythema migrans lesion shows superficial perivascular dermatitis, composed of lymphocytic infiltrate with plasma cells and eosinophils. Borrelial lymphocytoma is a pseudolymphoma; lymphocytes are top heavy, without nuclear atypia, and plasma cells can be present. Acrodermatitis chronica atrophicans shows superficial perivascular or lichenoid dermatitis, lymphocytic infiltrate with plasma cells, epidermal atrophy, dilated vessels in the upper part of the dermis and orthohyperkeratosis. Later on, degeneration of elastic and collagen fibres, as well as gland adnexae, could follow.

Differential Diagnosis

Erythema migrans should be differentiated from erysipelas, superficial tinea, fixed drug eruption, discoid cutaneous lupus erythematodes, granuloma annulare, morphoea and contact dermatitis.

Borrelial lymphocytoma could be similar to histiocytoma, keloid, angioma, Kaposi's sarcoma, granuloma faciale, granuloma annulare, sarcoidosis and lupus erythematodes. In all cases, histopathological examination is helpful. Malignant lymphoma can be distinguished by immunohistochemical examination.

Acrodermatitis chronica atrophicans can mimic circulatory insufficiency, perniones, morphoea and dermatomyositis; fibrotic papules and nodules are considered to be rheumatic nodules or gouty tophi.

General Principles of Treatment

Antibiotic therapy should be started as soon as possible after the diagnosis has been made. Some studies demonstrate that even an appropriate antibiotic regimen may not always eradicate the spirochete. On the one hand, the treatment of disseminated Lyme borreliosis for 3 months may not be sufficient: the spirochetes can remain in serum, skin and other tissues, and clinical relapses can occur. However, it remains unresolved whether the prognosis of patients with disseminated Lyme borreliosis could be improved by longer initial treatment. On the other hand, the outcomes of most persons diagnosed as having Lyme borreliosis who are treated with antimicrobial agents are excellent. Extracutaneous manifestations of Lyme borreliosis are described after any antibiotic regimen in up to 10 % patients. Recently, treatment trials for post-Lyme disease symptoms were revised, and authors did not find any data supporting the benefit of retreatment of the patients who had been treated with antibiotics previously.

Cutaneous manifestations disappear after the therapy, but immediate disappearance of borrelial lymphocytoma and acrodermatitis chronica atrophicans during antibiotic therapy is exceptional. Those lesions begin to fade and lose the swelling, but resolution can take up to 6 months. The degenerative changes in acrodermatitis are not reversible. No significant differences were found in the outcome of erythema migrans after 1 year in patients whose immune system was impaired compared to previously healthy individuals.

The immunological response after antibiotic therapy appears to be abrogated, so levels of antiborrelial antibodies cannot be used as proof of successful therapy. Furthermore, the antibody titre development after therapy is unpredictable and variable, and it is largely uncorrelated with the clinical course. It was also shown that even after the proper antibiotic therapy, *B. burgdorferi* DNA could persist up to 6 months.

Recommended Therapies

Borreliae are sensitive to four groups of antibiotics—penicillins, cephalosporins (third generation and cefuroxime axetil), tetracyclines and macrolides. The drugs of choice for oral treatment of Lyme borreliosis are doxycycline and amoxicillin and for parenteral treatment ceftriaxone, cefotaxime and penicillin G. Ceftriaxone is primarily used as a treatment for patients with extracutaneous (joint, neurological, cardiac) and multiple cutaneous manifestations. If the coinfection with ehrlichiosis is suspected, doxycycline is the drug of choice. Doxycycline is also preferred in cases of penicillin-cephalosporin allergy since erythromycin has inferior efficacy. Children with solitary erythema migrans could be treated with phenoxymethyl penicillin and cefuroxime axetil; however, drug-related side effects were more frequently observed with cefuroxime axetil. Minocycline causes teeth discoloration even in young adults and discoloration of the skin, nails, sclera and conjunctivae. Vertigo, ataxia and dizziness have been described during minocycline therapy. These symptoms are a major disadvantage, in particular for patients with neurological symptoms, as in Lyme disease.

Recommended therapies for uncomplicated erythema migrans include oral doxycycline

200 mg daily (divided into two doses every 12 h) or amoxicillin 3 g daily (divided into three doses every 8 h) for 15 days. If any general signs or symptoms (subfebrilia, malaise, fatigue, arthralgias, myalgias, meningism, conjunctivitis, etc.) are present even if for 1 day, the duration of antibiotic therapy should be 20 days. In case of penicillin of tetracycline allergy, azithromycin is prescribed (500 mg daily p. o. for 10 days and for 15 days in the presence of general signs or symptoms).

Borrelial lymphocytoma is treated with the same antibiotic regimen; only the duration of therapy is at minimum 20 days. Acrodermatitis chronica atrophicans patients are given the same oral antibiotics for 25–30 days, but in the presence of any extracutaneous manifestations, parenteral therapy is needed—ceftriaxone 2 g i. v. daily in one dose of penicillin G i. v. 20 million units daily (divided into 4 doses of 5 million units every 6 h) for 15 days followed by oral antibiotic (as in the early stage) for the next 15 days.

Special attention should be given to pregnant women with Lyme borreliosis. Penicillins, macrolides and ceftriaxone are used, but antibiotic administration depends on the time of tick bite; if the tick bite is suspected during the trimester, then parenteral antibiotics are used. On the other hand, if the tick bite occurs later in pregnancy and the patient has no extracutaneous symptoms or signs, oral antibiotics are sufficient for therapy.

Prevention

Prevention of Lyme borreliosis includes avoiding exposure to tick bites by limiting outdoor activities in endemic areas, using tick repellents containing diethyltoluamide (DEET) 10–35 % or picaridin 20 %, tucking in clothing and frequent skin inspection for early detection and correct removal of ticks. Persons who have undergone tick removal should be monitored up to 30 days for signs and symptoms.

Antibiotic prophylaxis has not been shown to be effective in reducing the risk of acquiring Lyme borreliosis. Some authors recommend local antibiotics after the tick bite; the other did not confirm the efficacy of topical antibiotics in preventing dissemination of the disease.

Vaccination trials showed that a single recombinant outer surface protein A (OspA) appears to be safe and immunogenic in man. A single antigen OspA vaccine in not effective in Eurasia, where more heterogeneous species of borrelia and more variable OspA are present. In Eurasia, compared to the USA, a vaccine must be effective against all subgroups of the borrelia spirochaete. Some protective immunity against borrelia infection in laboratory animals was demonstrated by some other *B. burgdorferi* proteins, e.g. OspB and OspC.

Recently, it was shown by the study from Northeastern US patients that those treated for early Lyme disease develop protective immunity that is strain specific and lasts for at least 6 years. Repeated serologic testing is of very limited value for assessing therapy efficacy and therefore not recommended in the follow-up of dermatoborrelioses patients.

Lymphogranuloma Venereum

57

Henry John Christiaan de Vries

Abbreviations

B.i.d.	Bis in die/two times a day
C	*Chlamydia*
LGV	Lymphogranuloma venereum
MSM	Men who have sex with men
NAAT	Nucleic acid amplification test
Q.i.d.	Quater in die/four times a day
STI	Sexually transmitted infection

Key Points

- Lymphogranuloma venereum (LGV) is a sexually transmitted infection (STI) caused by *C. trachomatis* genovar L (that primarily involves the lymphatics of the anogenital region).
- Left untreated, LGV can lead to irreversible lymph oedema and fibrotic sequelae.
- The disease is endemic in the tropical regions of Africa, Asia and South America.
- In 2004, it was found endemic in the Western world among men who have sex with men (MSM) with high-risk sexual behaviour.
- The standard algorithm to diagnose LGV is to first exclude *C. trachomatis* infection in suspected individuals via a commercially available routine nucleic acid amplification test (NAAT). In case this routine test is positive, genovar L has to be confirmed via an "in house" *C. trachomatis* genovar-specific *C. trachomatis* NAAT.
- Apart from HIV and STI screening, HCV testing should be offered to all LGV patients.
- The goal of therapy is to eradicate the pathogen.
- Late sequelae do not respond to antibiotic treatment and need to be managed surgically.
- Subjects who have had sexual contact with an LGV patient should be examined, tested for chlamydial infection and promptly treated.
- To exclude reinfections, STI screening during a follow-up visit 3 months after an LGV diagnosis should be offered.

Definition and Epidemiology

Lymphogranuloma venereum (LGV) has been renamed several times in the past and was known as tropical bubo, climatic bubo, poradenitis inguinalis, Durand-Nicolas-Favre disease, lymphopathia venereum and the fourth, fifth or sixth diseases. However, the name LGV is currently the standard name and should be distinguished from granuloma inguinale, a bacterial STI caused by *Klebsiella granulomatis*.

The causative agent of LGV is *Chlamydia trachomatis* genovar L. Worldwide, LGV is thought to account for 2–10 % of genito-ulcerative diseases in tropical climate areas such as India and Africa. In Europe, North America and Australia, LGV is endemic mainly among HIV coinfected men who have sex with men (MSM, homo- and bisexual men) and is for the large part caused by genovar L2b. Heterosexual transmission of this MSM-associated L2b strain has been described.

The degree of infectiousness and the reservoir of disease have not been accurately defined, but heterosexual transmission has been attributed largely to asymptomatic female carriers, and in the MSM population, asymptomatic rectal infection and/or penile infection is the likely source of onward transmission.

Basic Concepts of Pathogenesis

Chlamydia trachomatis types L1, L2 and L3 are the causative pathogens. Additional variants have been described such as L2b, the strain currently found in MSM. Genovar L strains are invasive organisms that disseminate via underlying connective tissue and spread to regional lymph nodes. As a result, most LGV infections cause (systemic) symptoms in contrast to infections with *C. trachomatis* genovars A–K that remain confined to the mucosa and are asymptomatic in many cases. The incubation period of LGV is 1–4 weeks.

Clinical Presentation

Depending on the site of inoculation, LGV can cause inguinal disease (usually after inoculation of the genitalia) or the anorectal syndrome (usually after inoculation via the rectum). The disease course usually follows three separate stages (Table 57.1).

Table 57.1 Clinical spectrum of lymphogranuloma venereum

Manifestations	Complications
Primary stage transient papule, pustule, herpetiform ulcer, nodular ulceration, non-specific urethritis, balanitis or balanoposthitis, bubonulus, cervicitis, salpingitis, parametritis	Phimosis, labial oedema, infertility
Secondary stage (inguinal syndrome) severe proctitis, bubo formation, inguinal multilocular abscess, groove sign of Greenblatt	Sinus tracts, frozen pelvis, infertility, systemic arthritis, pneumonia, hepatitis, perihepatitis, spondylitis, ocular inflammatory disease
Tertiary stage (genito-anorectal syndrome) genital syndrome, anorectal syndrome, proctitis, proctocolitis	Genital elephantiasis, ramrod or saxophone penis, esthiomene, vaginal stenosis, urethral strictures, fistulae (rectovaginal, urethrovaginal, vulval), rectal strictures, stenosis, abscess formation (perirectal, ischiorectal, supralevator), rectal adenocarcinoma, lymphorrhoids
Urethro-genito-perineal syndrome	Papillary genital growths, perineal sinus
Ocular manifestations mixed papillary-follicular conjunctivitis, episcleritis, corneal ulcers, iritis, iridocyclitis	Iritis, iridocyclitis
Cutaneous manifestations id eruption – transient generalised exanthemata, papules, pustules, nodules, urticaria, scarlatiniform eruption, erythema multiforme, erythema annulare centrifugum, erythema nodosum, photoallergic dermatitis	
Others LGV tonsillitis, pharyngitis, cholecystitis	

Adapted from de Vries et al. 2012

In the current LGV epidemic among MSM, proctitis is the primary manifestation of infection, usually presenting within a few weeks of sexual contact. It is characterised by severe symptoms of painful anorectal ulcers (Fig. 57.1) and bloody and/or purulent anal discharge. Tenesmus and

Fig. 57.1 Anorectal lymphogranuloma venereum (LGV) with perianal ulceration

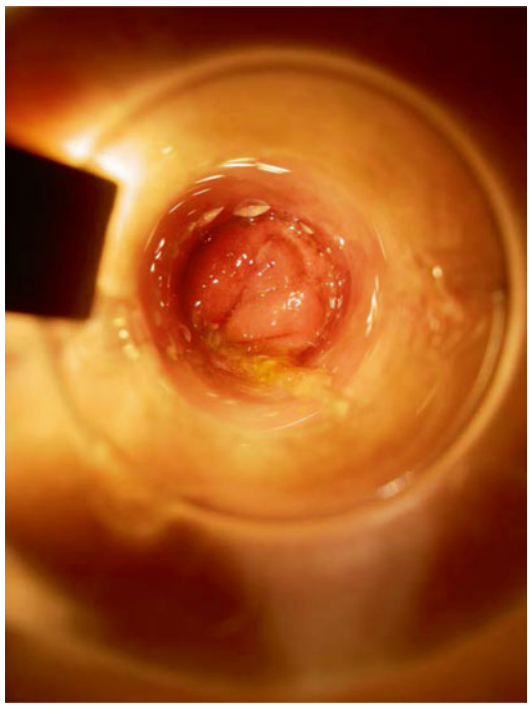

Fig. 57.2 Anorectal lymphogranuloma venereum (LGV) with discharge, mucosal inflammation and oedema (same patient as in Fig. 57.1)

constipation are also seen due to the mucosal and perirectal oedema. Anoscopic examination may reveal a granular or haemorrhagic proctitis with purulent exudate, mucosal ulceration and tumorous masses (Fig. 57.2). LGV proctitis is usually not accompanied by inguinal lymphadenopathy; but diagnostic imaging techniques may demonstrate pelvic node involvement. There is a debate about the proportion of asymptomatic LGV cases among MSM. In UK cohorts, almost all LGV infections appear to be symptomatic, in contrast to Dutch studies where a significant proportion of asymptomatic infections have been detected.

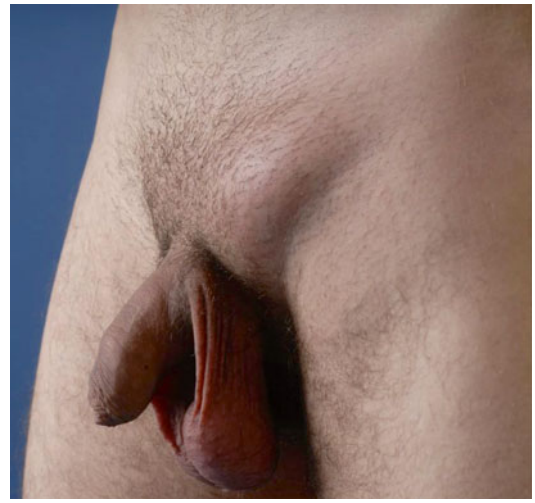

Fig. 57.3 Inguinal lymphogranuloma venereum (LGV) with a bubo in the groin area

The primary lesions are small painless papules or pustules that may erode to form a herpetiform ulcer. They usually heal within 1 week and often go unnoticed. In the secondary stage 2–6 weeks after onset of primary lesion, painful inflamed inguinal and/or femoral lymph nodes, usually one sided, arise (Fig. 57.3). These "buboes" may become fluctuant and rupture in every third patient (Fig. 57.4). Inguinofemoral lymphadenopathy is mainly seen when the inoculation site is located on the external genitalia, which is the case in many male patients. In contrast, women more often have primary involvement of the rectum, upper vagina, cervix or posterior urethra; as these regions drain to the deep iliac or perirectal nodes, inguinofemoral lymphadenopathy is not seen. The resultant intra-abdominal or retroperitoneal lymphadenopathy may lead to symptoms of lower abdominal pain or low back pain. Constitutional symptoms, such as low-grade fever, chills, malaise, myalgias and arthralgias, may present during the second stage of disease. A rare presentation is the pharyngeal syndrome affecting the mouth and throat. Cervical lymphadenopathy and buboes can occur.

The third stage of disease in LGV is often called the "anogenitorectal syndrome" and is more

Fig. 57.4 Late-stage inguinal lymphogranuloma venereum (LGV) with fistulae (From Dr. R. Hu, Dermatological Service, Paramaribo, Suriname)

often present in women. Patients initially develop proctocolitis followed by perirectal abscess, fistulas, strictures and stenosis of the rectum, possibly leading to "lymphorrhoids" (haemorrhoid-like swellings of obstructed rectal lymphatic tissue). Without treatment, chronic progressive lymphangitis leads to chronic oedema and sclerosing fibrosis, resulting in strictures and fistulas of the involved region, which can ultimately lead to elephantiasis, esthiomene (the chronic ulcerative disease of the external female genitalia) and the frozen pelvis syndrome. If left untreated, LGV proctitis can lead to rectal strictures, with subsequent sequelae of soiling, pain, constipation and the possible development of megacolon.

Differential Diagnosis

LGV proctitis can mimic chronic inflammatory bowel diseases like Crohn's disease, both clinically and in the pathological substrate. It is therefore often misdiagnosed by gastroenterologists confronted with MSM presenting with proctitis symptoms. The clinical and histologic picture of early LGV proctocolitis is similar to that seen in inflammatory bowel disease and LGV proctitis has been mistaken for Crohn's disease. This has led to delay in the correct diagnosis and suboptimal treatment.

Since LGV is characterised by a diversity of presentations (depending on the inoculation site and the different stages of disease evolution), it is extremely difficult to establish a definitive diagnosis by clinical examination alone. As a result, it can be a challenge to differentiate LGV from other dermatological and sexually transmitted diseases (Table 57.2).

The clinician often misses the primary inoculation site. If present, it may simulate genital herpes, primary syphilis, chancroid or traumatic ulceration and bacterial, candidal or traumatic balanoposthitis. A mucopurulent urethritis noted in a few instances of LGV is often mistaken for non-specific urethritis or gonorrhoea.

Table 57.2 Differential diagnosis of lymphogranuloma venereum (adapted from de Vries et al. 2012)

Primary stage
Genital herpes
Primary syphilis
Chancroid
Granuloma inguinale
Traumatic ulcer
Secondary stage (inguinal syndrome)
Chancroid
Syphilis
Genital herpes
Plague
Tularaemia
Tuberculosis
Cat-scratch disease
Septic lymphadenitis
Hodgkin's disease
Incarcerated inguinal hernia
Psoas abscess
Tertiary stage
Genital elephantiasis
Filariasis
Tuberculosis
Fungal infection
Parasitic infection
Toxaemia of pregnancy
Anorectal syndrome
Inflammatory bowel disease (esp. Crohn's disease)
Rectal stricture
Malignancy
Trauma
Actinomycosis
Tuberculosis
Schistosomiasis

The second stage of LGV manifests as regional lymphadenitis and perilymphangitis with bubo formation and is often confused with buboes caused by chancroid, syphilis, genital herpes, plague, tularaemia, tuberculous lymphadenitis, cat-scratch disease, septic lymphadenitis, Hodgkin's disease, incarcerated inguinal hernia or psoas abscess.

In the tertiary stage, genital elephantiasis may mimic filariasis, tuberculosis, fungal or parasitic infection, granuloma inguinale (pseudo-elephantiasis) or transient vulvar elephantiasis with toxaemia of pregnancy. The rectal strictures of LGV may resemble those caused by trauma, actinomycosis, tuberculosis, schistosomiasis or adenocarcinoma of the rectum.

General Principles of Treatment

Systemic antibiotic therapy is the cornerstone in the treatment of LGV infection. Despite a paucity of robust evidence regarding the efficacy of therapy for any rectal chlamydial infections (LGV or non-LGV), 3 weeks of oral doxycycline 100 mg twice daily to treat LGV is recommended (Centers for Disease Control and Prevention (CDC) 2004; Clinical Effectiveness Group of the British Association for Sexual Health and HIV (CEG/BASHH) 2006; Workowski et al. 2010). Doxycycline is contraindicated in pregnancy and breastfeeding.

Early and prompt treatment is essential to prevent ongoing transmission, serious complications and mutilating sequelae. The low incidence of the disease, its complex presentation and the natural history marked by spontaneous remissions and exacerbations have precluded any rigorous evaluation of management. Nevertheless, sporadic trials in the treatment of LGV have shown successful use of tetracyclines (especially doxycycline) and erythromycin. Early and prompt antibiotic treatment shortens the duration of buboes, ulcers, sinuses and rectal discharges. Prolonged treatment (at least for 3 weeks) is the norm and more than one course of therapy or alternating some of the antibiotics may be necessary for chronic cases. The vast majority of recent MSM case reports have observed complete responses to 3-week doxycycline therapy; shorter courses may not eradicate the organism. It has been shown that L biovar *C. trachomatis* RNA can persist for up to 16 days in LGV proctitis patients treated with doxycycline.

The following antibiotic chemotherapy recommendations have been made for uncomplicated LGV infections:

- Doxycycline, 100 mg orally b.i.d. × 21 days, or erythromycin, 500 mg orally q.i.d. × 21 days, or azithromycin, 1 g orally once weekly × 21 days (Workowski et al. 2010).
- Doxycycline, 100 mg orally b.i.d. × 14 days, or erythromycin, 500 mg orally, q.i.d. × 14 days, or tetracycline, 500 mg orally, q.i.d. × 14 days, or sulphadiazine, 1 g orally q.i.d. × 14 days (WHO 2003).
- For pregnant and lactating women or children below 8 years, erythromycin stearate is

prescribed (Banor et al. 1953). In children, the dose is 7.5–12.5 mg/kg/dose q.i.d. for 14 days.

Other mentioned antibiotic modalities which have been successfully used in treating acute bubonic LGV and LGV proctocolitis are minocycline, 300 mg orally initially, followed by 200 mg b.i.d. for 10 days. Azithromycin regimens have been suggested but the dosage and duration of therapy are not known.

Surgical Treatment

Fluctuant buboes are aspirated through the surrounding unaffected skin with a wide-bore needle and not incised. Perianal and perirectal abscesses must be surgically drained. Rectal strictures are dilated either manually or with elastic bougies at weekly intervals. When the stricture is impassable, a preparatory ileocolostomy followed by proctocolectomy is a justifiable procedure. Chronic intractable ulcerative lesions of the rectum may be treated by suitable single-stage surgical procedures, such as full skin cover by direct flaps, myocutaneous flaps or sliding flaps (floating island). A urethral stricture can be dilated with Lister's or Clutton's bougies.

The chronic manifestations of tertiary LGV such as rectovaginal fistulae, genital elephantiasis, vulvar growths, esthiomene or rectal strictures and stenosis do not respond to antibiotic therapy and require surgical intervention and plastic reconstruction. Polypoid excrescences of the vulva, pedunculated tumours or elephantiasic vulvae require local excision and partial or total vulvectomy.

Management of Patients with Proctitis

It is recommended to screen all MSM who report receptive anal sexual practices in the previous 6 months for anorectal *C. trachomatis* infection with a commercially available nucleic acid amplification test (NAAT). Subsequently, MSM with anorectal *C. trachomatis* infection are then screened for LGV proctitis using a genovar L-specific "in house" developed NAAT. In the recent MSM LGV epidemic, incident cases of both HIV and hepatitis C have been observed, and serological testing should be offered for both infections after appropriate window periods have elapsed according to relevant local guidelines. The prevalence of HIV among LGV cases ranges from 67 to 100 % in 13 descriptive studies (Rönn and Ward 2011). Tests for STI, including HIV (if not already known HIV positive), hepatitis B and hepatitis C should be offered before starting therapy.

Given the high incidence of STIs in MSM with proctitis complaints, the CDC recommends presumptive therapy in MSM with a high index of suspicion (Workowski et al. 2010) rather than waiting for positive cultures that can take more than a week to return (Box 57.1). Delay in treatment can lead to potential complications and "lost to follow-up" infections.

Box 57.1. Proctitis Syndromic Treatment Guidelines for High-Risk Individuals with Anal Complaints (Adapted from de Vries et al. 2013)

Syndromic treatment of a symptomatic proctitis or confirmed non-LGV *C. trachomatis* proctitis:

- Doxycycline 100 mg p.o., 2d.d. 7 days

Syndromic treatment of a suspected *N. gonorrhoea* proctitis (e.g. based on Gram-negative intracellular diplococci) or confirmed *N. gonorrhoea* proctitis:

- Ceftriaxone 500 mg i.m. single dose

PLUS

- Doxycycline 100 mg p.o., 2d.d. for 7 days

Syndromic treatment of LGV proctitis or confirmed LGV proctitis:

- Doxycycline 100 mg p.o., 2d.d. for 21 days

OR

- Erythromycin 500 mg p.o., 4d.d. for 21 days

Follow-Up

Patients are followed up clinically until signs and symptoms resolve. This may occur within 3–6 weeks. All patients diagnosed with LGV should be followed up at the end of treatment, to ensure resolution of symptoms and signs of infection, to check that adequate partner notification has been completed, to address any patient concerns and to arrange suitable follow-up testing for syphilis and blood-borne viruses including hepatitis B and C and HIV.

Doxycycline failure in LGV has been reported in 3 out of 75 treated patients (Rodríguez-Domínguez et al. 2014). If the recommended 21-day course of doxycycline is completed, a test of cure for LGV seems indicated only in those with persistent complaints. It should be noted that doxycycline can also cause gastrointestinal symptoms like mucous discharge and diarrhoea. A routine microbiological test of cure is usually not done.

Partner Management

It is essential that sex partner notification be initiated when the diagnosis is made. Partners who have had sexual contact with an LGV patient, should be promptly treated for LGV according to the above-mentioned therapy advice. STI testing should be offered to all sexual contacts within the last 3 months (or in case of symptomatic patients within 30 days before the onset of the patient's symptoms). Moreover, empiric antibiotic therapy should be recommended to partners, until STI has been excluded in the partner.

Prevention

Patients diagnosed with LGV should be counselled regarding prevention of other STIs including HIV and hepatitis C. Moreover, regular sexual health screening including HIV testing should be offered, condom use should be demonstrated and promoted, hepatitis A and B vaccination for MSM offered, and patients at risk of HIV infection should be advised of the availability of post-exposure prophylaxis for HIV. In particular, HIV-positive MSM should be made aware of recent trends in hepatitis C epidemiology and warned of the risks of unprotected anal sex, serosorting, recreational drug use and mucosally traumatic sexual practices such as fisting. Enema use prior to receptive anal sex should be discouraged since it is associated with rectal chlamydial infections and especially LGV proctitis. Although sharing of equipment was rare, it is prudent to advise against sharing any such equipment and to wash equipment thoroughly after use.

Sexual contacts must be traced and promptly treated. Patients on antibiotic therapy should be monitored for recurring symptoms over a period of 6 months following antibiotic treatment. Doctors and other health care workers must observe proper safeguards such as wearing gloves when touching infected sites or handling soiled dressings or other contaminated items. Health-seeking behaviour and health education of those at risk should be encouraged.

Future Perspectives

In the ongoing LGV epidemic, there is a need for better and cheaper screening tools to detect cases in larger groups of individuals at risk. This is of importance to prevent complications in the individual patient and to halt transmission in the community. Physicians should consider LGV in case MSM present with inguinal lymphadenopathy, genital ulceration or proctitis complaints. If chronic inflammatory bowel syndromes like Crohn's disease are considered, especially in MSM, LGV proctitis should always be excluded. Shorter antibiotic courses than the present ones of 21 days are needed to increase patient compliance to the treatment but require large controlled clinical trials. Lastly, a deeper understanding of the microbial and immunological background of LGV infection in relation to HIV could shed light on the considerable number of asymptomatic LGV cases found.

Primary Cutaneous Lymphomas

58

Wolfgang Bauer and Robert Knobler

Abbreviations

CR	Complete response
EORTC	European Organisation for Research and Treatment of Cancer
ISCL	International Society for Cutaneous Lymphomas
OR	Overall response
ORR	Overall response rate
R-CHOP	Rituximab cyclophosphamide, hydroxydaunorubicin, vincristine, prednisolone
R-COP	Rituximab cyclophosphamide, vincristine, prednisolone
TCR	T-cell receptor gene rearrangement

Key Points

- Primary cutaneous lymphomas are most often T-cell lymphomas.
- Most of these lymphomas have an indolent clinical course.
- The most common cutaneous lymphoma is mycosis fungoides.
- Up to now no curative treatment is available.
- Apart from the rare cases with aggressive clinical behavior, therapy should follow the principle of primum nil nocere.

Definition and Epidemiology

Lymphoid neoplasms can affect the skin either secondarily as manifestations of disseminated nodal lymphomas or primarily without evidence of further organ involvement at the time of diagnosis. This chapter will only deal with the latter. The skin is the second most common site of manifestation of extranodal non-Hodgkin's lymphomas (NHL, after the gastrointestinal tract), with an estimated incidence of approximately 1:100,000 inhabitants per year. The distinction between primary cutaneous and disseminated nodal NHL is obligatory due to the specific cellular pathobiology of these lymphomas, their clinical course, resulting treatment options, and prognosis.

Primary cutaneous T- and B-cell lymphomas (CTCL and CBCL) are classified based on clinical, histological, immunohistochemical, and molecular features (Table 58.1). Accordingly, treatment options vary between different types of cutaneous lymphomas and will be discussed separately.

Table 58.1 WHO-EORTC classification of cutaneous lymphomas (2005)

Cutaneous T-cell and NK-cell lymphomas
Mycosis fungoides (MF)
MF variants and subtypes
Folliculotropic MF
Pagetoid reticulosis
Granulomatous slack skin
Sézary syndrome (SS)
Adult T-cell leukemia/lymphoma
Primary cutaneous CD30+ lymphoproliferative disorders
Primary cutaneous anaplastic large-cell lymphoma (PCALCL)
Lymphomatoid papulosis (LyP)
Subcutaneous panniculitis-like T-cell lymphoma
Extranodal NK/T-cell lymphoma, nasal type
Primary cutaneous peripheral T-cell lymphoma, unspecified
Primary cutaneous aggressive epidermotropic CD8+ T-cell lymphoma (provisional)
Cutaneous γδ T-cell lymphoma (provisional)
Primary cutaneous CD4+ small-/medium-sized pleomorphic T-cell lymphoma (provisional)
Cutaneous B-cell lymphomas
Primary cutaneous marginal zone B-cell lymphoma
Primary cutaneous follicle center lymphoma
Primary cutaneous diffuse large B-cell lymphoma, leg type
Primary cutaneous diffuse large B-cell lymphoma, other
Intravascular large B-cell lymphoma
Precursor hematologic neoplasm
CD4+/CD56+ hematodermic neoplasm (blastic NK-cell lymphoma)

Relative frequencies and survival of the different entities are depicted in Table 58.2. Mycosis fungoides (MF) and its variants represent the most common cutaneous lymphoma with an indolent course, whereas Sézary syndrome is the most common aggressive CTCL.

Diagnosis and Staging of Cutaneous Lymphomas

A skin biopsy (if necessary multiple biopsies) with histological analysis and immunophenotyping forms the basis of the diagnosis. A complete

Table 58.2 Relative frequencies and disease-specific 5-year survival of primary cutaneous lymphomas (Trautinger 2011)

WHO-EORTC classification	Frequency (%)	Disease-specific 5-year survival (%)
Cutaneous T-cell lymphomas		
Indolent clinical behavior		
Mycosis fungoides (MF)	44	88
Folliculotropic MF	4	80
Pagetoid reticulosis	<1	100
Granulomatous slack skin	<1	100
Primary cutaneous anaplastic large-cell lymphoma (PCALCL)	8	95
Lymphomatoid papulosis (LyP)	12	100
Subcutaneous panniculitis-like T-cell lymphoma	1	82
Primary cutaneous $CD4^+$ small-/medium-sized pleomorphic T-cell lymphoma	2	75
Aggressive clinical behavior		
Sézary syndrome (SS)	3	24
Extranodal NK-/T-cell lymphoma, nasal type	<1	NR
Primary cutaneous aggressive epidermotropic $CD8^+$ T-cell lymphoma	<1	18
Cutaneous γδ T-cell lymphoma	<1	NR
Primary cutaneous peripheral T-cell lymphoma, unspecified	2	16

Primary cutaneous diffuse large B-cell lymphoma, other	<1	50
Intravascular large B-cell lymphoma	<1	65

physical examination including inspection of the entire skin and palpation of all lymph nodes together with the identification of any organomegaly should be performed. Imaging studies and laboratory analysis of blood, enlarged lymph nodes, and/or bone marrow biopsy should be performed according to the type of lymphoma and for accurate staging.

For staging of cutaneous lymphomas, the TNM classification as suggested by the ISCL-EORTC (2007) should be used. MF and Sézary syndrome share a distinct staging system which also has some prognostic relevance (Tables 58.3 and 58.4), in contrast to all other forms of cutaneous lymphomas (Table 58.5). More details on diagnosis and staging examinations are provided in the discussion of the specific entities.

Table 58.3 ISCL/EORTC revised classification of MF and Sézary syndrome (ISCL/EORTC 2007)

TNMB stages	
T: skin	
T1	Patches, papules, plaques <10 % of skin surface
	T1a: patches only
	T1b: plaque ± patch
T2	Patches, papules, plaques >10 % of skin surface
	T2a: patches only
	T2b: plaque ± patch
T3	One or more tumors (≥1 cm)
T4	Confluence of erythema ≥80 % body surface area
N: lymph nodes	
N0	No clinically abnormal peripheral lymph nodes
N1	Clinically abnormal peripheral nodes: histopathology NCI LN0-2
	N1a: clone negative
	N1b: clone positive
N2	Clinically abnormal peripheral lymph nodes: histopathology NCI LN3
	N2a: clone negative
	N2b: clone positive
N3	Clinically abnormal peripheral lymph nodes: histopathology NCI LN4; clone positive or negative
NX	Clinically abnormal peripheral lymph nodes: no histological confirmation
M: visceral organs	
M0	No visceral organ involvement
M1	Visceral involvement (must have pathology confirmation)
B: blood	
B0	Absence of significant blood involvement: ≤5 % atypical lymphocytes
	B0a: clone negative
	B0b: clone positive
B1	Low blood tumor burden: ≥5 % atypical lymphocytes
	B1a: clone negative
	B2b: clone positive
B2	High blood tumor burden: ≥1,000/μl atypical cells with positive clone

Clinical Endpoints in Evaluating Response to Treatment

To determine the response of a patient to any given therapy, it is desirable to follow objective criteria. Up to the present, unfortunately these have only been clearly defined for MF and Sézary syndrome. They take into account the response in the skin (modified severity-weighted assessment tool, mSWAT), lymph nodes, viscera, and blood. These individual factors are used to define a global response score (complete remission, partial remission, stable disease, progressive disease). In assessing response to treatment in other forms of cutaneous lymphomas, it is advisable to follow the same basic principles.

General Principles of Treatment

Treatment strategies have to consider the precise diagnosis, tumor stage, and preceding treatments. Due to the chronic course of many of the most common types of cutaneous lymphomas, a general principle is to choose a therapeutic regimen with the least associated toxicity. In case of indolent and early-stage cutaneous lymphomas, therapy directed only against the manifestation on the skin is often sufficient to manage and control the disease. In more advanced stages, systemic therapies complement topical ones.

Table 58.4 TNM staging of MF and Sézary syndrome (ISCL/EORTC 2007)

	T	N	M	B	
IA	1	0	0	0, 1	Early stage
IB	2	0	0	0, 1	
IIA	1, 2	1, 2	0	0, 1	
IIB	3	0–2	0	0, 1	Advanced stage
IIIA	4	0–2	0	0	
IIIB	4	0–2	0	1	
IVA_1	1–4	0–2	0	2

Table 58.5 TNM classification system for primary cutaneous lymphomas other than MF and Sézary syndrome (ISCL/EORTC 2007)

T: skin	
T1	Solitary skin involvement
	T1a: solitary lesion <5 cm diameter
	T1b: solitary lesion >5 cm diameter
T2	Regional skin involvement: multiple lesions limited to 1 body region or 2 contiguous body regions
	T2a: all-disease-encompassing in <15 cm diameter circular area
	T2b: all-disease-encompassing in >15 and <30 cm diameter circular area
	T2c: all-disease-encompassing in >30 cm diameter circular area
T3	Generalized skin involvement
	T3a: multiple lesions involving 2 noncontiguous body regions
	T3b: multiple lesions involving ≥3 body regions
N: lymph nodes	
N0	No clinical or pathological lymph node involvement
N1	Involvement of 1 peripheral lymph node region that drains an area of current or prior skin involvement
N2	Involvement of 2 or more peripheral lymph node regions or involvement of any lymph node region that does not drain an area of current or prior skin involvement
N3	Involvement of central lymph nodes
M: visceral organs	
M0	No evidence of extracutaneous non-lymph node disease
M1	Extracutaneous non-lymph node disease present

It is emphasized that whenever possible, patients with cutaneous lymphomas should be treated in specialized centers allowing access to best clinical practice and new therapeutic options in clinical trials.

In the following we will discuss the most common variants of cutaneous lymphomas.

Treatments of CTCL

Mycosis Fungoides (MF)

MF is the most common variant of cutaneous T-cell lymphoma and typically affects older adults. In most cases it is an indolent lymphoma slowly evolving from patches to plaques and finally tumors on the skin (Fig. 58.1). In late stages lymph nodes and visceral organs can be involved.

Histopathologically the lesions are characterized by infiltrating atypical epidermotropic $CD4^+$ T cells, which might show a characteristic loss of certain pan T-cell surface molecules (CD2, CD5). Rare cases of $CD8^+$ $CD4^-$ lymphomas are described and do not show a different clinical course. A transformation to a diffuse large-cell lymphoma (CD30 positive or negative) might occur and is associated with a worse prognosis.

Among the many variants, it is important to highlight folliculotropic MF, pagetoid reticulosis, and granulomatous slack skin due to their distinct clinicopathological manifestation. In folliculotropic MF, atypical lymphocytes infiltrate the hair follicles and lead to mucinous degeneration of the follicles and hence alopecia especially in the head and neck area. This manifestation is associated with a worse prognosis than classical MF. In pagetoid reticulosis, localized neoplastic T cells proliferate exclusively intraepidermally. In granulomatous slack skin, circumscribed areas of lax skin develop due to a granulomatous infiltrate of neoplastic T cells admixed with macrophages and giant cells, which lead to a destruction of elastic fibers. It shows a predilection of axillae and groins. The latter two variants of MF are not associated with a different clinical prognosis than classical MF.

Fig. 58.1 Patient with mycosis fungoides stage IIB disease showing patches, plaques, and tumors

Diagnosis and staging of MF are outlined above (see also Table 58.3). In addition, the determination of TCR gene rearrangement from skin samples can be helpful in corroborating the diagnosis. A complete blood cell count with manual differential, LDH, liver function tests, the analysis for abnormal lymphocytes (ideally by flow cytometry together with manual count of abnormal lymphocytes), and molecular identification of T-cell clones in the blood should be performed.

Therapy

Up to the present, mycosis fungoides is still considered an incurable disease. Nevertheless patients with early-stage disease can survive for a considerable long period of time (see also Table 58.2), and the outcome is not generally altered by use of early aggressive therapy. Indeed, patients with stage IA disease have a near-normal life expectancy; it is therefore considered legitimate to follow a "watch-and-wait" strategy treating only large or cosmetically annoying lesions, provided a careful monitoring of the disease is maintained.

In general, early-stage MF (IA–IIA) is thus treated with skin-directed therapies (Table 58.6) including topical steroids, PUVA (psoralen + UVA), and topical cytotoxic agents. UVB-311 nm should only be used in patients with patches. PUVA is usually administered two to four times per week until skin lesions have cleared. OR is very high reaching up to 95 %; CR can be achieved in approximately 58–83 % depending on the tumor stage.

Radiotherapy is very effective for thicker plaques, and patients with early localized disease or pagetoid reticulosis might even remain disease-free for very long times. In refractory patients second-line options include retinoids (bexarotene, acitretin), interferon (IFN)-α (alpha), low-dose methotrexate (up to 25 mg/week), or combinations of PUVA and IFN-α (alpha) or bexarotene.

Bexarotene is still the only retinoid exclusively available for the treatment of cutaneous lymphomas. In contrast to other retinoids, it was developed to bind specifically to the retinoid X receptors, thereby mediating effects on cell differentiation and apoptosis. It is approved in Europe for the treatment of advanced-stage CTCL in adult patients refractory to at least one systemic treatment. The usual daily dosage is 300 mg/m^2 and treatment can be continued indefinitely provided clinical response. Reported ORR is up to 45 %. The most common side effects are hypertriglyceridemia, hypercholesterolemia, and central hypothyroidism requiring careful

Table 58.6 Treatment recommendations for MF and Sézary syndrome

Stage	First line	Second line
Early stage	Watch and wait	Oral retinoid (bexarotene, acitretin)
	Topical steroids	IFN-α
	PUVA	Low-dose MTX
	UVB-311 nm (only for patches)	PUVA + IFN-α
	Local radiotherapy (≥30 Gy)	PUVA + bexarotene
	Topical NH2	TSEB
	Topical BCNU	Novel agents (clinical trials)
Late stage		
Tumor stage (IIB)	Radiotherapy	Bexarotene
	PUVA ± IFN-α	HDAC inhibitors
	PUVA ± retinoid	Denileukin diftitox
	Retinoid + IFN-α	Gemcitabine
	TSEB	Doxorubicin
Stage III–IV + Sézary syndrome	ECP	Bexarotene
	IFN-α	MTX
	PUVA + IFN-α	Denileukin diftitox
		HDAC inhibitors
		Alemtuzumab
		Chemotherapy: cladribine, fludarabine, cyclophosphamide CHOP-polychemotherapy
		Allogeneic stem cell transplantation

NH2 nitrogen mustard, *BCNU* carmustine, *MTX* methotrexate, *TSEB* total skin electron beam therapy, *HDAC* histone deacetylase inhibitors, *ECP* extracorporeal photopheresis

monitoring, treatment with lipid-lowering agents (gemfibrozil is contraindicated) and thyroid hormone, and dose modification in individual cases.

OR of IFN-α (alpha) monotherapy is reported to be 70 % with CR seen in up to 35 % of patients. Efficacy has been demonstrated regardless of tumor stage but is higher in early stages. Generally, three million units of IFN-α (alpha) three times a week are recommended; higher doses do not necessarily seem to provide an additional effect. The most common side effects of this treatment include fatigue, flu-like symptoms, and leukopenia, requiring careful monitoring. The combination treatment of IFN-α (alpha) with retinoids is regarded inferior to the combination with PUVA.

Total skin electron beam therapy is an excellent option for widespread disease or for patients no longer responding to other skin-directed therapies.

Patients developing one or a low number of tumors (stage IIB) also profit from local radiotherapy. PUVA in combination with retinoids or IFN-α (alpha), denileukin diftitox, and an HDAC inhibitor (histone deacetylase inhibitor) are all considered before treating these patients with systemic chemotherapy.

Treatment of patients with stage III–IV disease follows the same principles as in Sézary syndrome. Erythrodermic patients with B0–B1 blood involvement in particular seem to profit from extracorporeal photopheresis (ECP). In this apheresis-based treatment, leukocytes are separated from the rest of a patient's blood, exposed to 8-methoxypsoralen, irradiated with UVA, and then returned to the patient. Treatment is usually very well tolerated with only very few patients experiencing mild transient hypotension or mild anemia/thrombocytopenia. Initial treatment is performed every 2–4 weeks; subsequently treatment intervals can be extended to once every 4–8 weeks. Response to treatment can occur late and it is recommended to treat for at least 6 months for final evaluation of a response. OR

Fig. 58.2 Erythrodermic patient with Sézary syndrome

varies and has been observed in up to 80 %, CR in up to 30 % of patients (Table 58.6).

Single- or multiagent chemotherapy is only indicated in patients with massive lymph node (N3) or visceral involvement. Many different regimens have been tried; unfortunately response duration is most often very short. For single-agent treatment, gemcitabine and pegylated liposomal doxorubicin have resulted in OR of up to 75 and 88 %, respectively. Multiagent regimens are often based on cyclophosphamide, doxorubicin, vincristine, and prednisone and have shown similar response rates.

It should be mentioned that data on maintenance therapies in CTCL are lacking. Due to great experience and relative good long-term safety, oral retinoids, IFN-α (alpha), and ECP are excellent candidates for such a treatment modality. In fact patients responding to initial treatment with ECP are recommended to continue treatment with progressive extension of treatment intervals up to 8 weeks.

Sézary Syndrome (SS)

Although rare, SS is the most common variant of an aggressive CTCL with an estimated 5-year survival rate of about 24 % and a median survival between 2 and 4 years. It is characterized by the triad of erythroderma (Fig. 58.2), lymphadenopathy, and atypical tumor cells in peripheral blood. These cells have enlarged and indented nuclei (cerebriform) and can either be identified morphologically or by flow cytometry. They are usually $CD3^+4^+$ T cells that can show loss of markers such as CD2, CD3, CD4, CD7, or CD26 and lead to a shift in the CD4/CD8 ratio (required for diagnosis $\geq$10). The determination of a clonal TCR gene rearrangement in peripheral blood is another prerequisite for the diagnosis.

Specific histologic changes in the skin can be similar to those observed in MF but are missing in up to one third of all cases. Staging examinations are the same as in MF.

Therapy

Since Sézary syndrome is a systemic disease by definition, skin-directed therapies are not sufficient for the treatment. Topical steroids or PUVA can nevertheless be useful in alleviating erythroderma and pruritus. Extracorporeal photopheresis (ECP) plays an important role as a first-line therapy with a reported overall response rate of 30–80 % although response to treatment may take up to 6 months. It can be used alone or in combination with other systemic agents including IFN-α (alpha) or bexarotene. Alternatively PUVA in combination with bexarotene and/or IFN-α (alpha) is recommended. Second-line therapies include prolonged treatment with low-dose chlorambucil and systemic steroids, low-dose methotrexate, denileukin diftitox, HDAC inhibitors, TSEB, and alemtuzumab. In younger patients, bone marrow transplantation or conventional chemotherapy (e.g., single-agent chemotherapy with gemcitabine, fludarabine, cladribine, or pentostatin) can be considered.

Primary Cutaneous CD30+ Lymphoproliferative Disorders

These are the second most common types of CTCL and encompass two main diseases: lymphomatoid papulosis (LyP) and primary cutaneous anaplastic large-cell lymphoma (PCALCL). These tumors are histologically characterized by large pleomorphic and anaplastic tumor cells that share the expression of CD30 and have a very good prognosis in common. LyP and PCALCL are believed to represent two ends of a spectrum of diseases. Histology alone might not be sufficient for the diagnosis in some cases so that the clinical course decides about definitive diagnosis and choice of treatment. Treatment recommendations are summarized in Table 58.7.

Lymphomatoid Papulosis (LyP)

Chronic recurrent eruptions of self-healing papules and nodules with histological features of cutaneous lymphoma characterize this disease. Although LyP does not present a risk to survival itself, it is associated with other cutaneous or nodal lymphomas (MF, ALCL, M. Hodgkin) in up to 25 % of cases. This aspect has to be given special attention during follow-up of patients.

Due to the intrinsic benign nature of this disease, the main concept to follow when treating patients should be primum non nocere.

None of the reported therapies for LyP has been shown to alter the course of the disease or prevent secondary lymphomas. Therefore a watch-and-wait strategy is a possible first-line approach. PUVA and low-dose methotrexate (5–25 mg/week) show very good response rates, but after cessation of therapy, relapses occur fast and frequently. Hence maintenance therapy is sometimes needed. In these cases special care should be given to limit side effects including risk for nonmelanoma skin cancer or liver fibrosis. Very large and persisting lesions can be removed surgically or irradiated; however, non-regressing lesions should be monitored for progression to PCALCL.

Cutaneous Anaplastic Large-Cell Lymphoma (PCALCL)

PCALCL presents with solitary or localized, rarely multifocal rapidly growing, and ulcerating nodules and tumors. As in LyP, the skin lesions can show partial or complete regression in up to 44 % of patients and frequently relapse. Extracutaneous manifestation can be observed in about 10 % of cases, mainly involving local lymph nodes.

First-line therapy in solitary or localized lesions is surgical excision or radiotherapy. Relapses occur in about 40 % of cases and need not be treated differently. Multifocal cutaneous lesions can be treated with low-dose methotrexate. In cases with extracutaneous dissemination or rapidly progressive cutaneous lesions, doxorubicin-based multiagent chemotherapy is indicated.

Table 58.7 Treatment recommendations for CD30+ lymphoproliferative diseases

	Solitary lesions	Multiple lesions	Extracutaneous spread
LyP			
	Observation	Observation	
	Phototherapy	Phototherapy	
	Topical steroids	Methotrexate	
		Topical steroids	
		Alternatives: retinoids, INF-α	
PCALCL			
	Excision	Methotrexate	Single-/multiagent chemotherapy
	Radiotherapy	Alternatives: retinoids, IFN-α	

Treatments of CBCL

The three main types of CBCL are primary cutaneous marginal zone B-cell lymphoma (PCMZL), primary cutaneous follicle center lymphoma (PCFCL), and primary cutaneous diffuse large B-cell lymphoma, leg type (PCLBCL, LT), which can be stratified according to their clinical behavior in indolent (PCMZL and PCFCL) and aggressive (PCLBCL, LT).

If a cutaneous B-cell lymphoma is clinically suspected, a representative biopsy, ideally an excisional biopsy, should be obtained. Diagnosis is based on histologic and immunohistologic factors; a detection of clonal IgH gene rearrangements based on the BIOMED-2 protocol can be helpful in selected cases. In addition to the general staging principles mentioned above, the following parameters should be obtained: serum electrophoresis, flow cytometry of peripheral blood, *Borrelia* serology and *Borrelia* PCR from tissue sections in endemic areas, and a bone marrow biopsy in cases of PCLBCL (optional for PCMZL and PCFCL, although in the latter the authors recommend a bone marrow biopsy because of prognostic relevance). Imaging studies should include a CT scan (with or without a positron emission tomography) of at least the chest, abdomen, and pelvis and extending to all other body areas affected.

Treatment recommendations according to EORTC and ISCL are summarized in Table 58.8.

Primary Cutaneous Marginal Zone B-Cell Lymphoma (PCMZL)

PCMZL presents with solitary or multiple papules, plaques, or nodules preferentially on the extremities. In endemic areas it can be associated with *Borrelia burgdorferi* infection. Only in rare cases the disease will spread to extracutaneous sites but recurrence on the skin happens frequently. Histopathologically dermal infiltrates composed of small B cells, including marginal zone cells, lymphoplasmacytoid cells, and plasma cells predominate.

Therapy

Patients with solitary or only a few scattered lesions can be treated with local radiotherapy or excision. Due to the indolent course, it is also possible to follow a wait-and-see strategy under close monitoring of the patient. In such cases only symptomatic skin lesions are treated.

When patients present with extensive skin lesions, chlorambucil is still a widely used option. Alternatively rituximab intralesionally or intravenously can be used. In cases that show an association with *B. burgdorferi* infection, intravenous application of cephalosporins might represent a treatment alternative.

Primary Cutaneous Follicle Center Lymphoma (PCFCL)

PCFCL typically manifests itself with solitary or grouped papules and nodules on the head or trunk. The cellular infiltrate is composed of neoplastic follicle center cells that show a follicular, follicular and diffuse, or diffuse infiltration of the dermis. In 5–10 % extracutaneous dissemination is observed. After preliminary successful therapy, cutaneous relapses occur in up to 20 % of all cases.

Therapy

Solitary or localized diseases are preferentially treated with radiotherapy ($\geq$30 Gy) whereby the radiation field is extended to include a safety margin of clinically uninvolved skin of at least 1.5 cm. Small lesions can also be removed surgically.

Analogous to PCMZL, a wait-and-see strategy with active treatment only of symptomatic lesions or radiotherapy can be considered for patients with few scattered lesions.

In the case of disseminated skin lesions, systemic rituximab is considered first-line therapy. Combination chemotherapy (R-COP, R-CHOP) should only be considered in patients with progressive disease or in patients developing extracutaneous disease. Special consideration should be given to patients developing PCFCL on the legs since these tumors seem to clinically behave like PCLBCL, LT and should therefore be treated accordingly.

Table 58.8 Treatment recommendations for CBCL (EORTC/ISCL 2008)

Disease type and extent	First-line therapy	Alternative therapies
PCMZL		
Solitary/localized	Local radiotherapy	IFN-α i.l.
	Excision	Rituximab i.l.
	Antibiotics[a]	i.l. steroids
Multifocal	Wait and see	IFN-α i.l.
	Local radiotherapy	Rituximab i.l.
	Chlorambucil	Topical or i.l. steroids
	Rituximab i.v.	
	Antibiotics[a]	
PCFCL		
Solitary/localized	Local radiotherapy	IFN-α i.l.
	Excision	Rituximab i.l.
Multifocal	Wait and see	R-CVP/CHOP[b]
	Local radiotherapy	
	Rituximab i.v.	
PCLBCL, LT		
Solitary/localized	R-CHOP ± IFRT	Local radiotherapy
		Rituximab i.v.
Multifocal	R-CHOP	Rituximab i.v.

IFRT involved field radiotherapy, *i.l.* intralesional, *i.v.* intravenous
[a]In case of *B. burgdorferi* infection
[b]For patients developing extracutaneous disease or exceptional cases

Primary Cutaneous Diffuse Large B-Cell Lymphoma, Leg Type (PCLBCL, LT)

PCLBCL, LT typically presents with tumors on the legs, rarely at other sites, in elderly patients. Histopathologically they are characterized by diffuse infiltrates predominated by centroblasts and immunoblasts. The disease frequently relapses on the skin and can present with extracutaneous dissemination, which explains the worse prognosis than seen in other CBCL.

Therapy

Because of the similar clinical behavior, this tumor should be treated like systemic DLBCL. R-CHOP with or without involved field radiotherapy is considered first-line therapy. In patients not able to tolerate the toxicities of systemic chemotherapy, radiotherapy alone with or without rituximab or rituximab only can be considered.

Alternative and Experimental Therapies in Cutaneous Lymphomas

Continuous strive for better treatment of patients with (cutaneous) lymphomas leads to constant development of new therapeutic options. Patients who fail to respond to recommended drugs should therefore always be evaluated for new agents in clinical trials. In the following we sum up some of the agents newly available or in clinical testing.

Mechlorethamine (Nitrogen Mustard, HN2)

Nitrogen mustard is a cytotoxic agent acting by alkylating DNA and the consecutive formation of interstrand cross-links. When applied topically to the skin, additional immunomodulatory effects might contribute to its effects. In the past, topical HN2 has been used with success for the treatment of early-stage MF; lack of availability has limited its use. Recently the FDA approved the first

commercially available preformulated mechlorethamine gel (Valchlor®, 0.016 % gel) for stage IA and IB MF in the USA, and hopes are that the European Medicines Agency will approve its use throughout Europe. It is usually applied once a day for several weeks until lesions are cleared, followed by a maintenance treatment once or twice a week for several months. Overall response rates are up to 83 % with complete responses seen in up to 50 % of all patients. The main side effects are hypersensitivity or toxic reactions; the risk of developing nonmelanoma skin cancers seems to be small when used as a monotherapy.

Topical Imiquimod

Preliminary reports have shown efficacy of topically applied imiquimod cream in patients with MF, but controlled studies are lacking.

Retinoids

Retinoids have been a mainstay in the treatment of CTCL. Tazarotene is a novel synthetic retinoid that is applied as a 0.1 % gel. Preliminary reports have shown some efficacy in early MF.

Pralatrexate

This new antifolate shows higher affinity for tumor cells than methotrexate and is the first drug approved specifically for the treatment of peripheral T-cell lymphomas. In a phase II study, response rate in CTCL was 45 %.

Histone Deacetylase Inhibitors (HDACi)

Vorinostat has been approved for the treatment of relapsed, refractory CTCL in the USA but not in Europe. This has encouraged research in other HDACi like romidepsin, panobinostat, or belinostat.

Lenalidomide

Lenalidomide is an immunomodulatory drug derived from thalidomide in order to reduce known side effects such as peripheral polyneuropathy. It is used successfully in the treatment of multiple myeloma but also in many other NHLs and in Hodgkin's disease. It has been shown to be effective in refractory CTCL with an ORR of 28 % and, pending confirming studies, could become an option for maintenance therapy.

Monoclonal Antibodies

Alemtuzumab (anti-CD52 antibody) has been used in refractory cases of CTCL with ORR of up to 40 %. Nevertheless its use is limited by considerable immunosuppression. Experimental results have explained better response rates in Sézary syndrome than in MF. Its availability for this indication is questionable.

Zanolimumab (anti-CD4 antibody) has shown promising results in phase II studies and is evaluated in combination treatments.

Brentuximab vedotin is an anti-CD30 antibody coupled to the antimitotic agent monomethyl auristatin E (MMAE). It is approved for the treatment of relapsed or refractory Hodgkin's lymphoma and relapsed or refractory systemic anaplastic large-cell lymphoma. Hopes are high that this drug might be a future therapeutic option in patients with $CD30^+$ CTCL.

Another antibody-drug conjugate is ibritumomab tiuxetan, in which an anti-CD20 antibody is coupled via a chelator to yttrium-90 or indium-111. This drug is approved for the treatment of refractory or relapsed follicular lymphoma and might present a future treatment option in CBCL.

Other emergent monoclonal antibodies include new CD20 antibodies like ofatumumab, the anti-CD23 antibody lumiliximab, or the anti-CD40 antibody dacetuzumab for the treatment of PCLBCL.

Allogeneic Stem Cell Transplantation

In young patients with advanced MF or Sézary syndrome, with poor projected survival and multiple prior therapies, allogeneic stem cell transplantation might represent a future treatment option. In studies performed so far, it was possible to achieve a long-term disease control in 50–70 % of treated patients.

Conclusion

In the last decade, the field of cutaneous lymphomas has experienced significant advances associated with a better understanding of lymphocyte and lymphoma biology. The new combined WHO-EORTC classification has

paved the way for new diagnostic, staging, and therapeutic guidelines for most of the individual lymphoma subtypes and, even more, defined for the first time clinical endpoints and response criteria (MF and Sézary syndrome). This should lead to a standardization of future clinical trials and thereby to an improvement of treatment options in diseases that for the most part show an indolent clinical course but are not curable at present.

Mastocytosis

59

Arnold P. Oranje and Dirk Van Gysel

Definition

Mastocytosis is a disease of mast cells, as stated by the European Competence Network of Mastocytosis (ECNM), based on monoclonal proliferation – at least – in adults. The disease is generally characterized by the presence of abnormally dense infiltrations of mast cells in the dermis or other organs. Mastocytosis belongs to the Orphan diseases and is listed as such in the Orphanet database (Table 59.1) (Figs. 59.1 and 59.2).

History

Mastocytosis was first described by Nettleship and Tay as a "Rare form of Urticaria" in the British Medical Journal in 1869. The name mastocytosis was proposed in 1939. Recently, the knowledge on mastocytosis as Orphan disease has increased dramatically. The first consensus classification was proposed by Metcalfe in 1991. Many cellular, molecular and biochemical defects in mastocytosis were elucidated later and mastocytosis is currently considered as monoclonal (= neoplastic) in nature, although some think that the disease in childhood may be reactive. In 2001 and later in 2007, the WHO defined the criteria and the classification of mastocytosis (Valent 2006). Mastocytosis as such is defined as

Table 59.1 Mastocytosis clinical presentations and therapy – modalities based on symptomatology

Mastocytoma	Therapy usually not necessary
	Reassurance
	Sometimes corticosteroid (moderate potent) under occlusion/wet-wrap dressing
Cutaneous mastocytosis (CM)	Therapy usually not necessary
	Oral antihistamines, oral sodium cromoglycate
Bullous mastocytosis	Especially in first two years of life (CM and DCM); symptomatic therapy, in severe cases metabolic dysregulation making intensive care necessary
Diffuse cutaneous mastocytosis (DCM)	See bullous mastocytosis, in rare cases experimental therapy
Telangiectasia macularis perstans	Probably does not exist but is residual cutaneous mastocytosis. Therapy indicated for telangiectasia and will consist of pulse dye laser

Fig. 59.2 Positive sign of Darier in mastocytoma

a clonal haematopoietic disease. Recently, Hartmann proposed another classification (see later) and Escribano underlined that the WHO classification cannot be used in children because often a bone marrow examination is not performed.

Classification and Epidemiology

Mastocytosis covers a wide spectrum of proliferative mast cell diseases. The disease is a primary abnormal proliferative accumulation of mast cells.

Mast cell infiltrates occur almost primarily in the skin but may be present anywhere in the body. In particular, as a second organ, the bones may be involved.

The most accepted classification dates from 2007 (WHO classification) and is as follows:

1. Cutaneous mastocytosis (common in children)
2. Indolent systemic mastocytosis (also in children)
3. Systemic mastocytosis (with an AHNMD)
4. Aggressive systemic disease
5. Mast cell leukaemia (MCL)
6. Mast cell sarcoma
7. Extracutaneous mastocytoma

Recently, proposed: Polymorph and monomorph cutaneous mastocytosis, mastocytoma and systemic mastocytosis. Rogier Heide and Arnold Oranje earlier proposed terms such as childhood-type (big-spot) and adult-type (small-spot) mastocytosis, mastocytoma, diffuse cutaneous mastocytosis and systemic mastocytosis. This is in complete agreement with the WHO classification.

The prevalence of mastocytosis remains unknown. The disease may start at any age but starts in the first years of life in the majority of cases. Between 10 and 20 % of the adult mastocytosis starts in childhood. Familial cases have been described but are not common. The majority of the patients with mastocytosis do have a normal life prognosis. In children, mastocytosis may go into complete remission in more than 60 % of the cases during, shortly before or shortly after puberty. Adult mastocytosis starts in childhood in 10–20 % of the cases.

Basic Concepts of Pathogenesis

Mastocytosis represents a hyperplastic response to an abnormal stimulus and can be considered as a monoclonal proliferative disorder. The prognosis

is much better in the majority of the cases, especially the big-spot variants as described earlier in children.

Basic research is focused on mutations in the proto-oncogene receptor c-kit. Childhood mastocytosis is less frequently associated with c-kit mutations or with other c-kit mutations than that in adults (Verzijl et al. 2007).

Clinical Presentation

We generally distinguish cutaneous mastocytosis (CM) and systemic mastocytosis (SM). For classifications, see earlier in the text.

Maculopapular cutaneous mastocytosis (MCM) is a form of cutaneous mastocytosis (CM) characterized by the presence of multiple hyperpigmented macules, papules, nodules or plaques. It is the most common form of CM (accounting for up to 90 % of cases). This disease is most commonly reported among the Caucasian population and affects both sexes, almost equally. The majority of the patients present in infancy or childhood, but the onset may also occur in adulthood. As lesions vary in aspect, several subvariants were described in the past (plaque form, typical form, telangiectatic form and nodular form) but are all now grouped under the same entity. We distinguish big-spot (childhood-type) and small-spot (adult-type) mastocytosis as described earlier.

Cutaneous mastocytoma is a form of cutaneous mastocytosis (CM) generally characterized by the presence of a solitary or multiple hyperpigmented macules, plaques or nodules associated with an abnormal accumulation of mast cells in the skin. Mastocytomas are the second most frequent form of CM in children accounting for 10 % of the cases. Patients generally present during infancy, with most presenting in the first 3 months of life. This variant is only very rarely observed in adults. Mastocytomas usually appear as oval lesions with red-brown, pink or yellow pigmentation. The diameter varies from around 1 to 4 cm and the surface may be smooth or have a "peau d'orange" appearance.

Diffuse cutaneous mastocytosis (DCM) is a rare form of cutaneous mastocytosis characterized by a generalized erythroderma, various degrees of blistering and skin with a "peau d'orange" appearance. At least two DCM variants are recognized, one with extreme blistering (bullous) and one with infiltrations (pseudoxanthomatous). It accounts for less than 3 % of all the cases of CM and almost exclusively presents initially at birth or during infancy. The majority of patients present with a generalized erythroderma with a reddish to brown-orange discolouration and extensive bullae. The blisters may become haemorrhagic, may be grouped or linear and are usually located on the trunk, the extremities or the scalp. The bullous lesions typically resolve by the age of 3–5 years. A small number of patients have been reported with yellow-orange infiltrated and xanthogranuloma-like lesions. Over time, the skin becomes thickened and has a doughy consistency.

The course and the prognosis of childhood mastocytosis are often milder than that of adult-onset mastocytosis. The best prognosis has been observed in big-spot disease and is excellent in cutaneous mastocytoma. Nonetheless, more than 10 % of the adult mastocytosis starts in childhood.

Diagnosis

The diagnosis of mastocytosis can often be readily made by the clinical history and the visible skin lesions and their distribution. Rubbing or trauma of the affected skin results in a wheal with flare (Darier's sign) in more than 90 % of the patients. A biopsy for histopathological examination is indicated in almost all cases to verify the diagnosis.

Measurement of the released mediators can be used to support the diagnosis and help to identify possible systemic cases. The serum Tryptase level has become the golden standard in mastocytosis. However, an elevated serum Tryptase level in children does not directly indicate systemic mastocytosis with certainty. Follow-up in mastocytoma and noncomplicated maculopapular

mastocytosis with normal serum Tryptase levels without complaints is unnecessary (to be published).

Bone marrow examination in children is not indicated unless it has consequences. Further evaluation in such manner should be reserved only for those children with persisting high serum Tryptase levels after the age of 5 years.

Bone marrow should be examined if there is evidence of haematemesis, melaena and severe bone pain and bone involvement, abnormal haematological values such as unexplained anaemia and leucopenia and the presence of mast cells in the peripheral blood. Children should always be examined in such cases by a dermatologist in cooperation with a paediatrician. Both should also have a special interest in mastocytosis.

In adults, an elevated serum Tryptase level of 20 μmol/l or higher indicates thorough investigations by a specialized internal physician.

Screening for systemic involvement should include a complete blood cell count. Unexplained anaemia, leucopenia, leucocytosis and/or thrombocytopenia indicate bone marrow involvement and make a bone marrow examination necessary. An early osteoporosis should also be evaluated. Other complaints such as abdominal pain may require other investigations such as ultrasound or magnetic resonance examinations.

Differential Diagnosis

Differential diagnosis includes lentigines, freckles, histiocytosis, café-au-lait freckling, juvenile xanthogranuloma and post-inflammatory pigmentations. All of these require histopathological examination.

General Principles of Treatment

Treatment is not indicated in most cutaneous variants and noncomplicated cases without complaints and/or systemic involvement. In cases with complaints or suspicion of systemic involvement, multidisciplinary approach is indicated. A team will at least include a dermatologist and an internal physician (adults) and a paediatrician (children). The therapy consists of reassuring the patient and his/her family in the majority of the cases.

Treatment is directed at alleviation of symptoms because a more pathophysiological approach to mast cell hyperplasia is unavailable. As most variants of the disease usually run a benign course, therapy can often be limited to reassurance and avoidance of factors known to stimulate mast cell degranulation. Further treatment must be tailored to the symptom complex of the individual patient (Heide et al. 2008).

Limited lesions may be treated with topicals with or without occlusion; topical corticosteroids and pimecrolimus cream are effective as reported by for corticosteroids and Correia (2010) and Ma (2010) for the calcineurin inhibitor. Treatment of bullae is supportive and consists of local care and prevention of infection.

Pruritus, urtication and flushing respond to H1-receptor antagonists. Positive results of rupatadine have also been reported (Siebenhaar and Fortsch 2013).

H1-receptor antagonists (e.g. hydroxyzine maximum 2 mg/kg daily in three doses; cetirizine 10–20 mg daily for children aged 2–6 years and 5 mg twice daily for those older than 6 years, as in adults; rupatadine 20 mg daily for 4 weeks) can control symptoms such as pruritus, urtication and flushing (Siebenhaar and Fortsch 2013). The addition of an H2-receptor antagonist (e.g. cimetidine 20 mg/kg daily in three doses, ranitidine 4 mg/kg daily in two doses) may be warranted in children who exhibit gastrointestinal symptoms of hyperacidity or ulceration, although this is controversial. Patients with diarrhoea may benefit from treatment with an H2-receptor antagonist, with or without disodium cromoglycate (a stabilizer of mast cell membranes) orally 100 mg four times daily. Another mast cell stabilizer, ketotifen 1 mg/kg twice daily, has been demonstrated to reduce whealing and pruritus in patients with maculopapular cutaneous mastocytosis, although a more recent controlled comparison with hydroxyzine in paediatric cutaneous mastocytosis showed no advantage. Patients with significant malabsorption may need oral predni-

sone treatment at a dose of 1–2 mg/kg daily at the start, slowly tapering off (stress dose = 2 mg/kg daily). However, it includes a real danger of accentuating concomitant bone disease that is caused by the mast cells in the marrow.

Patients with diarrhoea may benefit from treatment with disodium cromoglycate (a stabilizer of mast cell membranes) orally 100 mg three to four times daily.

Ultraviolet A (UVA) or UVA combined with oral psoralens (PUVA) may be used in adolescents and adults for skin manifestations that are resistant to more standard therapy.

One may consider therapy with imatinib mesylate in more complicated systemic cases (Droogendijk and Kluin-Nelemans 2006). Most other therapies are experimental. Research is directed at drugs that target the mutations of the KIT receptor (Fuller 2012).

Cytoreductive agents should be avoided if possible in patients with indolent SM, where the disease cause is nonprogressive. For aggressive systemic mastocytosis, interferon-α therapy (Hauswirth and Simonitsch-Klupp 2004; Butterfield 2005) and cladribine (Kluin-Nelemans and Oldhoff 2003) are the first-line drugs of choice with response rates of approximately 50 %.

The expression of kit in neoplastic mast cells (MCs) has led to the development of targeted therapies (El-Agamy 2012; Fuller 2012) using tyrosine kinase inhibitors (TKI) like STI571 (such as the earlier-mentioned imatinib) (Akin and Metcalfe 2004; Droogendijk and Kluin-Nelemans 2006). Unfortunately, the c-kitD816V mutation is associated with relative resistance against STI571. However, TKIs with activity against c-kitD816V-positive cells have recently been developed, and some of them (dasatinib, nilotinib/AMN107, PKC412) have already been tested in phase I/II trials. Although both dasatinib and PKC412 display remarkable in vitro activity against c-kitD816V, the preliminary results from human clinical trials in adults have not been as impressive (Gotlib and George 2007; Rondoni and Paolini 2007). In addition, non-TKI-kit signalling inhibitors (e.g. geldanamycin, rapamycin) or monoclonal antibodies directed against neoplastic MCs may evolve as future therapeutic options (Sotlar 2007).

Anaesthesia and Mastocytosis: Risk of Anaphylaxis

There is controversy on the risk of anaesthesia in children with mastocytosis. Recently, Carter et al. (2008) examined peri-anaesthetic records of 22 patients with paediatric mastocytosis and conducted a literature review of the anaesthetic experience in paediatric mastocytosis. They concluded that deviations from routine anaesthesia techniques were not necessarily warranted. However, an understanding of the anaesthetic implications of the disease and meticulous preparation to treat possible adverse events were advised.

As all patients with mastocytosis are at risk for unprovoked anaphylaxis (Silva and Carvalho 2008), we still recommend preventive measures in complicated cases with elevated serum Tryptase levels (Heide et al. 2008) at narcosis in children with large or unknown disease burden, in children with a history of anaphylaxis, those with bullous skin lesions or diffuse CM and those with SM or with high serum Tryptase levels.

Prognosis

The prognosis has been mentioned already in different paragraphs. In children, about two-thirds of the cases will regress, particularly those with big-spot disease and with solitary or multiple mastocytomas. Mastocytoma is very rarely observed in adults so that they clear almost completely before puberty. Most mastocytosis patients can live a normal life. However, a minority of the cases do have major complaints and in most extreme forms is life threatening.

Conclusions

Mastocytosis is not a disabling disease and the life expectancy is normal.

However, it is wrong to tell the parents that they do not have to worry and that the disease will disappear. It does not happen in one-third of the cases.

Anaphylaxis is a threat only in a minority of the cases when EpiPen prophylaxis should be prescribed. Children with mastocytosis, bullous disease, high serum Tryptase levels and/or a history of anaphylaxis should be equipped with an epinephrine auto-injector (Simons and Gu 2002) and be prepared (very important) together with the parents for this self-medication.

Melanoma

60

Dimitrios Papakostas and Alexander J. Stratigos

Key Points

- Malignant melanoma shows a steady incidence increase by 3–7 % in fair-skinned Caucasian populations over the past four to five decades.
- Early recognition and diagnosis of thinner melanomas has resulted in the stabilization of mortality with improved 5-year survival rates in most countries.
- Phenotype (I–II), intermittent sun exposure, and genetic predisposition are key risk factors.
- The majority of sporadic melanomas associated with intermittent sun exposure are characterized by BRAF or NRAS mutations.
- Suspicious or atypical melanocytic lesions should be excised with a 2 mm safety margin deep to the subcutaneous fat.
- Sentinel lymph node biopsy (SLNB) is a diagnostic tool for the determination of stage, prognosis, and need for adjuvant therapy.
- Surgical excision is the primary treatment of melanoma, remains the mainstay in the treatment of locoregional metastasis, and has an increasing role in the treatment of limited disseminated disease.
- High-risk melanoma patients should be offered the option of adjuvant therapy after surgical excision of the primary tumor with the goal of reducing the risk of relapse and achieving a cure.
- Metastatic disease can be managed by systemic therapy, surgery, radiotherapy, or best supportive care. Until the emergence of novel targeted treatments in recent years, no drug demonstrated any substantial impact on survival improvement.
- Novel inhibitors of signal transduction such as the BRAF inhibitors vemurafenib and dabrafenib and immunomodulating monoclonal antibodies such as the CTLA-4 blocking autoantibody ipilimumab have revolutionized the treatment of metastatic melanoma.
- Follow-up of melanoma patients for a time period of up to 10 years aims to the early detection and treatment of recurrences and to an improved progression free and overall survival.

Definition and Epidemiology

Melanoma is a malignant melanocytic tumor developing in most cases from epidermal melanocytes. In 5 % of cases, primary extracutaneous manifestation with involvement of the eye (conjunctiva and iris), the meninges, and the mucosa may occur. After an initial horizontal or radial growth phase marked by pagetoid spread of malignant melanocytes within the epidermis and infiltration of the papillary dermis, a vertical growth phase with infiltration of the deeper dermis and subcutaneous fat follows. The vertical growth phase may lead to lymphogenic (intransit/lymph node metastasis) and/or hemotogenic spread (distant metastasis). Sixty percent of the metastases can be traced in the regional lymph nodes. Disease progression with involvement of the lung, the central nervous system (CNS), the bones, and the liver results to a poor prognosis and frustrating survival rates. Melanoma accounts for 5 % of all skin malignancies, but it is responsible for 85 % of the deaths by skin cancer.

A steady incidence increase of 3–7 % in fair-skinned Caucasian populations over the past four to five decades has utterly transformed the epidemiology and the socioeconomic impact of this previously infrequent skin malignancy. No other human malignancy with the exception of non-melanoma skin cancer (NMSC) has shown such a high yearly incidence increase. Indeed, the lifetime risk has risen from 1:1,500 in the 1920s in the USA to 1: 50 in 2010. In non-Caucasian populations, melanoma remains a rarity. Australia is the country with the highest incidence worldwide, with up to 60 new cases per 100,000 inhabitants per year compared to 20 new cases per 100.000 inhabitants per year in Germany. Despite the observed incidence increase over the last decades, early recognition and diagnosis of thinner melanomas in central and northwestern Europe, the USA, and Australia have been associated with stabilization of mortality and improved 5-year survival rates (>80 %), outranked only by prostate, thyroid, and testicular cancer. On the other hand, the disproportionate burden of thicker advanced melanomas due to late diagnosis in the elderly patients (>65 years), especially men, explains the mortality increase in this age group. Although the incidence peaks in elderly populations, melanoma can still affect younger adolescents and even children. Melanoma is rather rare in children, accounting for just 1 % of all new melanoma cases. Yet it is still the most common skin malignancy in this age group and usually associated with a poor prognosis.

Pathogenesis

Melanoma is a heterogeneous malignancy with a complex etiology. Phenotype, sun exposure, and genetic predisposition are principal risk factors in a complex etiological interaction with each other that explains the diversity of clinical manifestations and the epidemiology of the disease.

The consistent increase in incidence over the last decades could be attributed to the altered recreational habits in western industrial countries resulting to an increased sun exposure due to sun tanning on the beach or even indoor tanning. Indeed, melanoma preferably affects fair-skinned individuals of phenotype I or II who present with multiple lentigines and fair skin, hair, and eyes. There is a higher incidence in lower altitudes and among immigrant populations to areas of high ambient ultraviolet radiation. Furthermore, there is an association with sun-induced skin damage, actinic keratoses, and NMSC. Intermittent sun exposure due to recreational habits stimulates a high proliferative activity of melanocytes resulting potentially in the development of multiple melanocytic nevi and melanomas, particularly on truncal locations where most sporadic cases occur. Instead, chronic sun exposure allows a proper adjustment of the melanocytes at a low level of proliferative activity and is more commonly associated with actinic keratoses, NMSC, and melanoma on head and neck locations. The relative risk for malignant melanoma correlates to the number of common melanocytic and atypical/dysplastic nevi. However, only 30 % of all melanomas will develop on a preexisting

melanocytic nevus. Nevus-associated melanoma develops preferably on congenital nevi (60 %). Congenital melanocytic nevi are associated with a 0.7 % lifetime risk for melanoma, a risk that increases (2–3 %) in the case of giant congenital nevi (>20 cm in diameter). Clinically atypical or dysplastic nevi present with morphological asymmetry, are larger than 0.5 cm in diameter, have blurred and/or irregular borders, and contrary to common belief are rather common in general population (10 %). Although the relative risk of malignant transformation of the individual atypical nevus remains limited, multiple atypical or dysplastic nevi, especially in the setting of the dysplastic nevus syndrome and familial melanoma, are associated with an increased risk of melanoma and should be screened routinely.

Lately, the identification of molecular signatures or mutations based on anatomic location and sun exposure patterns has shed light on the molecular basis of melanoma. The majority of sporadic melanomas associated with intermittent sun exposure are characterized by BRAF/NRAS mutations, compared to cyclin-D1 and c-KIT alterations which are seen in tumors on chronically sun-damaged skin or c-KIT alterations in tumors located in areas without exposure, e.g., mucosal melanoma. About 50 % of sporadic cutaneous melanomas are BRAF mutated and 15–30 % have NRAS mutations, both of which are mutually exclusive. BRAF and NRAS are essential effectors of the MAPK/ERK kinase signaling cascade. Mutations result to an unregulated activation of this kinase cascade and uncontrolled tumor proliferation.

In familial melanoma (10 % of cases), germline CDKN2A and CDK4 mutations can be identified. Both genes play an essential role in cell cycle control and apoptosis regulation and are being currently considered as high-risk genes for melanoma, compared to low-risk genes such as TYR, TYRP1, and M1CR. The latter present as common variations or polymorphisms among the general population with a high frequency (>1 %) and are indicative for a lower lifetime risk compared to that conferred by high-risk genes.

Clinical and Histological Characteristics

The classical clinicopathological classification of melanoma in different subtypes, i.e., superficial spreading melanoma (SSM), nodular melanoma (NM), lentigo maligna melanoma (LMM), and acral lentiginous melanoma (ALM), covers about 90–95 % of all melanoma cases. In some cases (5 %), extracutaneous manifestations in the eyes, mucosa, or even the meninges may occur and can be associated with late diagnosis and poor prognosis. Rare variants of cutaneous melanoma such as the amelanotic, the desmoplastic, and the mucosal type as well as the melanoma in childhood should be also considered due to the challenging differential diagnosis and the importance of an early recognition and treatment.

Histologically melanoma presents as an asymmetrical melanocytic lesion with pagetoid spread of atypical melanocytes, heterogeneous in size and morphology, throughout the epidermis. Atypical melanocytes may form confluent nests, while infiltrating the dermis and extending down to the adnexa. There is no maturation of melanocytes in the deeper layers of the dermis. Mitoses and signs of regression may be also observed. Staining for HMB45 and Melan-A is helpful for better distinguishing cells of melanocytic lineage. S100 has a very high sensitivity for melanoma but is also widely expressed in a variety of spindle cell tumors. Tumor thickness in the dermis is measured in mm, formerly known as Breslow index, currently described as AJCC depth.

Superficial spreading melanoma is the most frequent type (60 %). It is located in areas of intermittent sun exposure such as the back of males or the legs of females. It starts as a superficially spreading asymmetric macule with blurred or irregular borders (horizontal phase), followed by secondary nodular growth (vertical phase) (Fig. 60.1).

Nodular melanoma is the second most common melanoma type (10–20 %). This type shows an aggressive biological behavior due to the rapid vertical growth phase without prior horizontal phase. It presents as a rapidly growing darkly

Fig. 60.1 Superficial spreading melanoma (SSM)

Fig. 60.2 Melanoma of the nail

pigmented nodule, although less pigmented and nonpigmented variants also exist.

Lentigo maligna melanoma can be spotted on areas of chronic sun exposure such as the face, the ears, the shoulders, and the extremities, preferably in elderly patients (60–70 years). LMM can develop on the ground of a preexisting atypical pigmented macule (lentigo maligna, in situ melanoma) accounting for about 10 % of all melanoma cases.

Acral lentiginous melanoma is a rather uncommon variant of melanoma (5 %), mostly on the palms and soles of elderly patients. In case of melanonychia, subungual melanoma should be always included in the differential consideration (Fig. 60.2).

Rare Melanoma Variants

Amelanotic melanomas account for 2 % of all melanomas. They lack the melanoma warning signs, particularly due to the absence of pigmentation and presence of reddish plaques or nodules, making the differential diagnosis from basal cell carcinoma or pyogenic granuloma a rather challenging quest.

Desmoplastic melanoma develops as a slowly enlarging area of thickened skin, resembling a scar, most commonly on exposed areas of the head and neck (>50 %). They are usually skin colored but may be pigmented as well, and they usually lack the classic recognition signs of melanoma often resulting in a late diagnosis. Proper histological diagnosis is a difficult task, since there is no or little spread of malignant cells within the epidermis. Instead, atypical spindle cells separated by a fibrous stroma are found within the dermis or subcutaneous fat.

Uveal melanoma preferably affects middle-aged patients with fair skin and is marked by GNAQ and GNA11 mutations. The choroid is the most common site of tumor development. Blurred vision, floaters, flashing lights, and shadows are usual visual symptoms reported by some patients, although others may have no symptoms at all. Late diagnosis is associated in most cases with poor prognosis.

Mucosal melanoma accounts for less than 5 % of melanoma cases. The majority of mucosal melanomas begin in the head and neck region, the anorectal region, and the female genital tract. Rare locations of primary mucosal manifestation include the esophagus, the gallbladder, the bowel, the conjunctiva, and the urethra. Mutations of the c-KIT gene are found in mucosal melanomas which are typically BRAF negative. There is no relation to UV exposure and no obvious identifiable risk factors.

Melanoma in childhood may be very rare, accounting for 1 % of all melanomas. There is no association with excessive sun exposure, and it usually arises within a giant congenital melanocytic nevus of >20–40 cm diameter. It is more often amelanotic (flesh colored, pink, or red), nodular, hemorrhagic, and ulcerated. Prognosis is usually poor.

Diagnosis

Melanoma usually presents as a melanin-rich lesion changing in size, shape, or color within weeks or months, or as a preexisting nevus with distinct clinical characteristics compared to other nevi ("ugly duckling" sign) without any history of change, or as a new nevus with atypical appearance and/or rapid change in size. The differential diagnosis may prove challenging, and the list of differential diagnosis includes a large number of melanocytic and nonmelanocytic tumors, such as lentigo, melanocytic nevi, seborrheic warts, pigmented basal cell carcinoma, angiokeratoma, dermatofibroma, and hemangioma, or even hematoma should be taken into diagnostic consideration.

For an early diagnosis, clinical examination and use of the ABCDE algorithm (*A*symmetry of a melanocytic lesion with irregular or blurred *B*orders, different *C*olors and *D*iameter >0.5 cm, *E*volving in time) may prove very useful: Dermoscopy, an in vivo noninvasive diagnostic magnification of skin lesions, can substantially improve the clinical diagnostic sensitivity in the hands of experienced dermatologists. An atypical melanin network, pseudopods in the periphery of an atypical melanocytic lesion, black dots (atypical melanocytes in the stratum corneum), regression structures, blue-whitish veil (orthohyperkeratosis), and gray veil (melanophages in the dermis) are suggestive for melanoma. Suspicious melanocytic lesions should be totally excised with a 2 mm conservative margin deep to the subcutaneous fat in order to remove the entire lesion and obtain adequate material for a proper histological diagnosis. Wider margins should be avoided upon primary excision in order to permit accurate lymphatic mapping at a second stage, if needed.

Sentinel Lymph Node Biopsy

Sentinel lymph node biopsy (SLNB) is a diagnostic tool for the determination of stage, prognosis, and the need for adjuvant therapy. Its impact on overall prognosis is unclear. It is performed in tumors thicker than 1.0 mm or even thinner (<1 mm) in the presence of additional risk factors such as ulceration, mitoses rate ≥1, or extensive regression. Other factors may play a role in the decision to perform SLNB such as the patients' medical background, age, and comorbidities.

Tumor Classification

The American Joint Commission on Cancer (AJCC) lately (2009) revised the staging system for cutaneous melanoma based on the TNM tumor classification. A multivariate analysis of 30,947 stage I, II, III and 7,972 stage IV melanoma patients from the AJCC patient database was conducted. T defines features of primary tumor (Table 60.1), N of regional disease (Table 60.2), and M of extra-regional disease

Table 60.1 AJCC 2009 TNM staging categories: T

Tis	Melanoma in situ	
T1a	Thickness ≤1 mm	Without ulceration and mitoses/mm2 < 1
T1b	Thickness ≤1 mm	With ulceration and/or mitoses/m2 ≥ 1
T2a	Thickness 1.01–2 mm	Without ulceration
T2b	Thickness 1.01–2 mm	Ulcerated
T3a	Thickness 2.01–4 mm	Without ulceration
T3b	Thickness 2.01–4 mm	Ulcerated
T4a	Thickness >4 mm	Without ulceration
T4b	Thickness >4 mm	Ulcerated

Table 60.2 AJCC TNM staging categories: N

N0	No evidence of lymph node metastasis
N1	1 metastatic lymph node
	(a) Micrometastasis
	(b) Macrometastasis
N2	2–3 metastatic lymph nodes
	(a) Micrometastasis
	(b) Macrometastasis
	(c) In-transit metastasis/satellite metastases without metastatic lymph nodes
N3	4 or more metastatic lymph nodes or matted nodes or in-transit metastasis/satellite metastases with metastatic lymph nodes

(Table 60.3). The T category is defined by tumor thickness and ulceration (T1–T4). Tumors thinner than 1.0 mm are upgraded in the presence of ulceration and dermal mitoses (≥1). The N category is defined by the number of metastatic lymph nodes, the observed micro- or macrometastases, and the presence of satellite or in-transit metastases. Finally, the M category is defined by distant metastases in the presence of normal or elevated LDH (Table 60.4).

Approximately 84 % of melanoma patients are diagnosed with local disease, 9 % with regional disease, 4 % with distant disease, and 4 % remain unstaged. Prognosis by means of survival rates depends on stage and ranges from a remarkable 98.3 % 5-year survival for patients with localized disease to 62.4 % for patients with regional disease and 16 % for patients with disseminated disease.

Table 60.3 AJCC TNM staging categories: M

M0	No evidence of extra-regional metastases
M1a	Extra-regional cutaneous-subcutaneous or lymph node metastases
	Normal LDH levels
M1b	Extra-regional lung metastases
	Normal LDH levels
M1c	Any other extra-regional metastasis with normal LDH levels
	or
	Any extra-regional metastasis with elevated LDH levels

Table 60.4 AJCC 2009: stage groupings

Stage	T	N	M
0	Tis	N0	M0
IA	T1a	N0	M0
IB	T1b	N0	M0
	T2a	N0	M0
IIA	T2b	N0	M0
	T3a	N0	M0
IIB	T3b	N0	M0
	T4a	N0	M0
IIC	T4b	N0	M0
IIIA	T1-4a	N1a	M0
	T1-4a	N2a	
IIIB	T1-4b	N1a, N2a	M0
	T1-4a	N1-2b, N2c	
IIIC	T1-4b	N1-2b, N2c	M0
	Any T	N3	
IV	Any T	Any N	M1

Initial Staging Workup

Baseline imaging should be generally recommended for stages ≥ IIC. Cross-sectional imaging methods like CT, PET/CT, and MRI are preferably recommended. For stages up to IIB, imaging could be considered only for evaluation of specific signs and symptoms. Whole-body CT and cranial MRI are not advised as a standard diagnostic procedure in asymptomatic low-risk patients with the diagnosis of primary melanoma. Lymph node ultrasound and the serologic marker S100 should be recommended in stages ≥ IB. Serum LDH has no prognostic validity upon primary diagnosis of melanoma and should be reserved for patients with stage IV melanomas.

Molecular Pathology Workup

High-risk patients in stages IIIB and above should be screened for BRAF, NRAS, and c-KIT, which are now commercially available. Novel targeted treatments have opened new therapeutic horizons and could be offered in case of inoperability and/or metastatic disease. About 50 % of all primary melanomas carry BRAF mutations and about 5 % of all mucosal or acral melanomas are positive for c-KIT mutations. NRAS mutations can be also found in 15 % of all melanomas. BRAF mutations are present throughout different phases of melanoma progression. If a biopsy of a metastatic lesion is not available, the most recent surgical sample, e.g., a positive lymph node or even the primary tumor, may be adequate.

General Principles of Treatment

Surgical Treatment

Surgical excision is the standard of care in the treatment of melanoma (Fig. 60.3). When melanoma is excised with intent to cure, a radical

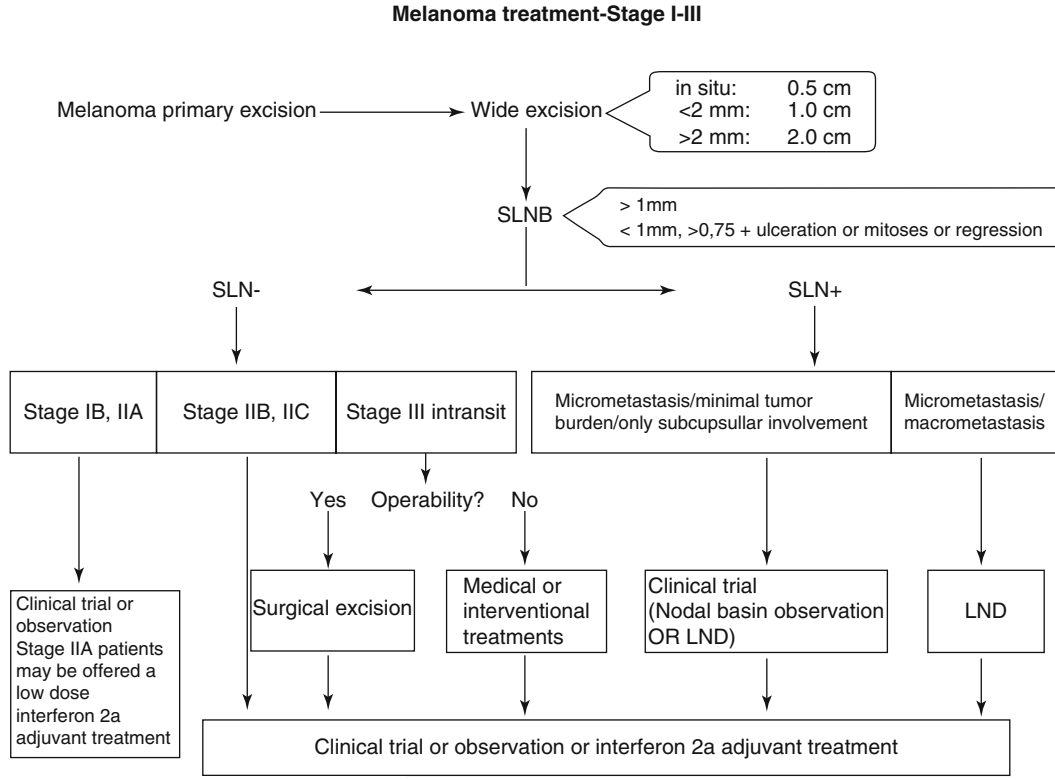

Fig. 60.3 Melanoma treatment: stages I–III

wide excision with adapted safety margins should be performed after the diagnostic primary excision in order to prevent local recurrences. Surgery remains the mainstay in the treatment of locoregional metastases and can be offered in a setting of interdisciplinary approach in case of limited disseminated disease or as a last palliative resort to improve patients' quality of life.

Wide Excision

A 5 mm safety margin is currently recommended for in situ melanoma. For large diameter lentigo maligna or lentigo maligna melanoma, surgical margins greater than 0.5 cm may prove necessary in order to achieve histologically negative margins; otherwise, local recurrences may occur. In invasive melanoma, wide excision with 1 cm safety margins should be performed for tumors up to 2 mm in histological depth and with 2 cm margins for thicker tumors (>2 mm). However, the issue of optimal surgical margins is yet to be clearly resolved and there are still regional guideline variations.

Surgical margins may be modified to accommodate individual anatomic or cosmetic considerations. A 1–2 cm margin might be acceptable in anatomically difficult areas, whereas a full 2 cm margin could be difficult to achieve. Further, micrographic surgery could be considered in special anatomic locations such as the face, the finger, and toes in order to minimize the necessary safety margin and avoid mutilating surgical procedures. However, data on the use of Mohs micrographic surgery in melanoma are limited, limited mostly to cases of lentigo melanoma, and this technique should be reserved for carefully selected cases.

Lymph Node Dissection

Regional lymph node dissection is not recommended if SLNB is negative since there is no therapeutic benefit of prophylactic lymphadenectomy. On the other hand, regional lymphadenectomy can be offered after histological (SLNB) or cytological detection of lymph node micrometastases with fine-needle aspiration cytology (FNAC). The decision for complete lymph node dissection in sentinel lymph nodes with a minimal tumor burden and/or subcapsular location must be made together with the patient and should take in consideration further risk factors such as tumor thickness, ulceration, tumor mitosis rate, number of positive sentinel lymph nodes, and anatomic site of the primary tumor (Fig. 60.3).

Patients presenting with clinically positive nodes (macrometastasis) without radiologic evidence of distant metastases should undergo complete lymph node dissection of the involved nodal basin in order to prevent regional recurrence and pursue a curative approach. If the indication has to be determined by findings other than SLNB, regional ultrasonography by an experienced examiner is superior to plain clinical examination by palpation. In case of a recurrence in a lymph node basin that has been previously operated, lymph node dissection should be considered, if there is no further evidence of metastases.

Surgical Treatment of Locoregional Metastases

Cutaneous metastases up to 2 cm from the excision scar of the primary tumor are described as satellite metastases, while those on the lymphatic course toward the regional lymph nodes are defined as in-transit metastases. In both cases, surgical excision of operable locoregional metastases remains the mainstay of treatment. In case of inoperability due to an increasing number of metastatic lesions, other interventional or medical options should be considered, e.g., intratumoral IL-2 injection, intratumoral electrochemotherapy with bleomycin or cisplatin, local immunotherapy with diphencyprone (DCP), radiation, and isolated limb perfusion with the chemotherapeutic melphalan (Fig. 60.3 and 60.4).

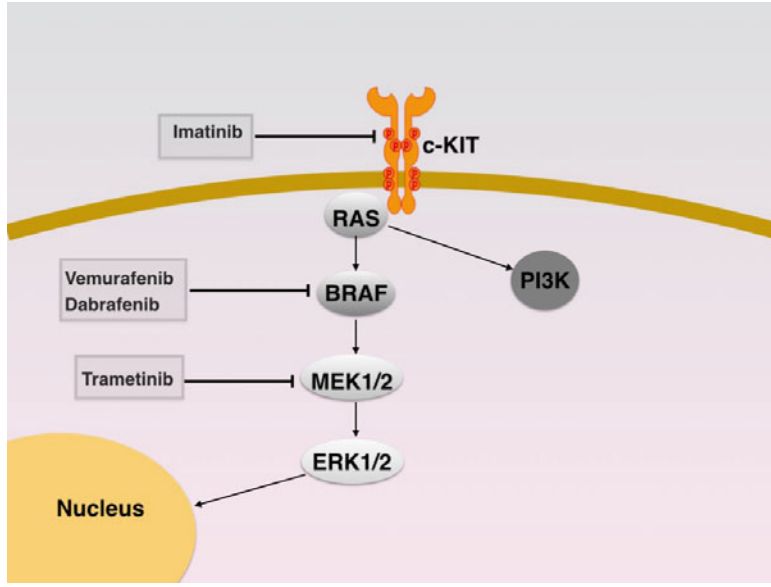

Fig. 60.4 MAPK/ERK kinase signaling pathway and targeted treatments

Treatment of Distant Metastases

Patients in stage IV with limited or localized metastatic disease should be offered a surgical excision of the metastases if a complete curative resection (R0) is technically feasible with no unacceptable functional deficit (Fig. 60.5). A low number of metastases and a long duration of the metastasis-free interval are currently seen as positive prognostic factors and should influence the treatment decision in favor of a curative surgical approach. Palliative surgery when an R0 resection is not possible remains an option in cases where the patient's quality of life could be distinctively enhanced.

Adjuvant Medical Treatment

High-risk melanoma patients should be offered an adjuvant therapy after surgical excision of the primary tumor with the goal of reducing the risk of relapse and achieving a cure. Provided treatment should have a reasonable safety profile though. The only approved agent for the adjuvant treatment of melanoma is interferon alpha. Vaccination therapies, immunostimulation with levamisole, isolated limb perfusion with melphalan ± TNF, and chemotherapy should not be considered in an adjuvant setting.

Interferon

Clinical trials so far have shown a small but significant benefit in overall survival and a significant benefit for recurrence-free survival in patients treated with interferon alpha. Yet no single interferon regimen has been shown to be significantly superior to others. A variety of different interferon agents (IFN a2a vs. IFN a2β, pegylated interferon), dosage schemes (high vs. low dose), patient subsets, treatment duration, and administration routes (subcutaneous vs. intravenous or

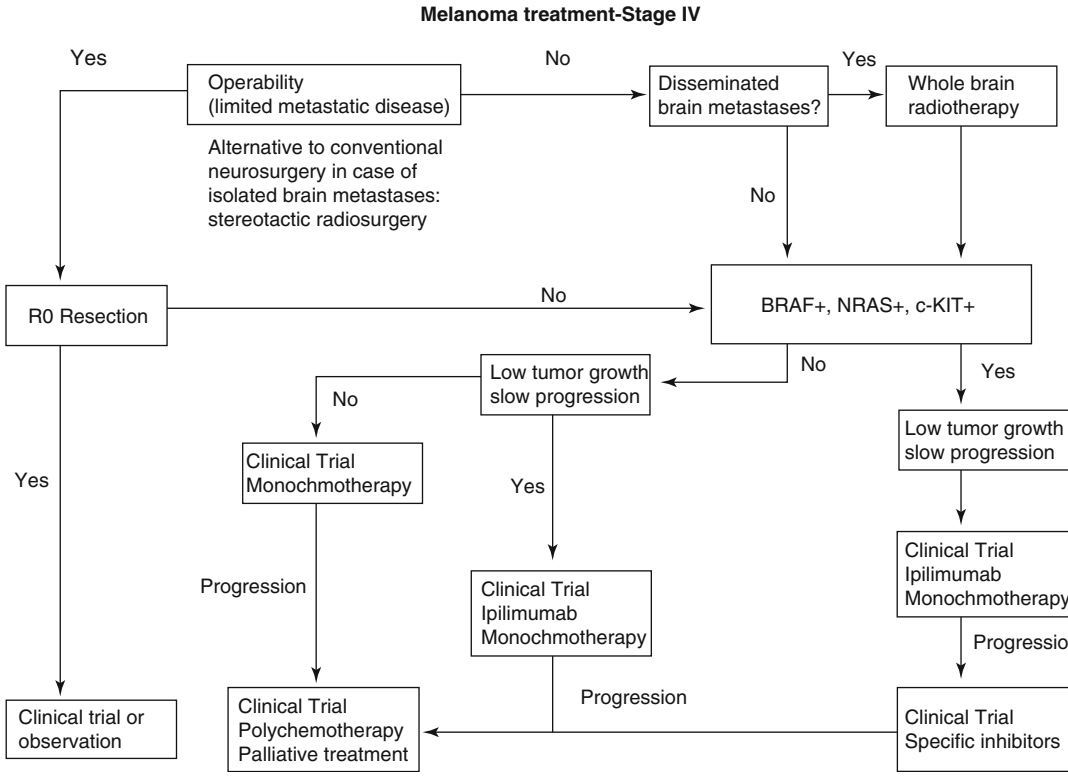

Fig. 60.5 Melanoma treatment: stage IV

pulsed intravenous regimens) have been discussed so far. A subset of patients may benefit from adjuvant treatment with interferon, but this benefit often comes at the cost of reduced tolerability. The most common adverse reactions include flu-like symptoms, depression, hair loss, and leukopenia.

The major regulatory authorities (FDA and EMEA) have approved a high-dose interferon regimen for high-risk patients in stages IIB/IIC and III. After the initial induction over 4 weeks with 20 MIU/m2 IV 5× per week follows the maintenance phase with 10 MIU/m2 SC 3× per week for 48 weeks. EMEA has also approved a low-dose regimen for patients in stage II with 3 MIU IV 3× per week for 18 months. An adjuvant treatment with pegylated interferon a2b once per week for 5 years is approved by the FDA for stage III patients and from Switzerland for stage IIIA patients.

With regard to currently existing guidelines, adjuvant treatment options for low-risk patients in stages IB and IIA include participation in clinical trials with interferon or clinical observation. After a proper consideration of the patients' medical background, and the potential adverse events and their effect on quality of life, stage IIA patients may be offered a low-dose adjuvant interferon treatment or clinical observation. High-risk patients in stages IIB/IIC and III should be offered the participation in clinical trials or the option of adjuvant treatment with interferon or clinical observation.

Nonsurgical Treatment of Locoregional Metastases

Patients with non-operable locoregional metastases should be treated, if possible, in context of clinical trials. If this is not the case, a wide spectrum of nonsurgical strategies can be considered. Intratumoral IL-2 injection, intratumoral electrochemotherapy with bleomycin or cisplatin, and local immunotherapy with diphencyprone (DCP) show the highest response rates. Other options include radiotherapy, CO2 ablation, and isolated limb perfusion with the chemotherapeutic melphalan. The latter should be considered in cases of rapid local disease progression, when the metastases remain uncontrolled under more conventional surgical and nonsurgical treatments.

In case of inoperability, when there is no indication for local treatments or after local treatment failure, systemic treatment options such as those for disseminated disease should be considered.

Medical Treatment of Disseminated Disease

Disseminated disease can be managed by systemic therapy or best supportive care (Fig. 60.5). Until the emergence of novel targeted treatments in recent years, no single agent had demonstrated any substantial impact on survival improvement. Standard chemotherapeutics included intravenous administration of dacarbazine and oral temozolomide. The combination of chemotherapy with interferon or IL-2 led to increased response rates but had no impact on overall survival. This situation has radically changed in recent years with the advent of novel inhibitors of signal transduction (Fig. 60.4) such as the BRAF inhibitors vemurafenib and dabrafenib and of novel immunomodulating agents such as the monoclonal anti-CTLA-4 antibody ipilimumab. Approval of vemurafenib/dabrafenib and ipilimumab has significantly changed the management of patients with metastatic melanoma, but with important limitations. Ipilimumab has a potential for serious autoimmune toxicities and clinical responses may take months to become apparent. Overall response rates are very limited, but there is a subset of patients with a long-lasting response. BRAF inhibitors, on the other hand, demonstrate high response rates, but the median response does not last longer than 5–6 months. Recent data from randomized clinical trials suggest that patients with BRAF-positive metastatic melanoma may benefit from the sequential treatment with ipilimumab and BRAF inhibitors or from the combination of ipilimumab with anti-PD-1 antibodies. This underscores the importance of participating in an ongoing clinical trial, whenever possible.

Inhibitors of Signal Transduction

Vemurafenib is a novel BRAF inhibitor which lately promised to revolutionize the treatment of metastatic melanoma due to unprecedented response rates of about 80 % and a clear impact on progression-free survival >6 months. In clinical trials the median overall survival of 15 months was significantly better than that of dacarbazine (6.5 months). Unfortunately response duration is limited due to resistance development after 5–6 months. Vemurafenib was the first selective BRAF inhibitor to receive FDA approval in 2011 and EMEA approval in 2012. The recommended dose for vemurafenib is 960 mg twice daily. About 50 % of all melanomas are BRAF positive, with 75 % harboring the BRAF V600E mutation and 19 % the BRAF V600K mutation. Both respond to BRAF inhibition with vemurafenib, in contrast to wild-type BRAF melanomas which should not be treated with vemurafenib because of the risk of marked disease acceleration. There is now clear evidence that the use of a BRAF inhibitor alone leads to reactivation of the MAPK/ERK pathway via receptor tyrosine kinase (RTK)-mediated activation of alternative survival pathways or activated RAS-mediated reactivation of the MAPK pathway, suggesting additional therapeutic strategies such as the combination of BRAF with inhibitors of MEK, a downstream effector. The reactivation of the MAPK/ERK pathway explains not only the limited response duration but a very important side effect of the treatment as well, the relative high incidence (18–24 %) of squamous cell carcinoma and keratoacanthomas in treated patients. Other common side effects include rash, arthralgia, and photosensitivity.

Dabrafenib is the second FDA-approved (2013) selective BRAF inhibitor. Dabrafenib is associated with significant episodic and recurrent fevers that should be managed by drug discontinuation and administration of antipyretics and/or NSAIDs. Furthermore, dabrafenib is associated with keratoacanthoma/low-grade squamous carcinomas but in contrast to vemurafenib manifests limited if any photosensitivity.

The combination of a BRAF inhibitor with a downstream inhibitor (MEK inhibitor) may prolong the response duration of BRAF inhibitors and even prevent or limit the development of cutaneous SCCs. Several MEK inhibitors are under development. Trametinib, the first FDA-approved (2013) MEK inhibitor, is not indicated for treatment of patients who have experienced progression of disease on prior BRAF inhibitor therapy. Instead, its principal indication is intolerance to BRAF inhibitors.

Imatinib is a tyrosine kinase inhibitor used in the treatment of multiple cancers, most notably Philadelphia chromosome-positive chronic myelogenous leukemia (CML). Recent observations suggest that melanoma patients with specific c-KIT aberrations may respond to c-KIT kinase inhibitor therapy, i.e., imatinib (400 mg/d). c-KIT mutations are generally rare in melanoma, and they most likely occur in acral lentiginous and mucosal melanomas. Adverse events are mild to moderate and include gastrointestinal symptoms, elevated liver enzymes, fatigue, and edema.

Immunomodulating Monoclonal Antibodies

Immune checkpoint blockade of lymphocytes has developed to a new powerful tool in cancer therapy and promises to revolutionize the role of immunotherapy in the treatment of metastatic melanoma, even in a first-line setting, regardless of the mutational status of the tumor.

Ipilimumab was the first FDA-approved (2011) human monoclonal antibody that activates the cytotoxic T cells by targeting CTLA-4, a protein receptor on the surface of T cells that downregulates the immune system. In Europe, it has been approved as a second-line treatment of metastatic malignant melanoma. Clinical trials have noted complete remission rates up to 14 % and a significant improvement in overall survival (median overall survival 10 months). Response to ipilimumab may be delayed and not evident until 12 weeks or even a few months after treatment initiation. The recommended dose is 3 mg/kg

administered intravenously over 90 min every 3 weeks for a total of four doses. Patients treated with ipilimumab who experience stable disease of 3 months duration after week 12 of induction or partial or complete response, who subsequently experience progression of melanoma, may be offered re-induction with up to four doses of ipilimumab at 3 mg/kg every 3 weeks. By activating the immune system, there is a potential for significant triggering of autoimmunity in different organs, namely, the gastrointestinal tract, lungs, skin, hypophysis, and urinary tract.

Nivolumab is a fully human IgG4 monoclonal antibody, currently under investigation, with an immunomodulating action that blocks the ligand activation of the programmed cell death 1 receptor (anti-PD-1). By targeting an immune checkpoint different than ipilimumab, nivolumab activates the immune system leading to an earlier antitumoral response with more limited side effects. There is recent evidence that a combination therapy with ipilimumab may prove of benefit for metastatic patients compared to monotherapy with an anti-PD-1 antibody. Programmed cell death 1 ligand 1 (PD-L1) antibodies targeting a different immune checkpoint than ipilimumab and nivolumab are currently under investigation.

Chemotherapy

Chemotherapy, either as mono- or polychemotherapy, has been the mainstay of treatment in the stage of distant metastases until the recent development of novel targeted treatments and immunotherapies. Conventional chemotherapeutic agents include the alkylating cytostatic agents dacarbazine (DTIC) and temozolomide, several platin-based chemotherapeutic agents such as cisplatin and carboplatin, the vinca alkaloid vincristine, the nitrosourea alkylating agent fotemustine, and the mitotic inhibitor paclitaxel.

DTIC has been most frequently used and serves as reference drug for metastatic melanoma; temozolomide, an imidazotetrazine derivative of DTIC, can be administered orally. Nonetheless, none of these chemotherapeutic agents has been proven of being superior to others, and they all demonstrate very modest response rates (under 20 %) in first- and second-line settings, without any effect on overall survival. Patients with tumor progression during previous systemic therapy or initial rapid tumor progression may be offered polychemotherapy. Common adverse events include leukopenia, thrombopenia, anemia, anorexia, nausea, and vomiting.

Biochemotherapy, the combination of conventional chemotherapeutic agents and biologic agents such as interferon and IL-2, may improve progression-free survival, but at the cost of increased toxicity and without improved overall survival rates.

Supportive Care

Patients with osseous metastases should receive aminobisphosphonates, e.g., ibandronate, pamidronate, and zoledronic acid, or a RANK ligand inhibitor such as denosumab. Treatment should be initiated upon detection of bone metastases and continued on a long-term basis to prevent a series of problems associated with bone metastases such as persistent or intermittent pain, fractures, spinal compression, and hypercalcemia.

Pain may have a profound impact on patients' quality of life and effective pain management is an essential part of supportive care. The pain ladder introduced by the WHO (1988) comes evidently into use for systemic pharmaceutical pain management and includes non-opioid analgesics (nonsteroidal anti-inflammatory drugs/NSAIDs), centrally acting analgesics (weak opioids), opioids and opiates, and adjuvant agents (psychotropic and antiseizure drugs, corticosteroids).

Antiemetic drugs should be administered during chemotherapy and radiation since vomiting and nausea are very common adverse events. 5-HT3 receptor antagonists, neurokinin-1 receptor antagonists, and steroids should

be employed in accordance with guidelines to give relief to the patient and improve treatment compliance.

Radiation

Radiation can be discussed in case of inoperable or not fully resectable (R1, R2) primary tumors with the goal of local tumor control, especially of LMM which is not suitable for conventional surgical treatment. Another indication of adjuvant radiation therapy includes desmoplastic melanomas, especially those with neurotropism, or when the excision with adequate safety margins is not technically feasible. Adjuvant radiation therapy after complete regional LND can be considered for high-risk lymph node disease if one of the following criteria is met: high-risk locoregional disease with ≥3 affected lymph nodes, lymph node diameter ≥3 cm, and capsule penetration. After recurrence in a dissected lymph node basin, radiotherapy should be performed after resection of the metastases. Postoperative radiation of a lymph node basin aims to a better local disease control, even though a positive effect on overall survival has yet to be established. A total dose of 50–60 Gy fractioned in 5× 1.8–2.5 Gy per week is recommended for lymph node disease. Fractioned regimens show equal efficacy with respect to local tumor control in comparison to higher individual doses.

Stereotactic radiosurgery and/or whole-brain radiotherapy may be administered either as primary or as adjuvant treatment following surgical resection of brain metastases. Furthermore, in patients with acute signs and symptoms due to epidural compression of the spinal cord, radiotherapy may be performed for local symptom control in a palliative setting. Contrary to common perception that melanoma is radioresistant, radiation often achieves good palliation of symptomatic metastatic disease. In the setting of distant inoperable metastases in the skin, subcutaneous tissues, bones, or lymph nodes, radiotherapy could be discussed with the aim of improving quality of life, preventing pain, and improving local tumor control.

Follow-Up

Follow-up of melanoma patients for a time period of up to 10 years is currently recommended in all major guidelines aiming to an early detection and treatment of recurrences and an improved overall survival. The duration, frequency, and diagnostic workup schedule remain controversial and vary regionally depending on socioeconomic parameters. Only 5 % of all recurrences will occur after 10 years; hence, the recommended 10-year follow-up appears reasonable. However, lifelong surveillance of all melanoma patients by means of a yearly dermatological examination and patient's self-examination is justified not only due to the 5 % risk of recurrence after 10 years for stage I–III patients but also due to the increased lifetime risk (4–8 %) for a second primary melanoma.

Self-examination has gained importance lately and should be recommended during and after the end of physician-orientated follow-up period. Melanoma patients should be instructed to look for suspicious new lesions or changes by regular whole-body inspection as well as palpation of postsurgical scars, locoregional lymph drainage areas, and regional lymph node basins for possible recurrences. Furthermore, skin cancer preventive education including sun protection measures should be promoted in both patients and their families.

Patients with a surgically treated in situ melanoma do not require follow-up, as there is no risk of metastasis. Stage IA patients should be examined clinically every 6 months in the first 3 years and consecutively once yearly up to the tenth year; stage IB–IIB patients should be seen initially every 3 months and every 6 months after the third year. High-risk stage IIC–IV patients should be examined every 3 months in the first 5 years and twice yearly from year 6 to 10.

Elevated serum S100 level may point to distant metastases. As it is dependent of tumor load, it should be measured in the first 3 years every 3 months in patients with stage ≥ IB and every 6 months in patients with stage ≥ IIC in the fourth and fifth year of the follow-up.

Locoregional lymph node ultrasonography is a sensitive way to detect local, in-transit, and locoregional lymph node metastases. Since the majority (>60–70 %) of initial metastases will occur, locoregional lymph node ultrasonography should be recommended as a sensitive, specific, and cost-effective diagnostic tool for early metastasis detection. Stage IB–IIB patients should be examined twice yearly in the first 3 years, while high-risk patients (stage ≥ IIC) should be assessed every 3 months in the first 3 years and twice yearly up to the fifth year.

Imaging procedures should be generally reserved for high-risk patients (stage ≥ IIC), twice yearly in the first 3–5 years of the follow-up. Chest X-ray and abdominal ultrasonography are not recommended any longer; cross-sectional imaging should be offered instead. Brain metastases are better detected with MRI, while, for the diagnosis of osseous metastases, PET/CT and MRI display similar accuracy. PET/CT has indeed a higher sensitivity in detecting distant metastasis compared to regular CT. Due to the substantial financial burden, PET/CT should be reserved for special diagnostic interventions. Hence, whole-body CT remains a sensitive, recommended, procedure for early distant metastasis detection and should be performed routinely in stage ≥ IIC. Nonetheless, extended imaging with MRI and PET/CT can be considered to screen for metastatic or recurrent disease in case of clinical suspicion at the discretion of the physician.

Clio Dessinioti, Torello M. Lotti,
Alexander J. Stratigos, Katerina Damevska,
and Andreas D. Katsambas

Key Points

- The exposure to ultraviolet radiation and genetic and hormonal factors are the most important causative factors of melasma.
- Melasma can be classified into four histological types, the epidermal type, the dermal type, the mixed type and the indeterminate type. The response to treatment depends on the melasma subtype.
- At present there is no standard therapy for melasma. Topical hydroquinone, alone or in a triple-combination formula, is the first line of treatment. It is the most widely studied agent with reported efficacy for patients with melasma.
- The mainstay of treatment is the use of sunscreen along with topical bleaching agents that inhibit melanogenesis. The use of sun protection in the patient with melasma is a lifetime commitment.
- Fractional laser is the only laser treatment approved by the FDA for melasma and it has shown promising results.
- Melasma treatment should be tailored to the clinical subtype and disease severity to optimize therapy.

Definition and Epidemiology

Melasma (from the Greek word *melas* meaning black) is a common acquired circumscribed, brown or sometimes greyish-brown hypermelanosis of the face, occasionally the neck and forearms. It is a chronic, often relapsing condition with a negative impact on the quality of life. Although all races are affected, melasma is more common in darker-skinned individuals of Hispanic, Asian or of African or Middle Eastern descent. The reported prevalence of melasma ranges from 8 % among Latinas in the United States to 30 % in Southeastern Asian populations. Women are affected in 90 % of cases.

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_61, © Springer-Verlag Berlin Heidelberg 2015

Basic Concepts of Pathogenesis

The major aetiological factors of melasma include genetic influences, exposure to ultraviolet (UV) radiation and female sex hormones. Other possible factors include thyroid dysfunction, cosmetics, phototoxic and antiseizure drugs, ovarian dysfunction, hepatic dysfunction and nutritional deficiency.

Sun exposure is a major triggering and aggravating factor in the development of melasma, likely because of direct melanogenic effects of UV on melanocytes.

Natural and synthetic oestrogen and progesterone have been incriminated for the pathogenesis of melasma because of its frequent association with pregnancy, use of oral contraceptive pills and oestrogen replacement therapy.

Since melanocytes contain oestrogen receptors, the melanocytes in patients with melasma may be inherently more sensitive to the stimulatory effects of oestrogens and possibly to other sex steroid hormones.

Histological examination has shown that melasma lesions, in addition to increased pigmentation, have more elastosis and vascularization than perilesional skin. No increase in the number of melanocytes was noted in those areas, but the melanocytes were larger and intensely stained with very prominent dendrites and showed increased melanogenesis.

Recent studies have proposed a role of the stem cell factor and vascular and neural components in the pathogenesis of melasma.

Clinical Presentation

Melasma is characterized by light to dark brown or brown-gray hyperpigmented patches with irregular borders. The number of hyperpigmented patches may range from one single lesion to multiple patches located usually symmetrically on the forehead, cheeks, dorsum of the nose, upper lip, chin, occasionally on the V area of the neck and forearms. Extra-facial melasma is more frequent in postmenopausal women. According to the distribution of lesions, melasma occurs in one of three patterns: centrofacial, malar and mandibular pattern:

1. The centrofacial pattern. This is the most common pattern. It involves the forehead, cheeks, upper lip, nose and chin.
2. The malar pattern. This involves the cheeks and nose.
3. The mandibular pattern. This involves the ramus of the mandible.

Based on Wood's light examination of the skin, melasma can be classified into four types, with good correlation with the depth of the melanin pigment:

1. Epidermal: light brown, with enhancement of pigmentation under Wood's light. Histologically, it is characterized by a melanin increase in the basal, suprabasal and stratum corneum layers.
2. Dermal: ashen or bluish-grey, with no enhancement of pigmentation under Wood's light. Histologically, there is a preponderance of melanophages in the superficial and deep dermis.
3. Mixed: dark-brown. Enhancement of pigmentation is present under Wood's light in some areas, while not in others. Melanin is increased in the epidermis, and there are many dermal melanophages.
4. Indeterminate: in individuals with dark-brown skin or skin type VI, examination with a Wood's light is of no benefit.

Dermal melanin deposition is common and is unrecognized under a Wood's lamp examination, which may explain the difficulty in treating patients with apparent epidermal melasma.

The Melasma Area and Severity Index (MASI) is a common outcome measure, used to assess melasma patients in clinical trials.

Diagnosis

The diagnosis is clinical and the patient's medical history will provide further necessary information, including pregnancy, use of oral contraceptives, a family history of melasma and history of sun exposure.

Differential Diagnosis

Post-inflammatory hyperpigmentation: distribution of the lesions; history of local inflammation.

Pigmented cosmetic dermatitis (Riehl's melanosis): reddish-brown pigmentation, reticulate pattern; positive patch testing

Hyperthyroidism: thyroid function tests

Actinic lichen planus: papular lesions, histology

HIV infection-related pigmentation: HIV-positive serology

Drug-induced facial hyperpigmentation: history of drug intake (antimalarials, amiodarone, minocycline, phenothiazines, tricyclic antidepressants, anticonvulsants, cytotoxic drugs), blue-grey hue of facial lesions

Poikiloderma of Civatte: reddish-brown, reticulate pattern with atrophy and telangiectasia, usually on the lateral cheeks and the sides of the neck

General Principles of Treatment

Melasma is a cosmetic problem that sometimes causes great emotional suffering. The majority of the existing treatments may temporarily depigment the melasma, but the condition usually relapses. There are, however, various therapeutic modalities that can offer a significant benefit. The principles for melasma therapy include the inhibition of the activity of melanocytes (protection from sunlight and avoidance of precipitating factors), the inhibition of the synthesis of melanin (bleaching agents), the removal of melanin (chemical peeling) and the disruption of melanin granules (lasers). Melasma treatment should be tailored to the clinical subtype and disease severity to optimize therapy.

General Measures

Sun exposure is the most important avoidable risk factor. Melanocytes in melasma are easily stimulated by both UVA and UVB as well as visible radiation. Avoidance of solar exposure is recommended. Broad-spectrum sunscreens should be applied daily during treatment and afterwards.

Discontinuation of oral contraceptives or other oestrogen progesterone agents is advised, if possible. Women, in whom melasma develops during pregnancy, should avoid exposure to sunlight and should use a broad-spectrum sunscreen every day throughout the pregnancy. These patients should have patience because melasma may fade or clear spontaneously within months after pregnancy. They should avoid scented cosmetic products for facial cleansing or make-up.

Topical Treatments

Bleaching Agents

There are three categories of bleaching agents: phenolic compounds, nonphenolic compounds and combination formulas (Fig. 61.1). The selection of the appropriate treatment should be based on pretreatment evaluation.

Hydroquinone (HQ)

Hydroquinone is the most commonly used bleaching agent and the gold standard for melasma treatment. HQ is a hydroxyphenolic compound that inhibits the conversion of dopa to melanin by the inhibition of tyrosinase; it also inhibits RNA and DNA synthesis of melanocytes and degrades melanosomes.

The effectiveness of HQ is related directly to the concentration of the preparation, to the vehicle used and to the chemical stability of the final product. Concentrations of HQ vary from 2 % (over the counter) to as high as 10 %. HQ preparations higher than 5 % have proven to be very irritating without improving the efficacy and are not recommended, except for refractory cases. With controlled use and monitoring, the side effects of these preparations are minimal.

The most suitable vehicle for the formulation is a hydroalcoholic solution (equal parts of propylene glycol and absolute ethanol) or a hydrophilic ointment or a gel containing 10 % alpha-hydroxy acids (AHA). HQ is easily oxidized and loses its potency; therefore, antioxi-

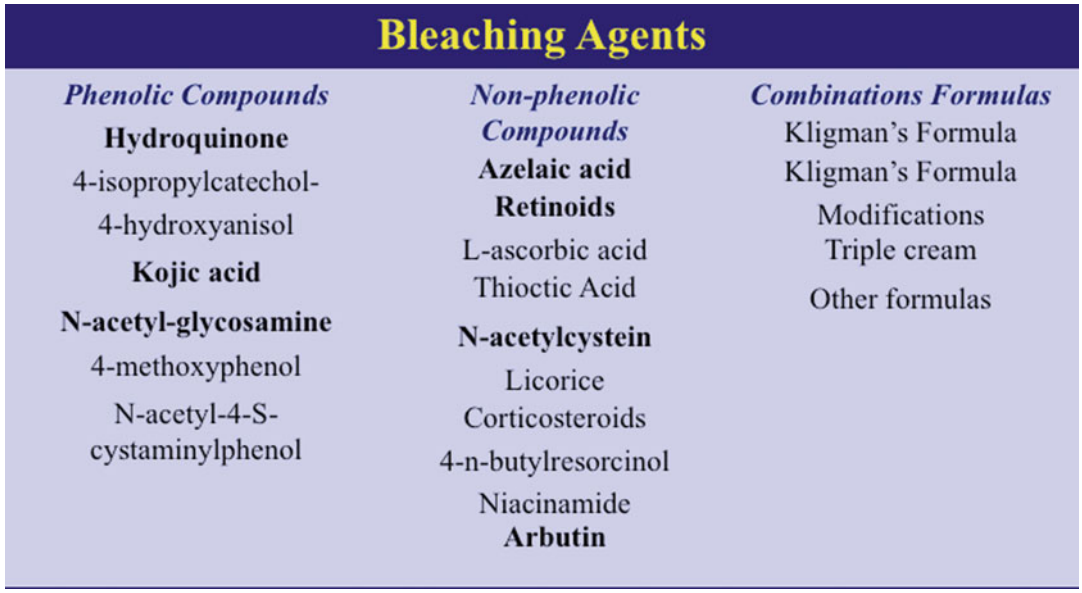

Fig. 61.1 Categories of bleaching agents for melasma

dants such as 0.1 % sodium bisulphate and 0.1 % ascorbic acid should be used to preserve the stability of the formulation. The bleaching effect of HQ may be expected from a few weeks to a few months after application.

Taking into consideration the desired HQ concentration, the vehicle and the chemical stability, the following formula can be prescribed:

- HQ 3 %–5 %
- In ethanol and propylene glycol 1:1 (or in a cream base or an AHA 10 % gel)
- Ascorbic acid 0.1 % (as preservative)

The side effects of HQ mostly include irritation and rarely allergic contact dermatitis, post-inflammatory hyperpigmentation and nail discoloration; these side effects are temporary and are resolved upon the discontinuation of HQ. A very rare complication of HQ use is exogenous ochronosis, especially in darker phototypes. Persistent hypopigmentation after the application of high-concentrated HQ formulas has been termed 'leukoderma en confetti'.

There have been some concerns with the safety of HQ over the last decade. In many countries around the world, the dispensing of over-the-counter hydroquinone formulations containing 2 % HQ has been banned. Indeed, HQ has been banned as a cosmetic skin-bleaching agent in Europe since January 2001 and it is available only in prescription form.

Combination Formulas

It has been demonstrated that the skin-lightening effect of HQ can be enhanced by adding various topical agents such as tretinoin and corticosteroids. Tretinoin accelerates epidermal transfer and cell turnover and facilitates the epidermal penetration of HQ; moreover, it suppresses the steroid atrophy and prevents HQ oxidation. The corticosteroids suppress melanin production and eliminate the irritation caused by HQ and/or tretinoin.

In general, combination therapies have a more effective bleaching effect than monotherapies, and treatment usually begins with one of these formulas applied once daily (at night) and continues with 2 % HQ treatment for maintenance.

Combination formulas are Kligman and Willis formula, Pathak's formula, Westerhof's formula and modifications of Kligman's formula.

The original Kligman and Willis formula utilized 5 % HQ, 0.1 % tretinoin and 0.1 % dexamethasone in ethanol and propylene glycol 1:1 or

in hydrophilic ointment. Depigmentation begins within 3 weeks after twice-daily application and it is used for a maximum of 5–7 weeks. This formulation is not preserved by antioxidants and therefore should never be more than 30 days old.

Pathak's formula contains 2 % HQ and 0.05 %–0.1 % tretinoin, omitting steroids and suggesting that they should be added only if irritation from HQ or tretinoin is observed.

Westerhof's formula consists of 4.7 % N-acetylcysteine, 2 % HQ and 0.1 % triamcinolone acetonide. The mode of action of N-acetylcysteine may be attributed to the intercellular increase of glutathione concentration that stimulates pheomelanin instead of eumelanin synthesis. The formula leads to significant bleaching within 4–8 weeks.

A modified formula proposed by Katsambas and Antoniou contains HQ 4 %, tretinoin 0.05 %, hydrocortisone acetate 1 % in ethanol and propylene glycol 1:1 or in hydrophilic ointment. In this formula the concentration of tretinoin is 0.05 % and hydrocortisone acetate 1 % is used instead of dexamethasone. By lowering the concentration of tretinoin and with the use of a nonfluorinated steroid, the aim is to minimize the irritation caused by tretinoin and eliminate local steroid side effects. The above formulation is applied twice a day until improvement with a maximum duration of 8–10 weeks. This formulation should be dispensed in a 25-mL volume, in a dark-coloured bottle with an airtight screw cap and it should be kept in a refrigerator at 2–4 °C.

Another treatment suggestion is the use of 0.05 % tretinoin, 2 % HQ and 1 % hydrocortisone acetate cream successively through the day.

Another modification of the Kligman and Willis formula is the following triple combination cream:

Hydroquinone	(HQ)	4%
Tretinoin	(TR)	0.05%
Fluocinolone Acetonide	(FA)	0.01%

in a hydrophilic cream base. In a total of 641 patients with facial melasma, Taylor et al. reported that this triple cream was better than the dual combination of HQ with either tretinoin or fluocinolone acetonide. At week 8, complete clearing of melasma was reported in 26.1 % of patients, and 70 % of patients had a 75 % reduction in pigmentation. The most common adverse events included erythema, skin peeling, burning and stinging.

4-Hydroxyanisole (Mequinol)

The combination of 2 % mequinol and 0.01 % tretinoin was shown to be effective in the treatment of melasma in men.

N-Acetyl-4-S-cysteaminylphenol (NAC)

NAC is a phenolic thioether that acts as a substrate for tyrosinase and selectively targets cells with active melanin synthesis; it is much more stable and less irritant than hydroquinone.

Nonphenolic Compounds

Azelaic Acid (AzA)

AzA is a naturally occurring dicarboxylic acid, isolated from *Pityrosporum* cultures and associated with the hypomelanosis seen in tinea versicolor. In vitro, azelaic acid reversibly inhibits tyrosinase activity and may also interfere with DNA synthesis and mitochondrial oxidoreductase. Azelaic acid does not appear to affect normal melanocytes but has an antiproliferative and cytotoxic effect on abnormal melanocytes; it has anti-inflammatory, antibacterial and antioxidant activities. At 10–20 % concentration, twice-daily application may treat melasma with minimal side effects; most patients report a mild but transient irritation and dryness of the skin at the beginning of the treatment. A recent study suggests that 20 % azelaic acid cream applied twice daily may be more effective than hydroquinone 4 % in improving mild melasma, while the combination with topical tretinoin 0.05 % and glycolic acid 15–20 % seems to augment its efficacy.

Kojic Acid

Kojic acid (5-hydroxy-4 pyran 4–1-2 methyl) is a fungal metabolite (*Aspergillus oryzae*) that inhibits the catecholase activity of tyrosinase and is a potent antioxidant. Kojic acid is used in concentration 2 %–4 %, alone or in combination with tretinoin, hydroquinone and/or a corticoste-

roid. Although kojic acid alone is less effective than HQ 2 %, the combination with glycolic acid 10 % and HQ 2 % seems to have a synergistic action.

L-Ascorbic Acid (Vitamin C, AsA)

As an inhibitor of the melanin formation, ascorbic acid is often used to treat melasma in 5–10 % concentrations and can be formulated with other depigmenting agents, such as HQ. Other advantages of vitamin C include antioxidant effects and anti-inflammatory and photoprotective properties. A weakness of AsA is its chemical instability in aqueous solutions; the hydrophilic nature of AsA also limits its skin penetration. Magnesium ascorbyl phosphate, ascorbyl palmitate and sodium ascorbyl phosphate are stable derivatives of ascorbic acid which differ in hydrolipophilic properties. Iontophoresis has been used to increase the penetration of vitamin C into the skin.

Topical Retinoids

Tretinoin accelerates the cell turnover promoting the rapid loss of pigment via epidermopoieses. Used at a concentration of 0.05 %–0.1 %, tretinoin is usually applied once nightly. Although tretinoin can be effective as monotherapy, it requires 20- to 40-week treatment periods. The most common adverse effects include burning, erythema and scaling. Retinoid dermatitis may itself lead to post-inflammatory hyperpigmentation, especially in dark-skinned individuals. Adapalene 0.1 % was also proposed as a safe and efficacious monotherapy in the treatment of epidermal melasma with a lower potential for skin irritation compared to tretinoin.

Miscellaneous Treatments

Multiple novel and experimental agents are being investigated for the treatment of melasma, including plant extracts, such as arbutin, licorice extract, aloesin, flavonoids, saponin, oregonin, soy, green tea, orchid extracts, coumaric acid, ellagic acid and liquirtin. At present there are no adequate controlled studies investigating the efficacy and safety of these compounds.

Chemical Peels

Superficial chemical peels can be used for the treatment of melasma in fair-skinned individuals. Alpha-hydroxy acids (AHAs) glycolic acid 50%–70 & peels (every 2–3 weeks) for 4–6 sessions, light Jessner's peels (every 2–3 weeks) for 4–6 sessions and trichloroacetic acid (TCA) 25 %–35 % once, have been used alone or in combination with other depigmenting agents. Glycolic acid peels may be a useful adjunct to topical treatment, especially after a patient's pretreatment with hydroquinone for 2 weeks to minimize the risk for post-procedure hyperpigmentation. However, it has to be emphasized that the response of melasma to chemical peels is rather unpredictable; there is a tendency for pigmentation changes after chemical peel, especially in darker-skinned individuals. After the peel, a maintenance therapy with HQ 2% is recommended.

Device-Based Therapies

Based on actual evidence, the use of this technology should be restricted to patients with recalcitrant disease. Post-inflammatory hyperpigmentation (PIH) remains the most important side effect, particularly in darker-skinned patients. Pretreatment and post-treatment maintenance with the use of bleaching creams is necessary.

Lasers

Various laser and light systems have been tried in the treatment of melasma, with variable results. Multiple treatments are required and recurrences are common. Melanin is the main chromophore, and melanosomes are the primary target of the laser-induced damage.

Sheth et al. reported that Q-switched ruby lasers and erbium-YAG lasers have been shown to worsen melasma. Also, the combination of CO_2 laser with Q-switched alexandrite laser is not beneficial for melasma and may induce PIH in darker-skinned persons. Fractional laser is the only laser treatment approved by the FDA for melasma with promising results. It has been proposed to use lower fluences and variable pulses and pretreatments with HQ for up to 6 weeks before laser therapy, in order to avoid the risk for hyperpigmentation especially in patients with a history of PIH.

The use of pulsed dye laser and the newer anti-angiogenic lasers (copper bromide laser) for the treatment of melasma is based on evidence showing an increased vascularization in melasma lesions as compared with the surrounding unaffected skin. A study by Passeron et al. comparing the use of Kligman's formula alone or combined with PDL (flat handpiece of 7 mm; pulse duration, 20 ms; fluency, 10 J/cm^2, dynamic cooling device, 30/40) showed significantly better results and fewer relapses with the combination approach.

Intense Pulsed Light

Intense pulsed light (IPL) is a nonlaser light source that emits light with wavelengths between 515 and 1,200 nm. From various experiences, it seems that epidermal melasma treated with intense pulsed light can reach a clearance of 70–100 % from baseline; but the risk of PIH still remains high. However, individuals with dermal and mixed melasma showed only a fair or poor clearance. It is a good approach to use low fluences and a long delay between pulses.

Conclusions

A recently published systematic review of interventions used for the management of melasma, by Jutley et al., identified only 20 eligible randomized controlled trials. All interventions, except tretinoin, were evaluated only in one study each. It was reported that there is no standard therapy for melasma. Topical HQ (3 %–4 %) was the most common topical monotherapy used. The triple-combination cream was more effective than any of the ingredients used in a dual-combination cream in one study. No studies provided long-term data or quality of life results. The authors mentioned that the evidence is insufficient to provide guidance for the clinical practice of treating melasma, due to the poor methodology of the trials, the lack of standardized outcome measures and the short duration of studies.

Mite Bites and Tick Dermatoses

62

Giorgio Leigheb

Mite Bites

Key Points

- Mites are arthropods belonging to the class Arachnida and to the subclass Acari. They have very small size (less than 1 mm. or little more than 1 mm.), four pairs of legs and are represented by numerous genera and species and have parasitic behaviour.
- Some mites such as *Sarcoptes* and *Cheyletiella* or *Neotrombicula* and *Dermanyssus* parasite specific animals (mammals, birds, insects) biting them with their mouth apparatus for feeding. Man is an occasional host; his only real ectoparasite is *Sarcoptes scabiei hominis*.
- Mite bites on human skin cause peculiar and frequently misdiagnosed entomodermatoses.
- Prevention consists in avoiding the contact with infested animals and in their treatment with acaricides, in the case of a contagion caused by domestic animals. Environmental mites (mainly parasites of insects) such as *Pyemotes* and *Ornithonyssus* are sensible to repellents such as DEET and pyrethroids used for prevention of their bites.
- Human infestation is treated with soapy baths or showers and topical application of permethrin, especially in case of trombidiasis. Itchy lesions are treated with corticosteroid creams.

Definition and Epidemiology

Besides the mite of human scabies (*Sarcoptes scabiei hominis*) (0.3–0.5 mm), many other acari which are parasitic on animals or which infest various vegetables, foods, organic waste or soil may occasionally attack man (facultative parasitism versus obligatory parasitism in the case of scabies). The bites of the mites considered in this chapter are the accidental cause of entomodermatitis. These represent very frequent events, especially in certain geographical areas or in peculiar habitat, but they often are not diagnosed. In some instances they can be considered professional diseases.

Basic Concepts of Pathogenesis

The most common acariasis is the various types of animal scabies or pseudoscabies. Frequent human infestations are caused by dog scabies

A.D. Katsambas et al. (eds.), *European Handbook of Dermatological Treatments*,
DOI 10.1007/978-3-662-45139-7_62, © Springer-Verlag Berlin Heidelberg 2015

(due to *Sarcoptes scabiei canis*), cat scabies (due to *Notoedres cati*), rabbit scabies and other domestic or pet animal scabies.

Cheyletiella (0.3–0.5 mm), a parasite of dogs (*C. yasguri*), cats (*C. blakei*) and rabbits (*C. parasitivorax*), can also infest man, causing multiple small papular lesions with serious itch. Often the dermatitis occurs after the introduction of a new animal from a kennel or a breeding house.

Avian gamasid mites that infest domestic poultry or birds wild or nesting in or near human habitation may parasite man, as *Dermanyssus gallinae* and *Ornithonyssus sylviarum*.

Acari present in the environment include so-called harvest mites such as "chiggers" (trombiculid mites). *Neotrombicula autumnalis* (1–2 mm), one of the most common in Europe, lives on vegetables feeding on small arthropods. The larvae (0.2–0.3 mm) (called red bugs or chiggers) can attack, also in great strength, vertebrate animals or man. The very itchy multiple lesions are papular with a central small hole where the parasite sucking lymph from the epidermis is present. The affection, more frequent in autumn, is known as trombidiasis or mange of the woods. Frequently affected are countrymen, gardeners, forest guards, hunters, excursionists and even children playing on fields or in gardens.

Mites of the genera *Tyroglyphus* and *Glycyphagus* (0.4–0.5 mm) cause lesions in warehouse personnel, stockmen and grocers. *Pyemotes ventricosus* (0.16–0.22 mm), an ectoparasite of the larvae of the coleopteran of the wood (infesting old furniture or timbers), is also a frequent occasional parasite of man. *Pyemotes tritici* (straw itch mite) is an ectoparasite of larval stage of lepidoptera and of coleopteran feeding on the alimentary agricultural products such as cereals; it lives in haycocks, straw and dead leaves. Environmental mites often infest man in great numbers not only on uncovered skin but also migrating under the clothes. Skin lesions are very erythematous, oedematous and itchy and last a long time. Infestation is frequent in the countryside after sitting on the ground or walking among the bushes. Itch may arise some hours after contagion.

Clinical Presentation

Animal pseudoscabies (animal scabies) in man is characterised by multiple, small, erythematous-pomphoid or erythematous-papular lesions, sometimes with a central small vesicle or pustule. The lesions cause severe itching. They are present on exposed parts of the skin or on the edge of tight-fitting garments. Contagion may be direct or indirect: clothing and seats, for example. The symptoms appear rapidly after contact with the mites. The infection heals promptly once contact with the affected animals is interrupted or when these are suitably treated but reappear every time the patient again comes into contact with the affected animals. The bites of gamasid mites of the genera *Ornithonyssus* (*O. sylviarum* is 0.45–0.50 mm) and *Dermanyssus gallinae*, parasites of poultry, birds and mice, cause intense itching and numerous, often haemorrhagic, papules in man.

Diagnosis

The history is important: contact with domestic or wild animals, profession, contact with vegetables and other affected persons in the same family. The absence of cuniculi in pseudoscabies is an essential feature in differential diagnosis with scabies. The lesions are rather characteristic and very itchy. It is usually hard to demonstrate the responsible mites in the cutaneous lesions except in trombidiasis as the small larva (0.2 mm) of *Trombicula* attached in the middle of the lesions is visible with a lens. The parasite remains on the host, feeding for 2–3 days. Itching starts some hours after the bite but papules appear 12–24 h later.

Infestation by *Tyroglyphus* and *Pyemotes* and by other environmental mites is associated with multiple or very numerous lesions, preceded by intense itching.

Differential Diagnosis

- Human scabies
- Urticaria
- Papular urticaria
- Prurigo
- Other arthropod bites (mosquitoes, Hymenoptera, bed bugs)
- Entomodermatosis caused by poisonous hairs of the caterpillars of some species of Lepidoptera
- Irritating exogenous factors (phytodermatitis, chemical compounds, irritating constituents of clothing, glass– wool)
- Drug-induced eruptions

General Principles of Treatment

It is not strictly necessary to treat animal scabies in man, in case of correct diagnosis, because the dermatitis heals spontaneously when contact with the affected animal ceases. In fact animal *Sarcoptes* do not like human skin after a bite and they do not reproduce on man. It is necessary to treat infested animals with insecticides.

Human lesions improve quickly with corticosteroid creams in a few days. ORAL antistamines can be used to relieve itching.

In case of environmental mite bites, hot soapy baths or showers will help remove attached and nonattached mites. For extensive or persistent infestation, the same antiparasitic remedies used for scabies can be applied (benzyl benzoate, pyrethroids).

For prevention, repellents such as dimethyl phthalate, diethyltoluamide (DEET) and permethrin are very active and are used also to impregnate clothing.

Recommended Therapies

In more severe cases of multiple mite bites, however, the use of acaricides is helpful. Many of them are the same products employed for scabies.

Polysulphide creams and pastes containing 2.5–10 % of sulphur and benzyl benzoate 10 % in galenical preparations, applied in adults and boys for 12–24 h, are now replaced by modern remedies but still used in poor sanitary conditions.

Pyrethroids are the more active pesticides and in particular permethrin, against mites and ticks.

Permethrin, a synthetic pyrethroid, is a pesticide and a repellent with a very low mammalian toxicity. It is non-staining, nearly odourless and resistant to degradation even after water immersion and maintains its activity for more than 2 weeks when applied on garments. Permethrin is available in emulsion, creams and sprays and is particularly active in 5–10 % concentrations for the skin which has to be washed 8–10 h later. For adults, do not apply more than 30 g of permethrin cream and for children (2 months–1 year old), no more than 3.75 g with medical control. Do not use in children under 2 months.

An active molecule, cyfluthrin (gel 0.1 %) is a good repellent.

The best repellents for prevention are DEET (N1N-diethyl-3m-toluamide), 10–30 % in lotions, sprays and creams used also for protection against mosquito bites, and permethrin. Both substances can be applied to the skin and clothing. Avoid application on eyelids, mouth and sensible skin.

Soapy baths are useful also in infestation by gamasid acari. Oral antihistamines will mitigate itching. Antibiotics are given in the case of superimposed bacterial infections. Topical or systemic corticoids are useful in the case of intense itching or infiltrated and refractory lesions.

Tick Dermatoses

Definition and Epidemiology

Ticks are very widespread cosmopolitan arachnid arthropods, haematophagous parasites to wild and domestic mammals, birds and reptiles. There are about 650 species of hard ticks (family Ixodidae) and about 150 species of soft ticks (family Argasidae). Besides their usual hosts, which represent the real reservoir of these parasites, they can adapt themselves to alternative hosts, including man. Ticks cause erythematous

and nodular cutaneous lesions (granulomas and necrosis) at the site of the bite and often provoke local or generalised allergic reactions especially in previously sensitised persons. They are also carriers of many bacterial and viral infections (borreliosis, rickettsiosis, tularaemia, viral neurologic infections), some of which have not yet been studied fully (e.g., arboviruses). The most common dermatoses due to tick bites are described briefly below. The most common species of hard ticks in Europe are *Ixodes ricinus* (sheep tick) and *Rhipicephalus sanguineus* (dog tick).

Clinical Presentation

Tick granuloma result from an erythematous-oedematous nodular lesion which appears after some days at the site of the bite. At first the lesion causes very little itching, so that the patient often remains unaware of the presence of the parasite, which can remain attached to the skin for several days sucking blood and enlarging its abdomen. Subsequently, the tick may drop off spontaneously having gorged on blood, or the hypostome (mouth apparatus) may remain fixed into the skin after vain attempts to detach the parasite. In the latter case, a foreign body granuloma develops. Thereafter, a delayed sensitisation reaction may develop. Itching is considerable and the lesion may persist for many months. In the case of further bites, common in farmers, gardeners, shepherds, sportsmen and hikes, for example, the local and systemic symptoms (eczematous patches or diffuse papulonodular lesions simulating the initial granuloma) become more serious and chronicise. Diagnosis often is misdiagnosed.

Diagnosis and Differential Diagnosis

The diagnosis is easily made when the tick is seen and bedded in the skin. After the parasite has dropped off, the presence of a small hole in the centre of the granuloma is pathognomonic. The delayed onset of itching and the history (presence of animals, presence in gardens or in the countryside) can also suggest the diagnosis. The differential diagnosis involves granulomas due to insect or mite stings and foreign body granulomas.

General Principles of Treatment

Besides adopting suitable preventive measures such as the use of boots and repellents (DEET, dimethyl phthalate, pyrethrum, permethrin), the disinfestation of affected animals and of the infested areas and to correctly remove the parasites embedded in the skin are important.

Recommended Therapies

The most effective method is to apply a cotton wool pad soaked with ether or petrol over the tick for 15 min. This causes paralysis of the parasite's muscles and hits subsequent spontaneous detachment. To avoid possible regurgitation of infective bacteria, many authors suggest an immediate removal of the tick with forceps. Alternatively, oil or liquid paraffin can be applied so as to suffocate the tick. The granulomas are treated with antibiotic and corticoid creams or with galenic preparations containing 5–10 % coal tar. Systemic corticosteroids are useful in the presence of disseminated secondary nodular or eczematous lesions due to sensitisation to the tick. ORAL antistamine are used as symptomatic measures to alleviate the pruritus.

In the case of lesions due to *Argas reflexus* (pigeon tick), which are becoming increasingly common on account of the presence of these birds in urban areas, suitable preventive measures consisting in the elimination of the pigeons and in the disinfestations of the windows, balconies, mouldings and roof gutters with chlorhexidine and pyrethrum preparations are essential. The cutaneous lesions are treated with antibiotic-corticoid creams. There remains the problem of the possible systemic complications that may arise in sensitised patients who, after being bitten, may develop serious, even fatal, anaphylactic reactions. Such cases require emergency medical treatments consisting of the administration of epinephrine, intravenous corticoids and antihistamines.

Many insecticidal formulations can be applied to domestic pets to rid them of their ticks: 0.5–5 % malathion, 1 % carbaryl, 0.1 % dioxathion, 1 % coumaphos, trichlorphon dusts applied to the coats of pets. The tick repellent collar for dogs is very active. Floors of doghouses, porches and balconies where infected animals sleep should be sprayed with oil solutions or emulsions of 1 % propoxur, 0.5 % diazinon and 2 % malathion.

Molluscum Contagiosum

63

Mirjana V. Milinkovic and Ljiljana M. Medenica

Key Points

- Molluscum contagiosum (MC) is a benign, self-limited viral disease of the skin and rarely mucous membranes caused by molluscum contagiosum virus (MCV), a double-stranded DNA poxvirus. The disease mainly affects children, sexually active adults, and immunocompromised individuals.
- The typical lesion is a shiny, pearly white, hemispherical papule with central umbilication and an average diameter of 3–5 mm. Giant lesions may be as large as 3 cm in diameter.
- In immunocompetent patients MC is a benign disorder that resolves spontaneously within 6–18 months, although it may persist for as long as 5 years. Disseminated lesions, as seen in immunocompromised patients, are persistent and recurrent, and they may be a marker of advanced disease.
- Diagnosis of MC is usually made relatively easy on the basis of clinical presentation. Rapid freezing with ethyl chloride or liquid nitrogen may accentuate their distinctive umbilication.
- Therapy of MC should be undertaken in an individualized manner; a specific treatment does not exist.
- Treatment method should be chosen after consideration of the age and immunocompetence of the patient, the extent of the disease, and the areas involved.
- Treatment has focused on removing the cutaneous lesions either by surgery or by producing epidermal injury and subsequent desquamation of the molluscum and surrounding uninvolved skin.
- Curettage is a relatively painless and easy-to-perform procedure. It is suggested to be performed if the lesions are young and small in number. A sharp curette is used to scrape the lesion. In children, pretreatment with topical anesthetic is applied.
- Cryosurgery can be completed with specially designed liquid nitrogen spray units or with cotton-tipped swabs (dipstick technique). It is less painful and it is not necessary to use local anesthetics.
- Application of cantharidin is very effective in children. It has the advantage of being a painless office procedure.

- Podophyllotoxin cream as a 0.5 % preparation is a safe, home-based first-line therapy for curing MC.
- Imiquimod cream 5 %, a topical immune response modifier, is suitable and safe for both children and adults.

Definition and Epidemiology

Molluscum contagiosum (MC) is generally a benign, self-limited viral infection of the skin and rarely mucous membranes caused by molluscum contagiosum virus. The disease mainly affects children, sexually active adults, and immunocompromised individuals.

MC is primarily a disorder of children, with peak incidence at 3–10 years of age and 10–12 years for school children. In the sexually active population, peak correlates with sexual contact; the greatest number of cases occurred among patients 20–29 years old. Published data estimate the incidence of MC to be between 1.2 and 22 % of the population worldwide. The prevalence of MC among HIV-infected individuals ranges from 5 to 18 %.

MCV is spread mainly by direct skin-to-skin contact; however, several routes of transmission are recognized for MCV. Viral transmission in children occurs by close contact with an infected individual or with fomites or by autoinoculation. The possibility of sexual abuse should be considered when MC is seen on the genital, perianal, and surrounding skin of children, even though the vast majority acquires infection by casual contacts. Infectivity is enhanced in warm, humid crowded environments. Use of swimming pools also correlates with childhood infection. In adults, MCV is most often sexually transmitted. It has also been reported in isolated cases among wrestlers, masseurs, and surgeons.

The incubation period is in the range of 7 days to 6 months.

Molluscum contagiosum is associated with several diseases with impaired cell-mediated immunity including atopic dermatitis, epidermodysplasia verruciformis, and HIV infection. Unusually disseminated molluscum contagiosum has been reported in patients with sarcoidosis and chronic lymphocytic leukemia and patients on immunosuppressive therapy and with HIV disease, suggesting that cell-mediated immunity is significant in the control and elimination of the infection.

Basic Concept of Pathogenesis

Molluscum contagiosum virus (MCV) is a member of the family *Poxviridae* (genus *Molluscipoxvirus*). MCV is a double-stranded DNA poxvirus which cannot be grown in tissue culture cells or in an animal model. It is the largest true human virus infecting only human beings. It replicates in the cytoplasm of infected cells and induces hyperplasia.

Three different MCV types have been identified in humans: MCV-I to MCV-III. MCV-I is more prevalent than others, accounting for up to 90 % of lesions. In patients infected by human immunodeficiency virus, majority of infections are caused by MCV-II. Lesions produced by either of the subtypes are indistinguishable.

The pathogenesis of the lesions is uncertain, but an epidermal growth-like polypeptide has been postulated to have a role in pathogenesis. In the basal layer of lesional skin, the rate of cell division is twice that of normal skin. The number of receptors for epidermal growth factor (EGF) increases in infected cells, which is indirect evidence that MCV synthesizes an EGF-like growth factor. The infected keratinocytes move more quickly than uninfected ones through the epidermis. Free virus cores have been found in all layers of the epidermis.

Although the role of humoral immunity in this disorder is not clear, dependent on the presence of viral antigen in infected cells, virus-specific antibodies can be detected in 80 % of patients with MCV. Most patients infected with MCV produce antibodies predominantly of the IgG class. Anticellular IgM antibodies and fibrillar anticellular IgM antibodies can be found in over 60 % of infected patients. Cell-mediated immunity is probably more important in the pathogenesis of the disease. Reinfections are common.

Fig. 63.1 Molluscum contagiosum – with white, hemispherical papule with central umbilication

Clinical Presentation

The typical lesion is a shiny, pearly white, hemispherical papule with central umbilication and an average diameter of 3–5 mm (Fig. 63.1). Rarely giant molluscus may be as large as 1.5–3 cm in diameter. The lesions may be flesh-colored, white, translucent, or light yellow in color. The number of lesions is usually less than 20, although a single lesion or several hundreds can be seen. There may be a surrounding eczematous reaction (so-called molluscum dermatitis). Patients with MC are usually asymptomatic, but few may complain of pruritus or tenderness.

Lesions may be located anywhere; in children, lesions are distributed on the face, trunk, and extremities, although the anogenital region may be also involved. In healthy sexually active adults, lesions are usually located on the groin, genital region, and on the lower abdomen and inner thighs. The disease rarely can affect the oral mucosa, conjunctiva, and cornea.

Molluscum contagiosum is a common viral disorder associated with HIV infection; its clinical features are often atypical, and its course is usually progressive and recalcitrant to treatment. The lesions most often involve the face, neck, and trunk.

In immunocompetent patients MC is a benign disorder that resolves spontaneously within 6–18 months, although it may persist for as long as 5 years. Temporary remission of up to 2 months has occurred. Disseminated lesions, as seen in immunocompromised patients, are persistent and recurrent, and they may be a marker of advanced disease.

Diagnosis

Diagnosis of MC is usually made relatively easily on the basis of clinical presentation. Rapid freezing with ethyl chloride or liquid nitrogen may accentuate their distinctive umbilication. Direct light microscopical examination of an unstained expressed core, skin biopsy, or ultrastructural studies of the lesional skin establish the diagnosis. Histopathological examination reveals a hyperplastic, cup-shaped invagination of the epidermis composed of multiple lobules. Characteristic intracytoplasmic inclusion bodies, molluscum bodies, are formed.

Differential Diagnosis

The differential diagnosis includes: basal cell carcinoma, histiocytoma, trichoepithelioma, keratoacanthoma, intradermal nevus, syringoma, hidrocystoma, sebaceous adenoma, warts, varicella, pyoderma, papillomas, lichen planus, Darier's disease, and dermatitis herpetiformis.

In HIV-infected patients, molluscum contagiosum must be differentiated from basal cell carcinoma, keratoacanthoma, and cutaneous horn. Conversely, in AIDS patients, cryptococcosis and histoplasmosis may mimic molluscum contagiosum; for these reasons, biopsy of atypical-appearing cutaneous lesions is often warranted.

General Principles of Treatment

There is no specific treatment for MC.

- The main question, as with warts, is whether to treat or not. In many cases lesions resolve spontaneously within 6–18 months without scarring. The decision is crucial and must take

into account that MC is a benign, self-limited condition and that treatment is far from being perfect. On the other hand, the lesions are a source of great embarrassment for both carers and children, often affecting attendance at school and limiting social activity.

- Therapy of MC should be undertaken in an individualized manner; a specific treatment does not exist. A vaccine is not available.
- Care should be taken not to traumatize patients unnecessarily with painful treatments, particularly children, who are the largest patient group. Benign neglect may be the most appropriate approach in immunocompetent children with the infection.
- Although MC may be self-limited and asymptomatic in healthy individuals, therapy is warranted to prevent autoinoculation or transmission of the virus to close contact, to relieve symptoms (if any), and, most often, for cosmetic and social reasons.
- Treatment method should be chosen after consideration of the age and immunocompetence of the patient, the extent of the disease, and the areas involved. The individual patient preference, fear, and financial status, as well as the distance from the office, should be also taken into consideration.
- Patients should be advised to avoid swimming pools, communal baths, contact sports, and shared towels, for example, until clear.
- Therapies for MC may be destructive, immune enhancing, or antiviral in nature. In general, treatment has focused on removing the cutaneous lesions either by surgery or by producing epidermal injury and subsequent desquamation of the molluscum and surrounding uninvolved skin.
- Sexual partners should be examined and treated, to prevent reinoculation.

Recommended Therapies (Fig. 63.2)

(a) Mechanical methods—curettage
(b) Cryotherapy—cryosurgery with liquid nitrogen
(c) Electrodesiccation
(d) Chemical agents

Mechanical Methods: Curettage

Curettage is a relatively painless and easy-to-perform procedure. It is one of the most commonly used office-based therapies for MC and is suggested to be performed if the lesions are young and small in number. A sharp curette is used to scrape the lesion. In children, pretreatment with topical anesthetic, such as the eutectic mixture of local anesthetics lidocaine and prilocaine (EMLA® cream), may be necessary. One hour before the treatment, a maximum of 10 g of EMLA® cream should be applied to the mollusca. One gram of the cream is sufficient to cover a skin area of approximately 2.5 × 2.5 cm. The cream is covered with an occlusive dressing (Tegaderm®) and after 60 min it is wiped off. The curettage usually commences within 5 min after the cream has been wiped off. Local reactions to the cream could be redness, pallor, and edema. Curettage is found to be more efficient and had a lower rate of side effects then other therapeutic options. However, it may be associated with scaring and is not well tolerated by children if performed repeatedly, owing to pain and fear. It is also a time-consuming procedure.

Other simple mechanical methods like expression of the contents of the papule by squeezing it with forceps held parallel to the skin surface, superficial curettage, or shaving off the lesions with a sharpened wooden spatula may each suffice, although it is usual to add an application of a caustic agents, such as silver nitrate stick, phenol, podophyllin, or strong iodine solution.

Cryotherapy

Cryosurgery can be completed with specially designed liquid nitrogen spray units or with cotton-tipped swabs (dipstick technique). It is less painful and it is not necessary to use local anesthetics. The lesion and a narrow border of normal surrounding skin should turn white before application is stopped. This usually takes 6–10 s. Destruction of the molluscum body (white, smooth, walled core) will result in resolution of an individual lesion. The treatment should be repeated at weekly intervals if lesions persist. Cryotherapy, though effective at controlling the

problem, practical, cost-effective, and has good cosmetic results, is also uncomfortable and often requires many weekly treatment sessions.

Electrodesiccation

Electrosurgical destruction of MC by electrodesiccation, as a physician-administrated treatment, can be done with little, if any, scarring. Small lesions may be treated without anesthetic. Subepidermal local anesthesia is required for big ones. The lesions should be prepared with a non-alcohol-containing skin cleanser. The electrode is brought into contact with the mollusca. Only a low spark should be generated in order to minimize excessive tissue destruction and to avoid scarring. The lesion usually changes in color and consistency as it is destroyed. It can be easily removed with a curette or simply by rubbing the site with gauze. Punctate bleeding can be controlled with pressure, spot electrocoagulation, or topical hemostatic agents such as aluminum chloride. Unfortunately, even with application of a local anesthetic, these ablative procedures may be associated with pain, irritation, soreness, and mild scarring.

Chemical Agents

(i) Cantharidin solution
(ii) Trichloroacetic acid
(iii) Topical vitamin A acid
(iv) Silver nitrate paste
(v) Propridine iodine solution and salicylic acid plaster
(vi) Podophyllotoxin cream
(vii) Imiquimod cream

Cantharidin

Cantharidin is derived from a beetle (*Cantharis vesicatoria*) that causes blistering of the skin if handled. Applied as a 0.7 % cantharone in a flexible collodion-type vehicle, cantharidin is a phosphodiesterase inhibitor that causes vesiculation of the skin. Skillfully employed by a physician, as a gentle local destruction of MC, it is safe and effective and may be a treatment of choice in young children. It should be used by precise application of a small amount to each lesion using a pointed stick (a toothpick) with treatment of a maximum of 20 lesions per visit. The patient should be immobilized for 3–5 min until the medication has completely dried to restrict the blistering agent to the lesions. Occlusion should only be used on lesions not responding to uncovered applications. When occlusive tape is used, it is mandatory to insure complete drying before applying the tape. Patients are instructed to rinse the treated areas with water after 2–6 h, with little discomfort afterwards. Usually between two and four such treatments, with a 7-day interval, are required to eradicate molluscum lesions.

Application of cantharidin is very effective in children. It has the advantage of being a painless office procedure. However, it may cause significant local irritation with blister formation several hours later, depending on the quantity applied, the duration of application, and the individual patient's sensitivity. Testing it on a few lesions at the initial office visit before treating all lesions is recommended. Residual erythema and depigmentation can occur temporarily, but scarring is absent. Cantharidin is not recommended for treatment of facial lesions or those in the diaper area.

Trichloroacetic Acid (TCA)

Trichloroacetic acid is a safe and effective agent that erodes the skin and generally is not absorbed systemically. Application of 25–50 % TCA with cotton-tipped swab often causes sufficient destruction to cure these lesions. The solution should be applied to individual papular lesions for a few seconds until they turn white. This causes a burning sensation that lasts a few minutes. The white treated papules will slowly form crusts and heal within 10 days. In order to reduce the significant irritation or pigment alterations, the pointed edge of broken cotton-tipped applicator can be used to repeatedly apply the TCA until a white frost appears. Care is taken to apply the solution only to the center of individual lesions while avoiding the surrounding healthy skin.

A TCA peel 25–50 % is a useful adjuvant therapy in the treatment of extensive MC in immunocompromised patients. MC lesions are typically recalcitrant to therapy in HIV-infected persons. First of all, a test site measuring

2.5 × 2.5 cm and including the greatest density of lesions on the face should be chosen to determine the most effective concentration of TCA. Serial peeling of the same test site is performed at 2–3-week intervals to determine the lowest effective concentration of TCA (25, 30, 35, 40, or 50 %). After that, full or partial peels should be performed every 2–3 weeks. The concentration of TCA is usually 25–35 %. There is no superinfection, delayed healing, or scarring.

Retinoic Acid (Tretinoin)

Successful therapy with self-administrated topical vitamin A acid has been described in patients with genital lesions. Twice daily application of 0.1 % or 0.05 % tretinoin cream or nightly in the highest tolerated concentration is proposed. The mechanism of action of vitamin A may relate to its ability to produce marked inflammatory reaction of the skin. Local irritation is common. It is not recommended to be used in children.

Silver Nitrate Paste

Widespread, small MC lesions, as often seen in atopic children, can be successfully treated with 40 % silver nitrate paste. It is as effective as the aqueous solution but does not run onto normal skin causing irritation. With the blunt toothpick, a small amount of the paste is dabbed on the center of each lesion and gradually spreads to the entire lesion. Within 1 day, black crusts form. After 2 weeks MCs drop off the skin. Lesions heal without leaving scars. It has a high cure rate, it is painless in most cases, and it is cost effective.

Propridine Iodine Solution and Salicylic Acid Plaster

Ten percent propridine iodine solution and 50 % salicylic acid plaster are recommended (a) for children and patients with multiple lesions as it is not painful, (b) for diabetic patients as the infection is less frequent, and (c) for use in the dermatology office without equipment for liquid nitrogen therapy, so it is less expensive for the patient.

The combined treatment is much more successful and shorter in duration than 10 % iodine solution or 50 % salicylic acid plaster alone. The procedure is performed once daily. The 10 % iodine solution is applied and left to dry. The 50 % salicylic acid plaster is cut into small pieces and patched onto the lesions, covering the area with micropore sticking tape. When the lesion becomes reddened, usually in 3–7 days, it is sufficient to apply only iodine solution until the lesion becomes flat. If necessary, the whole procedure can be repeated. The inflammatory sign (erythema) appears after 3–7 days. However, the more marked the erythema after the application, the more quickly the lesions disappear.

Podophyllotoxin Cream

Podophyllotoxin cream as a 0.5 % preparation is a safe, home-based first-line therapy for curing MC. It is easily self-administrated twice daily for 3 consecutive days. If total elimination is not achieved with one trail (six topical applications), the same treatment can be extended to 3 more weeks (24 topical applications), when 95 % of lesions are cured. Tolerable moderate to mild frequent side effects are erythema, burning, and pruritus.

Imiquimod Cream

Imiquimod, 1-(2-methylpropyl)-1H-imidazo[4,5-c]quinolin-4-amine, is a topical immune response modifier that produces a localized immune response at the site of application and stimulates the monocyte/macrophage and dendritic cells to produce interferon alfa (IFN-α), tumor necrosis factor (TNF), and several interleukins. Patients are instructed to apply imiquimod 5 % cream on each lesion with a cotton-tipped applicator before bedtime, 3–5 days per week, for up to 16 weeks, and to wash the areas in the morning. Adverse reactions, erythema, erosions, and post-inflammatory hyperpigmentation, are limited to application sites and are tolerable. Imiquimod cream is suitable and safe for both children and adults. It appeared to be the most efficacious in patients with HIV-1 disease and in the genital area in immunocompetent adults. Lesions on the face could be treated with imiquimod.

Combination topical treatment of MC with cantharidin, followed by imiquimod 5 % to new or

persistent lesions in children, has been suggested. Using a destructive therapy such as cantharidin to begin with will clear most of the lesions, making the immunomodulatory effect of the imiquimod achievable without significant cost.

Alternative and Experimental Treatments

Topical Agents

Potassium Hydroxide Solution (KOH)

Five percent KOH aqueous solution may be an effective and inexpensive alternative for the management of MC in children. It is based on its property of dissolving epithelial compounds. Parents are instructed to apply a small amount of the solution twice daily, with cotton swab to all lesions for 6 weeks. The stinging sensation is absent or minimal. Even perivaginal and perianal lesions can be treated the same way. A 5 % KOH solution proved to be as effective and less irritating when compared to the 10 % KOH solution.

Cidofovir

Cidofovir is a potent nucleoside analog of deoxycytidine monophosphate that has antiviral activity against a broad range of DNA viruses, when applied topically or administrated by intralesional injection. No significant systemic side effects have been noted, although application site reactions are common and can occasionally be severe. Successful use of topical 1–3 % cidofovir in a combination vehicle, once a day, 5 days a week, for 2–8 weeks, is an effective and well-tolerated therapeutic alternative option for treatment of recalcitrant MC in children and adults with AIDS and other immunocompromised patients.

Nitric Oxide (NO)

Nitric oxide has been shown to have antiviral affects in DNA, RNA, enveloped, and encapsidated viruses. Topical acidified nitrite cream is an NO liberating cream. It is shown to be an effective treatment for MC. Five percent sodium nitrite co-applied with 5 % salicylic acid, once a day for 3 months, is recommended. The treatment is time-consuming and can provoke local irritation.

Systemic Agents

Griseofulvin

This can be used orally for 4–6 weeks, at dosages of 500 mg daily to patients over 14 years of age and 250 mg to younger ones. No recurrence was seen in the 6–8-month follow-up period.

Cimetidine

Cimetidine, a histamine (H2) receptor antagonist with potent immunomodulatory effects, appears to offer a safe alternative form of therapy for multiple, widespread lesions of MC, particularly in atopic patients. It is started at a dosage of 40 mg/kg/day orally in three to four divided doses. A 2- to 3-month course may be safe and cost-effective.

Intralesional Agents

Topical Injection of Picibanil (OK-432)

OK-432 (penicillin-treated and heat-treated lyophilized powder by a substrain of *Streptococcus pyogenes* A3) was expected to be effective for immunosuppression. The skin lesions disappeared almost completely within 3 months.

Intralesional Interferon-α

That has been used to treat recalcitrant MC. Each lesion was injected with one megaunit of IFN-α weekly for 4 weeks. Molluscum less than 0.5 cm in diameter and those in patients without AIDS are more likely to respond.

Other Agents

Pulsed Dye Laser

Pulsed dye laser treatment may offer another therapeutic modality that is effective, quick, and safe in the treatment of widespread and recurrent MC. The lesions are treated by double-pulsing them with a 585-nm pulsed dye laser with a pulse duration of 450 μsec at 1 Hz (one pulse per

second). Spot sizes that are usually used (to match the diameter of the lesions) are 3 mm at fluences of 7.0–8.0 J/cm^2, 5 mm at fluences of 6.8–7.2 J/cm^2, and 7 mm for energy density 6–7 J/cm^2. The lesions could be quickly treated at the rate of one every 2 s. The laser is generally non-scarring and produces a brief snapping sensation on the skin. Because of a possibility of viral particles in the laser plume, a smoke filtration system is utilized.

Electron-Beam Therapy

The use of electron-beam radiation is a promising alternative treatment for patients with localized MC lesions. It is administered by using megaelectron voltage (9 MeV or 12 MeV) electron-beam energy, five times per week for up to 18 treatments per site. The daily proposed radiation dose is 180 cGy (face and neck) or 200 cGy (body). Response to irradiation is rapid and complete. Mild skin erythema is the only reported side effect.

Morphea (Localized Scleroderma)

64

Aurora Parodi

Key Points

- Morphea or localized scleroderma (LS) is a fibrosing disorder of the skin without systemic involvement.
- No causal treatment for LS exists but topical and systemic drugs are used to treat morphea as well as phototherapy.
- Topical treatments are adequate for limited morphea, while systemic therapy is needed for the generalized forms.
- Treatment should be used in the active phase of the disease.
- Topical corticosteroids are the mainstay of topical treatment.
- Calcipotriol and tacrolimus are also used and they seem improve some forms of morphea.
- UVA1 improves the skin scores.
- Among systemic treatments, methotrexate is considered the first-line option.
- Mycophenolate mofetil should be taken into consideration for the more aggressive and nonresponder forms.

Definition and Epidemiology

Morphea, also known as localized scleroderma, is a fibrosing disorder of the skin usually differentiated from systemic sclerosis based on the absence of sclerodactyly, Raynaud's phenomenon and systemic involvement.

Morphea is more common in whites and females but the prevalence is equal in adults and children. The incidence is between 0.4 and 2.7 per 100,000 people. About 90 % of children present the disease between 2 and 14 years of age; adults are often affected in the middle age.

Basic Concepts of Pathogenesis

The pathogenesis is not completely understood. The development of morphea requires an underlying predisposition and environmental factors. An imbalance of collagen production and destruction, inflammation and vascular changes are important features. Trauma and radiation have been reported before the onset of morphea. Drugs such as bisoprolol, bleomycin, D-penicillamine, bromocriptine, carbidopa, pentazocine and balicatib have also been associated with the development of morphea. Borrelia has been implicated as a possible infectious cause but other studies have refuted the association. Two to 5 % of children with morphea have another autoimmune disease such as vitiligo, insulin-dependent diabetes mellitus, Hashimoto

thyroiditis, Graves disease and ulcerative colitis. The role of microchimerism as in systemic sclerosis has been investigated but other data are needed to evaluate its importance in the pathogenesis of the disease. In conclusion the exact pathway by which the increased deposition of collagen happens remains a mystery. According to the endothelial theory of the pathogenesis of morphea, the endothelial injury releases cytokines that increase the expression of vascular cell adhesion molecule (VCAM-1), intercellular adhesion molecule (ICAM-1) and E-selectin. These adhesion molecules recruit T cells which produce profibrotic molecules such as IL-4, IL-6 and transforming growth factor-β (TGF-β). The upregulation of TGF-β increases the production of collagen, fibronectin and proteoglycan, decreases the production of proteases and increases the production of proteases inhibitors. Matrix metalloproteinases (MMP) are decreased, and antibodies capable of inhibiting MMP collagenase activity have been detected. In addition, patients with morphea have increased expression of insulin-like growth factor (IGF) which enhances collagen production, recruits fibroblasts and increases extracellular matrix deposition. Recent data on gene array analysis revealed evidence for four separate gene signatures subcategorized as inflammatory, proliferative diffuse, limited and normal-like. The inflammatory one was present in patients with morphea and limited and diffuse systemic sclerosis, the proliferative one only in patients with diffuse systemic sclerosis and the limited one only in patients with limited systemic sclerosis. This is important to distinguish the different forms of scleroderma as distinct disease subtypes.

Clinical Presentation

Morphea is classified based on its clinical presentation. In 1995, Peterson et al. recommended five subtypes of morphea:

1. Plaque type: including morphea en plaque, guttate, atrophoderma of Pasini and Pierini, keloidal and lichen sclerosus et atrophicus.
2. Generalized type when lesions involved two or more body areas.
3. Bullous type when bullae develop on the plaques.
4. Linear type when a linear morphology develops. This variant includes linear morphea of the extremities, morphea "en coup de sabre" and progressive facial hemiatrophy.
5. Deep type, including morphea profunda or subcutaneous morphea, eosinophilic fasciitis and pansclerotic morphea.

This classification is controversial; in fact it includes atrophoderma, lichen sclerosus et atrophicus and eosinophilic fasciitis which some clinicians consider separate entities. In addition, this classification does not include the mixed types of morphea.

In 2006 Laxer and Zulian suggested the following classification in five different types:

1. Circumscribed
2. Linear
3. Generalized
4. Pansclerotic
5. Mixed variants of morphea

The first stage of the disease is characterized by an erythematous-violaceous plaque; the central region becomes white and sclerotic while the active borders remain red (lilac ring). Over time the active stage subsides, leaving sclerotic plaques that can be white or pigmented. Adnexal structures are destroyed (Fig. 64.1).

Circumscribed morphea is the most common form of the disease, it may be both superficial and deep, and it is usually localized on the trunk. In adults, circumscribed morphea can develop in areas of trauma, and breasts are commonly involved with sparing of the nipples.

Generalized morphea is rarer than the circumscribed form. Sometimes it is difficult to differentiate this form from systemic sclerosis; however patients with generalized morphea do not present Raynaud's phenomenon and sclerodactyly (Fig. 64.2).

Linear morphea is the most common subtype in children. It is strongly correlated with the lines of Blaschko. About 25 % of the patients present a bilateral form. The "en coup de sabre" subtype usually occurs on the paramedian forehead and can be associated with underlying ocular and central nervous system involvement; it is usually associated with alopecia and typically follows Blaschko lines. The

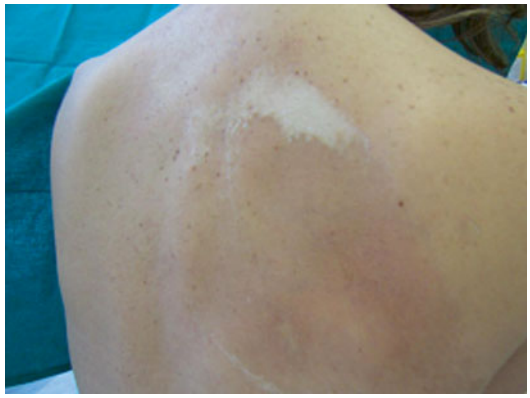

Fig. 64.1 Plaque-like morphea in an adult

Fig. 64.2 Generalized morphea

Fig. 64.3 Linear morphea of a limb

"progressive hemifacial atrophy", also known as Parry-Romberg syndrome, is characterized by significant atrophy of the subcutaneous tissue with minimal overlying cutaneous changes. Linear limb morphea is associated with muscle atrophy and joint contractures (Fig. 64.3).

Bullous morphea presents tense bullae on sclerodermoid affected plaques.

Deep morphea affects the deep dermis, panniculus, fascia or superficial muscle. It can lead to functional disability. Deep morphea includes eosinophilic fasciitis, subcutaneous morphea and morphea profunda. In eosinophilic fasciitis, the skin is normal because the inflammation is in the fascia. The inflammation usually spares the perivascular areas. Eosinophilia, hypergammaglobulinemia and increased sedimentation rate can occur. Hematologic malignancies have been reported in association with eosinophilic fasciitis.

Panscleroticmorphea is the most debilitating form of the disease. It affects subcutaneous tissues including bones at times. It is characterized by muscle atrophy, joint contractures and non-healing ulcers which have an increasing risk for squamous cell carcinomas.

Mixed variant morphea is a combination of two or more of the subtypes of the disease.

Diagnosis: Histology

In the early stage, a perivascular infiltrate of lymphocytes with plasma cells and eosinophils is found in the reticular dermis. In the late stage, the collagen bundles of the reticular dermis are thickened and crowding in on each other. The adnexal are atrophic and the subcutaneous fat appears "trapped" in the dermis. The histologic features of morphea cannot be differentiated from those of systemic sclerosis.

Complications

Myalgias, arthralgias and fatigue can be present. Neurologic manifestations, including seizures, head ache, peripheral neuropathy, vasculitis and ocular complications, are more common in "en coup de

sabre" or progressive hemifacial atrophy. Depression is common in patients with morphea. Positive autoantibodies (anti-histone, anti-DNA antibodies) are found in patients with linear scleroderma.

A novel antibody, antitopoisomerase II alpha, has recently been described. It is present in 85 % of patients with generalized morphea.

General Principles of Treatment

No causal treatment for localized scleroderma (LS) exists; however a variety of therapeutic options are available. In LS, treatment should be used in the active phase of the disease.

Topical and systemic drugs as well as phototherapy are used. Usually topical therapy is adequate for limited morphea, whereas systemic treatments are used for the generalized forms.

Topical Treatments

Corticosteroids are the mainstay of topical treatments. Moderate to high potent steroids should be used in the active phases of the disease; their application should be restricted to 3 months. Intralesional steroids could be used in linear forms. The injections should be performed into the active margins.

Topical calcipotriol 0.005 % twice daily was also used for the treatment of morphea. Two uncontrolled studies exist on the use of calcipotriol. In one study it was used along with low-dose ultraviolet A1 (UVA1) phototherapy, while in another study it was applied under occlusion. The studies suggest that calcipotriol should be used when sclerosis is superficial.

Topical tacrolimus 0.1 % was evaluated in open studies and in one double-blind placebo study. In this study it was seen to improve morphea significantly, in particular when early inflammatory lesions were evaluated.

In some patients imiquimod has been used. It seems to improve pigmentation, sclerosis and erythema. Its mechanism might be explained by induction of interferon (IFN)-γ which inhibits transforming growth factor (TGF)-β. However it is not suggested to treat morphea with imiquimod because more data are needed.

Phototherapy

In the 1990s, phototherapy was widely used to treat LS. The rationale is the fact that UV can induce interstitial metalloproteinases. Later, most authors have focused on the treatment of morphea with UVA because UVA penetrate deeper into the dermis; however, only one randomized controlled study was performed to compare UVA (low-dose UVA1 and medium-dose UVA1) and narrow-band UVB therapy. All three regimens improved the skin scores but medium-dose UVA1 was better than narrow-band UVB. Before initiating UV phototherapy, it should be considered that UV only penetrate into the dermis but not into deeper structures (fat tissue, fascia, muscle or bone), so the subtypes of deep morphea must not be treated with phototherapy. The disease is expected to begin improving after 10–20 treatments and most trials are stopped after 20–30 treatments. Some authors reported that patients continue to improve after treatment cessation. UVA1 are usually used at the dosage of 20–70 J/cm^2 for 20–30 treatments. Psoralen plus UVA (PUVA) was reported in uncontrolled studies and bath PUVA showed to provide benefit to some patients with morphea.

Systemic Treatments

Among systemic treatments, the best evidence exists for the use of methotrexate (MTX). The rationale is MTX inhibits cytokines that play a central role in sclerotic skin changes (IL-2, IL-4, IL-6). MTX is currently considered the first-line option for the severe forms of morphea (linear, generalized and deep subtypes). MTX doses are 15–25 mg/week in adults and 0.3–0.4 mg/kg/week in children. In a work of Zulian et al., MTX plus prednisone was compared with oral prednisone alone. Sixty-seven percent of the MTX-treated patients, compared with 29 % in the

control group, had a clinical response. Recently, the same group of authors reported the therapeutic role of MTX in children after a prolonged period of follow-up. The authors studied a cohort of young patients previously enrolled in a double-blind, randomized controlled trial. A group of patients was treated with MTX 15 mg/m^2/week plus prednisone for 3 months, and a second group was treated with prednisone alone 1 mg/kg/day (maximum 50 mg). After 3 months prednisone was gradually tapered over 1 month, while MTX after remission was achieved, was maintained for at least 12 months. About 74 % of the patients treated with MTX were responders, and, among them, 73 % maintained clinical remission for a mean of 25 months. The medication was generally well tolerated with rare occurrence of adverse effects. The authors concluded that long-term maintenance MTX treatment is beneficial for LS in young patients.

Mycophenolate mofetil (MMF) was assessed as a treatment adjunct in patients who were already taking MTX and systemic steroids. Most patients improved with the addition of MMF.

Other systemic therapies such as IFN-γ, oral steroids, penicillamine, antimicrobials and antimalarials are not supported by current evidence.

Physical therapy is often recommended particularly in linear morphea of the limbs and generalized and pansclerotic LS. This therapy does not appear to exacerbate the disease and may be of value in minimizing joint contractures.

Proposed algorithms to the morphea treatment.

Nevi (Benign Melanocytic)

65

Alexander C. Katoulis, Dimitrios Sgouros,
and Nikolaos G. Stavrianeas

Key Points

- Melanocytic nevi (MN) are benign hamartomas of the skin that are almost always present in light-skinned individuals.
- MN can arise in any anatomic location and can show up from birth to the sixth decade of life.
- They are classified into congenital and acquired. The latter are further categorized into common, dysplastic (atypical), blue, Spitz, and halo nevus.
- Dermoscopy is the gold standard method for the diagnosis and follow-up of MN.
- Their direct association with malignant melanoma is debated.
- Regarding their benign nature, as a general rule they do not require any treatment.
- However MN with a clinical-dermoscopic presentation simulating a melanoma or nevi showing changes that do not comply with their expected natural history have to be excised surgically.

Melanocytic Nevi (MN)

Definition, Epidemiology

Melanocytic nevi (MN) are benign neoplasms or hamartomas, clinically appearing as well-circumscribed pigmented lesions and histologically consisting of nevus cells.

Nevus cells derive from the neural crest and migrate during embryogenesis to selected ectodermal sites, primarily skin, central nervous system, but also eyes and ears. Through a process of maturation and downward migration, type A nevus cells (epithelioid) evolve into type B (lymphocytoid) and then into type C (neuroid) dermal nevus cells. The following morphological features differentiate nevus cells from melanocytes, the epidermal pigment-producing cells:

- Absence of dendrites
- Arrangement in nests
- Larger size
- More abundant cytoplasm, containing coarse granules
- Location in the epidermis and/or in the dermis and rarely in the subcutis

It has been suggested that nevus cells represent the final stage of evolution of a neural crest precursor cell, the nevoblast. On the other hand, some authorities believe that differences between nevocytes and melanocytes are secondary adjustments and that both types of cells originate from the melanoblast.

DOI 10.1007/978-3-662-45139-7_65,

MN are classified into:

Congenital

Acquired

Acquired MN are further classified into:

- Common acquired MN
- Dysplastic or atypical MN
- Blue nevus
- Spitz nevus
- Halo nevus

Basic Concepts of Pathogenesis

Melanocytic nevi are so common that some authorities believe they cannot be considered as defect or abnormality. Worldwide, the prevalence in ethnic groups with dark skin is lower than that observed in persons with fair skin. This could be attributed to the inherent protection of melanin against solar radiation. In addition, in light-skinned individuals, MN show a predilection for the trunk, while in dark-skinned individuals, for the extremities. Northern Europeans not uncommonly have large atypical nevi or a large number (>50, up to several hundred) of hypopigmented MN.

Although melanocytes have been postulated to exhibit some degree of sex hormone responsiveness (MN commonly darken and/or enlarge during pregnancy) due to cytosolic receptors for estrogens and androgens they possess, only subtle differences may exist in the prevalence of MN between women and men.

Congenital MN are present at birth, although some small congenital nevi are clearly tardive in their clinical presentation. The incidence of acquired MN increases throughout the first three decades of life, reaching its peak in the fourth to fifth decade of life. Then, the incidence decreases, and they slowly involute, becoming inconspicuous in the elderly. It must be noted that nevus subtype incidence may also vary with ages. Consequently, the appearance of a new "dysplastic," "blue", or "halo" nevus in persons older than 50 years should be considered suspicious.

MN are biologically stable and completely benign lesions. However, they can be found in association with melanoma. The exact risk of an individual nevus transforming into a melanoma is thought to be 1 in 200,000. The true frequency of malignant transformation is not known. The estimated prevalence of melanomas histologically associated with a precursor MN varies widely in the literature, from 10 % up to 40 %, or 50 % in patients younger than 30 years.

Both acquired and congenital MN are considered risk factors for the development of melanoma. Congenital MN, especially giant, hold the greater risk. This is believed to be a consequence of the fact that the number of lesional melanocytes within large lesions is greater, and thus the chances of a transformative event are proportionately greater.

The exact etiology behind the development of MN is complex and multifactorial and remains incompletely understood. The development of MN is believed to be influenced by genetic and environmental factors. The dysplastic nevus syndrome and the familial atypical mole and melanoma syndrome express an autosomal mode of inheritance. Their onset is believed to be, at least in part, a response to sun exposure. The so-called eruptive MN have been observed to develop after major blistering events, such as second-degree thermal burns or sunburns, toxic epidermal necrolysis, or hereditary epidermolysis bullosa. It appears to be induced by trauma through scattering of nevus cells and release of growth factors by proliferating keratinocytes.

Congenital MN result from an error in the development and migration of neuroectodermal elements originating from the neural crest. Therefore, they may be interpreted as congenital malformations or hamartomas. Errant embryological migration is also believed to be the source of melanocytic nevus cell "rests," observed in the capsules of lymph nodes and, occasionally, in the subcapsular space or within lymph node trabecula. Their importance is that they can sometimes be mistaken for metastatic deposits because of their extracutaneous location. These rests of cells are sometimes referred to as benign metastases because they may result from an intralymphatic migration of benign melanocytes. In contrast, acquired MN are considered benign neoplasms. They are believed to develop either from epidermal melanocytes that have completed their migration from the neural crest to the dermoepidermal junction in fetal life or to arise from dermal melanocytes that have become arrested in the dermis and have never reached their normal site.

Common Acquired MN

Definition and Epidemiology

Common acquired MN (CAMN) are small (<1 cm), well-circumscribed, evenly pigmented lesions that are composed of nevus cells. Depending on the location of the groups of nevocytes, CAMN are subdivided into junctional (cells at the dermoepidermal junction above the basement membrane), dermal (cells exclusively in the dermis), and compound nevi (cells in both the epidermis and the dermis).

CAMN are seen in almost all individuals with their number varying from few to hundreds. Caucasians, especially those with lighter skin color, have a greater prevalence of CAMN than black people or Asians, who have more nevi on the palms/soles and nail beds. Both sexes are equally affected. The number of CAMN increases with age, reaching a peak during adolescence and early adulthood. Thereafter, they may undergo involution. Increased number of CAMN has been observed among members of the same family. A strong positive correlation between sun exposure and number of nevi has been documented.

CAMN have a very low malignant potential. However, the association of CAMN with cutaneous malignant melanoma (CMM) is well established. Histological studies have shown that one-third of CMMs are associated with nevus remnants. In addition, increased numbers of CAMN is a risk factor for CMM.

Basic Concepts of Pathogenesis

Nevus cells are thought to derive either from nevoblasts or from melanoblasts, which migrate from the neural crest to the epidermis. Junctional nevi result from the proliferation of nevus cells within the epidermis. Migration and proliferation of nevus cells into the dermis give rise to compound nevi or to dermal nevi when no residual cells are found in the epidermis. Some authorities believe that the three types of CAMN represent sequential developmental stages in their life history, i.e., evolution from junctional nevus to compound, then to dermal, and finally involution with fibrosis.

Genetic and environmental factors (mostly solar radiation) seem to play a pathogenetic role.

Clinical Presentation

CAMN are asymptomatic, well-defined, round to oval lesions, smaller than 1 cm in diameter, with regular or slightly irregular borders and uniformly distributed color, usually shades of brown and black. They may occur anywhere on the body. Junctional nevi appear as macular hairless lesions, medium to dark brown in color, most commonly located on the trunk, the upper extremities, or the face (sun-exposed areas). Compound nevi are variably elevated papular lesions with smooth or slightly warty surface and dark brown to black coloration. Bristle-like terminal hair may be present. The face is the most frequent location. Dermal nevi are papular or nodular, dome-shaped, or, occasionally, papillomatous or pedunculated lesions. They are tan to light brown in color. Telangiectasias are often present. They are usually located on the face, neck, or trunk. CAMN of the nail bed present as brown longitudinal bands (melanonychia striata) with regular distinct margins and uniform pigmentation (Fig. 65.1).

CAMN tend to remain unchanged in color and in shape. Increase in size and/or in pigmentation may occur in adolescence and early adulthood or during pregnancy. In an Australian study, 16 % of benign melanocytic lesions changed over a digital follow-up period of 2.5–4.5 months, and the proportion was higher among persons aged 0–35 years.

Diagnosis

Diagnosis is mostly clinical.

Evaluation of the patient should include:

- Personal and family history for CMM or dysplastic nevi and other risk factors for CMM.
- Total body examination (presence and number of nevi).

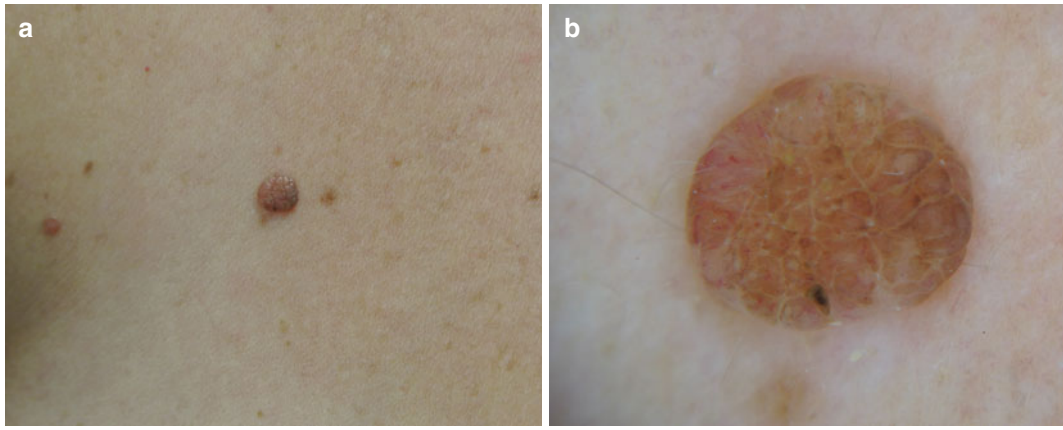

Fig. 65.1 Dermal nevus. (**a**) Papillomatous, skin-colored dermal nevus (Unna type). (**b**) Dermoscopic picture of dermal nevus exhibiting cobblestone pattern with remnants of pigmentation and comma-shaped vessels

- Dermoscopic examination: flat CAMN show symmetry and uniform pigmentation, a regular global pattern (reticular, globular, homogenous) with no specific or other local features. Dermal CAMN of the face (Miescher) are characterized by pseudonetwork or homogenous or unspecific global pattern, comma vessels, and, occasionally, milia-like cysts, comedo-like openings, and one to two prominent hairs. Dermal CAMN nevi of the trunk (Unna) exhibit a globular, cobblestone, homogenous or unspecific global pattern, comma vessels, and exophytic papillary structures as local features and, occasionally, milia-like cysts, comedo-like openings, and prominent hairs.

In unequivocal cases, excisional biopsy and histological examination can document diagnosis (nevus cells arranged in clusters in the epidermis and/or in the dermis).

Differential Diagnosis

Macular pigmented lesion:
- Freckle, solar lentigine
- Lentigo simplex
- Lentigo maligna
- Pigmented actinic keratosis.

Papular pigmented lesion:
- Seborrhoeic keratosis
- Dermatofibroma
- Neurofibroma
- Epidermal nevus
- Spitz nevus
- Blue nevus
- Dysplastic nevus (larger size; asymmetry; not well-defined, irregular border; multiple colors)
- Trichoepithelioma
- Pigmented basal cell carcinoma
- Nodular melanoma

General Principles of Treatment

For CAMN, no treatment is necessary. There is no reason to remove CAMN on a routine basis, although it is not contraindicated, whenever removal is thought necessary. Although not completely clarified as yet, it is highly improbable that manipulations, such as plucking hair from a mole, or repeated trauma may result in malignant degeneration.

Recommended Therapies

Any suspicious pigmented lesion must be removed completely by excisional biopsy down to the subcutaneous tissue and should be histologically evaluated, often with sectional examination. Reference to specialists is also a good practice.

Indications for excision of a CAMN are the following:

- Atypical clinical appearance, suspicious for CMM
- Changing lesion, e.g., size has increased or the color has become variegated or the border has become irregular
- Symptomatic lesion, i.e., if pain, pruritus, or bleeding is present
- Evidence of malignancy detected by dermoscopy
- New lesion rapidly growing in a high-risk individual or in an adult
- Lesion differing from all other moles of the same patient ("ugly-duckling sign")
- Sites of repeated irritation, or sites associated with increased risk for CMM, or sites that do not permit self-examination, such as palms, soles, penis, scalp, mucous membranes, anogenital region
- Cosmetically disfiguring lesion

Removal of CAMN should be performed by simple complete excision and closure by sutures. A histological examination should always follow, even when there are no clinical indications for atypicality. Destruction of the lesion by electrocautery, cryotherapy, or laser surgery is wisely avoided because these modalities do not allow histological evaluation and do not ensure complete excision. Nevertheless, if a destructive method is chosen, in case of recurrence, surgical excision and histologic examination are mandatory. On the other hand, after an incomplete surgical excision, the residual pigmentation at the scar site can be removed using electrodesiccation or cryotherapy, if atypicality or malignancy has been excluded.

Congenital MN

Definition and Epidemiology

Congenital melanocytic nevi (CMN) are benign pigmented neoplasms composed of nevomelanocytes that are usually present at birth. According to their projected adult size (Table 65.1), they can be distinguished as small (<1.5 cm in diameter), intermediate (from 1.5 to 9.9 cm), large (from 10 to 19.9 cm), and giant (>20 cm). The estimation of the projected adult size of a CMN in a given age takes into consideration the different growth dynamics of nevi in various anatomic locations and results from specific charts that derive by averaging parameters of nevus size, height, and weight for males and females from birth to adulthood. Population-based prevalence of CMN is estimated to be 0.6–6 % depending on the study. Large and giant CMN occur in 1 in 20,000 and 1 in 50,0000 newborns, respectively. There is no race or sex predilection. Familial tendencies have been described.

Table 65.1 Estimated size of nevus at birth necessary to reach 20 cm in full-grown adult

Location of CMN	Diameter at birth (cm)
Head	12
Hands, feet, torso, forearms, arms, buttocks	7
Thighs	5.8
Legs	6

Adapted from Marghoob et al. (1996)

Basic Concepts of Pathogenesis

Nevomelanocytes are derived from the neural crest as a result of a developmental defect of melanoblasts. CMN probably develop between the tenth and the 24th week of gestation. Many CMN have been found to harbor N-RAS mutations in contrast to acquired nevi or melanomas arising on intermittently sun-exposed skin, which typically have B-RAF mutations.

Clinical Presentation

CMN are almost invariably present at birth (birthmarks). Occasionally, they may arise during the first 2 years of life (congenital nevus tardive).

Small, intermediate, and large CMN appear as slightly elevated, round or oval, well-demarcated, hairy or hairless plaques with uniform light to dark brown coloration and regular or irregular contours. The surface is sometimes pebbly, rugose, or coarse. CMN may appear at any site. They are usually solitary. Fewer than 5 % are multiple.

Giant CMN present as deeply pigmented, irregularly shaped plaques with coarse terminal dark hairs and focal nodules or papules, termed "proliferative nodules," which can be clinically and pathologically confused with CMM. They cover large areas of the head, trunk, or the extremities, often having the distribution of a garment, such as a bathing trunk, a cap, a sleeve, or a stocking. Multiple smaller satellite lesions may also be present. These are actually small CMN and can be present at birth or arise months to years later.

With advancing age, CMN increase proportionally to the anatomical area they occupy. Occasionally, they become darker, or assume a verrucous appearance, or develop a halo.

The potential for malignant transformation is well documented for all CMN, regardless of size. Lifetime risk for CMM development is <1 % for small and medium CMN according to several studies. However, for giant CMN, the risk is estimated to be between 2.5 % and 13.9 %, since the risk of melanoma development is closely associated with the size of the nevus. Histological features of CMN have been found in 8.1 % of primary melanoma specimens studied. CMN-associated melanoma usually occurs early in childhood and has a poor prognosis. Rarely, malignant soft tissue tumors may arise on CMN. Additionally, giant CMN or multiple satellite nevi can be associated with involvement of the leptomeninges and/or brain parenchyme (neurocutaneous melanosis), resulting in neurologic manifestations (Figs. 65.2 and 65.3).

Diagnosis

Clinical diagnosis is based on history, physical examination, and dermoscopic assessment.

Dermoscopic characteristics of CMN are protean. The predominant patterns are the globular, reticular, homogeneous, and, often, multicomponent. The globular pattern usually corresponds to CMN of the head, neck, and trunk, whereas CMN exhibiting the reticular pattern are mostly located on the extremities. Dermoscopically, CMN show various shades of brown and black. Additional dermoscopic features include perifollicular hyper- or hypopigmentation, prominent hairs, milia-like cysts, and comedo-like openings. Several vascular structures, especially comma vessels and target network with vessels, can be observed.

Histological examination documents diagnosis: nevomelanocytes arranged in theques in the epidermis and the dermis, which often invade the lower reticular dermis or the subcutaneous fat, the walls of blood and lymphatic vessels, the skin appendages, the nerve fascicles, and the arrectores pilorum muscles. Nevertheless, the histologic findings are not always specific.

Differential Diagnosis

- Common acquired melanocytic nevus
- Nevus spilus
- Dysplastic nevus
- Spitz nevus

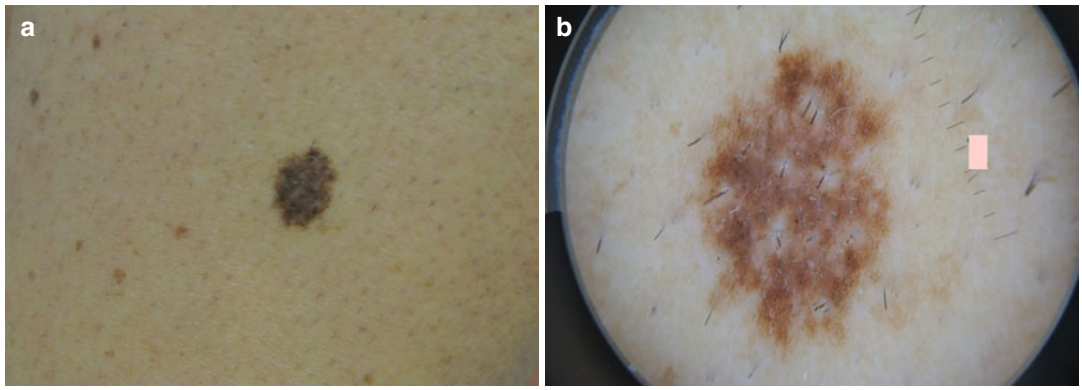

Fig. 65.2 Small congenital nevus (small CMN). (**a**) A small congenital melanocytic nevus on the shin. (**b**) Reticular pattern with perifollicular hypopigmentation and multiple dots

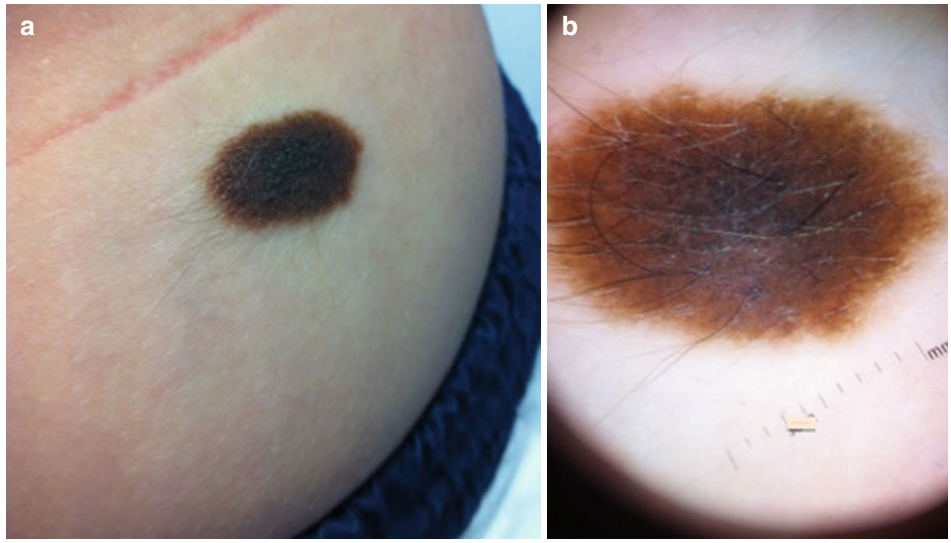

Fig. 65.3 Medium congenital nevus (medium CMN). (**a**) Medium-sized congenital nevus appearing as a well-demarcated *dark brown* plaque with multiple coarse terminal hairs. (**b**) A combination of cobblestone and homogeneous pattern with multiple hairs

- Congenital blue nevus
- Becker's nevus
- Malignant melanoma
- Pigmented epidermal nevus
- Pigmented basal cell carcinoma
- Seborrhoeic keratosis
- Paget's disease with pigmentation
- Nevi of Ota and Ito

General Principles of Treatment

Treatment is individualized depending on age, location, size, appearance, and risk for CMM. Since the lifetime risk of malignant transformation for small and medium CMN has not been proven to be significantly increased (<1 %), the prophylactic excision is no longer proposed, except for cosmetic reasons. CMN manifesting benign clinical and dermoscopic features should be managed with digital dermoscopy monitoring and regular follow-up. However, large and giant CMN show a well-established high risk of malignant transformation. Thus these lesions should be removed as soon as possible. Excision should be performed after the perinatal period when the risks from general anesthesia are diminished. Small and medium CMN or giant CMN that have not been excised should be monitored clinically with conventional and digital dermoscopy on a regular basis for life, and patients must seek medical advice when a change in the lesion has occurred.
